During preliminary work that led to the study reported on in the present paper we found that the substitution of 3% aqueous ammonia for the 0.75% Na_2HPO_4 electrolyte and the use of a higher current density than that used by Britton permitted a larger percentage of the total surface chromium to be electrochemically oxidized and hence brought about better correlation between coulometric results and the total surface chromium present as measured by standard colorimetric procedure.

Key words: chromium passivation films, tinplate passivation, chromium analysis, tinplate surface analysis.

Experimental

During the course of our preliminary investigation it became apparent that precise experiments could be performed which would explain the coulometry involved and prove or disprove the existence of metallic chromium in the CDC passivation film.

Accordingly, our experimental program employed accurate and precise measurements of the charge passed and the oxidation products generated (except O_2) during the galvanostatic polarization, followed by potentiokinetic polarizations to discern the contribution of O_2 evolution to the coulometry. Faraday's law was then applied to these data to establish the original valence state of the chromium.

Description of specimens.—For this study a quantity of sheets were sheared from a coil of normal production CDC-treated tinplate produced on an alkaline tinning line at Bethlehem's Sparrows Point Plant. The experimental specimens (surface area = 0.324 dm^2) were die-punched sequentially from the center position of these sheets and hence can be considered to be identical. Wet chemical analysis established that the experimental face of these specimens had a chromium level of 94 $\mu g/dm^2$.

Apparatus for coulometric experiments.—The galvanostatic experiments were performed in a glove box under an argon atmosphere. All solutions used were deaerated with argon to minimize analytical errors due to chemical oxidation of the tin surface. Currents were measured with a milliammeter (0.25% accuracy), and potentials were measured with a potentiometric recorder (0.1% accuracy). The power supplies used were low-ripple constant voltage supplies modified to supply constant current.

The potentiokinetic experiments were performed outside of the glove box, since no chemical analyses of oxidation products were to be performed. The potentiostat used was controlled by a motor potentiometer. The current *vs.* applied potential measurements were made by passing the cell current through a precision 1.0 ohm series resistor and recording the resultant *IR* drop *vs.* specimen potential on an X-Y recorder.

The electrochemical cell (Fig. 1) was a 600 ml beaker modified with a glass tee connecting tube centered on the bottom. The glass tee accommodated an electrical connection to the specimen and permitted the application of vacuum to hold the specimen tight against a Tygon gasket mounted in the bottom of the beaker. Reference and counterelectrodes were mounted in a No. 15 gum rubber stopper, which fitted snugly into the top of the beaker. The cathode was isolated from direct contact with the electrolyte by means of a fritted glass junction.

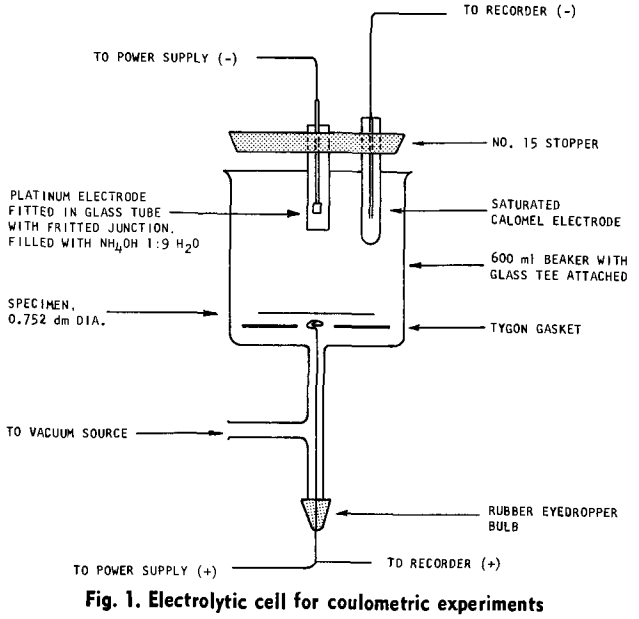

Fig. 1. Electrolytic cell for coulometric experiments

Galvanostatic Experiments

To determine the rates of the reactions occurring during galvanostatic polarization the specimens were polarized for various increments of time. The surface tin oxides were then determined by electrochemical analysis, and the tin and chromium in the electrolyte by chemical analysis.

Polarization procedure and surface tin oxide determination.—Seven specimens (labeled A through G) of the experimental material were transferred into the glove box. First, the original tin oxide level on the surface of specimen A was established coulometrically using a method generally referred to in the industry as the MCE test (4). Essentially, this test consists of the coulometric reduction, at constant current, of stannous and stannic oxides in very dilute HBr (1:5000).

Specimens B through G were then exposed to an electrolyte of 3% aqueous ammonia (NH_4OH 1:9 H_2O) for precisely 3 min, during which time they were anodically polarized at 8.00 mA (18.0 mA/dm^2) for intervals of 0, 15, 30, 45, 75, and 105 sec. After each polarization the electrolyte was set aside for chemical analysis of tin and chromium and the specimens were analyzed for surface tin oxides with the MCE test. The potential *vs.* time curve in Fig. 2 shows the levels to which the experimental materials were polarized.

Analysis for tin and chromium in the electrolyte.—The electrolytes were removed from the glove box, acidified with H_2SO_4, and diluted to volume in 200 ml volumetric flasks. Dissolved tin was determined polarographically after 100 ml aliquots were concentrated in 25 ml solutions of NH_4Cl by coprecipitation with Al and redissolution with HCl. The other half of the solutions were analyzed colorimetrically for Cr^{+6} with the sensitive diphenylcarbazide procedure, after a preliminary oxidation with silver catalyzed $(NH_4)_2S_2O_8$. The oxidation step was precautionary, because it was found that a small amount of tin dissolved chemically (no current) into the NH_4OH electrolyte which (if present as Sn^{+2}) could conceivably reduce a portion of the Cr^{+6}, and thus cause low results.

Quantitative results of the analyses are shown together with polarization times in Table I, with all quantities expressed as quantity/square decimeter. It can be seen from Table I that a tin oxide value of 11 MCE/dm^2 was originally present on the surface (sample A). A 3-min exposure to the electrolyte under static (no current) conditions (sample B) caused no increase in this quantity, but did result in the chemical dissolution of 16 $\mu g/dm^2$ of Sn.

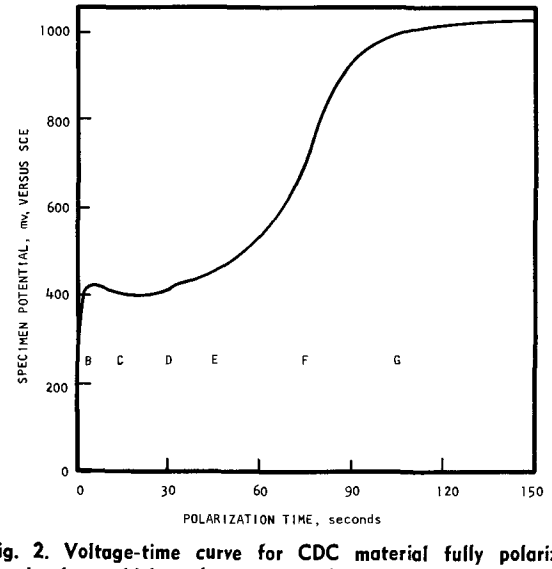

Fig. 2. Voltage-time curve for CDC material fully polarized. Shows levels to which each experimental specimen was polarized.

Table I. Results of tin and chromium analyses

Specimen	A Polarization time, sec	B Surface tin oxides, MCE/dm²	C Dissolved tin, μg/dm²	D Dissolved chromium, μg/dm²
A	—	11	—	—

C	15.0	54	41	18.0
D	30.0	111	59	34.5
E	45.0	165	83	48.2
F	75.0	288	133	65.8
G	105.0	392	171	69.9

Potentiokinetic Experiments

In order to discern the contribution of oxygen evolution ($2\,OH^- \rightarrow O_2 + 2H^+ + 4e$) to the coulometry of the galvanostatic experiments, potentiokinetic polarizations of the same material were made for the determination of the minimum potential at which that reaction can occur.

Procedure and results.—Using a potentiostat controlled by a motor-driven potentiometer, the potential of the specimen (*vs.* SCE) was increased linearly from 0 to 1100 mV at a rate of 50 mV/min. Figure 3 shows the resultant cell current *vs.* potential up to 1000 mV, as recorded on an X-Y recorder.

From 0 to 300 mV (*vs.* SCE) the cell current slowly increased from 0.0 to 0.4 mA. From this point it rapidly increased to a maximum (6.5 mA) at 420 mV, which is approximately the same voltage as the potential arrest (400 mV) noted during galvanostatic experiments (Fig. 2). The current then declined to a minimum of 1.5 mA at 750 mV. As the potential increased above 800 mV the current again increased rapidly to a maximum of 14 mA at 1100 mV (off scale) and the evolution of gas bubbles was observed on the specimen's surface.

This same specimen was polarized a second time, and no significant current flowed until the potential reached 750 mV. After 800 mV the current again increased to a maximum (Fig. 4).

When this experiment was repeated with a specimen of chromium-free tinplate the resultant curve was very similar to Fig. 4, except that a current of 0.2 mA began to flow at 250 mV. Again, when this specimen was polarized for a second time no current flowed until a potential of 750 mV was attained.

Discussion

Having obtained both the experimental data from the potentiokinetic experiments (which will show the potential at which O_2 evolution became significant) and the analytical data from the galvanostatic experiments, we can now determine the original oxidation state of the chromium.

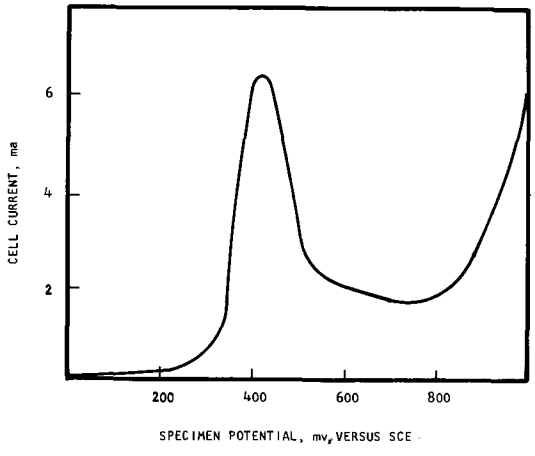

Fig. 3. Current-voltage relationship for first potentiokinetic polarization of CDC material. Potential increased 50 mV/min.

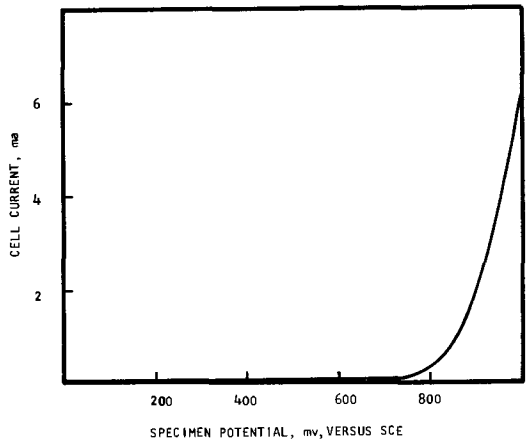

Fig. 4. Current-voltage relationship for CDC material polarized potentiokinetically a second time. Potential increased 50 mV/min.

Potentiokinetic experiments.—The recorded current peak at 420 mV for the CDC-treated specimens (Fig. 3) and the lack of such a peak for untreated tinplate indicate that the CDC passivation film was oxidized at that potential. However, the small current which began early for both CDC-treated and untreated samples must be due to the oxidation of the tin surface. In the case of the unpassivated specimen this current was smaller than for CDC-treated tinplate, because air oxidation of the unpassivated surface had proceeded to a higher degree.

The absence of measurable current until 750 mV was reached on the specimens polarized for a second time (Fig. 4) indicates that O_2 evolution ($2\,OH^- \rightarrow O_2 + 2H^+ + 4e$) was not an appreciable factor prior to that potential. This, in turn, means that O_2 played no significant role in the coulometry of the galvanostatic experiments before 750 mV was reached.

Galvanostatic experiments.—As previously stated, a tin oxide value of 11 MCE/dm² was originally present on the specimens, and the 3-min exposure to the electrolyte caused the chemical dissolution of 16 μg Sn/dm². In Table II these values are subtracted from the data, so that only electrochemical oxidation products are shown. Dissolved tin is now expressed as MCE/dm², since tin dissolving electrochemically at these potentials (≧400 mV *vs.* SCE) would be expected to be oxidized to the +4 state. Our experiments showed this to be the case, allowing the electrochemical equivalent of 3.25 coulombs/mg to be assigned. Figure 5 shows the electrochemical rates of tin dissolution and oxide formation.

Table II also presents another quantity, referred to as the "delta charge," which is that quantity of electricity (millicoulombs/square decimeter) not explained by the total oxidation of tin. The delta charge must therefore be the charge used in the oxidation of chromium and/or the evolution of oxygen on a specimen surface above 750 mV.

Figure 6 shows the dissolution of chromium *vs.* the delta charge. Chromium dissolves at a constant rate of 0.117 μg/Δmcoulomb for slightly more than 320

Table II. Relationship of coulometric charge to electrochemical oxidation products

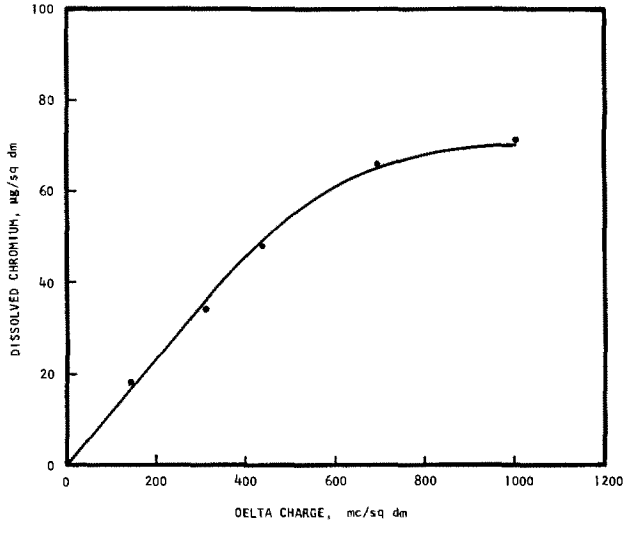

Fig. 6. Chromium dissolved in electrolyte during galvanostatic polarizations vs. delta charge.

Δmcoulombs/dm², a value which corresponds closely to the duration of the galvanostatic potential arrest at 400 mV (*vs.* SCE). From this point the rate decreases until chromium dissolution ceases and the decomposition potential of the electrolyte (O_2 overvoltage) is reached ($\simeq$1000 mV *vs.* SCE). At this potential the evolution of oxygen is easily observed.

The initial chromium dissolution rate of 0.117 µg/Δmcoulomb supposedly could be interpreted as the oxidation of Cr^{+3} at a current efficiency of 65%. However, since this initial rate occurs at a potential far below that at which oxygen evolution can occur (as shown in the potentiokinetic experiments) and since all other oxidation products have been accounted for, it follows that Cr° and Cr^{+3} are being oxidized simultaneously. When applied to data from Fig. 6, a simple equation (µg Cr° = [Δmcoulombs/5.565] − µg ΣCr), derived algebraically from the electrochemical equivalents of Cr° and Cr^{+3}, can be used to calculate the weight of Cr° oxidized and, by simple difference, that of the Cr^{+3}.

This equation shows that Cr° and Cr^{+3} are initially oxidized at a constant rate of (0.063 µg Cr° + 0.054 µg Cr^{+3})/Δmcoulomb. After 320 Δmcoulombs, the oxidation of Cr^{+3} rapidly decreases, ceasing entirely after 460 Δmcoulombs at a total weight of 19 µg/dm². The oxidation of Cr° consumes the excess charge until the potential reaches approximately 750 mV (*vs.* SCE), at which point oxygen evolution begins. By the time 970 Δmcoulombs has passed, chromium oxidation has ceased and the decomposition potential of the electrolyte has been reached. The amount of Cr° oxidized is about 51 µg/dm², or the difference between total dissolved chromium and the Cr^{+3}. This quantity corresponds to roughly 54% of the total surface chromium (94 µg/dm²).

Investigators have disagreed as to the identification of the residual chromium left on the specimen after polarization to the decomposition potential (24 µg/dm²). For example, Britton, who reported a much greater quantity of residual chromium than we found in our work, theorized that the residual material might be Cr^{+6} united with SnO_2. However, if his hypothesis were correct, the chromium would have been oxidized to the +6 state during galvanostatic polarization, a result which was not borne out by data we obtained in the following experiment.

The experiment consisted of exposing a fully polarized specimen to a solution of 0.1M oxalic acid for 5 min under an argon atmosphere to avoid air oxidation of the tin surface. (The work done during the development of the MCE test for the quantitative determination of tin oxide films had shown that the oxalic acid solution dissolves these films (4). This solution also dissolves Cr^{+6}.) After an oxidation step the solution was analyzed colorimetrically for chromium. None was found, indicating that the residual is not Cr^{+6} combined with the tin oxide film.

It is more reasonable to assume that the residual chromium is in its trivalent form and is either an inherently poor conductor or one with which good electrical continuity was lost due to the large growth of tin oxides. In any event, given the fact that the residual chromium was not oxidized during the galvanostatic tests, this chromium is not a factor in the coulometry of the polarization.

Conclusion

To sum up, the results of galvanostatic and potentiokinetic experiments interpreted analytically using Faraday's law proved that a substantial portion of the CDC passivation film on tinplate is chromium in the metallic state, the following reactions having occurred during the anodic polarization of the tinplate in 3% aqueous ammonia:

$$Cr^\circ \rightarrow Cr^{+6} + 6e$$

$$Cr^{+3} \rightarrow Cr^{+6} + 3e$$

$$Sn^\circ \rightarrow Sn^{+4} + 4e$$

$$Sn^\circ \rightarrow SnO_2 + 4e$$

$$2\,OH^- \rightarrow O_2 + 2H^+ + 4e$$

(only occurs above 750 mV *vs.* SCE)

For the specimens studied in detail the passivation film was found to contain approximately 54% metallic chromium.

Manuscript submitted Oct. 10, 1972; revised manuscript received Dec. 15, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

An Electrochemical Study of Electroless Gold-Deposition Reaction

Yutaka Okinaka*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electroless (autocatalytic) gold-deposition reaction, using potassium borohydride as the reducing agent, was studied by electrochemical methods. The results support the assumptions made previously that (*i*) the species that reduces aurocyanide ions is BH_3OH^-, an intermediate formed during the hydrolysis of BH_4^-, and (*ii*) the deposition reaction is preceded by competitive adsorption of reacting species.

The hydrolysis kinetics of borohydride ions, under conditions of the electroless process, was also studied using a polarographic method. The results allowed the calculation of rate constants and the variation of concentrations of BH_4^- and BH_3OH^- as a function of time during operation of the electroless plating bath.

The electroless gold-plating bath developed recently in this laboratory (1) contains $KAu(CN)_2$, KCN, KOH, and KBH_4, and is operated at 70°-80°C. The process is autocatalytic and deposits pure gold on gold substrates without incorporation of boron. In the initial study of this system of the dependence of deposition rate on various experimental variables, two rather unexpected results were noted (1). One was the decrease in deposition rate with increasing KOH concentration, a dependence which is opposite from what might be expected from the over-all deposition reaction which is believed to involve hydroxyl ions as a reactant. In view of the reasonably well-established reaction of borohydride ions (2-4), this result was accounted for by assuming that the species that actually reduces $Au(CN)_2^-$ to gold metal is not BH_4^- but BH_3OH^-, an intermediate formed during the course of hydrolysis of BH_4^-. Since the hydrolysis reaction is catalyzed by acids, the concentration of BH_3OH^- is expected to be lower at higher alkalinities. The other unexpected result was that with increasing $KAu(CN)_2$ concentration, the deposition rate increased to a maximum followed by a gradual decrease. This unusual dependence was one of the important factors considered in formulating optimum bath compositions to obtain not only an acceptable deposition rate, but also deposits of satisfactory physical properties (5, 6). In order to explain the observed effect of $KAu(CN)_2$ concentration on the deposition rate, it was postulated (1) that the deposition reaction is preceded by competitive adsorption of BH_3OH^- and $Au(CN)_2^-$ on the substrate surface. The purpose of this communication is to present and discuss results of an electrochemical study that supports the above assumptions.

Experimental

Chemicals.—Potassium hydroxide and potassium cyanide were of C.P. grade. Potassium aurocyanide (68+% Au) was a product of Technic, Incorporated, and potassium borohydride (98%) was obtained from City Chemical Corporation.

Equipment.—Current-potential curves were obtained with a set of equipment consisting of a Wenking potentiostat, motor potentiometer, and X-Y recorder. The electrolytic cell was a jacketed 200 ml Pyrex glass beaker, and the temperature was maintained at 75°C by circulating constant temperature water from a Lauda circulator.

Electrodes.—A rotating platinum disk electrode (diameter 0.77 cm), precoated with about 25 μm thick electrolytic gold, was used for the experiment of Fig. 11. For all other experiments involving the use of gold as the working electrode, a piece of rectangular gold sheet with an area of 1 cm^2 was employed. No insulating or masking material was used. A fine gold wire was welded onto a corner of the gold sheet, and the electrode was hung through a small hole drilled through the Teflon cover of the cell. The solution was gently stirred at a constant speed with a magnetic stirrer. Current fluctuation of ±5-10% was unavoidable under these experimental conditions, but the precision and reproducibility were considered to be acceptable for the purpose of this investigation. The current values reported for gold-sheet electrode experiments are the average of such fluctuating currents. The counterelectrode was a platinum coil placed in a compartment separated from the main cell by a fritted glass disk. A Hg/HgO reference electrode in 1M KOH at room temperature was connected to the cell through a salt bridge with a capillary tip filled with 1M KOH.

The dropping mercury electrode used had the following characteristics: $m = 2.07$ mg·sec^{-1} and $t = 4.02$ sec at −0.40V in 0.2M KOH at 75°C. Current measurements were made at the end of the life of mercury drops. Dissolved air was removed by bubbling purified nitrogen through solutions in all experiments.

Results and Discussion

BH_3OH^- as the reducing species.—It is fairly well established that the hydrolysis of BH_4^- proceeds in two steps (2-4)[1]

$$BH_4^- + H_2O \xrightarrow{k_1} BH_3OH^- + H_2 \qquad [1]$$

$$BH_3OH^- + H_2O \xrightarrow{k_2} BO_2^- + 3H_2 \qquad [2]$$

The polarographic investigation carried out by Gardiner and Collat (4) shows that at the mercury electrode, the BH_3OH^- ion formed as the intermediate is much more readily oxidized than BH_4^-. The anodic wave for the oxidation of BH_3OH^- according to

$$BH_3OH^- + 3\,OH^- \rightarrow BO_2^- + 3/2H_2 + 2H_2O + 3e^- \qquad [3]$$

appears at a potential about 0.5V more negative than that of BH_4^-

$$BH_4^- + 8\,OH^- \rightarrow BO_2^- + 6H_2O + 8e^- \qquad [4]$$

At platinum the anodic oxidation of these two ions does not occur at such discrete potentials (9, 10). The be-

Key words: electroless plating, autocatalytic plating, gold plating, borohydride, electrocatalysis, adsorption.

[1] Species such as $(BH_3)_{aq}$ (7), $BH(OH)_2$ (7), or $BH(OH)_3^-$ (8) have also been suggested for the hydrolysis intermediate, but the formula BH_3OH^- appears to have the most convincing experimental support.

havior of these ions at a gold electrode has not been reported in the literature to the author's knowledge. Thus, the question arises as to whether the species directly responsible for the electroless deposition of gold is BH_3OH^-, or BH_4^-, or both. An answer to this question was obtained by comparing potentials measured during the deposition of gold with current-potential curves for the anodic oxidation of borohydride solutions at a gold electrode.

Figure 1 shows the variation of open-circuit potential with the concentration of $KAu(CN)_2$ in the absence (line 1) and presence (line 2) of 0.1M KBH_4 in a mixture of 0.2M KOH and 0.2M KCN. The measurement was made at 75°C, a typical operating temperature of the electroless bath. In the absence of KBH_4 the potential changed linearly with $\log[Au(CN)_2^-]$, and the slope of the line, 64 mV, agreed well with the theoretical Nernst value of 69 mV for the reaction

$$Au(CN)_2^- + e^- \rightleftarrows Au + 2CN^- \qquad [5]$$

With KBH_4 in the solution, the measured potential was always more negative than the corresponding equilibrium potential and ranged from −0.7 to −1.0V in the concentration range studied (line 2, Fig. 1). The potential shift was greater at higher KBH_4 concentrations (line 3) as expected for a typical mixed potential reaction.

Anodic current-potential curves obtained in various solutions at 75°C are shown in Fig. 2. Currents varied with time, as will be shown later, because the concentrations of both BH_4^- and BH_3OH^- changed with time due to hydrolysis. Recording of the curves shown in Fig. 2 was begun approximately 10 min after the solution temperature reached 75°C. Curve 1 was obtained with 0.1M KBH_4 in a mixture of 0.2M KOH and 0.2M KCN. Curve 1′ was obtained without KBH_4 in the solution and represents the anodic dissolution of the gold electrode. The difference in current between curves 1 and 1′ is due to the anodic oxidation of a borohydride species, but because of the interference caused by the large dissolution current of the electrode, these two curves do not provide information as to which borohydride species is responsible for the anodic current. Curve 2 was obtained in a solution containing 0.1M KBH_4 and 0.2M KOH in the absence of KCN. Comparison of curves 1 and 2 shows that cyanide ions greatly inhibit the anodic oxidation of the species in question. It is likely that this inhibiting effect results from the adsorption of CN^- on the electrode surface. (The adsorption of CN^- also accounts for the fact that the cathodic hydrogen evolution in the presence of KCN occurs at a potential about 0.1V more negative than that in the absence of KCN. Compare cathodic ends of curves 1 and 2.) Because of the high concentration of KBH_4 used for curve 2, it was not possible to record the current over the entire potential range. A much smaller concentration of KBH_4 (2×10^{-4}M) was used to obtain curve 3. In the potential range of curve 2, no current is visible in curve 3 because of the low KBH_4 concentration, but it is clear that the reaction which causes the sharp increase in anodic current in curve 2 starting at about −0.7V is responsible for the large anodic wave in curve 3. From these two curves and their similarity to the known polarographic behavior of borohydride solutions (4) (see also the next section), it may be assumed that the first wave (curve 2) is due to the oxidation of the hydrolysis intermediate, BH_3OH^-, whereas the second wave (curve 3) results from the oxidation of BH_4^-.[2] From the proximity of curves 1 and 2 the reaction corresponding to curve 1 is most likely to be the oxidation of BH_3OH^- partially inhibited by the adsorption of CN^-. These assumptions were further substantiated by examining the dependence of current on time as described below.

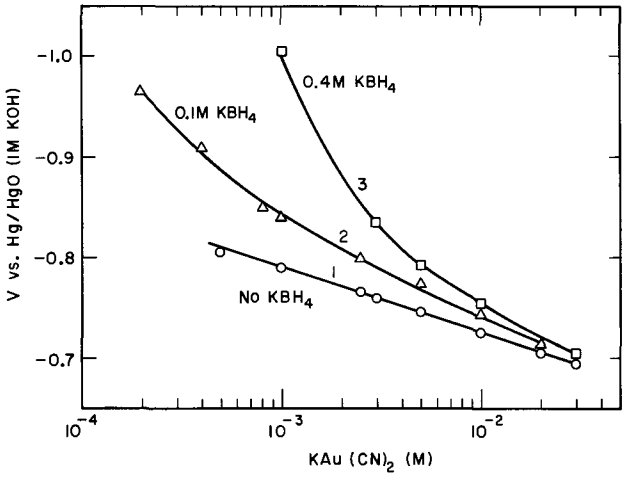

Fig. 1. Zero-current potential as function of $KAu(CN)_2$ concentration at various KBH_4 concentrations at 75°C. 0.2M KOH, 0.2M KCN.

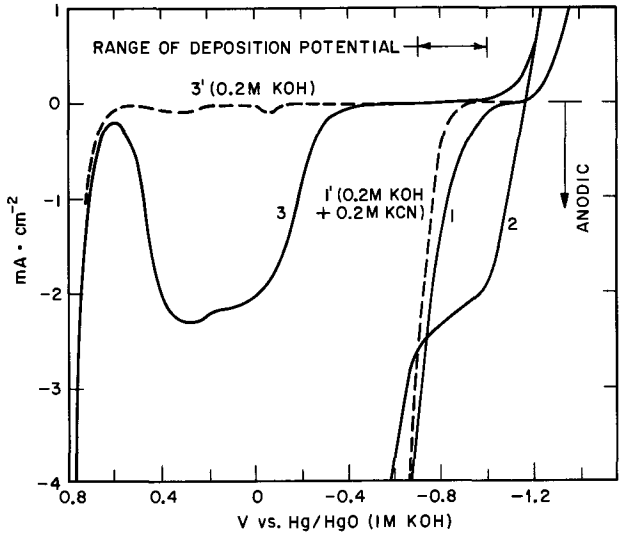

Fig. 2. Current-potential curves for oxidation of borohydride at gold electrode in various solutions at 75°C. Curve 1, 0.1M KBH_4 in 0.2M KOH plus 0.2M KCN; curve 1′, same as curve 1 without KBH_4; curve 2, 0.1M KBH_4 in 0.2M KOH; curve 3, 2×10^{-4}M KBH_4 in 0.2M KOH; curve 3′, same as curve 3 without KBH_4. Potential scanned from negative to positive at 5.56 mV/sec^{-1}.

According to the hydrolysis reaction scheme, Eq. [1] and [2], the concentrations of BH_4^- and BH_3OH^- at time t after the commencement of hydrolysis are given by the following equations (2)

$$(BH_4^-) = (BH_4^-)_o \, e^{-k_1 t} \qquad [6]$$

$$(BH_3OH^-) = \frac{(BH_4^-)_o}{(k_2/k_1) - 1} (e^{-k_1 t} - e^{-k_2 t}) \qquad [7]$$

where $(BH_4^-)_o$ is the initial concentration of BH_4^-, and k_1 and k_2 are the pseudo first-order rate constants of reactions [1] and [2] expressed in sec^{-1}. Thus, the mass-transfer controlled limiting current for the oxidation of BH_4^- should decrease exponentially with time, whereas that for the oxidation of BH_3OH^- is expected to increase first from zero at $t = 0$ to a maximum followed by a decrease with increasing t. The experimental results are shown in Fig. 3. The current measured at +0.100V in 0.2M KOH containing 2×10^{-4}M KBH_4 decreased continuously with time (curve 1), which is expected for the variation of (BH_4^-). On the other hand, the currents measured at −0.850V in mixtures of 0.1M KBH_4 and 0.2M KOH showed maxima in

[2] In 0.2M KOH without KBH_4 (curve 3′, Fig. 2) two small dips are noted: a well-defined narrow one with a peak at −0.06V and a broad, shallow one with a peak at about +0.3V. Comparison of this curve with curve 3 shows that the substance formed at the first dip (perhaps Au_2O) does not interfere with the oxide of BH_4^-, whereas this oxidation is greatly inhibited by the substance that forms at the second dip (Au_2O_3). The final current rise is undoubtedly due to the oxygen-evolution reaction.

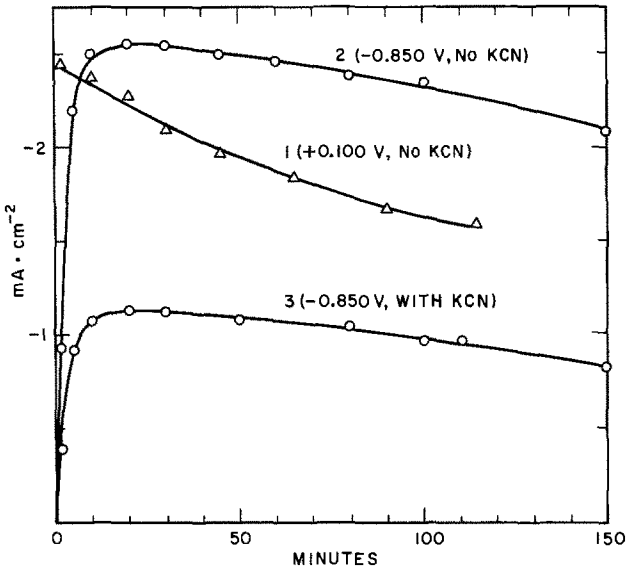

Fig. 3. Variation of oxidation current of borohydride with time at gold electrode at 75°C. Curve 1, 2 × 10^{-4}M KBH_4 in 0.2M KOH at +0.100V; curve 2, 0.1M KBH_4 in 0.2M KOH at −0.850V; curve 3, 0.1M KBH_4 in 0.2M KOH plus 0.2M KCN at −0.850V.

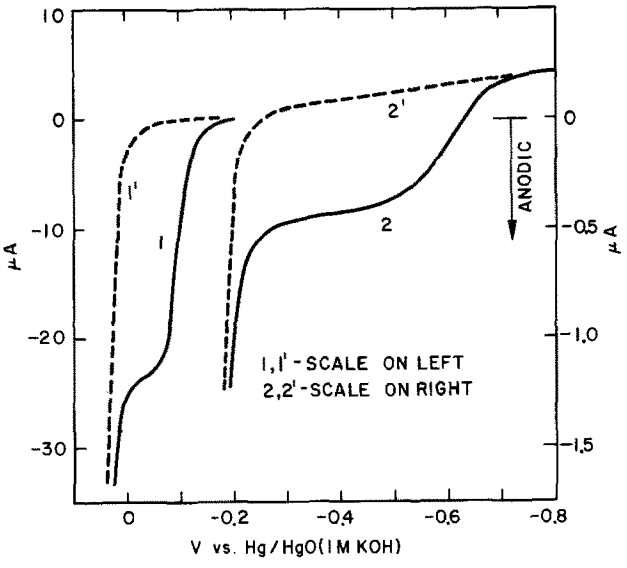

Fig. 4. Polarograms for anodic oxidation of BH_4^- (curve 1) and BH_3OH^- (curve 2) in 0.2M KOH at 75°C. Curve 1 taken with 5 × 10^{-4}M KBH_4 immediately after its addition, curve 2 with 2.5 × 10^{-3}M KBH_4 10 min after its addition. Broken lines, curves 1' and 2', residual current.

both the presence (curve 2) and absence (curve 3) of 0.2M KCN. This behavior is expected for the change in (BH_3OH^-) with time. In principle it should be possible to analyze quantitatively the current-time curves of Fig. 3 to calculate the rate constants. However, since the polarographic method using a dropping mercury electrode allowed much more precise measurements of current as described in the subsequent section, the data shown in Fig. 3 were not analyzed for quantitative purposes. Nevertheless, observed difference in the mode of variation of current with time at the two different potentials is sufficient to draw the conclusion that the current at −0.850V is due to the oxidation of BH_3OH^-, while that at +0.100V results from the oxidation of BH_4^-. As already noted in Fig. 1 and 2, the electroless deposition of gold takes place in the potential range of −0.7 to −1.0V, which precisely corresponds to the range where the oxidation of BH_3OH^- occurs. Thus, it is concluded that it is this intermediate species, and not BH_4^-, that acts as the reducing agent for the deposition of gold from $Au(CN)_2^-$.

Polarographic investigation of hydrolysis kinetics.— Knowledge of the rate constants, k_1 and k_2, for reactions [1] and [2] is of interest because it allows calculation of the concentrations of BH_4^- and BH_3OH^- at any time during the hydrolysis. This information is also useful because it can be used to calculate the amount of potassium borohydride to be added for the purpose of replenishment during the operation of the bath (11).

Gardiner and Collat (2) reported polarographically determined rate constants in various buffer solutions of pH values between 8.9 and 10.2 at temperatures below 35°C. Since estimation of the rate constants under operating conditions of the electroless bath from the data of Gardiner and Collat involves a large degree of extrapolation and uncertainty, it was decided to make actual polarographic measurements of rate constants. Polarographic waves for the anodic oxidation of BH_4^- (curve 1) and BH_3OH^- (curve 2) in 0.2M KOH at 75°C are shown in Fig. 4. The electrode reactions are given by Eq. [3] and [4]. The presence of KCN interfered because the anodic oxidation of the mercury electrode to form $Hg(CN)_2$ (12) occurred at a potential about 0.3V more negative than that for the oxidation of BH_4^-, and therefore all polarographic measurements were made in the absence of KCN. It was found that the effect of KCN on the rate of hydrolysis is relatively small, as may be expected from the fact that the hydrolysis reaction is catalyzed by acids (2) and the only acidic species present in the electroless system at a significant concentration is H_2O, regardless of the concentration of KCN. The following experimental result shows the small KCN effect. Ten milliliters of solution containing 0.2M KOH and 0.4M KBH_4 were heated to 75°C and the rate of hydrogen-gas evolution was measured. A closed vessel connected to a gas burette was used in this experiment. The gas volume increased approximately linearly with time over a period of 1 hr. The volume measured at the end of the 1-hr period was 56.0 ml at 1 atm and room temperature (average of three determinations). This corresponds to the hydrolysis rate of 15.6% per hour as calculated on the basis of the over-all hydrolysis reaction $BH_4^- + 2H_2O \rightarrow BO_2^- + 4H_2$, ignoring the effect of partial hydrolysis to BH_3OH^-, which is small as will be shown later. The measurement was repeated with the addition of 0.2M KCN to the above solution. The volume of hydrogen gas measured was 50.4 ml, corresponding to a hydrolysis rate of 14.0%. Thus, the effect of KCN was to decrease the hydrolysis rate by about 10% with respect to the rate in the absence of KCN. This is perhaps an effect of the increased ionic strength (2).

The experiment for the calculation of rate constants consisted of measuring the diffusion currents at −0.05 and −0.40V (see Fig. 4) as a function of time to follow the change in BH_4^- and BH_3OH^- concentrations, respectively. The very small ratio of $i_{BH_3OH^-}/i_{BH_4^-}$ found in a single solution necessitated separate measurements of the two currents in solutions containing different concentrations of KBH_4. The equations used were those derived by Gardiner and Collat (2); namely

$$i_{BH_4^-} = R_{BH_4^-}\,(BH_4^-)_0\, e^{-k_1 t} \qquad [8]$$

$$k_1 t_{max} = \frac{1}{(k_2/k_1) - 1} \ln (k_2/k_1) \qquad [9]$$

where $R_{BH_4^-}$ is the proportionality constant determined by the characteristics of the polarographic capillary used, and t_{max} is the time at which $i_{BH_3OH^-}$ is maximum. Equation [8] predicts that plotting log $i_{BH_4^-}$ against t yields a straight line, and k_1 can be calculated from the slope of this line. Equation [9] permits the calculation of k_2 from the value of k_1 thus determined, and t_{max} found in the $i_{BH_3OH^-}$ *vs.* t curve. The experimental results obtained are shown in Fig. 5 and 6. The rate constants calculated were as follows:

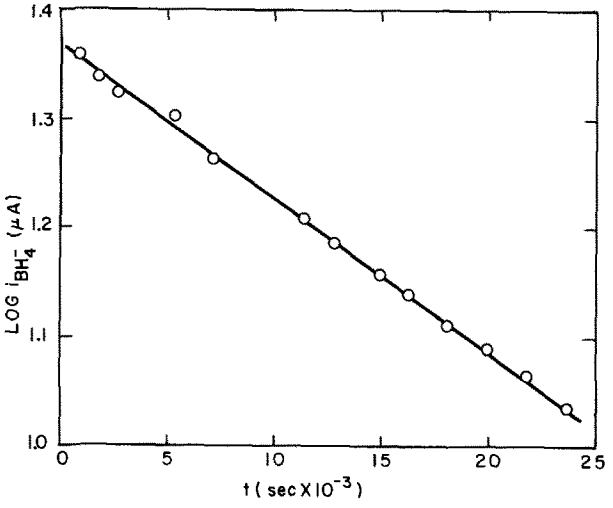

Fig. 5. Plot of log $i_{BH_4^-}$ vs. time. Current measured at −0.05V in 0.2M KOH at 75°C. Initial KBH_4 concentration, 5 × 10^{-4}M.

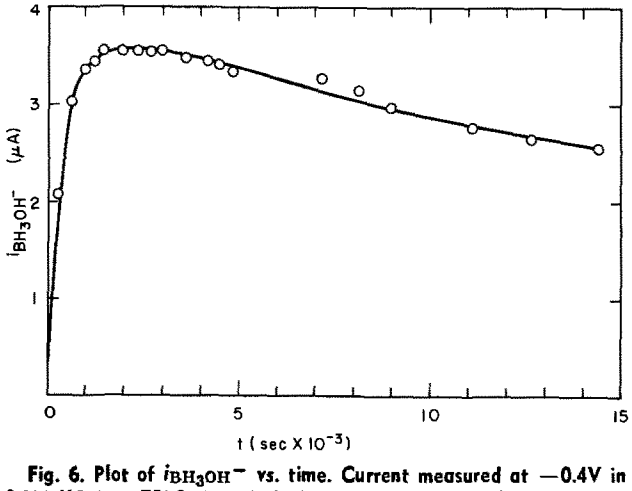

Fig. 6. Plot of $i_{BH_3OH^-}$ vs. time. Current measured at −0.4V in 0.2M KOH at 75°C; initial KBH_4 concentration. 0.01M.

$k_1 = 3.29 \times 10^{-5}$ sec^{-1}, $k_2 = 1.43 \times 10^{-3}$ sec^{-1} in 0.2M KOH at 75°C.

These values now being known, the instantaneous concentrations of BH_4^- and BH_3OH^- can be calculated for any initial concentration of BH_4^- with the aid of Eq. [6] and [7]. The ratios $[BH_4^-]/[BH_4^-]_o$ and $[BH_3OH^-]/[BH_4^-]_o$ calculated in this manner over a period of 8 hr are shown in Fig. 7. The curves represent the calculated values, and the points are the experimental values found polarographically. It is significant to note that the concentration of BH_3OH^- never exceeds about 2.2% of the initial KBH_4 concentration. Since BH_3OH^- is the species that acts as the reducing agent, it can be stated that the efficiency of utilization of KBH_4 in the electroless gold-deposition process is very low, and most of KBH_4 is lost by hydrolysis.

Competitive adsorption of reacting species.—The dependence of the deposition rate on $KAu(CN)_2$ concentration is quite unusual in that it exhibits a maximum at about 0.003M (1). The appearance of the maximum was previously assumed to be due to a competitive adsorption of $Au(CN)_2^-$ and BH_3OH^- on the substrate surface prior to the heterogeneous redox reaction. If $Au(CN)_2^-$ is more strongly adsorbed than BH_3OH^-, an increase in $Au(CN)_2^-$ concentration will tend to interfere with the adsorption of BH_3OH^-, thus decreasing the deposition rate beyond a certain $Au(CN)_2^-$ concentration. Experimental results and discussions presented below support this assumption.

Adsorption of BH_3OH^-.—In Fig. 2 it is seen that the anodic oxidation current of BH_3OH^- at the gold

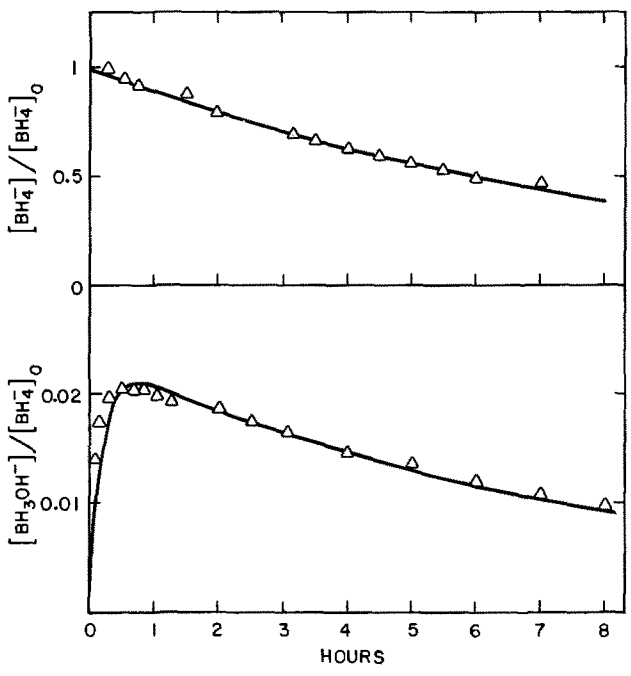

Fig. 7. Variation of concentrations of BH_4^- and BH_3OH^- with time with respect to the initial BH_4^- concentration in 0.2M KOH at 75°C. Lines calculated from rate constants; points experimental.

electrode in 0.2M KOH (curve 2) merges at the cathodic end (−1.2V) with the hydrogen-evolution current observed in the absence of borohydride (curve 3). This means that the BH_3OH^- oxidation occurs at a potential at least as negative as, or possibly more negative than, the hydrogen-evolution potential. At mercury, on the other hand, the oxidation of BH_3OH^- takes place at about −0.6V (see Fig. 4, curve 2), which is at least 0.5V less negative than the corresponding potential at gold. This potential difference corresponds to a difference in rate constant by several orders of magnitude, the exact difference being dependent on other kinetic parameters of the reaction. Such a large effect of electrode material (13) can be understood only by postulating a considerably greater electrocatalytic activity of gold due to the chemisorption of BH_3OH^-.

The dependence of the rate of electroless gold deposition on the crystalline orientation of the substrate is also of interest in this context. Sard and Wonsiewicz (14), using single-crystal copper substrates, found that the gold deposition rate decreases in the order (111) > polycrystal > (100) > (110). The rate on (111) surfaces was found to be about four times greater than that on (110). It is significant to note that this sequence is identical to that reported recently by Bagotzky, Vassiliev, and Pyshnograeva (15) for the electrocatalytic activity of various crystalline faces of platinum toward the hydrogen and oxygen evolution reactions as well as the anodic oxidation of methanol. Discussion of the cause of the orientation effect is beyond the scope of this paper, but there is little doubt that the chemisorption of reacting species is involved in these electrocatalytic reactions (13, 15) as well as in the electroless gold-deposition process.

Adsorption of $Au(CN)_2^-$.—On the basis of the dependence of current on concentrations at a constant overpotential, Maja (16) proposed a mechanism for the reduction of $Au(CN)_2^-$ in which this ion is postulated to be adsorbed on the gold electrode prior to the reduction. However, there is no direct experimental evidence available to prove the adsorption. On the other hand, it was found that $Au(CN)_2^-$ adsorbs strongly on the surface of mercury. This is evidenced by the large effect of $Au(CN)_2^-$ on the electrocapillary curves at potentials less negative than the potential where $Au(CN)_2^-$ begins to be reduced (Fig. 8). It is

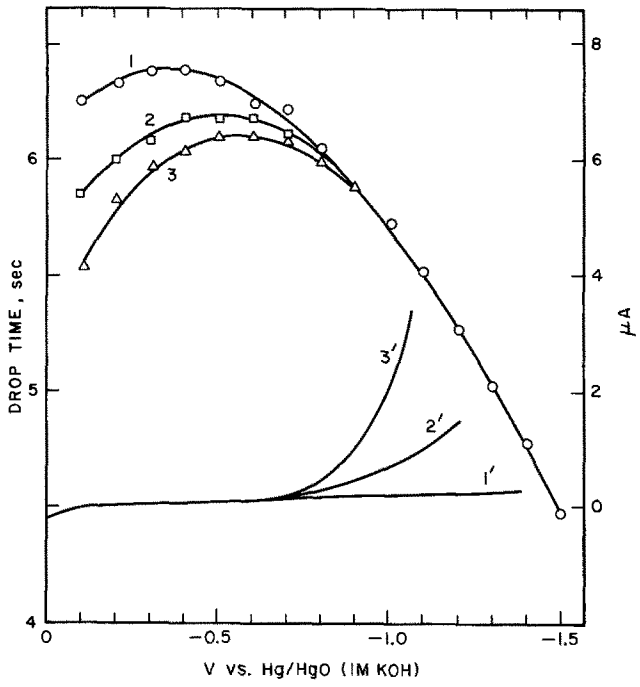

Fig. 8. Electrocapillary curves (1,2,3) and polarograms (1', 2', 3') at various concentrations of $KAu(CN)_2$ in 0.2M KOH at room temperature. Curves 1 and 1', no $KAu(CN)_2$; curves 2 and 2', 0.001M; curves 3 and 3', 0.005M.

also seen in Fig. 8 that the electrocapillary maximum is shifted toward more negative potentials and that the decrease in drop time is greater at less negative potentials. These results show that the adsorbed species is negatively charged.

Effect of $Au(CN)_2^-$ on anodic oxidation of BH_3OH^-.— The over-all deposition reaction can be considered to consist of the two partial electrochemical reactions, Eq. [3] and [5], occurring at an equal rate at the mixed potential. Thus, if there is no secondary kinetic interaction between the two partial reactions (*e.g.*, a reactant or product of one partial reaction affects the kinetics of the other), the cathodic-reduction current of $Au(CN)_2^-$ measured at the mixed potential in the absence of BH_3OH^- should be equal to the anodic-oxidation current of BH_3OH^- measured in the absence of $Au(CN)_2^-$. This relationship was found to hold when the $KAu(CN)_2$ concentration was very low as illustrated in Fig. 9 for the case of 2×10^{-4}M $KAu(CN)_2$.

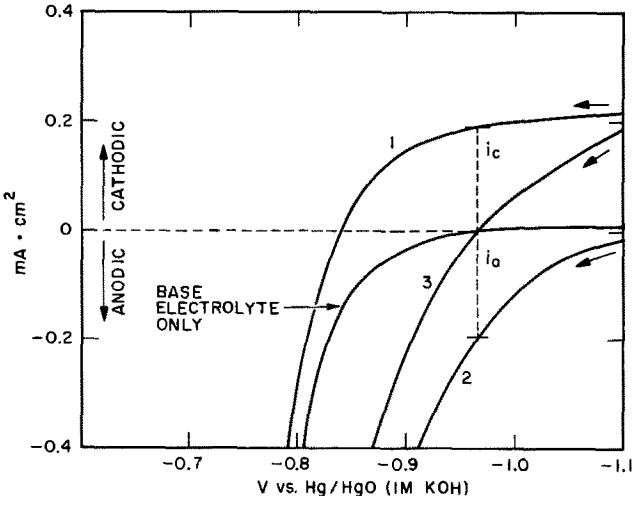

Fig. 9. Current-potential curves at gold electrode at 75°C. Base electrolyte, 0.2M KOH plus 0.2M KCN; curve 1, 2×10^{-4}M $KAu(CN)_2$ without KBH_4; curve 2, 0.1M KBH_4 without $KAu(CN)_2$; curve 3, 2×10^{-4}M $KAu(CN)_2$ and 0.1M KBH_4. Potential scanned from negative to positive at 5.56 mV/sec^{-1}.

The curves for solutions containing KBH_4 were recorded between 10 and 30 min after the addition of KBH_4, during which period the concentration of BH_3OH^- was practically constant (see Fig. 3). With increasing $KAu(CN)_2$ concentration, the deposition potential shifts in the positive direction (Fig. 1), and the contribution of the anodic-oxidation current of gold to the total anodic current becomes significant. Figure 10 illustrates the situation for the case where the $KAu(CN)_2$ concentration was 10^{-3}M. It is seen that the oxidation current of BH_3OH^-, designated as $i_{BH_3OH^-}$, must be calculated by subtracting the oxidation current of gold measured in the base electrolyte alone (0.2M KOH + 0.2M KCN) from the total anodic current i_a. Note that $i_{BH_3OH^-}$ is significantly greater than i_c in this case. This inequality was observed at all higher $KAu(CN)_2$ concentrations studied (up to 0.02M). In separate experiments it was found that gravimetrically determined deposition rates are equivalent to i_c rather than $i_{BH_3OH^-}$. These results show that the presence of $Au(CN)_2^-$ at concentrations greater than about 10^{-3}M does interfere with the anodic oxidation of BH_3OH^-. It is considered reasonable to ascribe this phenomenon to the adsorption of $Au(CN)_2^-$ on some of the sites where BH_3OH^- would adsorb if the solution did not contain $Au(CN)_2^-$.

Effect of $Ni(CN)_4^{--}$ on anodic oxidation of BH_3OH^-.— It was found that the $Ni(CN)_4^{--}$ ion exerts a similar effect on the oxidation of BH_3OH^-. This phenomenon is described here because the effect of $Ni(CN)_4^{--}$ is much more clearly visible than that of $Au(CN)_2^-$ owing to the fact that $Ni(CN)_4^{--}$ is not reduced in the potential range where BH_3OH^- is oxidized. Effects of 1×10^{-4} and 3×10^{-4}M $NiSO_4$[3] on the current-potential curve for the oxidation of BH_3OH^- are illustrated in Fig. 11 (curves 1-3). The reduction current of $Au(CN)_2^-$ is unaffected by nickel ions (curve 4). Striking similarities in the form of the two ions, $Ni(CN)_4^{--}$ and $Au(CN)_2^-$, and in their effect on the electrocatalytic activity of gold are noteworthy.

The poisoning effect of $Ni(CN)_4^{--}$ also accounts for the observation that the deposition rate of electroless gold decreases drastically when small amounts of nickel ions are added in the bath (18). A decrease in deposition rate with use of the bath was also noted when nickel metal was employed as substrate. This is due to the fact that the gold deposition on nickel metal takes place initially by the displacement reaction, in which nickel metal dissolves into the bath to

[3] In the 0.2M KOH-0.1M KCN mixture used, nickel is most likely to be present in the form of $Ni(CN)_4^{--}$ (17).

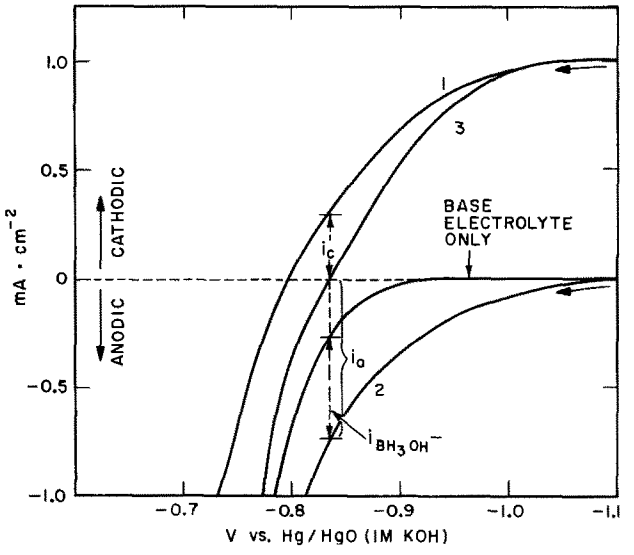

Fig. 10. Current-potential curves at gold electrode at 75°C. Conditions were the same as for Fig. 9 except that the $KAu(CN)_2$ concentration was 10^{-3}M.

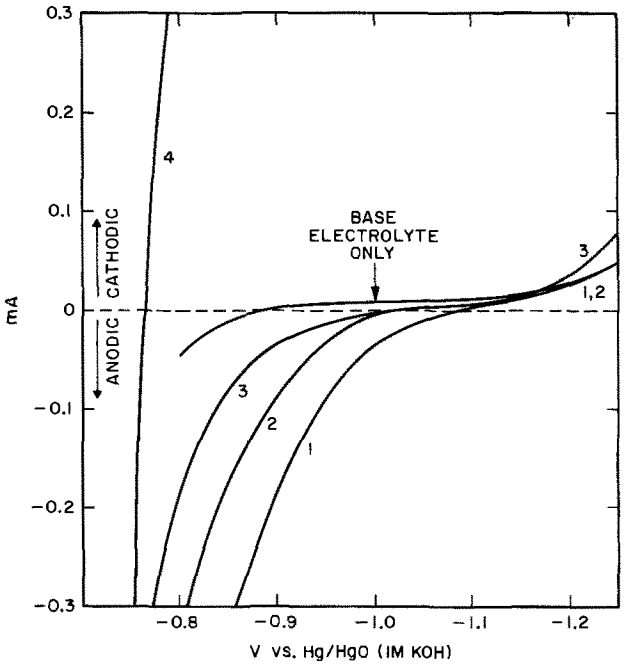

Fig. 11. Effect of nickel ions on anodic oxidation of BH_3OH^- at gold-plated rotating-platinum disk electrode (1600 rpm) at 75°C. Base electrolyte, 0.2M KOH + 0.1M KCN; curve 1, 0.1M KBH_4, no $NiSO_4$; curve 2, 0.1M KBH_4, 1×10^{-4} $NiSO_4$; curve 3, 0.1M KBH_4, 3×10^{-4}M $NiSO_4$; curve 4, 1×10^{-3}M $KAu(CN)_2$, no KBH_4, with or without 1×10^{-3}M $NiSO_4$.

form $Ni(CN)_4^{--}$ until it is completely covered with gold deposits.

Experimental evidences presented above are considered sufficient to support the originally proposed concept of competitive adsorption of $Au(CN)_2^-$ and BH_3OH^-. Further details of the reaction mechanism cannot be derived from the results of this study alone. However, based on the recent study of Holbrook and Twist (19) on the mechanism of surface-catalyzed hydrolysis of BH_4^-, it may be speculated that the chemisorption of BH_3OH^- is dissociative involving the splitting of B-H bonds to form adsorbed hydrogen atoms and boron-containing radicals. It is likely that the electrons necessary for reducing adsorbed $Au(CN)_2^-$ are supplied by the adsorbed boron-containing radicals, and two adsorbed hydrogen atoms simply combine with each other to form molecular hydrogen.

Summary and Conclusion

(*i*) The species that reduces $Au(CN)_2^-$ is BH_3OH^- and not BH_4^-. The former is an intermediate of the hydrolysis reaction of BH_4^-, and its concentration during the electroless deposition is only 2% or less of the initial BH_4^- concentration.

(*ii*) The pseudo first-order rate constants, k_1 and k_2, for the two stages of hydrolysis of borohydride ions were determined by the polarographic method in 0.2M KOH at 75°C. The values found were $k_1 = 3.29 \times 10^{-5}$ sec^{-1} and $k_2 = 1.43 \times 10^{-3}$ sec^{-1}. The addition of KCN decelerates the hydrolysis to a small extent.

(*iii*) Results of this study and the dependence of deposition rate on $KAu(CN)_2$ concentration reported previously (1) are both consistent with the assumption that the deposition process is preceded by competitive adsorption of $Au(CN)_2^-$ and BH_3OH^-.

Electrolytic Oxidation of Nitroalkane Anions

S. Wawzonek* and Tsung-Yuan Su

Department of Chemistry, University of Iowa, Iowa City, Iowa 52240

ABSTRACT

Voltammetric studies have been carried out with nitroalkanes in basic buffers in aqueous medium. Similar studies in dimethylformamide and in methanol were limited to 2-nitropropane. Large scale electrolyses of 2-nitropropane were carried out in dimethylformamide and methanol and gave 2,3-dimethyl-2,3-dinitrobutane. In methanol, 1-nitropropane gave a low yield of 1,1-dinitropropane, and 2,5-dinitrohexane in the same solvent gave 2,5-hexanedione.

Studies of the electrochemical oxidation of nitroalkane anions in the past have dealt mainly with large scale electrolyses and report the formation of a variety of products. Phenylnitromethane and 9-nitrofluorene (1) form in alkaline solution 1,2-dinitro-1,2-diphenylethane and 9,9'-dinitro-9,9'-difluorenyl, respectively.

In aqueous alkali, 2-nitropropane gave 2,3-dimethyl-2,3-dinitrobutane and 2,2-dinitropropane; 2-nitrobutane behaved similarly. If the oxidation is carried out in the presence of sodium nitrite, the amount of the 2,2-dinitropropane is increased (2).

The cross-coupling of sodium nitrite with nitroethane (3) and 1,1-dinitroalkanes (4) gave 1,1-dinitroethane and 1,1,1-trinitroalkanes, respectively.

Primary nitroalkanes are oxidized to vicinal dinitroalkanes and olefins (5). On the other hand, 1,6-dinitrohexane gave no cyclohexane derivative (6).

The use of triethylamine as a base in nitromethane, nitroethane, and 2-nitropropane gave nitroethanol, 3-nitro-2-butanol, and acetone, respectively (7).

The free radical nature of the reaction was demonstrated by the electrolysis of anions from 2-nitropropane and nitrocyclohexane in the presence of styrene and ethyl vinyl ether. Products were obtained containing both monomers (8).

Voltammetric studies of the oxidation of nitroalkane anions has been limited to a report of the oxidation potential of nitroethane and 2-nitropropane in methanol-benzene (1:1) (8).[1] Information of this type was considered to be desirable in understanding the mechanism of the oxidation and in devising electrolysis conditions which would maximize the yields of the dinitro derivatives.

Experimental

Voltammetric studies were carried out using a microplatinum electrode which was rotated at a constant speed of 571 rpm.

General procedure.—The stock solution (1 ml) which contained 0.01*M* nitroalkane in 30% methanol, was added to 9 ml of the buffer and the resulting solution was degassed at 25°C with nitrogen for 20 min. Polarograms were recorded with a Sargent Model 21 polarograph. The proximity of the oxidation curves to the residual current required a correction for the latter in order to obtain the half-wave potentials and limiting currents. The values for the latter using the saturated calomel electrode as a reference electrode were usually higher and more irregular than those obtained with a mercury pool cathode.

Polarographic reductions were carried out at the DME in the same solution prior to the oxidation. Values for capillary characteristics are given in Table I.

The buffer solutions were prepared according to the procedure described by Robinson and Stokes (9). The *p*H values were checked with a Beckman *p*H meter.

Lithium 2-propanenitronate (10), potassium 2-propanenitronate (11), 3,5-dinitroheptane (12), and 2,5-dinitrohexane (6) were prepared according to the directions in the literature.

Nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane were purified by distillation. Reagent grade methanol and reagent grade inorganic chemicals were used without further purification. Benzyltrimethylammonium methoxide (40% solution in methanol) was obtained from Aldrich Chemical Company and 2,5-hexanedione was obtained from Eastman Kodak Company.

General procedure.—Large scale electrolyses were carried out in a beaker with a rotating (571 rpm) platinum cylinder anode. The cathode was a copper wire coil and was placed in a porous porcelain cup. The procedure for a typical electrolysis is illustrated by the following. A solution of 2-nitropropane (44.5g) in 40% benzyltrimethylammonium methoxide in methanol (227g) was placed in a 600 ml beaker. The cathode

compartment consisted of a 5.3 by 10 cm porous cup and was filled with 40% benzyltrimethylammonium methoxide in methanol. A voltage of 12V gave a current of 2A which was maintained at this value for 7 hr by adding more electrolyte to the cathode compartment and methanol to the anode compartment during the electrolysis. The anolyte was cooled and the solid was filtered and washed with water. The yield of essentially pure 2,3-dimethyl-2,3-dinitrobutane was 23g, mp 209°-210° [literature (2) 208°-209°]. A mixture with an authentic sample melted at the same point. The *IR* spectra were identical. The methanol filtrate when treated with water gave an additional 3g of the dinitro compound.

Data obtained from other electrolyses using the cell described are given in Table III. The 1,1-dinitropropane (13) and the 2,5-hexanedione were identified by comparison of their *IR* spectra with those of authentic samples.

Chemical dimerization.—A solution of 2-nitropropane (90g) in methanol (300 ml) containing potassium hydroxide (56g) was treated dropwise at room temperature with a solution of iodine (127g) in methanol (900 ml). The solution turned dark after 80% of the iodine solution was added and was refluxed for 2 hr. Partial removal of the methanol followed by cooling gave a solid which was washed with water. The yield of 2,3-dimethyl-2,3-dinitrobutane was 49g; mp 209°-210°.

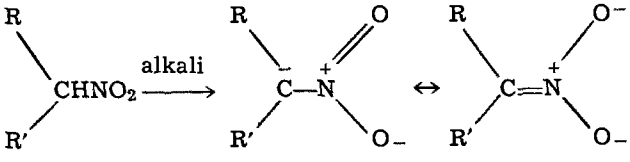
Results and Discussion

Voltammetric oxidation of nitroalkane anions was carried out in aqueous buffers, in methanol, and in dimethylformamide. The formation of the anion in the buffers was monitored by observing the polarographic reduction waves at a dropping mercury electrode. The results obtained in aqueous alkaline buffers are given in Table I.

Similar studies in acetonitrile, dimethylformamide, and dimethylsulfoxide were prevented by low solubilities of the alkali salts of the nitroalkanes. Lithium 2-propanenitronate is an exception and is moderately soluble in dimethylformamide. The same salts are very soluble in methanol and were prepared before hand or generated in this solvent. The data obtained are listed in Table II.

The yields obtained in large scale electrolyses are listed in Table III.

Examination of the polarographic results in Table I indicate that the nitroparaffin reduction waves diminished in alkaline solutions to zero with two exceptions; this decrease is caused by the tautomeric change of the nitroparaffins into the aci-form, which was not reducible within the range of potentials (down to 2.0V) used (14).



The two exceptions, nitromethane and 3,5-dinitroheptane, gave small waves in the pH 11.9 buffer. The wave for nitromethane is caused by the presence of a small amount of nitromethane. This compound has a pK_a of 10.24 (15) and therefore would not be converted completely to the anion.

The behavior of 3,5-dinitroheptane can be explained by a cleavage of this compound by alkali (reverse Michael reaction) to the anion of 1-nitropropane and 2-nitro-1-butene. The latter is converted by base to 2-nitro-1-butanol which undergoes a reverse aldol at

[a] DMDNB = 2,3-dimethyl-2,3-dinitrobutane.

pH 8 since a reduction wave was observed for formaldehyde. The half-wave potential of −1.41 (SCE) is in good agreement with that reported in the literature (16). At higher pH values the reverse aldol reaction apparently does not occur since the formaldehyde wave is absent. The more positive reduction waves observed are probably due to the 2-nitro-1-butanol since the half-wave potentials approximate values reported by others (17).

The results in Table II indicate that a one-electron oxidation occurs for the 2-nitropropane anion; in dimethylformamide its limiting current is approximately one-half of that observed for hydroquinone.

The limiting current in methanol varies with the electrolyte employed. The low value observed in a lithium nitrate solution can be ascribed to the lower concentration of the anion which would result from the following reaction

$$K^+[(CH_3)_2CNO_2]^- + CH_3OH \rightleftarrows KOCH_3 + (CH_3)_2CHNO_2$$

The close proximity of the anodic wave for the nitroalkanes to the residual current in aqueous media offers an explanation for the 2,2-dinitropropane formed in the electrolytic oxidation of 2-nitropropane in basic medium. At this potential either hydroxyl radicals or oxygen is produced and cross-coupling or oxidation of the radical can occur (12) and forms acetone and nitrite ion. The latter oxidizes at 0.87 at a pH 11.9 and would cross-couple with the 2-nitropropyl radical and form 2,2-dinitropropane.

In order to avoid these complications large scale electrolyses were carried out in methanol and in dimethylformamide as solvents and the results are given in Table III. Methanol proved to be the superior solvent and gave the best yield of 2,3-dimethyl-2,3-dinitrobutane from 2-nitropropane, and in contrast to aqueous solutions (2) gave no 2,2-dinitropropane. The maximum yield obtained was 64% using a nitrogen atmosphere and a temperature of 0°. Electrolysis in the presence of air with no temperature control gave only a slightly lower yield of 58%. This lower yield is no doubt caused by oxygen diffusing into the reaction mixture and oxidizing the intermediate radical to acetone and nitrite (18). Both yields are much higher than that (15%) obtained in aqueous media (2).

A similar yield of dimer was obtained chemically by treating 2-nitropropane in methanol containing potassium hydroxide with iodine. The yield (55%) is smaller than that (86%) obtained by treating the sodium salt of 2-nitropropane with 2-bromo-2-nitropropane (19) but the reaction is simpler and can be carried out in one step.

One possible side reaction which can occur and would prevent better yields in the electrolytic method is the decomposition of the intermediate radical into acetone and nitric oxide. Such a decomposition has been observed in the electrolysis of nitroalkanes containing triethylamine as a base (7). The nitric oxide thus formed in methanol would result in methyl

$$(CH_3)_2\dot{C} - NO_2 \rightarrow CH_3C(=O) - CH_3 + NO$$

nitrite which is volatile. In aqueous basic medium sodium nitrite would be formed. This type of decomposition is substantiated by the results obtained with the electrolysis of 2,5-dinitrohexane in methanol with potassium methoxide as the electrolyte at 0° under nitrogen; a 13.0% yield of 2,5-hexanedione was isolated. The other products formed in this oxidation were a resin and a solid (3% based on 2,5-dinitrohexane) which was not investigated further because of the small amount available.

A primary nitroalkane such as 1-nitropropane gave in methanol similar products to those found in water. The coupled product in the anion form

$$CH_3CH_2CHNO_2 \rightarrow NO_2^- + CH_3CH_2CH(=CH_2)$$
$$CH_3CH_2\dot{C}(NO_2)^- \qquad\qquad CH_3CH_2\dot{C}(NO_2)$$

eliminates nitrite ion and the resulting potassium nitrite partially precipitates from the methanol and can be isolated. The yield of the cross-coupled product 1,1-dinitropropane, because of the small amount of dissolved sodium nitrite, was therefore low. Only a very small amount of a liquid with a boiling point corresponding to the unsaturated nitro compound was isolated. The majority of the product was a tar.

Electrohydrodimerization Reactions

III. Rotating Ring-Disk Electrode, Voltammetric and Coulometric Studies of Mixed Reductive Coupling of Dimethyl Fumarate in the Presence of Cinnamonitrile and Acrylonitrile in Dimethylformamide Solution

Vincent J. Puglisi and Allen J. Bard

Department of Chemistry, University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The electrohydrodimerization reaction of dimethyl fumarate in the presence of cinnamonitrile and acrylonitrile was studied in dimethylformamide solution by rotating ring-disk electrode, voltammetric and coulometric techniques. At potentials where only dimethyl fumarate is electroactive, the rate and mechanism of decay of the dimethyl fumarate anion radical are only slightly perturbed from the results obtained in the absence of cinnamonitrile and acrylonitrile. This is an indication that little or no cross-coupling was occurring. At potentials where both dimethyl fumarate and cinnamonitrile are electroactive evidence for the occurrence of a solution oxidation-reduction reaction consuming cinnamonitrile anion radical and dimethyl fumarate parent was obtained. In addition, the role of *cis-trans* isomerization of radical anions in electrohydrodimerization reactions is discussed. Differences in the cyclic voltammograms of diethyl maleate in the presence of acrylonitrile when compared with those obtained in the absence of acrylonitrile and for dimethyl fumarate in the presence of acrylonitrile are observed.

We have previously reported (1) the use of rotating ring-disk electrode (RRDE) voltammetry, cyclic voltammetry, and coulometry in the elucidation of the mechanism of the electrohydrodimerization (electrolytic reductive coupling) of the three di-substituted olefins dimethyl fumarate (DF), cinnamonitrile (CN), and fumaronitrile (FN) in anhydrous dimethylformamide (DMF) solution. Potential-step chronoamperometry has also been employed to determine the electrohydrodimerization mechanism of diethyl fumarate (2). These studies showed that these hydrodimerizations proceed predominantly via a one-electron reduction

$$R + e \rightleftarrows R^{\cdot -} \qquad [1]$$

followed by a radical ion dimerization (EC reaction scheme) for each olefin

$$2R^{\cdot -} \xrightarrow{k_2} R_2^{2-} \qquad [2]$$

It is also of interest to examine the hydrodimerization reaction of a disubstituted olefin in the presence of a second activated olefin (R') by RRDE voltammetry (3) and coulometric techniques. The aim was to explore the conditions under which formation of cross-coupled products can occur, thus obtaining more insight into the mechanism of electrolytic reductive coupling.

This approach was first undertaken by Baizer *et al.* (4-7). These investigators discovered cross-coupled products of the form $R'RH_2$ after electrolysis of aqueous-DMF solutions at mercury electrodes containing high concentrations (up to 5*M*) acrylonitrile (AN) at potentials where R, but not R', was electroactive. They attributed these results, on the basis of this as well as cyclic voltammetric evidence (8), to the occurrence of an ECE mechanism; *i.e.*, a one-electron reduction (Eq. [1]) followed by nucleophilic attack by the radical anion on the parent molecule

$$R^{\cdot -} + R \xrightarrow{k_2'} R_2^{\cdot -} \qquad [3]$$

to form the electroactive species $R_2^{\cdot -}$ which can undergo further reduction to yield the

$$R_2^{\cdot -} + e^- \rightarrow R_2^{2-} \qquad [4]$$

nonelectroactive species R_2^{2-}. They surmised that in the presence of a second olefin R', because of its greater concentration at the electrode surface when compared with R, nucleophilic attack by $R^{\cdot -}$ on R' to form the electroactive species

$$R^{\cdot -} + R' \xrightarrow{k_2''} (RR')^{\cdot -} \qquad [5]$$

$(RR')^{\cdot -}$ occurs. This species can undergo further reduction to yield a cross-coupled product (9)

$$(RR')^{\cdot -} + e^- \rightarrow (RR')^{2-} \qquad [6]$$

The ratio of cross-coupled product to simple dimer (R_2H_2) would be dependent on the concentration ratio of R and R', on the rate of formation of the cross-coupled product relative to the rates of formation of the simple dimers (R_2H_2 and R'_2H_2), and on the rates of formation of the simple dimers relative to each other. They also found that the yield of cross-coupled product was substantially increased when electrolysis was conducted at potentials where both R and R' were reduced; this is an indication that cross-coupling via a radical ion-radical ion-coupling mechanism was occurring at a faster rate than the ECE

$$R^{\cdot -} + R'^{\cdot -} \rightarrow (RR')^{2-} \qquad [7]$$

mechanism postulated in Eq. [5] and [6].

Dimethyl fumarate was chosen to serve as the species R. Its radical decay rate constant (*i.e.*, dimerization rate constant) is at the lower limit of rate constants measurable with the particular RRDE used and thus any increase in the velocity of that reaction, as explained above, would still result in reasonable current levels at the ring. Also, the $E_{1/2}$ of its first reduction occurs well before that of cinnamonitrile and acrylonitrile (AN), the two species which would function as the R' species. CN was chosen because its hydrodimerization has been studied (1), because its second-order rate constant is only eight times that of dimethyl fumarate, and because it is more difficult to reduce than dimethyl fumarate. Acrylonitrile was chosen because of its use in previous studies (4-7). The mechanism and rate of dimerization of AN, however, have not been determined because the electrogenerated product reacts very quickly (9).

The diagnostic criteria which were used to determine the reaction path consisted of a qualitative examina-

tion of the dependence of the ring current (i_r) on disk potenital (E_d) at constant ring potential (E_r), a quantitative examination of the dependence of the kinetic collection efficiency, N_K, on the rotation rate and concentration ($XKTC$) (10-12), where

$$XKTC = (0.51)^{-2/3}\nu^{-1/3}D^{1/3}C^{\circ}\omega^{-1}k_2 \quad [8]$$

and ν is the kinematic viscosity, D is the diffusion coefficient, C° is the initial concentration, ω is the rotation rate, and k_2 is the second-order homogeneous rate constant, on the behavior of N_K with various disk currents ($CONI$) (3)

$$CONI = i_d/i_{d,l} \quad [9]$$

where i_d is the disk current and $i_{d,l}$ is the disk current at the limiting current plateau, and finally, controlled potential coulometric analysis.

Experimental

Reagents.—N,N-dimethylformamide (DMF), obtained from Baker Chemical Company, was purified by vacuum distillation and stored under He. Solvent purity was ascertained by cyclic voltammetric analysis of DMF solutions of tetrabutylammonium iodide (TBAI) obtained from Southwestern Analytical Chemicals, Inc. TBAI and tetrabutylammonium perchlorate (TBAP), also obtained from Southwestern Analytical Chemicals, Inc., were vacuum dried and stored over Drierite. Dimethyl fumarate (DF), sublimed prior to use, and cinnamonitrile, used as received, were obtained from K. and K. Laboratories. Acrylonitrile, Matheson, Coleman and Bell Chemicals, was used as received.

Apparatus.—A Tascussel Electronique Bipotentiostat, Model Bipad 2, was used for all RRDE experiments. A Digitec digital voltmeter, Model 204, and a Fairchild digital multimeter, Model 7050, were used to measure the steady-state ring and disk currents simultaneously. A Wavetek function generator provided a d-c potential ramp for voltammetric experiments recorded on a Mosley Model 2D-2 X-Y recorder. The platinum-Teflon rotating ring-disk electrode, having a disk radius (r_1) of 0.187 cm and inner (r_2) and outer (r_3) ring radii of 0.200 and 0.332 cm, respectively, was constructed by Pine Instrument Company, Grove City, Pennsylvania. The maximum collection efficiency, N, for the RRDE used in these experiments was 0.555 (1). The electrochemical cell, dispensing vessel, and motor and controller used to rotate the RRDE have been described previously (1). The reference electrode was a silver wire spiral (Ag-RE) whose potential was dependent on the identity and concentration of the supporting electrolyte. TBAI was used as supporting electrolyte in all RRDE experiments. A Model 170 Electrochemistry System (Princeton Applied Research, Princeton, New Jersey) was employed for all controlled potential coulometric experiments. A conventional coulometry cell was used. In these experiments, a platinum gauze served as the working electrode and a platinum spiral as the auxiliary. A saturated calomel electrode (SCE) was used as the reference electrode. The reference and auxiliary compartments were separated from the cathode compartment by medium porosity glass frits.

Procedure.—DMF, dispensed from the storage vessel into the dispensing vessel by positive He pressure, together with supporting electrolyte and, in most cases, the depolarizer, was subjected to a minimum of three freeze-pump-thaw cycles. In experiments where CN was present, it was first necessary to conduct a pre-electrolysis to remove an electroactive impurity present in the CN prior to addition of the DF. This was carried out at a Hg pool electrode in the RRDE electrochemical cell. In these experiments the DF concentration was determined from a working curve of the disk limiting current ($i_{d,l}$) *vs.* concentration. This curve was compiled from measurements on solutions of dimethyl fumarate in the absence of cinnamonitrile and validated with known mixtures of DF and CN.

Results

Dimethyl Fumarate-Cinnamonitrile

Electrochemical generation of the DF radical ion.—RDE voltammograms of DF and CN are illustrated in Fig. 1 and 2. DF (Fig. 1a) exhibits a one-electron reduction with half-wave potential, $E(i = i_{d,l}/2)$ of -0.8V *vs.* silver reference electrode (Ag-RE) followed by a current dip commencing at approximately -1.55V. This dip has been shown to occur at potentials corresponding to formation of the dianion and has been interpreted as resulting from polymerization initiated by that ion (8). Curve b is a ring current (i_r) *vs.* disk potential (E_d) trace with the ring potential (E_r) maintained at a constant value of 0.0V *vs.* Ag-RE. The ring current increase results from oxidation of the DF radical anion being formed at the disk electrode. At sufficiently negative disk potentials ($E_d > -1.55$V) reduction of DF to the dianion begins and the ring current decreases because of instability of the dianion in solution.

Figure 2 curves a and b, which describe the CN system, are analogous in interpretation to curves a and b in Fig. 1, respectively. The CN dianion participates to a lesser extent in polymerization reactions than does the DF dianion, thus an increase in cathodic current and a reduction wave 1.5 times the height of the first wave results. The half-wave potentials of the one- and two-electron reductions for CN are -1.21 and -1.83V, respectively.

Figure 3, curve a, shows a disk current-potential trace of the mixed DF-CN system in 0.15*M* TBAI-DMF. For convenience this voltammogram will be considered as consisting of four regions, as shown. Comparison with Fig. 1 and 2 reveals that reductions occurring in regions 1 and 3 can be ascribed to DF reductions, whereas those in regions 2 and 4 are CN reductions. The DF one-electron reduction limiting current is, within experimental error, unchanged upon addition

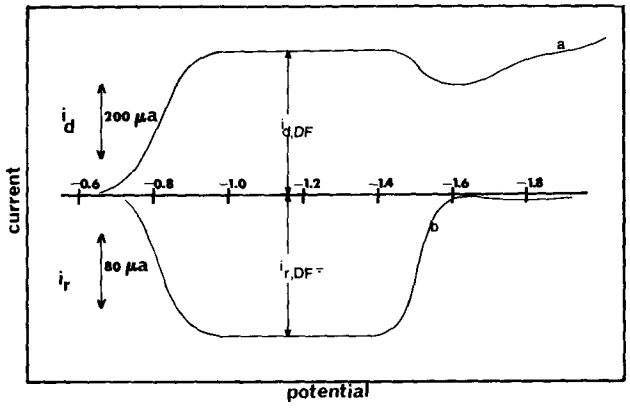

Fig. 1. Dimethyl fumarate (8.2 mM) RRDE voltammograms in 0.15M TBAI-DMF solution. $\omega = 47.6$ sec^{-1}; (a) i_d *vs.* E_d and (b) i_r *vs.* E_d, $E_r = 0.0$V.

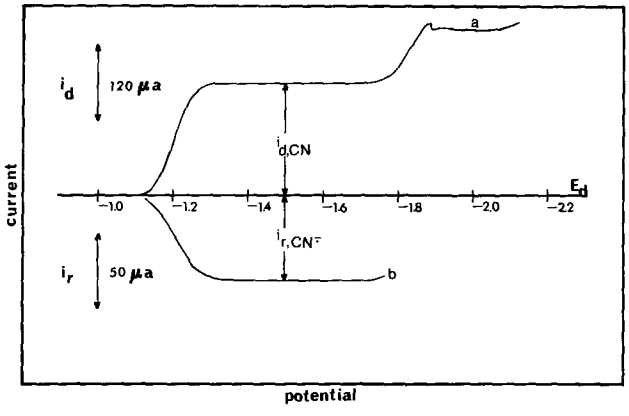

Fig. 2. Cinnamonitrile (3.8 mM) RRDE voltammograms determined at $\omega = 47.6$ sec^{-1}; (a) i_d *vs.* E_d and (b) i_r vs. E_d, $E_r = 0.0$V.

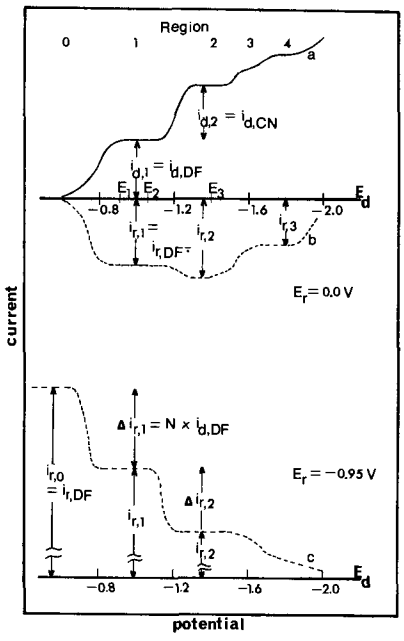

Fig. 3. Typical DF-CN RRDE voltammograms: (a) i_d vs. E_d; (b) i_r vs. E_d, $E_r = 0.0$V; and (c) i_r vs. E_d, $E_r = -0.95$V.

of CN. Further, the disk limiting current plateau (curve a, region 1), as well as the ring current plateau (curve b, region 1), exhibits essentially zero slope; evidence that processes occurring at the potential denoted E_1 do not differ from those at E_2. These results differ from those obtained from product analysis after exhaustive electrolysis of diethyl maleate (DEM) (6), where it was found that the products varied as a function of the working electrode potential and it was concluded that the processes occurring on the DEM limiting current plateau are a function of the applied potential in the mixed system.

Determination of N_K as a function of *CONI* for $i_d < (i_{d,l})_a$, where $(i_{d,l})_a$ is the DF limiting disk current in region 1, resulted in the experimental data shown in Fig. 4 and tabulated in Table I. This trend, N_K increasing with increasing 1-*CONI*, is the one reported to be characteristic of the EC dimerization mechanism

(Eq. [2]), but not of ECE mechanisms II and III (3). N_K *vs.* 1-*CONI* theoretical curves for the EC mechanism with *XKTC* equal to 0.06 and 0.25 are also given in Fig. 4. Calculation of the second-order rate constant for dimerization of DF anion radicals yields a value of $1.1 \pm 0.1 \times 10^2$ liter/mole-sec; the same value is obtained in the absence of CN (1).

A theoretical curve depicting the dependence of N_K on *XKTC* for the EC (I) mechanism, together with experimental values of N_K measured at potentials on the DF limiting current plateau and determined as functions of the rotation rate, are presented in Fig. 5. It can be seen that the experimental points closely fit the curve generated for the radical ion dimerization mechanism; this provides additional evidence that mechanism I is the path of choice, even in the presence of a second olefin.

These similarities, both qualitative and quantitative, which appear in the RRDE experimental dimethyl fumarate currents measured in the presence and in the absence of cinnamonitrile, are also evident from cyclic voltammetric studies. Figure 6 shows cyclic voltammograms of DF (curve a), CN (curve b), and the mixed DF-CN system (curves c and d). As with the RRDE data, curves c and d can be compared with curves a and b for purposes of assignment. The first reduction of DF exhibits a sizable anodic current on

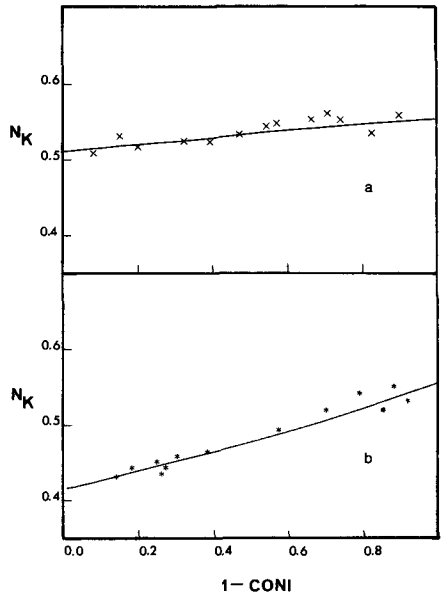

Fig. 4. Dimethyl fumarate collection efficiency (N_K) vs. 1-*CONI* at $\omega = 47.6$ sec^{-1} in the presence of cinnamonitrile: (a) DF = 1.85 mM and CN = 3.85 mM; (b) DF = 7.3 mM and CN = 3.8 mM. Solid lines are theoretical curves corresponding to mechanism I and (a) *XKTC* = 0.06 and (b) *XKTC* = 0.25.

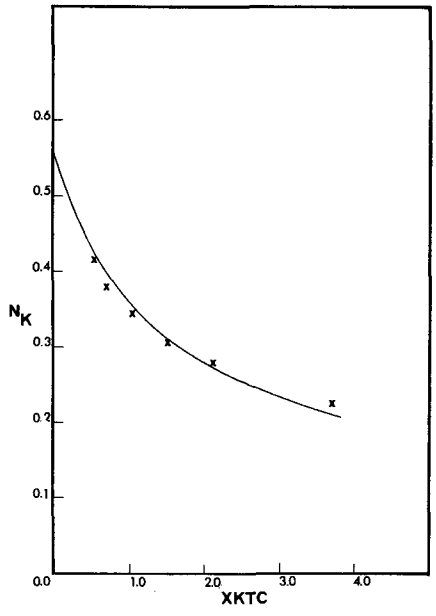

Fig. 5. Dimethyl fumarate (1.8 mM) collection efficiency (N_K) vs. *XKTC* plot in the presence of cinnamonitrile (3.8 mM). Solid line corresponds to the theoretical curve depicting the behavior of N_K for mechanism I.

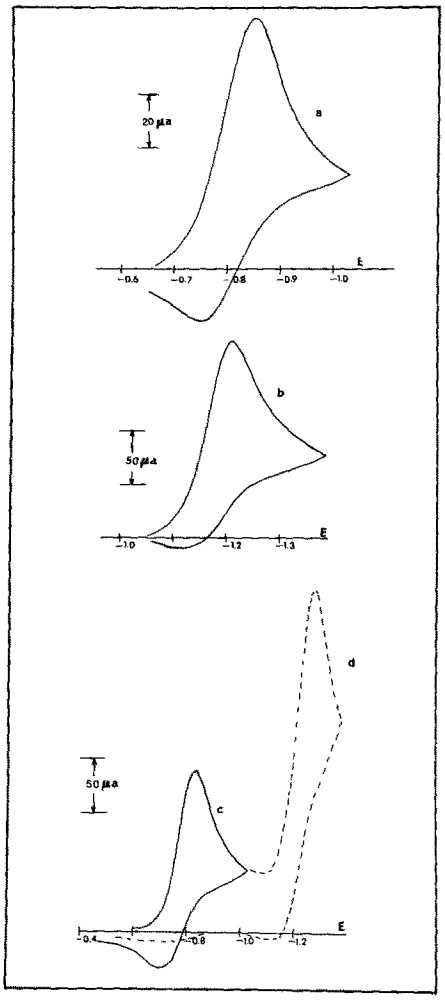

Fig. 6. Cyclic voltammograms recorded at 0.1 V/sec; (a) dimethyl fumarate (3.5 mM); (b) cinnamonitrile (2.6 mM); (c) dimethyl fumarate (1.8 mM), cinnamonitrile (3.8 mM); and (d) same as (c).

reversal (curve a) even in the presence of cinnamonitrile (curve c). The ratio of peak currents ($i_{p_l DF^-}/i_{plDF}$) and the peak current function ($i_{plDF}/C^o_{DF}V^{1/2}$) were found to be 0.38 and 96 μA/mM V sec^{-1}, respectively, in the absence, and 0.42 and 99 μA/mM V sec^{-1} in the presence of CN.

In addition, coulometric analysis at -1.425V *vs.* SCE, a potential on the DF first reduction current plateau but positive of potentials necessary for reduction of CN, resulted in an n_{app}-value of 0.63 for an equimolar DF-CN solution. The n-value predicted by each of the postulated hydrodimerization mechanisms is one (3). An n_{app}-value less than one results because of the occurrence of polymerization side reactions during the time scale of the coulometric experiment. Coulometry at -1.625V *vs.* SCE in the absence of cinnamonitrile yielded an n_{app}-value of 0.62. If the ECE mechanism involving reactions [5] and [6] occurred, the n_{app} in the presence of CN should have been greater than 0.62, and possibly even greater than one.

Simultaneous electrochemical generation of the dimethyl fumarate ($DF^{-\cdot}$) and cinnamonitrile ($CN^{-\cdot}$) radical anions.—To determine the extent of cross-coupling arising from a radical ion-radical ion mechanism (Eq. [7]), an examination of the DF-CN mixed system at potentials where both DF and CN undergo reduction to form their respective radical anions was undertaken.

Ring current *vs.* disk potential voltammograms where $E_r = 0.0$V (curve b) and $E_r = -0.95$ (curve c) are shown in Fig. 3. Curve b shows the oxidation of electroactive species being formed at the disk during processes shown in Fig. 3a or of any electroactive species being formed from reactions of disk products. From the study of the DF radical anion alone, we know that the ring current in region 1 under the electrode conditions imposed to obtain curve b [denoted $(i_{r,1})_b$] results solely from oxidation of the DF radical anion. If there were no interaction in the bulk between DF parent or radical anion and CN parent or radical anion, the measured ring current, $(i_{r,2})_b$, would simply equal the sum, $i_{r,s}$, of the DF and CN ring currents measured independently (*i.e.*, the ring currents i_{r,DF^-} and i_{r,CN^-} illustrated in Fig. 1 and 2, respectively). This is not the case and $i_{r,s}$ is greater than $(i_{r,2})_b$. Typical experimental values are given in Table II. These experimental values were collected at various concentrations and rotation rates. To determine the magnitude of the current contribution to $(i_{r,2})_b$ from oxidations other than that of the DF radical anion, the experiment recorded as Fig. 3c was conducted. The ring current $(i_{r,0})_c$, results from reduction of DF at the ring electrode. At disk potentials sufficiently negative (*e.g.*, $E = E_1$, shown in Fig. 3a), DF reduces at the disk and a decrease, $\Delta(i_{r,1})_c$, in the cathodic current measured at the ring electrode results because of a decrease in the amount of DF reaching the ring. This is termed shielding and $\Delta(i_{r,1})_c$ equals N times $(i_{d,1})_a$, the DF disk limiting current shown in Fig. 3a, region 1. The DF radical anion is not oxidized at the potential applied at the ring electrode and is, therefore, not detected. At more negative disk potentials (*i.e.*, Fig. 3a, $E = E_3$) both DF and CN are reduced at the disk electrode to the respective radical anions

$$DF + e^- \rightarrow DF^{-\cdot} \quad \text{(at the disk electrode [Fig. 3a, region 2])} \quad [10]$$

$$CN + e^- \rightarrow CN^{-\cdot} \quad [11]$$

and a second decrease in the ring current, $(\Delta i_{r,2})_c$ is observed. The measured current, $(i_{r,2})_c$, is the sum of two currents; a cathodic current component resulting from the one-electron reduction of DF and an anodic current component resulting from the oxidation of the CN radical anion

$$DF + e^- \rightarrow DF^{-\cdot} \quad \text{(at the ring electrode [Fig. 3c, region 2])} \quad [12]$$

$$CN^{-\cdot} - e^- \rightarrow CN \quad [13]$$

* DMF solution containing 0.15*M* TBAI. See Fig. 3 for definition of terms. All currents in microamperes.

At the applied ring potential, neither the CN parent nor the DF radical are electroactive. The current decrease, $|\Delta(i_{r,2})_c|$, cannot result simply from oxidation of the cinnamonitrile radical anion, since $|\Delta(i_{r,2})_c| > |(i_{r,CN^{\cdot-}})|$, where $i_{r,CN^{\cdot-}}$ is the ring current resulting from oxidation of CN radical anion in the absence of DF (Fig. 2b and Table II). For example, item 6 in Table II shows that the $CN^{\cdot-}$ ring current (*i.e.*, $|i_{r,CN^{\cdot-}}|$) for C = 3.58 m*M* and $\omega = 47.6$ sec^{-1} in the absence of DF is 44 μA. The decrease in the ring current, $\Delta(i_{r,2})_c$, is 82 μA. One would have anticipated a decrease less than or equal to 44 μA, but not greater than this if oxidation of $CN^{\cdot-}$ were the only additional process occurring in this region. Radical ion-radical ion cross-coupling could occur but this would decrease the stability of the CN and DF radical anions, leading to a smaller value of $\Delta(i_{r,2})_c$. One must also take into account, however, the occurrence of the electron transfer reaction

$$CN^{\cdot-} + DF \rightarrow CN + DF^{\cdot-} \qquad [14]$$

In the absence of any other kinetics (*e.g.*, dimerization) contributing to the instability of the species $CN^{\cdot-}$ and DF, the occurrence of reaction [14], in terms of measured ring current at $E_r = -0.95$, would have no observable effect and $\Delta(i_{r,2})_c$ would equal *N* times $i_{d,CN}$, where $i_{d,CN}$ is the CN disk limiting current. However, in this case both $DF^{\cdot-}$ and $CN^{\cdot-}$ undergo further dimerization reactions ([15] and [16]). Moreover, the rate constant of the CN dimerization reaction

$$2CN^{\cdot-} \rightarrow (CN)_2^{2-} \qquad [15]$$

is about eight times larger than that of the DF dimerization reaction (1)

$$2DF^{\cdot-} \rightarrow (DF)_2^{2-} \qquad [16]$$

Hence, the effect of reaction [14], if its rate is much larger than that of reaction [15], is to remove a less stable intermediate ($CN^{\cdot-}$) and form a more stable one ($DF^{\cdot-}$) in transit from disk to ring. This leads to a smaller amount of DF available for reduction at the ring and hence a larger-than-expected value of $\Delta(i_{r,2})_c$. This hypothesis, *i.e.*, the effect of the oxidation-reduction represented in Eq. [14], is supported by digital simulation of the RRDE experimental conditions.

This program assumed that the disk electrode was maintained at a potential where reduction of DF (Eq. [10]) and CN (Eq. [11]) to their respective radical anions proceeded at mass transfer controlled rates. The ring electrode was maintained at a potential where mass transfer controlled oxidation of the CN radical anion (Eq. [13]) and reduction of DF parent (Eq. [12]) occurs. Three homogeneous reactions were assumed to occur in the gap region: the radical ion-radical ion dimerizations of DF (Eq. [16]) and CN (Eq. [15], and the oxidation-reduction reaction represented in Eq. [14]). The rate constants for the DF (1.1×10^2 liters/mole-sec) and CN (8.8×10^2 liters/mole-sec) dimerizations, together with the specific experimental conditions (*e.g.*, concentrations, diffusion constant, etc.), were used to calculate the appropriate *XKTC* values. The oxidation-reduction reaction was assumed to occur at a diffusion-controlled rate. The simulation output parameters of interest were a dimensionless current parameter proportional to the disk current, and dimensionless current parameters proportional to the currents resulting from reduction of the DF and from oxidation of the CN radical anion at the ring electrode.

The current decrease, $\Delta(i_{r,2})_c$, was found to occur totally from a decline in the cathodic current due to loss of DF parent species in transit to the ring electrode, and with essentially no contribution to the current decrease from anodic current resulting from oxidation of the $CN^{\cdot-}$ species. That is, the velocity of the reaction represented in Eq. [14] is of such a high order of magnitude that the CN dimerization does not successfully compete with that reaction and all the $CN^{\cdot-}$ is consumed in reaction [14]. Under these conditions, the simulation accounted for approximately 90% of the experimentally measured current, $\Delta(i_{r,2})_c$.

Cyclic voltammograms of the DF-CN system show no oxidizable species other than the DF and CN radical anions that were observed. In addition a coulometric experiment, in which a solution of DF and CN, in approximately equimolar concentrations, electrolyzed at −1.90V *vs.* SCE was carried out. This potential is sufficient to produce both the DF and CN radical anions but not negative enough to produce the DF dianion. An over-all n_{app}-value of 0.81 was obtained. The average n_{app}-value obtained for the CN reduction in the absence of DF was 0.96. Assuming $n = 1.0$ for the CN reduction, the n_{app}-value for DF in the presence of CN is 0.64, essentially the same value obtained in the absence of CN. This value is less than that anticipated if the cross-coupling reaction [Eq. 7] was occurring to an appreciable extent, since this should reduce the extent of polymerization and result in $0.62 < n_{app} < 1.0$. The unchanged n_{app}-value for DF suggests that the DF radical anion is effectively insensitive to the presence of CN parent and the CN radical anion being electrochemically generated. The equivalents *vs.* time (*t*) and the current (*i*) *vs.* time curves for this experiment are shown in Fig. 7. The presence of two slopes in the equivalent *vs.* *t* curve and the break in the *i vs.* *t* curve indicate the possible existence of two consecutive reductions as opposed to two simultaneous reductions, although simultaneous reduction of DF and CN is occurring at the potential of the working electrode. The coulometric data can be explained by the occurrence of the oxidation-reduction reaction (Eq. [14]) in the bulk solution. The $CN^{\cdot-}$ produced at the electrode reacts with DF parent to yield CN parent and $DF^{\cdot-}$. Until a sizable amount of the DF parent has been consumed, the electrolysis is completely characteristic of a DF electrolysis, but at a faster rate than the controlled potential electrolysis of DF alone because of the additional coulometric titration of DF by $CN^{\cdot-}$. Thus, the coulometric, as well as the RRDE, results point to the importance of the oxidation-reduction reaction represented in Eq. [14], in the over-all reaction scheme.

Simultaneous electrochemical generation of the dimethyl fumarate dianion (DF^{2-}) and the cinnamonitrile radical anion.—In the DF-CN mixed system, the current dip anticipated at potentials where formation of the DF dianion commences, Eq. [17] does not occur, but instead additional cathodic current (Fig. 3a, re-

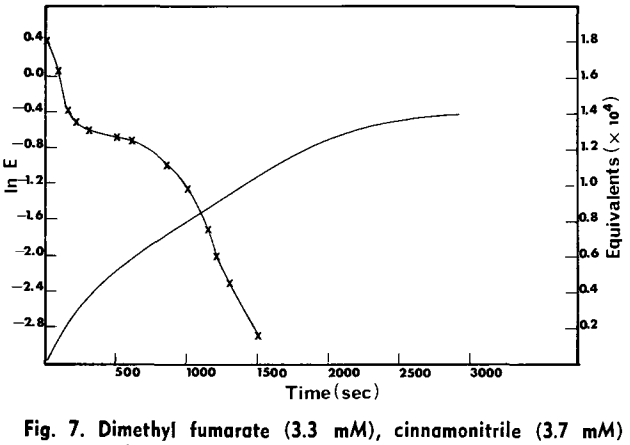

Fig. 7. Dimethyl fumarate (3.3 mM), cinnamonitrile (3.7 mM) equivalents electrolyzed *vs.* time (*t*) and current (*i*) *vs.* time experimental curves.

gion 3) results.

$$DF + 2e^- \rightarrow DF^{2-} \quad [17]$$

A possible explanation for the increase in cathodic current here is either the formation of an electroactive cross-coupled dimer

$$DF^{2-} + CN \rightarrow [(DF)(CN)]^{2-} \quad [18]$$

or the occurrence of the redox reaction

$$DF^{2-} + CN \rightarrow DF^{\cdot -} + CN^{\cdot -} \quad [19]$$

Either [18] or [19] would be expected to compete with polymerization of DF

$$DF^{2-} + p\,DF \rightarrow (DF)_{p+1}{}^{2-} \quad [20]$$

resulting in increased currents.

Dimethyl Fumarate-Acrylonitrile

Dimethyl fumarate in the presence of acrylonitrile (AN).—Figure 8 illustrates typical disk current-potential (curves a, b, and c) as well as ring current-disk potential (curves d and e) scans obtained at constant ring potential (E_r = 0.0V *vs.* Ag-RE) for DF in the absence (curves a, b, and d) or presence (curves c and e) of AN. The significance of curve a has been explained. Curve b is a voltammogram of a quiescent solution ($\omega = 0$). Curve c is a repeat of curve a following the addition of 0.2*M* AN. Curves d and e represent the ring current recorded as a function of disk potential while the disk electrode is simultaneously undergoing the processes shown in curves a and c, respectively. Values of N_K measured in the absence and in the presence of AN are given in Table III. In approximately equimolar concentrations there is no apparent perturbation. When AN is present in large excess, the rate of decay of the dimethyl fumarate radical is seen to increase as a function of DF concentration, but not to the extent anticipated were the ECE mechanism a major path. The N_K *vs.* 1-*CONI* plots for $i_d < i_{d,DF}$ are consistent with the trend predicted by digital simulation techniques for the EC dimerization (mechanism I) being the primary reaction path (Fig. 9).

Cyclic voltammetric studies reveal that the $DF^{\cdot -}$ has a measurable lifetime even in the presence of 0.2*M* AN

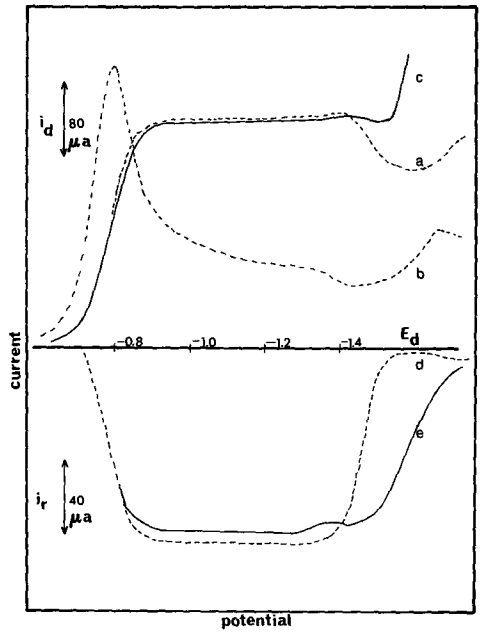

Fig. 8. Dimethyl fumarate (4.8 mM) RRDE voltammograms; (a) i_d *vs.* E_d, ω = 47.6 sec^{-1}; (b) i_d *vs.* E_d, ω = 0; (c) i_d *vs.* E_d, ω = 47.6 sec^{-1}, AN (0.2M) present; (d) i_r *vs.* E_d, E_r = 0.0V, ω = 47.6 sec^{-1}; and (e) i_r *vs.* E_d, E_r = 0.0V, ω = 47.6 sec^{-1}; 0.2M AN present.

Table IV. Coulometric results for mixtures of dimethyl fumarate and acrylonitrile[a]

Solution	E (vs. SCE)	Moles present DF (×10⁴)	Moles present AN	n_{app}-value
1	−1.625	0.66	0	0.62
2	−1.450	1.10	Equimolar	0.62
	−1.600	0.98	Equimolar	0.76
	−1.525	1.07	Equimolar	0.78
	−1.450	1.02	Equimolar	0.79
3	−1.750	1.09	Large excess	0.77
	−1.550	1.00	Large excess	0.80

[a] The solution was 0.15*M* TBAI in DMF and the working electrode was Pt.

tion of a DF sample following exhaustive electrolysis of the previous sample. The average n_{app} was 0.78. Thus, the presence of AN does perturb, on the coulometric time scale, the following reaction of the DF radical. Whether this perturbation in the n_{app} results from some cross-coupling or from interference by the AN in some other manner with the reactions which result in the n_{app}-value less than one in the absence of AN (*e.g.*, polymerization), it is difficult to determine with the experimental evidence at hand. Were n_{app} greater than one, cross-coupling by an ECE path would have been probable.

Electrochemical generation of the DF dianion.—The DF-AN system differs from the DF-CN system in that formation of the DF dianion occurs prior to the first reduction step of the R′ species (AN), as can be seen by comparing curve a to c (Fig. 8). Further, the DF radical anion is detected by the ring electrode over a greater potential range in the presence of AN (Fig. 8e) when compared with the potential range for detection of the radical anion in the absence of AN (Fig. 8d). In other words, in the presence of AN, $DF^{\cdot -}$ is being generated in a potential region normally associated with formation of the DF dianion. The anodic current measured at the ring electrode (curve e) is now seen to decrease at disk potentials corresponding to reduction of AN (curve c) at potentials more negative than those necessary to form the DF dianion (curve a). A possible explanation is the occurrence of a rapid oxidation-reduction reaction consuming dimethyl fumarate dianion and acrylonitrile parent and yielding the radical anions of DF and AN

$$DF^{2-} + AN \rightarrow DF^{\cdot -} + AN^{\cdot -} \qquad [21]$$

Thus, the amount of DF radical anion reaching the ring electrode remains relatively unchanged up to disk potentials corresponding to reduction of AN. Other possible explanations of this occurrence include the stabilization of the DF dianion by AN toward fragmentation or polymerization. However, no oxidations other than the oxidation of $DF^{\cdot -}$ were observed on varying the ring potential in RRDE voltammetry or on reversal in cyclic voltammetric experiments. In addition, the fact that the ring current does not change significantly at the more negative potentials is another indication that the identity of the species in transit to the ring is not a function of potential. Another possible explanation for this occurrence is the stabilization of the DF parent toward acceptance of the second electron. This, too, however, does not seem likely, since one would likewise expect stabilization of the DF parent species to acceptance of the first electron, and this is not observed.

Discussion

The mixed system results indicate that the mechanism which serves as the primary route for the disappearance of the dimethyl fumarate radical anion is not altered appreciably by the presence of a second olefin which is itself not electroactive at potentials sufficient to produce the DF radical anion under the conditions of our experiment. Further, the velocity of the radical decay remains, within experimental error, unchanged from the velocity measured in the absence of the second olefin when the second olefin is present in amounts about equal to that of DF; when AN is present in large excess, $DF^{\cdot -}$ decay increases to some extent. Considering the arguments presented, these RRDE results confirm the conclusion (1) that the major pathway in the electrodimerization of dimethyl fumarate in anhydrous DMF is the EC dimerization path (Eq. [16]).

The interpretation of the processes following the first DF reduction wave is more difficult. In the case of the DF-CN system, the CN one-electron reduction occurs prior to the DF two-electron reduction and appears unperturbed up to potentials necessary for formation of the dimethyl fumarate dianion. Analysis of the ring currents at various ring electrode potentials reveals that the stability of the $CN^{\cdot -}$ is decreased from its value in the absence of DF. This additional instability is attributed mainly to the electron transfer reaction between DF parent and CN radical anion, forming DF radical anion and CN parent. This hypothesis is supported by results of controlled potential coulometry conducted at electrode potentials where the radical anions of both DF and CN are formed which qualitatively indicate the occurrence of two independent reactions and quantitatively indicate little or no change in the coulometric n_{app}-value for the reduction of DF.

In the DF-AN system, the reduction of DF to the dianion occurs prior to reduction of AN. Thus, simultaneous generation of the DF and AN radical anions is not possible. The DF current-potential curve does not exhibit a dip at the second reduction potentials when AN is present. Further, the ring current resulting from oxidation of the DF radical anion extends into the region of disk potential normally associated with formation of the DF dianion and falls off only when the AN reduction commences. Here again the possibility of a redox reaction, this time involving the DF dianion, seems likely. That the ring current plateau does not change significantly at these potentials from its value in the disk potential region where formation of the DF radical anion occurs would lead one to conclude that the DF radical anion is the electroactive species being produced.

It is necessary to compare the results found here with previous studies of cross-coupling (4-7, 13). Our findings demonstrate that the DF-CN and DF-AN systems do not follow the path where cross-coupling occurs when the radical ion of only one species is produced in the presence of an equimolar concentration of the second olefin. For DF-AN concentration ratios of approximately 1 to 40 and 1 to 25, a slightly accelerated decay of the DF radical ion is observed, perhaps due to cross-coupling. Certainly, the cross-coupling reaction will be favored by very high concentrations of the second olefin. When radical ions of both reactants are produced, then the electron transfer reaction must be considered in addition to, or as a path to, the cross-coupling reaction. Baizer and co-workers (6) studied the cross-coupling reaction of the *cis*-isomer diethyl maleate (DEM) and AN and showed appreciable cross-coupled product formation at potentials where only the DEM radical ion is produced. Baizer also found coupling of DEF with AN under conditions of a very high ratio of AN to DEF (DEF added dropwise to AN containing tetraethylammonium p-toulene-sulfonate and a small amount of water) (4). Baizer and Chruma (14) have recently repeated this experiment and found substantial quantities of cross-coupled product (about one-fifth of the amount of the hydrodimer of DEF, tetraethylbutane tetracarboxylate) and no AN reduction products. The amount of cross-coupled product when DEM and AN are used

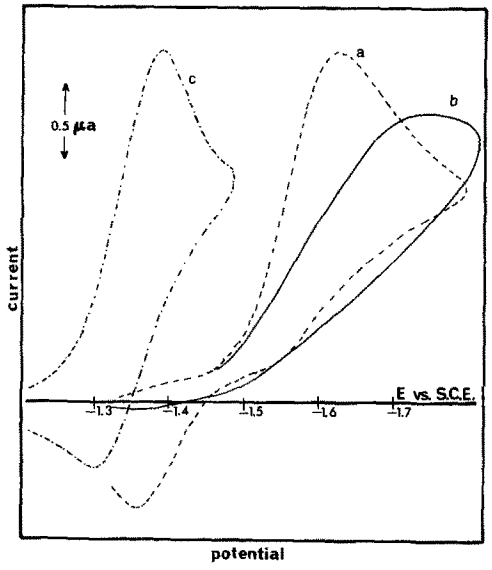

Fig. 11. Cyclic voltammograms at 200 mV/sec on a Pt working electrode: (a) diethyl maleate (3.9 mM), TBAP (0.15M), DMF; (b) diethyl maleate (3.9 mM) after the addition of AN (0.2M): (c) dimethyl fumarate (3.7 mM) in the presence of diethyl maleate and AN.

appears higher (6). On preliminary consideration, one would predict that the DEF-AN and the DEM-AN reactions would follow identical pathways, since DEF and DEM ultimately produce the same radical anion on reduction (15). However, recent results in our laboratory have shown that the behavior of DEM is very different from that of DEF. DEM is more difficult to reduce than its *trans*-isomer form, DEF; in addition, the diethyl maleate radical anion undergoes fast isomerization to form the diethyl fumarate radical and it appears that the direction of the isomerization lies exclusively toward the *trans* form (16, 17). Figure 11 is a cyclic voltammogram of a DEM-TBAP-DMF solution illustrating this isomerization. Following addition of excess AN, the wave shape becomes altered and no anodic current is observed on reversal (Fig. 11b). However, a cyclic voltammogram of the solution taken after the addition of dimethyl fumarate shows that the DF wave shape is qualitatively unaltered from that reported (1) and that anodic current is observed on reversal. One must conclude on the basis of this series of voltammograms that the *cis*-radical anion reacts with AN prior to isomerization, whereas the *trans*-radical anion is more stable with respect to reaction with AN. Cross-coupling of diethyl maleate and AN at potentials where only the diethyl maleate is electroactive and indeed, the occurrence of increasingly greater amounts of cross-coupled product with increasingly negative electrode potential when electrolyzing a mixture of DEM and DEF in the presence of AN can be explained in the light of the above observations. Further experiments are currently under way to uncover the nature of the difference between the reactivity of the *trans*- and *cis*-isomers. In conclusion these experiments demonstrate that cross-coupling will compete with dimerization only when the ratio of the second olefin (*e.g.*, AN) to the reduced olefin (DEF) is very large, and that cross-coupling can probably be carried out more efficiently by reducing both reactants (7).

Origin of Activation Effects of Acetonitrile and Mercury in Electrocatalytic Oxidation of Formic Acid

H. Angerstein-Kozlowska, B. MacDougall, and B. E. Conway

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

In the presence of catalyst poisons such as acetonitrile or mercury, it is shown that the currents for formic acid oxidation, measured in the potential range +0.4 to +0.8V E_H at Pt can be substantially increased. The effect is shown to originate from blocking of the surface at less positive potentials mainly in the H adsorption/desorption region (+0.05 to +0.35V E_H) where an inhibitor for the main formic acid oxidation reaction is normally formed in the absence of additive.

Under the latter conditions, steady-state oxidation currents are normally small and decrease with time due to build-up of an inhibiting species from the *HCOOH* or intermediates involved in its oxidation. Increases in the formic acid oxidation peak in the "double-layer" potential region at Pt can also be brought about in potentiodynamic experiments in the absence of additive, by cycling over a restricted potential range which excludes the H adsorption region. The inhibitor for formic acid oxidation is formed at potentials negative to 0.6V E_H by dimerization of COOH groups to give adsorbed formic anhydride. Its formation requires both time and available free surface. The competitive effects of Hg and CH_3CN are different insofar as a given extent of surface blocking causes different effects on the formic acid oxidation current. Comparative experiments on the effect of CH_3CN on methanol oxidation are described.

A general problem in the electro-oxidation of small organic molecules is the progressive decrease of rate (current density) of the reaction at a given potential and temperature, which occurs with time (1). This is usually not due to physical changes of the electrocatalyst structure except at elevated temperatures (2). Build-up of adsorbed species which inhibit (3) the main reaction sequence causes these effects. Periodic activation of the electrode, particularly by pulsing (4) to surface oxide formation potentials (5, 6), or by auto-oscillation (3, 7) regenerates electrode activity.

Activating effects in electrode reactions by what would normally be regarded as catalyst poisons were first observed by Monblanova and Kobosev (8); Binder *et al.* (9) found that partial coverage of the electrode by sulfur from sulfide enhanced the electrocatalytic activity of the surface for formic acid oxidation. Bockris and Conway (10) observed activating effects of traces of As and KCN in the H_2 evolution reaction. Satisfactory explanations for these effects have not yet been provided.

In the present paper, we report some interesting activating effects which arise in the electro-oxidation of formic acid at platinum electrodes when small concentrations of acetonitrile are present. The behavior is compared with that exhibited with methanol.

The present work indicates that the activating effect may be a general one in the case of formic acid oxidation and an account of the behavior may be given in terms of competitive adsorption effects (3) in an electrocatalytic process (11).

The electrochemistry of CH_3CN in aqueous medium has been described in previous papers (12, 13) from this laboratory and we have shown that acetonitrile itself is electroactive at Pt and the adsorbed species causes anodic H displacement (12, 14). Below 0.7V E_H, the adsorbed CH_3CN becomes progressively reduced. The molecule is attached to the Pt surface through the N atom at low concentrations while at high [CH_3CN] associative adsorption involving more Pt sites is involved.

Experimental

Methods of approach.—The kinetics of formic acid and formate oxidation have been studied previously and the results reported in various papers (15-18). Both "steady-state" galvanostatic (16, 19) and potentiodynamic (17) experiments have been described. Repetitive linear potential sweep experiments have been useful (17) in defining the potential ranges at Pt electrodes where appreciable anodic currents pass or where inhibition effects (3) arise. Although the steady-state approach is always necessary for defining the kinetic characteristics of the over-all reaction (since in the nonsteady-state, the surface concentrations of inhibiting or coreacting intermediates are not the steady-state or representative values, so that the reaction mechanism may be different from that in the steady state) the potentiodynamic method affords a convenient and sensitive way of controlling the prehistory of the electrode over various ranges of potential. Also, if the potential sweep is sufficiently slow (20), the main kinetic characteristics of the reaction are similar to those in the steady state. In the present work, both the steady-state and potentiodynamic current (i)-potential (V) characteristics of the reactions were examined.

Electrodes.—Pt electrodes were prepared by sealing Johnson-Matthey spec-pure Pt wire into glass bulbs in H_2 as described in previous work (21). The bulbs were broken beneath the solution in an all-glass cell (22) when required.

Solutions.—Solutions of 1N aq H_2SO_4, used as the supporting electrolyte, were prepared from B.D.H. micro-analytical grade H_2SO_4 using triply distilled water, the second stage of distillation being from alkaline $KMnO_4$. Electrochemical purity of the initial solutions was judged by the exhaustive criteria reported elsewhere (14), namely (in brief) resolution of the three surface oxidation regions of Pt between 0.85 and 1.1V together with the broad oxidation region from 1.2 to 1.5V; resolution of the H deposition and oxidation regions between 0.0 and +0.35V; and maintenance of the resolved H region without significant decrease of H coverage in potentiodynamic cycling between +0.05 and +0.75V (*i.e.*, in the absence of surface oxide formation) for 30 min. In all experiments, the reference i-V profile for the normal surface processes at Pt occurring between +0.05 and +1.4V E_H was first established before addition of formic acid

Key words: electrocatalysis, activation effects, formic acid oxidation, acetonitrile, mercury.

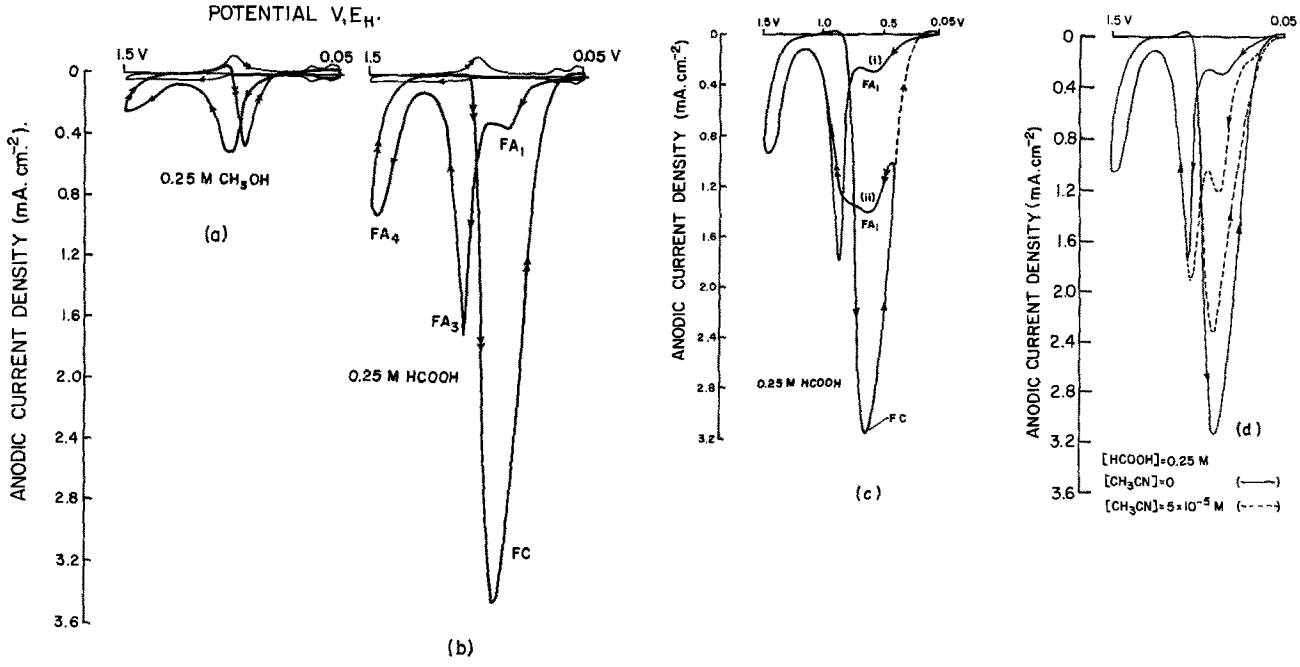

Fig. 1. Potentiodynamic *i-V* profiles at 50 mV·sec^{-1} for (a) 0.25M methanol and (b) 0.25M formic acid oxidation at Pt in 1*N* aq H_2SO_4 at 25°C over the potential range +1.5 to +0.05V E_H. (Current peaks "FA_1" and "FC", discussed in the text, are indicated.) Curve ii in (c) shows the *i-V* profile for formic acid oxidation over a restricted potential range, excluding the H region, in comparison with curve i in (c) over the full range to +0.05V. The curve in (d) shows the effect of 5 x 10^{-5} M CH_3CN.

and the other additives. All experiments were conducted at 25°C.

Formic acid and acetonitrile.—Formic acid was purified as described previously (16). Acetonitrile was purified according to the procedure of Mann *et al.* (23) using the Union Carbide reagent as starting material [as discussed previously (13)].

Instrumentation.—A Wenking fast-rise potentiostat was employed in the steady-state and potentiodynamic experiments. Linear potential sweeps were established using a Servomex LF 141 function generator. Current-potential relations were recorded on a Hewlett Packard XY recorder through a cathode follower.

Results and Discussion

Effects of Acetonitrile on the Oxidation of Formic Acid and Methanol in Aqueous Media

General: oxidation behavior of HCOOH and CH_3OH at Pt.—In an anodic-going potential sweep, formic acid exhibits distinct oxidation current peaks over three potential ranges (17) (Fig. 1b): (*i*) the H adsorption and double-layer (d.l.) regions, 0.25-0.6V E_H (FA_1);[1] (*ii*) the region where surface oxidation begins, *i.e.*, +0.85 to +0.95V E_H (FA_3), and (*iii*) a region of higher anodic potentials, *i.e.*, +1.225 to 1.525V E_H (FA_4). In the cathodic-going potential sweep, a large anodic current peak arises in the potential region where surface oxide reduction is nearing completion. Similar electrooxidation behavior at platinum is observed with methanol (24) (Fig. 1a) although, in this case, there is no current peak in the anodic-going potential sweep in the d.l. region. The potentiodynamic *i-V* profiles are shown for reference in Fig. 1a and b, while 1c shows the higher FA_1 peak when the scan is reversed at 0.35V E_H.

The oxidation of formic acid and methanol was first studied at platinum under anhydrous conditions with CH_3CN as solvent (25). Complete lack of reactivity of methanol and relatively small reactivity of formic acid was observed under these conditions; this led to an examination of the effects of large and small quantities of CH_3CN on the oxidation of the organic molecules at platinum in aqueous media. In this way, information could be obtained regarding the extent to which the concentration of CH_3CN determines surface blocking for the reaction of formic acid or methanol at platinum anodes. Effects of Hg on the formic acid oxidation reactions were also investigated.

Elsewhere (13), we have shown that CH_3CN is chemisorbed at Pt and undergoes reduction and oxidation entirely in an adsorbed state in cyclic voltammetry between +0.05 and +0.8V E_H, with a reversible reduction-oxidation peak in the d.l. (+0.35 to +0.8V E_H) region (13). Further reduction occurs in the H region (0.0 to +0.35V E_H) but even when the surface coverage by CH_3CN has reached its saturation value, H can be co-adsorbed to an extent of $\theta_H = 0.35$.

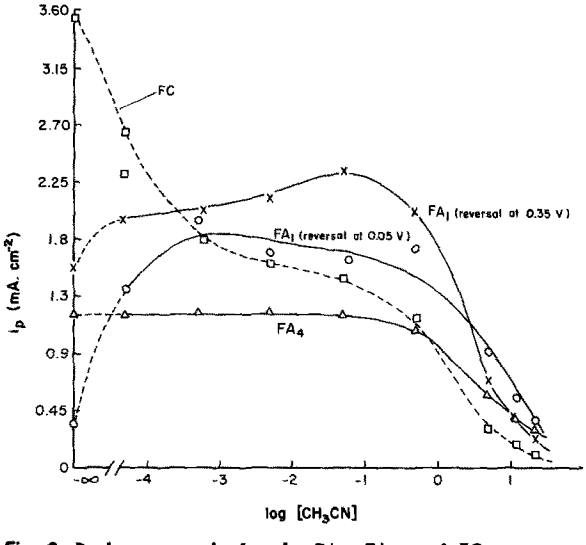

Fig. 2. Peak currents i_p for the FA_1, FA_4, and FC processes in formic acid oxidation at Pt at 25°C in 1*N* aq H_2SO_4 as a function of CH_3CN concentration: for FA_1 process with sweep reversal at +0.05V, for FA_1 process with sweep reversal at +0.35V outside H region, FA_4 process in oxide region, and FC process in cathodic sweep. When [CH_3CN] = 0, the difference between the initial points ○ and X represents the change of $(i_p)_{FA_1}$ when sweeps are taken to 0.05V compared with 0.35V.

[1] The symbol, FA_1, refers to the formic acid anodic oxidation reaction in the double-layer region at platinum; in an anodic-going sweep, it is the "first" process to be distinguished. In the remaining parts of this paper, the peak current for this "FA_1" process will be referred to, for brevity, as $(i_p)_{FA_1}$. Other processes, over the indicated potential ranges, are referred to as FA_3, FA_4. A second peak, "FA_2", arises under some conditions (13) but is not involved in the present work.

Effect of CH_3CN on formic acid oxidation in the double-layer potential range.—The most significant observation in the present work is that CH_3CN has an appreciable effect on the formic acid oxidation peak FA_1 over the d.l. potential region in an anodic-going potential sweep at platinum; the effect is one of activation rather than inhibition as shown in Fig. 1d. Figure 2 shows how the peak current $(i_p)_{FA1}$ for the process FA_1 increases with CH_3CN concentration in potentiodynamic sweep experiments. Results are shown for two ranges of potential, including and excluding the H adsorption region, for reasons to be discussed below. In a potentiodynamic cycling experiment conducted bewteen +1.5 and +0.05V E_H, the increase is about 600% for CH_3CN concentrations up to 5×10^{-2}M. At higher concentrations of the additive, the current begins to decrease; however, even at 2M, $(i_p)_{FA1}$ is still greater than its value measured in the absence of CH_3CN.

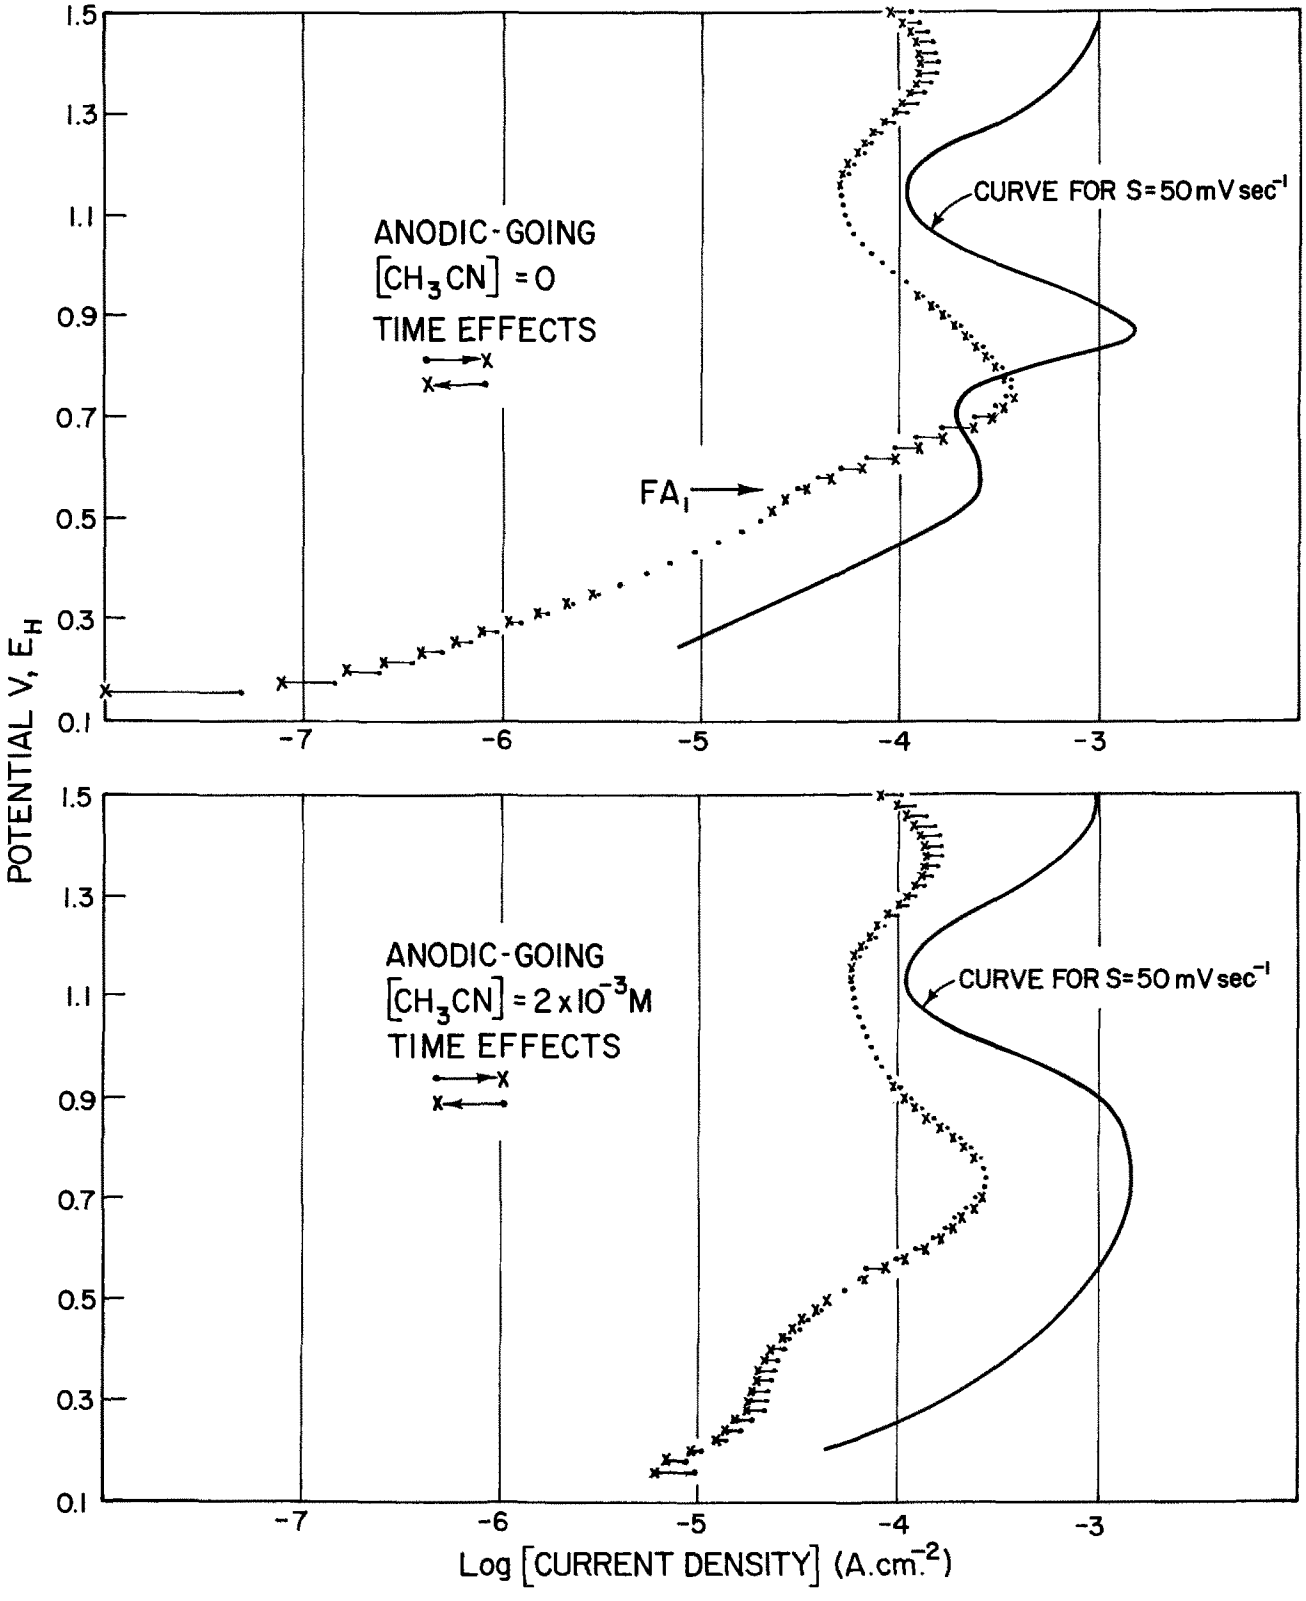

Fig. 3. Relation between steady-state point-by-point *i-V* curves for 0.25M formic acid oxidation in the presence and absence of CH_3CN (2×10^{-3}M in 1N aq H_2SO_4, 25°C) and the potentiodynamic *i-V* profiles taken at 50 mV·sec^{-1} over the same potential range in cathodic and anodic-going directions. Time effects in "steady-state" points are indicated by ●→—X over 90 sec.

That the effect of CH_3CN is not due to some trivial nonsteady-state effect under potentiodynamic conditions, is shown by the results in Fig. 3, where the steady-state, point-by-point i-V profiles are compared with the 50 mV sec^{-1} profiles. Slow time effects in the point-by-point curve are indicated by the direction of change from the X to the O points during 90 sec observation times. It is clear that the activating effects of CH_3CN on FA_1 peak currents are even larger on the steady-state curve than for the dynamical one and all the features of the results of Fig. 1b and 1d are retained in the steady-state behavior. Above 0.7V, both the steady-state and the potentiodynamic i-V curves are independent of the presence of CH_3CN. (Fig. 3).

Relation to the mechanism of formic acid oxidation in the double-layer region.—The effects of CH_3CN must be examined in the context of the mechanism of oxidation of formic acid itself, particularly with regard to the FA_1 process of HCOOH oxidation at the "bare" platinum surface and at a surface on which coadsorbed H is present.

Two main pathways for HCOOH oxidation have been proposed (16), one involving oxidative electrosorption at the carboxylic acid group, (particularly for the case of formate ion oxidation)

$$HCOOH \rightleftharpoons HCOOH_{ads.d.l.} \quad [1]$$

$$Pt + HCOOH_{ads.d.l.} \rightarrow HCOO\cdot/Pt + H^+ + e \quad [2]$$

$$HCOO\cdot/Pt \rightarrow CO_2 + H^+ + e \quad [3]$$

and the other (15, 17, 19) involving dissociative chemisorption with coupled electrochemical steps

$$HCOOH \rightleftharpoons HCOOH_{ads.d.l.} \quad [1]$$

$$2Pt + HCOOH_{ads.d.l.} \rightarrow PtH + PtCOOH \quad [4]$$

$$PtH \rightarrow Pt + H^+ + e \quad [5]$$

$$PtCOOH \rightarrow Pt + CO_2 + H^+ + e \quad [6]$$

The reaction mechanism [1], [4], [5], [6] is the principal one in acid media.

One of the main features of interest in the kinetics of formic acid oxidation is that the rate of the reaction at various potentials does not increase in relation to the coverage of chemisorbed species on the electrode as deduced from oxidative and reductive (by H accommodation measurement) transients. In fact, under some conditions (15, 18), the oxidation current falls as the coverage by adsorbed species increases, a conclusion which can only be interpreted (26) in terms of formation of a blocking species "P" produced in a step in parallel with the main reaction sequences shown above. P cannot, therefore, be $HCOO\cdot$ or $\cdot COOH$. P is also responsible for long-time deactivation effects (27) in HCOOH oxidation; its nature will be discussed in a later section.

Two proposals may be offered for the reaction which forms the inhibitor and leads to the effect of CH_3CN:

(*i*) The inhibitor is produced (15, 26) in a reaction between adsorbed H and an adsorbed species derived from formic acid, *e.g.*, $\cdot COOH$ (15) (from reaction [4]) which is involved in the main reaction sequence.

(*ii*) The poison is formed in a potential-dependent reaction between —COOH species, without the participation of atomic hydrogen. In this case, an additive such as CH_3CN could act as a "third body" interfering in an inhibitor-forming reaction (see below) between —COOH species.

Summary of Results and Conclusions from Experiments on CH_3CN and HCOOH Addition to aq H_2SO_4 in a Potentiodynamic Sweep Especially in or near the H Region

Experiments were carried out at a sweep rate of 50 mV sec^{-1} in 1*N* aq H_2SO_4. In some experiments, HCOOH was already present at 0.25M concentration and CH_3CN was added at selected potentials within a given potentiodynamic cycle; in other experiments, HCOOH was added during the potentiodynamic cycle in 1*N* aq H_2SO_4 in the absence of CH_3CN at selected potentials in either the cathodic-, or anodic-going sweep, *i.e.*, before or after H had been electrosorbed on the surface.

The purpose of these experiments was to establish if the CH_3CN acted independently as a catalytic material for the formic acid oxidation reaction or if it acted by diminishing the coverage by another inhibiting substance formed near or within the range of potentials over which H coverage is significant (0 to +0.35V E_H). The results and conclusions of these experiments are most conveniently recorded by means of Table I, in which reference is made to appropriate figures which provide the basis for the conclusions enumerated.

With increasing $[CH_3CN]$, $(i_p)_{FA_1}$ increases by *ca.* 7 times until about 66% of the H sites [full coverage by CH_3CN (13)] are blocked relative to those available at 0.05V; at higher concentrations, $(i_p)_{FA_1}$ falls somewhat. Although it would initially appear from this result and from the results in Table I that acetonitrile increases $(i_p)_{FA_1}$ by decreasing sites available for hydrogen adsorption, it will be shown that the role of acetonitrile in the formic acid reaction originates for different and indirect reasons, connected with blocking of sites for —COOH adsorption so that formation of P from such species is diminished.

Blocking of Surface Sites for H and/or COOH Species by Hg Electrosorption

In the experiments with CH_3CN and HCOOH, it was possible that CH_3CN could be displaced to some extent by formic acid depending on their relative concentrations (points 5 and 6 in Table I). It was desirable, therefore, to provide an alternative way of blocking the surface, for H and —COOH species, by an adsorbate which cannot be displaced by HCOOH. Electrodeposited mercury was found to meet this requirement very well.

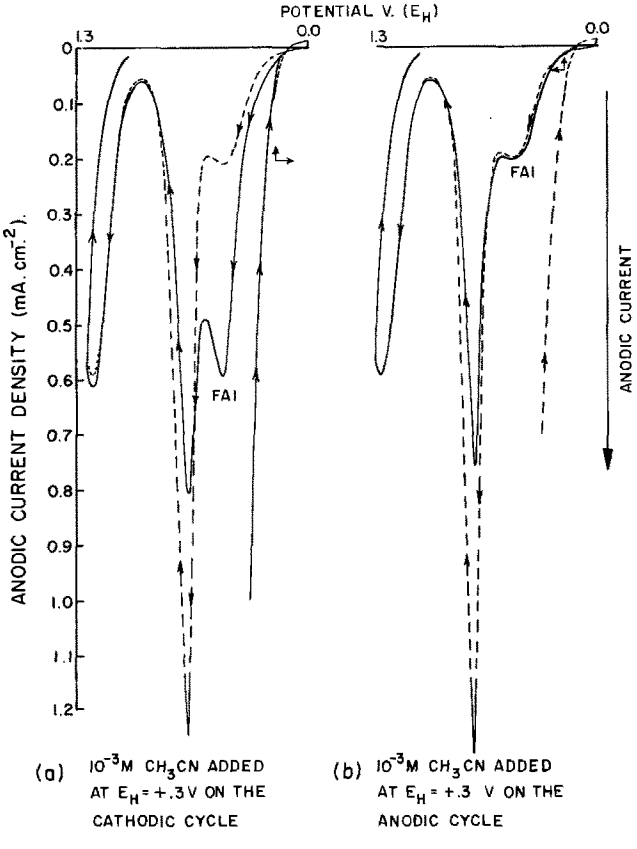

Fig. 4. Potentiodynamic *i*-*V* profiles for 0.25M formic acid oxidation at 50 mV·sec^{-1} at Pt showing effects of CH_3CN addition at 0.3V E_H (a) before and (b) after traversal of the H adsorption region in the sweep.

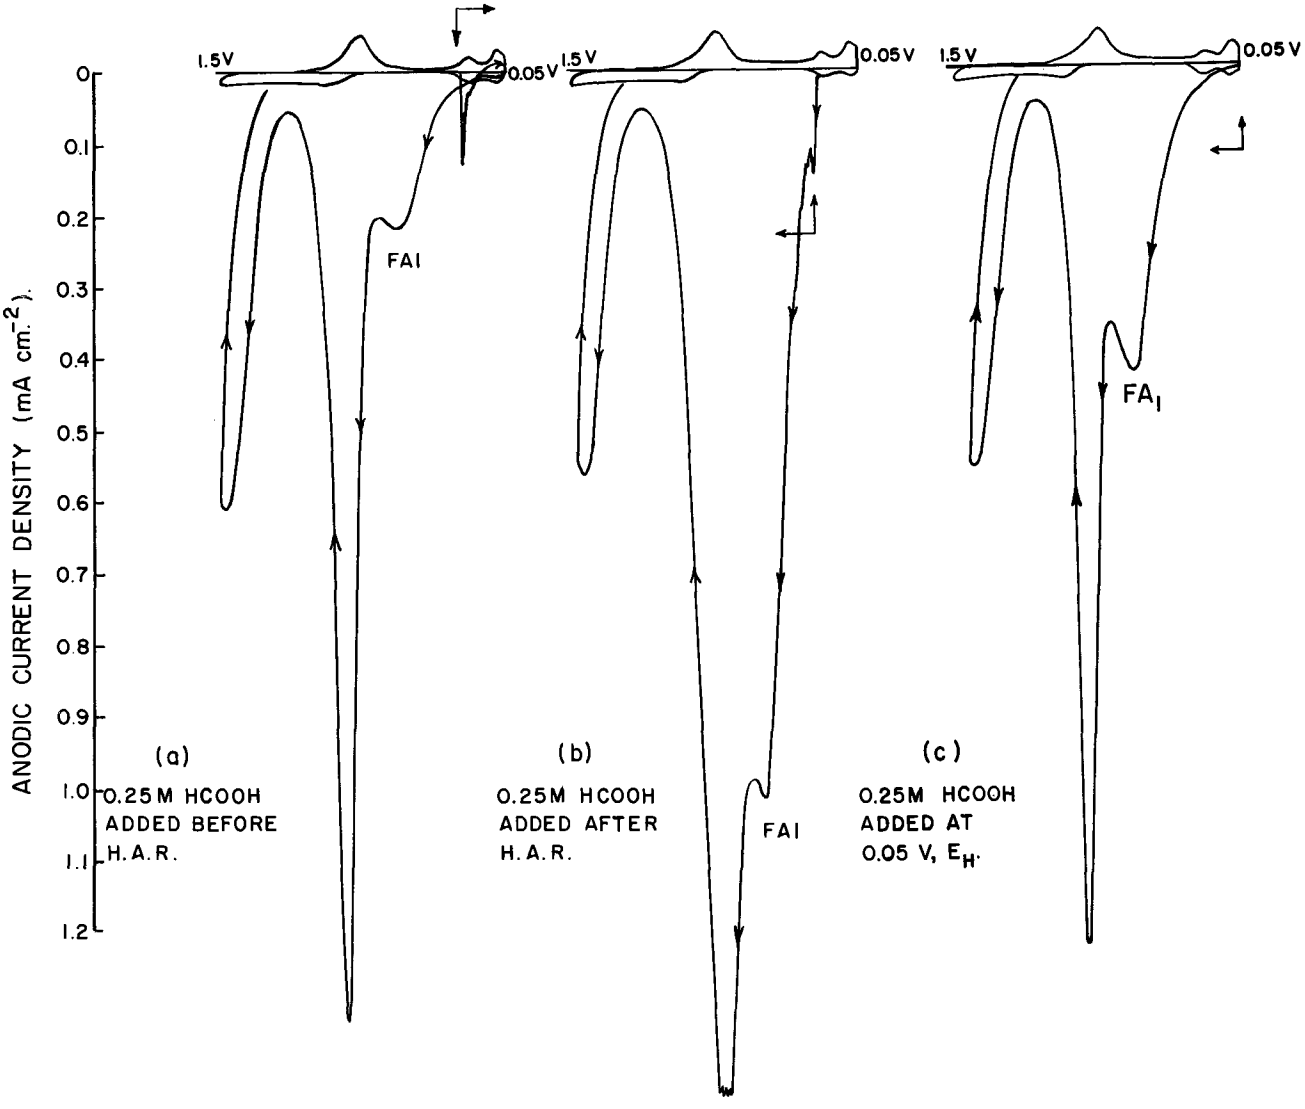

Fig. 5. Potentiodynamic *i-V* profiles for formic acid oxidation at Pt at 50 mV·sec^{-1} at Pt in the absence of CH_3CN: (a) for HCOOH addition at 0.3V on the cathodic-going sweep, (b) for HCOOH addition at 0.3V on the anodic-going sweep, and (c) for HCOOH addition at 0.05V as the sweep is reversed, where Θ_H is a maximum.

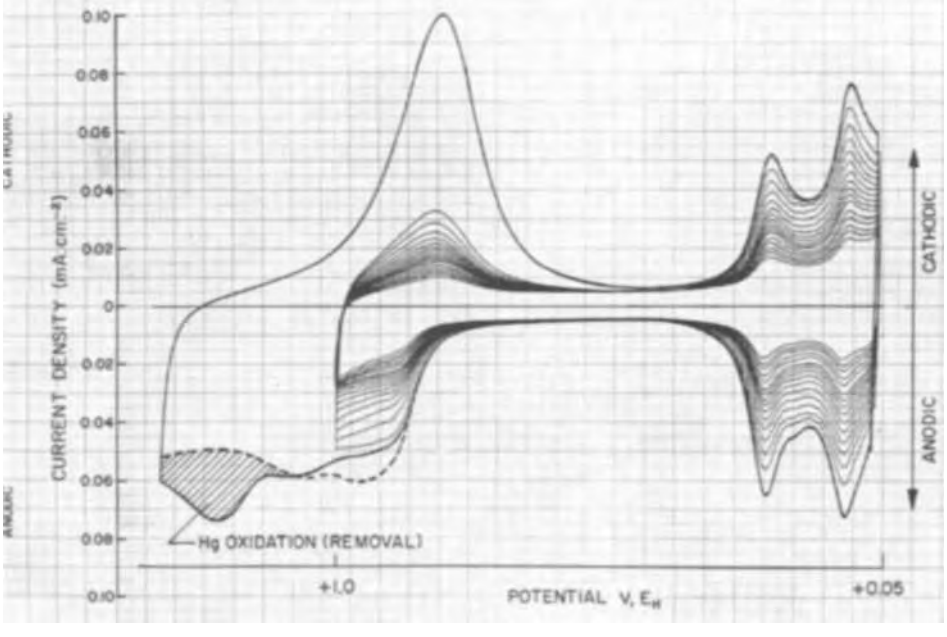

Fig. 6. Progressive blocking of H adsorption peaks (but with maintenance of their resolution) upon electrodeposition of Hg from 3 x 10^{-6}M aq $HgSO_4$ in successive cathodic sweeps. Quantitative oxidation of deposited Hg is measured in sweeps taken to 1.4V.

Mercury can be conveniently and controllably electrodeposited in submonolayer quantities at the platinum surface in aqueous H_2SO_4 using $HgSO_4$ under repetitive sweep conditions with the anodic reversal potential <1.0V E_H; cathodically deposited mercury is not then oxidized off the surface so that the mercury

coverage on successive sweeps progressively increases as indicated by corresponding decreases of hydrogen coverage (Fig. 6). The electrodeposited mercury can, however, be quantitatively oxidized from the surface in a sweep to 1.4V E_H, giving rise to the new peak seen in Fig. 6 at 1.2V E_H.

θ_H could be controlled over a wide range of values with only one concentration of mercury in solution. For progressively increasing Hg deposition, the two main H peaks still remain completely resolved down to $\theta_H = 0.1$. This indicates that mercury blocks H adsorption on an individual site-by-site basis[2] rather than changing the "state" of adsorbed H. This situation is of particular value for the studies with HCOOH where a large range of H coverages and corresponding values of free surface area were of interest.

Figure 7 shows the variation of the FA_1 peak current with θ_H controlled by Hg deposition in the presence of formic acid. It is supposed (see below) that θ_H observed in the absence of formic acid when the surface is progressively blocked by electrodeposited Hg (Fig. 6) changes in proportion to θ_H when formic acid is present.

The initial increase in $(i_p)_{FA_1}$ as mercury begins to decrease θ_H and/or the available free space for HCOOH adsorption, continues until approximately 25% of the platinum sites at which H can be electrochemisorbed has been blocked by mercury. Since the percentage of sites blocked at the inflection point is important when considering the reaction of formation of P, the 25% figure was checked by a procedure which did not involve the above assumption. In this case, known coverages of mercury were first electrodeposited on the surface and the formic acid was added afterwards; the FA_1 peak currents were then registered. This procedure was repeated in separate experiments for a series of θ_H values and the 25% figure was confirmed.

Relation between the Effects of Mercury and Acetonitrile

When $(i_p)_{FA_1}$ in Fig. 2 is plotted with respect to θ_H, corresponding to various acetonitrile concentrations, the reversal of direction of the increase in $(i_p)_{FA_1}$ was found to occur at *ca.* 70% surface coverage by nitrile; the same results were obtained when θ_H was controlled with a particular [CH_3CN] initially in the absence of formic acid, followed by formic acid addition to the system.

The difference between the results with mercury and acetonitrile must be attributed to the ability of formic acid to displace, to some extent, acetonitrile from the surface as mentioned above. Then the free space available for formic acid adsorption, measured by θ_H determined in the presence of acetonitrile, can be substantially different from the space actually occupied by formic acid molecules when the latter are coadsorbed with acetonitrile. Coverage by species derived from HCOOH can hence be higher, with resultant [cf. (14) and below] formation of P. Electrodeposited Hg is not easily displaced in the above manner and requires anodic oxidation for its removal (Fig. 6).

Effects of Time spent in the H Region during Potentiodynamic Sweeps on Inhibitor Formation

The time τ_H spent in a sweep over the potential range ΔV_H in the H region $\left(\tau_H = 2\Delta V_H \frac{dV}{dt} \right)$, is an important factor in the reaction which produces the inhibiting species P. The percentage change in $(i_p)_{FA_1}$, after sharply decreasing initially, soon approaches a limiting value with increasing τ_H, *e.g.*, to *ca.* 30 sec on going to lower dV/dt. Evidently, under the latter conditions, τ_H is sufficient to allow the production of P to be more or less complete.

[2] The possibility that the electrodeposited Hg simply forms two-dimensional islands of Hg with otherwise free Pt sites is ruled out because the FA_1 peak current is increased by Hg (Fig. 7). If Hg had the effect of simply cutting the available surface area, all currents would be uniformly decreased.

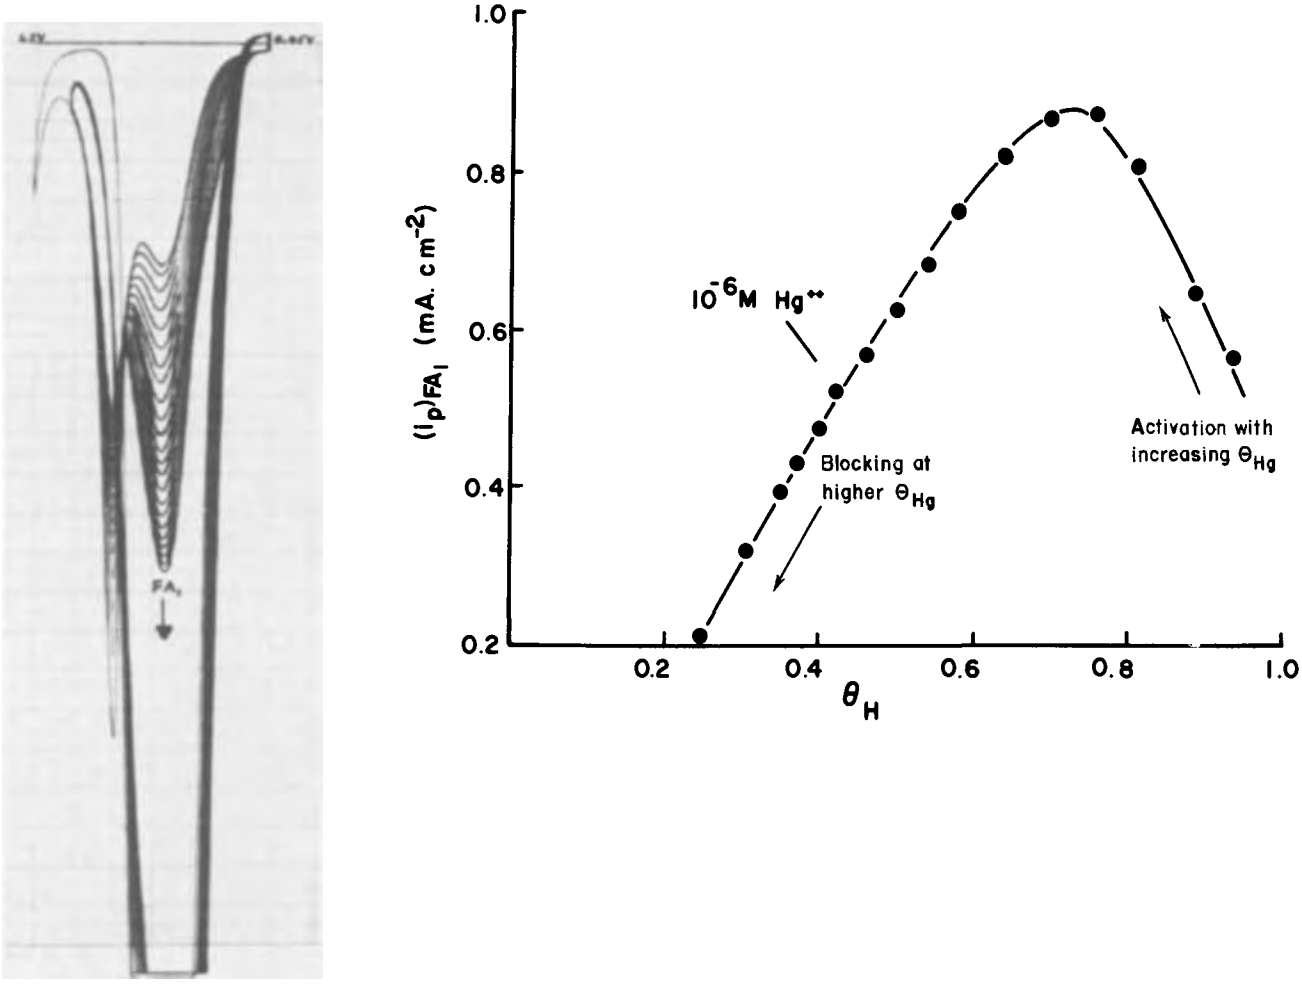

Fig. 7. Variation of $(i_p)_{FA_1}$ with H coverage at Pt controlled by Hg electrodeposition (Fig. 8) (HCOOH concentration 0.25M, 1*N* aq H_2SO_4, 25°C). (Lefthand set of curves shows the progression of *i-V* profiles with decreasing Θ_H down to 0.75).

Although the increase of $(i_p)_{FA_1}$ as the cathodic termination potential of the sweep is made more positive can be explained in terms of the production of less P, due to the tendency for Θ_H to diminish with increasing potential, the same, or an even higher degree of poisoning of the FA_1 reaction can be achieved by holding the potential for various times t_h at more positive values in the H region, where Θ_H is, of course, smaller. Figure 8 shows how $(i_p)_{FA_1}$ values depend on various holding times t_h at different reversal potentials in the cathodic-going sweep. It is to be noted that the maximum decrease of FA_1 peak current occurs at a reversal potential of *ca.* 0.22V E_H; in fact, 5 sec of cathodic holding at this potential gives a value of $(i_p)_{FA_1}$ as low as that observed after 40 sec of cathodic holding at +0.1V E_H.

There are evidently three factors which may determine the production of P: (*i*) the time spent at a given potential, (*ii*) the potential itself in the H region and/or Θ_H (Fig. 8), (*iii*) the free space available for dissociative adsorption of HCOOH to —COOH species which can then form the inhibitor P.

Support for the role of factor (*iii*) follows from the observation that the maximum poisoning effect with cathodic holding for times t_h occurs at about +0.20V E_H, where Θ_H can only be $\leq$0.25, *i.e.*, some free space is available. However, free space is not the only important factor since cycling to a potential of +0.20V E_H in the cathodic sweep results in an increase of $(i_p)_{FA_1}$ in comparison with that for cycling to +0.1V E_H (curve for t_h = 0 in Fig. 8). This complication can be rationalized in terms of the observation that formation of P is a slow reaction so that the extra time τ_H provided by cycling to a more cathodic reversal potential in the H region compensates for the increased Θ_H.

The time and potential effects in the H region on the FA_1 peak current are evidently complex but the two main factors determining P formation will be: competition of dissociative HCOOH adsorption with increasing tendency for H chemisorption at the least positive potentials; and decrease of —COOH coverage as the potential is made more positive, a situation that results from the mechanism [1], [4], [5], [6]. The minimum in $(i_p)_{FA_1}$ at finite t_h corresponds approximately with maximum adsorption of "HCOOH" species (18) and hence with maximum P coverage.

That the above effects are not due primarily to actual surface reactions with H was demonstrated by another holding experiment at 0.5V where $(i_p)_{FA_1}$ still fell to 27% of its value on the repetitive sweep during 60 sec holding at 0.5V, *i.e.*, outside the region where H is significantly adsorbed and at a potential where any H arising from HCOOH dissociation would be immediately ionized.

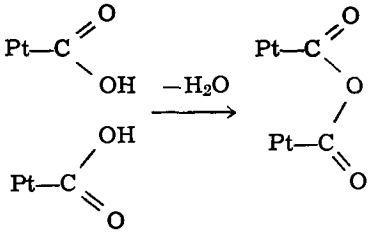
Nature of Inhibiting Species and Its Formation in Relation to Effects of CH_3CN and Hg

The results considered above indicated that formation of P is slow, the maximum rate occurring at *ca.* 0.2V E_H where coverage with formic acid species is a maximum. Also, the formation of P while influenced by H or potential in the H region does not require H. This leaves proposal (*ii*) on page 759 as a basis for formation of P and the effects of acetonitrile in the reaction.

Various possible inhibiting species, such as CO, "reduced CO_2,"≡C·OH, Cl^-, $HCOO^-$ anions, and CHO·COOH formed by dehydration of 2 HCOOH or by reductive coupling of CO, have been discussed (15). The first three have been discounted as the inhibitor (15, 19)

and adsorbed HCOOH itself (17) cannot be responsible for the observed behavior. CHO·COOH requires 3e for its oxidation to $CO_2 + H^+$, and it is difficult to see that it can occupy less than 3 or 4 sites; that is, its electron oxidation number per site will be <1. Brummer's experiment (15, 19) indicates oxidation charges in anodic galvanostatic experiments of *ca.* 370 μcoulomb per real cm². However, the galvanostatic method operated at large currents cannot be used reliably for desorption of a slowly oxidized intermediate while at smaller currents, reaction charge passes due to the diffusion-controlled reaction of reagent in solution in addition to the charge for oxidation of the adsorbed species. The end of the oxidation transient is also more difficult to define in comparison with that in potentiostatic-step or potential sweep-transients.

The results suggest that a formation of P must arise by a "dimerization" type of reaction on the electrode surface between adsorbed formic acid species leading to the lowering of coverage by the main electrochemically reactive species, —COOH. It cannot be a poison arising independently of the adsorbed formic acid species, *e.g.*, chloride ion (15), since there is no reason why displacement of one such a poison by another, acetonitrile, should increase $(i_p)_{FA1}$. The most plausible reaction between two adsorbed formic acid (—COOH) residues adjacent to each other on the electrode surface is dehydration leading to adsorbed formic anhydride[3]



[7]

This reaction diminishes the surface available for reactive —COOH species, transforming them instead into the anhydride species which is unreactive except at higher anodic potentials (> *ca.* 0.9V E_H). Adsorbed acetonitrile acts as a "third body," decreasing the coverage with neighboring adsorbed —COOH groups so that there is less chance for two reactive species to become adjacent to one another and undergo dehydration leading to dimerization.

The mechanism of reaction [7] may be written following known mechanisms of, and substituent effects in, anhydride formation (29). Although formic anhydride is unknown as a stable substance in solution, it is proposed that the above reaction is possible since the intermediate [I] is in a two-point adsorbed state on the platinum surface so that the resulting anhydride [II] can be stabilized.

The identity of the P species as formic anhydride is supported by the observed potential-dependence of the rate of formation of P. Significant P formation only occurs in the less positive potential regions, *i.e.*, when the electrode acts relatively as a source of electrons. This is consistent with the above reaction mechanism since increase of electron donating tendency by the platinum will tend (*i*) to increase the protonation of adsorbed COOH groups, leading to stabilization of the

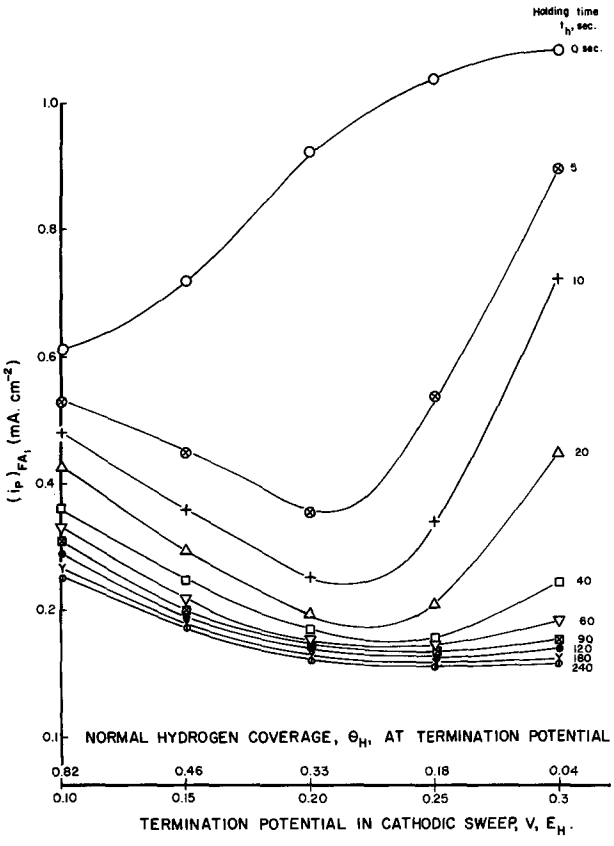


Fig. 8. Dependence of $(i_p)_{FA_1}$ on termination potential in the cathodic sweep for various holding times t_h at that potential. Also shown on nonlinear scale are corresponding H coverages (HCOOH concentration = 0.25M, dV/dt = 100 mV·sec^{-1} to minimize τ_H effect, in comparison with t_h in the H region.)

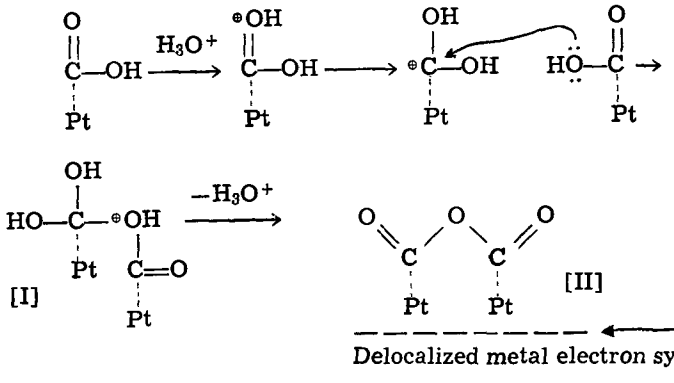

[8]

[3] A requirement for the above reaction will exist that would limit the reaction of anhydride formation to those adjacent COOH species on the surface which have the proper geometry. Formation of Brummer's intermediate, glyoxalic acid, requires dehydration between the OH and CH groups of two free formic acid molecules. This seems unlikely for organic mechanistic reasons and also because the inhibitor appears to be formed rather from already adsorbed intermediates, *e.g.*, -COOH, than from the normal free molecule HCOOH.

resulting protonated species and (*ii*) to increase the nucleophilicity of those adsorbed species which are not protonated, *i.e.*, the attacking species (29). At more positive potentials, the rate of reaction [7] should decrease since the platinum then acts as an electron withdrawing agent and the surface coverage by —COOH is also diminished as potential becomes more positive. Eventually, reaction [7] will become reversed, which is consistent with the change of direction of time effects with potential shown in Fig. 3.

The mechanism [7], [8], and the suggestion that the activating effect of CH_3CN arises from a "third body" effect which diminishes the probability of the dimerization reaction [7], receives further support from the results described earlier with controlled electrodeposition of Hg below monolayer coverage.

It is concluded that mercury acts in the same way as acetonitrile with regard to the FA_1 reaction by providing a "third body" which decreases the formation of poison P (reaction [7]). The situation giving rise to the maximum $(i_p)_{FA1}$ should correspond to the highest coverage by formic acid which can be attained without the presence of adsorbed "formic acid" (—COOH) species close enough to one another to give rise to reaction [7]. The maximum $(i_p)_{FA1}$ arises when the platinum surface is *ca.* 25% covered with mercury and the subsequent decrease of $(i_p)_{FA1}$ at higher mercury coverages (Fig. 7) is probably simply caused by mercury deposition on platinum sites where the main FA_1 reaction itself would normally occur. It is seen, however, that even when mercury has blocked 75% of the surface, $(i_p)_{FA1}$, after passing through its maximum value, has about the same value it had in the initial formic acid solution in the absence of mercury. This is consistent with the experimental findings of Brummer *et al.* (15) who concluded that the normal formic acid oxidation reaction occurs on only *ca.* 10% of the available platinum surface.

An approximate value of the mercury coverage which should give rise to a maximum $(i_p)_{FA1}$ by blocking dimerization between nearest neighbor —COOH groups can be obtained by reference to the geometry of adsorbed formic acid on a Pt (III) face (Fig. 9a). While one molecule of formic acid (as —COOH) can form a chemisorption bond to one Pt site, the whole unit effectively shields three platinum sites.[4] Maximum coverage by such adsorbed COOH groups arises when the surface is occupied as shown in Fig. 9b, as may be seen from space-filling models (Fig. 9a). For dimerization to be inhibited, nearest neighbor COOH positions must be blocked, *e.g.*, by Hg atoms. The highest coverage of COOH groups consistent with blocking adjacent positions (Fig. 9b) for COOH adsorption corresponds to that shown in Fig. 9c, where one in every four Pt sites has been blocked by electrodeposited Hg. This is consistent with the extent of blcoking of H adsorption (25%) at which the maximum in $(i_p)_{FA1}$ arises in Fig. 7. The blocking effects of Hg hence quantitatively support the view that the inhibitor P arises from COOH groups by a dimerization surface reaction. The corresponding situation for acetonitrile adsorption is shown in Fig. 9d where CH_3CN groups occupy 3 Pt sites each (13). In this case, CH_3CN must occupy all successive trigonal sites on two lines of Pt atoms and alternate groups of trigonal sites on the next two pairs of lines of Pt atoms. The pattern is then repeated.

[4] The adsorbed formic acid molecules are drawn as triangles in Fig. 9b (shielding three platinum atoms) for convenience of representation. The formic anhydride molecule can be seen from space-filling models to shield 5 platinum atoms. H coverage is assumed to correspond to approximately 1 atom per Pt of the lattice as found experimentally for the (111), (110), and (100) crystal faces. On the (111) face, this means that there are two trigonal holes for every H atom adsorbed.

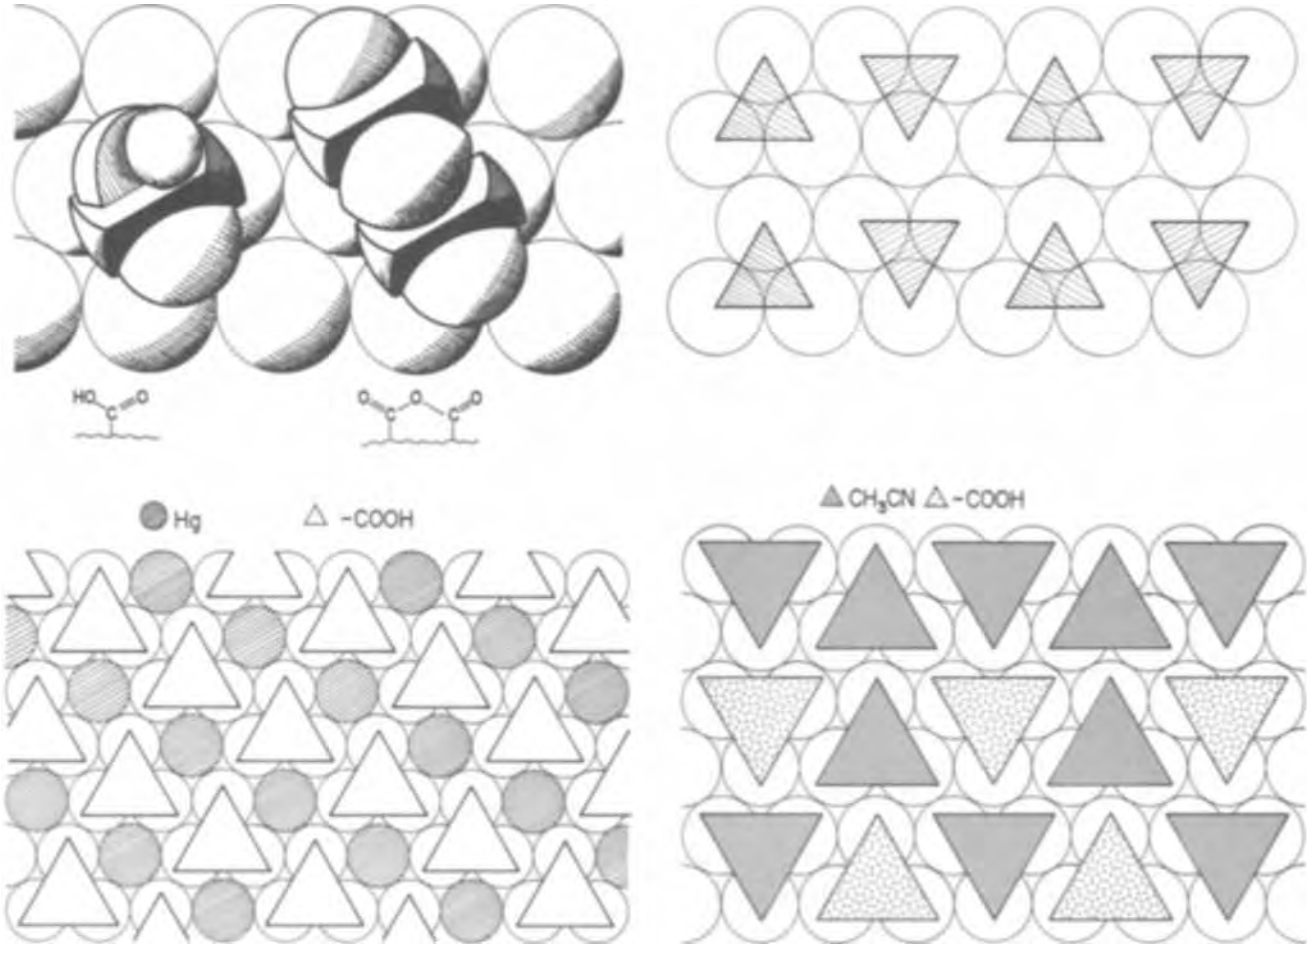

Fig. 9. Schematic diagram of (a, above left) adsorption of —COOH and the inhibitor in relation to (b, above right) H blocking, (c, below left) blocking by Hg, and (d, below right) blocking by CH_3CN.

This situation corresponds to 66% of the normal (13) maximum CH_3CN coverage attainable at Pt and is hence consistent with the observation that the maximum in $(i_p)_{FA_1}$ in the presence of CH_3CN occurs at *ca.* 70% relative blocking referred to H coverage at 0.05V. This does not represent saturation geometrical coverage by CH_3CN as it would (13) if CH_3CN were the only organic chemisorbed species. In the presence of HCOOH, co-adsorption of COOH must occur as shown in Fig. 9d. The results with Hg and CH_3CN cannot be easily accounted for if P were CO arising in a first order surface dehydration of HCOOHg nor are they consistent with the intermediate ≡C—OH involved in methanol oxidation (18).

Of course, the ordered arrangements of Fig. 9b-d are an idealization and the real surface undoubtedly has more random arrangements. The ordered patterns give, however, quite a good account of how the activating effects arise from partial blocking of sites for COOH adsorption. This blocking by the additive, Hg or CH_3CN, will also block H adsorption in the absence of HCOOH but it can be seen from the above diagrams how this can be a secondary effect so that H need not directly be involved in the production of P.

We stress the desirability, in interpretation of electrocatalytic processes, of considering the geometry of the metal lattice[5] in relation to the geometries of the probable chemisorbed species.

In impure solutions, but without an additive such as CH_3CN or Hg, potentiodynamic cycling over a potential range, which excludes (<0.85V) the Pt surface oxidation region, allows accumulation of adsorbed or electrodeposited impurities which are not then removed in the usual oxidative desorption provided by reaction with the oxidized Pt surface. After cycling for various periods of time, formic acid was added and $(i_p)_{FA_1}$ recorded. The peak current progressively increased as the surface became occupied with adsorbed impurities, evidently acting as a "third body," similar to Hg or CH_3CN, blocking the formation of P. Extension of the anodic limit of the potential sweep to +1.1V immediately lowered $(i_p)_{FA_1}$ on the next cycle due to removal, between 0.85 and 1.1V, of the impurities that had blocked formation of P. In pyrodistilled water (32), the above impurity effects are eliminated completely.

Effects of Acetonitrile on Other Formic Acid Oxidation Reactions and Comparison with the Behavior of Methanol

In addition to the FA_1 process, formic acid oxidation occurs by other mechanisms (15-19) near 0.9V E_H (FA_3), as surface oxide formation on Pt commences (31) and also at 1.3V (FA_4) on the more highly oxidized "PtO" surface. In the cathodic sweep, facile oxidation occurs ("FC" reaction, Fig. 2) again, just before completion of surface oxide reduction. The peak current FA_4 at +1.30V E_H is independent of the previous history of exposure of the electrode to formic acid in the H region and hence does not vary like that for peak FA_1. This is to be expected since the species P formed in the H region is oxidatively desorbed before a potential of 1.3V is reached.

The dependence on $[CH_3CN]$ of the peak currents $(i_p)_{FC}$ (see Fig. 1) and $(i_p)_{MC}$ for formic acid and methanol oxidations observed on the cathodic-going sweep is shown in Fig. 10. In these cases, there is a current decrease which follows, in a general way, the dependence of CH_3CN coverage at platinum on its concentration, reported elsewhere (13).

The rate of decrease of the current peak for the FC process on the cathodic sweep with $[CH_3CN]$ can be compared with that for methanol under similar conditions where the current has decreased to zero already at $[CH_3CN] = 2.5 \times 10^{-3}$ M (Fig. 10). The less

[5] Elsewhere (30), we have shown that the initial stages of oxidation of Pt which are resolvable below monolayer coverage by OH species ("PtOH") can be attributed to various stages of occupation of the Pt surface lattice by OH species in different geometrical arrays (cf. the conclusions from LEED work on surfaces not contaminated by carbonaceous residues).

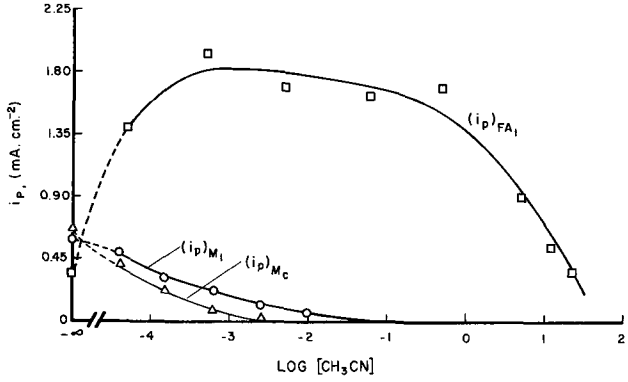

Fig. 10. Peak currents for the processes M_1 in the anodic-going, and M_c in the cathodic-going sweep for methanol oxidation in 1*N* aq H_2SO_4, 25°C, as a function of log [acetonitrile concentration] in comparison with $(i_p)_{FA_1}$ values for formic acid oxidation.

sensitive dependence of the currents for formic acid oxidation on $[CH_3CN]$ can be correlated with the requirement that only two free platinum sites are required for the dissociative chemisorption, HCOOH + Pt → PtH + PtCOOH, in comparison with that for methanol, represented (25) by: Pt + CH_3OH → Pt≡COH + 3PtH which requires a total of 6 sites.

While the formic acid oxidation peak FA_4 at +1.3V E_H is almost independent of $[CH_3CN]$ up to 5×10^{-2} M, the peak current for methanol oxidation on the anodic sweep at +1.3V E_H is found to continuously decrease with increasing $[CH_3CN]$ but it was not possible to separate this peak from that for oxidation of adsorbed (12) acetonitrile itself (13). The decrease in methanol oxidation current at *ca.* +1.3V E_H can be correlated with observations made previously (12, 13), that acetonitrile remains adsorbed on the electrode surface even at potentials in the oxygen evolution region at platinum.

Trace quantities of CH_3CN already decrease the two main current peaks for the methanol oxidation reaction at platinum. Figure 10 shows the dependence on CH_3CN concentration of the peak current M_1 (Fig. 1) for methanol oxidation in the potential region where surface oxidation of Pt commences. Methanol electrosorption requires (25, 28), as indicated above, three adjacent platinum sites so that coverage of the surface by CH_3CN species (12) and the corresponding blocking of sites for H chemisorption when $[CH_3CN] \geq 2 \times 10^{-4}$M makes it difficult for this site requirement to be fulfilled so that the reaction is very sensitive to poisoning of Pt sites.

Summary

The current for formic acid oxidation in the d.l. range of potentials at Pt is substantially increased in the presence of CH_3CN, adsorbed impurities, or Hg atoms. This arises from an indirect effect associated with prevention of formation of an inhibitor for formic acid oxidation which is otherwise spontaneously formed, particularly in the potential range 0.05 to 0.6V E_H. The additives which chemisorb and block inhibitor formation do so by a "third body" effect in which the rate of inhibitor production by a supposed dimerization reaction involving —COOH groups is diminished by blocking sites for nearest neighbor —COOH adsorption. It is shown that the inhibitor is probably adsorbed formic anhydride. The role of H coverage in inhibitor formation and in the activating effects is considered but it is shown that it is not a primary factor in the behavior reported. Similar activating effects do not arise in methanol oxidation because the electrochemical reaction does not involve the production of an inhibitor in a side reaction in that case.

The Anodic Oxidation of Hydrogen on Platinized Tungsten Oxides

II. Mechanism of H_2 Oxidation on Platinized WO_3 Electrodes

B. S. Hobbs[1] and A. C. C. Tseung

Department of Chemistry, The City University, St. John Street, London EC1V 4PB, United Kingdom

ABSTRACT

Electrochemical measurements on the anodic oxidation of hydrogen on platinized boron carbide and WO_3 supports reveal that the latter is an "active" support, participating directly in the over-all electrode reaction. In contrast, boron carbide is an "inert" support and takes no part in the electrode reaction. This work and previous investigations on the composition of the WO_3, confirm that the electrode reaction proceeds by the formation and oxidation of hydrogen tungsten bronzes (H_xWO_3)

$$WO_3 + x\text{Pt} - \text{H} \rightarrow H_xWO_3 + \text{Pt}$$

$$H_xWO_3 \rightarrow WO_3 + xe^- + xH^+$$

In this way the effective reaction zone area is extended onto the support, increasing the net electrode current.

Previous studies based on polarization curves of electrodes fabricated from various platinized substrates (*e.g.*, tantalum carbide, graphite, tungsten trioxide) indicated a synergic mechanism on WO_3 (1). Later, it was shown that hydrogen tungsten bronzes (H_xWO_3) are the sole products when platinized WO_3 electrocatalysts are exposed to hydrogen in $5NH_2SO_4$ between 20° and 80°C (2). A mechanism was proposed whereby these bronzes participated in the anodic oxidation of hydrogen, thereby enhancing the output of electrodes using Pt/WO_3 catalysts, viz

$$2\text{Pt} + H_2 \rightarrow 2\text{Pt}H_{ads}$$

$$\text{Pt}H_{ads} \rightarrow \text{Pt} + H^+ + e \quad \text{normal route}$$

$$x\text{Pt}H_{ads} + WO_3 \rightarrow \text{Pt} + H_xWO_3$$
$$H_xWO_3 \rightarrow xH^+ + WO_3 + xe \quad \Big) \text{ bronze route}$$

[1] Present address: Electrical Research Association, Cleeve Road, Leatherhead, Surrey, United Kingdom.

Key words: electrocatalysis, H_2 oxidation, WO_3 support.

The original polarization studies, however, do not confirm the above mechanism since the observed activity differences on the various substrates could also have arisen from differences in Pt morphology or physical electrode parameters such as wetting, permeability, etc. The extent of support participation in the electrode reaction can be determined in the presence of these complicating structural effects by examining the relationship between electrode activity and Pt loading, the support loading being held constant. Thus, assuming all the electrode current at a given overvoltage originates from the Pt, we can define a specific Pt activity ($j_{(p)}$), expressed in milliamperes/milligram of platinum

$$j_{(p)} = \frac{i(\eta)}{W_{(p)}}$$

where $i(\eta)$ is the electrode current density at a fixed overvoltage, η, in mA cm^{-2}, and $W_{(p)}$ is the Pt loading in mg cm^{-2}.

Alternatively, the Pt activity can be expressed in terms of milliamperes/unit surface area of Pt

$$j_{(ps)} = \frac{i(\eta)}{S_{(p)}} \quad \text{(mA per cm}^2\text{ Pt)}$$

where $S_{(p)}$ is the Pt area/cm^2 electrode.

Now $j_{(p)}$ (or $j_{(ps)}$) should remain independent of variations in the Pt loading, provided the Pt specific surface area and morphology remain constant. In this case $j_{(p)}$ represents the true Pt activity.

If however, the support also contributes to the electrode current, $j_{(p)}$ will apparently increase as the Pt loading decreases. Furthermore, if the support contributes the major fraction of the current, the relationship between $j_{(p)}$ and W_p will approximate to an inverse proportion, *e.g.*, halving the Pt loading will produce little effect on $i(\eta)$ if the support accounts for most of the current, but $j_{(p)}$ will apparently double.

Experimental

Catalyst preparation.—To ensure Pt morphology and specific surface area remained constant, loadings were varied by first impregnating a batch of WO_3 with Pt, then mixing samples of this with varying proportions of unplatinized oxide when preparing electrodes. In order to produce a high, uniform dispersion of Pt on the oxide, impregnation was carried out by means of a freeze-drying technique (2). The Pt content was analyzed by gravimetric extraction with NaOH solution as previously described (2).

Electrode preparation.—Electrodes of the polytetrafluorethylene (PTFE) bonded type, having very similar physical structures, while varying significantly in their Pt loadings, were prepared according to an optimized procedure described by Giner *et al.* (3): "weighed quantities of impregnated and plain WO_3 powders were slurried with aqueous P.T.F.E. dispersion and pasted onto 80 mesh, 18 Standard Wire Gauge (S.W.G.) gold-plated Pt gauze screens. After drying at 70°C, the electrodes were 'cured' at 300°C for one hour."

Complete transfer of the mix to the screen was impossible and the Pt loadings were therefore estimated from the screen weight changes before and after fabrication, assuming the components of the catalyst/PTFE paste to be transferred in the same ratio as the original pot mix.

Pt loadings were kept low to avoid masking any substrate activity by the intrinsic Pt activity. Oxide loadings of about 10 mg/geometric cm^2 of screen were used, with Pt contents ranging between 0.1 and 1% of the oxide weight (0.1-0.01 mg/cm^2 electrode). PTFE loadings were in the range 3-4 mg/cm^2 electrode.

Electrode testing.—Electrochemical measurements were made with a floating electrode cell described by Giner *et al.* (3) employing a gold counterelectrode, 5*N* sulfuric acid thermostated at 25°C, and a dynamic hydrogen reference electrode (DHE) (4), whose potential was −25 mV with respect to a normal hydrogen electrode in the same electrolyte. Hydrogen from a palladium diffuser was fed to the test electrode and steady-state anodic polarization curves were obtained using a Chemical Electronics TR40-3 Amp potentiostat. The resultant polarization curves were corrected for ohmic effects by the interrupter technique (5).

The limits of experimental deviation were determined from the maximum spread of measurements obtained from several electrode samples made from each batch of catalyst powder.

Boron carbide electrodes.—Boron carbide (B_4C) is an acid resistant (6, 7), conducting [$\rho = 0.455$ ohm-cm (8)] material which has been extensively employed in fuel cells as a catalyst or support (9-15). It possesses no activity toward H_2 oxidation, being inert to H_2 chemisorption, either directly or via predissociation on Pt (13). Hence B_4C is an ideal substrate to test the "Pt loading effect" for an inert support, and is preferred to either graphite, which can deactivate Pt (16), or TaC which can form resistive oxide films. It is emphasized however, that we cannot directly compare the polarization curves for B_4C and WO_3 substrates, owing to structural and morphological variations between the two types of electrode. We can only confirm the independence of $j_{(p)}$ on platinum loading for inert supports, such as B_4C.

Platinizing was carried out in an analogous manner to WO_3, but owing to the difficulty of dissolving B_4C to separate it from the Pt, no check on the Pt content was possible. Instead, Pt contents were calculated from the chloroplatinic acid used in the impregnation and since good agreement was obtained with WO_3 between this method and the gravimetric analysis, it can be assumed to be so for B_4C.

Electrode curing and drying were performed in a nitrogen stream to avoid oxidation of the B_4C.

Materials purification.—As previously described, H_2 was purified with a palladium diffuser. Analar sulfuric acid and distilled/deionized water were used to prepare the electrolyte, which was electrolyzed for several hours between gold electrodes before use.

The WO_3 and B_4C were repeatedly refluxed with 5*N* H_2SO_4 and analyzed by mass spectrography before use. Iron was the only significant impurity which was reduced to 20 and 150 ppm in the WO_3 and B_4C, respectively.

Results and Discussion

WO_3 electrodes.—None of the polarization curves exhibited a Tafel region and were essentially linear throughout the overpotential ranges studied (Fig. 1). The unusually wide overpotential range of linearity can be attributed to mass transfer effects (17). Platinum activities $j_{(p)}$ were determined from the

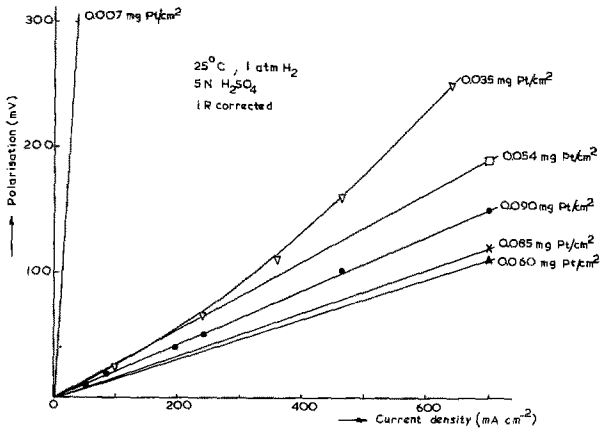

Fig. 1. Polarization curves for platinized WO_3 electrodes

electrode current at an arbitrarily chosen overpotential of 50 mV.

Figures 2 and 3 show the variations of specific Pt activity as a function of platinum loading and reciprocal Pt loading, respectively. In the range of Pt loading between 0.2 and 1% of the support weight (0.02 to 0.1 mg/cm^2) the experimental points lie very closely to the theoretical curves for an active support supplying the majority of electrode current.

When the Pt content was reduced below 0.2% of the oxide weight however, the electrode performance sharply declined. This critical Pt loading was observed during hydrogen uptake and bronze compositional studies (2) and corresponds to the condition at which the ratio of Pt to WO_3 particles was unity, calculated from the average particle sizes [from BET measurements on the WO_3 powder and extracted Pt black (2, 18)], assuming the particles to be perfect spheres. This effect is expected under steady-state polarization, if the oxide interparticle H-transfer rate is slower than the anodic oxidation of H_xWO_3. Ohmic polarization will then limit the electrode performance as WO_3 accumulates in the electrode. The fact that electrode activity is very high when there is at least one Pt particle per oxide particle, indicates that the Pt/oxide interparticle and WO_3 intraparticle H-migration rates are extremely fast.

Boron carbide electrodes.—Polarization curves were again essentially linear over the overpotential ranges investigated (Fig. 4) and Pt activities were similarly measured from currents at an arbitrary 50 mV.

Figures 5 and 6 show that the specific Pt activity was independent of Pt loading, as expected of an inert support.

A plain B_4C electrode showed some residual activity under H_2. This probably arose from trace impurities, especially iron, which is not easily removed completely from B_4C (7). Other current sources were exposed Pt at the electrode edges when cutting to size and possible pin holes or other defects in the gold plate.

Conclusions

Hydrogen bronzes, formed in platinized WO_3 hydrogen electrodes, contribute to the net anodic current, being formed chemically by H-atom migration from the Pt to the oxide, and oxidizing electrochemically. Thus the reaction zone is extended onto the support and the over-all electrode activity is increased. With Pt loadings in the range of 0.02-0.1 mg/cm^2 (or 0.2-1% of the WO_3 loading) high electrode performance was obtained which originated principally from the bronze reaction

$$H_xWO_3 \rightarrow xH^+ + WO_3 + xe$$

The rate of hydrogen atom migration to form bronzes is rapid provided there is direct contact between Pt and WO_3 particles. Hydrogen atom migration between oxide particles is relatively slow and, under conditions where this is necessary for current generation, a severe decline in activity is observed.

Although the oxide composition and H_2 oxidation mechanism has been conclusively established for platinized WO_3, complementary work is required on related substrates, *e.g.*, the lower tungsten oxides and

sodium bronzes, which show similar evidence of synergic effects (1, 20).

Technical Notes

Detection of CO_2 in Cavities in NiO Scales

M. J. Graham and D. Caplan

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada

In an investigation of the oxidation of Ni at high temperatures (1), cavities (voids) were observed to form in the NiO layer. Cavities are expected at the oxide-metal interface as the result of the condensation of cation vacancies, but voids throughout the oxide layer are less readily explained. One possible explanation is that gas pockets are formed in the oxide by oxidation of the carbon impurity in the metal to CO or CO_2. If so, higher carbon contents should produce more cavity, and CO or CO_2 should occupy the voids. To test this thesis a procedure was devised to analyze the gas content of cavities.

Three specimens, 1 × 5 × 0.03 cm, of pure Ni with carbon contents of 100, 9, and 2 ppm atomic were oxidized at 1270°C for 20 hr in 760 Torr O_2, producing oxide layers ~75 μm thick. To analyze for gases the oxidized sheet was placed on a flange in a metal, ultrahigh vacuum apparatus (Fig. 1) below a steel chisel which could be raised magnetically and dropped onto the specimen to break into the oxide. Any gas liberated was monitored by an A.E.I. Minimass spectrometer. Before a breaking experiment, weakly held gases were desorbed from the chisel, specimen, and apparatus walls by baking at 180°C. Metallographic cross sections were prepared from separate pieces of specimen. Figure 2 shows that many voids formed throughout the oxide on the Ni with 100 ppm atomic carbon, and few on the low-carbon Ni except near the oxide-metal interface.

Each blow of the chisel evolved a strong pulse of CO_2 from the oxidized Ni that had contained 100 ppm atomic carbon,[1] occasional pulses from Ni with 9 ppm atomic carbon, and no CO_2 from Ni with the lowest carbon. The relative amounts of CO_2 evolved are

[1] From the quantity of CO_2 evolved per pulse (~10^{-9} Torr liters), the pressure within the cavities can be estimated to be between 50-5000 Torr.

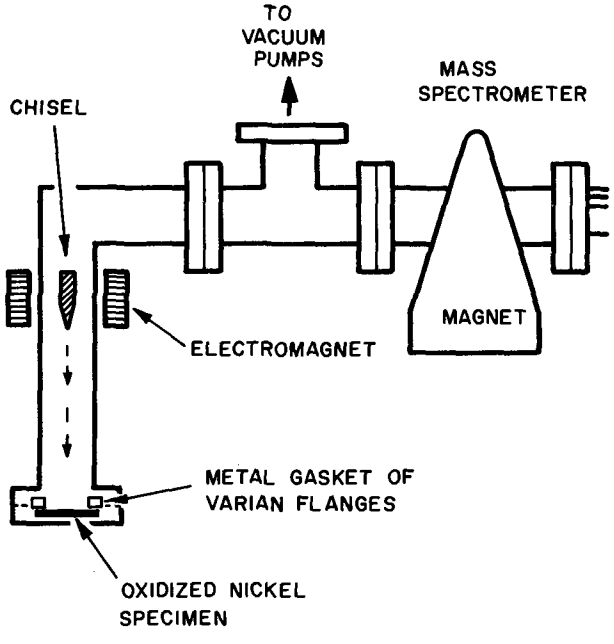

Fig. 1. Schematic diagram of oxide-cracking apparatus

Key words: nickel oxidation, cavities in oxide, CO_2 detection.

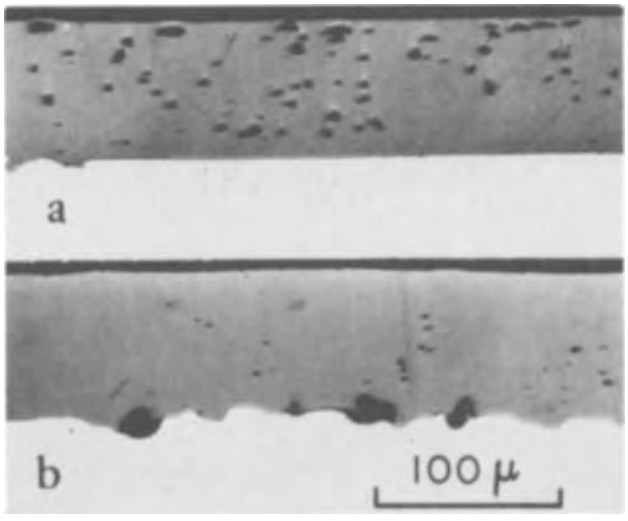

Fig. 2. Metallographic cross sections through oxide formed on Ni in 20 hr at 1270°C in 760 Torr O_2. (a), initial carbon 100 ppm atomic, cavities scattered through oxide; (b) initial carbon 2 ppm atomic, cavities near Ni-NiO interface, but few within the oxide. (×250)

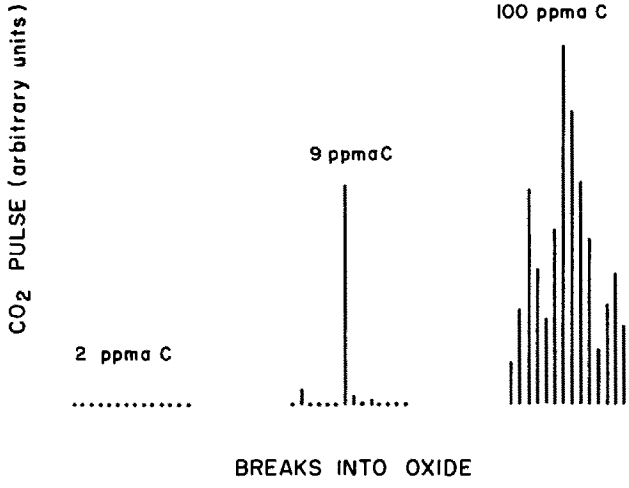

Fig. 3. CO_2 pressure pulses released by cracking of oxide. Bars represent 14 consecutive blows on nickel of 3 different initial carbon contents.

illustrated in Fig. 3, where the pulse height is recorded for an equal number of blows of the chisel into the oxide. The average CO_2 peak heights for the three grades of oxidized Ni are in the ratio 100:8:0. Analysis by spark-source mass spectrometry showed that oxidation reduced the carbon levels from 100:9:2 to 17:2:2, indicating that during oxidation the maximum possible CO_2 production would be in the ratio 83:7:0 (normalized to 100:8:0), which is in agreement with the observed CO_2 peak heights. (The close correspondence is fortuitous since the carbon analysis is uncertain by a factor of two.) Pulse heights of CO were monitored also but no similar correlation was observed; none was expected since the thermodynamics predict a high ratio of CO_2 to CO (2).

These experiments demonstrate that cavities in the NiO scales contain CO_2 at appreciable pressures and that the amount of cavity is related to the carbon content of the nickel. Carbon impurities apparently can have a significant effect on the formation of cavities in oxide layers. The general subject of cavities in Ni oxidation will be reported in a subsequent paper.

The Activity of In in Liquid In-Sb Alloys

D. Chatterji* and J. V. Smith

Aerospace Research Laboratories, Metallurgy and Ceramics Research Laboratory, Wright-Patterson Air Force Base, Ohio 45433

The physical and electrical properties of In-Sb alloys, especially the intermetallic compound InSb, have been studied in considerable detail (1). The thermodynamic properties of this alloy system have received only limited attention.

Schottky and Bever (2) measured the heat of formation of the compound InSb at 273°K by solution calorimetry and the heat of fusion by quantitative thermal analysis. From their measurements and the published In-Sb phase diagram (3), they calculated the free energy of the liquid phase, and concluded that the In-Sb melts showed negative deviations from ideality. Unfortunately, Schottky and Bever did not extend their experimental work to the entire In-Sb system.

Terpilowski (4) conducted a systematic study of the thermodynamic properties of liquid In-Sb alloys using galvanic cells based on fused-salt electrolytes. From open-circuit emf measurements on cells of the type

$$\text{In(l)}\,|\,\text{In Br in NaBr-KBr}\,|\,\text{In-Sb(l)} \qquad \text{[I]}$$

he determined the activity of In in a series of liquid In-Sb melts. He observed a negative deviation from ideality in the liquid phase in agreement with the conclusion reached by Schottky and Bever (2). However, free-energy calculations (5) based on Terpilowski's data for the alloy of equimolar composition did not agree with the values reported by Schottky and Bever for InSb.

Recently, Hoshino *et al.* (5) conducted a thorough investigation of the thermodynamic properties of liquid-In-Sb alloys using cells of the type

$$\text{In(l)}\,|\,\text{InI in NaI-KI}\,|\,\text{In-Sb(l)} \qquad \text{[II]}$$

The activity and free energy data obtained by Hoshino *et al.* at 900°K are in fair agreement with those determined by Terpilowski (4) at the same temperature.

* Electrochemical Society Active Member.

Key words: emf measurements, electrochemical cells, solid electrolytes, thermodynamic properties.

However, the excess enthalpies and entropies reported in the two investigations are quite different.

Terpilowski (4) as well as Hoshino and co-workers (5) assumed that the In ions in their electrolytes were monovalent, and used the relationship

$$\ln a_{In} = -FE/RT \quad [1]$$

to obtain the In-activity (with pure liquid In as the reference state) from the measured-cell emf. There is, however, no direct evidence to support the above-mentioned assumption. We therefore decided to reinvestigate the In-Sb system using cells where the In ions would exhibit an unambiguous oxidation state. With this objective in mind, the following types of cells were constructed

$$W, In\text{-}Sb(l), In_2O_3(s)|Zr_{0.85}Ca_{0.15}O_{1.85}|Air, Pt \quad [III]$$

$$W, In(l), In_2O_3(s)|Zr_{0.85}Ca_{0.15}O_{1.85}|Air, Pt. \quad [IV]$$

The electrolyte in these cells, $Zr_{0.85}Ca_{0.15}O_{1.85}$, is a well-known oxygen ion-conducting solid. In such oxygen-concentration cells, the In ions are clearly trivalent and the O ions divalent, and the over-all cell reaction involves the transfer of 3g equivalents of O ions. The In activity in the In-Sb alloy is then given by

$$\ln a_{In} = -3F(E_{IV} - E_{III})/RT \quad [2]$$

This procedure of taking the difference of the emf outputs of cells IV and III to calculate the In activity is obviously equivalent to, but less accurate than, direct emf measurement on the cell

$$W, In(l), In_2O_3(s)|Zr_{0.85}Ca_{0.15}O_{1.85}|In\text{-}Sb(l), In_2O_3(s), W \quad [V]$$

Nevertheless, cells [III] and [IV] were used instead of cell [V] for the following reason. Preliminary experiments indicated that W could be used as the lead material only if it contacted the liquid electrodes for a short time; long-time contact resulted in W dissolution. Consequently, arrangements had to be made in the cell assembly to lower and raise the W lead wires into and out of the molten electrodes. Such arrangements were easy to install (6) in cells [III] and [IV], but relatively difficult in cell [V].

Experimental

The cell assemblies used in the present work were similar to the ones described in an earlier paper (6). The details of the experimental procedure are also outlined in that publication.

Cell IV.—In a typical experiment, weighed amounts of In shot (99.99% pure) and In_2O_3 powder (99.99% pure) were placed in the electrolyte tube, and melted under a He atmosphere. The emf measurements were started when the cell temperature reached about 550°C. The equilibrium emf data obtained at different temperatures during repeated heating and cooling are presented in Fig. 1 (line 1). These emf values were found to remain constant to within ±0.5 mV for hours and were reproducible to within ±0.5 mV.

Cell III.—At the end of emf measurements on cell [IV], the cell was cooled down to room temperature, and a weighed amount of Sb metal (99.9% pure) was added to the In-In_2O_3 mixture. The system was evacuated and backfilled with He and heated to above 800°C to insure homogeneity in the molten alloy. Equilibrium emf measurements were then carried out at selected temperatures. Additional amounts of Sb were added at the end of successive runs and the procedure repeated. The upper limit of Sb concentration allowable in our cells was found to be only 50 atomic per cent (a/o) because small amounts of Sb_2O_3 formed over alloys containing more than 50% Sb. Although such a situation is thermodynamically unfavorable, it frequently occurs for kinetic reasons. Presence of Sb_2O_3 in addition to In_2O_3 caused undefined oxygen potentials to develop in the alloys, and resulted in erroneous emf readings. The present study was thus confined to four alloys: In-16.0 a/o Sb; In-27.5 a/o Sb; In-43.1 a/o Sb; and In-50.0 a/o Sb. Emf data from the cells containing these alloys are presented in Fig. 1.

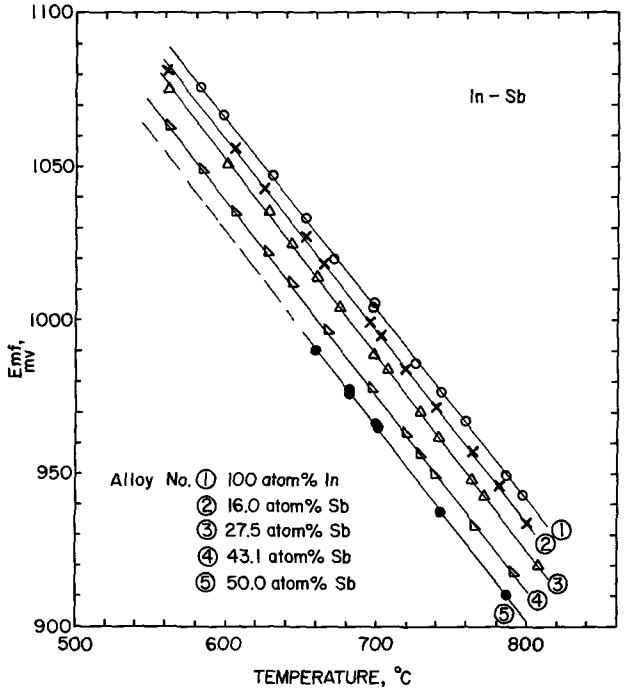

Fig. 1. Emf-temperature data from cell [IV] (alloy) and cell [III] (alloys 2-5) from 550° to 800°C.

Results and Discussion

Free energy of formation of In_2O_3.—As explained earlier, the emf data from cells [IV] and [III] were combined to calculate the In activities in the alloys through Eq. [II]. In addition, the standard molar free energy of formation of In_2O_3 could be directly calculated from the emf of cell [IV] after necessary thermal emf corrections (6) for the W-Pt couple

$$\begin{aligned} E_{IV}^{corr.} &= E_{IV}^{meas.} + E_{W\text{-}Pt}^{therm.} \\ &= (1606.9 - 0.620T) + (-21.4 + 0.037T) \\ &= 1585.5 - 0.583T \pm 0.5 \text{ mV} \\ \Delta G^\circ_{In_2O_3} &= -6FE_{IV}^{corr.} + 1.5\,RT \ln (0.21) \\ &= -219{,}400 + 76.03T \pm 200 \text{ cal/mole} \end{aligned}$$

The free-energy values calculated from this expression are in excellent agreement with the calculations based on similar expressions published in the literature (7, 8). This was considered to be convincing evidence of the correctness of our experimental techniques.

In activity in the alloys.—Table I presents the $(E_{IV} - E_{III})$ values for the four alloys at 900°, 973°, and 1073°K, and the corresponding In activities calculated from Eq. [3]. The activity values are plotted in Fig. 2 as a function of molar composition, and compared with the results obtained by Hoshino *et al.* (5). It is obvious that our results are in excellent agreement with the findings of Hoshino and co-workers for the same temperature (900°K). Our results also agree

Table I. Activity of In* in liquid In-Sb alloys at 900°, 973°, and 1073°K

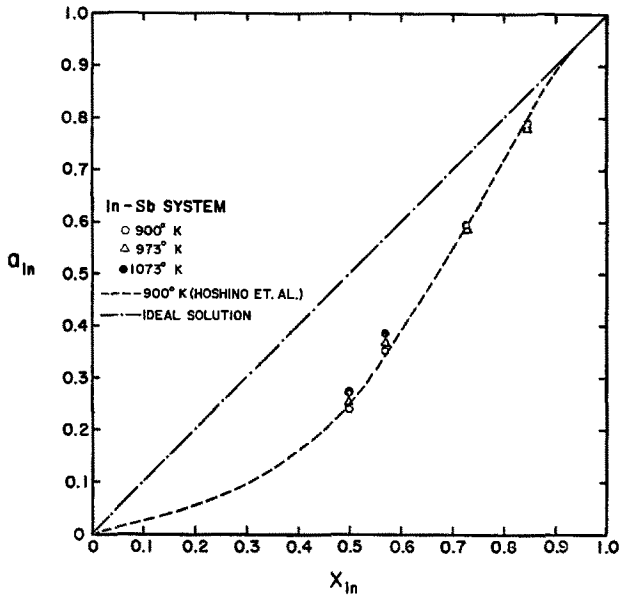

Fig. 2. Activity of In in liquid In-Sb alloys at 900°, 973°, and 1073°K.

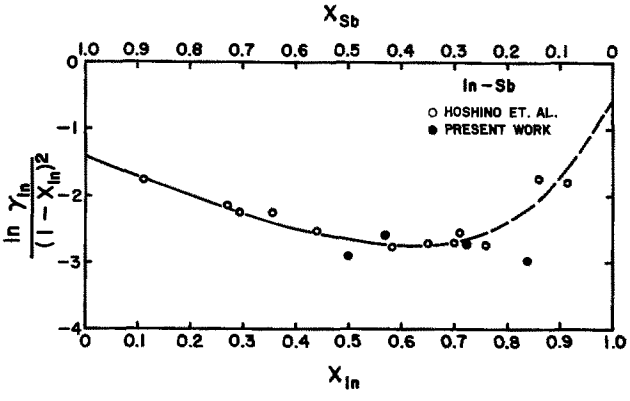

Fig. 3. α_{In} in liquid In-Sb alloys at 900°K

reasonably well with the activity values obtained by extrapolation of Terpilowski's data (4). These extrapolated activity values are not included in Fig. 2 for the sake of clarity; they are included in the paper by Hoshino *et al.*

As a further test of the agreement between our and Hoshino's work at 900°K, the two sets of activity data were converted to corresponding alpha functions (9)

$$\alpha_{In} = \ln \gamma_{In}/(1 - x_{In})^2$$

The calculated α_{In} values are shown in Fig. 3. The agreement is again satisfactory except for the In-16.0 a/o Sb alloy, where small errors in emf measurements may cause large errors in activity calculations.

The agreement between the results from our solid oxide-based investigation and the results from earlier studies involving In-halide based fused-salt electrolyte cells indicates that the assumption of monovalent In ions in halide melts is indeed valid. In light of this indication, it appears that the Sb activities (from In activities through Gibbs-Duhem integration using alpha functions) and excess thermodynamic properties calculated by Hoshino *et al.* (5) may be considered reliable. No such calculations were attempted in the present study because of the limited number of alloys investigated and the consequent uncertainties in Gibbs-Duhem integration.

Conclusions

Oxygen-concentration cells based on the electrolyte, $Zr_{0.85}Ca_{0.15}O_{1.85}$, have been successfully used to determine the In activity in liquid In-Sb alloys over 560°-800°C. Only In-rich alloys could be studied.

Our results are in agreement with the data obtained by earlier workers who used halide-based concentration cells, and assumed presence of monovalent In ions in their electrolytes. The present investigation therefore serves not only as an independent source of In-activity data but also as an indirect evidence of correctness of the assumption regarding the oxidation state of In ions in In-halide melts.

Brief Communication

A Preparative Graphite-Paste Electrode

J. M. Bobbitt,* J. F. Colaruotolo, and Samuel J. Huang

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

Pastes of graphite in various organic liquids have been developed and used extensively as analytical electrodes by Adams and his co-workers (1). Such electrodes have a good working range and are remarkably free of problems. We have been intrigued by the role that the liquid component of such a paste might play in determining the products of the reaction, and, to this end, have devised and tested a preparative form of the electrode.

Several possible configurations of such an electrode have been investigated including one in which the paste is pressed out of a tube into the cell rather like Adam's original idea (1). However, the best configuration is a simple one. The paste, prepared according to Adams (1), and about 5 mm thick, is packed into the bottom of a beaker against a platinum foil contact about the same size as the bottom of the beaker. Contact is made with the foil by an insulated Pt wire attached to the inside wall of the beaker. The reference electrode is placed just over the paste, and the electrolyte is layered over it. The auxiliary electrode (Pt foil) is placed over the center of the paste in a second compartment separated from the anode by a glass frit. Currents of 2-3 mA/cm^2 were obtained on a Nujol-graphite paste electrode, and the effective range is about the same as that of the analytical electrode (-0.9 to $+1.3$V *vs.* SCE in 0.1*M* $HClO_4$).

The cell was tested with two compounds, potassium hexacyanoferrate and the isoquinoline alkaloid corypalline (2-4). Aqueous solutions (200 ml) of 0.1*M* $HClO_4$ containing 0.6 mM of potassium hexacyanoferrate was oxidized at 0.6V (5) on a Nujol-graphite electrode about 35 cm^2 in area. The initial current was 30 mA which dropped off to the residual current of about 0 mA in about 10 hr. In one experiment, a coulometric measurement showed that 0.913 electrons per molecule were released. The oxidation of 1.0g of corypalline was carried out on the sodium salt in aqueous 0.1*M* KCl. The initial current at 0.35V was 85 mA which fell to 15 mA in 6 hr. The products were isolated as previously described (4) giving an over-all yield of dimeric products of 42% (38% carbon-carbon and 4% carbon-oxygen). In addition, 16% of a trimer (6) was obtained. On graphite felt (4) in acetonitrile, the products obtained were about 90% dimers (86% carbon-carbon and about 4% carbon-oxygen) and no trimer. However, the graphite felt reactions were carried out at lower potentials (0.0V *vs.* SCE). When higher potentials were applied to the felt system, appreciable amounts of trimer were formed. On a platinum working electrode in aqueous $Na_2B_4O_7$, the yields of dimeric products ranged from 44-60% (2) at potentials of about 0.35V. Thus, it would appear, in agreement with Adams (7), that the paste electrode is comparable to platinum.

The nature of the charge-transfer reactions within and on the surface of graphite pastes appears to be largely unknown (7) although it has been ascertained that the graphite particles are covered with a liquid film. Thus far, we have explored pastes made with Nujol and bromoform (1), benzonitrile (inferior because of paste fragmentation), optically active liquids such as α (+)-pinene and (+)-2-octanol, and the quaternary liquid-anion exchanger Aliquat 336.[1] The ion exchanger has been used in its chloride form and its hydroxide form. Although all of the pastes gave results comparable with those described above for phenol coupling reactions, the liquid-ion exchangers offer the greatest potential. It is possible, using them as a matrix, to prepare electrodes which, in themselves, have any desired *p*H or contain a large variety of ions. We have initiated work to further explore these possibilities with both liquid-anion exchangers and liquid-cation exchangers.

Acknowledgments

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 119, No. 5, 8, and 10; May, August, and October, 1972.

Anodic Oxidation of Ethylenediaminetetraacetic Acid on Pt in Acid Sulfate Solutions

J. W. Johnson, H. W. Jiang, S. B. Hanna, and W. J. James

(pp. 574-580. Vol. 119, No. 5)

P. Sidheswaran, V. K. Venkatesan, and H. V. K. Udupa:[1] During the steady-state oxidation of EDTA at platinum electrodes in acid sulfate solutions, Johnson *et. al.*, in the paper under discussion, identified various reaction products. A definite clue to the presence of CH_2O was obtained from the melting point of the DNP derivative. However, it is very easy to establish the presence of CH_2O with chromotropic acid by the method described elsewhere.[2] After 3 hr of electrolysis, we also noticed[3] a concentration of $>10^{-2}$M CH_2O formed from 0.5M EDTA. Our evidence strongly supports their observation that CH_2O is thrown out into the solution.

The formation of CH_2O has been indicated to be due to a reverse Schiff-type reaction and the authors of the above-mentioned paper proposed the following two steps

$$R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}CH_2\cdot + H_2O \rightarrow R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}CH_2OH + H\cdot \qquad [19]$$

$$R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}CH_2OH \rightarrow R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}H + CH_2O \qquad [20]$$

However, the second step should be either less probable or a simultaneous reaction occurs on the platinum electrode. This opinion stems from the following evidence: Podlovchenko *et al.*[4] have demonstrated that the presence of a hydroxyl function weakens the C-C bond; it has also been noticed by us[3] that primary alcohols preferentially get disintegrated into two fragments of which CH_2OH is one. The mechanism of formation of CH_2O from CH_2OH has already been proposed.[2] Hence, the following mechanism appears to be operative

$$2Pt + R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}CH_2OH \rightarrow R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}\underset{\displaystyle Pt}{\overset{|}{Pt}} + CH_2OH \qquad [1]$$

$$H{-}\overset{\displaystyle H}{\overset{|}{C}}{-}O{-}H \rightarrow H{-}\overset{\displaystyle H}{\overset{|}{C}}{=}O + Pt + Pt \qquad [2]$$

The observed Tafel slope of ~120 mV is in sharp agreement with $\beta \approx 0.5$ and $\Delta Ea/\Delta\psi r \approx 14$ kcal/mole/V. However, it is very difficult to establish exactly which step decides the rate of the entire reaction in as much as so many reaction intermediates are getting formed and oxidized.

J. W. Johnson, H. W. Jiang, S. B. Hanna, and W. J. James: We were very interested to learn of the similar work with EDTA that has been done by Sidheswaran, Venkatesan, and Udupa, and of the close agreement of the experimental results of the two studies. Our difference in interpreting the results appears to center around the disposition of the species, $R{-}\overset{\displaystyle Ac}{\overset{|}{N}}{-}CH_2OH$, which was proposed as an intermediate. In particular we have proposed a homogeneous, nonelectrochemical step (reverse Schiff-type) by which formaldehyde is ejected from the intermediate. Venkatesan *et al.* propose a heterogeneous step that results in two adsorbed fragments, one of which (CH_2OH) is the precursor of formaldehyde.

A sequence such as proposed by Venkatesan *et al.* was among the many that we considered. The one presented in our paper was favored because of the following reasons.

If bonding should occur between Pt and the nitrogen atom as shown in Step I (SVU sequence), several desorption and readsorption steps would be necessary to account for all the observed reaction products, *e.g.*, ED3A, U-EDDA, S-EDDA, and EDMA. This does not seem likely. A further consideration is the geometrical crowding around the nitrogen atom by other attached groups that makes its accessibility unfavorable for bonding with the electrode. Finally, protonation of the unshared electron pair on the nitrogen atom is also quite likely which would further hinder its adsorption.

If formaldehyde were produced as shown in Step II of the SVU sequence, the further ionization of the adsorbed H would be almost certain, and be associated with a 1 CO_2/2F coulombic relationship. This relationship was not observed experimentally, though the observed value could be accounted for by a combination of the SVN and JJHJ sequences.

Our studies indicate that EDTA is oxidized on Pt at potentials up to *ca.* 1.6V. It is doubtful that oxide-free sites would be available for bonding at these potentials[5] as required by the SVN sequence. Since no change in the reaction sequence with potential is indicated by the experimental results, we feel that direct bonding (adsorption) between Pt atoms and the EDTA species or any fragments therefrom should be excluded.

In summary, the sequence proposed by Venkatesan *et al.* is a logical one and cannot be completely eliminated as a possibility. Indeed it may be that both sequences (or others) are occurring. However, the above mentioned items caused us to favor the sequence we proposed.

Kinetics of Iron Corrosion in Concentrated Acidic Chloride Solutions

E. McCafferty and Norman Hackerman (pp. 999-1009, Vol. 119, No. 8)

G. Bech-Nielsen:[6] This paper, and also a virtually simultaneous publication by Darwish, Hilbert, Lorenz, and Rosswag,[7] report some important and rather unusual kinetic data for iron electrodes in strongly acid, strongly concentrated, chloride solutions. In the two papers reaction schemes of a similar type are proposed for explaining the observed kinetic parameters.

We would like to point out that such unusual kinetic parameters have been reported previously, to-

gether with the more usual ones, for iron electrodes in a wide variety of solutions.[8-11] It may well be that all of the unusual parameters will be found simultaneously only when using extremely concentrated solutions, whereas it has been shown that dilute, less concentrated, solutions present conditions for observing first (at lower anodic potentials) the usual behavior called the I_1-reaction[8-11] and then, following a characteristic transition region, the less usual or less often examined behavior of the I_2-reaction.

The most constant feature of this latter reaction is the higher Tafel slope (from *ca.* 80 to more than 120 mV), while the reaction orders with respect to different anions may be negative[10] or positive,[9] and the reaction order with respect to *p*H has been reported to be positive[10] or zero.[11] (A further indication of transition from negative to positive values has been found, but not yet published, in data from the experiments with an NH_4ClO_4-$NaClO_4$ solution, *p*H 5.5-3.0 described elsewhere.[9])

It is not surprising that neither the discussed paper nor that of Darwish *et al.* include descriptions of simultaneous observation of the two distinct reactions, since it can be seen,[11] and may be shown by general considerations,[12] that the regions, where a distinct behavior in accord with either of the reactions will be found, are likely to be separated by some 1-3 decades of current density (C.D.). When the I_2-reaction is recorded in the range of moderate anodic C.D.'s, it may be inferred that the I_1-reaction is only found in the C.D. range below the corrosion C.D., which is in accord with the usual inhibitive influence on this reaction of low *p*H and high chloride concentration together with the promotion of the hydrogen evolution reaction caused by lower *p*H.

Since we have observed that the I_1 and the I_2 reaction usually occur together as coupled, parallel reactions, we have suggested an outline of a kinetic model, which accounts for the potential-dependent transition between the two processes.[9] An explanation of this feature is evidently of primary importance, and further examination of the influences of *p*H and anions in the individual steps of the two reactions are now in progress.

In the last part of this comment we should like to consider the so-called reaction orders with respect to *p*H ($-\partial \log i/\partial \log [H^+]$). The analysis of coupled, parallel reactions developed by us indicates that the I_2 reaction proceeds via an intermediate complex of the composition $Fe^{II}(OH^-)_3(X)$, where X is a ligand, usually an anion.[8,9] In most cases known to us (of which one has been reported),[10] the reaction order with respect to *p*H for the I_2 reaction is between 0.2 and 0.3, *i.e.*, much lower than the number of OH^- ions taken up during formation of the intermediate complex. We therefore suggest that the observation of a negative reaction order with respect to *p*H for the I_2 reaction does not necessarily require the assumption of uptake of H^+ ions (especially not when the observation is possible at intermediate *p*H values, as we have seen). The steps in the mechanism following the formation of the above-mentioned complex should merely involve removal of one or more of the OH^- ions (in exchange for halide ions, for example) by H^+ ions, in order to result in an over-all negative reaction order with respect to *p*H (and at the same time a positive one for the halide ion).

E. McCafferty and Norman Hackerman: We thank G. Bech-Nielsen for his interesting comments and for calling our attention to the work of Darwish, Hilbert, Lorenz, and Rosswag.[7] These workers have confirmed our observation that both H^+ and Cl^- ions promote iron corrosion in concentrated acidic chloride solutions (*i.e.*, the reaction orders z_{H+} and z_{Cl-} are positive), in contrast to the usual cases more frequently examined (more dilute solutions) for which both z_{H+} and z_{Cl-} are negative.

Table I. Polarization resistance for iron in 6*N* chloride solutions.

N [H+]	Polarization resistance (ohm-cm²) Polarization curve	Calc'd from Stern-Geary Eq.
1.2	38.6	40.1
2.4	20.4	24.1
3.6	21.4	18.8
4.8	10.3	15.7
6.0	6.3	9.5

Both our results in the paper under discussion and the Darwish data[7] have shown that a high concentration of hydrogen ions in combination with a high concentration of chloride ions is necessary to give the new set of parameters $z_{H+} = +1$[7] as compared to $+1.8$ in our paper; $z_{Cl-} = +0.5$ in both our results; and $b_a = 60$-80 mV in our paper as compared to 120 mV in the work of Darwish *et al.*

These parameters are unusual in the sense that the signs of z_{H+} and z_{Cl-} in certain concentrated solutions are opposite to those in differing, dilute solutions. In contrast, in the work of Bech-Nielsen, the unusual parameters emerged only after considerable anodic polarization (usually about 200 mV) in the same solution. The possibility that the original surface could have been modified seems to have been recognized by the authors, who usually attributed the second Tafel region to the appearance of passivation precursors.

Whether or not the two sets of observations are linked through a general scheme of coupled, parallel, reactions having widespread validity remains to be seen. We did not examine the region below the corrosion current density in any great detail, but our own data do tend to show simple pre-Tafel behavior rather than the existence of a different, *i.e.*, I_1, reaction. Table I compares polarization resistances obtained from the linear polarization curve near the corrosion potential (Fig. 1) with those calculated from the Stern-Geary equation.[13] Agreement between the two sets of values is generally good, although a more thorough examination of the region close to the corrosion potential should be made, as suggested by Bech-Nielsen.

We next consider the suggestion that replacement of adsorbed OH^- ions by Cl^- (to give positive z_{H+} and z_{Cl-}) is equivalent to uptake of H^+ ions by adsorbed Cl^-. Consider the two reaction mechanisms in Table II. Mechanism I involves adsorption of Cl^- ions by replacement of chemisorbed water molecules,[14] followed by attraction of H^+ ions onto chemisorbed $FeCl^-_{ads}$, as

$Fe \cdot H_2O_{ads} + Cl^- \underset{-2}{\overset{2}{\rightleftharpoons}} FeCl^-_{ads} + H_2O$	$Fe \cdot H_2O_{ads} \underset{-2}{\overset{2}{\rightleftharpoons}} FeOH^-_{ads} + H^+$
$FeCl^-_{ads} + H^+ \underset{-3}{\overset{3}{\rightleftharpoons}} FeCl^- \cdot H^+$	$FeOH^- + Cl^- \underset{-3}{\overset{3}{\rightleftharpoons}} FeCl^-_{ads} + OH^-$
$FeCl^- \cdot H^+ \xrightarrow{4} FeCl^+ + H^+ + 2e^-$	$FeCl^-_{ads} \xrightarrow{4} FeCl^+ + 2e^-$
$FeCl^+ \underset{-5}{\overset{5}{\rightleftharpoons}} Fe^{++}(aq) + Cl^-$	

Table III. Results for Mechanism II

Case	Assumption	z_{H^+}	z_{Cl^-}
A	$\theta_{Cl^-} >> \theta_{OH^-}$	0	$(1-\theta_{Cl^-})$; $1 \rightarrow 0$ as θ_{Cl^-} goes from $0 \rightarrow 1$
B	$\theta_{OH^-} >> \theta_{Cl^-}$	θ_{OH^-}; $0 \rightarrow 1$	$+1$
C	$\theta_{OH^-} \approx \theta_{Cl^-}$	$(1-2\theta_{OH^-})$; $1 \rightarrow 0$ as θ_{OH^-} goes from $0 \rightarrow 0.5$	0
D	$\theta_w >> \theta_{OH^-} + \theta_{Cl^-}$	0	$+1$
E	$\theta_{OH^-} >> \theta_w + \theta_{Cl^-}$	θ_{OH^-}; $0 \rightarrow 1$	$+1$
F	$\theta_{Cl^-} >> \theta_w + \theta_{OH^-}$	0	$(1-\theta_{Cl^-})$; $1 \rightarrow 0$ as θ_{Cl^-} goes from $0 \rightarrow 1$
G	$\theta_w + \theta_{Cl^-} >> \theta_{OH^-}$	Same as case A	Same as case A
H	$\theta_w + \theta_{OH^-} >> \theta_{Cl^-}$	Same as case B	Same as case B
J	$\theta_{Cl^-} + \theta_{OH^-} >> \theta_w$	θ_{OH^-}; $0 \rightarrow 1$	$(1-\theta_{Cl^-})$; $1 \rightarrow 0$ as θ_{Cl^-} goes from $0 \rightarrow 1$

proposed earlier in the paper under discussion. In mechanism II, the chloride ion adsorbs by replacing chemisorbed hydroxyl ions rather than water molecules. In the steady state, mechanism I gives $b_a = 60$ mV, $z_{H+} = +1$, and $z_{Cl-} = 1 - \theta_{Cl-}$, so that z_{Cl-} is always positive and goes from 1 to 0 as θ_{Cl-} goes from 0 to 1. Necessary assumptions are $v_{-3} >> v_4$ and $\theta_{Cl-} >> \theta_{complex}$, where complex refers to $FeCl^- \cdot H^+$. Note that mechanism I is not exactly the same as proposed in our original paper under discussion, but differs in that only one rather than two H^+ ions are involved (to make a clear distinction between the different roles of H^+ in mechanisms I and II).

Results for mechanism II are given in Table III for various cases which compare: (*i*) the coverage of $FeCl^-_{ads}$ to $FeOH^-_{ads}$ (cases A-C); (*ii*) the coverage of one of the adsorbed species to the other two (cases D-F, θ_w refers to $Fe \cdot H_2O_{ads}$); and finally, (*iii*) the coverages of two of the adsorbed species to the other one. None of the cases yield both z_{H+} to be exactly $+1$ and $z_{Cl-} = 1 - \theta_{Cl-}$, as in mechanism I, but cases B, E, and J do give both z_{H+} and z_{Cl-} to be positive. However, in each instance, in order that $z_{H+} \cong +1$, θ_{OH-} must be near full coverage. This, in turn, makes it more likely that the reaction would proceed through the species $FeOH^+$, as for systems lower in $[Cl^-]$ or $[H^+]$, instead of through $FeCl^+$. Thus, replacement of adsorbed hydroxyl ions by chloride is not kinetically equivalent to H^+ attraction onto adsorbed chloride.

Calculation of the adsorption energy for $FeCl^-_{ads}$ and $FeOH^-_{ads}$ also suggests that Cl^- will not displace OH^- from an iron surface. These calculations follow Andersen and Bockris.[14] The attractive contributions to the adsorption energy are due to image and dispersion forces

$$U_{image} = -\frac{e^2}{4r} + \frac{e^4}{64W_a \cdot r^2} \qquad [1]$$

where e is the ionic charge, r the distance from the center of the ion to the outer surface of the metal atoms, and W_a the sum of the electronic work function and Fermi energy of the metal (1.83×10^{-11} ergs for iron). Also,

$$U_{disp} = -\frac{\pi N m c^2 \alpha_{Fe} \alpha_{ion}}{r^3 \left(\frac{\alpha_{Fe}}{\chi_{Fe}} + \frac{\alpha_{ion}}{\chi_{ion}} \right)} \qquad [2]$$

where N is the number of iron atoms per unit volume (8.50×10^{22} cm^3), and α and χ are the polarizabilities and diamagnetic susceptibilities of the interacting species (2.42×10^{-24} cm^3/atom and 1.68×10^{-29} cm^3/atom, respectively, for iron).[15] The repulsion term is

$$U_{repul} = \frac{2\pi NA}{(n-3)(n-2)r^{(n-3)}} \qquad [3]$$

where A and n are repulsion parameters. The total energy of adsorption for the unsolvated anion is then

$$U_{ads} = U_{image} + U_{disp} + U_{repul} \qquad [4]$$

Values of various parameters used in calculating U_{ads} are listed in Table IV. Calculation of U_{repul} is the least certain because the parameters A and n are not known for the interaction between an iron atom and a chloride (or hydroxyl) ion. However, these parameters can be estimated by comparison with data for alkali halide crystals,[20] because A and n are determined by the sizes of the ionic cores. Andersen and Bockris[15] used values of A and n for RbCl to calculate the repulsion between Hg and Cl^- because the radii of Hg (1.51Å) and Rb^+ (1.48Å) are nearly the same. In the case of Fe (1.24Å), there is no alkali metal ion of similar radius. G. A. Wright, with whom one of us has previously corresponded[21] on the problem of calculating adsorption energies for the series FeX^-_{ads} (X = Cl, Br, I) has suggested that n for Fe^0Cl^- be obtained from inter-

U_{ads} (kcal/mole)	−45.4	−58.1	Eq. [4]

polation of graphs of n *vs.* cation radius for LiCl, NaCl, KCl, and RbCl. The radius of the OH^- anion (1.33Å) is nearly the same as for F^- (1.34Å),[16] so n for Fe^0OH^- was interpolated by drawing a smooth plot through values for LiF, NaF, KF, and RbF. Values of n used in calculation of U_{ads} are given in Table IV.

The values of A corresponding to n can be obtained from solving the equation which results from the requirement that

$$\frac{\partial U_{ads}}{\partial r} = 0, \text{ when } r = r_{equil} \qquad [5]$$

with the equilibrium distance taken to be the ionic radius listed in Table IV. Results of the calculations are given in Table IV.[22] It is seen that the adsorption energy for $FeOH^-_{ads}$ is significantly higher than for $FeCl^-_{ads}$, so that replacement of adsorbed hydroxyls by chloride ions is not favored on an enthalpy basis. These calculated adsorption energies are for small initial coverages, but both values are expected to fall off in some complicated manner with increasing coverages.

Thus adsorption of Cl^- by competition with OH^- seems more likely than replacement of the latter by the former. For high bulk concentrations of Cl^- and H^+, adsorption of OH^- will not be favored, as shown in Eq. [44] of our paper under discussion, so that dissolution does not proceed through $FeOH^+$ but via the species $FeCl^+$.

Finally, evidence has been accumulating to indicate that there is attraction of H^+ ions in solution to the adsorbed chloride ions $FeCl^-_{ads}$. For example, various organic amines were more effective in inhibiting the corrosion of iron in HCl than in $HClO_4$.[23] This observation suggests that the inhibitor adsorbs not only at the metal surface, but also attaches via electrostatic attraction of the protonated amine to the adsorbed chloride ion. Similarly, additions of quinoline or dimethyl aniline reduced the double layer capacitance of iron more in HCl than in $HClO_4$,[24] again suggesting cooperative adsorption between the protonated inhibitor and the adsorbed anion. The kinetic data, of Darwish *et al.*[7] and in our paper under discussion, which show that a high Cl^- concentration alone will not give the unusual kinetic parameters but that a concomitant high concentration of H^+ ions is necessary also, point to cooperative adsorption between the two species. The positive value of z_{H^+} also persists if organic inhibitors are present in the concentrated acidic chloride solutions.[25]

Corrosion Fatigue of Copper and Alpha-Brass

Stuart S. Birley and Desmond Tromans

(pp. 1278-1285, Vol. 119, No. 10)

Ugo Bertocci:[26] In the paper under discussion the authors refer to a paper of mine[27] and describe the model in it as an electrochemical reaction under cathodic control. I would like to point out that this is incorrect. My model consists of a system in which anodic and cathodic electrode reactions occur without hindrance, so that both processes are diffusion controlled. Specifically, I commented that stirring would increase the corrosion rate but would not change the concentrations of the reactants at the metal surface. This, of course, is equivalent to predicting no change in electrode potential, which, in the absence of charge-transfer overvoltage, is the equilibrium potential for both reactions (not indicating ammonia ligands)[28]

$$Cu \rightarrow Cu^+ + e^- \qquad [1]$$

$$Cu^+ \rightarrow Cu^{++} + e^- \qquad [2]$$

Such a behavior with stirring can hardly be ascribed to a system under cathodic control.

It is not difficult to extend the consequences of my model to conditions under which the solubility product for Cu_2O is reached and a film is formed. Then the Cu^+ concentration at the metal surface is kept constant, and therefore for a given thickness of the diffusion layer, the amount of Cu^+ diffusing away depends only on the oxygen concentration in solution, but no longer on Cu^{++}. If equilibrium at the surface is maintained (that is, Cu^{++} at the metal surface is constant) more Cu^{++} will diffuse in and be reduced than Cu^+ will diffuse out. The material balance (as well as the electroneutrality of the corroding metal) is achieved by a continuous Cu_2O film growth. Stirring would only affect the rate of film formation, but no shift from the equilibrium value of the potential would be observed, contrary to the experimental results, but also inconsistent with a system under cathodic control.

In order to explain the results, a larger degree of irreversibility for the anodic reaction than for the cathodic one has to be postulated. After all, the assumption of complete reversibility for the electrode reaction made in my paper, although perhaps adequate for the purpose of estimating corrosion rates, cannot be taken literally, so as to exclude potential shifts of 10 to 20 mV when corrosion rates are fairly high. The authors of the paper under discussion favor a mechanism related to the protective properties of the Cu_2O film. This might be right, although the fact that the film is formed by precipitation does not seem to suggest a large degree of protection. I would like to propose that the charge-transfer overvoltage for reaction [1] could be larger than that for reaction [2], an explanation which is in qualitative agreement with recent faradaic impedance measurements.[29] If this explanation were correct, stirring should affect the potential in the same direction whether a film is present or not. I wonder if the authors of the paper under discussion have experimental data bearing on this point.

Stuart S. Birley and Desmond Tromans: We wish to thank the author of the above discussion for correcting our description of his model. In retrospect, we should have stated more explicitly that Bertocci's model was based upon diffusion control and that experimental testing of the model by Pugh and Green [30] (Ref. (36) in our paper which is being discussed) indicated that dissolution was cathodically controlled by the transport of cupric complex ions to the metal surface.

Bertocci's proposal regarding the effect of charge-transfer overvoltage is interesting. Unfortunately, all our studies concerning stirring effects were conducted in environments which produced corrosion films.

[22] G. A. Wright assessed A in a different manner (by graphical interpolation from values for the alkali chlorides), and calculated U_{ads} of $FeCl^-_{ads}$ to be −43.2 kcal/mole.

[28] A formal contradiction arises here with the statement in my paper[27] that the Cu^{++} activity at the metal solution interface is zero, a value inconsistent with the equilibrium of reaction [2]; the contradiction is solved if one observes that the equilibrium concentration of Cu^{++} is very small (probably less than 10^{-5}M) and although significant for defining the potential, is negligible for the evaluation of the concentration gradient.

The Kinetics of Thin Oxide Film Formation on Iron Using Proton-Impact-Excited X-Ray Analysis

P. B. Needham, Jr., H. W. Leavenworth, Jr., and T. J. Driscoll

College Park Metallurgy Research Center, Bureau of Mines, United States Department of the Interior, College Park, Maryland 20740

ABSTRACT

Studies of the oxidation of high-purity iron samples at 224°, 285°, and 350°C have been conducted in an oxygen partial pressure of 4×10^{-6} Torr for exposure times ranging from 25 to 2000 sec. The oxide films were measured and quantitatively analyzed for trace carbon impurities using proton-impact-excited characteristic x-rays. Analytical surface sensitivities to the equivalent of 10^{-3} monatomic layers have allowed direct studies of ultrathin (<50Å) oxide film kinetics. A two-stage logarithmic oxidation rate law was observed at all temperatures with the transition from the first to second stage occurring at oxide thicknesses of 25, 36, and 52Å at 224°, 285°, and 350°C, respectively. This observation is discussed in terms of Uhlig's theory for logarithmic oxidation. Quantitative measurements of carbon impurities on the iron surfaces show that an increase in the preoxidation surface coverage from 0.1 to 1.0 monolayer results in a significant suppression of the oxidation process. Detailed studies were made of the removal of residual carbon and oxygen impurities and 12-14Å air-formed oxide films from the iron surface by vacuum annealing at 715°C. Without H_2 reduction techniques, preoxidation iron surface coverages of 0.4 monolayer oxygen and one monolayer carbon were routinely obtained. Also, the residual surface carbon, present prior to oxidation, does not oxidize off of the surface during the oxidation process at these temperatures.

Previous studies (1-3) on the ultrathin film oxidation kinetics of iron at temperatures ranging from 100° to 500°C have been limited by the sensitivity of the techniques utilized for film measurement, and the data are most reliable only for oxide films thicker than 100Å. There have been no techniques used in iron oxidation studies which could quantitatively characterize trace impurities on the iron surface before, during, and after the oxidation process. Oxidation studies have generally been initiated with samples for whose preoxidation surfaces the assumption of uniformity with respect to the initial surface impurity coverage (including the air-formed oxide film) is based on standardization of the preoxidation sample preparation techniques; *i.e.*, electropolishing, chemical etching, vacuum annealing, and reduction of the iron surface using H_2 partial pressures at elevated sample temperatures (2-6).

Uhlig (7, 8) has proposed an oxidation theory in which an electron transfer mechanism is rate controlling, resulting in logarithmic rate law kinetics. According to Uhlig's model, a two-stage logarithmic oxidation process could occur where the electron transfer process from metal to oxide is initially controlled by formation of a constant density space charge region and, at some critical film thickness, is subsequently controlled by the succeeding formation of a diffuse space charge region. A two-stage logarithmic oxidation process has been experimentally observed by several workers (9-13), including one reported observation by Lustman (13) for thick iron oxide films. However, no results have been reported for ultrathin iron oxide films in which this two-stage logarithmic mechanism has been observed. Logarithmic oxidation kinetics on polycrystalline Ferrovac E[1] samples have been reported by Graham *et al.* (4) for oxidation temperatures ranging from 25° to 200°C, with a parabolic rate law observed at 200°C for O_2 exposures longer than 1.56×10^3 Torr-sec, and by Yolken and Kruger (14) for oxidation at 24°C. For temperatures above 200°C, thicker oxide films, and higher ($>10^{-5}$ Torr) O_2 partial pressures, the oxidation kinetics of iron have usually been found to obey a parabolic rate law (1, 2, 4, 6). Graham and Cohen (2) have also reported the effect of oxidation partial pressures (10^{-6}-60 Torr O_2) on the limiting oxide thickness and morphology for iron oxidation at 350° and 400°C. An induction period at the lowest ($<10^{-5}$ Torr) oxygen partial pressures was observed and attributed to the possible removal of oxidizable impurities (carbon) or to slow nucleation. Ferrovac E iron was used as their principal sample material, but they also reported data at 350°C for high-purity, floating-zone refined Battelle iron on which they found a much thicker final oxide film than was obtained for Ferrovac E samples under the same experimental conditions. It was suggested that this was due to grain size and orientation differences, the Battelle iron samples having larger, more highly oriented grains exposed.

Key words: double-logarithmic oxidation, proton-impact-excited x-rays, iron, carbon surface impurities.

[1] Reference to specific equipment is made to facilitate understanding and does not imply endorsement by the Bureau of Mines.

In the present paper, we are reporting on the ultrathin film oxidation kinetics of polycrystalline iron at 224°, 285°, and 350°C in an oxygen partial pressure of 4×10^{-6} Torr for exposures ranging from 100 to 8000 Torr-sec. These exposures are of considerably shorter duration than those generally reported by other authors (1, 3-6). A new and extremely sensitive technique, proton excitation of characteristic x-rays, was used for *in situ* measurements of the oxide film thickness and quantitative measurements of the surface impurity carbon atom content at every stage of the oxidation process. Measurements were made of initial carbon and oxygen impurity concentrations on the iron surface as a result of preoxidation cleaning procedures. The effects of varying amounts of initial carbon surface impurities on the oxidation kinetics at 285°C were also studied.

Experimental

Film measurement technique.—Direct oxygen and carbon impurity measurements obtained by the use of proton-impact-excited characteristic x-rays have been reported elsewhere in detail (15-17), and only a brief review is given here. Except for the system used by Sewell *et al.* (18-20), the standard x-ray techniques do not offer either the required degree of sensitivity or the required degree of quantitativeness for the measurement or elemental analysis of thin (<100Å) oxide films. The use of proton-excited x-rays (PEX) has several distinct advantages: essentially only characteristic x-rays are excited by proton impact, eliminating the need to separate the x-ray signal from a large continuum x-ray background; very high x-ray yields for low Z elements are obtained; and x-ray production cross sections are available which allow direct quantitative analysis without reliance on data calibration based on the use of a standard sample.

In these experiments, a proton beam from an ion accelerator was directed onto the iron samples, which were mounted and oxidized in an ultrahigh-vacuum target chamber (Fig. 1). Protons with kinetic energies of 120 keV were used for the carbon, oxygen, and sulfur impurity determinations. Proton beam currents were in the 50-2000 nanoampere region, and we have found that sputtering effects during any of the measurements reported here were no more than the equivalent of 10^{-2} monatomic layer.

In order to discriminate between carbon or oxygen x-rays that originate from the iron sample bulk impurities and those that originate from surface impurities, the processes of exciting the bulk impurity x-rays and extracting them from the sample have been considered in detail elsewhere (21). The depth into the sample from which bulk impurity x-ray information is extracted is determined by both the rate of energy loss for the proton as it penetrates the sample (resulting in a reduction in the x-ray yield in x-rays/proton) and the absorption of the carbon K (44.5Å) or oxygen K (23.7Å) x-rays by the sample itself as they return to the surface. For these x-ray wavelengths the bulk impurity x-ray information depth is determined primarily by the target self-absorption of the x-rays. In an iron sample, less than $1/e$ of the oxygen K x-rays detected at the surface originate deeper than 1485Å into the sample, and, similarly, less than $1/e$ of the carbon impurity x-rays originate deeper than 390Å (21). This bulk oxygen and carbon impurity contribution was considered as the background x-ray field which established the theoretical limit of analytical sensitivity in terms of signal-to-noise ratio (a conservative signal-to-noise ratio equal to one was chosen to define the sensitivity limit), where the noise is defined as x-rays due to bulk impurities, and the signal is defined as the x-rays due to oxygen or carbon impurities on the iron surface. To avoid model problems in considering the distribution of the oxygen and carbon bulk impurities throughout their information depths (1485 and 390Å, respectively), the assumption was made that all the bulk impurities in these sample depths reside on the sample surface. This, from the technique's sensitivity standpoint, is a worst-case-assumption.

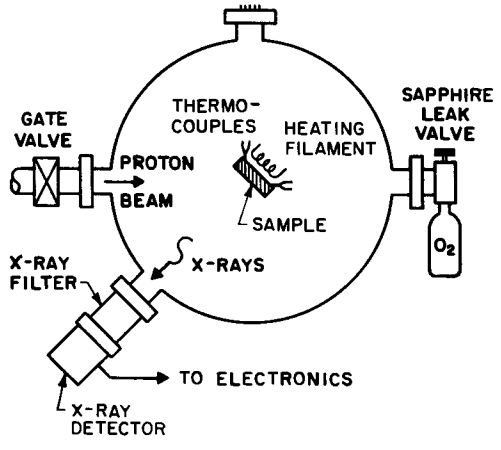

Fig. 1. Ultrahigh vacuum chamber in which the iron samples were mounted and vacuum annealed at 715°C, oxidized at 4×10^{-6} Torr O_2, and then analyzed by proton-impact-excited x-rays. Thermocouples were welded to the top and bottom edges of the samples, and the distance from the back of the sample to the tungsten heating filament was approximately ¼ in.

For the Battelle iron samples used in these experiments, the bulk impurity concentration of oxygen was 2.3 ppm and of carbon was 0.9-5 ppm,[2] contributing a background x-ray field equivalent to 10^{12} atoms of surface carbon per square centimeter and to 3×10^{12} atoms of surface oxygen per square centimeter. For an iron surface, this is equivalent to approximately 6×10^{-4} monatomic layer of carbon and 1.9×10^{-3} monatomic layer of oxygen, where a monolayer of impurity is defined as a one-to-one correspondence with 1.6×10^{15} iron surface atoms/cm² (22). In the studies reported here, therefore, the bulk impurity x-ray contribution to the measurement of one atomic layer of a surface impurity was six parts per ten thousand for carbon and two parts per thousand for oxygen.

The experimentally obtained x-ray yield, I_μ, is used to obtain oxide thickness or impurity coverage in micrograms/square centimeter from the equation $I_\mu = N\Delta r\sigma_x$ where N is the number of atoms/gram, Δr is surface coverage in grams/square centimeter, and σ_x is thick target x-ray production cross section in square centimeters/atom. This linear relationship between x-ray yield and coverage is valid for use where the x-ray yield is obtained from a thin layer in which the incident proton has lost less than 10% of its initial energy, and the accuracy has been shown to decrease with increasing film thickness from 0.01% at monolayer coverages to 15% at 10^3Å of Al_2O_3 (15). The calculation of Δr results in an uncertainty due principally to the uncertainty in σ_x; approximately ±5% for CK_α and ±12% for OK_α. For the case where I_μ represents the oxygen K_α x-ray yield, N is the number of oxygen atoms/gram in the oxide formed and Δr is the oxide thickness in grams/square centimeter. For these experiments, the oxide films were assumed to be magnetite, based on recent work (2,

[2] The analysis of the Battelle iron was kindly supplied to us with the iron ingot by Battelle Memorial Institute. All concentrations are in ppm. *Nonmetallics* [4]: oxygen (2.3), nitrogen (<0.1), hydrogen (<0.1), carbon (5 by combustion-conductometric, 0.9 by internal friction), sulfur (1.0). *Metallics* [19]: arsenic (0.2), boron (0.002), calcium (0.07), chromium (1.0), cobalt (3.0), copper (7.0), magnesium (0.2), manganese (4.0), molybdenum (0.2), nickel (0.1), phosphorus (0.1), potassium (0.2), sodium (0.3), tantalum (0.6), tin (0.3), titanium (0.6), vanadium (0.03), zinc (<0.6), zirconium (0.1). Although the bulk sulfur concentration was reported to be 1 ppm, during vacuum annealing processes we consistently observed the segregation of approximately ½-¾ monolayer of the bulk impurity sulfur onto the iron surface. Although the iron samples were repeatedly re-electropolished and vacuum annealed at 715°C, no reduction in the amount of sulfur segregating onto the surface from the bulk was observed, indicating that the bulk sulfur impurity concentration was at least 10-15 ppm rather than 1 ppm.

4, 23) in which Fe_3O_4 was the only oxide phase found to grow at oxygen partial pressures $<10^{-5}$ Torr.

Specimen preparation.—All oxidation measurements were made on square tabs, 25 × 25 × 1 mm, cut from electron beam-zone refined polycrystalline iron obtained from Battelle Memorial Institute. Preparation of the samples consisted of fine grinding with 180-600 grit paper, electropolishing in a 20/1 solution of acetic acid/perchloric acid, rinsing in distilled water, drying in a dry nitrogen blast, and vacuum annealing at a temperature of 715°C. The samples were mounted in the vacuum chamber (Fig. 1) within 1 min after the last of the external cleaning steps above. The chamber was pumped using a 450-liter/sec Orb-Ion pump and a 2000-liter/sec titanium sublimation pump. Prior to the chamber bakeout, a preliminary oxygen and carbon analysis of the sample surface was performed at 2×10^{-8} Torr. In this manner, a rigid control was maintained of the initial sample surface condition as a result of the external cleaning procedures. By establishing upper limits to the oxygen and carbon contamination at this stage, it was easier to attain specific ranges of impurity coverage during subsequent vacuum annealing procedures. After the preliminary surface analysis, the vacuum chamber was baked out and the operating pressure of 6×10^{-10} Torr was attained. The sample was then subjected to various cycles of heating by electron beam heating and, in some cases, an additional surface cleaning by argon ion bombardment. We have found that, by proper selection of the sample heating temperatures and heating times, a particular surface impurity coverage can be reproduced within 15% from one sample to another. In this present work, each iron sample was vacuum annealed at 715°C for two 300-sec cycles with a carbon and oxygen impurity determination performed after each cycle. The analysis time was approximately 30 sec for the carbon impurities and 120 sec for the oxygen. When a surface impurity level of 0.4 monolayer for oxygen and 1 monolayer for carbon (assuming carbon is present in the form of graphite on the surface) was attained, the oxidation cycles were begun. Argon ion bombardment was used to obtain further reductions in the surface impurity coverages in only one series of experiments which was performed to study the effect of carbon impurities on the oxidation process.

Oxidation technique.—For the oxidation cycles, the samples were heated radiatively by the thoriated tungsten filament used for the electron beam heating-annealing processes. The sample was heated to temperature (±2°C) within 180 sec and stabilized for an additional 120 sec. The temperature was measured by thermocouples welded to the top and bottom edges of the iron sample. The sample was at ground potential during oxidation runs with the heating filament at a temperature of approximately 1410°C. With the residual vacuum chamber background pressure at 1×10^{-9} Torr, oxygen was then leaked into the vacuum chamber through a sapphire seal leak-valve. The oxygen was an analyzed research grade obtained from Mathieson Company and contained 10 ppm total impurities. The oxygen pressure was raised in <2 sec to 4×10^{-6} Torr for oxidation times ranging from 25 to 2000 sec. At the end of the oxidation run, the oxygen was shut off and the chamber pumped to 2×10^{-8} Torr within 3 sec, reaching 5×10^{-9} Torr within 240 sec, at which time the gate valve to the accelerator beam line was opened, the proton beam directed onto the sample, and the oxygen and carbon measurements made. The beam-line gate valve was closed after completion of the analyses (180 sec), and the O_2 was reintroduced for another oxidation exposure. For a given total exposure of oxygen, it was found that the same oxide thickness was obtained at a given sample temperature no matter how many exposure increments were used to obtain that total exposure.

The same three tabs of Battelle iron were used for all oxidation runs and were mounted on the sample holder in such a manner that the proton beam analyzed the same 1/4-in.-diameter spot every time the sample was re-electropolished, rinsed, dried, and remounted in the vacuum chamber. Metallographic and scanning electron microscopic studies showed that the number and grain size distribution of each sample beam spot was reasonably equal. No attempt was made to determine the orientation of the major grains. The beam spot positions were chosen in order to minimize orientation and grain size effects so that the carbon impurity effects could be studied. Each sample was re-electropolished and reoxidized five to ten times.

Results and Discussion

Preoxidation cleaning.—The preliminary analyses of the Battelle iron samples performed at 5×10^{-8} Torr showed mean residual surface coverages of 12-14Å of oxide and 0.335 $\mu g/cm^2$ of carbon. After the two 300-sec, 715°C annealing cycles, the surface coverages were reduced to mean values of 0.125 ± 0.015 $\mu g/cm^2$ of carbon and 0.017 ± 0.003 $\mu g/cm^2$ of oxygen ($\simeq$0.4 monolayer). When utilized, an argon ion bombardment reduced the surface coverage of both oxygen and carbon another order of magnitude. Another result of the vacuum annealing process which we have observed was the diffusion of bulk impurity sulfur atoms to the iron surface, with the segregation of an equivalent of approximately 1/2-3/4 monolayer onto the surface. The accuracy for the sulfur impurity coverage determinations is less than those for the carbon and oxygen measurements since only a few sulfur measurements were performed.

For these present kinetic studies, no attempt was made to obtain a so-called "atomically clean" surface, and the preoxidation surface carbon and oxygen impurity levels (0.125 ± 0.015 $\mu g/cm^2$ and 0.017 ± 0.003 $\mu g/cm^2$, respectively) were obtained without the use of either argon ion bombardment or hydrogen reduction techniques.

Kinetics.—Figure 2 shows the results of oxidation at 224°, 285°, and 350°C in an oxygen pressure of 4×10^{-6} Torr. The curves are plotted directly as the measured oxide film thickness *vs.* the exposure time. Each point on a curve represents the mean value (listed in Table I) for three samples, each of which was re-electropolished and reoxidized three times. The total experimental uncertainty in the measurements was ±4%. The oxide thickness scale factor is uncertain to ±12% due to the uncertainty in the value of the

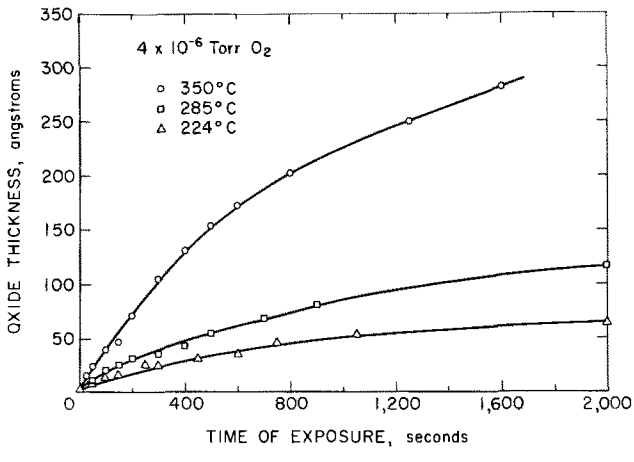

Fig. 2. Measured oxide film thickness *vs.* the exposure times in seconds are shown for Battelle iron samples at 224°, 285°, and 350°C. The oxygen partial pressure was 4×10^{-6} Torr O_2, and each point is the mean of nine oxidation runs. The estimated uncertainty is approximately twice the size of the data point symbols.

oxygen K_α x-ray production cross section. The maximum total durations of the oxygen exposures were 10^{-2} Torr-sec, or approximately 2.5×10^3 sec, except for the 285°C oxidation runs during which the effect of the initial carbon coverage was being studied. For the latter runs, the total exposure time was extended to 16×10^3 sec. In these experiments the oxygen exposures were not sufficient in length to allow the oxide films on the samples to reach their maximum thickness, since the initial stages of the oxidation process were of principal interest.

The kinetic data in Fig. 2 were plotted in Fig. 3 as two-stage logarithmic oxidation curves using a least squares fit. Logarithmic oxidation of the form $X = A \ln t + B$ (X = film thickness, t = exposure time) on iron at 24°, 100°, and 200°C has been reported by Graham, Ali, and Cohen (4), and both logarithmic and inverse logarithmic kinetics at 25°C were reported by Yolken and Kruger (14).

In most oxidation theories, logarithmic oxidation kinetics are associated with the transport of electrons from the metal to the oxide-oxygen interface being the rate-limiting (slowest) step. The electronic transport can occur either by thermionic emission of electrons

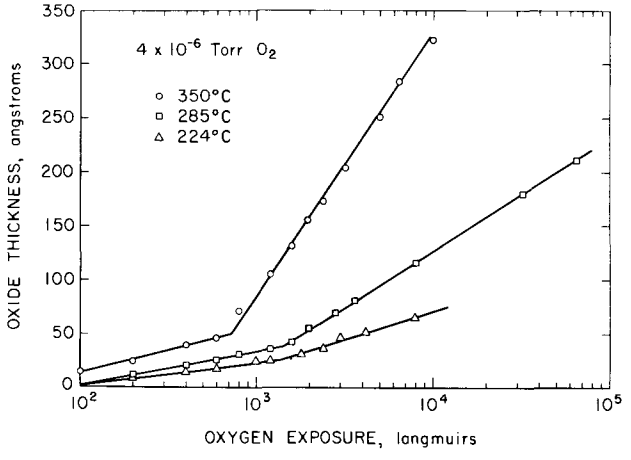

Fig. 3. Data from Fig. 2 are fitted to two-stage logarithmic oxidation kinetics by a least squares fit. The oxygen exposure is given in Langmuirs (≡ 10^{-6} Torr-sec). The transition points from 1st to 2nd stage are determined from the curves to occur at 25, 36, and 52Å for 224°, 285°, and 350°C, respectively.

from the metal or by quantum mechanical tunneling through the oxide layer. Several authors have suggested that for the early stages of oxidation (up to a few tens of angstroms) electrons can reach the oxide-oxygen interface very rapidly by quantum mechanical tunneling, in which case the rate-limiting step in the oxidation process would be ionic diffusion (iron or oxygen ions). Assuming substantial quantum mechanical tunneling, Mott (24) obtained a parabolic equation for the growth kinetics in low-temperature regions where there is no thermionic emission, and Cabrera and Mott (25) obtained inverse logarithmic kinetics for higher temperatures where thermionic emission also contributed to the electronic transport. For low-temperature oxidation, Fromhold and Cook (26) derived a kinetic rate law similar to that of Cabrera and Mott for oxide films up to 20-30Å, but beyond which electron tunneling became rate limiting and logarithmic kinetics would be obtained.

The logarithmic oxidation kinetics which we have observed for the studies reported here indicate that electronic rather than ionic transport was the rate-limiting step. However, the abrupt change in the rate constant of the logarithmic oxidation at each temperature is less easily explained. The separate oxidation stages may be associated with a change in the phase of the growing oxide film, or with a change in occupancy conditions associated with the trapping centers of the growing oxide as described by Uhlig (7) for thicker oxide films.

Uhlig (7) has proposed a theory of double logarithmic oxidation which assumes that thermionic emission of electrons through the oxide layer is the rate-limiting step. At some particular oxide thickness, where the energy difference between the Fermi level of the oxide film and the trapped charge in the oxide film approaches the thermal energy kT, all of the trapping levels will not be filled, and a diffuse space charge region can form in the oxide, overlaying the initially formed uniform oxide space charge region. An increase in the rate constant for logarithmic oxidation should occur at this transition thickness, L, where (27)

$$L = k_0 [\Delta E/kT - 1] \qquad [1]$$

and k_0 and ΔE are the rate constant and activation energy, respectively, for the first stage of oxidation. To test this theory with our data, we used for our first stage kinetics

$$X = k_0 \ln (t/\tau) \qquad [2]$$

where X is the oxide thickness, t is the exposure time, and τ is a constant. The values for k_0 and τ (Table II) were obtained from the curves in Fig. 3 and were used in the Arrhenius plot of Fig. 4 to obtain the apparent activation energy for the first stage, 3.58 kcal/mole. The values of k_0 and the activation energy were then used with Eq. [1] to calculate the transition point thicknesses, L (calc), and these were compared to our experimentally determined values, L (exp), in Table II. The ratio L (calc)/L (exp) ranges from 0.94 at 224°C to 0.67 at 350°C. The agreement between these experimentally measured and theoretically calculated values of L is reasonably good. However, we feel that this agreement may be fortuitous, since questions concerning the effects of the initial surface impurities (discussed below), of the precise stoichiometry of the oxide films, and of the crystallographic

orientation of the large substrate grains remain to be answered.

Effect of initial carbon and sulfur coverage.—Kinetic data are given in Fig. 5 for oxidation studies of iron samples having different preoxidation carbon impurity coverages. The samples were oxidized in 4×10^{-6} Torr O_2 at 285°C. The lower curve (Δ) is for the iron samples with the mean preoxidation surface impurity coverage of 0.125 ± 0.015 μg/cm² of carbon and 0.017 ± 0.003 μg/cm² of oxygen obtained by vacuum annealing at 715°C for 10 min. The data for the upper curve (0) are for the same samples, with the preoxidation carbon and oxygen coverages reduced an additional order of magnitude by using an argon ion bombardment as the final preoxidation surface cleaning step. For these data runs the mean initial coverages were 0.012 ± 0.005 μg/cm² for carbon and less than 0.002 ± 0.002 μg/cm² for oxygen. Again, each data point is the mean for the results of three different Battelle iron samples, each of which was oxidized three times.

The data for the samples with the cleaner preoxidation surface clearly indicate a much higher oxidation rate and resulting oxide thickness. At an exposure of 7×10^{-2} Torr O_2-sec, the data for surfaces with 0.125 μg/cm² of carbon (approximately one monolayer if we assume it is present in a graphite form) reaches

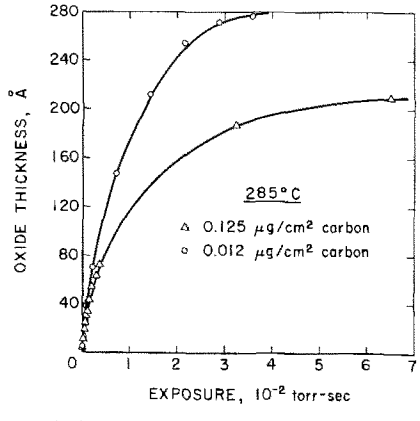

Fig. 5. Battelle iron samples with different initial carbon impurity coverages were oxidized at 285°C at 4×10^{-6} Torr O_2. Each iron sample was run at both initial carbon impurity levels in order to smooth out microstructure differences from sample to sample. The maximum oxide thickness in the upper (o) curve is estimated to be 300Å, whereas for the lower curve (representing the dirtier sample) the maximum oxide thickness is estimated to be 215Å.

an oxide thickness of approximately 215Å. The samples with the cleaner surfaces (0.012 μg/cm² carbon) reach an oxide film thickness estimated to be 300Å from extrapolation of the data curve. The creation of highly active oxidation sites by the argon ion bombardment as a possible explanation for thicker film on the cleaner surface was eliminated, we feel, by the use of a post-argon-ion-bombardment anneal at 550°C for 900 sec.

The role of the residual carbon impurities in slowing the oxidation process may be (*i*) through an oxidizing process whereby the oxygen gas phase molecules are utilized initially in the formation of CO, possibly resulting in the removal of carbon from the surface, or (*ii*) the utilization by the impurity carbon atoms of iron bonds which would otherwise be available for the iron oxidation process itself. The possibility of carbon oxidizing from the iron surface during the initial stages of oxidation was studied for all sample runs reported here. In the temperature range investigated here, the reduction in the initial carbon impurity level that could be attributed to removal of carbon from the surface during the oxidation process averaged less than 10%. The removal of carbon through oxidation would be expected to be very slight for lower oxidation temperatures. Evidence has been reported elsewhere (28) as indicating that these residual carbon impurities tend to continuously redistribute themselves throughout the growing iron oxide film, with a slight concentration at the iron oxide-gas phase interface.

Finally, a brief discussion should be made concerning the role of the other major surface impurity, sulfur, which was present during our oxidation experiments. The effect on the initial oxidation process of these sulfur surface impurities, which are a result of segregation onto the iron surfaces of the bulk sulfur impurities, has not been reported. During vacuum annealing at 600°-900°C, Harris (29) observed, using Auger electron spectroscopy, the segregation of sulfur onto the surfaces of nickel, iron, and other metals. He demonstrated, for nickel, that the source of the sulfur was bulk sulfur impurities in the metal. Sickafus (30) observed sulfur segregation on nickel (110) surfaces using low-energy electron diffraction and Auger electron spectroscopy, and concluded from his studies that sulfur is nonhomogeneously distributed over the surface in domains less than 40Å wide.

The iron samples of Fig. 5 with the 0.125 μg/cm² initial carbon coverage also had a 1/2-3/4 monolayer equivalent of sulfur on the surface. For the argon-ion bombarded samples, this initial sulfur coverage was reduced by about 80%, although the sulfur impurity measurements for the experiments reported here were not nearly as reproducible as the carbon impurity masurements. However, during the post-argon-ion-bombardment annealing cycle at 550°C for 900 sec, an equivalent of about 30% of the original (pre-ion-bombardment) coverage segregated back onto the iron surface, resulting in a net reduction of about 50% in the preoxidation surface coverage due to the ion bombardment process. From Fig. 5, the active impurity appears to have a large effect on the oxidation rate even at later (exposures longer than 1.2×10^{-3} Torr O_2 · sec) stages of the oxidation process. During iron oxidation at 200°C in 4×10^{-6} Torr O_2, preoxidation sulfur impurity coverages have been found (28) to remain at the metal-oxide interface during the growth of oxide films up to 20Å thick. We feel, therefore, that any direct, active role which the sulfur impurities play probably occurs only during the initial (chemisorption) stages of the oxidation process. Extensive work is continuing in this laboratory on the role of this sulfur or sulfur layer in the early stages of iron oxidation.

Graham and Cohen (2) have reported results comparing the oxidation of Ferrovac E iron and Battelle iron at 350°C in 10^{-3} Torr O_2. They detected little difference in the oxidation rates for both types of iron

during the first 600 sec of exposure. Subsequently, the Battelle iron oxidized at a higher rate with a larger final oxide film thickness. This was attributed to the difference in grain sizes of the two types of polycrystalline iron, the Battelle iron having larger and more highly oriented crystallites exposed than the Ferrovac E. They attributed the higher net oxidation rate of Battelle iron to its either having more exposed grains with higher oxidation rates or to its larger grain size preventing the spread of α-Fe_2O_3 from grains with high α-Fe_2O_3 formation rates onto grains less susceptible to α-Fe_2O_3 formation. Our results (Fig. 5) suggest that the variance in the final oxide film thickness may also be attributable to subtle variations in the surface carbon impurities at approximately monolayer equivalent levels.

A recent paper by Swanson and Uhlig (9) on thin film oxidation of copper concentrated on the effect on oxidation kinetics of the submicroscopic faceting of sample surfaces caused by pretreatment vacuum annealing in H_2 and N_2 atmospheres. They suggested that their results indicate that surface impurities are of no importance for the formation of thin oxide films on other metals as well as copper. While gaseous pretreatments of the iron surfaces were not used here, we suggest that for the initially formed thin film (0-200Å) on any metal surface, the role of the initial impurities cannot be dismissed.

Conclusions

The use of proton-excited characteristic x-rays has allowed us to quantitatively define iron surfaces with respect to impurities at every stage of cleaning, reduction, and oxidation at 224°, 285°, and 350°C in 4 $\times$ 10^{-6} Torr O_2. We have found that:

1. A two-stage logarithmic oxidation process occurs on Battelle iron at 224°, 285°, and 350°C for oxygen pressures of 4 $\times$ 10^{-6} Torr. The kinetics of this process were discussed in terms of Uhlig's oxidation theory, and good agreement at all temperatures was found between our experimentally measured oxide thicknesses at which the transition from the first stage to the second stage occurs, and empirical calculations suggested by Nwoko and Uhlig (27). It is felt that this agreement may be fortuitous in light of uncertainties relating to the roles played in the early stages of the oxidation process by initial carbon and sulfur surface impurities, stoichiometry of the growing oxide film, and orientation of the exposed grains on the iron substrate.

2. Vacuum annealing at 715°C resulted in removal of the natural air-formed oxide films and partial removal of the carbon impurities. All of the oxidation results reported here were initiated on preoxidation iron surfaces with oxygen impurity levels of about 0.4 monolayer equivalent and carbon impurity levels slightly greater than one monolayer equivalent.

3. Reduction of the preoxidation carbon impurity coverage on the iron surfaces from 0.125 to 0.012 $\mu g/cm^2$ resulted in a sharp increase in the oxidation rate and the oxide film thickness for extended oxidation times. This result is in the range of oxide film thicknesses where other authors (2, 9) have attributed similar effects entirely to submicroscopic structure of the metal surface.

Brief mention has also been made of the segregation of sulfur from the bulk onto the iron surface during preoxidation vacuum annealing. For Battelle iron the equivalent of 1/2-3/4 of a monolayer of sulfur diffused rapidly to the sample surface at an annealing temperature of 715°C.

Study by Nuclear Microanalysis and O^{18} Tracer Techniques of the Oxygen Transport Processes and the Growth Laws for Porous Anodic Oxide Layers on Aluminum

C. Cherki and J. Siejka*

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Tour 23, 11 Quai Saint-Bernard, Paris 5ème, France

ABSTRACT

The method of nuclear microanalysis of stable oxygen isotopes by the reactions O^{16} (d, p) O^{17*} and O^{18} (p, α) N^{15} was used to investigate the mechanisms of growth, dissolution, and transport associated with oxygen during the formation of relatively thin ($\leq$7000Å) porous anodic layers on aluminum. The average charge associated with an oxygen ion fixed in the film was calculated on the basis of the direct measurement of sulfur incorporation in the films. The current efficiency of the oxidation was determined (and found to be low, ~55%) by comparing the amount of oxygen fixed on the metal surface deduced from nuclear microanalysis to that deduced from the amount of charge fed into the circuit. The rate of chemical dissolution of the oxide was measured in open circuit and under polarization and was found to be two orders of magnitude lower than that which would explain the low current efficiency. Hence the existence of an electrochemical process of cation transfer must be assumed. It was found, by using oxygen 18 tracer techniques, that the growing oxide layer is formed at the metal/oxide interface by oxygen transport through the base layer. The results show that about 60% of the ionic current is transported by oxygen ions and about 40% by cations during the growth of porous oxide layers on aluminum.

Porous oxide layers produced by anodic oxidation of aluminum in acid solutions have been investigated for many years; however, no consistent model has as yet been elaborated to explain the formation of these films. The present paper reports new data on the growth and dissolution of porous anodic oxide films on aluminum in H_2SO_4 [15 w/o (weight per cent)]. The method of nuclear microanalysis of the O^{16} and O^{18} isotopes used in this paper has been applied previously to the investigation of anodic oxidation of metals (1-3) and semiconductors (4).

The nondestructive method of nuclear microanalysis allows one to determine the number of oxygen atoms/square centimeter fixed by oxidation on the surface of the metal specimen under investigation. Moreover, by using a solution in which the water was enriched[1] in O^{18} and by measuring and locating this isotope in films formed in solutions having various O^{18} isotopic concentrations, it is possible to tackle the problem of oxygen transport during growth and dissolution of porous films in a more direct way than would be possible by using other techniques, such as tracing with radioactive sulfur (5).

An analysis of previous work (6-8) leads to considering two main types of growth mechanism of porous layers: (*a*) migration of cations across the film, together with the oxygen bearing anions (OH^-, O^{2-}, SO_4^{2-}); these cations form directly a porous oxide at the film-electrolyte interface. Mechanisms of this type have been suggested to explain the uniform distribution of polyatomic anions incorporated in the films; and (*b*) cations and anions which migrate across the barrier layer continue to form a compact layer at the oxide-electrolyte and metal-oxide interfaces, respectively; then, by some process, this layer is transformed into a porous layer at a rate equal to that of barrier layer formation, thereby keeping the thickness of the latter at a constant value.

The latter type of growth mechanism seems to have been generally accepted in the literature; however, there is still much controversy, in particular as regards the conversion mechanism of the barrier layer into a porous layer. Keller *et al.* (9) have suggested a purely chemical process of transformation: the convergent flow of current was supposed to raise the temperature and concentration of the solution at the base of the pores, thereby accelerating the chemical dissolution of the oxide formed. Such a mechanism consisting in Joule heating of the solution has been accepted by numerous authors (7, 10). However, recent calculations by Nagayama and Tamura (11) have shown that the rise of temperature at the pore base is practically always negligible.

Hoar and Mott (6) have explained the dissolution at the pore base as being a field-assisted process. They assume that the oxide film formation occurs at the oxide-metal interface by OH^- migration. Under the effect of the electric field, the protons produced by this reaction would migrate toward the oxide-solution interface at the pore base. This process favors the dissolution of Al ions from the oxide into the solution. However, the origin of the OH^- ions and the mechanism of electrochemical dissolution have not been specified. Moreover, as pointed out by Young (12), no experimental evidence has been obtained for these mechanisms. Finally, this model has been in part rejected by Hoar himself and Yahalom (7).

Moreover, Nagayama and Tamura (11) have shown that the quantity of Al^{3+} in the solution after oxidation exceeds that of Al^{3+} originating from the formation of the pores. From this they inferred the existence of electrochemical dissolution of Al at the pore bases. This conclusion has been criticized several times by Diggle et al. (13). By S^{35} tracing, they have shown that the above difference is probably caused by an extensive chemical dissolution of the oxide all over the oxide-solution interface.

To gain some insight into these problems, in a first series of experiments we investigated the current efficiency of the formation of porous layers. The quantity of oxygen atoms/square centimeter of N_O fixed on the specimen surface, measured by nuclear microanalysis, was compared to the quantity N_{qox} of oxygen which is equivalent to the ionic charge Q_{ox} applied during anodic oxidation. To determine N_{qox} on the

basis of coulometric measurements, it is necessary to know the value of electronic losses and the charge associated with an oxygen atom. Information about this was found in the literature. Spooner (14) has shown that the electronic losses can be disregarded. This result was confirmed in Ref. (8).

Moreover, it is well known (2) that anodic films formed in concentrated acids contain a large number of anionic impurities of the $A_xO_y^{n-}$ type. According to Ref. (15), for aluminum oxidized in H_2SO_4 (15%) the incorporation of sulfate anions can be estimated to represent 14% of the total weight of oxide in the case of thick layers.

Using the method of back-scattering with $^4He^+$ ions at 1800 keV [see Ref. (1)] we measured the rate of sulfur incorporation during the formation of thin oxide layers and we evaluated the average charge of the oxygen atoms under our experimental conditions.

In a second stage, we investigated the dissolution of the oxide in open circuit and during growth. In a certain way, this investigation complemented the one described above, since the dissolution of the outer part of the oxide, which has been proposed to explain the poor current efficiency observed by the other authors, has not yet received quantitative evidence. In the present experiments, we produced a thin porous layer, enriched in O^{18}, superimposed on a porous layer depleted in O^{18}. Determining the O^{16} and O^{18} losses of this duplex layer after dissolution, it is possible to obtain quantitative information about the rate of dissolution in the pores and on the oxide surface, as well as to specify the origin of Al^{3+} in the oxidation bath.

The last part of these experiments was devoted to a study of the nature of charge carriers during the oxide formation by means of O^{18} tracer techniques. This method was introduced by Amsel and Samuel (16) for investigating the transport mechanism during the formation of compact films. In the present experiments, films of different thickness were obtained in solutions of the same chemical type (H_2SO_4, 15%) with various O^{18} isotopic concentration and the O^{18} was then located in these duplex films.

Experimental

Measurement of O^{16} and O^{18}.—The method of nuclear microanalysis used in this paper is based on the determination of the number of particles coming from the following nuclear reactions: O^{16} (d, p) O^{17*} and O^{18} (p, α)N^{15}. The basic principles of this method have been described in a series of papers by members of our laboratory [see Ref. (1) and (17].

Measurement of sulfur.—The energy of back-scattered particles is a function of the incident energy and of the masses of the incident particle and the target nuclei. This method, described elsewhere (1), allows one to measure the quantity of heavy impurities contained in a light matrix. A 1800 keV $^4He^+$ beam was used in the present experiments to determine the sulfur contained in aluminum oxide formed on an extra pure metal (99.999%) (see paragraph on Preparation of solution and specimens, below).

Location of O^{18}.—Isotopic analysis of oxygen at various depths in anodic layers was used for the first time by Amsel and Samuel (16) to investigate the migration mechanism of ionic charge carriers during the growth of compact aluminum anodic oxide films. This method consists in an analysis of the excitation curve as a function of bombarding energy in the vicinity of a narrow resonance of the O^{18} (p, α)N^{15} reaction, measured for the sample under investigation.

In this paper, we used the 2.5 keV wide resonance at 629 keV, according to a technique described by Amsel *et al.* (1, 18). By fitting the theoretical excitation curve, calculated for a given concentration profile, with the experimental curve we deduced the O^{18} concentration profile $C(x)$ in the oxide obtained by successive oxidation in two solutions of different isotopic concentrations.

Preparation of solutions and specimens.—We used annealed, rolled aluminum pure to 99.9 or 99.999%. Specimens of the latter type were supplied by Materials Research Corporation. The natural oxide layer on this metal is of the order of 50Å. The specimens were rectangular having an area of 2 cm^2. Before oxidation the surfaces were thoroughly cleaned with acetone and then washed with bidistilled water. The method of electrochemical polishing was not used here for the same reasons as explained in (3).

Two types of solutions were used: "$s_O{}^{18}$" enriched to about 10% and O^{18} and "$s_O{}^{16}$" depleted 20-30 times in O^{18}. A special oxidation cell (5 cm^3) was used because of the high cost of labeled electrolytes. The specimen holder has been described in (2) and (3). The temperature of the cells was controlled with an accuracy of 0.5°C and was equal to 15°C.

Experiments were carried out at constant voltage $V_{ox} = 10V$ for a fixed time by applying the voltage between the specimen and a helical platinum cathode. It was shown that there was practically no isotopic exchange between the oxygen of the oxide and that of the water (see below). For this reason the specimens were washed with running distilled water to remove any residual acid and then dried.

In agreement with the literature (19) we found that the isotopic exchange of oxygen between SO_4^{2-} and H_2O is negligible under the present experimental conditions. Therefore, the O^{18} labeling of the SO_4 groups is equal to 0.204% (natural abundance) both in $s_O{}^{18}$ and $s_O{}^{16}$ solutions.

Results and Interpretation

Analysis of back-scattering spectra.—For 1800 keV incident $^4He^+$ ions, Fig. 1 shows typical back-scattering amplitude spectra obtained: (*a*) from the pure metal and (*b*) from the metal covered with a 210Å oxide layer. The presence of the neatly resolved peak at 1126 keV corresponds to the presence of sulfur. Calculations, based on the Rutherford formula for elastic scattering cross sections, led us to the value of 7×10^{15} sulfur atoms/cm^2 with an accuracy of 10%,

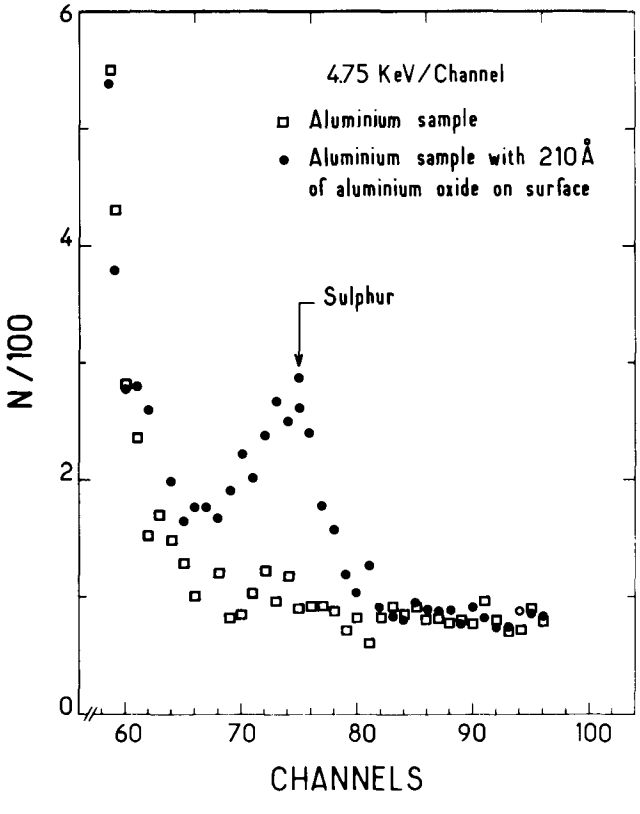

Fig. 1. Back-scattering amplitude spectra for $^4He^+$ ions at 1800 keV obtained on pure and oxidized aluminum.

this film containing on the other hand 122 × 10^{15} oxygen atoms/cm². Assuming that all the sulfur is in the form SO_4^{2-}, the percentage of oxygen incorporated in the form of sulfates is equal to 23 ± 6%. The literature gives (15) the sulfur content of those films as the weight percentage of the SO_3 group in thick films: the value reported is 12-14%. Recalculating the similar quantity on the basis of our results we find 14 ± 3% in reasonable agreement.

We shall now calculate the average charge required to fix an oxygen atom in the oxide. Let us assume first (assumption *a*) that the oxide is of the form

$$Al_2^{3+}\ [(O^{2-})_x,\ (SO_4^{2-})_y] \qquad [a]$$

We find readily that $x = 2.79$ and $y = 0.21$. The average charge is then: $(0.77 \pm 0.06) \cdot (-2) + (0.23 \pm 0.06) \cdot (-0.5) = -1.65 \pm 0.1$ where -2 is the average oxygen charge for pure oxide and -0.5 for pure sulfate.

It is reported in the literature (8) that SO_4^{2-} anions may be fixed by adsorption and can be accompanied by protons. The extreme assumption [*b*] will therefore be made that the oxide is of the form

$$(Al_2^{3+}\ O_3^{2-}),\ (H_2SO_4)_y \qquad [b]$$

with the oxygen charge in the sulfate being zero. Then $y = 0.22$, and the average charge is $(-2) \cdot (0.77 \pm 0.06) = -1.54 \pm 0.1$.

Current efficiency.—Experiments were performed at constant voltage ($V_{ox} = 10$V) and in steady-state conditions. The time when the porous film begins to grow under constant current, *i.e.*, when the steady-state conditions are reached, was used as an arbitrary reference. In our experiment, this time was equal to 30 sec. Coulometric measurements were made taking this instant as the origin of the time, *t*. Figure 2 shows the time dependences of: curve 1, the number of oxygen atoms/cm² N_O (t) measured by nuclear analysis (the initial quantities of oxygen fixed up to 30 sec being substracted); and curve 2, the quantities of oxygen N_{qox} calculated from coulometric measurements by giving to each oxygen atom the limits of the average charge deduced from model [*a*], *i.e.*, 1.55 and 1.75 electron charges (curve 2a and 2b), respectively. The variation of $N_O(t)$ and $N_{qox}(t)$ are linear and the ratio of the mean slopes gives the efficiency of the reaction which is constant over the range of oxidation times investigated ($t_{ox} \leq 10$ min). The efficiency obtained is 53 ± 3%. If the average charge deduced from model [*b*] is used the current efficiency obtained is 48 ± 3%.

Mason and Slundler (20), Mason and Fowle (21), and Spooner (14) measured the current efficiency, expressed in terms of coating ratio, of aluminum anodically oxidized in H_2SO_4 solutions under different concentrations, temperature, and current density conditions. The coating ratio is given by the expression

$$\frac{\text{weight of oxide formed}}{\text{weight of aluminum consumed}}$$

If the current efficiency for the conversion of aluminum to alumina were 100%, the coating ratio would be 1.89 (2.20 if SO_3 incorporated in the oxide represents 14% of the oxide weight).

Experimental observations suggest that the coating ratios measured are always less than these values and decrease as the electrolyte temperature and concentration increase and current densities decrease. Oxidation time is a complicated function of current density and temperature. For small current densities, the coating ratio decreases with time. If it is measured for very short oxidation times and at constant current densities ($t_{ox} \leq 2$ min, for $I \simeq 5$ mA/cm²), the coating ratios are obviously influenced by the coating ratio of barrier film formation which could be much higher than during porous film formation (7). This effect can be neglected for $t_{ox} = 10$ min. For these reasons, we have compared our results to those of Ref. (14), (20), and (21) obtained at $t_{ox} = 10$ min. For the oxide formation at conditions similar to ours ($t_{ox} = 10$ min, 15% H_2SO_4, $I \simeq 5$ mA/cm² at steady-state conditions) we found that according to Mason and Fowle (21) the coating ratios were equal to 1.47 at 10°C and 1.33 at 21.1°C (theoretical value: 2.20). These values correspond to current efficiencies of 66% and 60%, respectively. Similar results can be deduced from the measurements by Mason and Slundler (20) and Spooner (14). The current efficiency calculated from Ref. (11) is equal to 66% ($t_{ox} = 10$ min). This value was obtained from chemical analysis of the aluminum dissolved in the solution and compared to the coulometric curve. It can be noted that the value of the current efficiency calculated in Ref. (11) is independent of the model chosen for the oxide formed, *i.e.*, independent of the average charge of the oxygen fixed in the oxide. This value of current efficiency, although obtained at different conditions ($t = 27$°C, $I = 9.5$ mA/cm², 10% H_2SO_4), is practically the same as that measured by gravimetric methods (14, 20, 21) at our experimental conditions. Our value 53 ± 3% is about 20% smaller than those mentioned in the above literature data. It can be noted that the experimental errors due to the methods used in Ref. (11), (14), (20), and (21) were not discussed in these papers.

It is interesting to note that if one gives the average oxygen charge -2 to all oxygen fixed in the oxide, the current efficiency measured in our experiments comes to 64%. This value is practically the same as these deduced from Ref. (11), (14), (20), and (21). However, it is difficult to consider a mechanism which could explain the presence of sulfur in the oxide not in the form of sulfate but in some reduced form due, for example, to the chemical action of water. Therefore, on the basis of some data in the literature (8) we cannot exclude the hypothesis that incorporation of sulfates is lower in steady-state conditions than measured at the beginning of the oxidation (210Å). Thus the current efficiency would be in reality somewhat greater than 53 ± 3% and equal to a value within the limits 53-64%. Hereafter, we will base the discussion of these results on the assumption that the current efficiency is equal to 53 ± 3%. Anyway, the general conclusion of this work does not change if the current efficiency is taken to be equal to 64% instead of 53 ± 3%.

A simple calculation of the size and number of pores, based upon numerical estimations by Keller *et al.* (9) shows that the poor current efficiency is not simply due to the loss of aluminum from the volume of the pores. For oxidation in a 15% H_2SO_4 solution at 10°C, Keller *et al.* found that the radius of the pore r_o, at

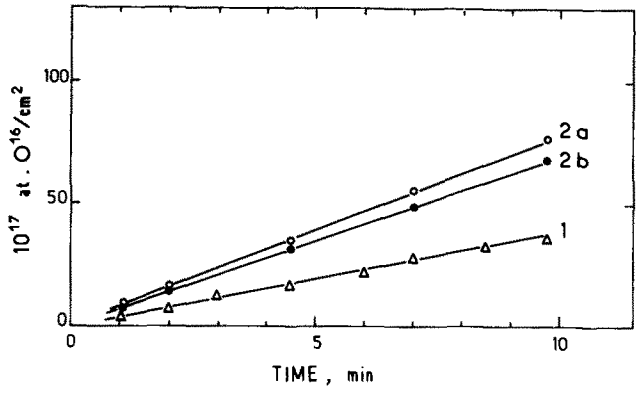

Fig. 2. Quantity of oxygen fixed on aluminum oxidized in steady-state conditions as a function of oxidation time in 15% H_2SO_4 at 10V and 15°C. Curve 1 is deduced from nuclear microanalysis and curves 2a and 2b from coulometric measurements assuming the average charge of oxygen to be 1.55 and 1.75, respectively.

the outer surface of the film, is equal to 60Å. The volume of the pores expressed in per cent of the total volume of the oxide, V_o, can be calculated from the empirical formula: $V_o = 78.5 \cdot r_o^2/R^2$, R being the radius of the cell; $R = AV + r_o$, where the wall thickness A is equal to 8 Å/V and V is the film formation voltage. One finds $R = 140$Å and the volume of the pores is calculated to be 14% of the total volume of the oxide.

It follows that the total surface, S, of the pores per square centimeter on the outer surface of the oxide is equal to 0.14 cm^2 assuming that the pores are cylindrical, *i.e.*, that lateral dissolution along their walls is negligible during film formation (this hypothesis will be confirmed in the following section). The number of pores per square centimeter, N, can be evaluated by dividing the total surface of the pores, S, by πr_o^2, *i.e.*, the surface of one individual pore. $N = 1.27 \times 10^{11}$ pores/cm^2 is the result obtained.

Recently, Wood *et al.* showed (22) by sectioning a film perpendicularly to the aluminum surface that the barrier layer and the pores were clearly visible. However, the dimensions of the cells displayed in this way were somewhat different from those indicated by Keller *et al.* (9). In particular Wood *et al.* found the diameter of the pores for films formed in 15% H_2SO_4, to be about 100Å, instead of 120Å as measured by Keller. It should be noted that in spite of certain quantitative disparities, Wood gives a perfect confirmation of the structural model proposed by Keller. Obviously, the volume of the pores (14%) cannot explain the poor current efficiency even if it is 64 ± 3% and not 53 ± 3%.

Open-circuit dissolution.—The ratio of the quantity of oxygen lost to the initial quantity of oxygen in the film is shown in Fig. 3 (curve 1) as a function of dissolution time in open circuit. Films formed at 10V, 15°C, for 6 min, 3 min, and 1 min 50 sec were dissolved in a 15% H_2SO_4 solution. An analysis of the results leads us to the following conclusions: (*a*) the apparent dissolution rate expressed as the percentage of oxygen lost depends only slightly on time throughout the range investigated (up to 200 min); and (*b*) the percentage of oxygen lost from the specimens investigated are independent of the initial thickness of the film.

In order to compare the dissolution rates of the frontal and lateral oxides (v_2, v_1) (see Fig. 4), we formed a duplex layer in a solution enriched to 10% in O^{18} (~150Å) and then in a solution depleted in O^{18} (~1800Å). When the total oxygen losses ($O^{16} + O^{18}$) are considered as a function of time the relation is the same as that given by curve 1, Fig. 3. Curve 2, Fig. 3, shows the time dependence of the percentage of O^{18} lost relative to the initial O^{18} content of the film; this percentage indicates the relative oxygen loss of the surface layer.

In order to be able to fully interpret these experiments, it appeared necessary to investigate the isotopic exchange of the oxygen contained within the film with oxygen contained in the solution, as, in principle O^{18} losses may be due not only to the dissolution of the film, but also to isotopic exchange. In order to increase the accuracy of our measurements, we investigated the oxygen exchange between films formed in solutions depleted in O^{18} and then immersed in a solution enriched in O^{18}. There appears to be no increase in the quantity of O^{18} inside the film after a 2-hr contact with the solution. On the other hand, there is a decrease of the total quantity of oxygen due to the dissolution. Although, due to this dissolution, such an experiment does not allow us to draw precise conclusions as to the value of the electrochemical oxygen exchange current, it appears clearly that the rate of isotopic exchange (the uptake of oxygen atoms per unit time) seems to be negligible compared with the rate of chemical attack.

We shall attempt to discuss the results obtained above under the assumption (suggested by several authors) that the constant rate of dissolution v_1 (cm/min) along the walls of the pore differs from the rate

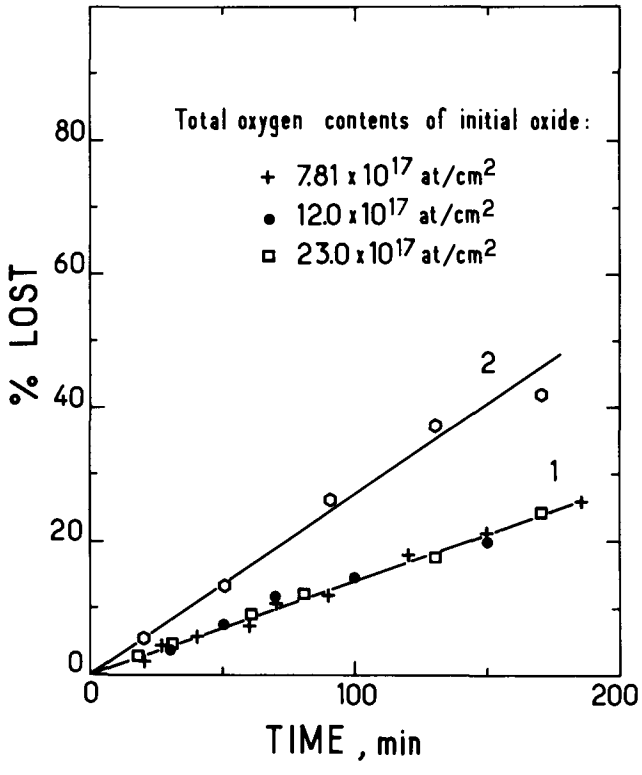

Fig. 3. Percentage of oxygen lost with respect to the initial quantity of oxygen in the film as a function of the open-circuit dissolution time in 15% H_2SO_4 at 15°C. Curve 1: films formed in $s_0 16$ solution; O^{16} losses with respect to the total initial quantity of oxygen. Curve 2: duplex film; O^{18} losses with respect to the initial amount of O^{18} in the film (see Fig. 4).

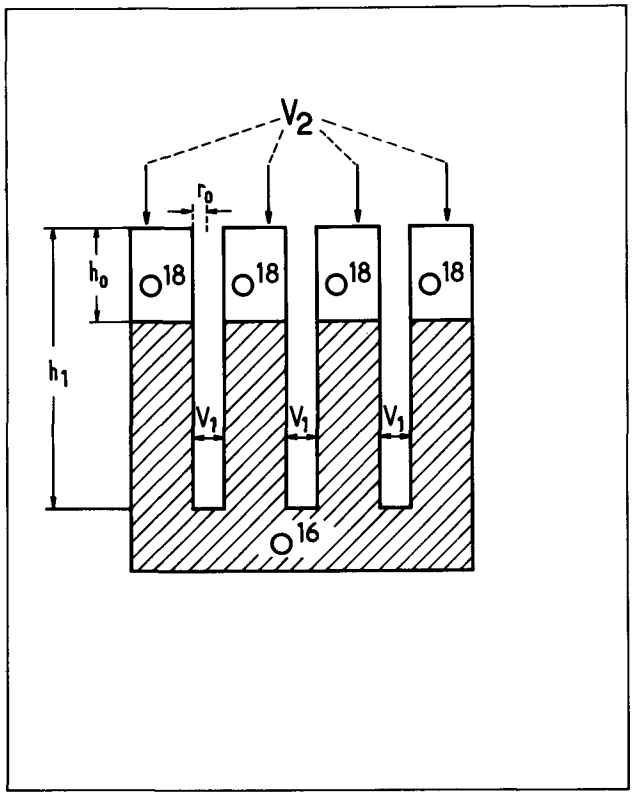

Fig. 4. Schematic structure of a porous layer: v_2 and v_1 are the frontal and lateral rates of dissolution of the oxide, respectively; r_o is the pore radius; h_o is the thickness of the enriched layer; h_1 is the total thickness of the porous layer.

of dissolution v_2 at the outer surface of the film (see Fig. 4). We shall apply Keller's geometrical model and quantitative evaluations in order to determine v_1 and v_2 which may be calculated by a method similar to that used in Ref. (11).

The ratio g_1 of the pore wall surface to the apparent surface of the specimen, at a given time θ is

$$g_1 = 2\pi rhN$$

where r is the average radius of a pore at time θ, and h is the thickness of the film (the thickness of the compact base layer is assumed to be negligible compared with the total thickness of the film). At a given time θ, the ratio g_2 of the outer film surface to the apparent surface of the specimen is

$$g_2 = 1 - \pi r^2 N$$

Because the rate of dissolution remains constant, r increases and h decreases linearly with time

$$r = r_1 + v_1\theta \text{ and } h = h_1 - v_2\theta$$

where h_1 and r_1 are the thickness of the film and the average pore diameter at $\theta = 0$, respectively.

The quantity of oxygen dissolved at a time t is given by

$$N_O(t) = \alpha v_1 \delta \int_o^t g_1 d\theta + \alpha v_2 \delta \int_o^t g_2 d\theta$$

where α is the fraction by weight of oxygen in the film and δ is the density of the film. After calculations this expression becomes

$$N_O(t) = \alpha\delta v_1 2\pi N \left[h_1 r_1 t + (v_1 h_1 - v_2 r_1)\frac{t^2}{2} - v_1 v_2 \frac{t^3}{3} \right] + \alpha\delta v_2 \left[(1 - \pi N r_1^2)t - 2\pi N r_1 v_1 \frac{t^2}{2} - N\pi \frac{v_1^2 t^3}{3} \right]$$

The total quantity of oxygen in the film prior to dissolution is

$$N_O = \alpha h_1 \delta - \alpha\pi r_1^2 h_1 N\delta = \alpha h_1 \delta (1 - \pi r_1^2 N)$$

In this expression, $\alpha\delta h_1$ is the quantity of oxygen which would be present in the film of thickness h if the film were free of pores and $\alpha\pi r_1^2 h_1 N\delta$ is the quantity of oxygen which would be contained within the pores.

The ratio of oxygen lost after a dissolution time t to the initial quantity of oxygen is

$$p = \frac{N_O(t)}{N_O} = \left[\frac{2\pi N r_1 v_1}{1 - \pi N r_1^2} + \frac{v_2}{h_1} \right] t + \frac{\pi N [v_1^2 h_1 - 2 v_1 v_2 r_1]}{h_1 (1 - \pi N r_1^2)} t^2 - \frac{\pi N v_1^2 v_2 t^3}{h_1 (1 - \pi N r_1^2)} \quad [1a]$$

Equation [1a] shows that the general expression for p as a function of dissolution time contains t^2 and t^3 terms, as well as a linear term. Experimental results show (Fig. 3) that under our conditions (dissolution time $t \leq 200$ min), p is essentially a linear function of the dissolution time. Thus, we shall only keep

$$p = \left[\frac{2\pi N r_1 v_1}{1 - \pi N r_1^2} + \frac{v_2}{h_1} \right] t. \quad [1b]$$

or

$$p = [A \cdot v_1 + v_2 \cdot h_1^{-1}]t \quad [1c]$$

where $A = 5.55 \times 10^{-3}$ Å^{-1}.

From Fig. 3, we can deduce two values of p; one for a total film thickness of 1800Å (curve 1) and a second value deduced using the thickness of the oxygen 18 enriched surface layer presented in Fig. 4 as h_o, *i.e.*, 150Å (curve 2). For an arbitrary dissolution time equal for example to 100 min, we can calculate from Eq. [1c] the values of v_1 and v_2. We find that these values are practically the same and equal to 2×10^{-9} cm/min: Consequently, the term v_2/h_1 (curve 1) is ten times smaller than the term $2\pi N r_1 v_1/1 - \pi N r_1^2$. In addition the nonlinear terms are indeed negligible in Eq. [1a] for these values of the parameters.

For $h_1 \geq 1800$Å the v_2 term can be neglected and

$$p \approx \frac{2\pi N r_1 v_1}{1 - \pi N r_1^2} t$$

This means that the oxygen loss is independent of the initial thickness of the film as was shown experimentally (curve 1, Fig. 3)

In fact, the value v_1 determined in this way depends on quantitative hypotheses based on the data of Keller *et al.* which certain authors consider to be underestimated. Furthermore, the determination of the value v_2 depends on the accuracy of the value h_o used for the surface film thickness (Fig. 4). Although these remarks cast a certain doubt on the reliability of the values of v_1 and v_2, it should be clear that the dissolution rates along the pore walls and on the outer surface are of the same order of magnitude. On the other hand, it seems significant that the values of v_1 and v_2 established by investigating the oxygen losses (15% H_2SO_4 at 15°C) are of the same order of magnitude as those obtained by Nagayama and Tamura at 27°C in 10% H_2SO_4 (7.5×10^{-9} cm/min) by analyzing the aluminum dissolved.

Dissolution during oxide growth.—In the previous paragraph we showed that in the case of open-circuit dissolution there is no appreciable difference between the dissolution rate at the outer oxide-solution interface and the dissolution rate along the pore walls. We are now faced with the problem of knowing whether there is a high dissolution rate at the outer oxide-solution interface during film formation and, if so, whether this can account for the poor current efficiency observed. To settle this question, we attempted to estimate the variations of the quantity of O^{18} in the films initially formed in an enriched solution and subsequently reoxidized in a depleted solution. Such a film was formed for 15 sec in s_o18 at 10V and then reoxidized for 10 min in s_o16. Measurements showed that there was an increase in O^{18} of $2.6 \pm 0.1 \times 10^{15}$ atoms/cm^2 in the final duplex film compared to the original film which contained 15×10^{15} atoms O^{18}/cm^2.

Further measurements showed that a film formed for 10 min in s_o16 at 15°C, 10V, contains $3 \pm 0.15 \times 10^{15}$ atoms O^{18}/cm^2, which comes partly from the O^{18} of the depleted solution and, above all, from the incorporation of SO_4 ions of natural isotopic concentration. It can be concluded from the difference between the values measured that there is a loss of $0.4 \pm 0.25 \times 10^{15}$ atoms O^{18}/cm^2 at the film-solution interface during reoxidation. Curve 2 of Fig. 3 shows that open-circuit dissolution for 10 min results in a loss of 0.4×10^{15} atoms O^{18}/cm^2 for a film which contains, like the original duplex film specimen, 15×10^{15} atoms O^{18}/cm^2. Thus, the oxygen losses during reoxidation and the losses under open-circuit dissolution seem to be of the same order of magnitude.

Growth mechanism.—In order to understand the physical meaning of the above results, it was thought necessary to examine the possible configurations of the isotope distribution throughout the duplex film, according to various transfer mechanisms.

During reoxidation, a new layer having a different isotopic composition from that of the first layer can form at the three interfaces: (*i*) porous layer-solution (Fig. 5a), (*ii*) compact layer-porous layer (Fig. 5b), and (*iii*) metal-compact layer (Fig. 5c).

(*i*) In the case of the first configuration (Fig. 5a), the oxide forms at the porous layer-solution interface

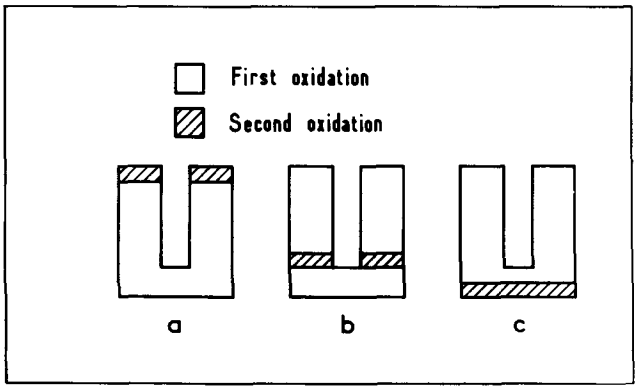

Fig. 5. Oxygen transport during porous formation. New layer formed (a) on the top of the porous film, (b) at the porous/compact layer interface, and (c) at the compact layer/metal interface.

by cation migration across the compact and porous layers.

(*ii*) According to Fig. 5b, the oxide forms at the compact layer-porous layer interface either by long range cation migration or by an order conserving oxygen propagation transmitted from neighbor to neighbor across the compact layer. The new layer immediately transforms into a porous layer maintaining constant the thickness of the compact layer.

(*iii*) In the third configuration (Fig. 5c), oxide formation occurs at the compact layer-metal interface by long-range migration of oxygen coming directly from the solution. In this case, too, the thickness of the compact layer does not change because of immediate transformation into a porous layer.

Figure 6 shows the excitation curves for three types of specimen obtained near the resonance at 629 keV. Curve 1 refers to a porous oxide film formed for 15 sec in 15% H_2SO_4 enriched in O^{18} (solution $s_0 18$) at 10V. Curve 2 has been obtained for a duplex film, first formed for 3 min at 10V in 15% H_2SO_4 depleted in O^{18} ($s_0 16$) and then reoxidized at the same potential for 15 sec in $s_0 18$. The quantity of O^{18} added is equal within 10% to the quantity of O^{18} in the specimen of curve 1. Curve 3 refers to a duplex layer formed under conditions similar to those described above, with an initial oxidation time in $s_0 16$ equal to 6 min. Analysis of the curves shows that the resonance maximum is shifted toward higher energies. This seems to indicate that all the O^{18} atoms added during reoxidation are embedded in the bulk of the oxide and that their depth relative to the film-solution interface depends on the original porous layer formed in $s_0 16$. However due to energy straggling of the protons the spread of the O^{18} distribution around its mean value cannot be determined with sufficient accuracy from the observed broadening of the excitation curves. In particular, no assertion can be made as to whether the oxygen atoms coming from reoxidation accumulate near the metal-compact layer interface (Fig. 5c) or whether they are distributed throughout the duplex film. Anyway, this consideration makes configuration 5a impossible.

To gain a deeper knowledge of this fundamental aspect of the transport mechanism, tests were carried out exchanging the two oxidations. After formation of an original layer with O^{18} followed by reoxidation with O^{16}, the original O^{18} layer would remain at the surface if the oxygen atoms coming from reoxidation were located at the metal-compact film interface. In this case, one would observe a narrow resonance peak corresponding to that obtained from the layer prior to reoxidation, whatever the additional thickness of the oxide layer. If the oxygen atoms were found at the compact film-porous film interface, there would be two peaks originating from deep-seated and surface O^{18}, respectively. Figure 7 shows the theoretical excitation curve corresponding to such a case (curve 3).

Figure 7, curve 1, shows the excitation curve for a film formed in $s_0 18$ (10V, 15 sec). Curve 2 shows the excitation curves for duplex films formed in $s_0 18$ (10V, 15 sec) and then reoxidized at the same potential in $s_0 16$ for various fixed times (1 min, 30 sec; 3 min; 6 min).

It can be seen that there is only one peak coinciding with the resonance peak, whatever the additional thickness. Thus, the actual picture of the isotopic distribution is shown by Fig. 5c. It is impossible to ascer-

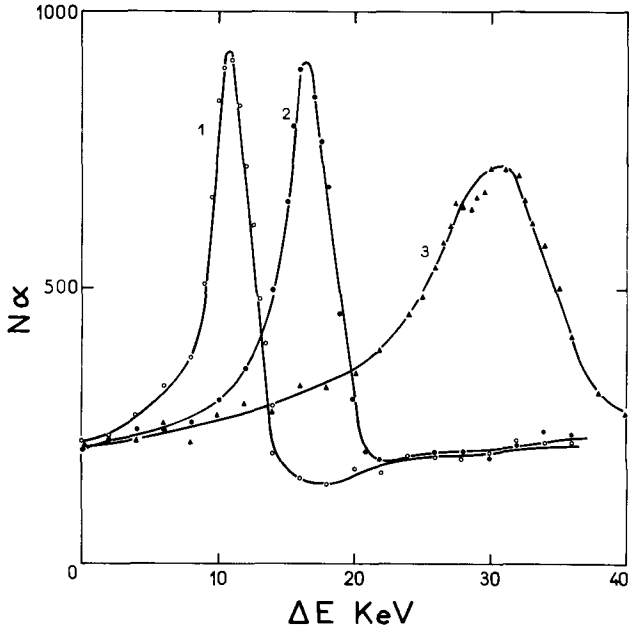

Fig. 6. Excitation curves of O^{18} (p, α) N^{15} reaction near the 629 keV resonance. Curve 1: thin porous film formed in O^{18} enriched solution (15 sec); curves 2 and 3: duplex films, first formed in a solution depleted in O^{18} for 3 and 6 min, respectively, and then reoxidized at the same potential for 15 sec in an O^{18} enriched solution (v = 10V; t = 15°C; 15% H_2SO_4).

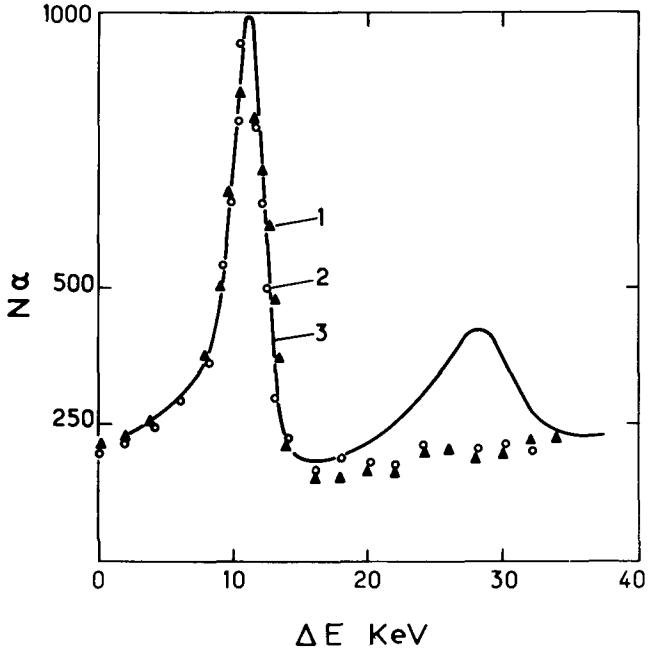

Fig. 7. Excitation curves of O^{18} (p, α)N^{15} reaction near the 629 keV resonance. Curve 1: thin porous film formed for 15 sec at 10V and 15°C in O^{18} enriched solution: curve 2; duplex film, first formed in an O^{18} enriched solution (see above) and then reoxidized at the same potential in an O^{18} depleted solution for fixed times of 1 min 30 sec, 3 min, 6 min; curve 3: theoretical curve of the duplex film (6 min reoxidation) calculated when one-half of the initial O^{18} layer remains at the metal-oxide interface.

tain whether there is a mixing of O^{18} and O^{16} beyond a depth of ~200Å below the surface layer, because of the limited investigating possibilities of our experiment.

Nevertheless, it should be noted that the validity of the conclusions as regards the choice of the transport mechanism does not depend on the absence or presence of this relatively small mixing.

Discussion

The above experimental results lead to the determination of the various terms of the current forming the porous layers disregarding electronic losses (8, 14). For steady-state conditions [see Ref. (3)]

$$I_{tot} = I_{ox} + I_{dis} \quad [2]$$

Obviously, I_{ox} is proportional to the current efficiency of film formation, which is found to be constant in our experimental conditions ($t_{ox} \leq 10$ min). It represents 53 ± 3% of I_{tot} (I_{tot} = const). Thus, I_{dis} is 47 ± 3% of I_{tot}. According to Diggle *et al.* (5, 8), I_{dis} is the sum of two terms; I_{dec} and I_{chim}:

I_{dec} is the charge per unit area, per unit time, required to form a volume of oxide equal to the volume of the pores.

I_{chim} is the charge per unit area, per unit time needed to form the oxide dissolved chemically. Therefore

$$I_{dis} = I_{dec} + I_{chim} \quad [3a]$$

I_{chim} depends on the pore geometry which is itself dependent on the anodizing time used in film formation

$$I_{chim} = i_{chim} \cdot S$$

where i_{chim} is the oxide dissolution rate of the oxide per real square centimeter; in our experimental conditions, we obtained $v_1 = v_2 = 2 \times 10^{-9}$ cm/min, *i.e.*, equivalent to a current density per real unit surface of 0.3 μA/cm^2; S is the ratio of the total real surface of the pores to the apparent surface of the specimen. S can be calculated from the expressions

$$S = 2\pi r_1 \cdot h_1 \cdot N$$

For $r_1 = 60 \times 10^{-8}$ cm, $N = 1.27 \times 10^{11}$ pores/cm^2, and $h_1 = 7 \times 10^{-5}$ cm, (which is the maximum thickness of films studied in this work), we found: $S = 33.7$. Thus, the maximum value of I_{chim} is equal to 10.1 μA/cm^2. In our experiment, $I_{tot} \approx 5$ mA/cm^2 and I_{dis} (47% of I_{tot}) $\approx$ 2.4 mA/cm^2. This means that for $t_{ox} \leq 10$ min the maximum value of I_{chim} is much smaller than 1% of I_{dis} and can be disregarded.

The value of I_{dec}[2] can be deduced from the volume of the pores and can be determined from the data of Keller *et al.* (9) to be about 9% of I_{tot}. It should be noted that the value of I_{dec} is independent of the oxide dissolution mechanism for producing pores. According to literature data [see for example Diggle *et al.* (23)], it is a field-assisted process, the mechanism of which, however, has not been specified.

Thus, our results cannot be explained by Eq. [3a]. It is logical to suppose that I_{dis} has a third component (I_{Al}) and can be written as Eq. [3b]

$$I_{dis} = I_{dec} + I_{Al} + I_{chim} \quad [3b]$$

which, in our experimental conditions ($t_{ox} \leq 10$ min) is reduced to [3c]

$$I_{dis} \simeq I_{dec} + I_{Al} \quad [3c]$$

According to our results ($I_{dis} \approx 47\%$ of I_{tot}), I_{Al} is equal to 38% of I_{tot}. Using the data from Ref. (11), ($I_{dis} \approx 33\%$ of I_{tot}), I_{Al} was found to be about 22% of I_{tot}. It should be noted that Nagayama and Tamura (11) arrived at the same conclusions but the physical meaning of this effect was not discussed in their paper.

We found above that the dissolution current I_{dis} is not accompanied by significant losses of oxygen. Thus it is logical to suppose that all the dissolution current (I_{dis}) is purely a cationic effect, *i.e.*, that is represented in the solution only by aluminum cations.

[2] $I_{dec} = I_{ox} \cdot 0.14/0.86$.

It must be emphasized that I_{Al} and I_{dec} are completely different from the physical point of view. I_{Al} can be represented by the movement of the aluminum sublattice (hole movement) or by the interstitial movement of cations from the metal to the solution. Thus I_{Al} can be defined as the current of direct discharge of cations in the solution; whereas I_{dec} arises in the bottom of the pores at the oxide-solution interface as a result of field assisted "dissolution" of the oxide to form the pores. It is probably represented by the movement of aluminum species toward the solution and oxygen species toward the oxide-metal interface, where the new oxide is formed. It should be noted that I_{ox} (53% of I_{tot}) is caused by the movement of oxygen coming from the solution which ensures the growth of the oxide at the metal/oxide interface. The results concerning the ionic movements during the field-assisted dissolution of the oxide and the discussion of the asserting models will be reported in a separate paper.

It should be recalled that the numerical values of the different terms of the current were calculated on the basis of the current efficiency equal to 53 ± 3%; replacing this value by 64%, one obtains: I_{ox} = 64% of I_{tot}; I_{dis} = 36% of I_{tot}; I_{dec} = 10% of I_{tot}; and I_{Al} = 26% of I_{tot}. The numerical values of these terms are different for both cases; anyway, they provide evidence for the existence of a direct discharge of cations in the solution current (I_{Al}). This current exceeds by at least one hundred times the chemical oxide dissolution current for oxide thicknesses less than 10^{-4} cm. Similar conclusions have been drawn from experiments on the formation of compact alumina layers in ammonium citrate (3), in agreement with the data of Davies *et al.* (24).

The value of the dissolution rate of the oxide determines a limiting value of thickness beyond which there occurs no further growth of the oxide layer, defined by the increase of oxygen content in the films. At 15°C and V_{ox} = 10V this limiting thickness h corresponds to the formation of pore surfaces ensuring a chemical dissolution current equal to the maximum value of I_{ox} (56% of $I_{tot} \sim 2.7$ mA/cm^2). The precise value of h is difficult to calculate. However, assuming the pores to be cylindrical by neglecting the pore widening process, the maximum value is readily found to be $\sim 2 \times 10^{-2}$ cm.

On the basis of the results obtained, we shall attempt to shed some light on certain aspects of the growth mechanism of porous layers. It should be emphasized that the oxygen atoms coming from the solution migrate across the base layer, thereby ensuring oxide growth at the oxide-metal interface. Experiments performed previously in our laboratory on the mechanism of oxygen transport (16, 25) have shown that the oxygen atoms are fixed according to their order of arrival during the formation of amorphous compact layers on aluminum or tantalum. In other words, the oxygen atoms belonging to a new layer are located at the oxide-solution interface. If the base layer formed during porous growth also had an amorphous structure, a reversing of the order of oxygen atoms would involve an interstitial type of oxygen migration. Such a type of oxygen transport in the form OH^- has been taken into consideration by Hoar and Mott (6); as mentioned in the beginning of this paper, it has been frequently criticized in the literature. This type of oxygen transport, which is very different from the transport mechanism during the formation of compact layers, seems quite untenable if the base layer is also amorphous. However, there is some experimental evidence [see, *e.g.*, Dorsey (26)] that the base layer has a substructure and that it is composed of anhydrous microcrystallites (highly polymerized Al_2O_3) and of a hydrated microphase equivalent to aluminum trihydroxide. Similar conclusions were obtained by La Vecchia *et al.* (27) on the basis of results obtained by electron micrographs. According to these authors,

the base layer contains microchannels which should not be considered as ordinary channels but rather as easy paths through which charge carriers flow preferentially. The existence of such a substructure of the base layer would account for the inversion of the order of oxygen during the growth process, if the isotopic oxygen exchange between oxygen traveling through the easy paths and oxygen contained within the crystallites can be disregarded.

A partial inversion of the order of oxygen has been observed during the formation of compact layers on zirconium (28). Since the mobility of oxygen in the microchannels (containing hydrated alumina) exceeds that of oxygen in the anhydrous microcrystallites, it could be concluded that oxygen migration increases in the presence of OH^- groups. Recent investigations on the isotopic effect of hydrogen on the rate of porous growth (29) seem to confirm this hypothesis. Results of these investigations will be reported in a separate paper.

Acknowledgments

The authors wish to thank Dr. G. Amsel for his numerous comments and suggestions during this work. They are grateful to Mr. C. Ortega and Dr. J. P. Nadai for enlightening discussions. The technical assistance of Mr. A. Laurent was much appreciated. The comments of Dr. R. S. Alwitt, which contributed to a better presentation of this paper, were greatly appreciated too. This work was supported by the Centre National de la Recherche Scientifique (RCP No. 157), the DRME, and the DGRST.

Manuscript submitted June 5, 1972; revised manuscript received Jan. 25, 1973. This was Paper 90 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

The Incorporation of Tellurium in Liquid Phase Epitaxial (LPE) GaP: Implications for Oxygen Incorporation

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The dependence of the Te concentration in GaP LPE layers was studied as a function of doping level and temperature in the range from ~935° to ~1135°C. The results are interpreted in terms of surface-controlled, as well as bulk-equilibrium, incorporation of the Te, and indicate that, at the lower doping levels, the Te solubility is appreciably lower than the bulk equilibrium value. A similar behavior is postulated to explain conflicting data on the solubility of O in GaP.

Group VI donor impurities play a major role in GaP red and green light-emitting diodes (LED's). In particular, oxygen, in the form of Zn-O nearest neighbor pairs, is the center responsible for the red electroluminescence in GaP (1), while tellurium is a commonly used donor for the preparation of n-type regions in both red and green LED's (2). Thus, it is of practical importance to understand the incorporation of these impurities in GaP. In addition, there is considerable fundamental interest in the incorporation mechanism of Group VI donors, since their solid-solu-

bility behavior disagrees with the conventional thermodynamic analysis of impurity incorporation for bulk phases in equilibrium. In essence, this analysis predicts that the functional variation of the ionized donor or acceptor concentration on the dopant concentration in the external phase (*i.e.*, liquid solution) changes from linear to square-root dependence at $\sim n_i$, the intrinsic electron concentration (3-5). Zn-doped GaP (3, 5) and GaAs (4) are the prototype systems where the above behavior is clearly manifested and best understood. However, the available experimental data for Te, Se, and S-doped GaP (3) and GaAs (6, 7) cannot be reconciled with the consequences of the thermodynamic analysis invoking bulk equilibrium. On the one hand, the 1000°C solid-solubility isotherm of Te (7), as well as the 1238°C (melting point) solubilities of Te and Se in GaAs (6), is linear at all observed donor concentrations, much exceeding the estimated values of n_i (8). On the other hand, a break to a square-root solubility behavior has been observed to occur above n_i for the incorporation of Te, Se, and S in GaP at 1040°C (3), and S in GaAs at 1238°C (6).

In this paper, we present the results of radiotracer (^{129m}Te) and surface-barrier capacitance measurements on Te-doped GaP layers grown by liquid-phase epitaxy (LPE) over limited temperature ranges using a sealed-tube slider technique (9). The major objectives of this work were the following: (*i*) To more accurately determine the solid solubility isotherm of Te at ~1040°C, especially at lower doping levels than previously studied [*i.e.*, $\lesssim 10^{-2}$ atomic per cent (a/o) Te additions to the LPE solution corresponding to doping levels employed to grow LED material]; (*ii*) To obtain solid solubility isotherms below and above 1040°C in order to establish whether the presence and anomalous position of the break was temperature dependent; (*iii*) To relate these results to the surface band-bending model of Zschauer and Vogel (10) and Casey *et al.* (7); (*iv*) To compare the results on Te-doped GaP prepared by different techniques (sliding, tipping, vapor-transport, liquid-encapsulated Czochralski, and thermal gradient).

As a final objective, an attempt was made to examine the consequences of the findings with respect to Te incorporation in the apparently disparate results concerning the incorporation of O donors in GaP.

Experimental

Crystal growth.—The Te-doped GaP layers were grown on liquid-encapsulated Czochralski (LEC) substrates,[1] by LPE from GaP-saturated Ga solutions containing Te or ^{129m}Te. To eliminate vapor transport of the dopant and to ensure the termination of growth at any chosen temperature, a sealed-tube slider assembly (9) located in an isothermal furnace (with less than 1°C variation over the capsule) was used to grow the epitaxial films. Although most experiments were performed in an Al_2O_3 (G. E. Lucalox) slider, occasionally a fused-quartz slider was also employed.

In a typical run, the substrate and the solution containing Te, ^{129m}Te, or a mixture of the two were placed into the appropriate compartments of the slider assembly which was sealed in a quartz capsule after evacuation to 10^{-6} Torr. Next the ampoule was heated to about 15°C above the initial growth temperature and held for 30 min to achieve saturation. Subsequently, epitaxial growth was initiated by moving the Ga-rich solution contained in an opening cut through the slider, onto the GaP substrate. After cooling the solution at a rate of ~0.8°C/min over a limited temperature range, growth was terminated by retracting the slider to its original position following which the ampoule was removed from the furnace. The GaP LPE layers were grown in the following limited temperature ranges: 1145°-1125°C, 1050°-1030°C, and 950°-920°C. The typical epitaxial film thicknesses were ~50, 25, and 15 μm, respectively, corresponding to the average growth temperatures 1135°, 1040°, and 935°C.

Tellurium analysis.—Radiochemical analysis and surface-barrier capacitance measurements were the two methods used to determine the solid solubility of Te in the GaP LPE layers. The radiochemical analysis procedure was similar to that previously applied to the solubility of Te in GaAs (7) and was based on the detection of the 0.48 MeV gamma-emission peak resulting from the decay of ^{129m}Te (half-life = 33.5 days). From counting statistics an accuracy of ±3% is estimated for this analytical method and the detection sensitivity was 3×10^{-9}g of Te.

In order to ascertain that Te was not lost during a run via vapor transport or a refractory reaction, and to eliminate weighing errors, a radiochemical analysis of the LPE solution following growth was performed. In essence, the solution was dissolved in HNO_3 and its ^{129m}Te content determined by comparing the count-rate of an aliquot of this acid solution with that of a ^{129m}Te standard.

Essentially, two complementary methods were used in the LPE layer analysis. In the first method, following lapping the edge and back growth, the LPE layer was sectioned by incrementally removing ~3 μm thick layers using a chlorine-methanol solution. During sectioning the uniformity of the dopant distribution across the layer was frequently checked by means of autoradiographs. The Te concentration in a given section was determined by a comparison of the count-rate in the etching solution with appropriate ^{129m}Te standards and from the weight loss and area of the sample. In the second method, subsequent to the removal of between 2 to 6 sections, the average Te concentration in the remaining layer was evaluated from its total count-rate, area and thickness, the latter being obtained by microscopic measurement of cleaved or angle-lapped surfaces. Since sectioning is a laborious procedure, it was hoped that after a few sectioning steps, the Te concentration in the last increment would approach that in the remaining layer. Unfortunately, this condition could not be met for the LPE layers grown at the highest temperature (~1135°C). At that temperature mechanical difficulties were often encountered with the slider, preventing the desired abrupt termination of growth and resulting in a thick layer with a heavy Te accumulation in the last portion to crystallize.

The net impurity profile (N_D-N_A) was determined for several Te-doped layers by means of surface-barrier capacitance measurements on angle-lapped samples as described previously for the analysis of Zn (11) and Te (12) in GaP LPE layers. The background value of $N_D - N_A$ was $\sim 9 \times 10^{15}$ cm^{-3} for a LPE layer grown from an undoped solution.

Results and Discussion

Surface controlled and equilibrium incorporation.—The Te concentrations in the LPE alloys (x^l_{Te}) and the corresponding solid solubilities of Te (C^s_{Te}) in the GaP LPE layers expressed in units of atom fraction and atoms/cm^3, respectively, are summarized in Table I. In general, good agreement was achieved between the values of x^l_{Te} derived from radiotracer analysis of the solutions and those determined by weighing. A comparison of the two methods by statistical means[2] yields a standard deviation of ~6%. However, for minute ^{129m}Te additions to the solution, tracer analysis was considered more reliable than weighing; hence, below 10^{-3} a/o additions, tracer concentrations are listed in Table I.

[1] The source materials used for these experiments were phosphine-grown polycrystalline GaP (Monsanto) and Te (United Minerals), both with 99.9999% nominal purity. A batch of 99% enriched ^{128}Te was irradiated for 6 weeks in a neutron flux of 9×10^{13} cm^2/sec to yield ^{129m}Te (Union Carbide, Tuxedo, New York). The undoped LEC substrates, mechanically polished on the phosphorus (B) face, were obtained from Bell Laboratories, Reading.

[2] In the absence of errors, the ratio of the i'th concentration determined by the tracer and weighing techniques, C^i_t/C^i_w should be unity. Hence, the standard deviation $\sqrt{(\Sigma_i (C^i_t/C^i_w - 1)^2)/n}$ where n is the number of measurements, is a reasonable representation of the pertinent error.

Table I. Solid-solubility data for Te in GaP

Average growth temperature (°C)	x^{l}_{Te} (atom fraction)	C^{s}_{Te} (atoms/cm³)

The tabulated ^{129m}Te solubility data for ~935° and ~1040°C were obtained, in general, by averaging the concentrations determined by the two above mentioned methods. However, on account of the previously discussed heavy Te accumulation in the first few sections, the listed ~1135°C solubility data are based on the analysis of the remaining layer. Extrapolation of the N_D-N_A profiles to the electrical junction yielded the additional data presented in Table I where it is assumed that $C^{s}_{Te} = N_D$-N_A.

The tabulated values of C^{s}_{Te} as a function of x^{l}_{Te} are plotted in Fig. 1 for the LPE layers grown at ~1040°C, and in Fig. 2 for those grown at ~935° and ~1135°C. Solid-solubility data from the investigations of Trumbore *et al.* (3) and Saul and Hackett (12) are also shown. The data of Trumbore *et al.* (3) were based on the spectrophotometric analyses of the total Te concentration in crystals grown by a thermal gradient transport (TGT) technique over a period of 5

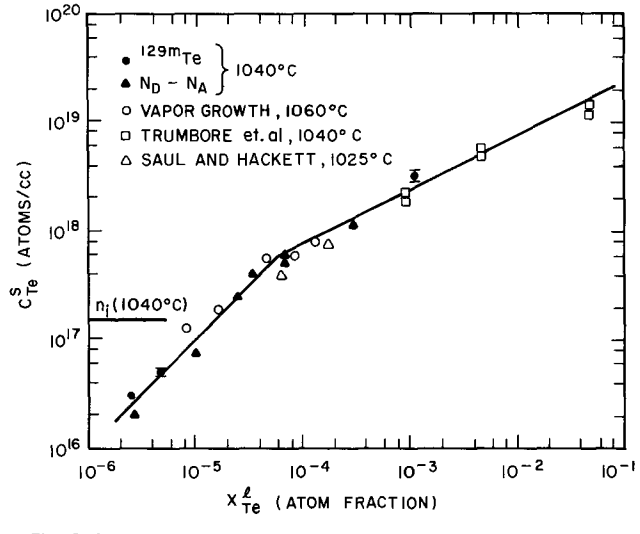

Fig. 1. Te concentration in GaP as a function of the Te content of the LPE solution at ~1040°C. The error bars indicate the concentration limits obtained by sectioning and the total count-rate of the remaining layer. In the linear incorporation regime, the solid line was based on Eq. [8]. The abscissas for vapor-grown crystals are actually calculated Te activities which correspond to Te atom fractions for an ideal solution.

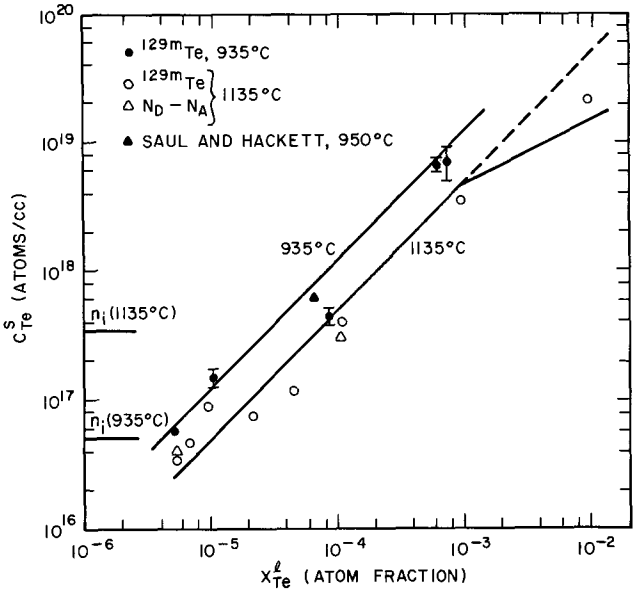

Fig. 2. Te concentration in GaP as a function of the Te content of the LPE solution at ~935° and ~1135°C. The error bars indicate the concentration limits obtained by sectioning and the total count-rate of the remaining layer. In the linear incorporation regimes, the full lines were based on Eq. [8]. The dashed line at ~1135°C shows the extrapolation of surface-controlled incorporation behavior to high doping levels.

weeks at ~1040°C.[3] Combining the N_D-N_A and calculated temperature profiles of epitaxial layers, Saul and Hackett (12) determined at a constant x^{l}_{Te} the temperature dependence of the Te solubility in GaP grown by sealed-tube tipping over a wide temperature range. Here only values of N_D-N_A at the junction corresponding to their two measured initial tipping temperatures are shown. The agreement among the three sets of data, where they overlap, is reasonably good and is probably within the experimental errors of the various investigations.

In addition to the above data obtained for crystals grown from saturated solutions, Fig. 1 also includes the Te solubility in epitaxial layers prepared at ~1060°C by the water-vapor transport process (13). The Te-doping of these samples was accomplished via the gas phase by the H_2 transport of Te from a reservoir held at a constant temperature to the deposition zone. The plotted values of C^{s}_{Te} were obtained from x-ray fluorescence analysis (14), while the following thermodynamic reasoning led to the assignment of x^{l}_{Te}. Knowing the reservoir temperature, the weight-loss of Te, the flow-rate, and the duration of a run the partial pressure of Te was calculated as a function of reservoir temperature from the ideal gas law. The recently tabulated vapor pressure (15) of $Te_2(g)$ is in reasonable agreement with the values derived from the experimental data (13). However, in the absence of kinetic factors, $Te_2(g)$ almost completely dissociates to Te(g) of partial pressure p_{Te} at the deposition temperature. Hence, the activity $a_{Te} = p_{Te}/p^{o}_{Te}$ can be computed for vapor growth where p^{o}_{Te} is the vapor pressure of pure superheated Te(l) (15) at the deposition temperature. In Fig. 1 values of a_{Te} are plotted on the abscissa which equal x^{l}_{Te} assuming ideal liquid-solution behavior. In view of these approximations and the differences in growth temperatures, the similarity in the solubility behavior between vapor growth and solution growth is quite striking.

An analysis of the solubility data requires a knowledge of the incorporation chemistry of Te in GaP. By analogy with the incorporation of Te in GaAs (7), the simplest defect reaction describing the incorporation

[3] The N_D-N_A data of Trumbore *et al.* (3) are not included in Fig. 1; they generally disagree with the present results at low concentrations and also show heat-treatment effects, the cause of which was not determined.

of a singly ionized donor from an external phase (liquid) is given by

$$Te(l) + V_P = Te_P^+ + e^- \quad [1]$$

Assuming that species in the crystalline solid form an ideal dilute solution and Te is completely ionized, then the equilibrium constant K for Eq. [1] can be written as

$$K = \frac{C^s_{Te}\, n}{\gamma_{Te} x^l_{Te} C_{VP}} \quad [2]$$

where n and C_{VP} are the electron and phosphorus vacancy concentrations in GaP, respectively, and γ_{Te} is the activity coefficient of Te in the ternary (Ga-P-Te) solution. At a constant temperature and for dilute solutions, γ_{Te} and C_{VP} can be assumed to be constant so that Eq. [2] becomes

$$\kappa \simeq \frac{C^s_{Te}\, n}{x^l_{Te}} \quad [3]$$

where $\kappa = K\gamma_{Te}C_{VP}$ is the new equilibrium constant.

Combining Eq. [3] with the electroneutrality condition ($C^s_{Te} + p = n$) and the mass action relationship for electrons and holes ($pn = n^2_i$) (an operation permissible if the external phase is in equilibrium with the bulk of the growng crystal) an explicit expression between C^s_{Te} and x^l_{Te} is obtained. From this relationship the following two limiting results are derived

$$C^s_{Te} \simeq K' x^l_{Te} \text{ if } C^s_{Te} < n_i \text{ (intrinsic case)} \quad [4]$$

$$C^s_{Te} \simeq K'' (x^l_{Te})^{1/2} \text{ if } C^s_{Te} > n_i \text{ (extrinsic case)} \quad [5]$$

with a break from linear to square-root behavior centered at $C^s_{Te} \simeq n_i$.

Taken as a whole, the data in Fig. 1 confirm the change from a linear to square-root dependence of C^s_{Te} on x^l_{Te} with increasing doping, as suggested by Trumbore *et al.* (3). However, the break occurs at $\sim 6 \times 10^{17}$ cm^{-3},[4] well above the presently accepted value of $n_i \simeq 1.5 \times 10^{17}$ cm^{-3} at 1040°C (8) and is lower by 1-2 orders of magnitude than the break points for S and Se in GaP at the same temperature (3).

No such shift from linear to square-root behavior was found by Casey *et al.* for Te in GaAs (7). These authors reported a linear dependence of C^s_{Te} on x^l_{Te} in LPE layers grown at 1000°C even at doping levels nearly two orders of magnitude higher than n_i. To explain the lack of a square-root behavior, Casey *et al.* (7) invoked the surface-band bending (SBB) model of Zschauer and Vogel (10). According to this model, for a slowly diffusing impurity, such as Te, at rapid growth rates equilibrium is established between the external phase and the semiconductor surface, but not between this surface and the bulk of the crystal. Considering the growth interface as a liquid-metal semiconductor Schottky barrier, the electron concentration at the surface, n_s, remains constant, independent of doping, due to the pinning of the Fermi level at the surface. Thus a constant n_s (function of temperature only) would be substituted for n in Eq. [3] and hence a linear dependence of C^s_{Te} on x^l_{Te} represented by

$$C^s_{Te} = K'_{SBB} x^l_{Te} \quad [6]$$

is to be expected at all doping concentrations (7).

There is no doubt that surface-controlled incorporation (SCI) of slowly diffusing impurities is a common occurrence in semiconductor crystal growth as evidenced by the well-known "facet" (orientation) effect. Whether or not the SBB model can explain all of the observed results to date is not yet clear and other mechanisms have been proposed to explain SCI in elemental as well as III-V semiconductors. For example, Banus and Gatos (16) interpreted the orientation dependence of S-doping in pulled InSb crystals in terms of adsorption isotherms which vary with orientation but approach each other at high impurity concentrations. Lavrent'eva *et al.* (17) have recently explained the orientation dependence of doping in heteroepitaxial Ge films by means of Chernov's theory of step-layer growth, which assumes that the diffusion length of the adsorbed impurity atom is much greater than that of Ge. That "faceting" also occurs in GaP is shown by the recent observation of "coring" in n-type LEC ingots (18). Recognizing the possibility of alternate SCI mechanisms, we shall attribute the linear portion of the curve in Fig. 1 to Te incorporation controlled by SBB.

The fact that within experimental error the chemically determined Te concentration is equal to N_D-N_A is taken as evidence that the simple incorporation reaction given in Eq. [1] is indeed the appropriate reaction to consider in the concentration range involved. If we accept Eq. [1], we conclude that the square-root regime corresponds to bulk-equilibrium behavior presented in Eq. [5]. Naturally, the question arises as to the reasons for the switch from surface-controlled to bulk-equilibrium behavior. A possible explanation may be provided by the work of Zschauer and Vogel (10) showing that bulk equilibrium is approached if the diffusion coefficient of the impurity (*e.g.*, Te) is sufficiently large compared to the growth rate of the crystal.[5] Hence, if the diffusion coefficient sharply increases with increasing impurity concentration, a shift to the square-root regime occurs. Unfortunately, at present there is only limited data on the concentration dependence of the diffusion coefficients of Group VI impurities in GaP to decide whether this factor governs the apparent equilibrium behavior of relatively highly Te-doped GaP (as well as S, and Se-doped GaP, and S-doped GaAs).[6] However, the temperature dependence of the solid solubility to be discussed below, may shed some light on this question.

Regardless of the mechanism involved, the observed equilibrium behavior at higher doping levels leads to the following interesting conclusion: at the lower doping levels, less than the bulk equilibrium solubility of Te in GaP is being achieved.[7] This is a consequence of the fact that Eq. [4] and [5] require a break from linear to square-root behavior to occur around n_i. Hence, we may extrapolate the bulk equilibrium portion of the curve to lower doping levels to a first approximation as shown in Fig. 3. As discussed later, this observation could have important implications in connection with the incorporation of oxygen in GaP and the efficiency of red LED's.

Temperature dependence of the solubility behavior: evaluation of the distribution coefficient.—The Te solid-solubility data obtained at ~935°C (Fig. 2) shows a linear dependence of C^s_{Te} on x^l_{Te} up to nearly $\sim 10^{19}$ cm^{-3} doping levels, more than two orders of magnitude above n_i at that temperature.[8] There is no break to a square-root behavior as at ~1040°C (Fig. 1) and the observed linearity is similar to the behavior reported by Casey *et al.* (7) for Te in GaAs at 1000°C. It seems reasonable to attribute this difference in the ~1040° and ~935°C behavior to lower diffusion coefficients for Te at the lower growth temperature, thus permitting SCI, in general, or SBB, in particular, to prevail at all doping concentrations.

However, this rather plausible explanation of the temperature effect is tempered by the ~1135°C data (Fig. 2). Here, one presumably would expect higher diffusion coefficients than at ~935° or ~1040°C, resulting in a closer approach to bulk equilibrium. Apparently, this is not the case at ~1135°C, since the

[4] This break is about a factor of three lower than the one reported by Trumbore *et al.* (3) which was inferred from questionable N_D-N_A data (see footnote 3).

[5] The fact that Zn in GaP follows bulk-equilibrium behavior was attributed to its large diffusion coefficient by Trumbore *et al.* (3).

[6] It is interesting to note that Young and Pearson (19) observed a cusp in the 1235°C diffusion coefficient of S in GaP at the same concentration where the break appears ($\sim 2 \times 10^{19}$ cm^{-3}) in S-doped crystals grown by TGT at ~1040°C.

[7] Earlier Trumbore and Nash (20) arrived at this same conclusion in a comparison of the solubility behavior of Bi with S, Se, and Te in GaP.

[8] Similarly, in vapor-grown GaP, Taylor (35) has observed a linear dependence at a temperature as low as 800°C.

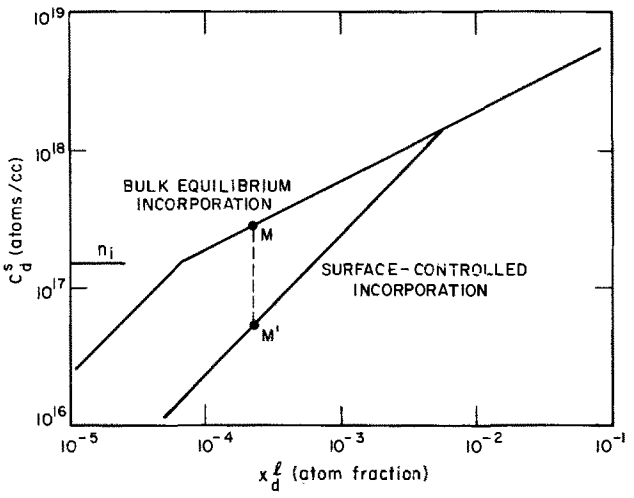

Fig. 3. A schematic comparison of bulk-equilibrium and surface-controlled incorporation at ~1040°C. This diagram is essentially a generalization of the behavior found in Fig. 1. It shows the donor concentration (C^s_d) in GaP as a function of the donor content (x^l_d) of the tipping solution. The points M' and M roughly correspond to the substitutional oxygen solubility approached by surface-controlled and bulk-equilibrium incorporation at oxygen saturation in the ternary Ga-P-Ga_2O_3 solution.

break to square-root behavior, if present at all, occurs in the mid 10^{18} cm^{-3} doping level range, well above the break point found at ~1040°C. (The increase in n_i in going to ~1135° from ~1040°C is a little over a factor of two). The appreciable scatter in the experimental data at ~1135°C, together with the fact that the diffusion coefficient of Te is an unknown function of both doping level and temperature, precludes a self-consistent explanation in terms of diffusion at this time.

Nonetheless, the linear segment at low Te concentrations, extending well above n_i, is a common feature of the solid-solubility isotherms at all three temperatures. Hence, a concentration-independent, distribution-coefficient, k_{Te}, can be derived as a function of the average growth temperature. Since data have been obtained over a wide concentration range and there is appreciable scatter, it was thought appropriate to apply the method of logarithmic least squares to the analysis (5). Briefly, at a given temperature for the i'th solubility determination the following relationship holds

$$\log x^{s,i}_{Te} = \log k_{Te} + \log x^{l,i}_{Te} \qquad [7]$$

where $i = 1, 2 \ldots n$ and $x^{s,i}_{Te}$ is the atom fraction of Te in GaP. The n equations represented by Eq. [7] can be solved for the "best" value of log k_{Te} (intercept) by the method of single parameter least squares (21) to yield

$$\log k_{Te} = \frac{\Sigma \log x^{s,i}_{Te} - \Sigma \log x^{l,i}_{Te}}{n} \qquad [8]$$

The solid lines drawn in Fig. 1 and 2 in the linear regime were based on the "best" values of k_{Te} calculated according to Eq. [8].

In Fig. 4 we present values of k_{Te} as a function of reciprocal-growth temperature, together with the standard deviations of k_{Te}.[9] These results are complemented with values of k_{Te} at ~1025° and ~950°C, obtained from the previously discussed work of Saul and Hackett (12), and at the melting point of GaP (1465°C), determined by Nygren *et al.* (18) on Te-doped LEC ingots, all derived from surface-barrier capacitance measurements. A monotonic decrease of k_{Te} with increasing temperature is apparent from the data in Fig. 4. Indeed, such temperature dependence of

[9] Transforming the well-known expression for the standard deviation in the intercept of linear least squares (21) we obtain the formula $[\Sigma(\log k^{i}_{Te}/k_{Te})^2]^{1/2}/n$ for use in this analysis where $k^{i}_{Te} = x^{s,i}_{Te}/x^{l,i}_{Te}$.

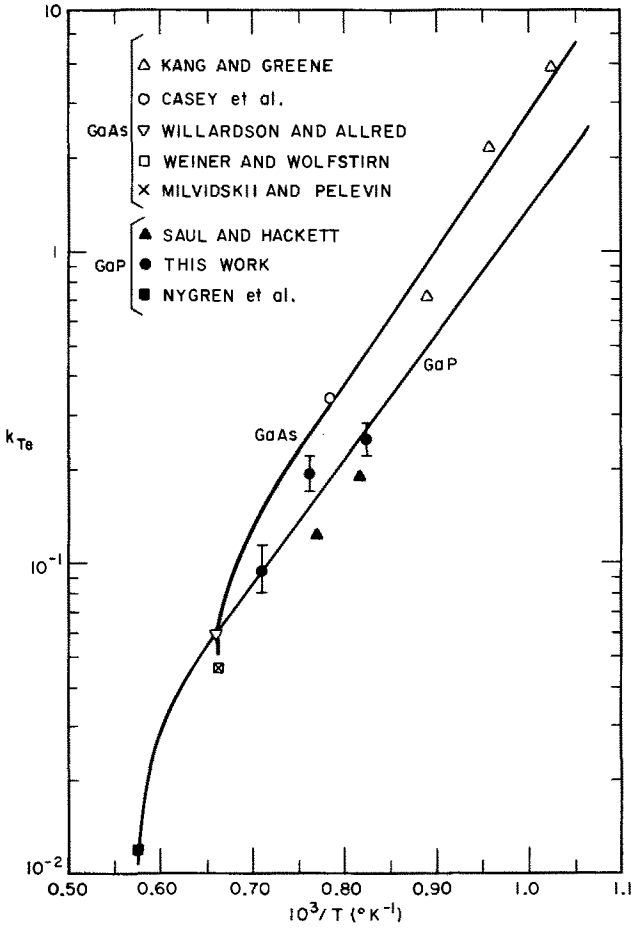

Fig. 4. A comparison of the calculated (Eq. [11]) and experimental distribution coefficients for Te in GaP and GaAs (along the respective Ga-rich liquidus curves) as a function of reciprocal temperature.

k_{Te} has been observed by Saul and Hackett (12) in their temperature range.

In addition to values of k_{Te} for Te-doped GaP, Fig. 4 also includes similar data for Te-doped GaAs. The 1000°C data of Casey *et al.* (7) on LPE layers were determined by radiochemical analysis. The melting point (1238°C) data of Willardson and Allred (22) on Czochralski pulled ingots, and of Milvidskii and Pelevin (6) on crystals grown by horizontal directional crystallization, were obtained by Hall coefficient measurements (confirmed by mass spectroscopy) and chemical analysis, respectively. The k_{Te} values derived from all three investigations were based on linear-solubility behavior which was shown to extend over a wide concentration range. However, a single doping concentration at a given temperature characterizes the surface-barrier capacitance results of Kang and Greene (23) on epitaxial films grown by a modified TGT technique and the radiochemical determination of Weiner and Wolfstirn (24) on a LEC ingot pulled at 1238°C, all of which we assume to belong to the linear incorporation regime.

It is immediately obvious from Fig. 4 that, although at a given temperature the k_{Te} values for GaAs are somewhat higher than for GaP, similar trends prevail in the temperature dependence of k_{Te} for both compounds, the slopes being nearly equal. Hence, we conclude that if surface-band bending is responsible for the linearity of Te incorporation in GaAs at 1000°C, as advocated by Casey *et al.* (7), then it seems likely that the linear region for both compounds at all temperatures is associated with the same mechanism.

Having established the common features of k_{Te} for GaAs and GaP, it is desirable to devise an extrapolation and interpolation technique to describe the ex-

perimental data. Although in principle the analysis could proceed directly from Eq. 2, we begin with a modification of Eq. [1] due to computational convenience as C_{VP} is not known. Let us add the defect reaction

$$P_P = V_P + P(l)$$

to Eq. [1]. Then, eliminating C_{VP} we obtain

$$Te(l) + P_P = P(l) + Te_P^+ + e^- \quad [9]$$

Since the concentration of phosphorus atoms on their own sites is nearly constant and we provisionally accept the SBB model, the equilibrium constant for Eq. [9], K_{Te}, can be written in the form

$$K_{Te} = \frac{a_P C^s_{Te} n_s}{\gamma_{Te} x^l_{Te}} = \frac{a_P k_{Te} n_s \times 4.94 \times 10^{22}}{\gamma_{Te}} \quad [10]$$

where a_P is the phosphorus activity in the Ga-P-Te ternary liquid solution which for small Te additions nearly equals a_P in the Ga-P binary.

In general, log K_{Te} varies linearly with $1/T$ over the entire temperature range, while the log k_{Te} *vs.* $1/T$ plot is linear only at low temperatures. Thus, to extrapolate log k_{Te} up to the melting point of the compound, some assumptions must be made concerning the temperature dependence of the unknown quantities in Eq. [10]. Specifically, we assume that log γ_{Te} and log n_s, compared to the variation with temperature of the other relevant quantities, are linear functions of $1/T$ within a good approximation over the entire temperature range. Hence, a new equilibrium constant, K'_{Te}, is defined and Eq. [10] becomes

$$\frac{K_{Te}\gamma_{Te}}{n_s \times 4.94 \times 10^{22}} \approx K'_{Te}(T) = a_P k_{Te} \quad [11]$$

Obviously, if the subscript As is introduced in place of P, equations similar to Eq. [10] and [11] also hold for Te-doped GaAs.

Values of $K'_{Te}(T)$ were evaluated for GaP and GaAs by combining the k_{Te} data plotted in Fig. 4, excluding results at the melting points, with the activities a_P and a_{As} obtained from the work of Thurmond (25). The linear dependence of log $K'(T)$ on $1/T$, which follows from Eq. [11] and the assumptions involved in its derivation permitted the application of the method of least squares to the $K'(T)$ data to calculate the line of best fit. Then, the solid curves, illustrated in Fig. 4, for k_{Te} in GaP and GaAs were evaluated over the entire temperature range by combining the respective line of best fit with values of a_P and a_{As} according to Eq. [11].

As seen in Fig. 4, a generally good agreement is achieved between the calculated k_{Te} curves and the experimental points.[10] Of particular importance here is the predicted downturn in k_{Te} for both compounds in the vicinity of their melting points. This indicates that the calculation is self-consistent since the melting point data which were excluded from the analysis are also described by the curves. Although not shown in Fig. 4, log k_{Te} is actually a double-valued function of $1/T$, thus for crystals grown from a P or As-rich solution, k_{Te} should turn over, *i.e.*, probably rise again with decreasing temperature. Finally, as is the case for the equilibrium constants for the incorporation of Zn in GaP and GaAs (5), the k_{Te} curves are nearly parallel for Te-doped GaP and GaAs.

Implications for the surface-controlled and bulk-equilibrium incorporation of O in GaP.—A high concentration of substitutional oxygen in GaP is considered to be desirable for the attainment of high efficiency LED's since it leads to an increased number of nearest neighbor pairs. However, in spite of its importance, the incorporation chemistry of oxygen is the least well understood of the significant dopants in GaP. Recently, several investigators have reported on the oxygen solubility in GaP. Although many of these results disagree, they generally lie within a concentration range which is less than an order of magnitude.

The solubility of oxygen in GaP, taken from Saul (26) and Lightowlers *et al.* (27) is shown as a function of reciprocal temperature in Fig. 5. By a combination of surface-barrier capacitance measurements on Zn and Zn-O-doped LPE layers, Saul (26) deduced the concentration of ionized oxygen donors on phosphorus sites $C^s_{O_P}{}^+$. Surprisingly his $C^s_{O_P}{}^+$ data exhibit a maximum ($\sim 2.7 \times 10^{17}$ cm^{-3}) in the vicinity of the normal LPE growth temperatures ($\sim$1000°-1050°C).[11] The results of Lightowlers *et al.* (27), based on prompt α-particle nuclear microanalysis of the total oxygen concentration in Zn-O-doped LPE layers grown by a sealed-tube slider technique (9) in a restricted temperature range, are about a factor of five lower ($\sim 5 \times 10^{16}$ cm^{-3}) for layers grown at a temperature near Saul's maximum, although the analytical value very likely includes interstitial oxygen. Both studies took note of the work of Kowalchik *et al.* (9) concerning the coprecipitation of Ga_2O_3 with GaP from tipping solutions which contain Ga_2O_3 additions in excess of values permitted by the Ga-P-Ga_2O_3 ternary eutectic valley (9). Since they were grown from solutions with a large excess of Ga_2O_3 added, Saul's (26) LPE layers contained precipitates, assuring oxygen saturation. In contrast, the LPE solutions used by Lightowlers *et al.* (27) were barely saturated with Ga_2O_3, since the

[11] It should be noted that Saul's results (26) at the higher temperatures may be affected by a significant background contribution.

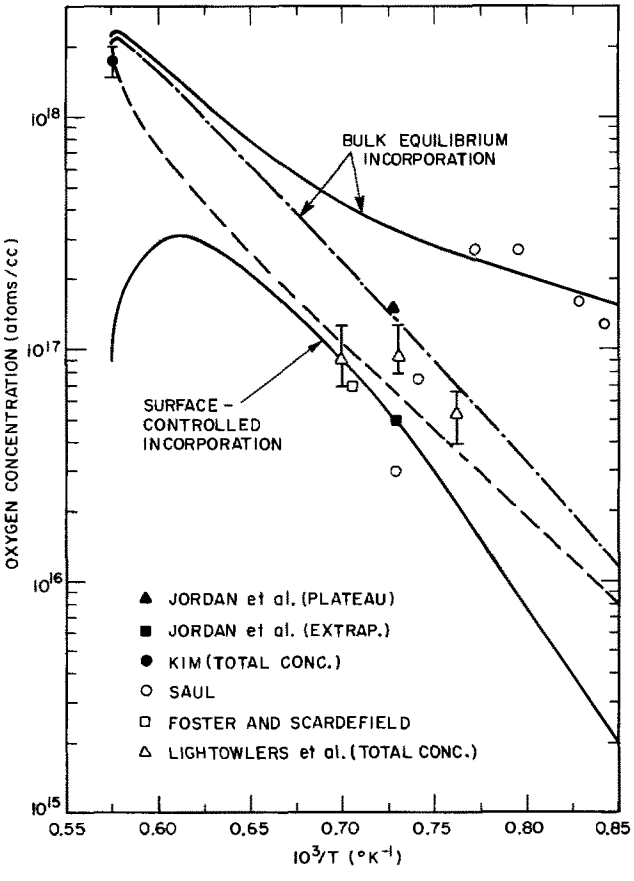

Fig. 5. Oxygen solid solubility in GaP as a function of reciprocal temperature. The lower solid line shows the estimated oxygen solubility by surface-controlled (Eq. [13]) incorporation. The upper solid line and the line -·-·-·- represents bulk equilibrium incorporation (Eq. [16], [17]) for $\bar{C}^s_{ZnGa^-} = 5 \times 10^{17}$ and $\bar{C}^s_{ZnGa^-} = 0$, respectively. The line – – – – represents interstitial solubility and is based on the data of Berman (30) which was obtained between ~900° and 1325°C.

[10] Note that the intermediate k_{Te} data of Saul and Hackett (12), based not on a measured, but calculated, growth-temperature history of an LPE layer, are in accord with the k_{Te} line for GaP. Likewise, for Zn-doped GaP their simple method (11) led to good agreement with independently obtained solid-solubility calculations (5).

presence of precipitates precludes any meaningful determination of the oxygen in solid solution.

Accepting the validity of both sets of data, we attempt to resolve their disagreement in terms of the absence or presence of precipitates which governs, in our view, the predominant mode of oxygen incorporation, namely surface controlled or bulk equilibrium. We have previously concluded, in conjunction with Fig. 3, that for a slowly diffusing impurity, such as Te, at lower doping levels the solubility corresponding to SCI is less than that by bulk-equilibrium incorporation. Let us assume a similar situation prevails for oxygen. In the absence of precipitates (Lightowlers *et al.*'s case), SCI predominates and the solubility of substitutional oxygen increases with increasing Ga_2O_3 addition to the maximum value M' (Fig. 3). However, if the Ga_2O_3 contained in the LPE solution exceeds the abscissa of M' (Saul's case), coprecipitation of Ga_2O_3 takes place simultaneously with the initial SCI of M' oxygen atoms. Once a segment of the epitaxial film is grown, the presence of Ga_2O_3 precipitates permits equilibration with the GaP matrix, in a manner that eventual O solubility is no longer surface controlled. For a sufficiently large density of precipitates, diffusional limitations, even for a slowly diffusing impurity, are minimized; hence the bulk-equilibrium value of substitutional oxygen solubility can be reached while the crystal is still at a relatively high temperature in the LPE furnace. Thus the actual value of $C^s_{O_P+}$ moves from M' to M (Fig. 3) as measured by Saul (26).

The substitutional oxygen concentration estimated from photoluminescence measurements on $Zn(PO_3)_2$ doped, solution-grown platelets (28) seems to support the above interpretation. A linear extrapolation of the oxygen concentration for platelets grown from a solution containing $\sim 3.1 \times 10^{-2}$ a/o O to the ternary liquid-solubility limit ($\sim 4.8 \times 10^{-2}$ a/o O) yields $5 \pm 2.5 \times 10^{16}$ cm^{-3} at the average growth temperature of 1100°C. The oxygen concentrations in three other crystals grown from solutions with higher and varying amounts of $Zn(PO_3)_2$ added to the melt lie on a plateau closely centered around 1.5×10^{17} cm^{-3}. With respect to these values which are plotted in Fig. 5, we suggest that the low one corresponds to SCI, while the plateau point reflects bulk-equilibrium incorporation.[12]

A more concrete description of these two modes of incorporation can be given by estimating the temperature dependence of oxygen incorporation in GaP by means of simplified defect chemical analysis. First, we attempt to calculate the variation of $C^s_{O_P+}$ with temperature if SCI predominates. Let us rewrite Eq. [9] to represent O instead of Te incorporation. Then, we have

$$O(l) + P_P = P(l) + O_P^+ + e^- \qquad [12]$$

Accepting the assumptions leading to Eq. [11] including specifically the SBB model, we find

$$K'_O(T) = a_P k_O \qquad [13]$$

A combination of the $\sim$1100°C value of $C^s_{O_P+} = 5 \times 10^{16}$ cm^{-3}, derived from the work of Jordan *et al.* (28) with the O solubility in the Ga-P-Ga_2O_3 (9) ternary solution, yields $k_O = 2.25 \times 10^{-3}$. We may assume, as before, that for the SBB model log $a_P k_O$ is a linear function of $1/T$, but lacking any information concerning the slope of log k_O as a function of $1/T$, additional assumptions are required.

Let us assume that at low doping levels the incorporation of the Group VI dopants O, S, Se, and Te obeys the SBB model and that equivalents of Eq. [9] hold for S and Se. This permits a correlation of the slopes of these Group VI distribution coefficients. In particular, the slope of log k_{Te} *vs.* $1/T$, related to the enthalpy of incorporation, was directly obtained from the low temperature portion of Fig. 4. The corresponding slopes for S and Se were obtained from curves similar to Fig. 4. These curves were constructed on the basis of equations of the type given in Eq. [9] from the data of Trumbore *et al.* (3) at 1040°C and Nygren *et al.* (21) at the melting point of GaP in combination with values of a_P taken from the work of Thurmond (25). Then, by a linear extrapolation of the slopes $d \log k_d / d\ 1/T$ as a function of the normalized Pauling tetrahedral (29) radius differences $(r_d - r_P)/r_P$, where d denotes the donors S, Se, or Te, d log k_O/d 1/T corresponding to the abscissa $(r_O - r_P)/r_P$ was determined. A knowledge of the low temperature slopes d log k_O/d $1/T$ and d log a_P/d $1/T$ together with the 1100°C values of k_O and a_P yields the function $K'_O(T)$. Finally, a combination of the ternary eutectic valley (9) describing the liquid composition, the $K'_O(T)$ function and a_P provides the maximum solid-solubility $C^s_{O_P+}$ allowed by surface-controlled incorporation in the absence of Ga_2O_3 precipitates. This is plotted as the lowest curve in Fig. 5.

Next, we estimate the variation of $C^s_{O_P+}$ with temperature for bulk-equilibrium incorporation. If precipitates are present in the matrix (or if excess Ga_2O_3 is contained in the growth system), the incorporation of O can be described by the equilibrium

$$Ga_2O_3(s) = 2Ga_{Ga} + V_{Ga} + 3O_P^+ + 3e^- \qquad [14]$$

To find a more convenient relationship for subsequent analysis, let us add the reaction

$$V_{Ga} + P_P = P(l)$$

to Eq. [14]. Then, we have, eliminating V_{Ga}

$$Ga_2O_3(s) + P_P = 2Ga_{Ga} + 3O_P^+ + 3e^- + P(l) \qquad [15]$$

The equilibrium constant, K_B, for Eq. [15] is given by

$$K_B = (C^s_{O_P+})^3 n^3 a_P \qquad [16]$$

Assuming that the oxygen donors are completely ionized in p-type (Zn-doped) material, a detailed consideration of the simultaneous Zn and O incorporation yields n in Eq. [16] in the form

$$n = 2n^2 \frac{C^s_{O_P+} + \sqrt{(C^s_{O_P+})^2 + \zeta^2}}{\zeta^2} \qquad [17a]$$

where

$$\zeta \equiv \sqrt{(\bar{C}^s_{Zn_{G\bar{a}}})^2 + 4n_i^2} + \bar{C}^s_{Zn_{G\bar{a}}} \qquad [17b]$$

and the bar in $\bar{C}^s_{Zn_{G\bar{a}}}$ signifies that it is the zinc acceptor concentration in GaP grown from a solution containing only Zn at the same zinc and phosphorus activities and temperature which are employed in the growth of the Zn-O-doped crystal.[13] Accepting that bulk-equilibrium incorporation of oxygen alone is responsible for the solubilities reported by Saul (26) up to perhaps 1025°C, we evaluated log K_B as a function of $1/T$ from Eq. [16] and [17] in combination with the experimental data. Extrapolation of the log K_B data to the melting point of GaP allows the calculation of $C^s_{O_P+}$ from Eq. [16] and [17] at all temperatures and zinc acceptor levels of interest.

[12] Likewise, recently Saul and Hackett (36) have shown for GaP layers grown at $\sim$1025°C that increasing the oxygen addition to the solution from 1.5×10^{-2} a/o (which is below the solubility limit of 2×10^{-2} a/o) to the range between 6×10^{-2} and 1.05 a/o leads to a drastic rise in the oxygen donor concentration from 3×10^{16} to a constant plateau value of 2.7×10^{17} cm^{-3}.

[13] The basis for this calculation has been presented by Saul and Hackett (11). Briefly, six equations are available for the eight unknown variables $\bar{C}^s_{Zn_{G\bar{a}}}$, $C^s_{Zn_{G\bar{a}}}$, $C^s_{O_P+}$, $\bar{p}$, p, $\bar{n}$, n, and K_{Zn}. Hence, one can express at any T, n as a function of $C^s_{O_P+}$ and $\bar{C}^s_{Zn_{G\bar{a}}}$. The equations for Zn and Zn-O-doped crystals are the hole-electron equilibrium relationships ($\bar{p}\bar{n} = n_i^2$, $pn = n_i^2$), the electroneutrality conditions ($\bar{p} = \bar{n} + \bar{C}^s_{Zn_{G\bar{a}}}$, $p + C^s_{O_P+} = n + C^s_{Zn_{G\bar{a}}}$) and the defect equilibria

$$P(l) + Zn(l) = Zn_{G\bar{a}} + e^+ + P_P$$

for which $K_{Zn} = \bar{C}^s_{Zn_{G\bar{a}}} \bar{p}/a_{Zn} a_P = C^s_{Zn_{G\bar{a}}} p/a_{Zn} a_P$

In Fig. 5 we show two zinc isoconcentration curves for the bulk-equilibrium incorporation of substitutional oxygen. One curve (dash-dot) at $\overline{C}^{s}_{Zn_{Ga}} = 0$ is for a hypothetical n-type oxygen-doped crystal; the other one (solid line) corresponds to $\overline{C}_{Zn_{Ga}} = 5 \times 10^{17}$ cm^{-3}. The two curves nearly overlap at the melting point and the position of the curves for intermediate values of $\overline{C}^{s}_{Zn_{Ga}}$ can be easily imagined.

In addition to these curves representing the two modes of substitutional oxygen incorporation in GaP, we also give in Fig. 5 (dashed line) an extrapolation to the GaP melting point of the interstitial oxygen data of Berman (30) based on an analysis of the infrared absorption spectra of annealed LEC crystals (31). To perform the extrapolation let us add the following reactions, assuming the presence of neutral interstitials, to Eq. [14]

$$3O_P^+ + 3V_i + 3e^- = 3O_i + 3V_P$$
$$2P(l) = 2V_{Ga} + 2P_P$$
$$3V_{Ga} + 3V_P = 0$$

Then, we find

$$2P(l) + 3V_i + Ga_2O_3(s) = 2Ga_{Ga} + 2P_P + 3O_i \quad [18]$$

where the subscript i refers to interstitial species. Since the concentration of V_i is large and insensitive to temperature, the equilibrium constant K_i for Eq. [18] can be written as

$$K_i = \frac{(C^{s}_{O_i})^3}{a_P^2} \quad [19]$$

where $C^{s}_{O_i}$ is the concentration of interstitial oxygen atoms. Applying Eq. [19] to Berman's data (30), log K_i was evaluated as a function of $1/T$ and extrapolated to the melting point of GaP. Subsequently $C^{s}_{O_i}$ was calculated from Eq. [19] over the entire temperature range of interest.

Finally, Fig. 5 includes the oxygen solubilities reported by Foster and Scardefield (32), deduced from the degree of compensation in Zn, O-doped crystals grown from solutions at 1144°C,[14] and Kim (33), obtained by ^{3}He activation analysis (34) of O-doped LEC crystals.

The following interesting, although tentative conclusions can be drawn from Fig. 5:

(*i*) It appears that the total oxygen concentration reported by Lightowlers *et al.* (27) is the sum of the interstitial and surface-controlled substitutional solubilities.

(*ii*) The value of Jordan *et al.* (28) along the plateau is likely due to bulk-equilibrium incorporation since it is comparable to the low temperature results of Saul (26), if the temperature range for solution growth and the error associated with the optical estimate (~50%) is taken into account.

(*iii*) Although the average growth temperature of Foster and Scardefield (32) is to some extent uncertain, their incorporation mechanism is probably surface controlled which is also consistent with the small Ga_2O_3 additions employed (0.048 a/o O).

(*iv*) The maximum and downturn in the data of Saul (26) (above ~985°C) is caused by a transition from bulk-equilibrium to surface-controlled incorporation as the density of precipitates for a constant Ga_2O_3 addition to the solution decreases with increasing temperature.

(*v*) Kim's result (33), a total oxygen measurement, seems to be predominantly due to interstitial oxygen.

If the above explanation is indeed correct, some precipitation is desirable to obtain higher oxygen concentrations and consequently higher efficiency red LED's. However, excessive precipitation leads to contacting difficulties and degraded device performance (9). In addition, the postulated importance of Ga_2O_3 precipitates could account for much of the difficulties in reproducing the same efficiency from run to run or even obtaining uniform efficiencies. Obviously, further experimental work is required to confirm these ideas concerning the two modes of oxygen incorporation in GaP.

[14] Actually Foster and Scardefield (32) terminated their solution-growth experiments at 850°C; hence, the average growth temperature may be lower than the reported liquidus temperature.

Characteristics of [115] Dislocation-Free Float-Zoned Silicon Crystals

T. F. Ciszek[1]

Dow Corning Corporation, Hemlock, Michigan 48626

ABSTRACT

Dislocation-free silicon crystals with [115] crystallographic orientation were grown by the float-zone method. The relatively high (115) surface free energy allows more uniform growth, particularly for dopant incorporation, than that which is characteristic of low surface free energy planes such as (111). The macroradial variation of resistivity in phosphorus-doped [115] crystals is typically less than 5%. Also, low surface-state charge densities can be achieved using low oxygen content [115] float-zoned crystals. (100) wafers, circular within 4%, may be cut from these crystals.

The majority of float-zoned silicon crystals for semiconductor use have historically been grown in <111> orientations. This was favorable for early alloy junction devices since the {111} planes tended to define a sharp junction boundary. In the early 1960's, crystal suppliers attempted <100> crystal zoning and were successful up to diameters of about 18 mm. As diameters were increased above 20 mm, large angle grain boundaries were found to occur, preventing the growth of good quality crystals; thus essentially all zoning efforts again reverted to the <111> orientations. Recently, the advances in dislocation-free and large diameter <111> float-zoning technology have made float-zoned crystals attractive for MOS devices. For this application, <100> crystals are desirable because of the low {100} Si/SiO_2 surface-state charge density (1) and favorable device die separation. Thus there is a revival of interest in <100> growth by the float-zone method.

The <115> crystallographic directions have been found to be viable orientations for dislocation-free silicon float-zoning; and <115> crystals have several properties of interest for MOS applications as well as other applications where uniform doping is of importance.

[115] Orientation

Figure 1 illustrates the geometric relationship between the [115] direction and other common directions in the silicon lattice. There is an angle of 15.8° between [001] and [115] directions and a 39° angle between [115] and [111] directions. The <115> directions are significant in that growth twins, which occasionally occur during the growth of <111> axis silicon crystals, change the growth axis to either <115> or another <111> orientation since the twin plane is of the {111} family (2). Normally, the occurrence of such growth twins during dislocation-free <111> zoning leads to degradation of the crystal perfection (dislocations, subsequent twins, or large angle grain boundaries usually occur shortly after twinning).

Key words: silicon crystal growth, float-zoned silicon crystals, [115] oriented silicon crystals, [115] silicon crystal properties, radial resistivity, dislocation-free [115] silicon crystals.

Back-reflection and transmission Laue x-ray diffraction photographs taken of a (115) silicon surface with a 5 cm sample to film distance are shown in Fig. 2 along with a simplified stereographic projection. Little symmetry is present in the arrangement of the diffraction spots; there is only mirror symmetry across the (110) plane which is vertical and perpendicular to the page. The prominent spots present in the back-reflection pattern are (001), (113), and (112). Standard Laue or diffractometer x-ray techniques can be used for specimen orientation; the (115) interplanar separation is 1.04510Å based on the lattice constant value $a = 5.43050$Å (3).

Comparison of [115] and [111] Crystal Growth Mechanisms

A difference in growth mechanism of (115) *vs.* (111) solidification fronts is believed to account for the more uniform electrical properties seen in [115] crystals. Dislocation-free, float-zone silicon crystal growth is apparently dominated by the lateral or sheet-like propagation of (111) planes (4). When dislocation-free

crystals are zoned close to the [111] orientation, substantial (111) singular or faceted planar regions develop on those supercooled portions of the interface where new (111) layers nucleate (4, 5). For example, if the sold-liquid interface is convex toward the melt, the singular region will be in the central core of the crystal (Fig. 3), while normal or rough growth will take place on the remainder of the interface.

The tendency for facet-like growth to dominate the coolest or "leading" regions of the interface is predominantly an inverse function of the angle between (111) and the leading interface surface. This occurs because the (111) surface has the lowest surface free energy, is the atomically smoothest, and is the only surface to show strong faceting tendencies during melt growth. However, it is possible that other low indice surfaces corresponding to less prominent minima in the polar surface free energy plot may also have some tendency (albeit less pronounced) to form faceted or singular interfaces. Ideally, the most uniform electrical properties for crystals grown with a curved interface should result when the average interface plane corresponds to a maximum in the polar surface free energy plot, is the atomically roughest, and is angularly distant from (111) planes and other low indice planes. While there is no experimental evidence that the (115) surface totally fulfills these criteria, it should be more likely to do so than low indice surfaces.

In [115] zoning, {111} planes are inclined to the interface at angles of 38.9°, 56.3°, and 70.5°; thus, only minute regions develop facets on the crystal periphery, and crystal growth is essentially uniformly normal or rough in nature over the entire interface area.

The [115] and [111] dislocation-free crystals were zoned under attempted identical experimental conditions, in that the same apparatus (ECCO zone refiner), operator, growth speed (3 mm/min), rotation rate (20 rpm) and geometry (two-turn stationary rf coil) were used. Seeds were oriented to the appropriate direction and dislocation-free growth was initiated by the "necking" technique (6, 7). Both crystals were vertically zoned with the crystal beneath the melt and the feed rod above, in argon, from silicon doped with phosphorus to a resistivity of approximately 50 ohm-cm. A half dozen attempts were made to zone [100] dislocation-free crystals under these same conditions and none were successful; dislocations and loss of singularity occurred early in growth in every case.

Comparison of [115] and [111] Crystal Properties

Solid-liquid interface shapes of the two crystals were determined by etching longitudinal sections (4), and

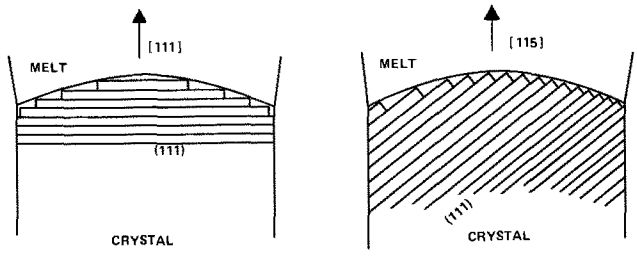

Fig. 3. Schematic representation of (111) layer growth in [111] and [115] float-zoned, dislocation-free crystals.

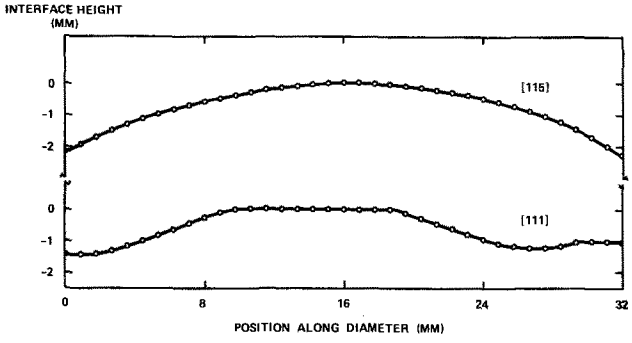

Fig. 4. Solid-liquid interface profiles for [115] and [111] dislocation-free crystals zoned under similar conditions.

are in accord with the growth mechanisms discussed above. The interface of the [115] crystal was continuously curved and convex toward the melt, while the interface of the [111] crystal was partially curved and partially flat. The flat or faceted areas occurred at the center and at the periphery of the solidification front (Fig. 4). It has been previously shown (5) that the peripheral (111) facets give rise to ridges or bulges which extend along the length of the crystal and cause a deviation from roundness in the cross section of the crystal; the lack of these facets in [115] crystals allows a nearly circular cross section. Figure 5 shows x-ray topographs of cross-sectional slices from the two crystals and illustrates the difference in cross-sectional shape as well as the absence of dislocations.

It has also been shown previously (4) that the central (111) facet on [111] crystal interfaces is associated with a greater adsorption of impurities or dopants with segregation coefficients, k_o, less than 1.0. For example, the incorporation of phosphorus ($k_o = 0.4$) is approximately 20% greater in the faceted or "core" region. Resistivity measurements were made by the one-probe technique at 0.5 mm increments on thin filaments (1 × 1 mm cross section) cut along the diameter of the [115] and [111] 50 ohm-cm, n-type crystals. The resultant radial resistivity profiles are shown in Fig. 6. Decreased resistivity values (increased dopant concentrations) are seen in the faceted region of the [111] crystal, whereas the [115] crystal, free of interface facets, exhibits a more uniform (±5%) resistivity. Although the [115] crystal resistivity is relatively uniform on a long range (axis to periphery) basis, it does exhibit resistivity striations on a smaller microscale which are similar to those seen in [111] crystals. The extreme to which these can be observed is a function of the spatial resolution of the measuring technique.

In addition to the preceding growth-related consequences of the [115] geometry, there are some purely orientation-dependent properties of interest. Since there is an angle of 15.8° between the (115) and (001) planes, {100} wafers which deviate from roundness by only $[(1/\cos 15.8°) - 1] \times 100\% = 4\%$ can be cut from [115] crystals. Thus, nearly round {100} wafers of float-zone purity[2] can be attained (direct [100] zoning is difficult). Also, the (115) surface is comparatively rough on an atomic scale, which may have implications for epitaxy or alloying treatments. Surface-state charge density at Si/SiO_2 interfaces is another orientation-dependent property, and has been found to be lowest for (100) surfaces, highest for (111) surfaces, and midway between for (110) surfaces [see for example, Gray and Brown (8)]. Since the [115] direction is relatively close to the [100] direction, a relatively low surface-state charge density is expected for the (115) surface. Preliminary measurements indicate that the value for the (115) surface is between that for (100) and that for (110) (9).

Summary

The float-zone growth of [115] dislocation-free silicon crystals is a means of obtaining high purity, low defect wafers for applications where low radial resistivity gradients, low surface-state charge densities, or atomically rough, high surface free energy wafer surfaces are desirable. In addition, nearly round (within 4%) (100) wafers can be cut from [115] crystals.

Most of the differences between [111] and [115] float-zoned crystals are expected to also hold true in Czochralski growth; an exception is that [111] and [115] Czochralski crystals are comparable in roundness.

[2] The oxygen content of float-zoned crystals is typically 10^{16} atoms/cm^3.

The Crystal Growth of Boron Monophosphide from Metal Phosphide Solutions

T. L. Chu,* J. M. Jackson, and R. K. Smeltzer*

Electronic Sciences Center, Southern Methodist University, Dallas, Texas 75222

ABSTRACT

The crystal growth of boron phosphide, BP, has been investigated using two approaches: (*i*) the addition of phosphorus to a boron-nickel or boron-copper melt, and (*ii*) the recrystallization of boron phosphide from a nickel phosphide or copper phosphide solution in a temperature gradient. To determine the optimum conditions for the growth processes, the solubility of boron phosphide in nickel phosphide ($Ni_{12}P_5$) and copper subphosphide (Cu_3P) was determined over a wide temperature range. The solubility of boron phosphide in nickel phosphide was found to be higher than that in copper phosphide. Boron phosphide crystals of about 3-mm size were obtained by the addition of phosphorus to a boron-nickel or boron-copper melt at 1300°C or above, followed by slow cooling. The temperature gradient recrystallization of boron phosphide from nickel phosphide at 1200°C has produced larger crystals. The solution-grown crystals were in the form of hoppers and platelets with platelets dominating. The platelets had main faces of {111} orientation and were formed by the twin-plane re-entrant-edge mechanism. The solution-grown crystals are usually n-type with a room temperature resistivity of about 0.5 ohm-cm and a dopant concentration of about 10^{18} cm^{-3}. They have been used successfully as substrates for the epitaxial growth of boron phosphide.

Boron monophosphide (BP, referred to as boron phosphide hereafter) crystallizes in the zincblende structure and has an indirect energy gap of about 2 eV (1). Because of its relatively large energy gap, this material has potential applications for high-temperature devices and for visible light-emitting devices. However, these devices have not been developed because of the difficulties involved in the growth of single crystals of boron phosphide of controlled chemical and structural perfection. Conventional melt-growth techniques are not feasible for the crystal growth of boron phosphide because of its high melting point (3000°C) and its dissociation into boron subphosphide (B_6P) at temperatures considerably below the melting point (2). Boron phosphide crystals have been grown from metal phosphide solutions and by the chemical transport technique under conditions where its thermal dissociation is negligible.

The growth of boron phosphide crystals from metal phosphide solutions has been briefly reported in several investigations (1, 3-5); however, no information concerning the effects of various process parameters is available. In the present work, the process parameters in the solution growth of boron phosphide have been extensively studied with the objective of producing

* Electrochemical Society Active Member.

Key words: boron phosphide, crystal growth, nickel phosphide, semiconductors, twin planes.

larger crystals suitable as substrates for the epitaxial growth of boron phosphide (6); the epitaxial growth technique is believed to be the most promising approach for the preparation of boron phosphide device structures, since the concentration and distribution of dopants in the epitaxial layer can be reproducibly controlled. Copper and nickel phosphides were used as solvents, and the growth process was carried out by the addition of phosphorus to a boron-metal melt and by the recrystallization of boron phosphide from a metal phosphide solution in the presence of a temperature gradient. The experimental procedures and results are summarized below.

Solubility of Boron Phosphide in Metal Phosphides

The most important parameter in the solution-growth process is the choice of a suitable solvent. The solvent must either be essentially insoluble in boron phosphide, or it must be electrically inactive if it has significant solubility.

Several metals, such as copper, iron, nickel, and platinum, are possible solvent-formers for the solution growth of boron phosphide, and copper and nickel phosphides appear to be the most useful ones on the basis of the available information. An examination of binary phase diagrams (7-9) reveals the following relations: (*i*) boron is soluble in copper and nickel over a wide temperature range: nickel forms four borides (Ni_2B, Ni_3B_2, NiB, and Ni_2B_3) and copper forms no borides, (*ii*) nickel forms at least eight phosphides: Ni_3P, Ni_5P_2, $Ni_{12}P_5$, Ni_2P, Ni_5P_4, NiP, NiP_2, and NiP_3, and the first four phosphides have melting points below 1200°C, and (*iii*) copper forms two phosphides: Cu_3P and CuP_2 (10). Thus, the B-Cu-P system is relatively simple, and the use of nickel phosphide for the solution growth of boron phosphide may involve rather complicated mixtures.

To determine the conditions for the growth of boron phosphide crystals from solutions, the solubilities of boron phosphide in nickel and copper phosphides were determined over a wide temperature range. Polycrystalline boron phosphide, nickel phosphide, and copper phosphide were first prepared as follows.

Boron phosphide was prepared by the thermal reduction of a boron tribromide-phosphorus trichloride mixture with hydrogen in a gas flow system. A mixture of hydrogen, boron tribromide, and phosphorus trichloride, at flow rates of 8×10^{-2}, 1.5×10^{-3}, and 3×10^{-3} moles/min, respectively, was introduced into a fused silica tube heated at about 1100°C in a resistance-heated furnace. The reaction took place on the wall of the silica tube, depositing boron phosphide. The excess of phosphorus trichloride in the reactant prevented any phosphorus deficiency in the deposit. The deposit was confirmed to be boron phosphide by the x-ray Debye-Scherrer technique. Approximately 30g of boron phosphide was formed during an 8-hr period.

Nickel phosphide was synthesized by the reaction of phosphorus vapor with nickel under conditions similar to those used for the solution growth of boron phosphide, and a schematic diagram of the apparatus is shown in Fig. 1. An alumina boat containing a nickel ingot was fitted into a cylindrical graphite sleeve of 1 in. ID and 1¼ in. OD, which was used as a susceptor for rf heating. The susceptor was positioned in a fused silica spacer so that the graphite contacted the spacer only at four points. This assembly and an excess of red phosphorus were placed in a fused silica tube of 50 mm ID and 55 mm OD which was evacuated to less than 10^{-5} Torr and sealed. The reaction tube was about 45 cm long after sealing. The end of the tube containing the susceptor and phosphorus was heated to sublime all phosphorus to the other end of the tube. The susceptor was heated at the desired temperature, 1200°-1400°C, with an rf generator, and a resistance heater surrounding a major portion of the reaction tube was used to maintain the phosphorus pressure in

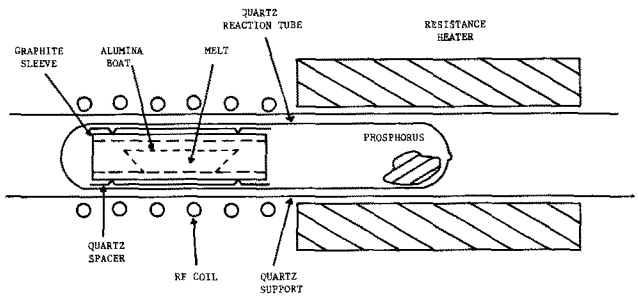

Fig. 1. Schematic diagram of the apparatus used for the synthesis of nickel phosphide and the solution growth of boron phosphide.

the tube at about 2 atm. The nickel appeared to be saturated with phosphorus after several hours; however, the reaction time was usually 24 hr or longer to assure saturation. The x-ray Debye-Scherrer pattern of the resulting product was identical with that of $Ni_{12}P_5$ (11). Nickel phosphides with higher phosphorus content were not obtained.

Copper phosphide was synthesized by the reaction of phosphorus vapor with copper in a closed tube. Weighed amounts of copper and red phosphorus were placed in a fused silica tube, evacuated to less than 10^{-5} Torr, and sealed. The reaction tube was then placed in a two-temperature zone furnace. Copper located at one end of the tube was heated at 1150°C, and the temperature of the other zone was maintained to yield a phosphorus pressure of about 1 atm. Depending on the Cu/P molar ratio in the reactants, Cu_3P or CuP_2, identified by their x-ray Debye-Scherrer patterns (10, 12), were obtained.

To determine the solubility of boron phosphide, a pulverized mixture of 1.0g boron phosphide, 0.04g red phosphorus, and 10.0g nickel phosphide ($Ni_{12}P_5$) was sealed in an evacuated fused silica tube of 10 mm ID and 16 mm OD; phosphorus was used to suppress the decomposition of boron phosphide at high temperatures. The boron phosphide was sieved through a 74μ screen so that the amount of recrystallized material, which would have considerably larger particle size, could be easily determined. The silica tube was fitted into a cylindrical graphite susceptor. The susceptor was sealed into a second silica tube containing about 0.2 atm of argon (the argon pressure was used to suppress the expansion of the inner tube at high temperatures), and the susceptor was at least 1 cm from the tube wall so that the susceptor could be heated to high temperatures. The graphite susceptor was then heated with an rf generator at the desired temperature, 1200°-1400°C for 5-24 hr. The content of the reaction tube was treated with a nitric acid-hydrofluoric acid mixture to dissolve all species except boron phosphide. Whenever recrystallization had occurred, the residual boron phosphide was found to contain small orange-red crystals in addition to the original powder material, and the crystals were separated by sieving the mixture through a 74μ screen. The recovered powder material was undissolved boron phosphide, and the collected crystalline material was recrystallized boron phosphide. In all cases, boron phosphide was not completely recovered due presumably to the complexity of the Ni-B-P system. At 1300°C, for example, 0.75g of boron phosphide dissolved in 10g of nickel phosphide, whereas only 0.23g recrystallized from the solution. The weights per cent of boron phosphide dissolved in, and recrystallized from, nickel phosphide at various temperatures is shown in Fig. 2. It is seen that it has a significant solubility in nickel phosphide at 1200°C, even though this temperature is just above the melting point of nickel phosphide.

The melting point of copper subphosphide, Cu_3P, is 1022°C. The solubility of boron phosphide in copper subphosphide was determined at 1150° and 1220° in a manner similar to that described above. Boron phosphide was found to be essentially insoluble in copper

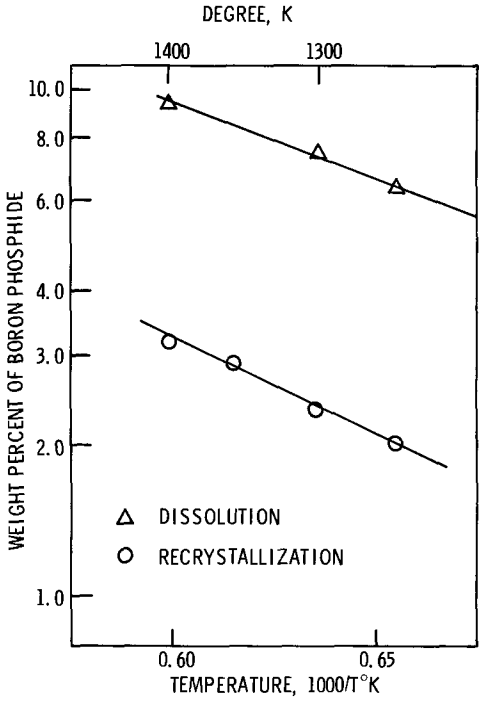

Fig. 2. Dissolution and recrystallization of boron phosphide as a function of temperature using nickel phosphide as a solvent.

subphosphide at 1150°C. When the experiment was carried out at 1220°C for 48 hr, about 85% of the boron phosphide was recovered, and 0.64% (weight) of the initial boron phosphide recrystallized. Thus, boron phosphide is less soluble in copper subphosphide than in nickel phosphide. Also, boron phosphide was found to be insoluble in copper diphosphide, CuP_2, at temperatures up to 1200°C.

Growth of Boron Phosphide Crystals by the Addition of Phosphorus to a Boron-Metal Melt

The slow cooling of a phosphorus-saturated solution of boron in nickel was used for the growth of boron phosphide crystals. The apparatus is the same as that used for the preparation of nickel phosphide shown in Fig. 1. A boron-nickel ingot was prepared by melting weighed quantities of boron and nickel in an alumina boat in a hydrogen atmosphere. Typically, 40g of nickel was used, and the melt was maintained at 1400°C for at least 1 hr to form a homogeneous mixture. The resulting ingot was then sealed in the reaction tube in a manner as shown in Fig. 1. After maintaining a phosphorus pressure over the melt at a predetermined temperature, boron and nickel were converted into the corresponding phosphides. The solution was slowly cooled, and the resulting material was treated with nitric acid to isolate the boron phosphide crystals.

The important process parameters including the phosphorus pressure over the solution, the initial concentration of boron in solution, the temperature of the solution, the reaction time, and the cooling rate, were studied in a number of experiments. A phosphorus pressure of 2-3 atm was found to be optimum; lower pressure resulted in the formation of boron subphosphide B_6P, and higher pressures created such strong convection currents in the reaction tube that the phosphorus pressure could not be controlled. The concentration of boron in nickel was first selected on the basis of the data shown in Fig. 2. The boron-nickel alloy used for crystal growth at 1325°C should contain 2.3% (weight) boron so that, after saturating with phosphorus, the resulting solution of boron phosphide in nickel phosphide would be slightly undersaturated. The solution was maintained at 1325°C for 4 hr and then cooled at a rate of 10°C/hr to about 1150°C. The boron phosphide crystals obtained in this manner were up to 3 mm in size, and the yield was about 50% on the basis of the amount of boron used. Several changes in the process parameters were then made. Higher temperatures did not noticeably change the size distribution or yield of the crystals; however, crystals were smaller on the average at temperatures below 1300°C. The use of higher concentrations of boron in nickel, up to 10%, also did not change significantly the size of boron phosphide crystals. By maintaining the solution at high temperatures under the phosphorus pressure over extended periods, the yield of boron phosphide crystals was slightly increased, but the results were no better in other aspects. Also, no improvements in crystal size were obtained with cooling rates of less than 10°C/hr. Experiments were also carried out by slowly pulling the reaction tube out of the rf coil, and the results were inferior to the slow cooling of the entire solution. To eliminate the possibility that particulate matter from the graphite susceptor had induced excessive nucleation in solution, one experiment was carried out using a molybdenum susceptor and produced very similar results.

A series of experiments was carried out using the addition of phosphorus to a boron-copper melt. Although the solubility of boron in copper is less than that in nickel, the effects of the alloy composition, temperature, reaction time, and cooling rate on the size distribution of crystals were essentially the same as the use of a boron-nickel melt.

Growth of Boron Phosphide Crystals by Recrystallization from Metal Phosphide Solutions

The addition of phosphorus to a boron-nickel or boron-copper melt requires a reaction temperature of at least 1300°C for obtaining boron phosphide crystals of reasonable size. Lower temperature techniques are preferable, and the temperature dependence of the solubility of boron phosphide in metal phosphides was utilized for the crystal growth of boron phosphide by the temperature gradient recrystallization technique. In this technique, a small temperature gradient is maintained across a saturated solution of boron phosphide in a metal phosphide with a polycrystalline boron phosphide source in the higher temperature region. A concentration gradient is thus set up across the solution, and this gradient results in the transport of boron phosphide from the polycrystalline source to the lower temperature region in the solution. The nucleation process in this region can be controlled to yield relatively large crystals.

The recrystallization experiments were carried out in vertical fused silica tubes using a resistance-heated furnace for recrystallization temperatures up to 1200°C and rf heating for higher temperatures. Since the density of boron phosphide is considerably lower than that of metal phosphide solutions, the top of the reaction tube was in the highest temperature region in the majority of the experiments. In a typical high-temperature experiment, 1.5g of polycrystalline boron phosphide and 35g of copper subphosphide were placed in a graphite cylinder of 1 in. ID and 3 in. in height. The crucible was supported by a fused-silica holder and sealed in a fused-silica tube with sufficient phosphorus to yield 2 or 3 atm pressure during recrystallization. The graphite crucible was heated with an rf generator. The top of the solution was maintained at about 1300°C and the bottom was a few degrees cooler. The crucible was slowly cooled after one day, and the resulting boron phosphide was completely recrystallized with crystals up to 2 mm in size. These results were not significantly improved by using nickel phosphide as the solvent or by using a silica liner in the graphite crucible. The relatively small size of boron phosphide crystals obtained in these experiments are presumably due to the high recrystallization rate resulting from the difficulty of controlling a small temperature gradient with rf heating.

The recrystallization experiments at lower temperatures have produced crystals superior to the high-temperature experiments. The best results were obtained with nickel phosphide solutions. In a typical experiment, 0.5g of boron phosphide, 15g of nickel phosphide, and 0.08g of phosphorus were placed in a fused silica tube of 10 mm ID × 16 mm OD, which was evacuated and sealed. The tube was held in a vertical furnace so that the top of the solution was at the highest temperature, 1200°C, and a 5°C gradient existed across the solution. After three weeks, boron phosphide crystals, mostly in the form of platelets up to 4 mm in size, were obtained. At 1150°C or below, no measurable recrystallization was observed after two weeks. Thus, among the techniques investigated in this work, the temperature gradient recrystallization of boron phosphide from nickel phosphide at 1200°C appears to be best suited for the growth of boron phosphide crystals.

Properties of Solution-Grown Boron Phosphide Crystals

Boron phosphide crystals obtained in this work were in the form of hoppers and platelets, with platelets dominating among crystals grown by the recrystallization technique. They are chemically inert, insoluble in aqueous acids and alkalis. Molten potassium hydroxide or a molten mixture of 3:1 sodium hydroxide-sodium peroxide was used as a preferential etchant to reveal structural defects in boron phosphide crystals.

The platelets are usually in the six-sided form, intermediate between a regular hexagon and an equilateral triangle. Figure 3 shows several boron phosphide platelets obtained by the recrystallization technique. The platelets usually have one smooth main face, and the x-ray Laue back-reflection technique indicated that the main face is of {111} orientation. The platelets are also characterized by a twinned structure with twinning taking place about {111} planes. Figure 4 shows the angle-lapped and chemically etched surface of a boron phosphide platelet; the parallel lines are grooves and are the intersections of the twin planes with the angle-lapped surface. In this case, the twin planes are 2-4μ apart. Twinning has been shown to be essential for the growth of the platelets (13). Since the {111} faces are the slowest growing, a stable octahedral structure bounded by these planes would be formed without twinning, and additional growth onto this structure would be difficult because of the high energy of nucleation on the {111} faces. In the twinned structure, however, intersection of the twins forms re-entrant grooves on alternating edges in three of the six equivalent <211> directions that lie in the plane of the twins. The twins intersect at ridges on the other three edges. The grooves provide locations for multiple attachment of new atoms so the energy of nucleation is lowered and growth can ensue preferentially in those directions.

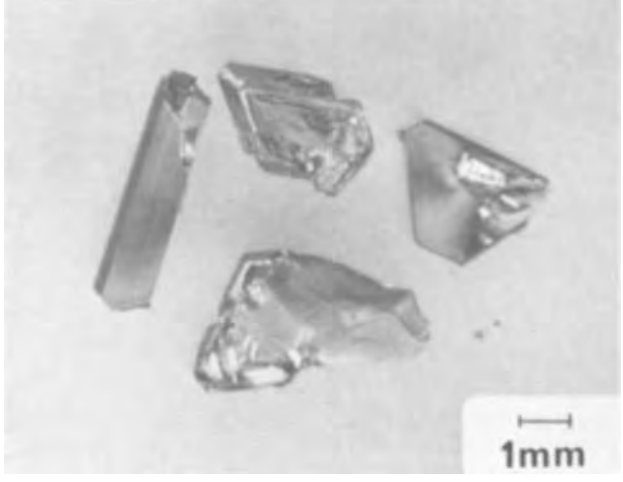

Fig. 3. Typical boron phosphide platelets grown by recrystallization from a nickel phosphide solution at 1200°C.

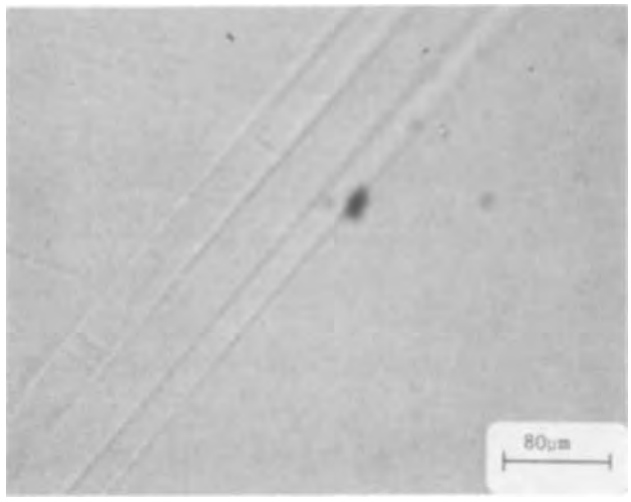

Fig. 4. Angle-lapped and chemically etched surface of a boron phosphide platelet showing the presence of twins.

The hopper-faced boron phosphide crystals were frequently obtained from solutions with a high boron concentration. The crystals consist of separate but often interleaved {111} platelets grown out at different levels from intersecting faces. Edges are favored growth sites in this structure. Although the presence of hopper crystals indicates that many of the solutions were too concentrated, the size and shape of the well-formed twinned crystals did not vary with the presence or absence of the hopper type.

The solution-grown boron phosphide crystals exhibit both n- and p-type conductivity with the n-type predominant. Their electrical conductivities have been measured in the temperature range 77°-500°K. Ohmic contacts were obtained by evaporating indium onto the surface of the crystal followed by annealing at 500°C. A typical conductance-temperature relation of an n-type crystal is shown in Fig. 5. An activation energy of about 0.13 eV dominates in the temperature range 200°-500°K; however, the conductivity is controlled by shallow levels which could not be determined from the data here. Typical resistivities are 0.5 ohm-cm at room temperature and 50 ohm-cm at 77°K.

The room-temperature carrier concentration in solution-grown boron phosphide crystals was estimated from Schottky barrier measurements. Gold dots of 0.01-in. diameter evaporated onto the surface of the crystal were used as the barrier. Capacitance-voltage data from a number of samples has yielded net donor concentrations on the order of 10^{18} cm^{-3}.

The solution-grown boron phosphide crystals are not directly useful for device purposes because the dopant concentration and distribution in these crystals cannot be readily controlled. However, they are ideal as substrates for the epitaxial growth of boron phosphide. Both n- and p-type epitaxial layers with controlled dopant concentration have been deposited on the solution grown crystals by the thermal reduction of a boron tribromide-phosphorus trichloride mixture with hydrogen. The properties of these epitaxial layers will be discussed in another publication.

Summary and Conclusions

Single crystals of boron phosphide have been prepared from metal phosphide solutions by two techniques: (*i*) the addition of phosphorus to a boron-nickel or boron-copper melt at 1300°C followed by slow cooling of the resulting solution, and (*ii*) the recrystallization of boron phosphide from a nickel phosphide or copper phosphide solution at 1200°C in a temperature gradient. The solution-grown crystals are in the form of hoppers and platelets with platelets domi-

nating. The twin-plane re-entrant-edge mechanism is responsible for the formation of platelets The solution-grown crystals have a dopant concentration on the order of 10^{18} cm^{-3} and are not useful directly for device purposes. They have been used successfully as substrates for the epitaxial growth of boron phosphide.

The Equilibrium Behavior of the Silicon-Hydrogen-Bromine and Silicon-Hydrogen-Iodine Systems

L. P. Hunt* and E. Sirtl*

Dow Corning Corporation, Solid State Research and Development, Hemlock, Michigan 48626

ABSTRACT

A thorough evaluation of the Si-H-Br and Si-H-I systems was made by considering many compounds to coexist at equilibrium. Compound partial pressures are presented as a function of temperature (300°-1700°K) for a halogen to hydrogen ratio of 0.01. Diagrams relating the X/H ratio (0.01-10) to the Si/X ratio indicate the equilibrium state of the system with respect to the corresponding increase or decrease of silicon in the gaseous phase. Experimental data are presented proving the existence of a high-temperature ($\gtrsim$ 1300°K) cold-to-hot transport reaction in the Si-H-I system in contrast to what is predicted in the Si-H-Br and known in the Si-H-Cl systems. The cold-to-hot transport reaction is the result of the high-equilibrium partial pressure of monatomic iodine at temperatures approaching the melting point of silicon.

The common methods used in the semiconductor industry for the chemical vapor deposition of silicon involve either the pyrolysis of silane or the hydrogen reduction of the chlorosilanes $SiCl_4$, $SiHCl_3$, and more recently SiH_2Cl_2 (1). In comparison to the chlorosilanes, the body of information available concerning the decomposition of the other halosilanes is very slight. The fluorosilanes have attracted little attention because of their comparatively high thermal stability, while the bromo- and iodosilanes have been largely ignored for both economic and technical handling reasons.

Key words: silicon, thermochemical equilibrium, transport, vapor deposition.

Within the Si-H-Br system, silicon tetrabromide has been studied (2, 3) on a very limited basis as a source material for silicon deposition. In the other extreme, the etching of silicon by H_2-HBr mixtures has been shown (4) to have advantages over the more commonly used H_2-HCl mixtures. Interest in the Si-H-I system, or more specifically the Si-I system in the absence of hydrogen, has been higher than in the corresponding bromine system since the chemistry is somewhat altered by the low stability of SiI_4 at medium temperatures and the greater stability of monatomic iodine at higher temperatures. Although work in the etching area has been somewhat limited (5), studies in polycrystalline silicon deposition (6-8) initiated additional investigation into epitaxial deposition (9-14) from SiI_4 by pyrolysis, hydrogen reduction, and chemical transport reactions.

The purpose of this paper is to generally describe the equilibrium behavior of the Si-H-Br and Si-H-I systems in order to provide a frame of reference to which experimental data can be compared. Calculations are based on a detailed thermodynamic analysis of each system in a manner very similar to that used for the Si-H-Cl system (15). Earlier thermodynamic analyses of the Si-H-I system (10-13) have been quite specific in terms of interpreting experimental data of a limited nature.

Thermodynamic Data

The computational method, based on that reported by Cruise (16), and described more thoroughly elsewhere (15), requires a knowledge of the standard enthalpy of formation, $\Delta Hf°_{298}$, the standard entropy, $S°_{298}$, and the temperature function of the heat capacity equation, $C_p°(T)$, for each species in an equilibrium system. Since many of these basic quantities have not been determined for the halosilanes and subhalides in the Si-H-Br and Si-H-I systems, a thorough analysis of the equilibrium situation requires a careful evaluation and estimation of the missing data.

Standard enthalpy of formation.—As is the case with chlorosilanes, the absence of enthalpy of formation data for the tri-, di-, and monohalosilanes (X = Br, I) necessitates their estimation by interpolating between the well-established values for the tetrahalosilanes (17) and for monosilane (18). This method has been shown (15) to be accurate to within about 1 kcal/mol for trichlorosilane. The interpolated values appear in Table I.

[a] Zero by definition.
[b] Estimated in this paper.
[c] A regression analysis was performed on the cited data.

Reliable data for the standard enthalpy of formation of both $SiBr_2$(g) and SiI_2(g) have been published by Schäfer *et al.* (17). No known experimental determinations of the enthalpies of the silicon mono- and trihalides have been made however. Therefore, their values are estimated using the data for the silicon subchlorides (15) as a guide line. Since the deviation from the straight line between Si(g) and $SiCl_4$(g) of the enthalpy values of SiCl and $SiCl_3$ are about 5 and 10 kcal/mol, respectively, we have algebraically added these off-set values to the "straight line" values in the bromine and iodine series to accordingly obtain the enthalpies of SiBr, $SiBr_3$, SiI, and SiI_3. Even though this type of estimation leads to values of limited accuracy, later calculations will show equilibrium partial pressures of the mono- and trihalides to be quite negligible under the conditions studies.

Since experimental enthalpy of formation data have not been published for either Si_2Br_6(g) or Si_2I_6(g), the values were estimated in the same manner as has been explained earlier for Si_2Cl_6 (15). This method essentially involves adding twice the enthalpy of the hypothetical "ideal" SiX_3(g) molecule, obtained by linear interpolation, to one-half of the atomic sublimation energy of silicon.

Standard entropy.—The standard entropy of $SiHI_3$(g) and SiH_2I_2(g) can be accurately estimated by plotting the known data for the halosilanes in the coordinating diagram (19) shown in Fig. 1. Here use is made of the near linear relationship between the logarithms of the entropy and molecular weight for similar series of compounds. This same approach was also used to calculate the entropy of $SiBr_3$(g), SiI(g), and SiI_3(g) as shown in Fig. 2.

The entropies of Si_2Br_6(g) and Si_2I_6(g) were calculated from the entropy of Si_2Cl_6(g) based on the near constant incremental standard entropies of 11 eu between the chlorine and bromine compounds and 8 eu between the bromine and iodine compounds for gaseous CX_4, SiX_4, and C_2X_6 (20).

Heat capacity.—Where heat capacity data were not available in the equation form $C_p° = A + BT + C/T^2$, a regression analysis was performed on the originally tabulated data. Although reliable data exist for all the bromosilanes, there are no available values for either di- or triiodosilane. The coefficients of the heat capacity equation for these compounds can be very accurately estimated in a diagram, such as Fig. 3, where the value of each coefficient is plotted as a function of the compounds in the series $SiH_4 \rightarrow SiI_4$. The smoothness of such curves can be seen in the case of the chloro- and bromosilanes where all data are available. This method has also proved very successful in estimating missing

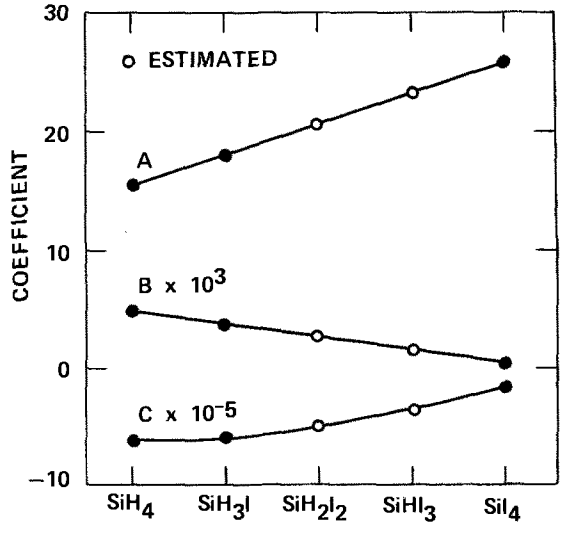

Fig. 3. Heat capacity coefficients from the equation $C_p^\circ = A+BT+C/T^2$ for the series $SiH_4(g) \rightarrow SiI_4(g)$.

heat capacity data for the methysilanes and methychlorosilanes (21).

Heat capacity data for the silicon subbromides were assumed equal to that of the JANAF (22) data for the corresponding aluminum bromides due to close agreement in the data for the silicon and aluminum subchlorides. The unavailability of data for $AlBr_2(g)$ required that it be interpolated, as in Fig. 3, from the series $Al(g) \rightarrow AlBr_3(g)$.

Since reliable data do not exist for either the silicon or aluminum subiodides, the heat capacities of SiI, SiI_2, and SiI_3 were estimated, as in Fig. 3, from the series $Si(g) \rightarrow SiI_4(g)$ by comparison to the similar series for the subchlorides and subbromides.

The heat capacity of $Si_2Cl_6(g)$ was assumed earlier (15) to be equal to that of $C_2Cl_6(g)$. The lack of published data for $C_2Br_6(g)$ and $C_2I_6(g)$, however, makes it necessary to estimate the heat capacities of $Si_2Br_6(g)$ and $Si_2I_6(g)$ from their corresponding aluminum analogs (22). Even though comparison of the heat capacity-temperature curves for C_2Cl_6 and Al_2Cl_6 shows them to be somewhat different (their molecular structures are different), the approximation is justified here due to the very low partial pressure of Si_2Cl_6 found to exist at equilibrium (23). Since initial calculations using the heat capacity of Al_2Br_6 and Al_2I_6 for Si_2Br_6 and Si_2I_6, respectively, showed the latter compounds also to have very low partial pressures at equilibrium, the estimates were assumed to be accurate enough for this work.

Results and Discussion

Si-H-Br and Si-H-I systems.—Calculations for the Si-H-Br system assumed various initial bromosilane-hydrogen mixtures to be in contact with a solid phase of silicon at specified temperatures. The resulting equilibrium partial pressures of the various species are presented in Fig. 4 for an initial Br/H ratio of 0.01 (0.5% SiI_4) over a temperature range of 300°-1700°K. The absence from the diagrams of some of the species listed in Table I is due to their very low equilibrium partial pressures. It is possible to ignore the following gaseous species while maintaining greater than 98% accuracy: Si, Br, Br_2, SiBr, $SiBr_3$, SiH_4, SiH_3Br, and Si_2Br_6.

Comparison of the equilibrium gas phase data in Fig. 4 for the Si-H-Br system to analogous data for the Si-H-Cl system (23) shows nearly exact agreement except for two species, one of which, of course, is Br(g). The partial pressure of $SiHBr_3$ is lower relative to that of $SiHCl_3$ since the enthalpy of the latter compound was determined (15) to be 1.2 kcal/mol more negative than the interpolated value between SiH_4 and $SiCl_4$.

The Si-H-I system was treated similarly to the Si-H-Br system. The iodine system can be calculated to greater than 97% accuracy by leaving out all the species corresponding to those already mentioned in the bromine system with the exception of I(g). The equilibrium partial pressures of the compounds in Fig. 5 are found to be very nearly equal to the partial pressures of the corresponding compounds in the Si-H-Cl and Si-H-Br systems up to about 1200°K. Above this temperature, however, the stability of monatomic iodine results in the Si-H-I system being quite different from the chlorine and bromine systems. The stability of I(g) increases with temperature to such an extent that it actually causes a maximum to occur in the partial pressures of HI and SiI_2. This is in contrast to the chlorine and bromine systems where HX and SiX_2 are monotonic functions of temperature.

Further insights into the Si-H-Br and Si-H-I systems are available through Fig. 6 and 7 which show the silicon content (Si/X ratio) of the gas phase as a function of the initial gas phase composition (X/H ratio) for temperatures between 300°-1700°K. A thorough description of the general trends found in curves

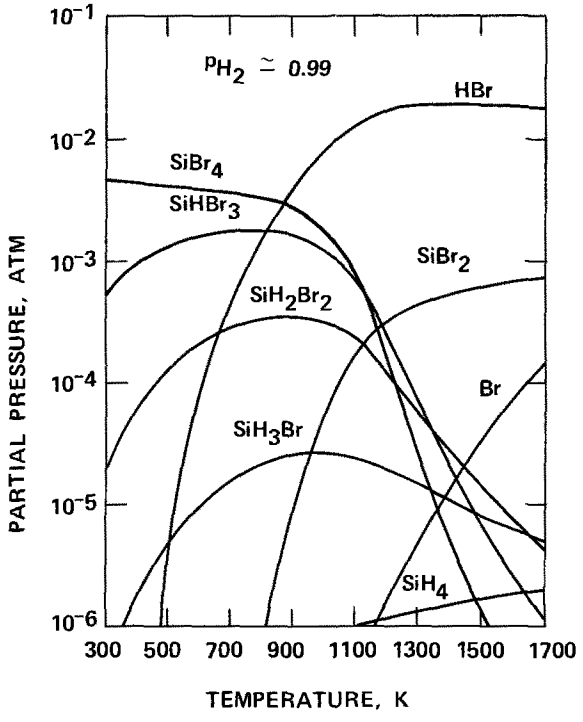

Fig. 4. Equilibrium partial pressures of species in the Si-H-Br system as a function of temperature for Br/H=0.01.

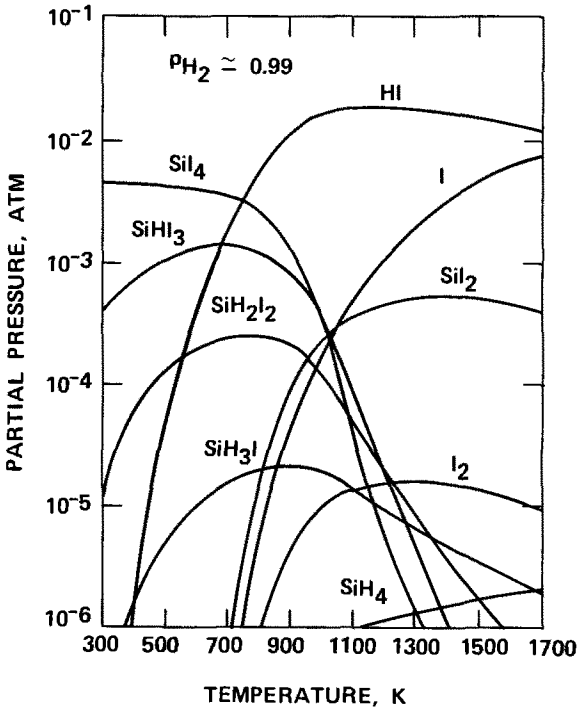

Fig. 5. Equilibrium partial pressures of species in the Si-H-I system as a function of temperature for I/H=0.01.

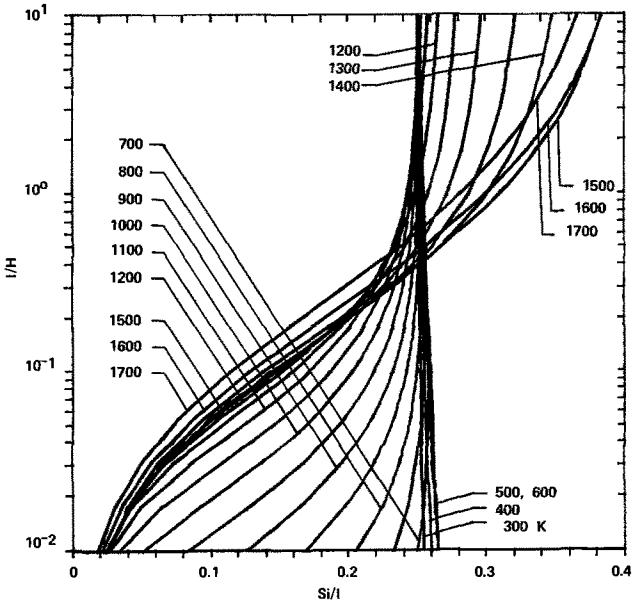

Fig. 7. Silicon content of the Si-H-I system gas phase as a function of the I/H ratio at 1 atm total pressure for 50° temperature increments.

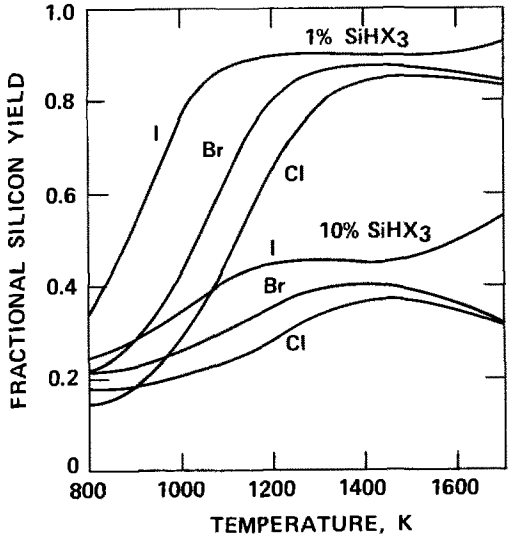

Fig. 8. Temperature variation of the fractional silicon yield from various $SiHX_3$-H_2 mixtures.

of this type has been given elsewhere (15). At low X/H ratios and temperatures $\lesssim$ 1200°K, the isothermal curves in the bromine and iodine systems show a shift toward lower Si/X values when compared to the chlorine system due to the higher partial pressure of SiX_4 (Si/X = 0.25) relative to $SiHX_3$ (Si/X = 0.33). This is attributed to the standard enthalpy of $SiHCl_3$ not being an interpolated value as is the case of $SiHBr_3$ and $SiHI_3$.

Figure 8 shows the temperature function of the silicon yield for 1 and 10% initial mixtures of $SiHCl_3$, $SiHBr_3$, and $SiHI_3$ in H_2. The thermal stability of the compounds are found to be $SiHCl_3 > SiHBr_3 > SiHI_3$ for temperatures up to the melting point of silicon. Although the data in Fig. 8 show nearly the same silicon yields from both the Si-H-Cl and Si-H-Br systems at high temperatures, equivalent experiments in this laboratory have indicated that 5% $SiHBr_3$ in H_2 yields a 40% greater polycrystalline silicon deposition rate than the corresponding $SiHCl_3$ mixture at 1400°K (24). It is obvious, however, that silicon deposition in flow systems is kinetically controlled and that equilibrium conditions are not attained in either case.

The high partial pressure of monatomic iodine at $\geqslant$ 1200°K is the reason for the increased complexity of Fig. 7 for the Si-H-I system over Fig. 6 for the Si-H-Br system. At approximately 1400°K, the partial pressure of I(g) becomes so high that the major silicon-containing compound in the gas phase, SiI_2, passes through a maximum and consequently causes the silicon yield, as seen in Fig. 8, to pass through a minimum. Since a similar behavior has been theoretically predicted and experimentally verified in the germanium-iodine system (25), the transport experiments described in the Appendix were performed to prove our thermodynamically predicted yield curve.

In the Si-H-Br system the only experimental yield or deposition rate data available in the literature for comparing our thermodynamically determined data to is the hydrogen reduction of silicon tetrabromide by Miller and Grieco (3). Their deposition rate-mole fraction curve was found to be considerably below the

calculated curve as has been shown to also be the case for $SiCl_4$ and $SiHCl_3$ as source materials in the Si-H-Cl system (23). The same case is found to exist for the data by Seki and Araki (13) in the Si-H-I system.

Si-I system.—The two common processes carried out in this more limited system (hydrogen concentration equals zero) are silicon transport using an initial gas phase of SiI_4 or I_2 and silicon deposition by the pyrolysis of SiI_4. The partial pressure-temperature data in Fig. 9a and b show that SiI_4, SiI_2, and I are the only species that must be considered to be in equilibrium with solid-phase silicon over a total pressure range of 0.01-1.0 atm. In addition to these data, Fig. 10 indicates that SiI_4 can be expected to be stable up to a temperature of about 800°K. The Si-I system is

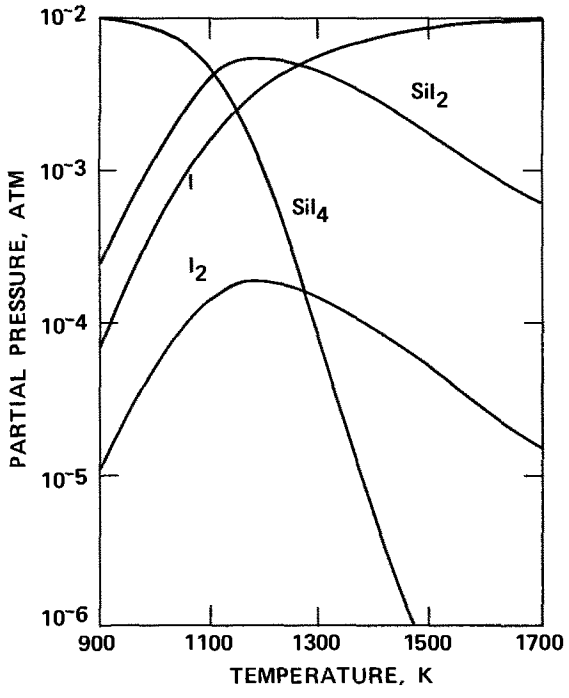

Fig. 9a. Equilibrium partial pressures of species in the Si-I system as a function of temperature at 0.01 atm total pressure.

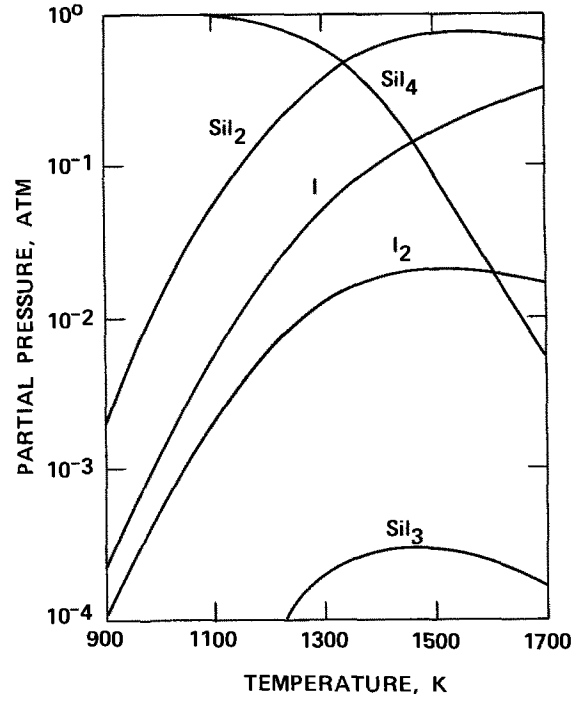

Fig. 9b. Equilibrium partial pressures of species in the Si-I system as a function of temperature at 1.0 atm total pressure.

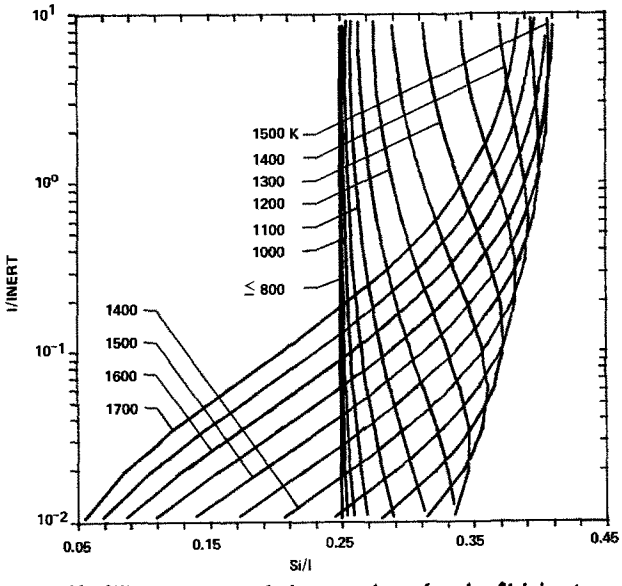

Fig. 10. Silicon content of the gas phase for the Si-I inert gas system as a function of the I/H ratio at 1.0 atm total pressure for 50° temperature increments.

unique with respect to the Si-H-X systems in that it is theoretically possible to obtain the same silicon yield (Si/I ratio) from different initial compositions of the gas phase at a high constant temperature, *e.g.*, 1300°K.

A check on the accuracy of our calculated data has been made by comparing it to the equilibrium data reported by Schäfer and Morcher (26) in their studies of the pressure dependence of the transport direction of silicon by silicon diiodide. Their data showed no transport to exist between temperature zones of 1223° and 1423°K at a total pressure of 79 mm. This is seen to be the case in Fig. 10 when one assumes the value of 79 mm (0.104 atm) is nearly equal to an I/inert ratio of 0.1. Fair agreement is also found between our computed silicon yield data and the ones calculated by Wajda and Glang (10) based upon reported (26) equilibrium constant data.

In a final attempt to set all the previously described systems in proper perspective to themselves and to the Si-H-Cl system, we have presented four threshold curves in Fig. 11. These curves indicate the threshold

between silicon etching and deposition for various temperatures and initial silicon tetrahalide concentrations.

Conclusions

A thorough thermodynamic analysis of the Si-H-Br and Si-H-I systems allowed many potential compounds to be rejected as being significant due to their low equilibrium partial pressures. Good reliability was therefore associated with the computed equilibrium data since thermodynamic data was either available or could be estimated with sufficient accuracy for the remaining predominate compounds. Consistency was found between our calculated data and the limited amount of experimental data found in the literature for the Si-H-Br, Si-H-I, and Si-I systems. A high-temperature minimum in the silicon yield curve theoretically postulated for the Si-H-I system was experimentally verified by the study of transport reactions. The high-temperature Si-H-I system differs from the Si-H-Cl and Si-H-Br systems because the concentration of the main silicon-bearing species SiI_2 passes through a maximum due to the increasing stability of monatomic iodine with temperature.

Acknowledgment

We wish to thank D. H. Sawyer for performing all of the experimental work associated with the transport reactions.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

APPENDIX

The general trend of the silicon yield-temperature curve shown in Fig. 12 was determined by measuring the rate of silicon transport in a temperature gradient between two silicon slices using the "sandwich technique" (32). A horizontal, induction-heated, quartz tube reactor was fed with a 250 ml/min hydrogen stream that passed through an iodine sublimator so as to maintain an 11% I_2 mixture. The source and substrate were 0.6 mm by 13 mm diameter, polished, float-zoned silicon wafers of <111> orientation that had been previously cleaned in solvents. The wafers were separated by 0.2 mm spacers.

Transport reactions were carried out at the corrected pyrometric temperatures (±5°K) for time periods up to 60 min. Deposition rates were determined microscopically by measuring the deposited layer thickness on a cross section of the substrate.

Circular and Hexagonal Stacking Faults in Bulk Silicon Crystals

Lawrence D. Dyer* and Fred W. Voltmer

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Circular and hexagonal defects were formed in bulk silicon crystals by annealing and slow cooling. Some of these circular defects were unusual in possessing spoke-like radial lines in <110> directions. By use of the rule that the Burgers vector is invariant against displacement of the Burgers circuit through good crystal regions, the radial lines are shown to have zero net Burgers vector and thus are probably dislocation dipoles. A mechanism is presented that accounts for the observed defects in terms of the formation of Frank sessile loops and half-loops. The principal significance of this interpretation is that when the circular defects containing radial lines appear, precipitates are present in the material.

In the course of a development program to improve yields of polished slices for epitaxial substrates, some rather peculiar defects were noted in slices from ordinary silicon boules that had been annealed. These defects were identified by their etching characteristics as circular and hexagonal stacking faults. Similar faults have previously been observed in annealed bulk silicon crystals doped with gold (1-4) or oxygen (5). Also, truncated circular stacking faults occur when silicon is annealed in steam or wet oxygen, particularly if polishing damage remains (6-13). These defects can seriously affect device performance and yields, either by themselves or by causing further defects in epitaxial layers grown after their generation.

The source of the circular stacking faults in bulk silicon has previously been attributed to line defects (3, 4) and to precipitates (3-5). Dislocation networks have been reported within the circular stacking faults, but details are lacking (5). The present article shows that circular faults can form in annealed bulk crystal without intentional gold or oxygen treatment. In addition, in the present work radial dislocation lines (spokes) occur within the faults. In this case, precipitates are almost certainly present, although they have not been positively identified in this study. The Burgers vectors of the various dislocation lines in the ring-spoke combinations are worked out and a mechanism for their formation is presented. A later paper will show infrared evidence for precipitates and will deal with the nature of the precipitation and the distribution of the faults.

Experimental Procedure

The silicon crystals used in this study were grown in the <111> orientation by the Teal-Little modification of the Czochralski technique (14). The crystals were sawed into 3-4 in. lengths and were annealed in this form, either at 1100°C for 20 hr or at 1225°C for 4 hr. Cooling times to 700°C varied from 5 min to 2 hr, and the furnace atmosphere was 99% N_2, 1% O_2.

A number of 2-in.-diameter samples were sliced from the silicon crystals 1½°-2½° off the {111} face and were chemically-mechanically polished on one side to a thickness of approximately 0.012 in. The slices were Sirtl etched (15) for 4 min and inspected with a Reichert Zetopan microscope equipped with Nomarski interference contrast equipment.

Observations

Figure 1 shows a group of defects on one of the slices. They appear as circles and grooves lying in three <110> directions. (In all the photographs, a <110> direction is parallel to the bottom of the picture). The circles are generally as large as the grooves in the same vicinity.

The etched circular defects may exhibit any or all of six radial lines which lie in $<1\bar{1}0>$ directions. These will hereafter be called spokes. Figure 2 shows all the types of rings with 1, 2, 5, and 6 spokes. Figure 3 shows all the types of rings with 3 and 4 spokes. Figure 4 shows other types that can occur: a, hexagonal; b, c, and d, concentric rings of various types; e, rings with a central dot; f, cases of non-$<1\bar{1}0>$ spokes within the ring. In the latter case note the etch pits that occur in the $<1\bar{1}0>$ grooves. Figure 5 shows an example of a ring with a diametral line that terminates in two etch pits.

Some rings appear with one side open (Fig. 6). When this happens all such partial rings on the slice are open

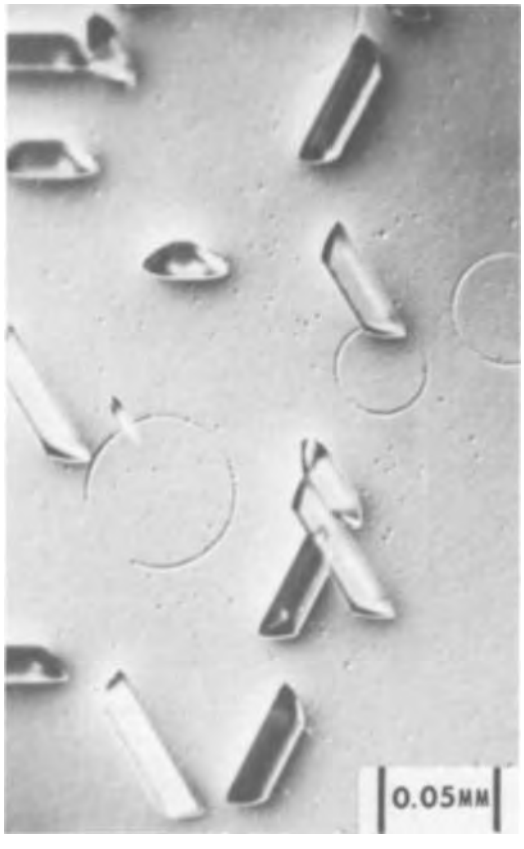

Fig. 1. Circular defects in <111> bulk silicon crystal. Interference contrast.

Key words: precipitates in silicon, dipoles, fault nucleation.

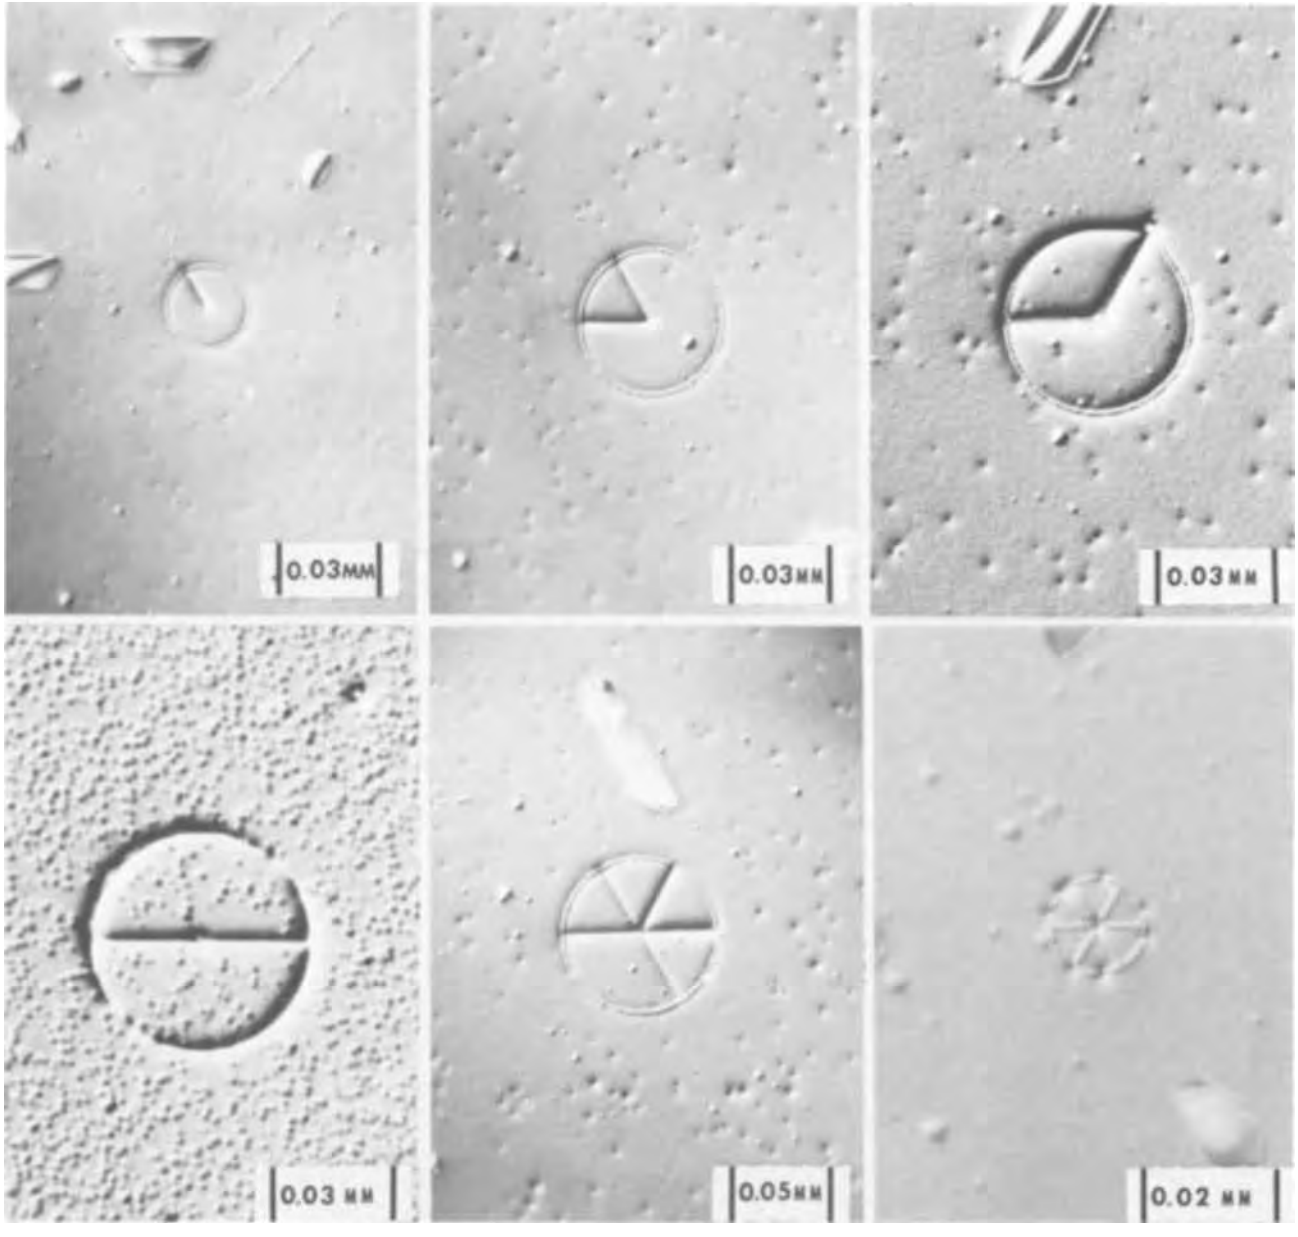

Fig. 2. Circular defects with 1, 2, 5, and 6 radial lines (spokes). Interference contrast

on the same side. No etch pits appear where the partial rings terminate.

The rings and the spokes etch differently. Figure 7 shows a polarization interferogram of a fault having a diametral line. The line is a ridge 0.3 μm high, while the ring is a shallow groove with raised edges.

No dislocation etch pits from plastic deformation were observed in the slices.

The faults were observed in both n- and p-type slices having resistivities of 10-200 ohm-cm. There was a general tendency for the defects to be larger in the case of slower cooling rates and in the lower portion of the boule. Also, there was a radial variation of defect size within the slices. These aspects will be discussed in a later paper.

Discussion and Interpretation of Results

The Sirtl etch technique is known to reveal circular stacking faults in the same manner as seen here, *i.e.*, a stacking fault leaves a deeply etched groove when it intersects the (111) plane of the slice surface, and the surrounding partial dislocation etches as a shallow groove when the stacking fault is parallel to the (111) surface of the slice (3, 4). Patrick (5) has shown that when the circles and the grooves appear in the same region of the slice, the grooves are (111) intersections of loops, identical with the circular ones. Thus it is supposed that we are dealing with four sets of circular stacking faults, three on inclined {111} planes and the fourth in the (111) plane that is 1½°-2½° off the slice surface. The latter set would give rings open on one side should the slicing operation happen to cut through any circular faults. It appears that the spokes are some type of dislocation, since they are revealed as etch pits in cases where they intersect the (111) surface at a large angle. (See Fig. 4, lower right). The possibility that the spokes are precipitates emanating from a nucleation center is eliminated by the existence of forms such as Fig. 4c.

First it will be shown that the spokes lying inside the circular faults are dislocation dipoles by virtue of having a zero net Burgers vector. Various possible sources of formation of the fault are eliminated by this finding. Next, a probable mechanism of ring and spoke formation will be presented. Finally, it will be shown that all of the partial dislocations in the rings and spokes have the 1/3 <111> Burgers vector normal to the plane of the ring, so that each sector of a ring-spoke combination consists of a Frank sessile loop (16).

Net Burgers vector of spokes.—The spokes will be shown to have a net Burgers vector of zero by refer-

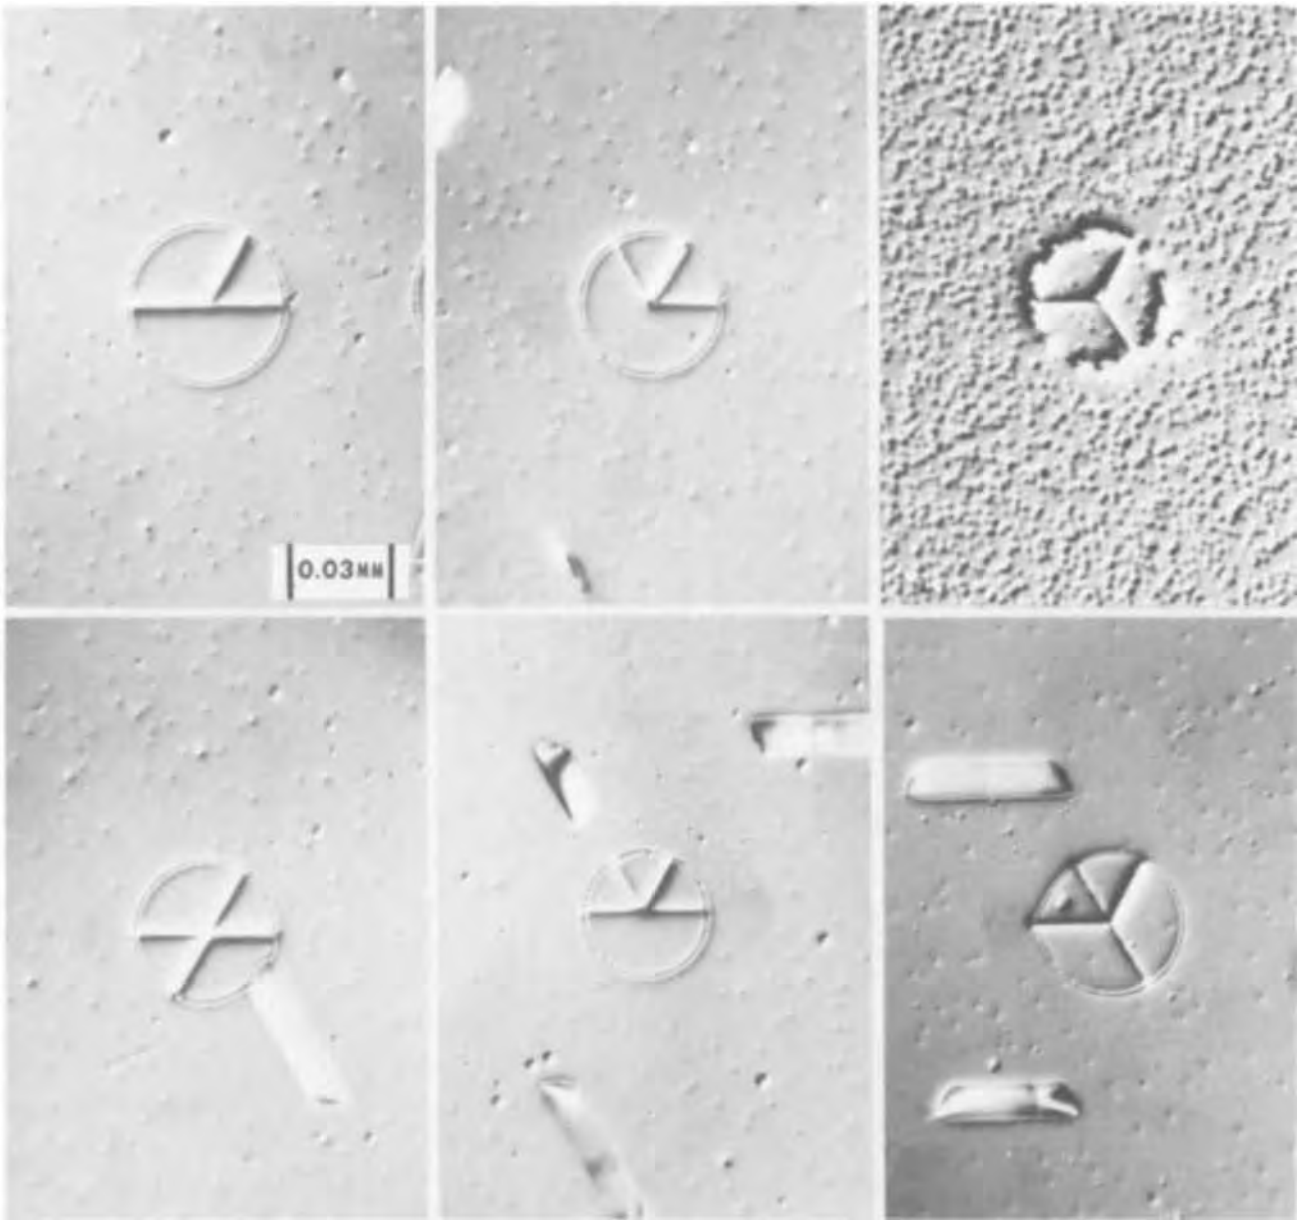

Fig. 3. Circular defects with 3 and 4 spokes. Interference contrast

ence to Fig. 8. The rule that the Burgers vector is invariant against displacements of the circuit through good crystal regions (17) will be used. The Burgers circuits are indicated on the figure by •−−−−−+ (• in, + out). By this is meant a polygonal circuit around the dislocations, such as given by Hornstra (18), which circuit is to be compared with an associated path in the ideal reference crystal for determining the resultant Burgers vector of all the dislocations within the circuit. On the figure, the dislocations are labeled by numbers where necessary: 11′, 22′, etc.; writing the two numbers on either side of the dislocation secures the proper reversal of sign as the dislocation is looked at from one end or the other. With this notation, the addition and subtraction of Burgers vectors may be handled in the same way as with the Thompson notation (19). In the following analysis note that no specific Burgers vector needs to be determined by the fundamental lattice comparison procedure, and that, since the circuits are always taken in good crystalline regions, the construction of Burgers circuits is not complicated by the presence of the stacking fault.

The two circuits taken in Fig. 8a show that any dislocation ring has a zero net Burgers vector, in other words, the two opposite sides of the ring have equal and opposite Burgers vectors when viewed from the same end (19).

In Fig. 8b, the circuits taken show that the net Burgers vector of the single spoke is also zero. In Fig. 8c, we cannot thus far assume that arc 4 has the same Burgers vector as arc 1, so they are separately labeled. First, taking the two Burgers circuits lying horizontal in the figure

$$11' + 22' + 33' + 1'1 = 0 \quad [1]$$

Then taking the other two circuits

$$11' + 22' + 44' = 0 \quad [2]$$

and

$$11' + 3'3 + 44' = 0 \quad [3]$$

Therefore

$$22' + 3'3 = 0 \quad [4]$$

Combining [1] and [4]

$$22' = 0 \quad [5]$$

Substituting in [4]

$$3'3 = 0 \quad [6]$$

Replacing [5] and [6] in [2] and [3]

$$11' = 4'4$$

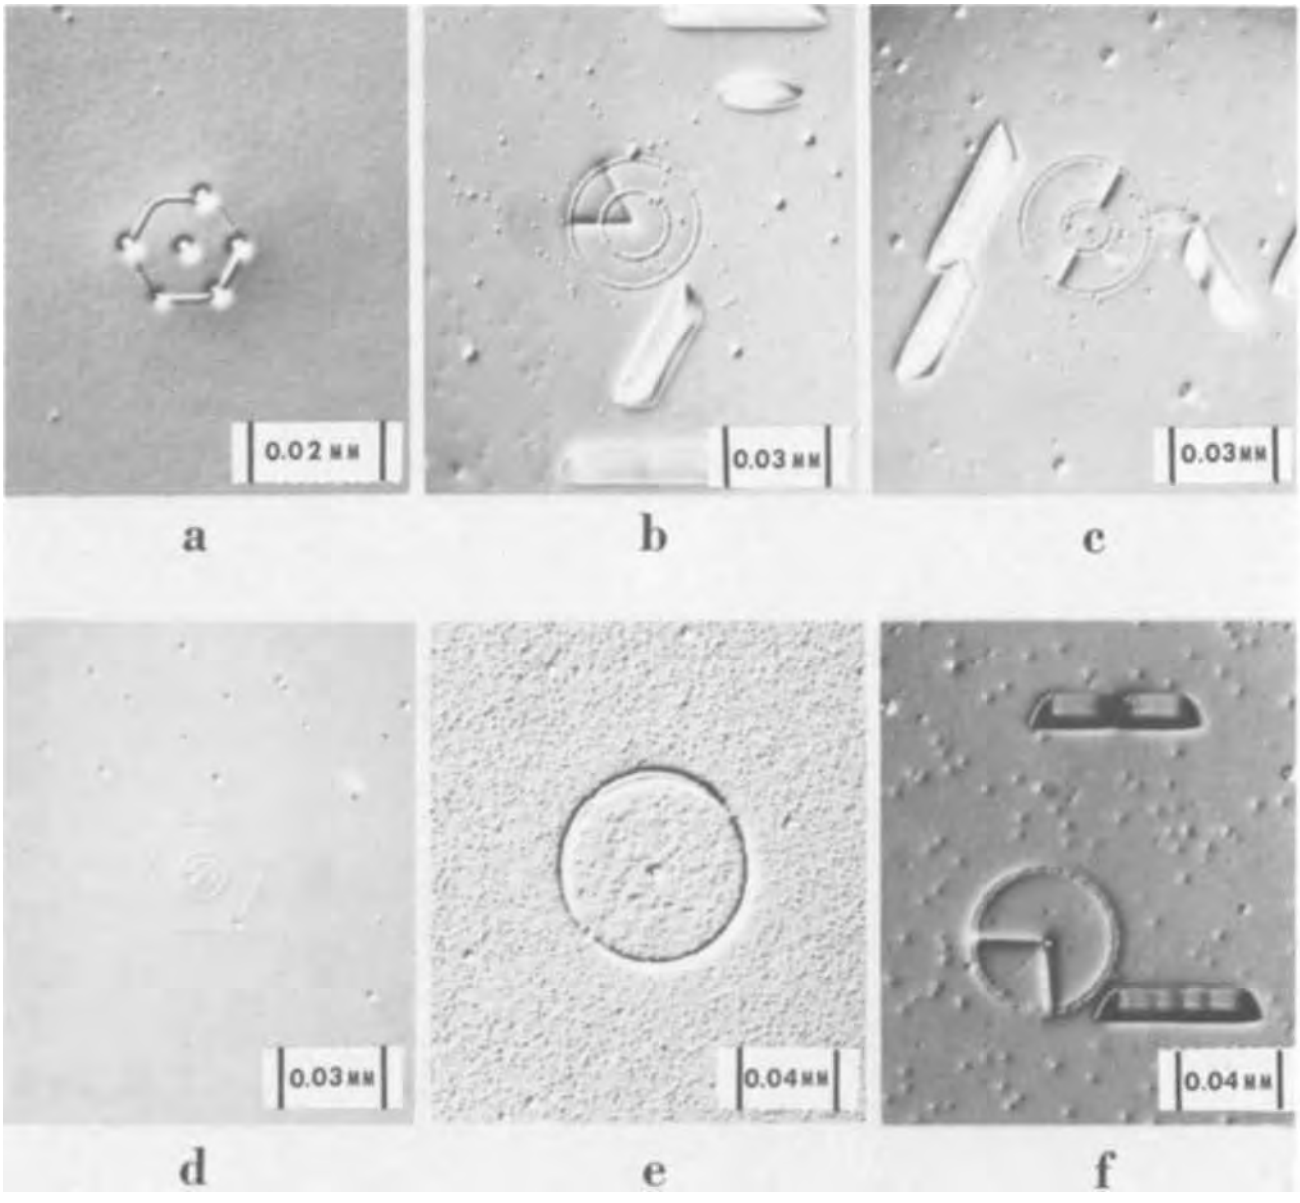

Fig. 4. Ring defects of various types: a, hexagonal; b, concentric rings with spokes in both rings; c, concentric rings with spokes between rings; d, concentric rings with spokes in inner ring; e, ring with a central dot, f, ring with non-<110> spoke. Interference contrast.

i.e., the entire ring has the same Burgers vector. By the same process as for Fig. 8a, the spokes have zero net Burgers vector and are therefore dislocation dipoles.

Although it cannot be shown, it is reasonable to expect that the forms with more spokes are similarly constituted of dislocation dipoles as spokes and a ring having one Burgers vector.

The termination of a diametral line within the circular stacking fault (Fig. 5) can now be understood as the pinching off of a dislocation dipole at both ends and the attendant formation of short lengths of dislocation at either end of the dipole. These short lengths are sufficiently vertical to the plane of the slice to leave standard dislocation etch pits.

The circular stacking fault that contains only one spoke (Fig. 2) deserves some attention. The one spoke should exhibit a dislocation etch pit at the center of the fault unless the dipole terminates at a precipitate at this point. Justification will be presented in the following section for such a precipitate.

Sources of ring and spoke formation.—In the previous section it was shown that the spokes within the rings were dislocation dipoles and that all arcs of each ring had the same Burgers vector. The various possible sources of the ring-spoke combinations. *i.e.*, line sources dislocation loops, and precipitates, will now be discussed.

Two types of line sources will be considered: single lines and multiple lines. Bardeen-Herring line sources have been suggested as the cause of the circular stacking faults (3, 4). Also, the line source in the Silcock and Tunstall mechanism (8, 9, 20) is attractive for explaining the formation of the faults, since a stacking fault is produced in back of a partial dislocation and this partial has what will later be shown to be the correct Burgers vector. For one of these sources to generate the ring-and-spoke combinations of Fig. 1-6, it would have to encounter multiple obstacles that were located close to the source and were arranged around the source, then encounter no other such obstacles during the growth of the fault to full size. The obstacles would have to be capable of diverting the various sectors of fault to separate levels in the crystal. In addition, some evidence for the pinning of the source by dislocations or precipitates should be seen, such as etch pits at both ends of the source. These considerations show that it is very improbable that the circular faults originate at single line sources.

Multiple line sources could conceivably generate the observed combinations. However, since the overwhelming majority of dipoles radiate from a center,

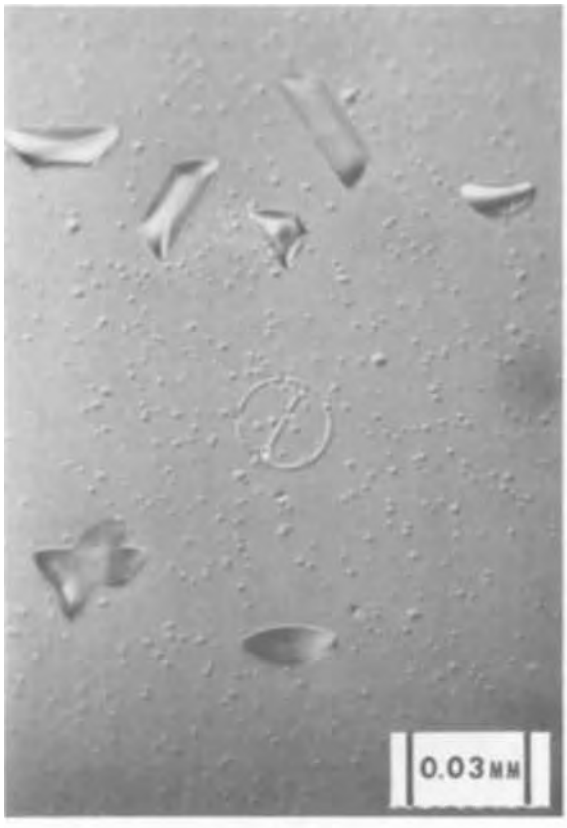

Fig. 5. Ring with diametral line terminating in etch pits. Interference contrast.

Fig. 7. Ring with diametral line. Polarization interference

Fig. 6. Rings with one side open. Interference contrast

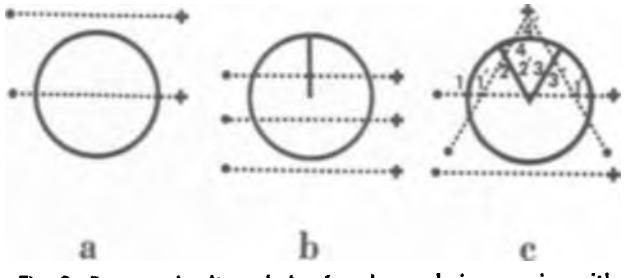

Fig. 8. Burgers circuit analysis of spokes and ring: a, ring with no spokes; b, one spoke; c, two spokes.

these sources would again have to be close to that center and be arranged about it. They would also have to have the same Burgers vector. Such a situation is not likely since we are assuming the line sources to be independent.

Single dislocation loops would also have to form the spokes by passing through an unlikely arrangement of obstacles. Such loops are not considered the probable sources, therefore, whether they are faulted or unfaulted. With the elimination of line sources and single dislocation loops as possible sources, precipitates seem to be the only plausible remaining cause.

Iizuka and Kikuchi (3, 4) suggested that the faulted loops are Frank sessile loops that are nucleated from oxygen precipitates and that they grow by a mechanism similar to that controlling the climb of straight dislocations. In the following section a mechanism is presented by which each circular fault containing dipoles is formed from several Frank sessile loops that are nucleated on a precipitate.

Mechanism of ring and spoke formation.—The fact that the spokes are dipoles implies that they were formed by dislocations arriving on parallel but separate planes. The fact that the fault consists of sectors bounded by circular arcs of partial dislocations suggests that each sector originated from a faulted dislocation loop or half-loop on a center of nucleation such as a precipitate. Spherical precipitates could form circular faults on four intersecting {111} planes. Since most of the present faults occur singly, the precipitate

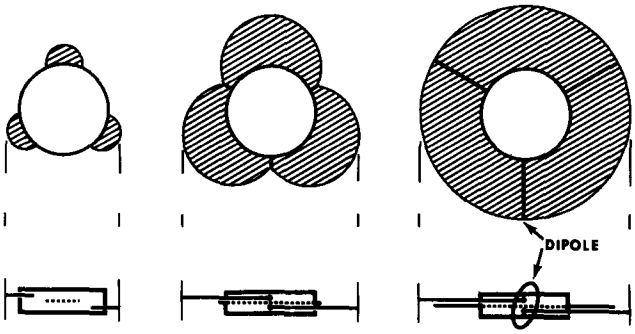

Fig. 9. Mechanism of ring and spoke formation in the case of ring with three spokes: a, faulted loops arise on three separate levels around a precipitate of tabular habit; b, loops expand by climb and form dipoles where they meet; c, continued growth of faulted loops results in ring with spokes (dipoles).

is probably of tabular habit. Figure 9 shows the mechanism by which the faulted loops can arise around a precipitate of tabular habit and result in one of the observed ring-spoke combinations. As the half-loops expand they are attracted to one another at their edges, but only annihilate readily if they were created on the same plane. Thus, in many cases dipoles are formed and take the $<1\bar{1}0>$ directions for minimum energy. The fact that non-$<1\bar{1}0>$ spokes sometimes appear may mean that other energy minima occur besides $<1\bar{1}0>$ around the [111] zone.

The observation that the rings and spokes etch differently can now be understood, because the rings consist of single partial dislocations whereas the spokes consist of a pair of oppositely oriented partial dislocations.

Burgers vector of ring.—Let us consider the possible Burgers vectors of all the loops making up ring-spoke combinations having two or more regions (such as those in Fig. 3 and 4). We will assume that each region separated from others by spokes is formed from an independent faulted dislocation loop. If nonvertical Burgers vectors are possible, then the rotational symmetry of the crystal face requires that at least three such vectors are possible for each loop. But some spokes could then exist in which the net Burgers vector was finite, which was shown to be false. The only vector that would not violate the rotational symmetry condition is vertical to the ring, *i.e.*, $<111>$. The actual Burgers vector is very probably 1/3 $<111>$; in other words, each loop is a Frank sessile loop.

The formation of the Frank sessile dislocations around the precipitate can now be visualized as the insertion of either an extra layer of silicon atoms or of the collapse of a layer of vacancies at each place of nucleation around the precipitate, and the subsequent expansion of each Frank partial dislocation by climb. One might ask why the dipoles do not readily annihilate by climb which would involve much smaller distances than the climb taking place in expansion of the fault. Such annihilation would require bending of the fault which has a very strong kinematic restraint (17). This probably occurs only when the two faults are created on planes that are very close to one another, possibly one or two atom diameters apart.

The foregoing explanation may also account for the formation of stacking faults in steam-oxidized silicon, especially when there is no surface damage to generate Frank sessile loops (10). In this case the faults have been found to be extrinsic, which implies that the growth of the fault occurs by evolution, rather than accumulation, of vacancies.

If the precipitate is large enough, more than six Frank sessile dislocations could presumably form simultaneously on separate planes. These would grow and yield more than six spokes. The most that have been observed thus far have been six. This result may be due to the decreased probability of forming more Frank loops, or it may mean that there is some other constraint on the formation of the loops, such as having a preferred azimuth (such as $<110>$) at which loop generation can take place.

Conclusions

Circular and hexagonal stacking faults formed during the annealing treatment of melt-grown silicon crystals were found to contain radial line defects. The circular faults are formed by the nucleation of one or more Frank sessile dislocations around a precipitate of tabular habit, followed by the growth of the sessile half-loops by climb and the formation of radial lines (dislocation dipoles) where the loops meet on parallel but separate planes.

The mechanism may also be applicable to stacking faults formed in damage-free steam-oxidized silicon.

Stability and Stirring in Crystal Growth from High-Temperature Solutions

Hans J. Scheel

IBM Zurich Research Laboratory, 8803 Rüschlikon, Switzerland

and D. Elwell

Physics Department, Portsmouth Polytechnic, Portsmouth, United Kingdom

ABSTRACT

Crystals normally grow in solution in a destabilizing supersaturation gradient. The observation of inclusion-free growth to large crystal sizes may be described in terms of a metastable region of the supersaturation gradient which is associated with the mechanism of growth on the habit faces. Stirring has a beneficial effect on growth stability especially by reducing or removing the supersaturation inhomogeneity across the face of a polyhedral crystal. The effect of convection and of various stirring techniques is briefly described.

The widespread use of high-temperature solution techniques for the growth of bulk crystals (as distinct from crystalline films) has been retarded by a tendency towards the formation of small crystals by multinucleation and by the frequent occurrence within the crystals of solvent inclusions. The former problem may in general be overcome by the use of seeding, by cyclic temperature variations, or by careful control of the temperature distribution within the crucible, and many examples are now known of crystals weighing 50g or more.

On the other hand, the conditions under which stable growth may occur up to large crystal sizes in solution have not been clearly established, and quantitative criteria of growth stability which may be readily used by experimentalists are still lacking. "Stable growth" in the context of growth from solution may be taken to imply inclusion-free growth, since solvent inclusions will result from various forms of growth irregularities.

Formal theoretical treatments of growth stability normally treat the problem of morphological stability, or whether a specified shape is stable against infinitesimal perturbations. This problem differs from the related question of whether a given shape or habit is preserved as the crystal grows.

Morphological stability treatments are restricted to simple crystal shapes. Mullins and Sekerka (1) examined the stability of a spherical crystal with isotropic surface kinetics growing in a supersaturated medium. They concluded that the sphere is stable only if its radius is below a critical value, in the region of 0.1 μm. This value may be increased to about 10 μm by the inclusion of surface diffusion (2), but even the latter value is much below the size of inclusion-free crystals which can be grown from solution.

In the case of a plane surface of unlimited extent growing in a doped melt, there is general agreement between the perturbation treatment (3) and the constitutional supercooling criterion (4, 5) which was introduced independently by Ivantsov (6) as "diffusional undercooling." According to this criterion, instability results if the growth rate exceeds some critical value which depends on the temperature gradient at the crystal-liquid interface.

In this paper the concepts of a critical size and critical growth rate will be examined in detail with reference to the theory of solution growth and, where possible, to experiments on high-temperature and aqueous solutions. The importance must be recognized in any treatment of crystal growth from solution of the strong tendency of the crystals to form facets. A realistic theory must therefore treat the growth of finite polyhedra, and the stabilizing effect of the interface kinetic processes on the habit faces must be taken into account.

The importance of stirring for the enhancement of growth stability will be demonstrated, and the effectiveness of stirring by natural and forced convection will be discussed.

Key words: crystal growth, hydrodynamics, growth mechanism, growth stability, crystal/solution interface.

Stages in Growth from Solution

The factors which are of crucial importance in determining whether or not growth will be stable under chosen experimental conditions is likely to depend on which stage in the growth process is rate-determining. The process of crystal growth from solution may be treated as a sequence of stages as discussed, for example, in the review of Parker (7) or by Laudise (8), and as illustrated in simple form in Fig. 1. The removal of solute from the solution by the growing crystal creates a flow of solute towards the crystal surface. This flow is mainly by diffusion which can be imagined to take place through an "unstirred" boundary layer

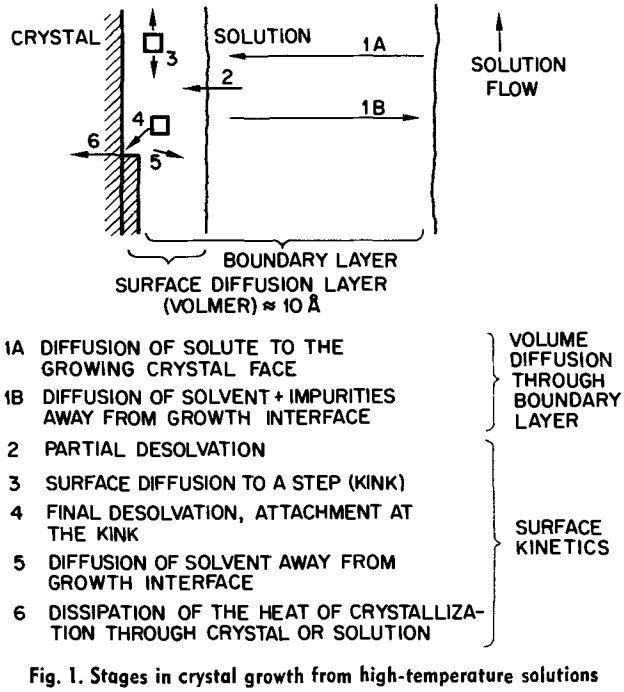

Fig. 1. Stages in crystal growth from high-temperature solutions

(9) of thickness δ (stage 1A)[1] and there will be a corresponding counterdiffusion of solvent and of impurities away from the crystal-liquid interface (stage 1B). At the surface, partial desolvation (stage 2) and surface diffusion of solute (step 3) will occur in the adsorption or Volmer layer which will be a few molecular diameters in thickness. The integration of solute into the crystal (stage 4) will occur at a kink site, with further desolvation. On a habit face, growth takes place by the spreading of steps over the crystal surface and kinks will be present at the edges of these steps. The heat of crystallization is dissipated (stage 6) through the solution or through the crystal if the latter is cooled. Stages 2-6 may be regarded as the surface kinetic mechanism which has been treated in the classical paper of Burton, Cabrera, and Frank (10); by Bennema (11); Gilmer, Ghez, and Cabrera (12); in the Parker review (7) and; with special reference to high-temperature solutions, by Elwell and Neate (13).

Apart from a choice of solvent and temperature, the experimenter normally attempts to influence the growth conditions by varying the supersaturation (either directly or indirectly by changing the cooling rate or rate of solvent evaporation) or by varying the boundary layer thickness δ by changing the rate of relative motion between crystal and solution. If the solution flows at a rate u past a stationary crystal face of length l, the value of δ has been estimated by Carlson (14) and by Bennema (11) as

$$\delta = \left[0.463 \left(\frac{\eta}{\rho_s D} \right)^{1/3} \left(\frac{\rho_s u}{\eta l} \right)^{1/2} \right]^{-1} \qquad [1]$$

where η is the viscosity and ρ_s the density of the solution and D the diffusion coefficient of the solute. Carlson prefers a model with nonuniform solute concentration along the crystal surface, whereas Bennema assumes a uniform concentration, in which case the factor 0.463 should be replaced by 2/3.

If diffusion through the boundary layer is rate-limiting, stirring will tend to increase the growth rate as originally postulated by Nernst (15). The linear growth rate is given by

$$v = \frac{n_e K \sigma}{\rho_c} \qquad [2]$$

where ρ_c is the density of the crystal, n_e the equilibrium concentration of solute, and σ the relative supersaturation $(n_s - n_e)/n_e$, with n_s the concentration in the bulk solution. K is an activity coefficient which, for volume-diffusion limited growth, is D/δ. Therefore the growth rate in this case is

$$v = \frac{n_e D \sigma}{\rho_c \delta} \qquad [3]$$

At low supersaturation (and for strong agitation) K is determined by surface kinetics and is a function of the supersaturation.

When both volume diffusion and surface kinetics influence the growth rate, the value of v may be approximated by the relation

$$\frac{v \delta \rho_c}{D n_e} + \left(\frac{v}{A} \right)^{1/m} = \sigma \qquad [4]$$

which is similar to that derived by Brice (16). Equation [4] reduces to Eq. [3] in the limit where $A \to \infty$, while $v = A\sigma^m$ is the kinetic-controlled limit as $\delta/D \to 0$. The variation of the linear growth rate with δ for various values of supersaturation is illustrated in Fig. 2. In a normal crystal-growth experiment, the rate at which solute is deposited from the solution will be determined only by the volume of solution, by the solubility curve, and by the rate at which the solution is cooled. For a given surface area of crystal on which growth is occurring the supersaturation will adjust itself (for a given value of δ) until the linear growth rate has the value indicated by Fig. 2. As shown on the diagram, too high a value of the supersaturation will lead to nucleation of more crystals. Stirring thus has the beneficial effect of permitting growth at lower supersaturation through a reduction in the value of δ, according to Eq. [1]. The limitation of the growth rate by surface kinetics at high stirring rates (small δ) is indicated approximately on the diagram for $\sigma = 0.005$ and $\sigma = 0.01$.

At high supersaturation and high stirring rate a maximum stable growth rate is reached which is independent of σ, n, or δ. This ultimate rate of stable growth will be determined by the surface kinetics (possibly by desolvation or the density of kink sites) or by the heat flow, especially at high values of the solute concentration. In the limiting case of growth from a pure melt, the maximum growth rate is given (17) by

$$v_{max} = \frac{K_s}{\Delta H_v} \frac{dT_s}{dx} \qquad [5]$$

where ΔH_v is the latent heat per unit volume, K_s the thermal conductivity of the solid, and dT_s/dx the temperature gradient in the solid. In the more typical case of the growth of oxides from molten salts at solute concentrations of 10-30%, the maximum stable growth rate appears from experiment to be in the region of 200-500Å sec^{-1} (18). The origin of an ultimate stable growth rate is not clearly established and techniques which would permit stable growth from solution at faster rates than those indicated above would be highly beneficial. In the subsequent discussion we shall as-

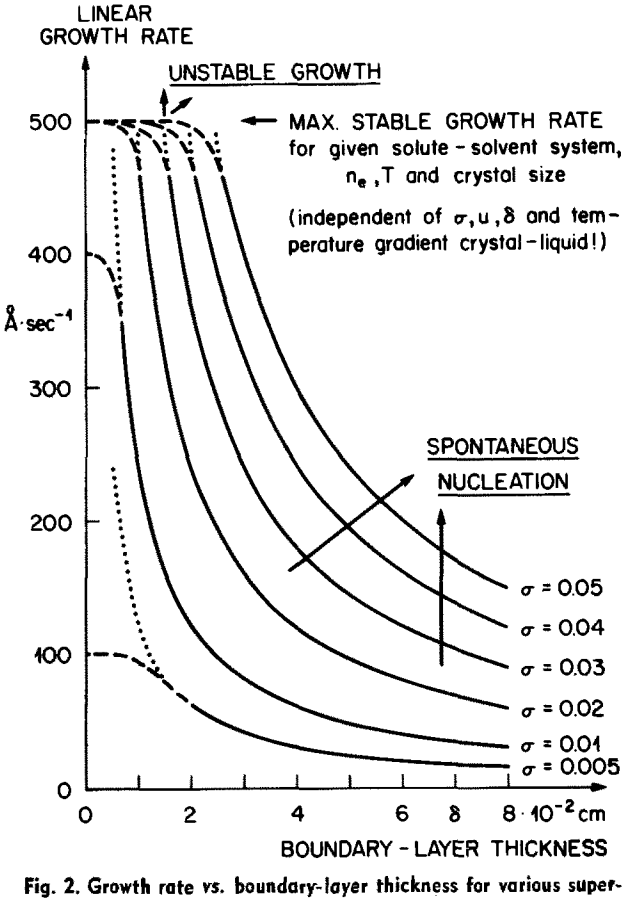

Fig. 2. Growth rate vs. boundary-layer thickness for various supersaturations.

[1] In this paper δ refers to the solute diffusion boundary layer which in solution growth is normally of the same order of magnitude as the hydrodynamic boundary layer.

sume that growth occurs at some value below this limit and that the rate of removal of the heat of crystallization has a negligible effect on the growth rate. The latter assumption appears to be justified under normal conditions of solution growth (13).

Supersaturation Gradient Criterion

In growth from the pure melt, the stability criterion which has been of greatest value is that of constitutional supercooling. A similar condition may be expected to apply to solution growth, since the rejection of solvent by the growing crystal is closely analogous to the rejection of impurities in melt growth. However the term "constitutional supercooling" is not wholly appropriate for growth from solution, and it is desirable to re-examine the stability condition specifically for the case of solution growth.

The occurrence of volume diffusion in some boundary layer is inevitably associated with a gradient of solute at the crystal-solution interface. If a protuberance develops by random fluctuation on an otherwise flat interface, this protuberance will encounter a higher solute concentration than that of the flat region and will therefore tend to grow with respect to this region. This tendency towards instability of the interface may be eliminated by the application of a sufficiently large temperature gradient, the important factor being whether or not there exists a gradient in the supersaturation normal to the crystal surface. For stable growth of an interface at $x = 0$, we therefore require that

$$\left(\frac{d\sigma}{dx}\right)_{x=0} < 0 \qquad [6]$$

or, as is equivalent for small supersaturations

$$\left(\frac{dn}{dx}\right)_{x=0} < \left(\frac{dn_e}{dx}\right)_{x=0} \qquad [7]$$

where dn/dx is the solute gradient normal to the interface and n_e the equilibrium concentration of solute as before.

If the capture of solute by the moving crystal surface is neglected as a first approximation, the solute gradient is related to the linear growth rate by

$$v = \frac{D}{\rho_c}\left(\frac{dn}{dx}\right)_{x=0} \qquad [8]$$

For an ideal solution $n_e = n_\infty \exp(-\Delta H/RT)$, with n_∞ a constant, so that

$$\frac{dn_e}{dx} = \frac{\Delta H\, n_e}{RT^2}\frac{dT}{dx} \qquad [9]$$

and substitution from Eq. [8] and [9] into [7] gives the condition for stability as

$$v < \frac{Dn_e\,\Delta H}{\rho_c RT^2}\left(\frac{dT}{dx}\right)_{x=0} \qquad [10]$$

This condition is in substantial agreement with that obtained by Tiller (19) by a modification of the constitutional supercooling criterion.

Using typical experimental values of $D = 10^{-5}$ cm^2 sec^{-1}, $n_e = 1$g cm^{-3}, $\Delta H = 50$ kJ mole^{-1}, $\rho_c = 5$g cm^{-3}, and $T = 1500$°K, the maximum stable growth rate according to Eq. [10] will be about 0.5Å sec^{-1} for $(dT/dx)_{x=0} = 1$ deg cm^{-1} and a gradient of 1000 deg cm^{-1} will be required for the stable growth of crystals at 500Å sec^{-1}, which has been mentioned above as typical of the highest growth rates to be achieved experimentally. Equation [10] is therefore in clear conflict with experiment, since growth at 100-200Å sec^{-1} has been widely reported to occur in crucibles located in an enclosure at uniform temperature or even in a negative temperature gradient, with the heat of crystallization ΔH being removed by conduction through the melt.

In order to account for this discrepancy it must be assumed that the supersaturation gradient is insufficient for the growth of a protuberance relative to the rest of the surface. Therefore the crystals grow in a metastable region of the supersaturation gradient in which the protuberance grows at a negligibly slow rate with respect to the crystal surface. This region may be considered analogous to the well-known metastable (Ostwald-Miers) region in which a melt or solution is cooled below its equilibrium liquidus temperature without onset of nucleation.

The metastable region of the supersaturation gradient is illustrated in Fig. 3, in which the temperature distribution is particularly considered since this may be conveniently varied. Figure 3(a) shows the variation in the solute concentration ahead of the crystal surface together with the equilibrium value at the crystal-solution interface. The solute concentration at the interface is close to the equilibrium value, a condition which will be fulfilled if volume diffusion is the rate-limiting stage. The validity of the latter assumption for the examples of $NiFe_2O_4$ and $NaNbO_3$ in unstirred borate solutions is supported by experiment (20, 21).

Figure 3(b) shows the liquidus temperature T_L corresponding to the actual solute concentration n_s and the actual temperature distribution T_{eff} in the solution. Stable growth according to Eq. [10] requires that the temperature gradient at the interface should exceed that of the line denoted T_0 which is tangential to the curve of T_L at $x = 0$. T_{crit} represents the assumed

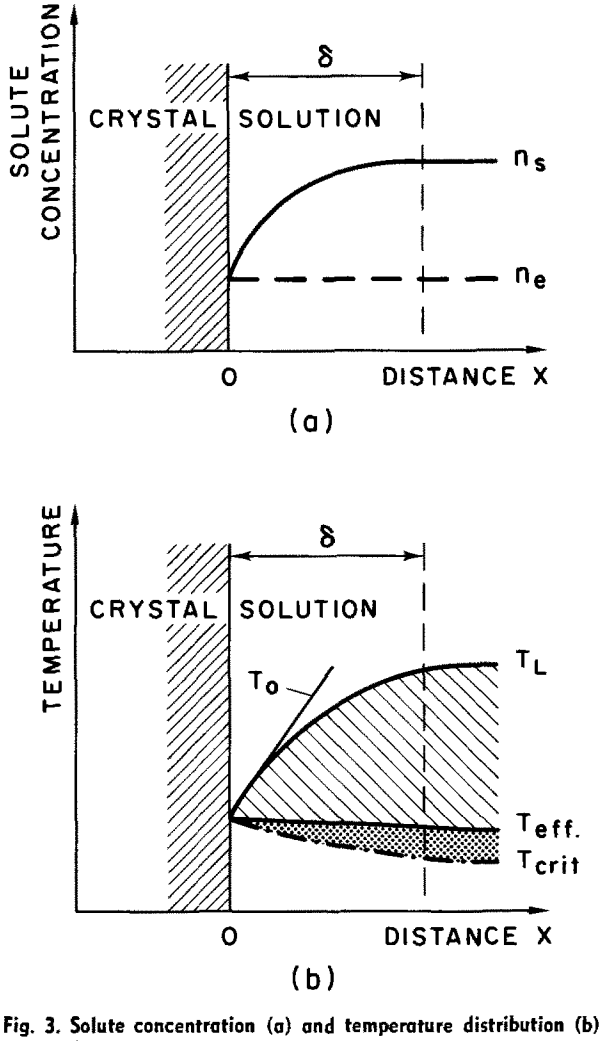

Fig. 3. Solute concentration (a) and temperature distribution (b) in front of a crystal growing from unstirred solution.

metastable limit so that the shaded area denotes the metastable region. Growth will occur without solvent inclusions so long as the gradient of T_{eff} at the interface is higher than that of T_{crit}, as is assumed in the example shown. The value of this critical gradient of temperature (or supersaturation) may be expected to depend on the crystal growth rate, the solute concentration, the interface temperature, the type of solvent and on impurities. Of particular importance is complex formation in front of the growing crystals which may have either a positive or negative effect on the critical supersaturation gradient. Also by analogy with the Ostwald-Miers region, the probability that an instability will develop should be increased if the growing crystal is subjected to any thermal or mechanical shock or vibration. Experience has shown that the size of inclusion-free crystals which can be grown increases if vibrations are minimized and the furnaces are located in separate enclosures in order to reduce any disturbances.

The increased stabilization which permits the stable growth of crystals in solution in a supersaturation gradient must result from the growth mechanism on the faceted habit planes. That interface kinetics can stabilize growth has been demonstrated by Coriell and Parker (22) and by Tarshis and Tiller (23). The particular case of growth on large facets has been considered qualitatively by O'Hara *et al.* (24), who postulate two main sources of stabilization. The first is the lower driving force for lateral growth of surface layers compared with normal growth and this will oppose the effect of any perturbation which tends to create more layers. The second is the capillarity term which is a consequence of the low energy associated with the habit planes, the orientation of which normally corresponds to a cusp in a Wulff (surface energy *vs.* orientation) plot. These effects could in principle be included by the introduction of appropriate anisotropic terms in the morphological stability treatment, but quantitative calculations would be very difficult and have not yet been reported.

Effect of Stirring on the Supersaturation Gradient

According to the simple model of the solution growth process outlined above, the effect of stirring is to reduce the width of the boundary layer and thus to cause a transition from diffusion-controlled to kinetic-controlled growth. The first effect tends to increase the supersaturation gradient, while the second decreases it so the net effect depends on the interface kinetics.

The flow of solute towards the crystal surface is given (25) in the steady state by

$$\frac{Dd^2n}{dx^2} + v\frac{\rho_c}{\rho_s}\frac{dn}{dx} = 0 \qquad [11]$$

the solution of which equation gives for the solute distribution

$$n - n_i = (n_s - n_i)\frac{[1 - \exp(-xv\rho_c/\rho_s D)]}{[1 - \exp(-\delta v\rho_c/\rho_s D)]} \qquad [12]$$

Here n_i is the solute concentration at the interface and the thickness δ of the boundary layer has been defined by the boundary condition that $n = n_s$ when $x = \delta$. The second term in Eq. [11] represents the capture of solute by the moving crystal surface, which has been neglected in our earlier approximations.

Equation [12] gives the solute concentration gradient at $x = 0$ as

$$\left(\frac{dn}{dx}\right)_{x=0} = \frac{(n_s - n_i)v\rho_c}{[1 - \exp(-\delta v\rho_c/\rho_s D)]\rho_s D} \simeq \frac{n_s - n_i}{\delta} \qquad [13]$$

The approximation is expected to be generally good since $v/D \sim 10^{-1}$ cm^{-1} and $\delta \sim 10^{-1} - 10^{-3}$ cm depending upon the solution flow rate.

The value of the solute gradient for a given n_s and solution flow rate u (and hence δ) will thus be determined by the value of n_i, and hence on the kinetic coefficient A of Eq. [4]. The solute distribution ahead of the crystal in a stirred solution is shown in Fig. 4(a), and the corresponding temperature distribution is indicated in Fig. 4(b). It has been assumed in this diagram that the solvent gradient is reduced by the stirring so that stability is enhanced. Figure 4 differs from a similar diagram of Tiller (19) whose interpretation of a sharp increase of the supersaturation gradient with increasing flow rate may hold only for a sudden increase of agitation. If a stabilizing temperature gradient is applied, this will tend to steepen due to mixing within the solution on stirring and some additional stabilization may be expected on this account (21).

Morphological stability treatments by Hurle (26) and Delves (27) confirm that stirring can provide some degree of stabilization of a plane interface. Experimental confirmation of the stabilizing effect of stirring is provided by observations of the surface of crystals grown from a melt in which the stirring is suddenly interrupted. Stability theory predicts (3, 27) a self-excited oscillatory motion of the interface near the breakdown of stability. In Fig. 5 a set of fine inclusions may be seen at the surface of a large $GdAlO_3$ crystal grown from a high-temperature solution in which stirring was stopped prior to removal of the excess solu-

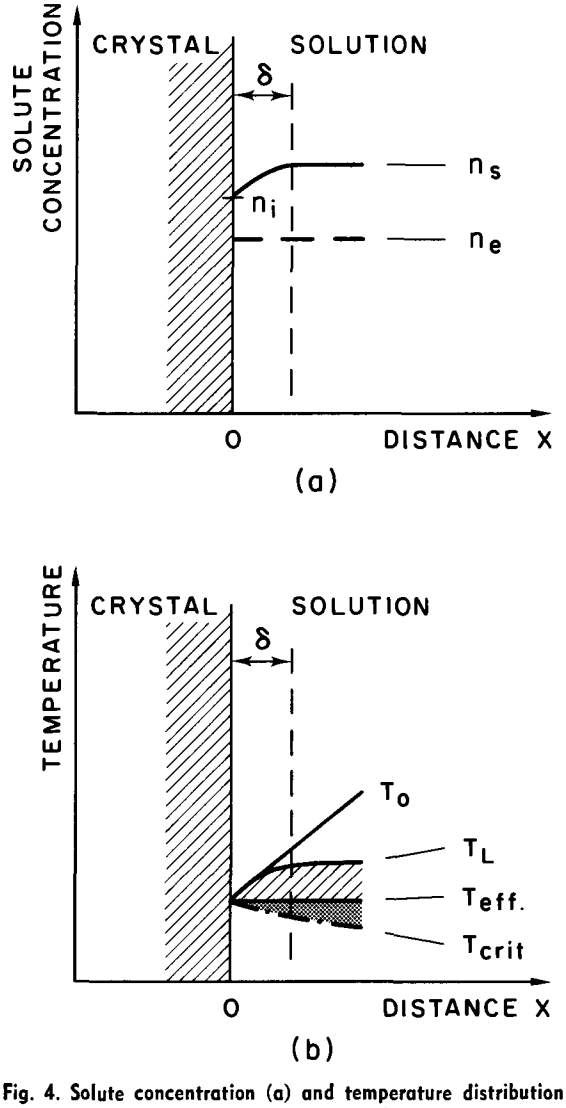

Fig. 4. Solute concentration (a) and temperature distribution (b) in front of a crystal growing from a stirred solution.

Fig. 5. Solvent inclusions near the surface of a 210g $GdAlO_3$ crystal due to interruption of stirring at the end of the growth experiment.

tion. The periodicity of the inclusions is about 30 μm which is in good agreement to the order of magnitude with theoretical predictions. A coarse inclusion structure intersecting the fine bands at an angle of 35°-36° may be due to a complex transient flow pattern on sudden cessation of forced stirring.

Stability of Polyhedral Crystals

The discussion of the previous sections was concerned with crystal surfaces of unlimited extent, whereas crystals in reality are finite polyhedra. The new problem introduced by taking into account the finite size of crystals is that of the supersaturation inhomogeneity across the surface. Because of the enhanced diffusional flow to the corners and edges of a crystal, the supersaturation in these regions is much higher than that at the face centers. This inhomogeneity has been measured in many examples of crystals growing from aqueous solution and amounts to about 25% in the case of sodium chlorate (28).

The stability of polyhedral crystals growing in solution has been considered by Cahn (29) and Chernov (30). Cahn took as his stability condition the requirement that the supersaturation should not vanish in the center of a face and provided theoretical justification for the well-established observation (31-33) that the stable linear growth rate must decrease as the crystal size increases. Chernov (30) proposed that the supersaturation inhomogeneity is compensated by the development of vicinal faces. The slope to the crystallographic habit plane at the face center may differ from that at the edges by about 2° if the increased kinetic coefficient at the center is to balance the lower supersaturation, but instability will result if the curvature at the center exceeds some critical value.

In both Cahn's and Chernov's treatments, substitution of typical data leads to a predication that the maximum size of crystals for stable growth should be of the order of 10^{-1} mm, which is clearly in conflict with experiment. The discrepancy arises from the assumption that solute is distributed over the crystal surface only by volume diffusion. In practice some allowance must be made for convective mixing within the solution, since it is clear that a crystal growing in a well-mixed solution will generally preserve its shape during growth. Carlson (14) demonstrated the necessity of stirring for the growth of large inclusion-free crystals of ammonium dihydrogen phosphate and derived an expression for the maximum size l of inclusion-free crystal

$$l = \frac{0.214\, Du(n_s - n_e)^2}{(\eta/\rho_s D)^{1/3}\rho_c^2 v^2} \qquad [14]$$

Equation [14] has been found to give values for the maximum linear growth rate for crystals of macroscopic size which are in general agreement with experiment, and temperature programs for crystal growth by slow cooling have been proposed by the authors (34).

For a given value of l, the maximum value of v which can be used without the onset of instability will increase according to Eq. [14] with the solution flow rate u. If the value of u is too low to achieve the necessary homogeneity, the higher supersaturation at the edges of the crystal will lead to enhanced growth in these regions and the mechanism of growth will be by layers nucleated at the crystal edges. Layers spreading towards the center of the face are frequently overgrown by those nucleated subsequently, with the formation of large inclusions at the face centers. Further increase in the supersaturation beyond the stability limit results in terraced or "hopper" growth and eventually in dendritic growth with branched projections spreading in the fast growth directions.

Role of Natural Convection in Flux Growth

In the foregoing discussion the necessity of high-solution flow rates at the growing crystal face was demonstrated. In unstirred solutions as in the normal flux practice with stationary crucibles the only means of producing some solution flow is thermal and solutional convection. This has been discussed by Parker (7), Wilcox (35), Cobb and Wallis (36), and by Schulz-DuBois (37).

For idealized systems a critical dimensionless number characterizes the onset of thermal convection according to the Rayleigh criterion as reviewed by Chandrasekhar (38). In crystal-growth experiments, convection currents almost always occur because of temperature gradients and solute flow due to crystallization. However, no quantitative data are available on the magnitude of convection flow rates. For a simple model as shown in Fig. 6 the average flow rate of thermal convection can be estimated (36) by

$$u = \frac{K}{\rho_s L c_p}\left[0.208\,(L^3\alpha\theta)^{1/4} - 1\right] \qquad [15]$$

where α is the convection parameter $\rho_s^2 c_p g\beta/\eta K$ with c_p specific heat of the liquid, β the volume expansion coefficient, and K the thermal conductivity. It can be seen from Eq. [15] that the convection flow rate depends on the solution and on the liquid height L and the temperature difference θ which may be varied by the experimenter. Figure 7 shows flow rate *vs.* liquid height L for various convection parameters and a temperature difference of 10°C. After the first steep increase due to the critical Rayleigh number, the flow rate is not much influenced by L. Even for extremely large values of α (a typical value of α in high-temperature solutions is 1500) the flow rate does not exceed 0.05 cm sec^{-1}.

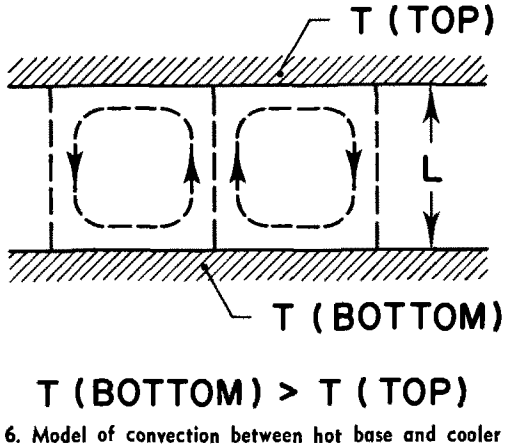

Fig. 6. Model of convection between hot base and cooler top

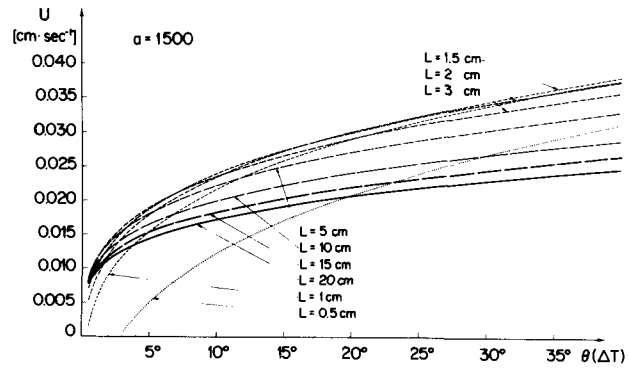

Fig. 7. Convection flow rates vs. liquid height L for various convection parameters α and temperature difference of 10°C.

The effect of the temperature gradient on the flow rate for the convective modulus 1500 and for various liquid heights L is demonstrated in Fig. 8. For small θ the critical value of L is 1 cm, below which convection decreases rapidly. For $L > 1$ cm a temperature difference of 5° is sufficient to achieve flow rates of approximately 0.02 cm sec^{-1} which do not increase much with larger θ.

It follows that natural convection produces too small solution flow rates for the achievement of high stable growth rates. Solutional convection as discussed by Wagner (39) and Jakeman and Hurle (40) will improve the situation. However, the convection flow rates will not increase by more than an order of magnitude under typical growth conditions. Therefore forced convection by stirring is applied in crystal growth from solutions wherever possible.

Stirring Techniques in Flux Growth

In flux growth, immersed rotating seed crystals have been used by Laudise, Linares, and Dearborn (41) with nonvolatile solvents. Pulling of rotating seed crystals was summarized by Scheel (18). Growth of rotating seed crystals slightly below the liquid surface, thereby decreasing excessively steep temperature gradients in the growing crystals, was first reported by Miller (42) and recently by Belruss *et al.* (43) as "top-seeded solution growth." The stirring action of a rotating seed is the same as that in Czochralski growth which has been described by Carruthers and Nassau (44) and by Robertson (45) and is possible only with nonvolatile fluxes. The Ekman flow pattern has been analyzed by Hide and Titman (46) and by Ellison and Cornet (47), and the boundary-layer thickness along a rotating disk was estimated by Burton, Prim, and Slichter (48).

Experimentally, it is extremely difficult to apply conventional stirring with the excellent but volatile

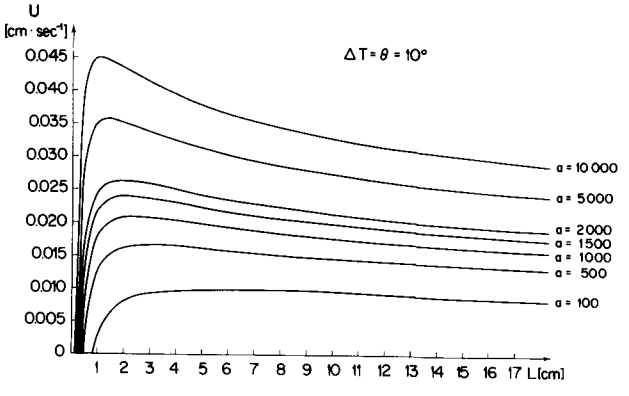

Fig. 8. Convection flow rates vs. temperature difference for various liquid heights and the convection parameter 1500.

lead oxide, lead fluoride, and other volatile solvents. Here the beneficial effect of the accelerated crucible rotation technique (ACRT) was discovered (18, 37, 49), which allows, by its homogenization of the solution and by combination with localized cooling, the growth of large inclusion-free crystals. By periodic acceleration and deceleration of the crucible rotation, a smooth and more or less laminar solution flow can be produced.

Conclusions

The necessity of stirring in crystal growth from high-temperature solutions has been demonstrated. The concepts of the boundary layer and of the metastable region of supersaturation gradient are necessary for an optimum choice of all experimental parameters in order to achieve good results in high-temperature solution growth. The high quality of solution-grown crystals proven by their low dislocation densities (50) as well as the general applicability of this method will lead to its technical use for the growth of special crystals with applications in electronics, optics, magnetics, or acoustics.

A more detailed discussion of many of the points raised in this paper will be given in a forthcoming book on high-temperature solution growth (51).

ABSTRACT

Nickel chromite formation was studied using dense polycrystals and single crystals of NiO and Cr_2O_3. The influence of time, temperature, and oxide purity on spinel structures and formation rates was determined. Experiments were performed by reacting pure Cr_2O_3 pellets with pure and manganese-doped pellets of NiO. All reactions were done in air for times ranging from 24 to 640 hr, and at temperatures from 1200° to 1500°C.

The rates of nickel chromite formation in dense, crack-free specimens are two orders of magnitude smaller than the rates of formation in porous specimens, or at surfaces of dense specimens. These solid-state reaction rates are affected, and possibly controlled, by the rate of chromium dissolution in the nickel oxide, while the reaction rates at free surfaces are controlled by diffusion of Ni^{2+} and Cr^{3+} through the spinel.

There have been several experimental attempts to determine the mechanism of formation of nickel chromite from its component oxides (1-6). In a prior review (7) it was shown that none of these experiments provided conclusive determination of the rate-controlling mechanism. Prior experiments were inconclusive for two major reasons. First, the starting oxides used were too porous to eliminate complications arising from vapor-phase transport. Second, marker experiments failed. Inert metal markers disappeared during the reactions at elevated temperatures (2, 5), while natural markers (interface between polycrystal and single crystal starting oxides) produced results which did not support the mechanism concluded by the author (6).

The purpose of this paper is to describe studies of nickel chromite formation in which dense high-purity oxides were used and for which metal markers provided definitive information of the reaction mechanism.

Experimental

Oxide preparation.—Techniques for the preparation of high-purity oxides commonly consist of purification of salts followed by thermal decomposition. Of these various methods, the oxalate decomposition method of Brown (8, 9) was reported to yield oxides of high purity (99.999%) which would also sinter to high density after simple cold pressing and sintering. Similar procedures were used to prepare the high-purity and manganese-doped nickel oxides used in this study.

Pellets of high-purity and manganese-doped nickel oxides (2.5 cm diameter, 2-5 mm thick) were prepared by cold pressing, drying, and firing in air at 1500°C for 250-350 hr. After initial firing, groups of pellets of each type were equilibrated with air at 1200°, 1300°, and 1400°C in order to provide starting oxides for experiments to be made at such temperatures.

Pellets (5 cm diameter, 3-5 mm thick) of reagent-grade chromium oxide were prepared by hot pressing for 1 hr at 1450°C. After pressing, the pellets were fired in air for 250-350 hr at 1500°C. Groups of chromium oxide pellets were then equilibrated with air by firing for 100 hr at 1200°, 1300°, and 1400°C. In addition to the studies using the polycrystalline oxides, a limited number of experiments were made with single crystals of nickel oxide and chromium oxide. These crystals were obtained from sources listed in Table I.

** Based on the following theoretical densities: NiO, 6.808 g/cm³; Cr_2O_3, 5.202 g/cm³.

Spinel formation reactions.—The following procedures were closely followed for most spinel formation experiments. Pellets for reaction at a given temperature were selected from groups that had previously been equilibrated at or near the desired temperature. Pellets were selected on the basis of density and freedom from obvious flaws such as cracks.

Three types of markers were used in these studies: (*i*) thick platinum foils (6μ by 1 mm by 1 cm); (*ii*) thin platinum foils (1.5μ by 1 mm by 1 cm); and (*iii*) iridium powder approximately 0.1-1μ diameter.

The assembled specimens with markers were placed in silicon carbide heated muffle furnaces capable of temperatures to 1550°C. Alumina blocks were then placed on top of each specimen to produce a compressive stress of approximately 1 kg/cm^2. The furnaces were then rapidly heated to the desired reaction temperature. All experiments were done in air, and temperatures were measured with two Pt + Pt-10%Rh thermocouples. Temperatures measured with both thermocouples were always within ±5°C of each other, and the temperatures remained within ±10°C of the reported value during each experiment.

Results

Compositions, densities, and structures of starting oxides.—The compositions and densities of the oxides used are shown in Table I. The nickel oxides prepared by oxalate precipitation and decomposition were of somewhat higher purity than commercial reagent-grade oxide. The major impurity was cobalt oxide. As shown in Table I, the manganese oxide concentration in the nickel oxide was very close to the desired 1 mole per cent (m/o) value.

The immersion densities of all the nickel oxides prepared by cold pressing and firing ranged from 92 to 97% of the theoretical value. These percentages were based on a theoretical density of 6.808 for nickel oxide. The densities obtained with hot-pressed chromium oxide were always within 98% of theoretical density. In addition, the densities of the surfaces of these pellets were higher than the over-all density. In general, all spinel reactions were made with chromium oxides approaching 100% of theoretical density.

Nickel chromite formation from pure oxides.—The observations to be discussed in this section apply to the spinel formation from the reaction of reagent-grade chromium oxide with both reagent-grade and high-purity nickel oxide. For ease of presentation, the surface effects and the internal effects will be described separately.

Surface features.—During early experiments, the chromium oxide pellets appeared to shrink during the spinel reaction anneals. Details of this shrinkage were determined by cutting prebonded pellets into small rectangular prisms and firing at temperatures from 1200° to 1500°C. All such specimens took the shape shown in Fig. 1 after firing, the most pronounced shape changes occurring at the highest temperatures and longest times. The initial shape of the specimen is shown by the dashed lines. The nickel oxide half of the specimen expanded, the maximum expansion occurring near the reaction interface.

Examination of the reaction interface in greater detail revealed small crystallites on the surface of the spinel. These crystallites were not strongly bonded to the spinel and could easily be brushed off. The crystallites were small octahedrons and were identified as nickel chromite by x-ray diffraction. In addition to these features, small crystallites resembling etch pits formed on the surfaces on the nickel oxide during the spinel reaction. These crystallites appeared to form preferentially on cube faces of the nickel oxide crystals. The amount of crystallite formation on the nickel oxide decreased as the distance from the reaction interface increased. No such crystallite formation was ever observed on the surfaces of nickel oxides that had been fired in the absence of chromium oxide. These observations suggest that the crystallites on the surface of the nickel oxide may be the first stages of nickel chromite spinel formation by a solid NiO-"vapor" Cr_2O_3 mechanism. The spinel crystallites on the surface of the spinel probably form by a vapor-phase reaction of both nickel and chromium oxides.

Internal features.—Characteristics of the internal features of nickel chromite spinel formation are summarized schematically in Fig. 2 and examples of some of these features are shown in Fig. 3-8. The thickness of the spinel formed during a given diffusion anneal varied considerably depending on the location within the specimen. At the surface of the reaction interface (location A in Fig. 2), the spinel was very thick. However, inside the dense, crack-free, regions of the specimen (location B), the spinel layer was thin. Thick spinel layers also formed at internal cracks exposed to air (location D). These internal layers could either be thicker or thinner than the surface layers, depending on the geometry of the crack. Although cracking of the reactants was common, the diffusion couples were generally well bonded. This behavior contrasted sharply with the easy separation of reactants which had been observed in prior studies (1, 5, 6). In this

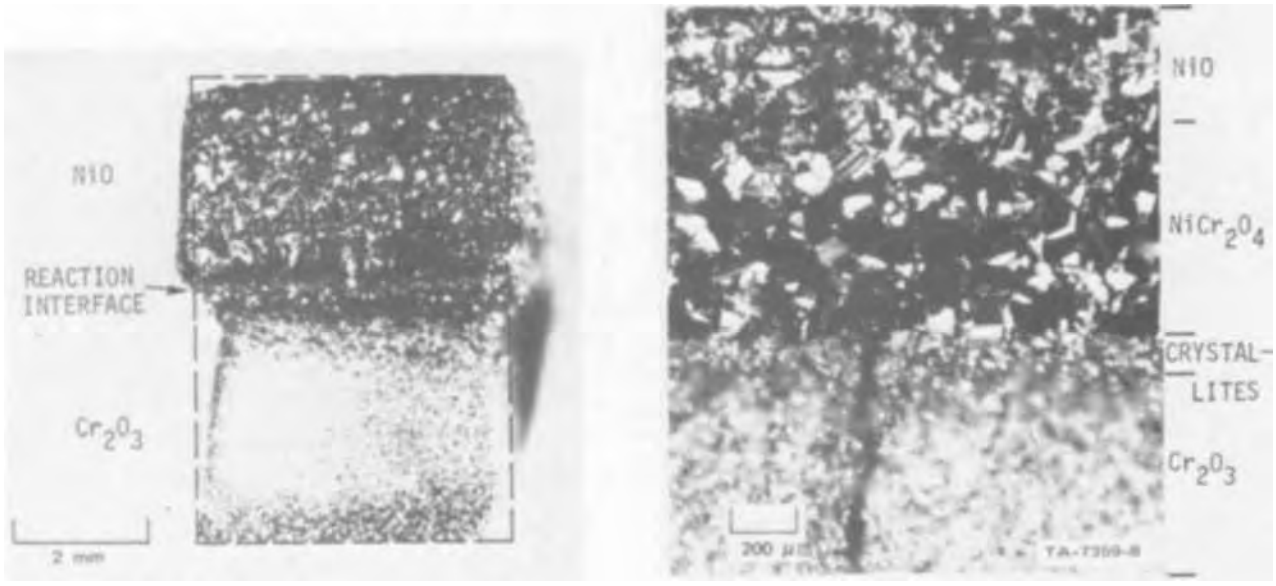

Fig. 1. Nickel oxide/chromium oxide diffusion couple: (a, above left) microstructure showing nonuniform shrinkage of chromium oxide; (b, above right) details of surface at reaction interface.

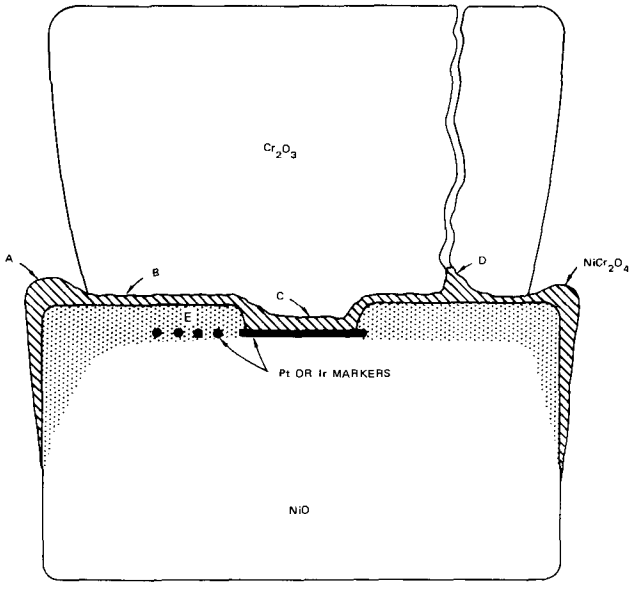

Fig. 2. Schematic representation of internal features observed in nickel chromite formation from pure oxides: (a) surface spinel (spinel formed at corners of pellet exposed to air); (b) internal spinel (spinel formed in dense, crack-free, regions of pellets); (c) spinel formed at thick marker; (d) spinel formed internally but exposed to air by a crack; (e) spinel precipitate in nickel oxide.

study, easy separation of the reactants was observed in only one special experiment. The details of this experiment and its implications in the mechanism of spinel formation will be given in a later section. Thick spinel layers also formed at thick (approximately 6μ) platinum markers (location C). An example of thick spinel formation at such a marker and thin spinel formation from a region of the specimen that has no marker is shown in Fig. 3. The large difference in the thickness of the spinel at these two locations is evident.

The last predominant internal features (location E) were found at the thin (1-2μ) or discontinuous platinum or iridium markers. These thin markers were always buried within the nickel oxide. The depth to which the markers were buried increased with the time and temperature of exposure. The time dependence was parabolic, and the temperature dependence was Arrhenius in form. No differences were observed in the depths of the platinum and iridium markers after identical reactions. Examples of buried markers are shown in Fig. 4 for a specimen reacted for 64 hr at 1300°C. Also visible in the nickel oxide, both in specimens that contained markers and in specimens that did not contain markers, were very fine Widmanstatten precipitates. These precipitates extended well into the nickel oxide, and could be resolved on both sides of the markers. In addition to these features it was observed that nonplanar diffusion interfaces formed between the spinel layer and the chromium oxide (Fig. 4). However, the interface between the spinel and the nickel oxide was always planar (when complications arising from the presence of thick markers did not interfere).

Phase analysis and precipitate identification.—The precipitates were identified by combining x-ray diffraction and metallographic techniques. A specimen that had been reacted and slowly cooled to room temperature (to accentuate the precipitation) was carefully ground parallel to the reaction interface. The ground face was examined by x-ray diffraction using Cr Kα radiation. The NiO (111), Cr_2O_3 (104), and $NiCr_2O_4$ (220) reflections were measured after grinding. The results of these measurements (Fig. 5) showed that the precipitates were nickel chromite spinel. The spinel precipitates could readily be detected at a distance of 80μ from the dense spinel layer.

Marker behavior.—The identification of the nickel chromite precipitate particles in the nickel oxide provides an explanation for the formation of thick spinel layers at (defect-free) thick markers and thin spinel layers away from the markers. The nickel chromite precipitation in the nickel oxide is the result of dissolution of the spinel ($NiCr_2O_4 + 3Ni^{2+} \rightarrow 4NiO + 2Cr^{3+}$) at the nickel oxide/spinel reaction interface. Consequently, if the rate of dissolution of the spinel by nickel oxide is of the same order of magnitude as the rate of formation of the spinel, one can expect the resultant layer to be thin where there are no dissolution barriers and thick where barriers are present. A confirmation of this model was provided in part by morphology of the reaction interface at an imperfect platinum marker and by the chromium and nickel concentration profiles at defected and defect-free regions of the marker.

The structure and composition of the reaction interface at a defected platinum marker are shown in Fig. 6. The electron backscatter image and the Ni Kα x-ray image show the spinel layer to be very irregular at the spinel chromium oxide interface. More impor-

tantly, both images show that a small defect in the marker resulted in the formation of a hemispherical intrusion of nickel oxide into the chromium oxide. Electron-microprobe scans across the specimen along paths A and B of Fig. 6 revealed the composition profiles shown in Fig. 7. As shown, the chromium concentration in the nickel oxide intrusion is significantly higher than in the nickel oxide at the planar reaction interface. Consequently, it can be concluded that the thick platinum markers cause the formation of thicker

spinel layers because they are barriers to chromium dissolution in the nickel oxide.

The structures shown in Fig. 6 and 7 also help explain the location of the thin and/or discontinuous markers in the nickel oxide (location E, Fig. 2). If the markers are discrete particles, they do not interfere with the simultaneous formation of spinel at the NiO/Cr_2O_3 interface and spinel dissolution in the nickel oxide. Thus the simple countercurrent diffusion reaction is replaced by a moving-boundary diffusion reaction, in which there is a flux of material into the spinel and a concurrent flux (of the same order of magnitude) into the nickel oxide (2, 10). Consequently, the markers remain at the original interface, and the spinel layer moves toward the chromium oxide half of the diffusion couple. When thick platinum markers are used, spinel dissolution is prevented, and the spinel will remain at the original interface.

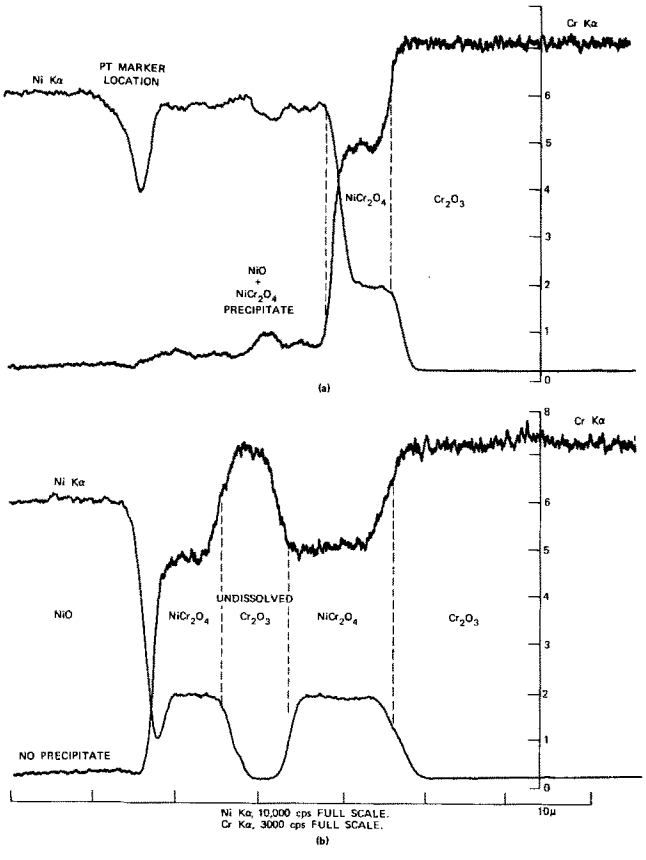

Fig. 7. Influence of thick platinum marker on the concentration of dissolved chromium in nickel oxide. (a) at marker defect and (b) at continuous marker.

An example of this effect with thick markers is shown schematically in Fig. 2 and explicitly in Fig. 8 where the final interface has advanced away from the initial interface defined by the thick platinum marker.

Single crystal experiments.—Experiments with single crystals were performed for comparison with the various observations of spinel formation from dense polycrystalline specimens. In general, results obtained with single crystal reactants were similar to results obtained with polycrystals. Reaction of single crystals of NiO and Cr_2O_3 produced structures identical to those produced by reaction of polycrystals. Thin spinel layers were formed (Fig. 9) between the starting oxides, and precipitation of nickel chromite spinel was clearly visible in the nickel oxide. In addition, the reaction interfaces between the spinel and both starting oxides were not planar.

The single crystal experiments proved that the penetration of the chromium into the nickel oxide occurred by a solid-state diffusion mechanism, and not by a vapor-transport mechanism through pores (as was possible with the polycrystalline nickel oxide specimens). In addition, it was evident that this penetration occurred without the formation of porosity in either the nickel or chromium oxide single crystals. Further, the calculated parabolic reaction rate constants (described in a later section) were consistent with the rate constants derived from dense polycrystalline specimens. These observations therefore supported the conclusion that the results obtained with the polycrystalline specimens used in this study reflect the solid-state spinel reaction mechanism. The lack of visible porosity in the single crystals allowed for the determination of a mass balance across the reaction interface.

Electron-microprobe measurements of the chromium Kα radiation from the same area shown in Fig. 9 were made by point counting at 3-6μ intervals using a beam

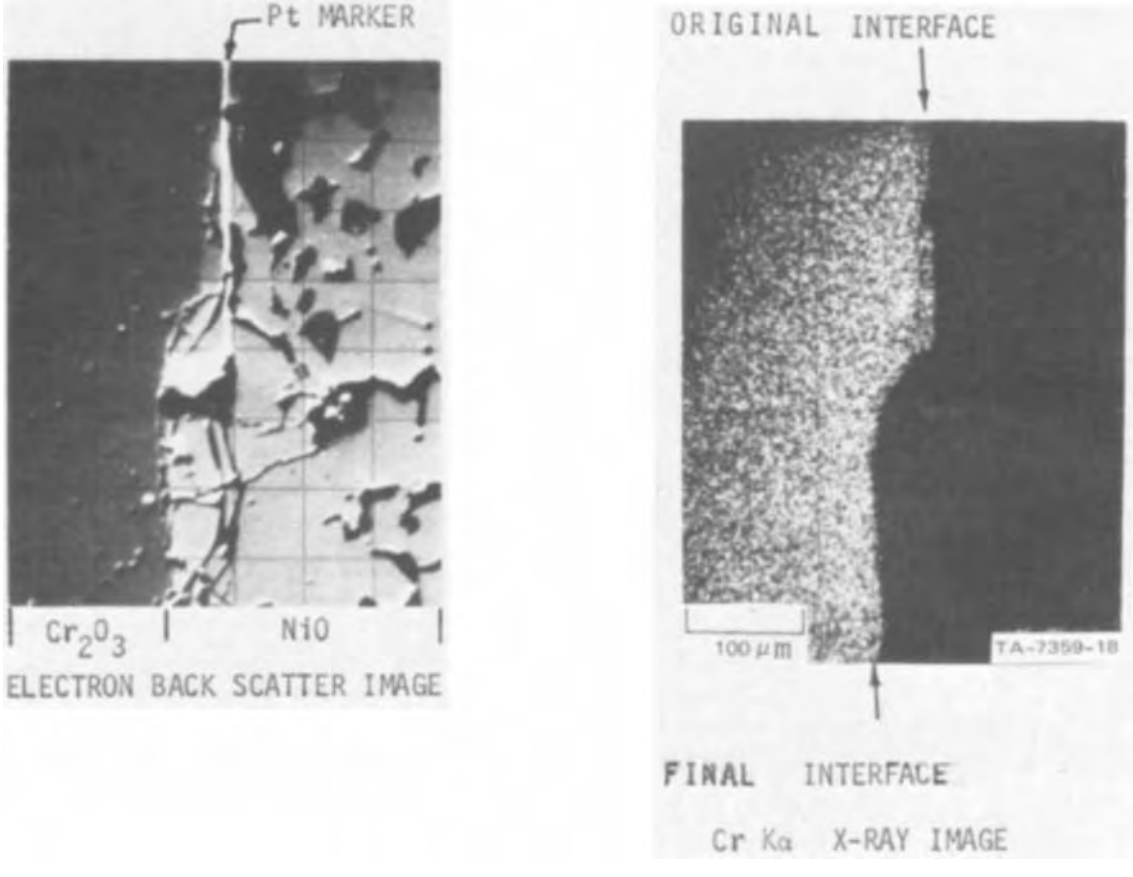

Fig. 8. Example of moving interface during nickel chromite formation. The thick (~6μ) platinum marker does not move during the reaction. Specimen reacted at 1235°C for 1 x 10^6 sec.

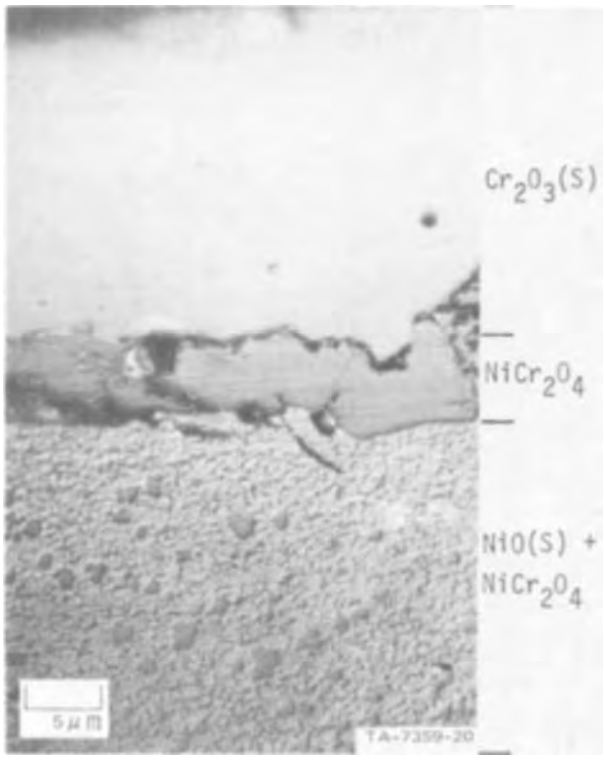

Fig. 9. Structure of nickel chromite reaction layer between nickel oxide and chromium oxide single crystals. Specimen heated at 1410°C for 7.6 x 10^5 sec.

diameter of ~6μ. The chromium Kα x-ray intensity profile across the reaction interface (Fig. 10) showed the depth to which the chromium had penetrated into the nickel oxide. Measurable amounts of chromium could be detected at a distance of 625μ from the spinel/nickel oxide interface. Figure 10 shows that the intensity-distance profile in the nickel oxide was very irregular, as would be expected from the presence of spinel precipitates in the single crystal nickel oxide. The spinel layer itself was too thin to be resolved by the point counting technique, however, the chromium spinel intensity was calculated from comparison with the intensity data from thicker layers and the 6μ spinel layer was drawn accordingly. The position of the platinum marker in another area of the specimen is also shown, and will be used in the discussion of the reaction mechanism.

Vapor-transport experiment.—Vapor-phase transport of one or more of the reacting species has been widely reported in the literature (1, 5, 6, 11-13) and has been used as a general explanation for the commonly observed phenomenon of easy separation of reactants

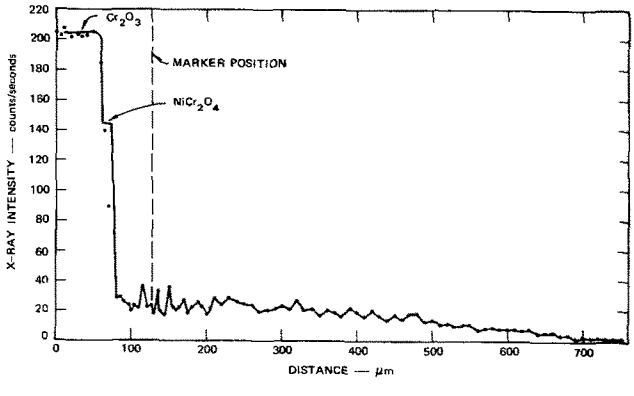

Fig. 10. Cr Kα composition profile. Point count data show sufficient dissolved chromium in nickel oxide to account for marker position.

after the spinel reaction. Schmalzried (11) has stated that this phenomenon results from the vapor transport of the more volatile species to the other reactant when nonideal contact conditions exist between the two pellets. According to this mechanism, the more volatile species travels, via the gas phase, to the less volatile pellet, and reacts to form the spinel. Since there is never any solid contact, the pellets separate easily, and the spinel layer is bonded to the less volatile material. For example, in the formation of zinc aluminate, one would expect the spinel to bond to the aluminum oxide, while in the formation of magnesium chromite, one would expect the spinel to bond to the magnesium oxide. Extrapolating this generalization to the nickel chromite system, one would expect the spinel to bond to the nickel oxide after an experiment in which nonideal contact exists, because the vaporization rate of chromium oxide is greater than that of nickel oxide (5).

An experiment utilizing nonideal contact was performed to test this model and to provide a comparison with experiments in which ideal contact was assumed. The specimen assembly consisted of a flat, polished, nickel oxide pellet separated from a flat, polished, chromium oxide pellet by 2μ thick foil markers. No load other than the nickel oxide pellet was placed on the diffusion couple, and the resultant compressive stress level was of the order of 2 g/cm². The experiment was performed at 1450°C in order to produce a high vapor pressure of the chromium oxide, and thus assure nonideal contact. After the diffusion anneal was completed, the specimen was slowly cooled to room temperature.

The reactants were easily separated by lifting the nickel oxide pellet off the chromium oxide pellet. The reaction surfaces of the two pellets were similar in appearance, and both showed traces of the former marker locations. The surface of the nickel oxide pellet had depressions at the marker locations while the surface of the chromium oxide pellet was elevated at the marker location. The markers themselves could not be seen, and were either buried in the spinel, in the nickel oxide, or at the spinel/chromium oxide interface.

Micrographic examination of the cross-sectioned pellets revealed spinel formation on the chromium oxide, platinum markers buried in the nickel oxide, and spinel precipitation in the nickel oxide.

The spinel layer thickness on the chromium oxide was used to calculate a reaction rate constant, and this rate constant was consistent with the rate constants obtained at the same temperature using ideal contact. Consequently, the specimens behaved as though they were under ideal contact during the spinel reaction, although they were very lightly loaded and they separated readily. If nonideal contact had existed, the spinel should have formed on the nickel oxide (as it forms on the corners of nickel oxide specimens exposed to chromium oxide vapors and air). Since this structure did not occur, one can conclude that the easy separation of pellets does not necessarily provide any indication of the reaction mechanism.

A schematic drawing of the proposed sequence of events which occurred in this experiment is shown in Fig. 11. At the first stage of reaction, ideal contact occurred between the two pellets by a combination of deformation of the markers and the oxides. Reaction to form nickel chromite then proceeded with simultaneous chromium dissolution by the nickel oxide. The dissolution of the spinel at the marker, however, was inhibited by the presence of the markers. In the third stage, the spinel/nickel oxide interface continued to move away from the original interface, and intrusions of nickel oxide began to form as defects formed in the marker by surface tension forces. In stage four, the marker had agglomerated enough that the spinel/nickel oxide interface moved away from the marker. The discontinuity in the reaction interface at the prior

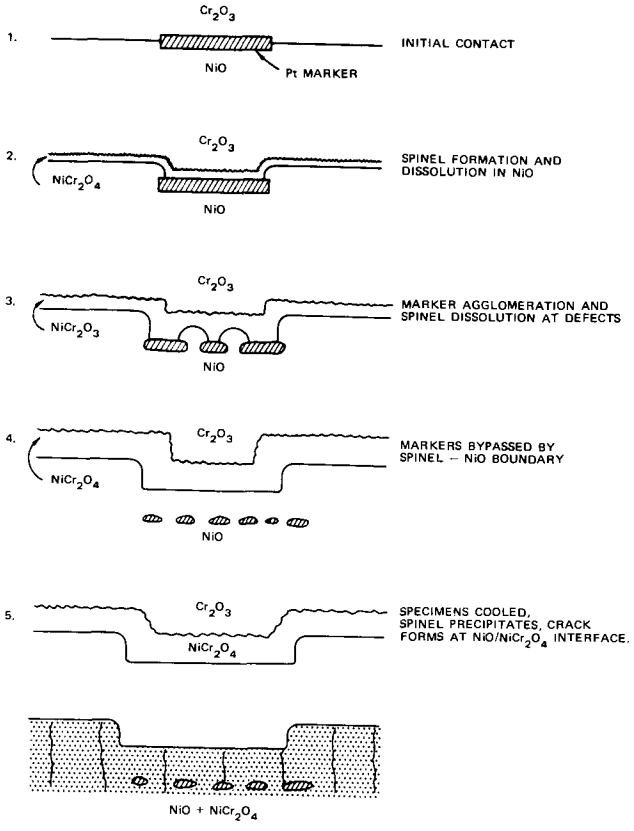

Fig. 11. Schematic representation of reaction mechanism in vapor-transport experiment.

marker location remained, however, because the starting time for the dissolution reaction was delayed by the presence of the marker. At stage five, the specimen was cooled and separated at the spinel/nickel oxide interface by the formation of interfacial cracks. This mechanism leaves the spinel bonded to the chromium oxide, elevations on the chromium oxide at the former marker location, and depressions in the nickel oxide at the former marker location as observed experimentally.

Additional information on the mechanism of nickel chromite formation from the solid state can be determined from the electron-microprobe data of Fig. 10. As is shown, the spinel layer thickness formed between single crystal nickel oxide and single crystal chromium oxide was approximately 6μ thick. In addition, the marker was buried in the nickel oxide single crystal at a distance of 56μ from the nickel oxide/nickel chromite interface. By measuring the area under the Cr Kα penetration curve in the nickel oxide, and dividing by the Cr Kα intensity for pure nickel chromite, a dissolved spinel layer thickness of 75μ was determined. From these measurements, the ratio of the spinel thickness on the nickel oxide side of the markers to the spinel thickness on the chromium oxide side was determined to be 1:3[1] in qualitative agreement with the Wagner mechanism of countercurrent diffusion of Cr^{3+} and Ni^{2+}.

Nickel chromite formation from Mn-doped nickel oxide.—Various experiments were performed with diffusion couples in which the nickel oxide was doped with 1 m/o manganese oxide. In general the spinel formation reaction with the manganese-doped nickel oxide was the same structurally and kinetically as the spinel formation reaction with the pure oxide. The only significant difference between the spinel formed from the pure and the manganese-doped nickel oxide was the manganese enrichment of the spinel phase when formed from the latter oxide. A quantitative estimate of the degree of manganese enrichment in the spinel was obtained by electron-microprobe scans across the reaction interface. These scans showed that the manganese concentration in the spinel is approximately 4 times greater than in the doped nickel oxide.

Kinetics of nickel chromite spinel formation.—To confirm the previously reported observations that spinel formation was diffusion controlled (1, 2, 5), the thickness of the spinel surface layer was determined as a function of $t^{1/2}$ for two reaction temperatures. These measurements (Fig. 13) showed that the spinel thickness was indeed a linear function of $t^{1/2}$, and therefore controlled by diffusion processes. The reaction constant (K_p) for each experiment was calculated from the measured thickness (Δx) and the reaction time (t) using Eq. [1]

$$K_p = \Delta x^2/2t \qquad [1]$$

The spinel thicknesses at the specimen surface (Fig. 2, location A) and the dense interior of the specimen (Fig. 2, location B) were measured and used to calculate rate constants. In addition, the distance from the spinel/nickel oxide interface to the markers buried in the nickel oxide was measured and used to calculate a rate constant. It is proposed that each of these rate constants represent different reactions. The influence of temperature on the reaction rate constants for surface spinel and internal spinel formation is shown in Fig. 13.

There was a difference of two orders of magnitude between the reaction rate constant for spinel formed at the surface of the specimens (Fig. 2, location A) and for spinel formed inside the dense, crack-free, parts of

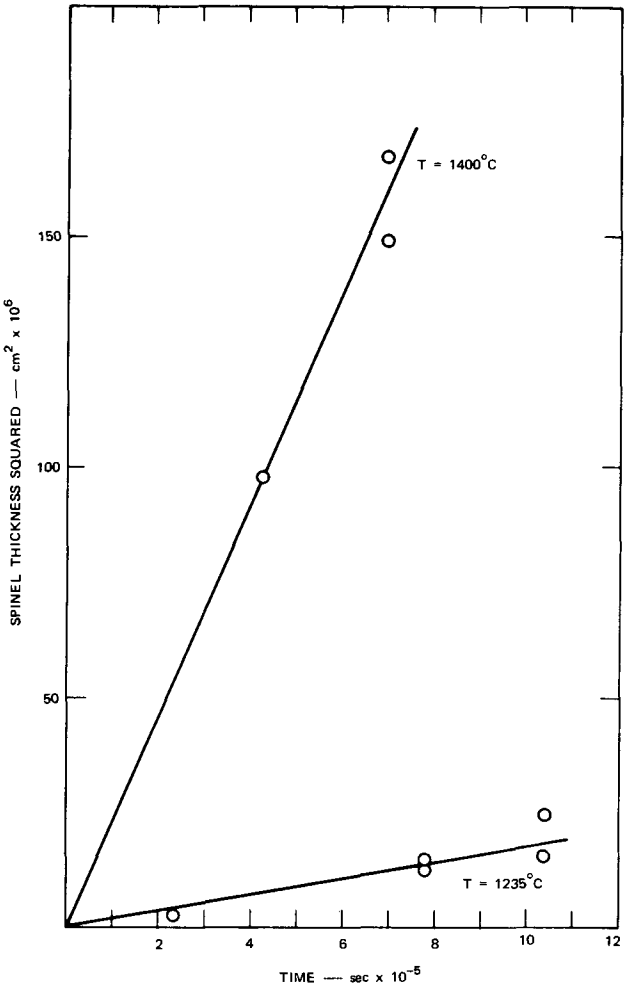

Fig. 12. Time dependence of nickel chromite thickness

[1] To maintain electrical neutrality, 3 Ni^{2+} ions must pass through the reference interface to balance the charge of 2 Cr^{3+} ions diffusing in the opposite direction. The nickel ions form three molecules of $NiCr_2O_4$ on the chromium oxide side of the marker while the chromium ions form one molecule of $NiCr_2O_4$ on the nickel oxide side.

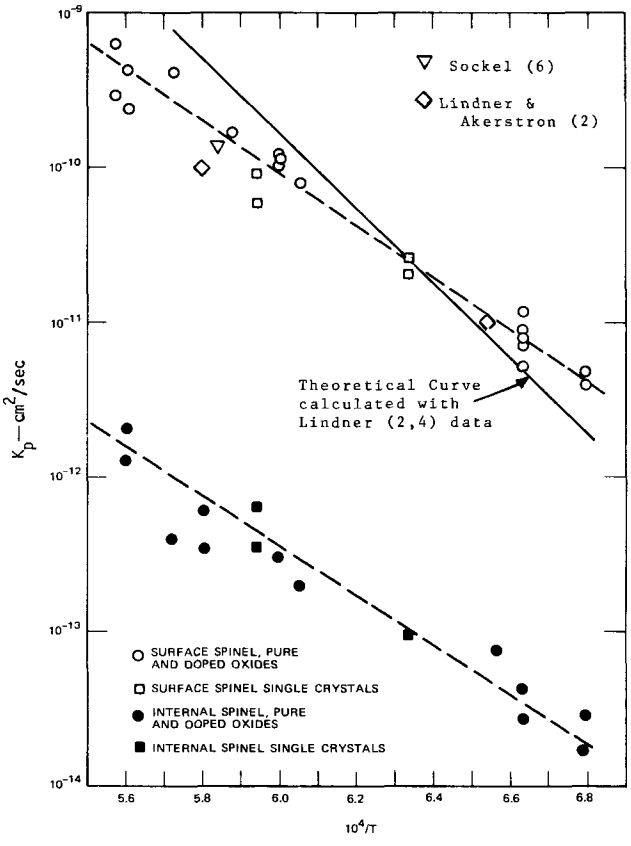

Fig. 13. Reaction rate constants for nickel chromite formation

the specimen (Fig. 2, location B). Even though there is considerable scatter in these data, the extreme difference in these rates clearly shows that two different mechanisms are operating.

Also apparent from Fig. 13 is the absence of any impurity effects in either the surface or internal reaction rate constants. The rates are essentially the same (within experimental scatter) for nickel chromite formed from pure chromium oxide, high purity, or manganese-doped nickel oxide. In addition, the rates of surface and internal spinel formation are the same for single crystal specimens as for dense polycrystalline specimens.

The reaction rate constants reported in prior studies (2, 6) are also shown in Fig. 13. These constants agree well with the surface spinel rate constants of the present work. This agreement is further proof of the porosity of the specimens used in prior studies, and the influence of vapor-phase transport on the rate constants. A least squares fit through the data reveals that the temperature dependences are

$$K_p \text{ (surface)} = 1.04 \exp(-76.4 \times 10^3/RT)$$

$$K_p \text{ (internal)} = 3.26 \times 10^{-4} \exp(-68.3 \times 10^3/RT)$$

The temperature dependence of the rate constants for interface motion with respect to the markers is given by

$$k_{\text{marker}} = 2.20 \times 10^{-2} \exp(-67.5 \times 10^3/RT)$$

The activation energy for the nickel oxide/nickel chromite interface motion is identical to that for internal spinel formation, and does not appear to be significantly affected by oxide composition or by the crystalline structure of the starting material.

Discussion

These experiments form the basis for the following model of nickel chromite spinel formation. The model is simple and is supported by the experimental data. Internal, or solid-state nickel chromite formation (*e.g.*, Fig. 2, location B) occurs by the countercurrent diffusion of Ni^{2+} and Cr^{3+} through the spinel, and simultaneously, through the nickel oxide. The rate of spinel growth is strongly affected by the rate of chromium dissolution and diffusion in the nickel oxide. Because the rates of transport through the spinel and the nickel oxide are of the same order of magnitude, there is a coupling of these two processes and it is not possible to specify one or the other as rate controlling. This model explains: (*i*) spinel precipitation in NiO; (*ii*) marker effects, including intrusion formation at marker defects, and thick spinel formation at thick markers; (*iii*) internal spinel thickness; and (*iv*) the motion of the spinel layer with respect to the markers.

Surface (*e.g.*, Fig. 2, location A) spinel formation occurs by a modified Wagner mechanism in which spinel dissolution is compensated for by geometrical effects. The cooperative diffusion of Cr^{3+} from vertical and horizontal surfaces of the specimen rapidly saturates the nickel oxide (17), and allows the spinel to grow by countercurrent diffusion of Ni^{3+} and Cr^{3+} through the spinel layer.

Comparisons were made of the measured spinel formation rates with the Wagner-Schmalzried theory.

Data for the free energies of formation were taken from Tretjakow and Schmalzried (18), and diffusion coefficients were chosen on the basis that the diffusion rate of Ni^{2+} controls spinel formation. This is basically correct, because the diffusivity of Ni^{2+} is less than that of Cr^{3+} over the temperature range of interest (2, 4, 19).

Two sets of diffusivity data for Ni^{2+} in $NiCr_2O_4$ are available. Although both sets were measured by the same authors, the diffusion coefficients calculated from one set (2, 4) are approximately one order of magnitude larger than those calculated from the other set (3). As would be expected, the values of the diffusion coefficients totally control the theoretical values of K_p. For example, at (T = 1400°C) the reaction rate constant equals $1.2D_{Ni}$. At lower temperatures (1200°C), K_p equals $0.45D_{Ni}$. The theoretical values of the reaction rate constants were calculated by using both sets of Lindner diffusivity data. The rate constants calculated on the basis of one set of data (2, 4) are shown in Fig. 13 and are in good agreement with measured rate constants. The rate constants calculated on the basis of the other set of data (3) were a factor of 7 lower than the measured rate constants.

In an earlier analysis of these data (20) it was concluded that agreement between the experimental and theoretical rate constants for nickel chromite formation was fortuitous. This conclusion was supported by the following facts. The theory was developed to apply to the formation of dense, defect-free, reaction product layers, while the experimental measurements were made with porous specimens or dense specimens whose surfaces were exposed to air (as in this study). In addition, the experimental rates for surface spinel formation are affected by chromium dissolution in the nickel oxide. Therefore, the theory, which does not account for vapor transport through pores, and dissolution of one component of the spinel by the other reactant, should not agree with the measured rates in which these effects prevail. However, it is possible that the structure of porous specimens (or surfaces of dense specimens) compensates for spinel dissolution by rapidly saturating the nickel oxide with chromium via vapor-phase transport. If the spinel layer is densified in the process, the experimental conditions will approach those required by theory.

Only qualitative statements will be made concerning the influence of impurities on the mechanism of spinel formation. There are two reasons for this. First, this is the first experimental study in which these effects have been considered. Second, these systems are more complex than normal spinels with respect to phase structure, defect structure, and thermodynamic definition (21). As described in the text, the addition of 1 m/o manganese oxide to nickel oxide did not sig-

nificantly affect the structure rate of formation of nickel chromite. However, manganese enrichment in the spinel (by a factor of 4) was observed.

A qualitative explanation for the enrichment of manganese in the spinel can be based on the polyvalent characteristics of the ions. Manganese can exist either as $MnO(Mn^{2+})$ or $Mn_2O_3(Mn^{3+})$ and can form its own spinel (Mn_3O_4) in which it exists in two valence states (22, 23). Consequently, the manganese ions can fit in both octahedral and tetrahedral sites in the spinel lattice. Therefore, the reaction of 1 mole of nickel oxide to form 1 mole of nickel chromite produces 3 times the initial number of sites in which the manganese ion can fit.

Conclusions

There are a number of conclusions from this work which have general application to spinel studies. These conclusions are associated with the two major experimental observations of this study: density effects and spinel dissolution effects. First, and perhaps most important, it has been shown that experimental results obtained from the reactions of high-density oxides can be significantly different from those obtained from the reactions of porous oxides. Spinel formation rates from dense oxides can be orders of magnitude slower than rates in porous oxides. Mechanisms of spinel formation from porous oxides can be affected, or controlled, by vapor-phase transport phenomena, while reaction mechanisms in dense oxides cannot. Simple marker experiments can be interpreted when dense oxides are used, whereas these markers are often destroyed or lost when porous oxides are used.

Dissolution effects, of the spinel in the reactants or the reactants in the spinel, must be accounted for in future studies. As has been shown in this work, such effects can control both the mechanism and kinetics of spinel formation. It is recognized that dissolution effects would be accounted for if observed. However, the experimental observations of these effects requires the use of dense reactants and careful specimen preparation and examination.

Another general conclusion from this work is that reaction mechanisms must be determined by direct experimental techniques. Determination of reaction mechanisms by comparison of experimental and theoretical reaction rate constants are totally dependent on measured rates of diffusion of cations through their respective spinels. There is sufficient variability in the diffusion data for these systems that nearly any experimental measurement will fit within an order of magnitude of a theoretical value. Any true test of the validity of a theoretically determined rate constant must be based on precise diffusion data through fully dense polycrystalline or single crystalline spinels, and theoretical data must be compared with experimental kinetic data determined from similar or (preferably) identical oxides.

Specific conclusions obtained from this study are:

1. The mechanism of nickel chromite formation from its component oxides is countercurrent diffusion of Ni^{2+} and Cr^{3+} through the spinel layer.
2. The rates of nickel chromite formation at surfaces of dense specimens or at interfaces of porous specimens are equal.
3. The rate of nickel chromite formation in dense oxides is two orders of magnitude less than the rate of formation at surfaces, and is strongly affected by the rate of chromium dissolution in nickel oxide.
4. Dissolution of Cr^{3+} in nickel oxide occurs at high (>1200°C) temperatures. The solubility of chromium oxide in nickel oxide is of the order of 10 weight per cent. On cooling to room temperature, the Cr^{3+} precipitates as nickel chromite in the nickel oxide.
5. The location and morphology of thin inert markers after spinel reactions can be explained as a result of chromium dissolution.
6. Additions of manganese (at the level of 1 m/o) to nickel oxide will not affect the rate of nickel chromite growth. However, manganese enrichment of the chromite layer will occur.

Technical Notes

Nondestructive Location of Oxide Breakdowns on MOSFET Structures

P. L. Garbarino and R. D. Sandison

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

An experimental investigation of the mechanism of silicon dioxide degradation leading to MOS oxide breakdown has highlighted the need for a reliable nondestructive method of pinpointing the breakdown location. A situation commonly presents itself where electrical test has pointed to a short (breakdown) in a "chain" of as many as several hundred thin oxide regions, all tied in electrical common by a metalization pattern. The use of an oxide chain arises naturally and necessarily from the limited number of terminals on a test chip, and the requirement that extremely large numbers of individual regions be tested to generate just a few breakdown failures at high bias-temperature stress. The problem is then to narrow the short location to an area that is manageable for meaningful study by visual, x-ray, or electron-optical means. That is, the breakdown must be located nondistructively to a single thin oxide area; or better, to a fraction of one area.

The purpose of this note is to report that cholesteric liquid crystal together with a thin amorphous carbon coating is ideally suited to breakdown location in the small areas typical of thin oxides on MOS devices. The procedure should have wide applicability in the failure analysis of bipolar LSI devices as well.

Liquid crystals (1, 2) are substances which selectively scatter incident white light, the wavelength of the scattered light scaling inversely with the temperature. The thermal characteristics of the liquid crystal are operationally specified by two parameters: (*i*) the lowest temperature at which color first appears, which we call the transition temperature; and (*ii*) the temperature range over which the entire spectrum is displayed, which is referred to as the thermal bandwidth (3). The crystal can be simply considered to be a thermometer which translates the thermal gradient around the powered short into a color pattern. As Fig. 1 indicates, the location of the short is revealed as a color profile on a colorless background.

Procedure

The mounted chip (either header or otherwise) is placed in good thermal contact with a thermally massive temperature controlled substage. The liquid crystal, mixed with its volatile suspension medium, is applied to the chip either with an eyedropper or an air brush to a thickness of 3-5μ. The temperature of the as yet unpowered chip may be cycled through the thermal bandwidth of the crystal several times (the color transition of the crystal is reversible) and the color quality observed. It is important to have a continuous film of as uniform a thickness as possible. If the color quality is poor, an additional liquid crystal application may be used to enhance it. However, a crystal thickness of more than 10μ is detrimental as it broadens the thermal profile around the short, compromising the obtainable spatial resolution.

Key words: SiO_2 degradation, oxide breakdown, shorting, failure analysis, nondestructive.

The temperature of the substage is adjusted to be about 2°C below the transition temperature of the crystal, and the device powered until the temperature at the short is well into the thermal bandwidth of the crystal. A schematic of the substage assembly is shown in Fig. 2.

In practice, it is found that the reflected white light from the metalization pattern is of much greater intensity than that of the selectively scattered radiation,

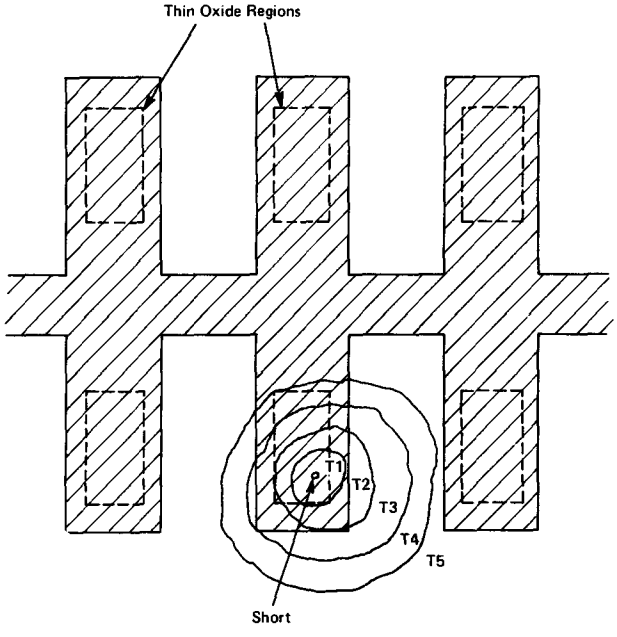

Fig. 1. Schematic of a defective gate chain. The cross-hatched areas indicate the metalization pattern forming the chain. Gate areas are outlined by dashed lines. The rough circles around the short represent isotherms of the temperature profile around the powered short. Temperatures $T_1 > T_2 > \cdots > T_5$ are the average temperatures in their respective regions. Under action of the liquid crystal region 1 will appear blue; region 2, green; region 3, yellow; region 4, red; and region 5, colorless.

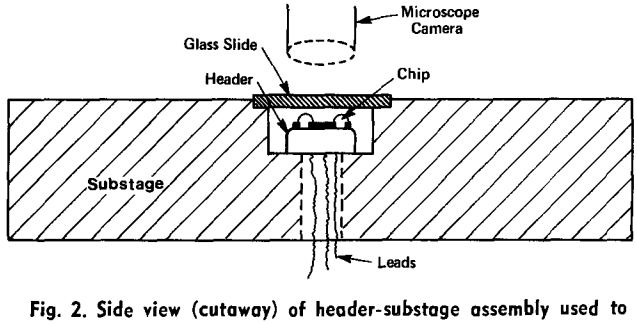

Fig. 2. Side view (cutaway) of header-substage assembly used to provide temperature control.

rendering the color pattern difficult or impossible to see. A layer of carbon black deposited on the chip surface prior to crystal application will counter this difficulty. The carbon layer must be thick enough to shield most of the reflected light but thin enough so that the metalization pattern may still be seen; carbon thicknesses of from 0.2 to 0.4μ will strike this balance. Commercial mixtures of dye and liquid crystal, and flat black paints are not adequate because of nonhomogeneity of coverage or complete opaqueness.

Carbon layers of the above thickness were found to be of high enough electrical impedance so as not to alter the electrical characteristics of the test chip. The carbon may be deposited in an evaporator, or most simply by rapidly passing the chip through the sooty flame of a paraffin candle several times. The carbon layer as well as the liquid crystal can be removed by ultrasonic agitation in a chloroform bath.

Spatial Resolution

Based on a study of extremely thin chromium resistors deposited on glass substrates, Lukianoff (3) has concluded that the limit of spatial resolution of liquid crystal is 1μ. In the case of fault location on MOSFET structures, one must contend with a heat source that is not directly on the surface but is buried under the metal of the gate electrode and the applied carbon coating. For our devices, the resolution limit, due to the broadening of the thermal pattern by the material over the heat source, is about 0.3 mils (7.3μ). That is, in a one-mil square gate area one can, by careful observation of the thermal profile, expect to narrow the short location to about 1/10 of the gate area. These numbers are estimates and may vary with the construction characteristics of the particular MOSFET device in question.

This technique eliminates the tedium involved in cutting and probing the metalization pattern to narrow the short location electrically, and has proven to be highly reliable in locating the breakdown. In several instances, visual inspection of a failed thin oxide region after metalization removal, showed more than one abnormally. Comparison with the liquid crystal photograph was indispensible in determining which fault was actually responsible for the electrical short. An SEM photograph of an oxide breakdown located with liquid crystal is shown in Fig. 3.

Some Factors Influencing the Luminous Decay Characteristics of $Y_3Al_5O_{12}: Ce^{3+}$

E. F. Gibbons, T. Y. Tien,* R. G. DeLosh, P. J. Zacmanidis, and H. L. Stadler*

Ford Motor Company, Scientific Research Staff, Dearborn, Michigan 48121

Fast decay phosphors based on Ce^{3+} activation have been used for many years. Under electron beam excitation these phosphors typically have a decay time (I_{max}/e) of less than 100 nsec and have a broad-band emission spectrum peaking in the near ultra violet or blue. Several recently developed phosphor materials have moved the cerium emission peak to much longer wavelengths, green emission being reported for $CaS:Ce^{3+}$ (1) and green to yellow-orange for various garnet hosts (2-4).

Visible emitting fast decay phosphors have a number of useful applications. One such application, which was the primary motivation for this investigation, is in flying-spot scanner tubes such as those used by the Post Office in their automatic letter sorting system. The phosphors mentioned above, however, have one disadvantage which limits their usefulness, *i.e.*, the luminescent decay curve is very nonexponential. Bril *et al.* (3) report that for $Y_3Al_5O_{12}:Ce^{3+}$ the emission intensity is still 6% of its maximum value 80 μsec after cessation of excitation, while Lehmann and Ryan (1) observed that $CaS:Ce^{3+}$ had an afterglow lasting for several milliseconds. This nonexponential decay behavior is very undesirable for flying spot scanner applications since it creates a large background illumination which appears as noise to the signal processing system. This, of course, lowers the signal to noise ratio of the system and, in the case of the Post Office mail sorter, reduces the percentage of the mail that can be sorted.

This note reports the effect of several parameters on the decay characteristics of $Y_3Al_5O_{12}:Ce^{3+}$, with some sets of conditions resulting in almost purely exponential decay curves.

Experimental

Phosphor samples used were 2 mole per cent (m/o) Ce^{3+} activated $Y_3Al_5O_{12}$. The preparation of this phosphor has been reported previously (5).

The phosphors were settled on 1 in. $\times$ 3 in. microscope slides using the conventional potassium silicate-barium acetate settling technique. The slides, after

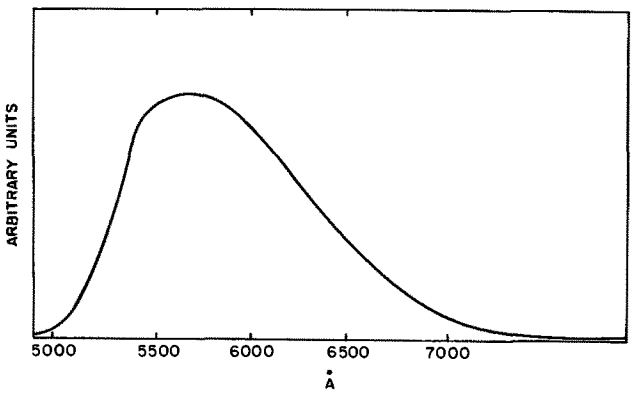

Fig. 1. Cathodoluminescent emission spectrum of $Y_3Al_5O_{12}:Ce^{3+}$

aluminizing, were measured in a demountable electron beam gun system. All measurements were made at 15 kV beam voltage and current densities of approximately 10 mA/cm². The electron beam gun, normally biased into cutoff, was pulsed on by means of an external pulse generator capacitively coupled to the grid. Pulse widths used in these experiments were 0.2, 3, and 20 μsec.[1]

The light pulse was detected by a 9558Q photomultiplier tube with the resulting signal being analyzed by a PAR Model 160 Boxcar Integrator. It was found that the photomultiplier tube required an electrically shielded, noninductive 50 ohm load to insure the elimination of spurious electrical effects. Also, with such a small load resistor, care had to be taken not to overload the photomultiplier. If the incident light intensity on the photomultiplier cathode was too high, the resulting high electron density at the anode would produce an electrical signal lasting tens of microseconds after the termination of the light pulse. This is probably caused by a momentary heating effect at the anode. Suitable neutral density filters eliminated this "tail" effect.

The output from the boxcar integrator was plotted on an x-y recorder. Since the minimum gate open time for the boxcar integrator was 10 nsec, this represented the ultimate resolution obtainable from the system.

Intensity data were taken by applying a 1 in. by 1 in. raster to the phosphor-coated slide and measuring the luminous intensity by means of a Spectra Pritchard photometer, Photo Research Corporation Model 1970 PR.

The emission spectra were measured in a second demountable system attached to a ¾ meter Czerny-Turner spectrometer.

Results

The emission spectrum for $Y_3Al_5O_{12}:Ce^{3+}$ is shown in Fig. 1. This spectrum did not change with different firing atmospheres as long as the cerium concentration remained constant. The emission peak does shift, however, with cerium concentration. Firing in an oxidizing atmosphere limited the amount of cerium that the garnet would accept to 2%, with a second phase appearing if the starting concentration of cerium was higher than that, while a reducing atmosphere permitted up to 6% cerium to be incorporated into the host. These solubility limit and emission peak shift results are presented in detail elsewhere (5). All systems studied in this experiment had a cerium concentration of 2%.

Figure 2 shows the luminescent decay curves for a 3 μsec excitation pulse resulting from three different firing conditions. It can be seen that the afterglow becomes progressively more pronounced as the firing atmosphere goes from oxidizing to inert to reducing. Also, for the material formed in an inert or reducing environment, there is a gradual build-up of the emission intensity during the period of excitation. These two results would be consistent with the idea of energy storage traps in the phosphor. These traps would slowly fill during the excitation period, taking up less and less of the excitation energy as more traps become filled. This would produce the sort of cerium emission increase seen during the excitation period. These traps could then slowly feed their energy to the cerium ions after the electron beam pulse was turned off, thus producing the observed afterglow. A likely candidate for such energy traps would be lattice defects, possibly oxygen vacancies, since the build-up and afterglow effects are greatly diminished when the phosphors are prepared in an oxygen atmosphere. If this is true, then one would expect to be able to anneal out at least some of these traps by refiring in air material that had been prepared in a reducing atmosphere. Figure 3 shows the results of such an experiment where a 20 μsec duration excitation pulse has been used. It is obvious that the refiring has greatly diminished the build-up and afterglow observed in the original material.

Also, since the number of traps that are filled depends on the duration of the excitation, one would expect that the afterglow effect would be more pronounced for long excitation pulses. This trend is shown

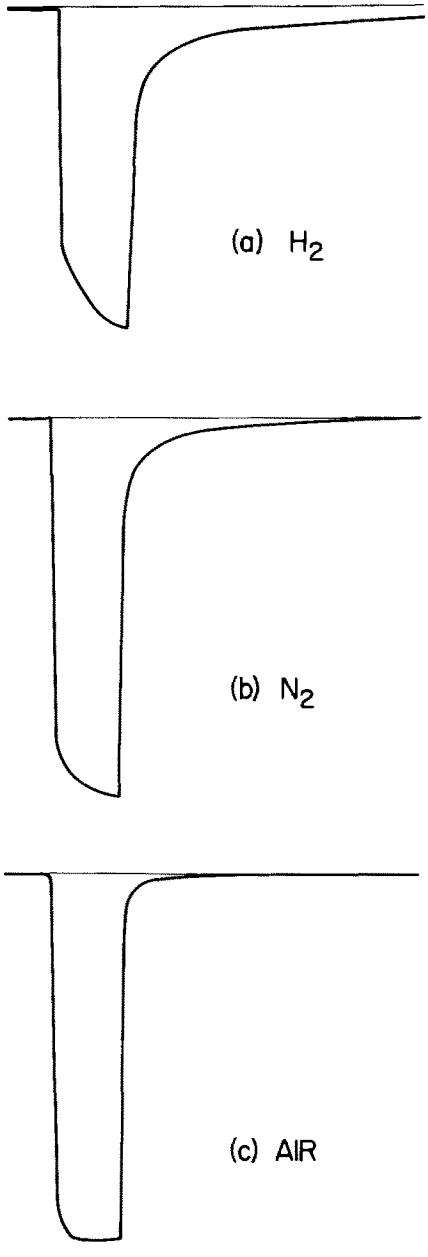

Fig. 2. Light intensity profiles for 3 μsec excitation pulses for materials fired in (a) H_2, (b) N_2, and (c) air.

[1] The 0.2 and 3 μsec values correspond to the beam dwell time on a phosphor particle in a Post Office Optical Character Reader when the system is in either its "search" or "read" mode (6).

Table I. Effect of firing atmosphere and excitation pulse width on the luminous decay of Ce^{3+} and effect of firing atmosphere on relative intensity

Material	Firing atmosphere	0.2 μsec pulse		3 μsec pulse		20 μsec pulse		
		$I_{max/10}$ (μsec)	$I_{max/20}$ (μsec)	$I_{max/10}$ (μsec)	$I_{max/20}$ (μsec)	$I_{max/10}$ (μsec)	$I_{max/20}$ (μsec)	Relative intensity
$Y_3Al_5O_{12}$: 2% Ce	Air	0.23	0.30	0.26	0.42	0.28	0.75	85
	H_2	0.32	0.62	3.2	8.5	12.0	35.0	100
	H_2-Air*	0.21	0.30	0.72	1.4	0.75	2.7	70
	N_2	0.29	0.48	1.1	2.0	4.4	13.5	70
$Y_{2.7}Gd_{0.3}Al_5O_{12}$: 2% Ce	Air	0.29	0.49	1.0	2.3	2.9	8.6	85

* Sample was fired for 2 hr in H_2, then refired 5 min in air.

in Table I which lists the time after excitation for the light intensity to fall to its 10% point and 5% point. These data are given for different pulse widths and for different firing conditions. All samples show a tendency toward longer decay times under longer pulse conditions. However, the effect for the air-fired sample is only very slight, while the H_2-fired sample shows a much greater afterglow for the longer excitation pulses. The material refired in air has a much more improved decay characteristic than did the original H_2-fired material, being equivalent to the air-fired sample at the shortest pulse width, and only slightly worse for the longer pulses. The N_2-fired sample is intermediate to the above cases.

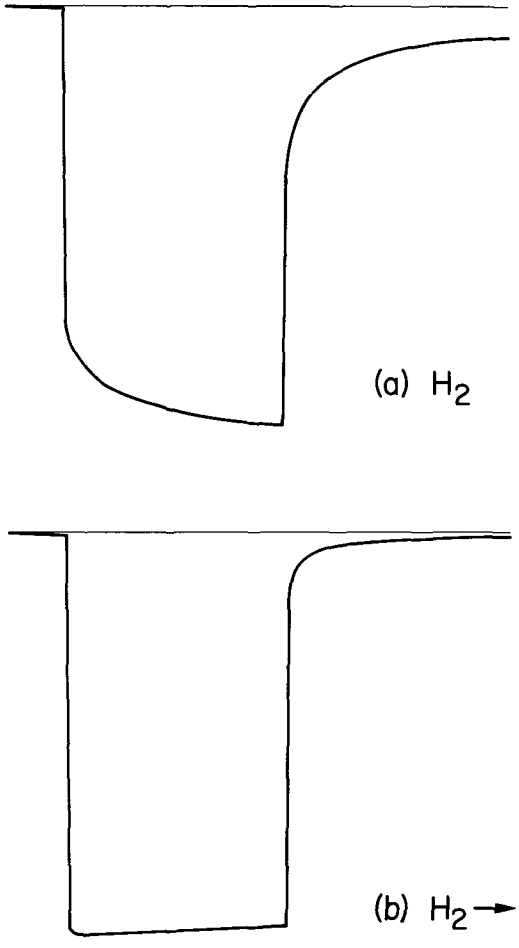

Fig. 3. Light intensity profiles for 20 μsec excitation pulses for material fired in (a) H_2, and (b) same material refired in air.

The table also gives data for $Y_{2.7}Gd_{0.3}Al_5O_{12}:Ce^{3+}$, a material in which 10% of the yttrium has been replaced by gadolinium. Although this material was fired in air, the longer excitation conditions show an afterglow effect considerably more pronounced than the pure $Y_3Al_5O_{12}:Ce^{3+}$ fired in air. It could be that the addition of Gd to the system caused sufficient distortion of the garnet crystal to introduce other types of energy traps.

Table I also shows the relative intensity data for the samples fired in different atmospheres. Hydrogen-fired samples have a somewhat greater intensity, as measured by a spot photometer, than do the air-fired samples.

The results then indicate that under certain firing conditions and excitation conditions, $Y_3Al_5O_{12}:Ce^{3+}$ shows very little afterglow effect. Even in cases of long pulse width excitation, nonexponential decay characteristics can be minimized by using the appropriate forming conditions.

Anomalies Observed in Some Discrete Device and Integrated Circuit Substrates

Ivars Irbe

Rome Air Development Center, RBRM, Griffiss Air Force Base, New York 13441

Several phenomena, not yet reported in the literature to the author's knowledge, have been observed during physical analysis of in house fabricated avalanche diodes and some commercially available integrated circuits and ion-implanted MOS field effect devices.

The first of the phenomena, denoted "bulk stain effect," was observed on freshly angle-lapped surfaces of samples which had previously been angle lapped and stained (concentrated HF under intensive light), or the top surfaces of which had been treated with concentrated HF. In each case, without application of the staining agent to the freshly angle-lapped surfaces, stainlike discolorations were evident in the p-diffused areas, generally not exceeding laterally the respective diffusion window boundaries and extending down to a varying fraction of the diffusion depth. Since bulk silicon material is removed during an angle-lapping operation, the appearance of such discoloration implies that staining had occurred inside the silicon material during the preceding staining cycles, hence the term "bulk stain effect." Comparison of horizontal and vertical dimensions of the volumes removed by the angle-lapping cycles indicates that the bulk staining occurs predominantly from the top of the silicon chips, *i.e.*, from the top surfaces of the respective diffusion windows. The total time of HF treatment applied to the chip surfaces before the appearance of bulk stain effect ranged from 20-30 sec (circuit chip shown in Fig. 2) to well over 30 min (time accumulation from 15 angle lapping and staining cycles applied to a circuit chip during failure analysis; not shown here). Application of the staining agent to angle-lapped surfaces which already display the bulk stain effect produces the normal staining patterns, except that the bulk stained areas remain distinguishable due to different shades of discoloration and/or depressions in these areas. The effect was observed within devices or circuit configurations fabricated in epitaxial silicon substrates, and within some ion-implanted devices. In the latter case, it was not known if the substrates were epitaxial wafers. On circuit chips with silicon nitride surface protection, the bulk stain was observed only in areas which were not covered by silicon nitride during the preceding staining cycles.

An etching of silicon surfaces was in some instances observed to occur during chemical treatments (concentrated HF or KOH) of devices and circuits by chemicals which normally [KOH at room temperature on (111) surface] would not attack silicon, or would do so at a very slow rate. The etching was most pronounced within devices and structures formed by high impurity concentration diffusions, especially n^+ (phosphorus) diffusion. The etching was also observed on some silicon surfaces following only a thermal oxidation in steam. All of the areas in which etching was observed had received at least a 20 min aqua regia treatment after the silicon dioxide had been removed (etched away). In the case of the MOS device, the etching occurred in areas which had been diffused and subsequently ion implanted. This device was not subjected to aqua regia or other nitric acid based chemical treatment.

Figure 1 displays the bulk stain effect and a normal subsequent staining pattern on the same angle-lapped surface observed within an avalanche diode structure fabricated by p^+ diffusion (7.5×10^{19} boron atoms/cc final impurity concentration at the surface) into an $n^- \text{-} n^+$ epitaxial silicon substrate (10.0 ohm-cm, 8.0μ thick epitaxial layer on 0.01 ohm-cm substrate. These parameters apply also to devices shown in Fig. 3 and 4). Note in Fig. 1b the darker shade of color and the depression of the bulk stained area within the normal staining pattern. The bulk stain effect within a silicon nitride passivated circuit chip is shown in Fig. 2b. A 30 sec staining cycle, sufficiently long to remove all the exposed silicon dioxide, was applied to the surface shown in Fig. 2a. A subsequent lapping cycle revealed the bulk stain effect, except for the areas which had been protected by the silicon nitride layer and that part of the silicon dioxide layer removed last by the preceding staining cycle. This behavior was observed also during consecutive staining and lapping cycles. Note the appearance of the bulk stain in the contact areas which were not protected by silicon nitride. In addition to the bulk stain effect shown in Fig. 3a, both Fig. 3a and 3b display silicon surface etching effects inside the device diffusion window and on the chip surface outside the laterally diffused areas. The differences in height are indicated by the interference fringes. The silicon areas outside the diffusion window did not receive any processing other than initial oxidation (2½ hr at 950°C in steam) and boron drive in (20 min at 1150°C in steam) cycles. Surface etching is also evident in Fig. 4. The structure indicated by the arrow constitutes a scribe line from which the oxide was removed prior to aluminum metalization. The area was alloyed (450°C for 15 min) during the contact formation process. A preferential surface etching outside the laterally diffused areas is evidenced by a ridgelike structure on the right side of this photograph. Based on junction depth measurements, it appeared that the scribe lines and the laterally diffused areas were etched very little or not at all. The devices in Fig. 3 and 4 were treated with aqua regia for an additional 20 min after the removal of the metalization lines and silicon dioxide layer. Bulk stain and surface etching effects within the structure of a diffused and

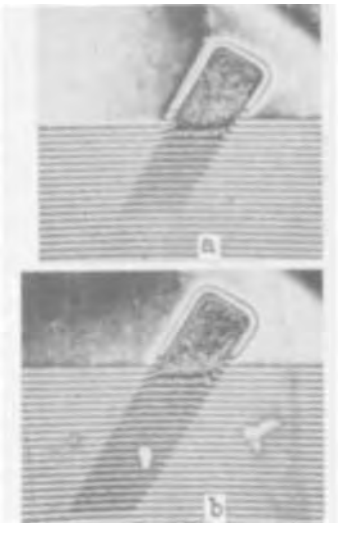

Fig. 3. (a) A freshly angle-lapped surface displaying bulk stain effect; (b) same surface after staining. A ridgelike structure covering the laterally diffused area is evident in both photographs. Magnification 130×.

ion-implanted MOS field effect device are shown in Fig. 5. Previous angle-lapping and staining cycles indicated 1.9μ diffusion and 0.4μ ion-implantation depth. Subsequent angle-lapping cycles revealed a bulk stain effect up to 1.5μ depth (Fig. 5a). A consecutive 2 min treatment with concentrated KOH completely removed all silicon (Fig. 5b) in areas outlined by the bulk stain discoloration leaving the channel areas intact as a ridge-like structure. Note the interference fringes on the angle-lapped parts of the channel structure. All angle lapping shown in the photographs was done with a 2° lapping block. A Zeiss interferometer (thallium light, $\lambda/2 = 0.27\mu$) was used for the measurements.

Based on these observations and on additional work done on devices fabricated by high concentration diffusion into single resistivity (nonepitaxial) silicon substrates, which showed no bulk staining, it is postulated that both effects are primarily caused by imperfections in, and/or gross damage to, the crystalline structure of the substrate material. The bulk stain effect takes place whenever the silicon material can be penetrated by the staining agent (HF) causing, upon reaction with available p-type impurities, discolorations in the bulk material. In the cases of the surface etching effects, the penetrants would be provided by the nitric acid components of the applied chemicals. Absence of etching in alloyed and laterally diffused areas indicates that it might be possible to improve the crystalline structure of the material by judiciously applied processes. The possibility of penetration of silicon substrate material by chemical agents points to a potential problem area with respect to device and integrated circuit reliability.

Porous Carbides as Evaporation Sources for Vacuum Deposition of Metal and Semiconductor Layers

J. J. A. Ploos van Amstel and E. Kooi*

Philips Research Laboratories, Eindhoven, Netherlands

In vapor deposition techniques the material in question is usually evaporated from a crucible or a filament. In this paper we will describe the preparation of evaporators of a porous nature, usually rod or tube shaped, and consisting of the carbide of either aluminum, silicon, titanium, or zirconium. The porosity of these evaporators, which is due to their particular manufacturing process, makes it possible for them to contain a fairly large amount of material to be evaporated. Capillary action causes a rapid distribution of molten material in the porous structure. This enables such an evaporator to be connected to a separate source of material, so that a continuous supply of fresh material may occur during a vapor deposition process.

Possibilities for continuous supply of material have been described earlier by one of us (1) and an example is shown schematically in Fig. 1. A long rod-shaped evaporator, as indicated, is heated by passing through an electric current. One end of the evaporator is connected to a crucible, placed at the top end in Fig. 1. The crucible contains the material to be evaporated and has a small hole in its bottom, through which the evaporator is connected to the material in the crucible. This material can be melted by heating with aid of a small furnace, as indicated in the figure. The molten material flows along the evaporator only when the latter is hot. If the temperature of the evaporator is sufficiently high, evaporation will occur from it in all directions. Substrates on which deposition is to take place can be arranged around the evaporator. In this manner homogeneous deposition can be obtained over large areas. The choice of the material for the evaporator will depend on the material to be evaporated. It is obvious that the evaporator must be able to withstand sufficiently high temperatures to permit evaporation. Further, it is desired that there be a certain amount of wetting of the evaporator by the molten material in the crucible. Otherwise a flow of droplets may occur to the lower end of the evaporator without resulting in effective evaporation. We have found that in many instances twisted wires of refractory metals can be very useful. Twisted tungsten wire evaporators, for example, have been applied successfully for evaporation of metals like Cu, Au, and Ag.

In search of useful materials for this evaporation method, we have developed methods of preparing the carbide evaporators to be described. They may indeed be applied as indicated in Fig. 1, but their use is certainly not limited to that procedure. The preparation of Al_4C_3, SiC, TiC, and ZrC was performed via reactions between the elements, using commercially available graphite cords as the starting material for the carbon constituent. These cords are flexible and can easily be handled; they can even be knotted, if desired. As the cords are "hollow," one may be pulled over another; this is useful for the preparation of thicker evaporators. The cords have a woven structure; consequently, a carbide formed from it looks similar (see Fig. 2) and has a high degree of porosity. Due to capillary action, flow of molten material in such a carbide evaporator is not restricted to the direction of gravity. In a set-up like that shown in Fig. 1, a vertically placed carbide evaporator may be connected to a molten source of material even at its lower end. An upward flow of molten material then occurs to replace material which is evaporated, thus guaranteeing a constant evaporation rate.

In Table I we have listed the melting points of the four carbides as well as those of the elements Al, Si, Ti, Zr, and Cr, and the temperatures at which the vapor pressure of the pure elements is 10^{-2} Torr. The latter values indicate the temperatures needed to get a reasonable rate of evaporation of the given element. Usually Al is evaporated from Al_4C_3, Si from SiC, and so on. The element Cr has been added to the list because we consider this a useful example of another element which can be evaporated via one of the above carbide evaporators (ZrC). The special method to perform this will be described later in this paper.

Preparation of Aluminum Carbide and Silicon Carbide Evaporators

In Fig. 3 the method of preparing Al_4C_3 and SiC evaporators is shown. The crucible contains either Al or Si and can be heated. It is placed either at the top end or at the lower end of a vertically stretched graphite cord. In the case of SiC, preparation reaction between Si and C can be started simply by heating the whole assembly. The reaction then proceeds along the cord, thus converting it completely to a SiC rod. Due to the contact with the liquid in the crucible, the rod contains an excess of silicon. Figure 2 shows a photograph of a carbon cord and a resulting SiC rod-shaped evaporator.

For the preparation of an aluminum carbide rod it is necessary to heat the cord to a higher temperature. This can easily be done by passing an electric current through the cord. After the reaction has started, a reaction zone is seen to pass along the cord. The aluminum carbide formed contains an excess of aluminum because of the contact with the aluminum in the crucible.

Preparation of Titanium Carbide and Zirconium Carbide Evaporators

Because of the high melting points of TiC and ZrC as well as of elementary Ti and Zr, the method of preparation as used for Al_4C_3 and SiC is hardly possible as crucible materials for contamination-free melting are not available. In these cases contact between Ti or Zr and the graphite cord is established either by pulling the cord into a spiral of Ti or Zr wire, or by threading a wire of one of these elements through the

Table I. Melting points of a few elements and carbides

Element	Melting point (°C)	Temp for 10^{-2} Torr (°C)	Carbide	Melting point (°C)
Al	670	1200	Al_4C_3	2100
Si	1420	1550	SiC	2800[d]
Ti	1700	1700	TiC	3100
Zr	1850	2400	ZrC	3500
Cr	1900	1400		

The third column indicates the temperatures at which the vapor pressure of the elements is 10^{-2} Torr and may thus be considered as an indication of the temperature needed for evaporation at a reasonable rate.

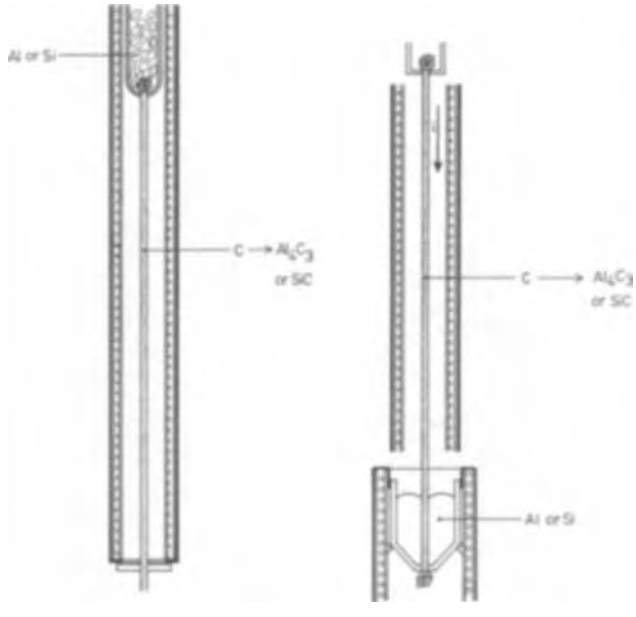

Fig. 3. Methods of preparation of Al_4C_3 and SiC evaporators. A graphite cord is connected to a crucible with molten aluminum or silicon, placed either at the upper or the lower end of the cord. Note that the cord is stretched by knots at the ends. Reaction occurs along the cord if sufficient heat is supplied.

cord (Fig. 4). The reaction can be made to occur by the heating produced by passing of an electric current. It starts near one of the contacts and a very hot zone can be seen to move quickly along the cord. These carbide evaporators may also contain a large excess of the metallic element. It should be remarked that, if an evaporator is formed by inserting a metal wire inside the cord, the resulting carbide will show a hollow structure (see Fig. 5).

The Use of Carbide Evaporators

Preparation by one of the methods described above yields carbide evaporators containing an excess of

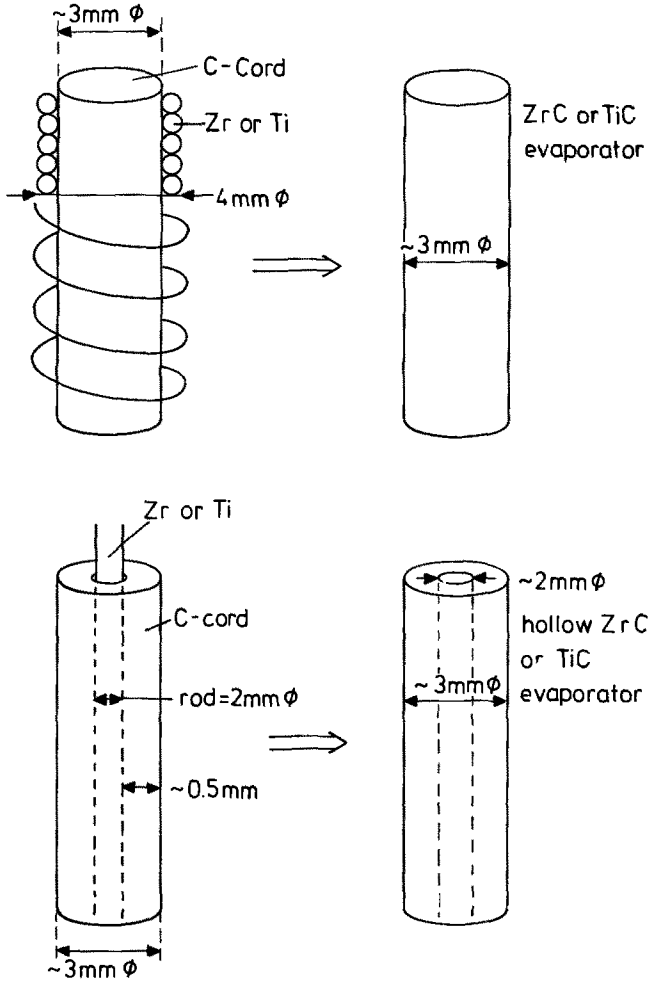

Fig. 4. Preparation of TiC and ZrC evaporators. A metal wire is either wound spirally around a graphite cord or inserted in it. In the latter case a hollow evaporator results (see Fig. 5).

either Al, Si, Ti, or Zr. They may thus be used for vacuum deposition of these elements by heating them (for example by passing an electric current) to a sufficiently high temperature. By using setups like that of Fig. 1 it is possible to supply material to the evaporator continuously, so that thick layers can be deposited. As an example of a deposition rate used to obtain thick layers, we have observed silicon deposition at a rate of 20 μm/min on substrates placed at a distance of 3 cm from the evaporator by passing 200A through the evaporator (about 0.5V per cm length needed). In Fig. 6 a cross section of a dielectrically isolated transistor structure of an integrated circuit is shown. The transistors are in this case made in monocrystalline silicon islands in a polycrystalline substrate, produced by the described deposition technique. A silicon oxide layer separates the islands from the substrate.

Another useful application in the semiconductor industry is the deposition of metal films or silicon devices and integrated circuits. In particular for MOS (metal oxide semiconductor) devices, the use of "clean" aluminum films is desirable. It is often found that aluminum deposited from tungsten filaments is not "clean." Instability effects in MOS structures attributed to the presence of sodium are then observed. These sodium ions probably originate from the tungsten filament, and electron-beam evaporation of aluminum from a cooled crucible is often utilized to produce stable MOS structures. We have found that evaporation from a carbide evaporator results in MOS structures of a quality similar to that of MOS structures obtained by means of electron-beam evaporation.

The deposited films may contain some carbon, especially when high deposition rates are used, *i.e.*, when the evaporator is heated to a high temperature. For the case of the system Si-SiC, for example, it is known that the partial pressure of Si_2C can be a few per cent, if the temperature is high enough (3). In fact, we have been able to detect the presence of a few per cent of carbon in silicon films which had been deposited at a high rate (chemical analysis). In aluminum films we have not been able to detect carbon.

It should be realized that during evaporation the solid carbide phase of the evaporator is in equilibrium with a melt which may contain rather a large amount of carbon. As an example, Fig. 7 shows part of the phase-diagram of the system Zr-C. Assuming a temperature of about 2400°C to be necessary for a reasonable rate of evaporation (see Table I), the melt apparently contains a few per cent of carbon. The percentage becomes greater as the temperature is increased. Given the presence of an excess of metal, complete melting can occur below the melting point of ZrC. Such an effect is occasionally observed to occur at one spot of the evaporator, where, due to some inhomogeneity, the electrical resistance is highest, and therefore also the temperature. When this occurs the evaporators fall into two parts.

Except for Al_4C_3 the above types of carbide evaporators can be stored in atmospheric air. Aluminum carbide reacts slowly with water; if such an evaporator is not kept dry, it may crumble to powder in a few weeks.

The use of the carbide evaporators is not restricted to the evaporation of the four elements mentioned. As one very useful example we would mention the vacuum deposition of chromium layers from ZrC evaporators. In this case a tubular evaporator is filled with small chromium particles and then heated; again simply by the passing of an electric current. Table I

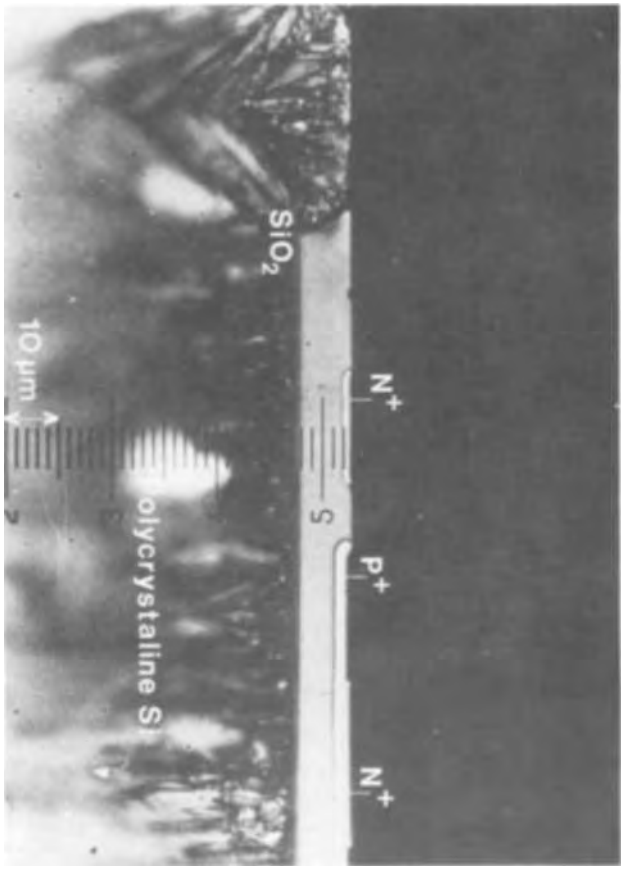

Fig. 6. Dielectrically isolated transistor structure. The polycrystalline substrate consists of silicon deposited from an SiC evaporator.

indicates that it is not necessary to melt chromium in order to obtain evaporation. Sublimation occurs at a reasonable rate even at about 1400°C. At this temperature the partial pressure of zirconium is still negligible and this element could not in fact be detected in the deposited chromium layers. With reference to Fig. 7 it may be remarked that the sublimation temperature is still too low to lead to melting in the Zr-C system. It is not known exactly how the Cr penetrates through the wall of the ZrC(+Zr) tube in this vacuum deposition process, the rate of which was about 0.1 μm/min (distance between evaporator and substrate 10 cm). The deposition was found to be homogeneous over a total substrate area as large as 2000 cm². The length of the evaporator was in this case 25 cm; with an applied voltage of 20V the current through the evaporator was 65A.

Vacuum deposition from carbide evaporators can also be used to getter gases from the vacuum system. For this purpose we are applying the titanium evaporation from a TiC evaporator which we have set up in experimental laboratory equipment and which has worked satisfactorily already for a few years. One might fear that the carbon content of the evaporator might cause the formation of CH_4, but this appears not to be the case. This is probably due to the fact that during the evaporation the TiC phase is surrounded completely by molten titanium.

Conclusion

Long porous evaporators consisting of the carbides of either Al, Si, Ti, or Zr can be prepared by reaction of these elements with commercially available graphite cords. The resulting evaporators are rod or tube

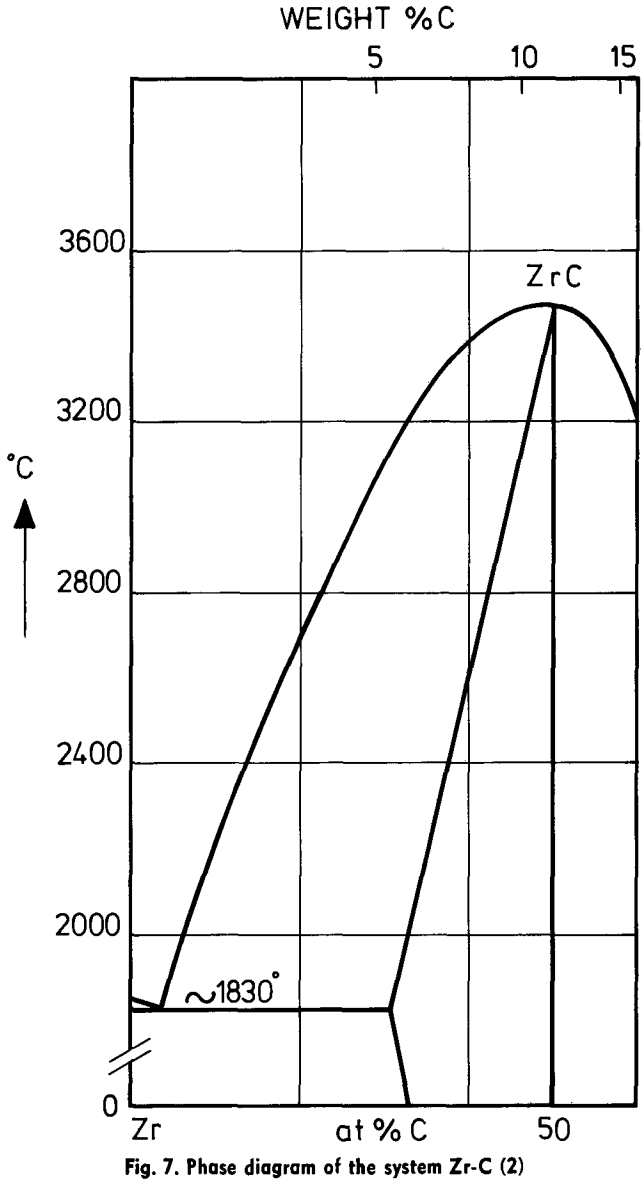

Fig. 7. Phase diagram of the system Zr-C (2)

shaped and may contain a fairly large amount of material to be evaporated. Connection to a continuous supply system is possible as capillary action causes a rapid distribution of molten material along the evaporator.

Brief Communications

Anodic Oxide Films on GaP

J. M. Poate, P. J. Silverman, and J. Yahalom[1]
Bell Laboratories, Murray Hill, New Jersey 07974

The growth of oxides on compound semiconductors is of considerable importance in such problems as surface passivation and the formation of insulating or masking films. In the pioneering work of Dewald (1), anodic films were grown on InSb; more recently, several groups have examined anodic oxides on GaAs (2-4). In the previous work on GaP (5), oxides were

[1] Permanent address: Department of Materials Engineering, Technion Israel Institute of Technology, Technion City, Haifa, Israel.

Key words: gallium phosphide (GaP), anodic oxide films, Rutherford scattering.

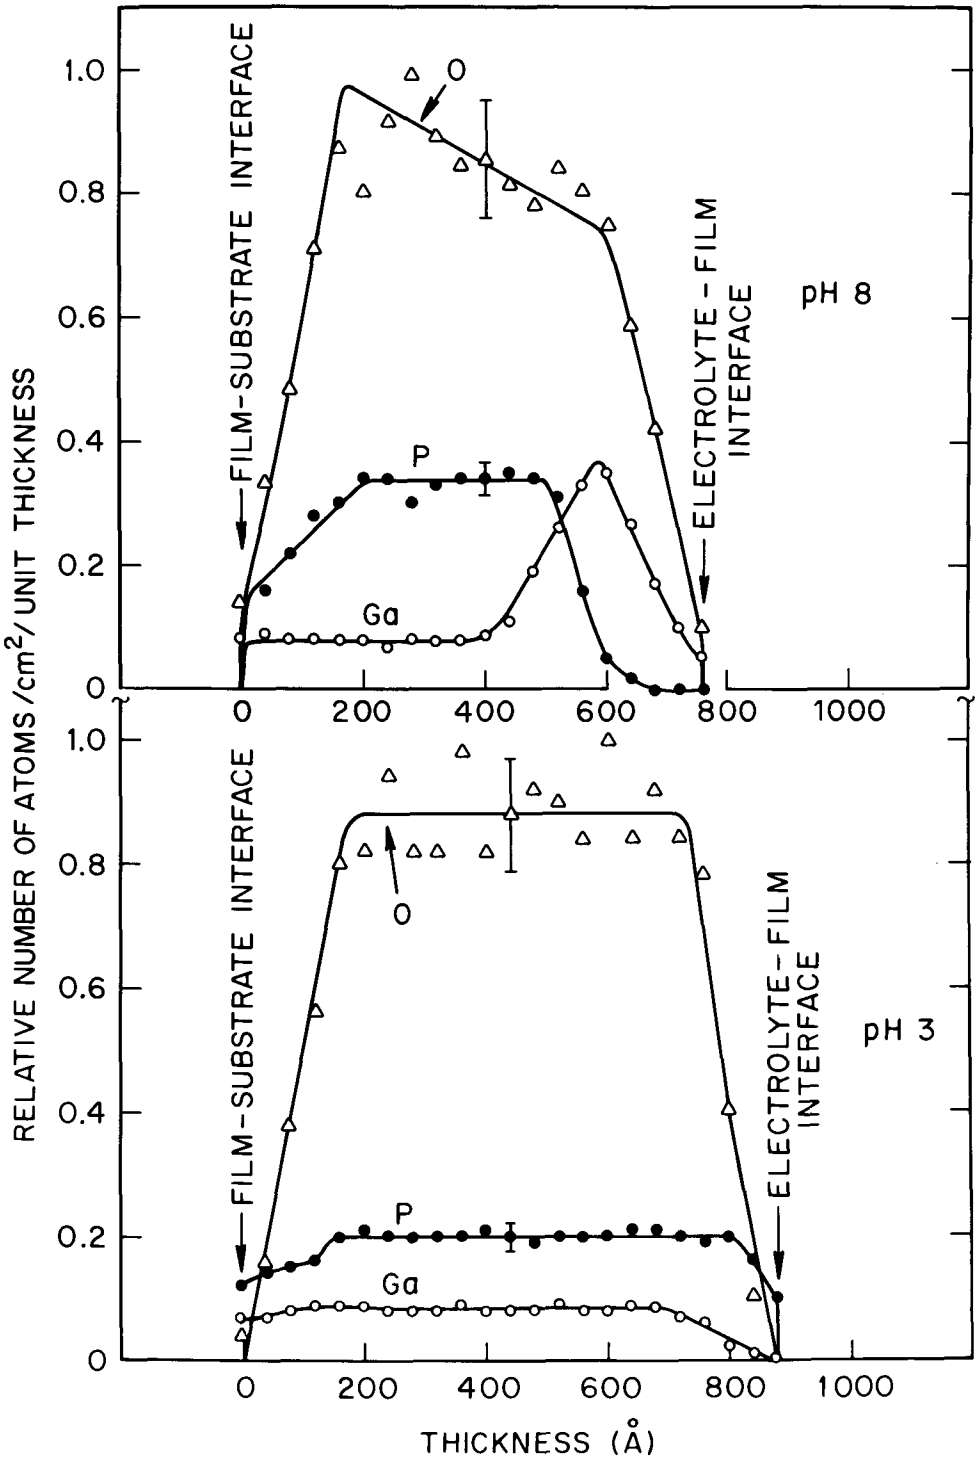

Fig. 1. Depth profiles of Ga, P, and O extracted directly from the backscattered energy spectra of (a) a nonuniform film grown in a pH 8 electrolyte and (b) a uniform film grown in a pH 3 electrolyte. The lines are drawn simply to guide the eye, not necessarily as a best fit for the data points. Typical error bars are shown on the O and P profiles; the error bar on the Ga is ~ the dot size.

grown anodically and galvanically in H_2O_2. Because the anodic oxides could be grown with more facility than the galvanic oxides, and the growth mechanisms of the anodic oxides should include the particular case of the galvanic oxides, it was decided to undertake a systematic study of GaP anodization.

(111)-oriented GaP slices were cut from n-type, Se-doped, Czochralski-grown crystals. The P-face of each slice was etched and polished in bromine-methanol. Anodization was carried out in a Teflon cell with a platinum counterelectrode; anodic connection was made to the unpolished side of the slice with a gold electrode. Because studies (6) have indicated a strong pH dependence of the dissolution of gallium oxides, aqueous buffered solutions ranging from pH 3 to 10 were used as electrolytes. A range of constant current densities between 1 and 100 mA/cm^2 was used so that the resistive voltage drop across the GaP substrate was essentially constant throughout an anodization and could be subtracted to obtain the actual voltage drop across the anodic film. A slice area of 1 cm^2 was exposed to the electrolyte, and anodization was terminated after passage of 0.2 coulomb. The wafer was then quickly removed from the electrolyte, rinsed with water and methanol, blown dry, and stored under vacuum.

The composition and depth profiles of the anodic films were analyzed by Rutherford backscattering of 1.7-2.0 MeV He ions in combination with ion channeling. The technique has proved eminently suitable (7) for the analysis of such films on single crystal substrates in that no calibration procedures are required and depth information is obtained in a straightforward fashion. This method revealed two distinct types of films: those with uniform composition throughout the thickness of the film, and those in which there is a Ga-rich and P-deficient layer near the film-electrolyte interface. Figure 1 shows the Ga, P, and O depth profiles extracted directly from the backscattered energy spectra of typical uniform and nonuniform films grown in pH 3 and 8 solutions, respectively (see Table I). Depth resolution for these films was ~100Å. The extreme peaking of the Ga in the outer half of the nonuniform film and the almost complete lack of P within ~200Å of the surface are clearly seen in Fig. 1a. Ga apparently migrates through the films during anodizing much more rapidly than P and forms an outer layer, probably of the form Ga_2O_3, in the nonuniform case. Between this layer and the substrate, the anodic film contains P in excess of Ga by a factor of ~3. Figure 1b illustrates the uniformity of the pH 3 grown film over most of its thickness. The composition of the uniform film is somewhat similar to the deep layer in the nonuniform film, indicating that in the uniform case a large fraction of the migrating Ga is continually being dissolved as it arrives at the oxide-electrolyte interface. The growth mechanism of this uniform core may depend on the in-diffusion of the oxidizing species to form a matrix which grows as the majority of the Ga diffuses through it.

Table I. Integrated stoichiometries and thicknesses of films produced in typical aqueous buffered electrolytes

pH	Electrolyte composition	Current (mA/cm^2)	Integrated Ga:P:O	Thickness Å
3	Potassium hydrogen phthalate, sulfuric acid	10	1:2.4:6.5	550
		100	1:2.4:8.5	800
8	Potassium dihydrogen phosphate, sodium hydroxide	10	1:1.2:3.7	600
		100	1:1.6:4.9	900

Film thickness was calculated using the densities of P_2O_5 and Ga_2O_3, weighted according to the P:Ga ratio in the oxide. Errors in the stoichiometries and thicknesses are expected to be ~10-15%.

In all cases it was found that for the same anodization charge higher current densities produced thicker films, as judged by surface densities and interference colors. This is to be expected if dissolution during anodization is an important factor, since a lower current density requires the slice to be immersed in the electrolyte for a longer time. In certain electrolytes, particularly at high pH values, the voltage rose linearly to typical values during anodization, but little or no film was found on the slices after they were removed from solution. The voltage rise indicated that film was growing during anodization; apparently strong dissolution occurred mainly after the current was stopped. This dissolution may have been prevented during anodization by either a field repulsion of film-dissolving cations or by a local decrease in pH, caused by H^+ production near the anode, which disappeared when the current was stopped. Since the electrolyte was buffered and stirred, the latter explanation seems unlikely. Several slices were also anodized in buffered solutions of identical pH but different composition. The differences between these oxides indicate that the properties of the anodic films may depend on the constituents of the electrolyte as well as on the pH.

Films of sufficient thickness exhibit interference colors similar to those seen in anodic Ta_2O_5, ranging from pale yellow for the thinnest to purple or blue for the thickest. Of all the electrolyte used, phosphate solutions (pH 6-8) produced films that were the most stable and uniform in appearance. Oxides produced in other solutions were often mottled or became so shortly after exposure to air, apparently by absorption of water.

This Rutherford backscattering examination of GaP anodic films has revealed the complex film structures that can arise in compound or alloy systems because of such competing factors as varying cationic mobilities and dissolution rates. A particularly interesting manifestation of these processes is the surfeit of Ga that can occur at the oxide-electrolyte interface. A complete account of the results and interpretation of this experiment will be given elsewhere (8).

Bonding of Gallium Arsenide Crystals

T. L. Chu* and R. K. Smeltzer*,[1]

Electronic Sciences Center, Southern Methodist University, Dallas, Texas 75222

Gallium arsenide crystals are grown commercially by the Czochralski or the gradient freeze technique, and available crystals are usually no larger than 1½ in. in diameter. These crystals are much too small for some applications, such as optical windows. One approach of obtaining large area gallium arsenide crystals is to bond a number of commercially available crystals by the alloying technique. In this investigation, germanium was selected as an alloying agent on the basis of three reasons: (*i*) germanium does not react chemically with gallium arsenide and their mutual solubility is very small; (*ii*) the lattice parameter and thermal expansion coefficient of germanium (5.66A and 5.8 $\times$ 10^{-6} $°C^{-1}$, respectively) are essentially the same as those of gallium arsenide (5.65A and 5.9 $\times$ 10^{-6} $°C^{-1}$, respectively); and (*iii*) the germanium-gallium arsenide pseudobinary system has a simple eutectic containing 15 mole per cent (m/o) gallium arsenide and melts at a conveniently low temperature, 865°C (1). The experimental procedures and results are summarized below.

To utilize the alloying technique for the bonding of gallium arsenide crystals, germanium is deposited on the faces of the crystals to be bonded, and the two faces are placed in contact with each other so that they are crystallographically parallel. This assembly is then heated in an arsenic atmosphere at a temperature above the eutectic temperature of the germanium-gallium arsenide system. The extent of dissolution of gallium arsenide and the amount of liquid solution are determined by the thickness of the germanium layer and the alloying temperature in accordance with the phase diagram. After equilibrium is established, the germanium-gallium arsenide assembly is slowly cooled to yield epitaxial, single crystalline, gallium arsenide and germanium which are bonded to the original gallium arsenide crystals. The bond is expected to be strong mechanically because of the nearly identical lattice parameters and thermal expansion coefficients of germanium and gallium arsenide. The important parameters in this process are therefore the thickness of the germanium layer, the alloying temperature, and the cooling rate.

Gallium arsenide crystals used in the bonding experiments had main faces of {100} orientation and were polished on a Pellon pad using sodium hypochlorite as an etchant. In a typical experiment, 1-2μ of germanium were deposited onto the polished faces by vacuum evaporation. The faces to be bonded were placed in contact and heated at 900°C in a sealed silica tube containing a few Torrs of arsenic pressure. According to the phase diagram of the germanium-gallium arsenide system (1), the thickness of gallium arsenide dissolved at 900°C under equilibrium conditions is approximately one-half of that of the germanium layer. The cooling was carried out at a rate of 10°C/hr, and a strong bond was formed between the two crystals. A series of experiments were carried out using different thicknesses of germanium at alloying temperatures up to 1000°C, and a strong bond was formed in all cases. Angle-polishing and chemical-etching techniques were used to examine the interface region of several samples, and this region was found to be 4-14μ in thickness, in qualitative agreement with what one would expect from phase diagram considerations. The flatness and cleanliness of the gallium arsenide surfaces were found to be important factors affecting the perfection of the interface region, particularly when very thin layers of germanium were used. Figure 1 shows the angle-polished surface of a bonded specimen where the voids in the interface region are due presumably to nonuniform wetting of the gallium arsenide surface.

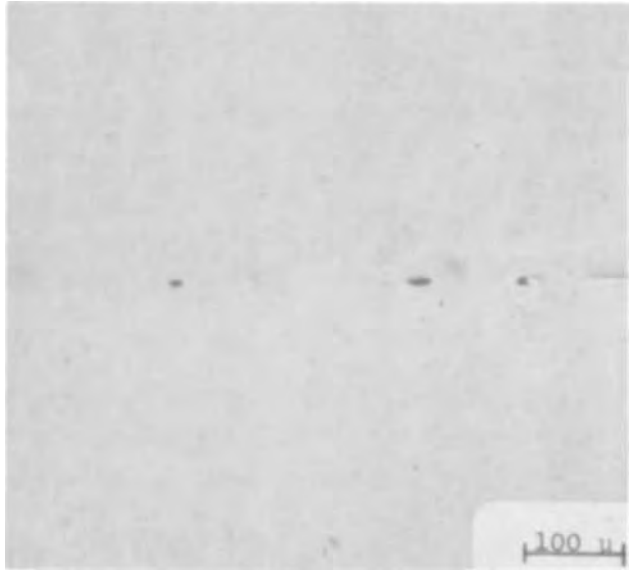

Fig. 1. Angle-polished surface of a bonded gallium arsenide crystal showing defects in the interface region.

In summary, germanium has been shown to be a suitable alloying agent for the bonding of gallium arsenide crystals at relatively low temperatures. The extent of dissolution of gallium arsenide is determined by the thickness of the germanium layer and the alloying temperature, and the perfection of the interface region is determined predominately by the surface preparation of gallium arsenide.

Control of the Deposition of Silicon Nitride Layers by 2537Å Radiation

C. H. J. v. d. Brekel and P. J. Severin
(pp. 372-376, Vol. 119, No. 3)

K. Navrátil and I. Ohlídal:[1] Brekel and Severin in the paper under discussion described a method of control and determination of the thickness of the deposition of Si_3N_4 on silicon from the extremes of the curve expressing the dependence of the reflectance of the system Si_3N_4–Si on the phase angle at a constant wavelength of light 2537Å.

In our discussion we would like to raise some critical objections concerning the theoretical part and hence the following conclusions of the paper cited. The authors characterize the system mentioned as a nonabsorbing layer on a nonabsorbing substrate. On the basis of measurements by Reizmann and van Gelder[2] the authors of the paper under discussion assume the index of refraction of Si_3N_4 for the given wavelength to be $n_1 = 2.18$; and the index of refraction of silicon according to Philipp and Taft[3] is $n_2 = 1.65$, where they have neglected the index of absorption of silicon as indicated in Appendix A by the authors. Here the authors of the paper being discussed, as shown in the following discussion have committed a comparatively relevant error. Philipp and Taft[3] give for the index of absorption the value $k_2 = 3.5$. It is evident that, in the region of the wavelengths, silicon cannot be considered to be nonabsorbing, but on the contrary, a relatively considerable absorbing matter.

Next we shall give a short outline of a correct procedure of deriving the reflectance of the system Si_3N_4–Si in the case where the absorption of silicon, *i.e.*, the system of nonabsorbing layer/absorbing substrate, is considered.

According to Vašíček[4] the resulting Fresnel coefficient for reflectance on a thin layer has the form

$$\hat{r} = \frac{r_1 + \hat{r}_2 e^{-ix}}{1 + r_1 \hat{r}_2 e^{-ix}} \qquad [1]$$

where $\hat{r} = re^{i\delta}$, and

$$r_1 \equiv \frac{n_0 - n_1}{n_0 + n_1} = r_1 e^{i\beta}, \quad \hat{r}_2 \equiv \frac{n_1 - \hat{n}_2}{n_1 + \hat{n}_2} = r_2 e^{i\alpha} \qquad [2]$$

$$\hat{n}_2 = n_2 - ik_2, \quad x = \frac{2\pi}{\lambda} 2n_1 d_1$$

In relation [2] $n_0 = 1$, n_1 is the index of refraction of the layer, $\hat{n}_2$ is the complex index of refraction of silicon, $n_2 = 1.65$ is the real part of the index of refraction of silicon, and $k_2 = 3.5$ is the index of absorption of silicon, r_1 and $\hat{r}_2$ are the Fresnel coefficients of the upper and lower boundary, x is the phase angle, d_1 is the thickness of the layer, α is the phase change at the boundary Si_3N_4–Si, and the angle β obtains the values

$$\beta = \begin{cases} 0 \text{ for } n_0 > n_1 \\ \pi \text{ for } n_0 < n_1 \end{cases}$$

From this point of view the assumption by the authors of the paper under discussion that change of the phase occurs about π at the boundary of Si_3N_4–Si is not correct. In their paper they consider silicon as a nonabsorbing matter; it is $n_2 < n_1$ and the phase change cannot occur.

Relation [1] may be rewritten into the form

$$re^{i\delta} = \frac{r_1 e^{i\beta} + r_2 e^{i\alpha} e^{-ix}}{1 + r_1 e^{i\beta} r_2 e^{i\alpha} e^{-ix}} \qquad [3]$$

here r_1 and r_2 are the absolute values of the Fresnel coefficients. From Eq. [3] it may be easy to obtain the formula for reflection

$$R = \frac{r_1^2 + r_2^2 + 2r_1 r_2 \cos(x - \alpha - \beta)}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos(x - \alpha - \beta)} \qquad [4]$$

The phase change at the boundary layer with silicon follows then by simple calculation from Eq. [2]

$$\tan \alpha = \frac{2k_2 n_1}{n_1^2 - n_2^2 - k_2^2} \qquad [5]$$

Optical constants of our system will then evidently hold $\tan \alpha < 0$. According to Vašíček[4] it is valid that

$$\tan \alpha_0 = \frac{2k_2 n_1}{n_2^2 + k_2^2 - n_1^2}$$

and thus $\tan \alpha_0 > 0$ in this case. The differences in expressions correspond with the introduction of single parameters. It may, however, be written $\alpha = \pi - \alpha_0$. By substitution in Eq. [4] we obtain a relation agreeing with Vašíček[4]

$$R = \frac{r_1^2 + r_2^2 + 2r_1 r_2 \cos(x + \alpha_0)}{1 + r_1^2 r_2^2 + 2r_1 r_2 \cos(x + \alpha_0)} \qquad [4a]$$

as in our case is $\beta = \pi$.

In Fig. 1 the dependence of R on the phase angle $(x + \alpha_0)$ is plotted. A qualitative difference of the course of dependencies in comparison with Fig. 4 of the paper being discussed is apparent. The reflectance with increasing thickness decreases from the value for a clean surface of silicon without the layer to a minimum, and then increases to a maximum value $R_{max} > R_0$, where R_0 is the reflectance of clean silicon. This course is in accordance with that of the reflectance of the system of nonabsorbing layer metal as mentioned[4] for approximately the same optical constants of the substrate and layer.

In Table I conditions are indicated for which the extreme values of reflectance occur according to a correct relation [4a] and those when assuming silicon to be nonabsorbing. We would like to direct the authors' attention to the misinterpretation of the phase angle in the form

$$x = \frac{2\pi}{\lambda} n_1 (d_1)_0$$

The difference of the thickness of the layer determined under the assumption of silicon to be nonabsorbing and according to the correct relation (see Table I) may be stated. This difference is constant

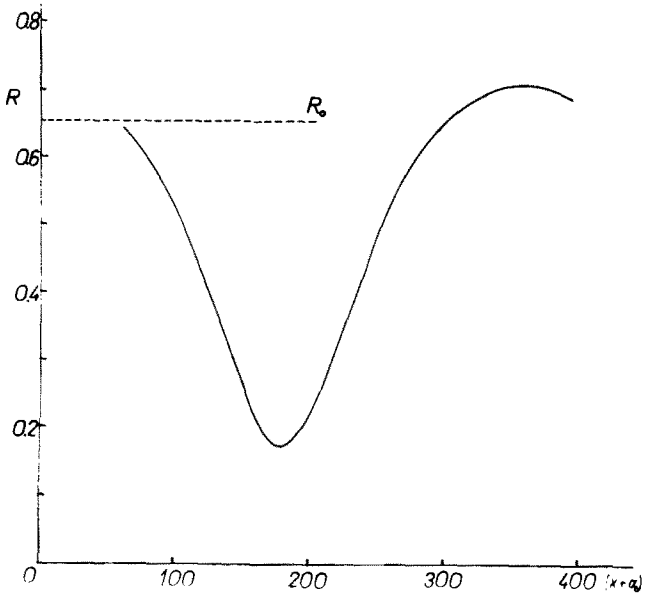

Fig. 1. Dependence of reflectance of the system Si_3N_4–Si on the value of the phase angle $(x + \alpha_0)$. The dependence is calculated using relation [4a].

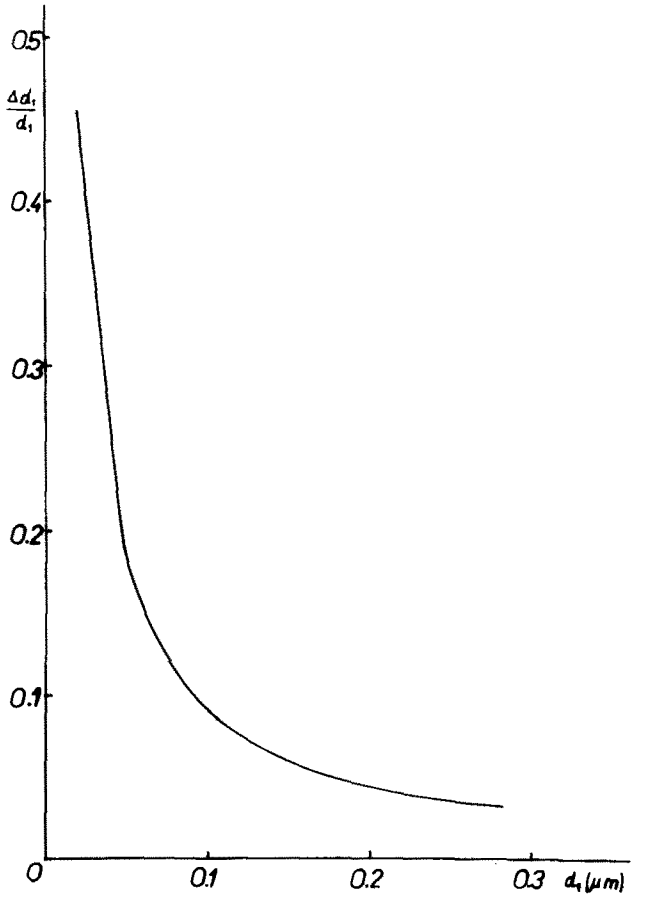

Fig. 2. Dependence of the relative error when determining the thickness dependent on the magnitude of the thickness of the layer.

$\Delta d_1 \equiv (d_1)_0 - d_1 = \alpha\lambda/4\pi n_1$ and is equal to 91Å. The relative error in determining the thickness of dependence on that of the layer d_1 is given in Fig. 2. It is evident that this error is considerable, namely, in the region of small values of d_1.

This discussion was intended to show how neglect of the absorption of the substrate can affect the statement, especially for small thicknesses. In case the relative experimental error is greater than $\Delta d_1/d_1$, the correction stated does not take place. Nevertheless, Chopra[5] mentions the sensitivity in determining thickness by this method $\lambda/300$. Hence it is apparent that neglecting the absorption of silicon takes place substantially when controlling the thickness by the method mentioned at $\lambda = 2537$Å.

Table I

	Correct conditions for occurrence of the extreme	Conditions for occurrence of extremes under the assumption of silicon to be nonabsorbing
Minimum	$x + \alpha_0 = (2k - 1)\pi$	$x = 2k\pi$
	$\frac{4\pi}{\lambda} n_1 d_1 + \alpha_0 = (2k - 1)\pi$	$\frac{4\pi}{\lambda} n_1 (d_1)_0 = 2k\pi$
Maximum	$x + \alpha_0 = 2k\pi$	$x = (2k - 1)\pi$
	$\frac{4\pi}{\lambda} n_1 d_1 + \alpha_0 = 2k\pi$	$\frac{4\pi}{\lambda} n_1 (d_1)_0 = (2k - 1)\pi$

k are the integers.

C. H. J. v.d. Brekel and P. J. Severin: In their comment on our paper Navrátil and Ohlídal quite rightly state that the vacuum-Si_3N_4–Si system should not be characterized by simply assuming that the absorption is negligible. In fact we indicated in appendices A and B of our paper under discussion along which lines a calculation could possibly be undertaken assuming real refractive indices. Knowing that this assumption does not hold we only used the model to show the agreement with the periodic dependence actually measured. Knowing that the relevant parameters were not available we did not compare the experiments to a more sophisticated theory.

Navrátil and Ohlídal are right in their conclusion that the introduction of the phase shift δ_{12} at the Si_3N_4–Si interface modifies the thickness of the layers by a fixed amount. However, the actual magnitude is subject to the following considerations. The refractive index of silicon has been deduced by Philipp and Taft[3] from the spectral dependence of the reflectance, 65% at 4.8 eV. They found $n = 1.65$ and $k = 3.5$, but it should be doubted whether the frequency range used to evaluate the Kramers-Kronig integral relation was large enough,[6,7] particularly in the range of strong absorption near 5 eV. Verleur[8] also measured the reflectance, 80% at 4.8 eV, and fitted it to an expansion in terms of a set of classical oscillators. Matching the whole spectrum between 0.5 and 10.0 eV he finds $n = 0.9$ and $k = 3.1$. This set of data is also quoted by Moses.[9] The above data refer to room-temperature measurements whereas the parameters needed at the growth temperature of 200°C are not available. Using the results of Philipp and Taft, Navrátil and Ohlídal calculated the difference in thickness due to δ_{12}, neglected in our simplified model, to be 91Å. However, this claim to accuracy and precision exceeds the experimental possibilities to a large extent.

Chemical Vapor Deposited Polycrystalline Silicon

line silicon, Cowher and Sedgwick discuss Hall mobilities for both n- and p-type samples which are as high as 1/2-1/3 of bulk mobility values in the 10^{14}-10^{17} cm^{-3} concentration range. In this doping range mobilities have typically been much lower than this, presumably because of potential barriers at the grain boundaries which have a greater scattering effect at lower carrier concentrations than at higher concentrations. Also, they find that the total dopant concentration (phosphorous), as determined from neutron-activation analysis, is much larger than the electrically active dopant concentration as determined from Hall measurements. To explain their unusually high mobility values and the discrepancy between total and electrically active dopant concentrations, Cowher and Sedgwick propose a model in which the electrically inactive dopant atoms are preferentially deposited at the grain boundaries where they compensate local structural defects and reduce carrier scattering. They also postulate an alternative model in which the hydrogen ambient at their low growth temperatures eliminates or compensates the structural defects at the grain boundaries. Either of these models seems reasonable and could explain their mobility values being 1/2-1/3 of bulk values.

However, Cowher and Sedgwick in the paper under discussion state that our previously developed conducting inhomogeneity model[12,13] cannot explain their high mobility values because the total amount of dopant required greatly exceeds that which is present in their samples. (It is not clear whether they are referring to total or electrically active dopant concentration.) This statement, of course, is misleading, since our conducting inhomogeneity model is independent of doping level. It is not obvious how this misinterpretation could have occurred. We have previously discussed in our work why high apparent mobilities might be observed in polycrystalline samples.[13] In as-grown single crystalline GaAs samples we have observed mobility values which are twice bulk values[14] in the same concentration range where in polycrystalline silicon Cowher and Sedgwick in their work see 1/2-1/3 of bulk values. These results are easily explained with the conducting inhomogeneity model. Theoretically, we have also shown that conducting inhomogeneities in a Hall sample can result in apparent (not real) mobilities which are too high by as much as several orders of magnitude.[12,13] This is because in a Hall sample with conducting inhomogeneities the resistivity measurement gives an average resistivity for the sample including the conducting inhomogeneities, whereas the Hall constant measurement preferentially gives the Hall constant of the medium surrounding the conducting inhomogeneities, Thus, the mobility calculated from the Hall constant divided by the resistivity is too high. Physically, this is because there is less current flow in the inhomogeneities in a magnetic field (Hall constant measurement) than in zero magnetic field (resistivity measurement).[15]

This can be shown to hold true for any arbitrarily shaped, three-dimensional conducting inhomogeneity in the following manner: the component of current density normal to the surface of the inhomogeneity, J_{ni}, at any point is related to the normal and tangential components of the electrical field, E_{ni} and E_{ti}, respectively, at the same point by

$$J_{ni} = \left(\frac{\sigma_i}{1 + \beta_i^2} \right) (E_{ni} + \beta_i E_{ti}), \quad i = 1, 2$$

where σ_i is the conductivity, β_i is the product of the real mobility; μ_i, and the orthogonal magnetic field, B, and $i = 1, 2$ denote the surrounding medium and the inhomogeneity, respectively. Since there are no current sources at the boundary between the inhomogeneity and the surrounding medium, $J_{n1} = J_{n2}$, and because of conservation of energy, $E_{t1} = E_{t2}$. With these relations it is easy to show that

$$J_{ni} = \frac{\left(E_{n1} - \frac{\beta_1}{\beta_2} E_{n2} \right)}{\left(\frac{1 + \beta_1^2}{\sigma_1} \right) - \frac{\beta_1}{\beta_2} \left(\frac{1 + \beta_2^2}{\sigma_2} \right)}$$

From this expression it can be seen that the current into any inhomogeneity decreases with increasing magnetic field, and, in fact, approaches zero as the magnetic field approaches infinity.

For the case in point then, it is clear that the conducting inhomogeneity model is generally valid, is independent of doping level, and cannot be arbitrarily discounted for any sample with unusually high measured values of mobility without more extensive measurements, as has been previously discussed.[12,13]

M. E. Cowher and T. O. Sedgwick: The authors of the above discussion correctly point out that the applicability of their model[13] for the anomalously high mobility of inhomogeneous semiconductors is independent of doping and cannot be ruled out as a possible partial explanation of the high mobilities observed in our lightly doped polycrystalline Si samples in the paper being discussed. However, this inhomogeneity model probably cannot account for more than a factor of two, at most, in our results. First, our samples were measured at a $\beta \leq 4 \times 10^{-2}$ (assuming a maximum $\mu = 10^3$ cm^2/V sec) which according to their Fig. 4[16] gives at most $\mu_{App}/\mu = 2$ which occurs at $\alpha = 0.7$. We have no way of estimating α for our samples, but μ_{App}/μ is less than 2 for all other values of α. Secondly, it is difficult to know how precisely their model, for a sample with a single inhomogeneity, may be applied to our samples which are very fine grained, and where the inhomogeneities, if they exist, are small, but possibly large in number.

Errata

In the paper "Control of the Deposition of Silicon Nitride Layers by 2537Å Radiation" by C. H. J. v. d. Brekel and P. J. Severin which appeared on pp. 372-376 in the March 1972 JOURNAL, Vol. 119, No. 3, the authors have found that the parameter ϕ as used in the paper should be $\phi = 4\pi hn/\lambda$, twice as large as defined in Eq. [1a]. Then Eq. [A-4a] and [A-4b] should read $h = 635$Å and $h = 317$Å, respectively.

The authors further state that the experiments appear to be in agreement with the erroneous definition of ϕ. This could be traced to be caused as follows. The thickness measurements made every minute were noted with the detailed color chart (1) for SiO_2 as if the layer grown were SiO_2. The thickness of the Si_3N_4 layer actually grown should be obtained by multiplying by the refractive index ratio 1.48/1.97 = 0.7, but the observer divided by 0.7 so that the thickness plotted is too large by a factor of two. This did not arouse suspicion because of the mistake made in the definition of Eq. [1a], which, subconsciously perhaps, generated the error. Hence after correction of Eq. [1a] and dividing the ordinate scale in Fig. 5 by a factor of two, the model adequately describes the experiments.

Equations [A-2] and [B-3] should read

$$R = 1 - \frac{(1 - r_{01}^2)\ (1 - r_{12}^2)}{(1 - r_{01}r_{12})^2 + 4r_{01}r_{12}\sin^2(-\phi/2)} \qquad [A\text{-}1]$$

$$\frac{1}{G} = \frac{1}{2}\frac{ED}{E^2\sin^2\phi/2 + \cos^2\phi/2} \qquad [B\text{-}3]$$

In the section on Theory, first paragraph, lines 13-15 should read "Absorption in the Si_3N_4 layer is neglected and light reflects at the Si_3N_4 surface with a phase change π.

A Battery Analog

Clarence M. Shepherd*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

The current density distribution inside a battery can be very well approximated by assuming the current flow is perpendicular to the electrodes. The ratio of electrode spacing to electrode height is found to have a negligible effect on this approximation. A battery analogue was constructed that consisted of resistances alone and eliminated any polarization effects. Measurements made on it were in excellent agreement with those predicted mathematically.

A number of mathematical equations have been and are being developed that describe the current density distribution and other cell characteristics inside a battery during charge and discharge. Many of these derivations are based on the proposition that the current flow in the electrolyte is perpendicular to the electrodes, an assumption that is an excellent approximation when the ratio of the electrode spacing D to the electrode height H is sufficiently small. The effect on cell characteristics as D/H becomes large is considered here.

A thorough discussion of the mathematical model and symbols have been given previously and is applicable here (1, 2). It is assumed that the electrodes are thin, flat, parallel, rectangular, of uniform width and spacing, and are in a close fitting cell case.

H = total electrode height, cm
h = height above bottom of electrode, cm
m = H $-$h, cm
D = distance between electrodes, cm
d = distance measured perpendicularly from the anode, cm
L = resistance of a parallelogram 1 cm^2 in cross section extending from anode to cathode, ohm-cm^2
$R_e = LD^{-1}$ = resistivity of electrolyte, ohm-cm
R_o, R_d = resistance of a 1 cm wide section of the anode and the cathode, respectively, per unit length in the h direction, ohm
$R = R_o + R_d$, ohm
e is the sum of the potential drop in the anode and cathode measured from the top of the electrode to a point at height h, V
$x = -R^{-1}\, de/dh$ is the current per unit width flowing vertically past a point on the electrode at height h, A-cm^{-1}
$i = dx/dh$ is the current flowing between electrodes, per unit area at height h, A-cm^{-2}
i_H = current density, i, at top of electrode ($h = H$)
i_M = current density at the midpoint of electrode
i_o = current density at the bottom of the electrode
E_d = the potential drop due to the discharge current I and is the sum of all the potential drops in the cell due to resistances and polarization, V

$\lambda_o = R_o DHL^{-1}$, dimensionless
$\lambda_D = R_d DHL^{-1}$, dimensionless
$\lambda = \lambda_o + \lambda_d$
b_o, b_d = absolute values of the slopes of the single electrode potential *vs.* current density curves for anode and cathode, respectively, ohm-cm^2
$K = b_o + b_d$
$\mu_o = Db_o L^{-1}H^{-1}$, dimensionless
$\mu_d = Db_d L^{-1}H^{-1}$, dimensionless

$$\Psi = \left(\frac{\lambda_o + \lambda_d}{DH^{-1} + \mu_o + \mu_d}\right)^{1/2} \text{ dimensionless}$$

$$= \left(\frac{R}{L + K}\right)^{1/2} H \text{ dimensionless} \qquad [1]$$

$J(m, d)$ = value of the stream function at (m, d) in the cell (2), A-cm^{-1}

Tobias and Wijsman (2) have shown that

$$\frac{J(m,d)}{I} = \frac{m}{h} + \sum_{n=1}^{\infty} \frac{2}{n\pi}\left(\sin n\pi \frac{m}{H}\right)\frac{A}{B} \qquad [2]$$

where

$$A = [\lambda_d(\lambda_o + n^2\pi^2\mu_o)\mathrm{Sh}(n\pi dH^{-1}) + \lambda_o(\lambda_d + n^2\pi^2\mu_d)\mathrm{Sh}(n\pi\{D-d\}H^{-1}) + n\pi\lambda_d \mathrm{Ch}(n\pi dH^{-1}) + n\pi\lambda_o \mathrm{Ch}(n\pi\{D-d\}H^{-1})] \qquad [3]$$

and

$$B = [\lambda_o\lambda_d + n^2\pi^2(1 + \lambda_o\mu_d + \lambda_d\mu_o) + n^4\pi^4\mu_o\mu_d]\mathrm{Sh}n\pi DH^{-1} + [n\pi(\lambda_o + \lambda_d) + n^3\pi^3(\mu_o + \mu_d)]\mathrm{Ch}n\pi DH^{-1} \qquad [4]$$

If it is assumed that the current flow in the electrolyte is perpendicular to the electrodes then it can be easily shown that the cell characteristics at the beginning of a discharge are described by the following equations (1, 2)

$$\frac{x}{I} = \frac{\sinh[h/H)]}{\sinh \Psi} \qquad [5]$$

$$\frac{iH}{I} = \frac{\Psi \cosh[\Psi(h/H)]}{\sinh \Psi} \qquad [6]$$

* Electrochemical Society Active Member.

Key words: current density distribution, battery design, cell, electrode resistance, electrolyte resistance, polarization, cell characteristics.

$$\frac{e}{HIR} = \frac{\coth \Psi}{\Psi} - \frac{\cosh [\Psi(h/H)]}{\Psi \sinh \Psi} \quad [7]$$

$$\frac{E_d}{HIR} = \frac{\coth \Psi}{\Psi} \quad [8]$$

where (x/I), Ψ, (iH/I), (e/HIR), and (h/H) are dimensionless.

Results and Discussion

It can be shown here that Eq. [2] approaches Eq. [6] as a limiting value when D/H approaches zero in value by putting $D/H = 0$ and $d = 0$ in Eq. [2] and taking the derivative with respect to m/H. As a result

$$\frac{iH}{I} = 1 + \sum_{n=1}^{\infty} 2 \left(\cos n\pi \frac{m}{H}\right) \left(\frac{n\pi\lambda_d + n\pi\lambda_o}{n\pi\lambda_d + n\pi\lambda_o + n^3\pi^3\{\mu_o + \mu_d\}}\right) \quad [9]$$

Substituting Eq. [1] gives

$$\frac{iH}{I} = 1 + \frac{\Psi^2}{\pi^2} \sum_{n=1}^{\infty} 2 \left(\cos n\pi \frac{m}{H}\right)\left(\frac{1}{n^2 + \Psi^2/\pi^2}\right) \quad [10]$$

$$= 1 + \frac{\Psi^2}{\pi^2} \cdot \frac{\pi}{\Psi} \cdot 2 \frac{\Psi}{\pi} \sum_{n=1}^{\infty} \frac{\cos n\pi\, m/H}{n^2 + \Psi^2/\pi^2} \quad [11]$$

From Ref. (3) or (4)

$$\frac{iH}{I} = 1 + \frac{\Psi}{\pi}\left[\frac{\pi \cosh \Psi/\pi\,(\pi - \pi\, m/H)}{\sinh \Psi} - \frac{\pi}{\Psi}\right] \quad [12]$$

$$= \frac{\Psi \cosh [\Psi(h/H)]}{\sinh \Psi} \quad [13]$$

which is identical to Eq. [6] and can be used to derive Eq. [5], [7], and [8] by integration. Thus Eq. [5] to [8] can be derived from Eq. [2] as a limit that is approached when D/H approaches zero in value or they can be derived by assuming that the current flow is perpendicular to the electrodes. It will be shown here how the error in Eq. [5] to [8] increases as D/H increases above zero in value.

The derivation of Eq. [5] to [8] as well as that of Eq. [2] is based on an assumption that the total drop in potential due to polarization is a linear function of the current density (1, 2). The coefficient of polarization K has the same dimensions as the electrolyte resistance L and since the two are added in defining Ψ, it makes no difference in Eq. [5] to [8] whether the polarization is large or small; the results are defined only by the sum of $L + K$.

The techniques used in deriving Eq. [2] are not readily adaptable to nonlinear polarization. The assumption of perpendicular current flow, which will be studied here, makes possible a simple numerical analysis for any nonlinear polarization and in a number of cases makes possible a mathematical solution. By applying a correction factor to Ψ, Eq. [5] and [6] can give a good description of many of the nonlinear solutions (1). The relationships described in Eq. [5] to [8] have been plotted in Ref. (1) and to a limited extent in Fig. 4 and 5. It can be seen from Eq. [6] that i_H/i_o, the ratio of the current density at the top of the electrode to that at the bottom, is equal to cos Ψ. This relationship has been plotted in Fig. 1 as a function of Ψ and shows the current density distribution over the face of the electrode to be fairly even for values of $\Psi < 1$. As Ψ approaches zero, i_H/i_o approaches one in value and the current density distribution becomes uniform. As Ψ increases above one in value, the variation in current density distribution increases rapidly and eventually other factors such as nonlinearity of the polarization will become significant and affect the accuracy of the mathematical descriptions. Large variations in current density can cause or be associated with appreciable lowering of the discharge potential, the capacity, the efficiency, and the maximum discharge rate and may also cause serious overheating at the top of the battery. A major purpose of this paper is to eliminate such undesirable conditions by establishing here some of the underlying principles that can be used to properly design batteries so that the value of Ψ will be small. It is desired to determine here what limitations are placed on using Eq. [5] to [8], particularly at low values of Ψ, by comparing the results obtained from Eq. [6] to those obtained from Eq. [2].

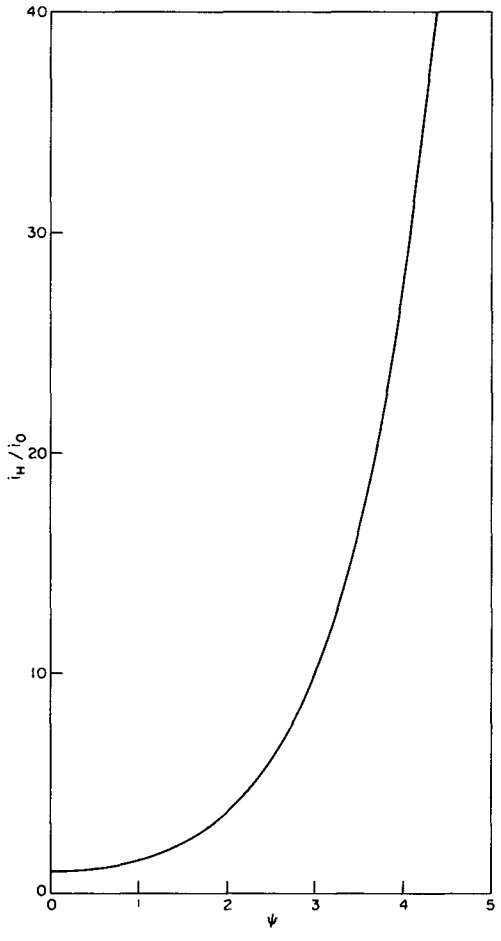

Fig. 1. i_H/i_o, the ratio of the current at the top to the current flowing at the bottom of a battery.

By putting $d = 0$ and $d = D$ in Eq. [2] the current distribution at the electrodes can be obtained and is found to be different on the two electrodes when one has a high resistance and one has a low resistance. Tobias and Wijsman have studied the case where polarization and terminal effect are restricted to one electrode by putting $\lambda_d \cong 0$ and $\mu_d \cong 0$. They also studied this case in the absence of polarization effects by making $\lambda_d \cong 0$, $\mu_d \cong 0$, and $\mu_o \cong 0$ and found that as D/H decreased in value the current density distribution approached in value the approximation described in Eq. [6]. This is illustrated in Fig. 2 where iH/I, the ratio of the current density at a given height to the average current density, is plotted as a function of h/H, the ratio of that height to the total height. At $\Psi = 0$, $iH/I = 1$ and the discharge current is distributed evenly over the face of the electrode as seen in curve C. Curve A, Fig. 2 is the approximate solution for $\Psi = 1$ using Eq. [6]. Curve B is the exact result obtained from Eq. [2] for $\Psi = 1$ where $D/H = 0.5$, $\lambda_d = 0.5$, $\lambda_o = 0$, $\mu_d = 0$, and $\mu_o = 0$. When D/H is reduced to 0.1 and Ψ is kept equal to 1 by decreasing λ_d to 0.1, the results, which are shown as circles in Fig. 2, move much closer to the approximate solution and

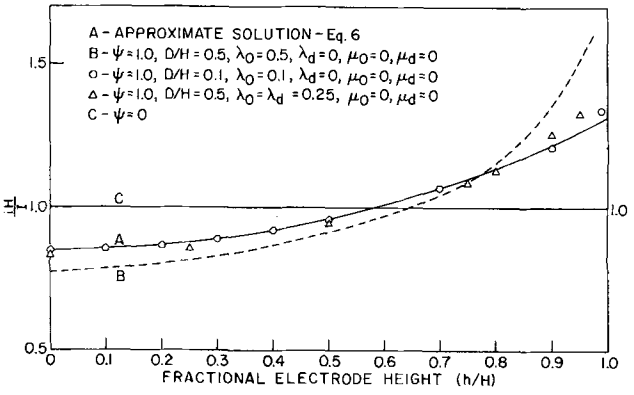

Fig. 2. Effect of *D/H* on the accuracy of the approximate solution

nearly coincide with it. At the extreme top of the electrode the current density predicted by Eq. [2] would be quite large and in a cell would be greatly reduced by the polarization that would be incurred.

A case such as this where the resistance of one electrode was quite large and the other quite small, would not be found in most battery constructions. In general, the grid resistances are kept as small as feasible and are generally fairly equal in value. This case can be studied in the absence of polarization by putting $\mu_o = 0$, $\mu_d = 0$, and $\frac{1}{2}\lambda = \lambda_o = \lambda_d$. Under these conditions Eq. [2] is symmetrical and the current distribution at each electrode for $d = 0$ and $d = D$ is the same. Consequently (2)

$$\frac{J(m,0)}{I} = \frac{J(m,D)}{I} = (1 - x/I)$$

and Eq. [2] becomes

$$(1 - x/I) = \frac{m}{H} + \sum_{n=1}^{\infty} \frac{2}{n\pi} \left(\sin n\pi \frac{m}{H} \right) C \qquad [14]$$

where

$$C = \frac{(n\pi)^{-1}(\frac{1}{2}\Psi^2 D/H)\,\mathrm{Sh}(n\pi D/H) + 1 + \mathrm{Ch}(n\pi D/H)}{(n\pi)^{-1}(\frac{1}{2}\Psi^2 D/H)\,\mathrm{Sh}(n\pi D/H) + n\pi(\frac{1}{2}\Psi^2 D/H)^{-1}\mathrm{Sh}(n\pi D/H) + 2\mathrm{Ch}(n\pi D/H)} \qquad [15]$$

Differentiating Eq. [14] with respect to m/H, gives the current density, i, flowing between electrodes at a height equal to h.

$$\frac{iH}{I} = 1 + \sum_{n=1}^{\infty} 2 \left(\cos n\pi \frac{m}{H} \right) C \qquad [16]$$

Equation [6] can be obtained from Eq. [16] by putting $D/H = 0$.

The triangles in Fig. 2 show values, calculated from Eq. [16] for $\Psi = 1$, $D/H = 0.5$, and equal electrode resistances. They are in much better agreement with curve A than curve B which has the same value of Ψ and very unequal electrode resistances.

The per cent error introduced in the current density by assuming current flow is perpendicular to the electrodes and using Eq. [6] instead of Eq. [16] has been plotted in Fig. 3 for various values of D/H and Ψ at a point at the bottom of the electrode which is fairly typical. As h/H increases from 0, this per cent of error decreases, and near the top of the electrode becomes larger again as can be seen in Fig. 2. A study of Fig. 3 shows that the error increases as D/H increases. A well designed battery will have a fairly even current density which means the value of Ψ must be small, probably less than 1.0. At $\Psi = 1.0$, the use of Eq. [6], gives an error of about 1% for $D/H = 0.5$ which is acceptable for design purposes.

In virtually all battery constructions a high value of D/H is not compatible with a high value of Ψ, since the former requires a relatively low value of H and the latter a relatively high value of H. Rewriting Eq. [1], neglecting polarization and substituting the defined values of λ_o, λ_d, and R_e gives

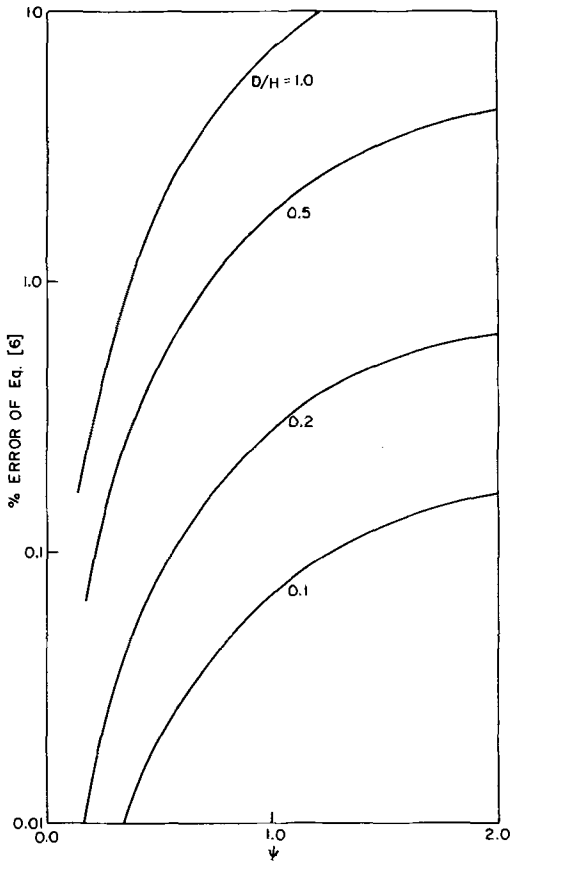

Fig. 3. Effect of *D/H* and Ψ on the accuracy of the approximate solution.

$$\frac{D}{H} = \frac{RH}{\Psi^2 R_e} \qquad [17]$$

The smallest value of R_e that is found among most electrolytes is approximately 2 ohm-cm. At a value of $\Psi = 1$ this would give $DH^{-1} = \frac{1}{2}\,RH$ from Eq. [17]. It would take an unusual combination of very high resistance grid material in one electrode plus very tall, very widely spaced electrodes to give a value of RH that would make D/H much greater than 0.01, a value that Fig. 3 indicates would be in a region of very low error. Conversely, if we assume a value of DH^{-1} equal to 0.5, then Ψ^2 would be approximately equal to RH and Ψ would be very much less than 1.0 in value and would be in the region of low error. Consequently, the assumption is tenable that the current flow in batteries is approximately perpendicular to the electrodes and it can be used as a basis for deriving the characteristics of batteries where the polarization is nonlinear as well as where it is linear as in Eq. [5] to [8].

It was desired to construct battery analogs with resistances connected together analogous to the way they are in a battery, which would not be subject to polarization effects and which could be used experimentally to check Eq. [5] to [8] and which could also be used to determine either Ψ or R, the electrode or grid resistance for an unknown battery. In many cases R is difficult to measure since it is very small in value and it is difficult to calculate because of the nature of most grid construction.

In the first attempt, two plates of good conducting material such as copper or silver which corresponded to the electrodes were clamped on each side of a poorer

conducting material which corresponded to the electrolyte. This failed due to the low resistances involved and the poor electrical contacts. Next various relatively high resistance alloys were melted and allowed to solidify between copper plates. While occasional successes were obtained, most cases failed, once again due to poor contacts. Experiments using thick metal sheets of copper or silver to correspond to the electrodes and mercury in place of the electrolyte were highly successful. A typical construction used two silver plates 3/8 in. thick, 3 in. wide, and 9 3/4 in. high, spaced 3/8 in. apart in a Lucite cell case. An electrical lead was connected to the back of one silver plate and brought out through the Lucite case which was then sealed. A similar connection was made on the other plate at the same height and the entire operation was repeated at a number of different heights. Connections were made at the top of the two silver plates, mercury was added to the desired height, and a constant high amperage d-c current (200-400A) was passed through the system. Measurements were made rapidly to avoid amalgamation effects. Potential drops were measured between the plates at the various heights and also down the plates at the various heights. Various characteristics, such as the variation of current density distribution with height, can be calculated from this data. The system is analogous to a battery in which there is no polarization.

In Fig. 4 current density distributions measured at different electrode heights for various values of Ψ are compared to curves plotted from Eq. [6]. In Fig. 5 values of e/HIR, which is proportional to the potential drop down the electrode, are compared to curves plotted from Eq. [7]. Equally good fits have been obtained from Eq. [5] and [8].

These results show that the assumption that current flow is perpendicular to the electrodes is quite

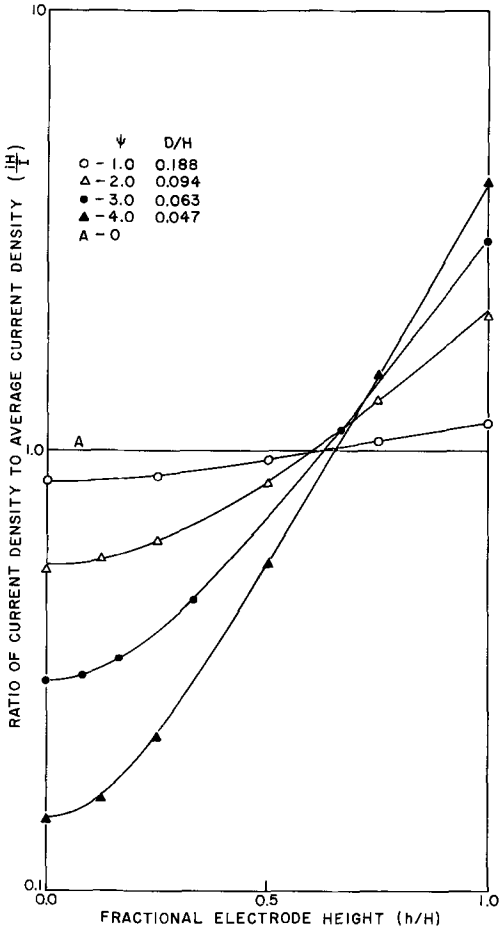

Fig. 4. Measured values of current density distributions over the face of the electrode compared to curves calculated from Eq. [6].

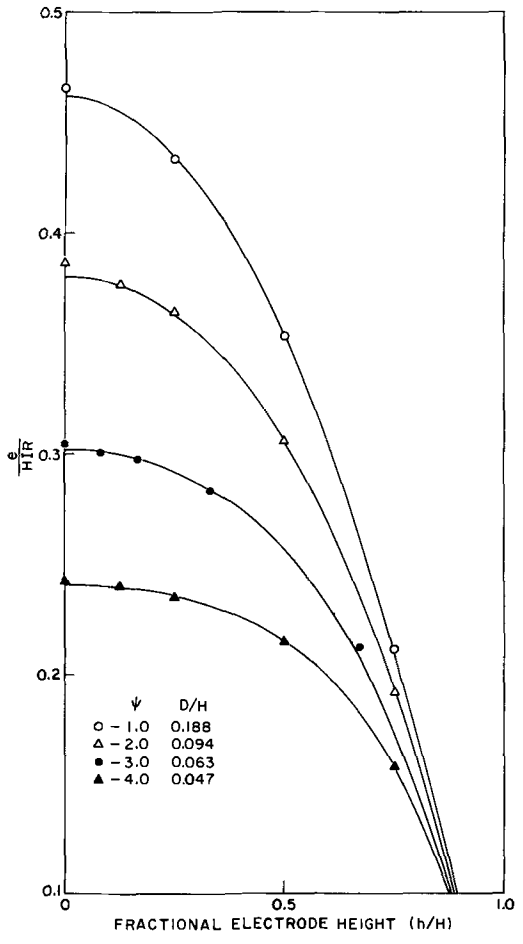

Fig. 5. Measured values of potential drop down the electrodes compared to curves calculated from Eq. [7].

accurate if D/H is not too large in value. Consequently, Eq. [5] to [8] can be used to describe the cell characteristics of almost any battery whenever the polarization is negligible or is a linear function of the current density, i. The above assumption also makes it relatively easy to analyze these cases where the polarization is nonlinear (1).

The value of Ψ is readily calculated from the electrode height, H, the spacing, D, the electrolyte resistivity, R_e, and the electrode resistance, R, using Eq. [1]. Since most grids have various kinds of holes or pockets in them, R may be difficult to calculate mathematically and it may be difficult to measure directly due to its low resistance. However, R can be measured readily by use of the battery analog. Two of the grids or plates or a suitable fraction thereof are spaced a fairly large distance apart, in a moderately close fitting container which is then filled with mercury. Insulated leads are sealed to the bottoms of the two electrodes. Potential drops between the two electrodes are measured at the top and the bottom of the electrodes. The ratio of these two potential drops, i_H/i_o, equals cosh Ψ which is plotted in Fig. 1. From Eq. [1] it can be seen that $R = L\Psi^2H^{-2}$. If i_o is very small, it may be more practical to measure the potential drop between the mid-points of the two electrodes. The potential ratio B is equal to i_H/i_M and

$$\cosh \Psi = 0.25B^2 + (0.5B^2 + 0.0625B^4)^{1/2} \quad [18]$$

In each of these cases there is no polarization present. The difference between the open-circuit potential of a cell and the potential when a given current, I, is flowing should theoretically be, and often is, equal to E_o. This value of E_o can be used in Eq. [8] to determine a value of Ψ. If the polarization is linear, Ψ can be compared to the value of Ψ as calculated or measured by the analog, which we will call Ψ_o. Since

$$\Psi_0 = \left(\frac{R}{L}\right)^{1/2} H \quad [19]$$

and Ψ is defined by Eq. [1], the two equations can be combined to show that

$$K = \frac{L(\Psi_0^2 - \Psi^2)}{\Psi^2} \quad [20]$$

thus determining the coefficient of linear polarization.

Calculations such as these are easily made and are of importance in cell design whenever Ψ becomes sufficiently large in value as it may whenever H is large and/or very thin, closely spaced electrodes are being used.

The analyses discussed here are applicable only at the beginning of a discharge. In the early stages of a constant current discharge, the active material is being consumed faster in a high current density region, the true surface area is decreasing faster, and the polarization is increasing faster than in a low current density region. As a result, the current densities in the high current density region will decrease and those in the low current density region will increase as the discharge progresses.

Investigations of an Alkaline Electrolyte for Zn-PbO_2 Cells

M. L. B. Rao*

Laboratory for Physical Science, P. R. Mallory and Company, Incorporated
Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

Investigations of electrolytes for the operation of Zn-PbO_2 primary cells indicated that an ammoniacal zinc salt solution was satisfactory for the purpose. The stability of PbO_2, the solubility of PbO, and the corrosion rate of zinc in the electrolyte were acceptable. Cell evaluation was carried out in wound-electrode and bobbin-type C-size cells. The cell characteristics and performance are compared with zinc-carbon cells. The limitations of the new system are discussed.

Various metal oxide cathodes have been reported (1, 2) for application in primary cells. Of these, manganese dioxide and mercuric oxide are used extensively in commercial cells. The economic advantage of the former and the high volumetric energy density of the latter are key factors in the widespread employment of these active materials with zinc anodes. New battery systems that may be competitive with zinc-carbon or Zn-HgO cells would have to possess either or both the virtues of MnO_2 and HgO cathodes. One such candidate that is of interest in the context is lead dioxide. This is illustrated in Table I.

The application of PbO_2 as active material in storage cells is well known (3). Reserve cells containing acid electrolytes and PbO_2 cathodes have also been described (4-8). A nonreserve primary cell using a sulfamic acid electrolyte has been proposed by Ruben (9). McCallum (10) has patented a Pb-PbO_2 cell in phosphoric acid. Zn-PbO_2 primary cells based on ammonium phosphate electrolyte is disclosed by Johnson (11).

The instability of zinc and PbO_2 in acid (12, 13) and the high solubility of PbO, the discharge product of PbO_2 in sodium or potassium hydroxide (14), renders both very low and very high pH electrolytes unsuitable for Zn-PbO_2 cells. A lower limit of pH 4 was considered for the electrolyte as zinc is expected to be stable and PbO_2 would cease spontaneous evolution of oxygen in the medium (15). In a search for electrolytes meeting these requirements, attention was given to investigations on PbO_2 cathodes in ammonium hydroxide solutions. The choice of the electrolyte was based on the fact that PbO solubility was measured to be 10^{-4} moles/liter. This paper reports some aspects of this investigation.

Experiments and Results

Stability of PbO_2.— The stability of PbO_2 in 8M NH_4OH solution was determined by iodimetry in acetic acid media in the presence of ethylenediaminetetraacetic acid (EDTA). Experiments carried out by treating 2g of PbO_2 in 50 ml 8M NH_4OH at 80°C for 100 hr indicated no change in the oxidation number of the test sample. Hence PbO_2 was concluded to be reasonably stable in the ammoniacal medium.

Electrolyte conductivity.—The conductivity of ammonium hydroxide was three orders lower than potassium hydroxide of comparable molarity. To improve the conductivity of the solution 1M $ZnCl_2$ was added. The conductance data are given in Table II.

PbO solubility.—The solubility of PbO was measured by polarography by taking known volumes of

PbO equilibrated ammoniacal solution in acetate buffer.

Zinc corrosion.—Weight loss method was used to determine the zinc corrosion rate in the ammoniacal solution. The data are given in Table II and are compared with similar experimental data in zinc hydroxide containing potassium hydroxide solution.

Wound electrode cells.—To test the material efficiency of discharge of PbO_2 in the ammoniacal zinc chloride solution, cathode limiting C-size cells were assembled using pasted plate electrodes in wound structures. The cathodes were 1 × 15 in. in dimension and contained 75% PbO_2, 10% graphite, 10% carbon, 5% proprietory binder, and a stainless steel expanded metal grid. Anodes were also of pasted plate configuration with 95% zinc (10% Hg) powder, 5% binder. The cells were of 2.8 A-hr PbO_2, 3.9 A-hr zinc, and contained filter paper as the separator material. The cells were discharged at 0.2, 0.6, and 1.0A after filling with 1M $ZnCl_2$ in 8M NH_4OH electrolyte. The open-circuit voltage of the cell was 1.52V, and the discharge curves (Fig. 1) indicated 60.7%, 44%, and 25% utilization of PbO_2 (2*e* basis) at 0.2, 0.6, and 1.0A currents, respectively.

Leclanché type cells.—The applicability of ammoniacal-electrolyte to bobbin-type Zn-PbO_2 cells was tested. Thick nonporous cathodes formulated for C-cells gave poor performance. Upon modification of the cathode structure by incorporating a soluble salt such as NH_4HCO_3 to generate porosity, the cell performance improved. The cathodes used in the test cells were fabricated according to the following procedure.

Twenty-eight to thirty-two grams of PbO_2 was mixed with 4g of graphite powder, 4-8g of ammonium bicarbonate, and 2-3g of binder. The mixture was pressed to a cylindrical bobbin of 0.75-0.81 in. diameter and 1.2-1.375 in. height with a carbon rod of 0.25 in. diameter driven through the axis of the pellet. The Leclanché type cells were assembled using the cathodes, two layers of filter paper separator, 1M $ZnCl_2$, 8M NH_4OH electrolyte, and a calculated excess of amalgamated zinc anode. The C-cells so assembled were of 6 A-hr based on PbO_2 capacity. In the presence of ammonium bicarbonate in the cathode, the

open-circuit voltage of the cell was 1.8V. The freshly assembled cells were subjected to continuous discharge across a 4-ohm load. The number of hours of service for cells assembled with different types of zinc anodes is provided in Table III. Figure 2, curve 2, illustrates the discharge data of a typical cell.

Discussion

One of the major problems in adopting potassium or sodium hydroxide electrolyte for Zn-PbO_2 cells is the solubility of PbO formed during discharge. This is because the dissolved lead species reacts with zinc anode and causes self-discharge of the cells. It is seen from the data in Table II that by the use of 1M $ZnCl_2$, 8M NH_4OH electrolyte the solubility of PbO has been reduced to 10^{-4} moles/liter. This magnitude of solubility may be considered acceptable. Although the specific conductivity of the ammoniacal electrolyte is lower than that of KOH solutions, the decreased solubility of PbO is of considerable merit. It has been shown that PbO_2 is reasonably stable, and the zinc corrosion rate is similar to that in alkali in the ammoniacal electrolyte. These characteristics and the discharge data in Fig. 1 and Table III, render this electrolyte interesting for application in Zn-PbO_2 cells.

The open-circuit voltage of the Zn-PbO_2 cells tested is 1.52V. This value is close to that expected from the following

$$Zn + 2\,OH^- = ZnO + H_2O + 2e \quad E^\circ_b = 1.24V \quad [1]$$

$$PbO_2 + H_2O + 2e = PbO + 2\,OH^- \quad E^\circ_b = 0.25V \quad [2]$$

Cell reaction

$$Zn + PbO_2 = ZnO + PbO \quad E^\circ_b = 1.49V \quad [3]$$

Half-cell measurements carried out employing cathode-limiting cells indicated the discharge efficiency of PbO_2 electrode correspond to a 2 electron transfer reaction as proposed in Eq. [2]. X-ray diffraction studies, on partially discharged PbO_2 cathodes indicated the presence of PbO_2, PbO, $Pb(OH)_2$, $PbCl_2$, and lead oxychloride. The presence of PbO and $Pb(OH)_2$ in the

Whr/$in.^3$	4.8	8.6

discharge product is according to Eq. [2]. The presence of $PbCl_2$ and lead oxychloride is hypothesized as due to the kinetic factors dependent upon the effect of rate of discharge on the reaction mechanism.

A change in open-circuit voltage from 1.52V to 1.8V is observed to occur in the presence of ammonium bicarbonate in the cathode matrix. This may be due to reactions leading to the formation of $PbCO_3$ and the changes in pH in the interior of the cathode. The differences observed in the service hours delivered by various cells in Table III indicated that a large surface area zinc anode is necessary for the operation.

A comparison of the characteristics and performance capability of $Zn-PbO_2$ and zinc-carbon cells is provided in Table IV and Fig. 2.

It is seen from the data in Table IV that the gravimetric energy density of $Zn-PbO_2$ cells are of similar magnitude as that of zinc-carbon cells, and the volumetric energy density of the former is approximately double that of the latter. Based on this data and the performance characteristics represented in Fig. 2, it is concluded that the development of $Zn-PbO_2$ cells is feasible in the ammoniacal zinc chloride electrolyte. It is of interest to point out the following limitations of the new system.

(*i*) The low conductivity of the electrolyte renders the rate capability of the $Zn-PbO_2$ system inferior to that of alkaline $Zn-MnO_2$ cells.

(*ii*) The freezing point of the electrolyte is $-10°C$. Thus a limited low temperature performance is expected for the $Zn-PbO_2$ cells.

(*iii*) The electrolyte is highly corrosive, hence commonly used container materials such as nickel coated steel should be avoided in the cell formulation.

(*iv*) The electrolyte has higher vapor pressure than acidic zinc chloride solution used in Leclanché cells. Hence, cells based on the electrolyte under investigation are not suitable for vented cell structures.

(*v*) It is an open question whether PbO_2 reacts with the ammonia in the electrolyte during long term storage.

Laboratory Cell and Hydrodynamic Model Studies of Magnesium Chloride Reduction in Low-Density Electrolytes

R. D. Holliday and P. McIntosh

University of Newcastle, New South Wales 2308, Australia

ABSTRACT

A large laboratory cell of a new type, which uses low-density electrolytes and electrodes inclined at a small angle to the vertical, has been used to study production of magnesium from anhydrous $MgCl_2$. Current efficiency and power efficiency have been measured to within 1% at current densities up to 2.0 A/cm^2 in both LiCl-KCl and pure KCl solvents at temperatures between 700°-850°C. The gas-lift pumping of the electrolyte between the electrodes by chlorine evolved at the anode has been simulated in a hydrodynamic model. The model has shown that the back mixing of electrode products which causes loss of current efficiency is strongly influenced by cell geometry, and the important parameters are the electrode slope, interelectrode spacing, depth of melt above the electrodes, and the surface area available for gas liberation from the melt. The observations provide an explanation for the effects of changes in cell-operating conditions on current efficiency and have provided a basis for design improvements. The design finally evolved has a much higher productive capacity and lower specific energy requirement than conventional cells.

Magnesium is produced commercially by electrolysis of $MgCl_2$ dissolved in molten chloride solvents, and conventional cells use electrolytes of higher density than the metal produced, so that the product accumulates at the melt surface (1). In recent years a number of chloride solvents for $MgCl_2$ have been developed which are of lower density than the metal, and so permit collection of the metal on the base of cells, similar in concept to the Hall cells used in aluminum manufacture (2).

In magnesium electrolysis, the use of low-density electrolytes opens the way to development of new cell designs in which full advantage is taken of the fact that both the anode and the cathode reactions take place on solid nonconsumable electrodes. One such design, proposed and developed in the present work, embodies pairs of parallel planar electrodes, inclined at a small angle to the vertical and arranged so that metal deposited on the upward-facing cathodes flows to the bottom of the cell, while chlorine is held by buoyancy forces within an envelope near the down-facing anode surfaces.

The resulting countercurrent flow of electrode products contrasts with the cocurrent flow pattern of the conventional cells. It was postulated that cells of the new type should be much less subject to metal losses caused by back reaction between magnesium and chlorine than conventional cells in which efficient separation of electrode products is difficult (1). The main prospective advantages of the proposed design are that operation at a higher current density and with reduced interelectrode spacing would be possible without serious impairment of current efficiency, while cell structure would be greatly simplified by avoidance of the need to separate products above the electrolyte. These improvements should bring about reductions in both operating and capital costs of the process.

To evaluate the design, experiments were conducted in which a large laboratory cell was operated over a range of conditions likely to be considered for commercial use. The design of the cell, and the interpretation of results obtained from it, were facilitated by the use of a room-temperature hydrodynamic model. In this model, the flow patterns of gas and liquid could be readily followed and recorded photographically. The necessary conditions for modeling of the fused-salt system by aqueous solutions are well established (3, 4), and in fact models of similar type have been used in studies of flow patterns in conventional magnesium cells.

Key words: electrolysis, current efficiency, molten chlorides, magnesium.

Experimental

Objectives.—The primary aim of the experimental program was to measure the main operating characteristics, current efficiency, and power efficiency, in cells of the new type sized large enough to permit predictions of the performance of production-scale cells. It was desired to measure the performance characteristics with a precision and reproducibility of better than 1% under conditions of current flow and melt circulation identical to those in the full-size cells. This could be achieved by using a laboratory cell with planar, parallel electrodes, geometrically similar to the scaled-up version in section perpendicular to the electrodes. The essential difference between laboratory and full-size cells was the reduction of the electrode width, so that the model constituted a slice of an electrode pair of the full-scale unit. Moreover, the model contained only one set of electrodes rather than the multiple pairs necessary to attain high amperages in the scaled-up version.

In the addition to the measurement of current efficiency and power efficiency in the laboratory cell, the melt-flow patterns induced by the gas-lift pumping action of chlorine at the anode were studied in a separate program using a hydrodynamic model of the laboratory cell. This program was designed to elucidate the influence of geometrical parameters, melt properties, and current density on the recirculation and retention of anode gas before the final cell design was prepared.

It was recognized that data obtained under rigorously monitored laboratory conditions would likely represent the upper limit of efficiency figures attainable under commercial conditions, which would, of necessity, be less stringently controlled. The aim of the program, accordingly, was to obtain basic data on the effects of geometry and electrolyte properties in cells of the new type. It was of course not intended, even if it were possible, to duplicate the types of disturbances which might occur in an industrial plant; in this sense, the work represents a feasibility study rather than a final economic evaluation.

The cell was operated with reagent-grade electrolyte materials and with anhydrous $MgCl_2$ feed of the highest purity attainable. This was considered neces-

sary in order to simplify as far as possible the interpretation of data on response of the cell to changes in electrolyte composition and operating conditions. The data so obtained should then provide a base line against which the effects of such factors as operating disturbances and electrolyte contamination can be assessed.

Design and construction of the experimental cell.— The large planar-electrode cell used in the main part of the experimental program is shown in Fig. 1. This cell embodies many features that were evolved during preliminary work with small cells of 100-500A capacity and of cylindrical geometry, one form of which is shown in Fig. 2.

The main feature of the design is the use of parallel, planar electrodes with working surfaces inclined at a small angle to the vertical. The central electrode is the anode, constructed from graphite plates 24 in. in over-all length, and tapered over the lower 12 in. to an included angle of 20°. Cathode plates of mild steel conform to the anode slope, and are welded to the steel shell at their upper ends to maintain a uniform separation [anode-cathode distance (A.C.D.)] of 1.5 in. between anode and cathode surfaces. The current flow path is perpendicular to the electrodes and leakage of current to the sides of the cell is prevented by 1 in. thick insulator sheets cut from fused-cast alumina brick.

The shell to which the cathode plates are welded is constructed in two parts. The upper section of ½ in. mild steel plate houses the gas-collection chamber and

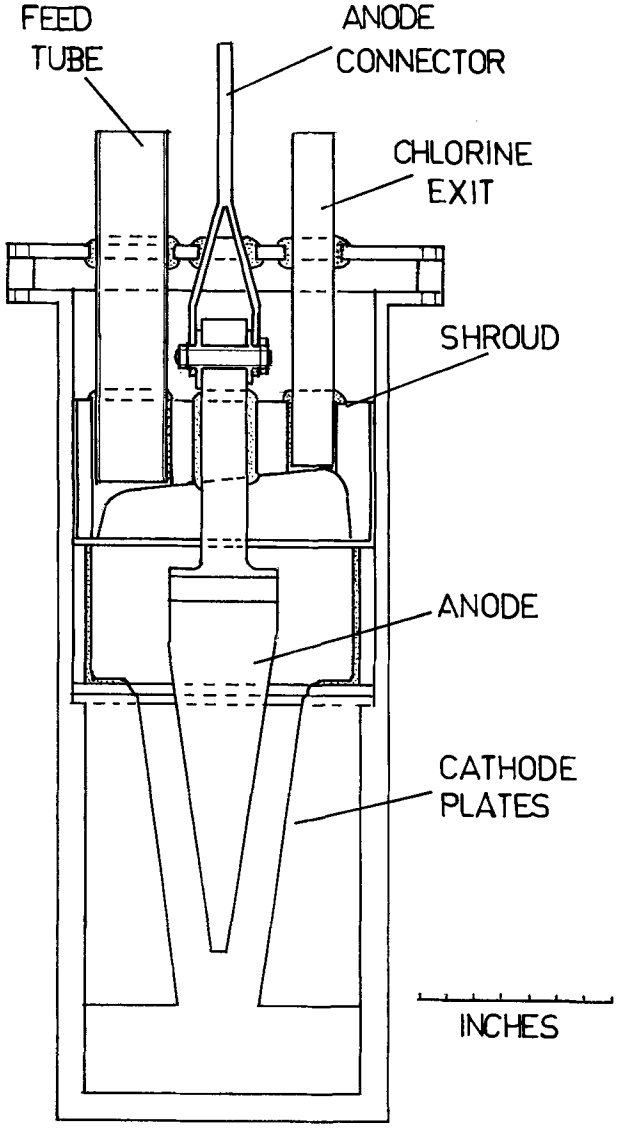

Fig. 1. Planar-electrode cell, cathode area 1100 cm²

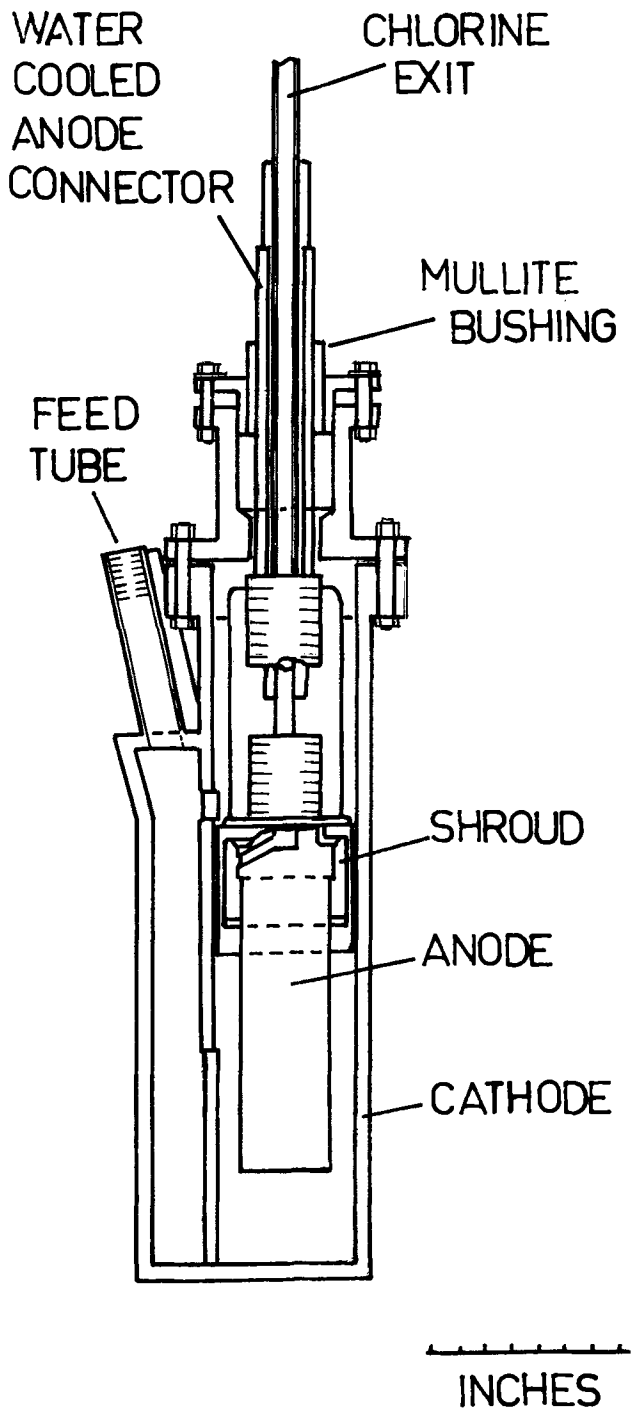

Fig. 2. Cylindrical cell, cathode area 500 cm²

permits a cold seal to be made at the upper flange, which is located some 12 in. above the heater zone of the auxiliary furnace. The flange temperature is always below 200°C, and an asbestos gasket with a silicone-based filler may be used. Although the flange seal is vacuum tight, the gas space is maintained at 2 in. water gauge below atmospheric pressure and back purged with Ar to ensure that no loss of chlorine can occur.

Direct contact between chlorine and metal is avoided throughout the structure. A rectangular-box shroud made from impermeable high-alumina castable refractory serves as a gas-tight cover over the entire melt surface. The shroud is supported on a ledge in the steel shell where the gas collection chamber joins the lower 1 in. thick M.S. chamber housing the electrodes. The height of the shroud above the electrodes is increased as required by mounting it on a sillimanite liner, and sealing it with alumina cement. During cell opera-

tion the electrolyte level is maintained well above the base of the liner so that chlorine above the melt contacts only the refractory. Mullite tubes sealed into the shroud afford access for feeding, chlorine exit, temperature measurement, and melt-level control.

The lower part of the cell houses the electrodes and communicates via a 1 in. slot at the base with a compartmented side chamber. The side chamber is designed so that as metal accumulates in the base of the cell, a barometric leg of metal in the side chamber overflows a weir. In this way, a constant metal-pad depth is automatically maintained and metal may be tapped from the cell without disturbance of the electrode compartment.

The cathodes are connected to the power supply by copper flexes joining the shell to the negative terminal, and measurable voltage losses occur only at the contacts. The connection to the anode is made above the shroud by a water-cooled copper pressure pad. A size limit is imposed on the upper section of the anode by the dimensions of the shroud and the gas collection chamber which houses it. As a result, resistive-voltage losses in this section of the circuit account for 80% of the total loss external to the electrolyte. In a full-scale cell, this loss would be halved because of the freedom to increase conductor dimensions.

Cell operation.—The electrolyte is premelted in gas-tight steel crucibles under Ar purge in a gas-fired muffle furnace. By pressurizing the crucible with Ar, the melt may be syphoned into the electrode compartment via a stainless-steel feed tube. The melt may be withdrawn from the cell by reversing the procedure and syphoning into the crucibles under reduced pressure. Metal is removed in the same way, from the overflow weir in the side chamber.

The as-received feed material was a good quality Kroll process recycle $MgCl_2$, supplied in the form of massive blocks cast in drums by Commonwealth Scientific and Industrial Research Laboratories, Melbourne, Australia. Before use, this material was further purified by remelting and stirring in contact with pure molten Mg under carefully controlled conditions, so that essentially all the MgO, dissolved H_2O, and metallic impurities were removed. Feed to the cell assayed above 99.85% $MgCl_2$, the major impurities being a maximum of 0.1% MgO and 0.05% metallics, principally Fe and Ti.

The $MgCl_2$ was syphoned from the purification chamber and solidified as cylindrical slugs which were fed into the cell via the mullite feed tube under a protective Ar purge.

Power is supplied to the cell by a Westinghouse Type RXAF 5.5/5000 silicon diode rectifier with a maximum output of 5000A at 5.5V. Changes in cell current are detected by recording the voltage drop across a calibrated shunt on the 1 mV scale of a Bausch and Lomb recorder fitted with a zero suppressor. Manual adjustment of a saturable-reactor controller is made to ensure that current does not deviate on the average by more than 0.1% from the set point during a run. Total cell voltage is measured at the output terminals of the rectifier, and voltage drops across sections of the circuit are measured by probe contacts at intervals during a run.

Chlorine is withdrawn from the cell under slightly reduced pressure, and passed through a filter and a bubbler to remove entrained particulate before it is absorbed by NaOH solution flowing countercurrent through a packed tower. The NaOH solution is recycled and samples are withdrawn at intervals from the accumulator for analysis by a modified Mohr titration. The absolute error in the analysis results in an uncertainty of 0.5% in the measured yield of chlorine during 30 min at the 700A level, and 0.2% at 2000A.

Basis for design of the hydrodynamic model.—Bukhbinder, in modeling gas evolution in the conventional magnesium cell, has established which physical factors control the flow pattern within the electrolyte (3). The average electrolyte velocity, w, under conditions of pumping by gas evolved at the anode, is determined by the kinematic viscosity (ν), the total anode immersion depth (h), the A.C.D. (1), and the specific rate of gas evolution (v). The average size of bubbles evolved also exerts an important effect, and it is suggested (5) that the critical detaching diameter, α, of the bubbles is given by the semi-empirical equation

$$\alpha = 0.0208\theta(\sigma/\gamma)^{1/2}$$

involving contact angle θ, surface tension σ, and density γ of the electrolyte.

Dimensional analysis (4) leads finally to the relationship

$$(wh/\nu) = B \cdot (vh/\nu)^m \cdot (gh^3/\nu^2)^n \cdot (\sigma/\gamma v^2 h)^q \cdot (h/l)^p$$

which contains the term $(\sigma/\gamma v^2 h)^q$ to take into account the melt properties that affect bubble size. In this relationship, B is a constant of proportionality; the exponents m, n, q, and p are numerical constants for a particular flow regime, and g is the gravitational constant. From this relationship the conditions for similarity between the fused-salt system of the experimental cell and an aqueous model are obtained. These conditions are

(*i*) v cell = v model

(*ii*) ν cell = ν model

(*iii*) σ/γ cell = σ/γ model

together with equality of linear dimensions. Conditions (*ii*) and (*iii*) are satisfied if 10% $NaNO_3$ solution is used as model fluid (Table I).

An additional factor of importance is the contact angle, θ, which determines the average bubble size. Ukshe (4) found in studies of chlorine evolved by electrolysis on graphite in $MgCl_2$-KCl-NaCl electrolyte, that bubble size ranged from 0.35 to 0.70 mm. A similar size distribution was found for bubbles obtained by forcing N_2 gas through porous graphite in 10% $NaNO_3$ solution.

Marrucci and Nicodemo (6) found that the bubble size depended upon the ionic concentration but decreased asymptotically to a limiting value as concentration increased, independently of the nature of the electrolyte. The size of the bubbles decreases as the concentration increases because mutual repulsion between bubbles is promoted by increased surface concentration of ions.

It is apparent that the required similarity between the chloride melts and the modeling solution is satisfied by using strong ionic solutions which have comparable densities, viscosities, and surface tensions to chloride melts. Such solutions should show comparable size distributions for bubbles liberated at a submerged surface, regardless of their mode of origin.

Construction and operation of hydrodynamic model.—The physical model is hence based on the use of concentrated ionic solutions, and geometrical similarity is achieved by constructing the model to the same dimensions as the cell itself. The width of the model may be made much less than that of the cell, since only the A.C.D. and vertical dimensions can affect the flow pattern.

Exploratory observations showed that only the anode gas evolution had a major effect on the flow of electro-

σ/γ (m^2)	0.0616	0.0632	0.0695

lyte, and the effect of liquid-metal flow in a layer approximately 0.1 in. thick at the cathode would be negligible.

A two dimensional model was constructed in which it was possible to vary the geometrical factors such as A.C.D., surface area for gas evolution, electrode-immersion depth and slope, as well as current density. The general construction of the model is shown in the cinephotographs, Fig. 7-9, and the important geometrical parameters are indicated in Fig. 3. It consists of a tank of transparent plastic in which a 2 in. layer of salt solution, *i.e.*, the model electrolyte, is contained between ¼ in. walls. Both electrodes fit tightly within the walls, but can be manipulated by means of attached rods after supporting clamps are loosened. The cathode and the melt reservoir above it are constructed from metal sheet and serve essentially to define the electrolyte flow path.

The simulated anode consists of a closed box with an active wall of porous material, through which gas is forced to simulate evolution of chlorine. The active face is constructed from sillimanite and is tapered in thickness to allow for the effect of liquid head on gas-evolution rate. Nitrogen gas is supplied to the anode at flow rates equal to the volumetric production rate of chlorine at cell temperatures and current densities from 0.5 to 2.5 A/cm^2. With the profile adopted, gas evolution is uniform over the immersed surface, and the range of bubble diameters, 0.3-0.7 mm, is close to that expected in chloride melts.

Two different techniques were used to photograph the bubble patterns. The first was a stop-motion still technique which employed illumination from behind the tank, using a diffuser screen and a Mayer Type 035 strobe light. The camera, a Linhof 4 in. by 5 in. with a Symmar F 5.6/100 mm lens, was located on the opposite side of the tank and synchronized with the strobe to achieve very low exposure times.

In the second approach, high speed cinephotography was used to obtain a large number of frames under a particular combination of cell parameters to ensure that the photographic data were representative of average flow conditions. A 16 mm Vinten camera with a speed range of 100-250 fps was used, and it was found that at 100 fps bubble movement could be stopped on an individual frame, and the movement of individual bubbles could be followed in adjoining frames.

Experimental Results

Hydrodynamic model studies of cell geometry.—An initial survey was undertaken to determine which geometrical factors controlled the evolution of gas from the melt and the back mixing of electrode products. The first experiments used the cell geometry, as initially proposed, and revealed that the design did not secure efficient separation of products (Fig. 4).

The early experiments showed that the ascending gas forms an envelope of discrete bubbles along the surface of the anode, and the electrolyte near the anode is drawn into the envelope to acquire an upward velocity equal to that of the gas. At the surface the two-phase mixture forms a well-defined foam layer, the thickness of which depends upon the gas rate, the area of the liquid surface, and the physical properties of the liquid.

The liquid which has been pumped to the surface flows horizontally from the face of the anode and along the surface until it meets the cell wall and is directed downwards to form a vortex. Gas that has not escaped at this stage is carried down into the liquid, where it may flow in one of two directions: around the vortex and back to the surface, or into the interelectrode space with the returning melt. As the liquid flows back between the electrodes, it is again influenced by the ascending gas stream and its velocity decreases as it moves toward the bottom of the cathode.

The preliminary experiments showed that it was necessary to clarify the roles played by each of the geometrical parameters shown in Fig. 5 in determining the flow pattern.

Anode slope proved to be of major importance because the thickness of the gas envelope is strongly affected by the buoyancy forces which compress the bubbles against the anode surface. However, if the slope is large, compactness of the cell is sacrificed.

The A.C.D. must be large enough to permit melt to flow back between the electrodes without interfering with the ascending gas envelope.

The importance of the other parameters, the surface area and the depth of liquid above the electrodes, was only fully appreciated after observations had been made on the model. The surface area of the melt in fact controls the rate of gas evolution while the upper liquid layer serves to accommodate the foam and exerts an important effect on the circulation rate of the liquid.

The effects of anode slope at two levels of current density are shown in Fig. 6. The marked decrease in the amount of gas carried back between the electrodes at the higher angle results from a lessening of the

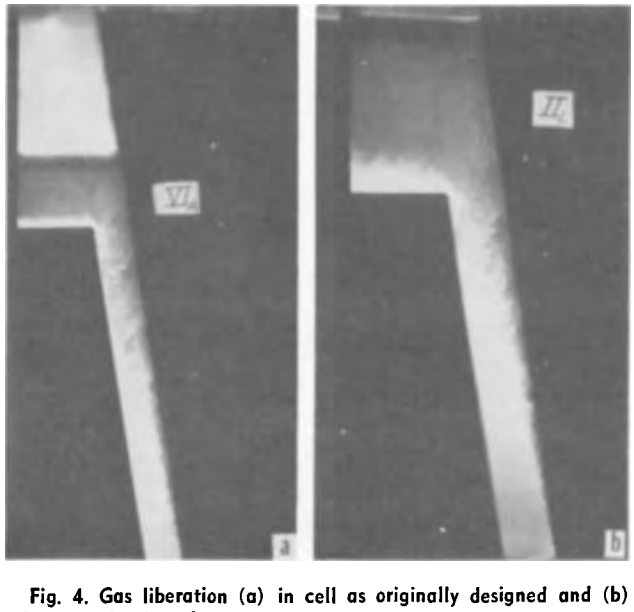

Fig. 4. Gas liberation (a) in cell as originally designed and (b) after optimization of geometry

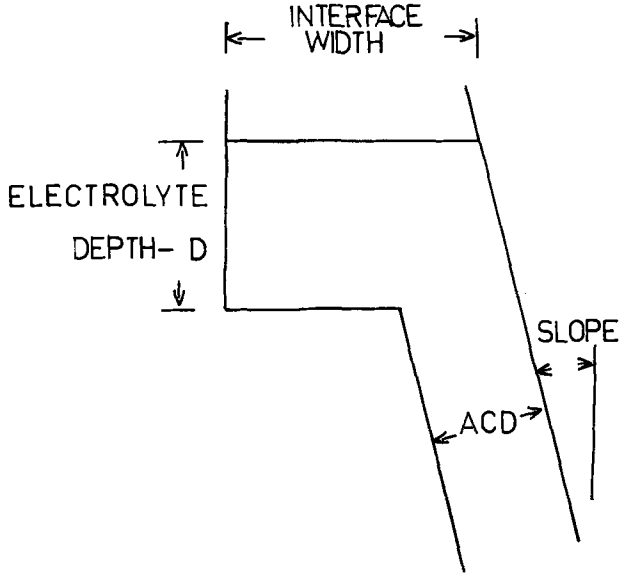

Fig. 5. Cell dimensions controlling flow pattern due to anode gas pumping

interaction between returning electrolyte and the gas envelope.

A.C.D. functions similarly to the electrode slope in controlling the interaction between the envelope and the returning electrolyte. Figure 7a shows that at 1 A/cm^2 and 1 in. A.C.D. a substantial quantity of gas is torn from the envelope by returning melt; at 1.5 in. the quantity is markedly reduced, and at 2.0 in. the effect is eliminated, as shown in Fig. 7b. At 2.0 A/cm^2, even a 2 in. A.C.D. does not suppress the interaction completely, and quite strong interaction is observed at 1.5 in.

The strong influences of surface area and melt depth are illustrated in Fig. 8, where it is apparent that a decrease in melt depth from 4.0 to 1.5 in. above the cathode forces the two-phase layer well into the region between the electrodes at 1.0 A/cm^2. Reduction of the surface area of the melt by a factor of 2.5 has a similar and even more pronounced effect even if melt depth is adequate. The most compact cell geometry is attained only by joint variation of these parameters to secure optimum gas liberation from electrodes of given size.

As a result of a systematic investigation of the geometrical parameters the dimensions selected for the experimental cell were: A.C.D., 1.5 in.; anode slope, 10°; melt depth, 4 in.; surface width, 3.5 in. A comparison of gas liberation in a model with these dimensions and in one conforming to the original cell design shows a clear improvement (Fig. 4).

Table II. Effect of melt depth on current efficiency

Large Planar Electrode Cell

Verification of the hydrodynamic model.—Initial electrolysis runs in the large cell were designed to check the validity of the hydrodynamic model. Once optimum values for the geometrical parameters had been established in the model, it was necessary to select as experimental variable a parameter that could be easily varied without structural modification of the cell. One of the easiest to vary, and one which showed an unexpectedly strong effect on gas recirculation in the model tests, was the depth of the liquid layer above the cathode, dimension D in Fig. 5.

Runs were conducted at two temperature levels and at two levels of current density, using melt depths ranging from 1.5 to 5.0 in. above the cathode. Results shown in Table II support the conclusion drawn from the aqueous model tests. The effect of increasing the depth to 5 in. in the cell as constructed was to raise the foam level in the gas space so that the gas-exit tube was partially blocked and gas-space recirculation markedly increased. The result is a severe fall in current efficiency.

Further evidence for the validity of the model was obtained from current efficiencies measured in the 500A cells, which were operated at two levels of interelectrode spacing, 1.0 and 1.5 in. The predicted falloff in current efficiency occurs as A.C.D. is decreased, as indicated in Fig. 3. The geometry of the 500A cell is such that current densities at anode and cathode are unequal, so that quantitatively the data do not describe behavior of the large planar electrode cell, but the trend predicted by the model is supported.

Reliability of current-efficiency measurements.—An essential preliminary part of the program was the assessment of the accuracy and reproducibility of measurements of current efficiency, the main index of cell performance. This was accomplished by conducting a series of replicate runs at relatively low current, where the effects of errors of measurement would be most pronounced. A typical set of replicate data is shown in Table III. At 700A results are reproducible within 0.45%, while at 400A the spread is 1.4%, again only slightly greater than the error in the measurement of the yield of chlorine.

As more data accumulated, it became possible to obtain a further check on the efficiency measurements by establishing a mass balance between the directly measured yield of chlorine in the absorber and the chlorine equivalent of the $MgCl_2$ fed to the cell. A typical balance obtained in this way is summarized in Table IV. In general the $MgCl_2$ content of the melt by

direct analysis of syphoned samples was in agreement with calculations based on the mass balance to within 0.5%.

Further check runs interspersed in the later campaigns confirmed that the absolute error in the current-efficiency (C. E.) measurements was of the order 0.2% at 2000 A, that is, near the upper end of the range of current investigated.

Influence of cell-operating conditions and electrolyte properties on current efficiency.—The main benefit of the cold-model studies was that they permitted an optimum geometrical design to be established, within the limits of the size of the equipment, with a minimum number of high-temperature experiments in the cell itself. Once the parameters were selected, the cell was constructed and used to determine the effects of nongeometrical variables on current efficiency and power efficiency.

The factors expected to influence current efficiency (C.E.) were the physical properties which affect melt circulation and gas liberation from the surface of the melt. The most important of these physical properties are density and viscosity, both strongly dependent on composition and temperature. The other primary variable affecting melt circulation was the rate of gas production, which is proportional to current density.

In all the systems investigated, C. E. was found to increase as current density was raised through the range 0.36-1.5 A/cm². Above 1.5 A/cm², the C.E. fell off; the hydrodynamic model shows that re-entry of chlorine into the electrode gap is becoming significant above this current density (Fig. 9). Typical C.E. data

22 $MgCl_2$-28 KCl-50 LiCl	2200	2.00	86

for a range of electrolyte compositions are shown in Table V.

Sampling of melts was carried out by syphoning from the interelectrode space during runs and also immediately after current was switched off. In all samples, globules of Mg, 1-3 mm in diameter, were found. It was not possible to decide whether the proportion of dispersed metal changed with operating conditions, but the indications were that such variations were small.

It is proposed that the main mechanism by which current-inefficiency losses occur is back reaction between chlorine in the anode-gas envelope and globules of metal dispersed within the melt. At the highest current densities, direct contact between the gas envelope and the coherent film of metal on the cathode probably occurs also.

At low current densities the loss due to back reaction is a significant fraction of the total metal produced, and for all the electrolytes investigated, C.E. is below 85% at 0.36 A/cm². C.E. in fact is lowest in melts of high LiCl content at low current densities, and at 0.64 A/cm² C.E. in the 35% LiCl melt is only 84%, compared to 89% in the straight KCl-$MgCl_2$ binary at this current density.

As current density is increased, C.E. improves because even if the total amount of metal dispersed per unit of volume of the electrolyte is unaffected, the proportion of the deposit that is brought into contact with the anode gas envelope will diminish. The improvement is particularly significant in the case of melts containing medium to high proportions of LiCl. In the 35% LiCl electrolyte, C.E. increases to 91%, and at 50% LiCl to 90%, when current density is raised to 1.5 A/cm².

The model studies suggest that a second factor contributing to improved separation of electrode products as current density is raised in the low to medium range is the downward motion of the melt returning to the region between the electrodes. This downward flow is strongest in the vicinity of the upper cathode, and will tend to direct entrained metal particles away from the anode-gas envelope.

However, at the highest levels of current density, 2.0 A/cm² and above, a new feature of the flow patterns begins to control contact between electrode products. As the thickness of the ascending gas envelope and the velocity of the stream of electrolyte returning to within the electrode gap both increase, a point is reached at which interference between the two streams occurs, and gas starts to become torn away from the anode envelope to form incipient vortexes within the interelectrode space itself. At still higher current densities, gas is incompletely removed within the vortex above the electrodes, and an increasing proportion is redirected to the interelectrode region with returning electrolyte. It is this behavior that causes the efficiency to decrease from 90% to 86% as current density is raised from 1.5 to 2.0 A/cm² (Table V).

Physical properties of the electrolyte appear to exert a relatively small but still significant effect on the flow pattern, and hence on the C.E. The most pronounced effects attributable to differing physical properties are found in the lower ranges of current density and at relatively low temperatures (Table VI and VII). For all compositions investigated, it was found that in the range of 0.36-0.64 A/cm² C.E. rose as temperature decreased, but the increase was far less marked in the high LiCl melts. At high current densities, C.E. was practically independent of temperature. At low current densities, viscosity exerts a dominant effect on the rate of melt circulation and on the rate of separation of globules from the cathode deposit. Thus higher viscosity will tend to reduce the degree of back reaction at a particular current density. The viscosity of the KCl-$MgCl_2$ binary increases quite strongly as the temperature is lowered from 850° to 800°C, since the lower temperature is close to the liquidus, and in this system the strongest effects of temperature on C.E. are to be expected. In the systems containing LiCl, the viscosity of the melts is lower and the effect of temperature on viscosity is smaller because the cell operating temperature range is well above the liquidus. The result is that in the 35 and 50% LiCl melts the C.E. changes very little between 700° and 850°C.

At high current densities, gas pumping rather than viscosity will control the melt circulation rate; consequently C.E. should show a relatively weak dependence on temperature. In fact, above 1.5 A/cm² essentially no change of C.E. with temperature occurs at the 50% LiCl level, and only a 1% decrease is observed in the 35% melts as temperature is changed by 150°.

Voltage and power efficiency.—Gross cell voltage is the primary factor determining specific energy consumption during electrolysis. Accordingly, an important part of the study was the determination of the total voltage required to maintain electrolysis, and the distribution of this voltage between components of the circuit as operating conditions were varied. Total operating voltages were measured between anode and cathode bus outlets of the power supply, and thus included components due to contact resistances at bus and electrode connections as well as the conductor resistances of the anode, cathode shell, flexes, and electrolyte itself. Also included within the over-all measured values were overvoltages for both anode and cathode reactions.

Table VI. Dependence of current efficiency on temperature at low-current densities

The least reproducible components were those arising at contact resistance. Voltage drops at each accessible contact point were checked during runs, but the contact voltages at internal connections and the resistive voltage drop through the anode could not be measured directly when the cell was operating. Experience coupled with resistivity measurements made on cell components before assembly, indicated that the uncertainty introduced by variation in these components did not exceed 0.02V, but no attempt was made to routinely determine voltages with greater accuracy than this.

Measurements were made of resistances of all components of the cell circuit at room temperature, and all accessible components were checked again at operating temperature. The resistance of the path through the electrolyte itself could be calculated with good accuracy for the $MgCl_2$-KCl binary, and with somewhat less confidence for the LiCl-KCl-$MgCl_2$ ternary. The total cell resistance may be compared with the resistance estimated from the gradient of the plot of total cell voltage *vs.* total cell current and agrees to within 2%. Over the current range of 500-2000A, cell-voltage requirements changed by 2.5V in the case of the best conducting electrolyte, containing 50% LiCl.

The voltage loss in connectors, electrodes, and contacts ranged from 0.42 to 1.31V as current density ranged from 0.64 to 2.0 A/cm^2. The greater part of this ohmic loss occurs within the upper thin section of the anode, and at the anode-connector contact. In a normal production scale cell, both resistances would be halved. The relatively high experimental-cell resistance causes the power requirement to be exaggerated, and the power efficiency to be understated. In Table VIII, the directly measured power requirements for representative electrolytes are compared with figures typical of conventional production scale cells.

An important check on cell operations was afforded by measurement of the open-circuit emf developed when current was interrupted after steady-state electrolysis had been established. Reproducible values of back emf were attainable after only 1 or 2 min of electrolysis, and these values remained constant until electrode products had been dispersed, which took several minutes.

No attempt was made to determine transient components of the emf with decay times of less than 0.01 sec, and transients with decay times greater than this were detected only at the highest levels of current density.

The open-circuit emf values measured in this way agreed with values calculated from the free energy of formation of $MgCl_2$ and the excess free energy of solution in a particular solvent (7, 8). Typical data are shown in Table IX, from which it is apparent that the voltage increase attributable to nonideality or complex-ion formation is markedly less in pure LiCl than in solvents containing KCl. At 800°C, in 20% $MgCl_2$ solutions, the difference is a significant contributor to the lower energy requirement for production of Mg from the high LiCl electrolytes.

Table VIII. Specific energy requirements for metal production in conventional cells and in large planar electrode cell

System	Current density (A/cm^2)	Cell voltage measured (full-scale)		Current efficiency (%)	Specific energy (kw-hr/lb Mg measured)

20 $MgCl_2$-80 LiCl	850	2.45	2.45

Conclusions

The vertical-electrode cell designed for the study of reduction of $MgCl_2$ has proved capable of yielding data on current efficiency consistently to within 0.5% in relatively short experimental runs. The cell is adaptable to study of similar electrolytic processes in which metal of higher density than the electrolyte is deposited as a liquid at an inert cathode and chlorine is evolved at the anode.

One of the most pleasing features observed in operating the cell with the magnesium system was the ease with which it was possible to form and collect a very clean pad of metal on the base of the cell; indeed, this factor made it possible to use an underflow weir to collect metal without disturbance of the electrolysis compartment. The ability to operate without opening the cell was undoubtedly a major factor responsible for the absence of sludging. Over the course of several months, no noticeable oxide buildup occurred in either the electrolysis chamber or the tapping weir. Melt samples at all stages were water clear, further confirming the absence of oxide within the cell.

The Mg system studied is one in which the liquid metal is deposited at a cathode of mild steel inclined at a small angle to the vertical, and accumulates to form a coherent layer at the base of the cell. Chlorine evolved at the anode causes vigorous circulation of the electrolyte by gas-lift pumping. The anode gas flowing upwards is released through the surface of the electrolyte, or may recirculate in a complex flow pattern involving vortex production at the surface and formation of a well-defined foam layer.

The gas-liquid system has proved amenable to study in a room-temperature hydrodynamic model, and by this means the important parameters which promote the liberation of gas from an electrode system of given A.C.D. have been identified. The main geometrical factors are the surface area of melt available to the electrodes, the depth of liquid in the zone above the electrodes, and the angle of inclination of the electrodes to the vertical.

The cell data and the model studies support the conclusion that the main factor which determines the degree of back reaction between electrode products is the contact between the anode-gas envelope and the metal on the surface of the cathode or dispersed within the electrolyte near the cathode. The main support for this view is provided by the way in which current efficiency measurements conform to changes of flow pattern produced by changes of electrolyte depth, A.C.D., and current density.

The hypothesis that the reaction at the interface between chlorine gas and metal is the prime mechanism for reduction of faradaic yield is also in agreement with recent measurements of the relative rates of reaction between magnesium metal, either dissolved or dispersed within the melt, and chlorine gas, again either dissolved or dispersed in the electrolyte (9). The inference from these reaction-rate studies is that only the reaction between liquid magnesium and chlorine gas can yield over-all rates sufficiently high to account for observed rates of loss of metal.

Additional support is obtained from the way in which physical properties of the electrolyte affect the current

efficiency. Basically two types of flow regime are possible in the electrolyte-anode gas system: one predominates at low current density, and is controlled by viscosity, while a second, controlled by gas-evolution rate, becomes established at high current density. Consequently, the variation of current efficiency with temperature is larger at lower current densities and in melts of high viscosity.

Cell experiments have demonstrated that the system using parallel electrodes inclined at a small angle to the vertical with mainly downward flow of metal is actually more efficient than the conventional system for Mg production in which both metal and gas flow toward the top of the cell. The improvement is such that current efficiencies above 90% are attainable at current densities of 1.5 A/cm^2, some three times the operating level of the conventional cells.

The improved operating characteristics of cells with the counterflow separation of electrode products lead to higher power efficiencies and much lower specific energy requirements. Performance figures for the cells are compared with those for conventional types in Table VIII.

It is recognized that to demonstrate the ability of new systems of the present type to sustain current efficiencies over very long periods of operation, and to assess the effects of operating disturbances that might occur under industrial-plant conditions, a suitably long-term pilot plant evaluation will be necessary. In this program, evaluation of the durability of cell materials, the stability of the geometry, and the effects of progressive buildup of even minute concentrations of contaminants, will all be of the highest importance. It is again emphasized that the data obtained in the present program refer to a relatively small element of a commercial cell, and to one operating under rigorous conditions of control with high-purity materials.

Subject to these qualifications, it appears that the most important benefit conferred by the new system is the increase in output attainable from a cell structure of given shell dimensions. This results directly from the ability to operate at high current density with relatively high current efficiency and at low interelectrode spacing. If no additional engineering problems are revealed during scale-up, so that the experimental-cell data can be translated directly into performance of full-scale units, then the initial capital cost of the electrolysis plant can clearly be substantially reduced.

Besides contributing to lowering the cost of magnesium metal, a less expensive cell improves the case for using magnesium metal as a reducing agent in the CRASO process (10) for manufacture of aluminum from $AlCl_3$. In the CRASO process a combined electrolytic cell and chemical reactor is used, and the cell is the main item of capital expense.

ABSTRACT

The fiber textures of nickel electrodeposits grown in the presence of unsaturated organic compounds are studied by x-ray diffraction and shown to be related to the nature of the unsaturation present in the molecule. The structural environment of this unsaturation influences the magnitude of the additive activity. A number of compounds with an ethylenic unsaturation were extensively studied. The [110] axis fiber texture is then preferentially formed. In the presence of other compounds, *e.g.*, acetylenic or aryl-sulfonic compounds, the fiber texture is [100] or [211]. These modifications of crystal growth are interpreted by the adsorption-hydrogenation-desorption process. The nature of bonds between the metallic surface and the adsorbed molecule can differ according to the unsaturation, and so the quantity of adsorbed hydrogen atoms involved in the hydrogenation step.

It is known that the addition of extremely small quantities (10^{-5}-10^{-3} molar) of a wide variety of organic compounds in electrolytic solutions for nickel deposition, considerably modifies the mechanism of crystal growth of the deposit. The activity of an organic molecule depends on the presence of certain types of unsaturations between atoms of carbon, nitrogen, and oxygen (or certain sulfur-containing radicals). Numerous unsaturated compounds, of various and often complex structure have been classified by Brown (1, 2) and Saubestre (3, 4). These additives are considered as "brighteners" or "leveling agents." The leveling effect, which is a macroscopic phenomenon related to transport of the molecules toward the cathode by convective diffusion, is not considered here. We are interested only in modifications of the structural properties of the deposit and particularly the fiber texture and the grain size. The latter is of interest because the brightening effect is related to the ability of the metal to be deposited as small crystallites.

Only fragmentary experimental data and theory are available concerning the fiber texture formation in the presence of organic compounds. In this mode of crystal growth, all the crystallites constituting the deposit present the same (hkl) axis perpendicular to the cathode plane. No theory exactly accounts for the experimental observations, even if organic molecules are not present in the electrolytic solution. Among the factors proposed in these theories to cause a fiber texture, are the cathodic overvoltage in the two-dimensional nucleation (5), or the hydrogen coverage modifying the growth rates of the different crystal faces (6) The eventual structural defects of metallic lattice may also play a major role. When the organic molecules are present in the electrolyte, sparse results appear in the literature: DuRose (7) points out that acetylenic alcohol favors a [211] texture; Weil notes the presence of a [100] texture due to coumarin (8); Leidheiser and co-workers (9, 10) relate the grain size and the orientation of deposit to the chemical structure of the compounds, which were, however, studied in only one concentration.

Now it appears that a systematic study on how the fiber textures are modified, or initiated, by the presence of organic compounds and how this phenomenon is affected by their chemical structure, is a good method to reach a better knowledge of their role. This role seems essentially to modify the sites of incorporation in the crystal lattice of the nickel ions, certain sites being blocked by adsorbed molecules. The relation between activity and unsaturation suggests indeed the formation of interactions between π-orbitals and metallic atoms of the cathode, as in a hydrogenation reaction over a nickel catalyst. As experimental proof of the electrolytic hydrogenation of unsaturated bonds on nickel, Rogers and Taylor (11), introducing 2-butyne 1,4 diol or cinnamic alcohol into a Watts-type solution, after electrolysis, recovered the saturated derivative in yields exceeding 90%.

Key words: adsorption, ethylenic alcohols, fiber texture axis.

Experimental Procedure

Choice of organic compounds.—Among the numerous unsaturated compounds classified by Brown and by Saubestre, a simple and interesting choice is that of doubly or triply bound carbon atoms; the ethylenic bond permits greater possibilities in the choice of the environment, in that the number of variable adjacent substituents is four instead of two, and the reduction in a single step to the saturated state can simplify the understanding of the involved phenomena. We have therefore chosen to study the ethylenic alcohols. These have a good solubility in Watts solution and there are no problems of pH change which may result from organic acids. It is, however, necessary to verify that there is no specific effect of the alcoholic hydroxy group. Thus, we selected fourteen compounds, starting with the simplest ethylenic alcohols with an aliphatic chain of four carbon atoms; this permits comparison with an acetylenic additive, 2-butyne 1,4 diol, which is, in practice, one of the most important brighteners. In order to determine the possible action of the alcoholic hydroxy group, we have also studied four saturated compounds. Table I gives the formula, preparation, and control of purity for each organic compound used.

Study of the deposits.—Taking in account our objective, we attempted to relate the action of organic compounds to the structural properties of the electrolytic deposit, particularly the fiber texture. To determine the latter, we used x-ray diffraction at an oblique angle. An apparatus with a cylindrical chamber al-

Coumarin		Commercial product, Touzart et Matignon, France	mp 66°-67°C

The noncommercial products were synthetized in this laboratory as indicated.

(a) Hydroxylation of cyclohexene by Woodward's procedure (iodine and silver acetate in wet acetic acid), and subsequent saponification by a hydroalcoholic potassium hydroxide solution. VPC analysis showed only one product excluding the presence of the *trans* isomer.

(b) Hydroxylation of cyclohexene by Prevost's procedure (iodine and silver benzoate in dry benzene) and subsequent saponification by a hydroalcoholic potassium hydroxide solution. VPC analysis showed only one product excluding the presence of the *cis* isomer.

(c) Selective hydrogenation of pure 2-butyne-1,4 diol over Lindlar's catalyst and subsequent fractionation under reduced pressure. VPC analysis showed only one product, excluding the presence of the acetylenic starting material, the ethylenic *trans* isomer, and the saturated corresponding compound.

(d) Hydrolysis of pure *trans* 1,4-dibromo-2 butene by an aqueous solution of sodium carbonate and purified by crystallization and subsequent distillation under reduced pressure. VPC analysis showed only one product. The starting material was prepared by addition of bromine to butadiene in chloroform solution and purification by fractional crystallization.

(e) Selective hydrogenation of the corresponding pure acetylenic alcohol over Lindlar's catalyst and subsequent fractional distillation. VPC analysis showed only one product excluding the presence of the acetylenic starting material, the *trans* isomer, and the saturated corresponding compound.

(f) Reduction of crotonaldehyde by lithium aluminum hydride, followed by fractional distillation. VPC analysis showed only one product.

(g) Reduction of commercial cinnamic alcohol by lithium aluminum hydride.

(h) Selective hydrogenation of the corresponding acetylenic compound over Lindlar's catalyst and subsequent distillation under reduced pressure (0.5 mm Hg). VPC and IR analysis excluded the presence of the acetylenic starting material, the ethylenic *trans* isomer, and the saturated corresponding compound.

(i) Reaction of dimethyl sulfate with maleic acid disodium salt. VPC and IR analysis showed only one product, excluding the presence of the *trans* isomer.

(j) Reaction of dimethyl sulfate with fumaric acid disodium salt. VPC and IR analysis showed only one product excluding the presence of the *cis* isomer.

lowed us to obtain diffraction patterns in the form of concentric circles. The presence of an oriented crystal structure is manifested by an enhancement of the intensity at certain points on the circles. The orientation is deduced directly from the position of the spots, with the aid of charts established by Bozorth (12). Uniform circumferential intensity of the rings corresponds to a sample devoid of preferred orientation.

We have also studied the deposits in the electron microscope. The crystal habits are examined by the medium of surface carbon replicas. In certain cases, thin foils of deposit are also examined by transmission. This examination allows us to measure the width of the crystallites.

It is convenient to measure also the average height of the crystallites. In fact, we determined the root-mean-square roughness, σ, of the surface by a spectrophotometric method (13). This method is an application of the theory of reflection of electromagnetic waves for the cases where the dimensions of the irregularities of

the surface are much less than one wavelength. The diffuse (Rd) and global (Rt) reflection factors of the surface are recorded as a function of the wavelength λ from 0.25 to 2.5 μm. The roughness σ is related to the ratio Rd/Rt by $Rd/Rt = 4\pi\sigma/\lambda^2$ and it is characteristic of an average roughness of the deposit over an extended area (of the order of 0.3 cm^2). One can thus associate a simple quantitative factor with the "brightness" of the surface, an essentially subjective concept which is an interpretation of the relative fraction of the specularly reflected luminous energy. The simultaneous determination of σ and of the lateral grain dimensions, estimated by electron microscopy, permits complete characterization of the brightening action of an additive.

Preparation of the deposits.—The electrolytic nickel deposits were all obtained from a Watts solution of the following composition: 300 g/liter $NiSO_4 \cdot 7H_2O$, 35 g/liter $NiCl_2 \cdot 6H_2O$, 40 g/liter H_3BO_3. The temperature was 50°C and the *p*H was 4.5. The electrolytic cell has a volume of 200 cm^3, and the solution was stirred by a revolving paddle. Both position of the stirrer, with respect to the cathode, and its speed of rotation were kept constant from one experiment to another. As certain additives are transported to the cathode by convective diffusion, their concentration near the cathode surface depends on the speed of stirring. The soluble anode of nickel was large compared to the cathode. It was important that the anode be ultrasonically cleaned after each use, because pits in the anode can retain decomposition products of the additives. Our analytical technique required a deposit of several square centimeters. or spectrophotometric and electron microscope studies, the cathodic substrate was the plane face of a brass cylinder, 23 mm in diameter, prepared with abrasive papers, and then polished with different diamond pastes to 1 μm size. For the x-ray study, a sheet of brass was used which was later dissolved in a mixture of sulfuric and chromic acids, leaving the deposits stripped of their substrates. We adopted a constant 15 μm thickness for all the deposits studied here by maintaining the electrolysis for a time inversely proportional to the employed current density. The results are presented, as most authors have done, as a function of "current density" since deposits were produced under galvanostatic control and not by a control of the cathodic overpotential. The results have a slightly different presentation when expressed in the one or the other parameter, because the additives can change the overpotential.

Experimental Results

The experimental results are presented in the form of graphs where the abscissa is the current density at which the deposit was prepared, and the ordinate is the concentration of additives. The abscissa therefore corresponds to the distribution of textures for a Watts bath devoid of additives. In Fig. 1, we have reproduced the *p*H-potential diagram of textures (14) for this Watts bath. At a *p*H equal to 4.5, the succession of orientations with increasing current density is [110], [211], [100], [110]. We must note that, at low *p*H, the [211] orientation does not exist; instead, a [210] texture appears, corresponding to deposits with a strong hydrogen inclusion.

However, the current density at which one texture is replaced by another one is a somewhat fluctuating value; this value is very sensitive to a number of factors, such as the geometry of the cell; for example, according to this geometry, the current density corresponding to the transition from [110] to [211] can possibly change from 0.5 to 1 A/dm^2. Even for a well-defined cell geometry, the current density corresponding to this transition must be considered as a medium value, because we generally observe the coexistence of the two types of crystallites with [110] and [211] fiber axis texture between 0.5 and 1 A/dm^2. An analogous phenomenon exists for the transition from [211] to [100]: the transition between two fiber textures is never sharp, but generally gradual.

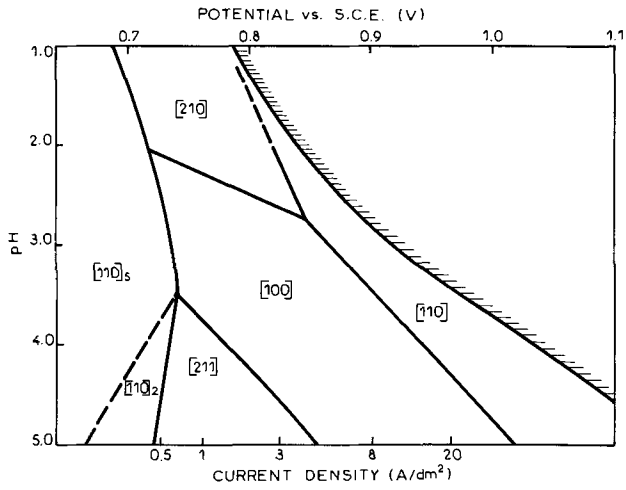

Fig. 1. Diagram of *p*H-potential (or current density) for deposits obtained in a Watts-type solution. Temperature 50°C.

In the following experimental results, we limited ourselves to a range of current densities from 0.5 to 20 A/dm^2, because in the presence of organic additives, the deposits are generally poorly formed at high current densities. This range excludes the [110] texture which appears in the deposits placed under a high current density in a Watts bath. In Fig. 2, 3, 5, and 6, the displacements of the current densities corresponding to the change from [110] to [211], and from [211] to [100] texture are shown as the concentration of organic additives increased. A medium value of the transition current density is retained to draw the lines separating the regions of existence of each orientation.

These graphs show two characteristics of the additives. The first is the texture axis favored by the presence of the additive, which characterizes its action on the mode of crystal growth. Second, for a specific growth mode, it is useful to be able to associate a quantity to the activity of each compound. The concentration, Cm, of the additive, at which the texture characteristic of a Watts bath without additives is replaced by the texture characteristic of the additive for a current density of 3 A/dm^2, was selected. The choice of 3 A/dm^2 is somewhat arbitrary; it is a current density used in practice and at which the deposits in the Watts bath present the [211] texture; now, the [211] orientation can be considered as typical of the Watts bath free of active organic additives, as it generally disappears as soon as such compounds are present in the electrolyte.

For a particular texture, several habits can exist. In certain cases, the regions of existence of the texture are separated in "sub-regions" corresponding to the different habits, see Fig. 2, 3, 5, and 6.

In Table II, the main characteristics of the deposits obtained in the presence of the studied additives are summarized. The table shows the texture axis favored by the additive, the value of Cm, and the minimum value of rms roughness, σm, of the deposits obtained in the presence of the additive. In certain cases, the type of the more common habit is given.

The unsaturated compounds are generally employed up to the maximum concentration, above which the deposits have poor mechanical resistance, as a result of excessive internal stresses. This explains the different ranges of the additive concentrations, on Fig. 2, 3, 5, and 6. But we should be able to further increase the concentration of the saturated additives, without damaging the deposits.

Figure 2 points out the specificity of the role of each unsaturated bond. Butane-1,4 diol, even at high concentrations, does not modify the texture and the roughness of the deposits. The slight effect observed for

Table II. Characteristics of deposits

Compound	Figure No.	Favored texture	Habit	Cm, mM	σm, A
2 Butyne-1,4 diol	2c	Weak [211]	—	—	50

Sodium benzenesulfonate		[100]	—	3	100

concentrations higher than 25 mM can be explained because the cathodic surface is crowded by numerous organic molecules, which hinder the discharge of nickel ions. The small size of the crystallites which develop when 2-butyne-1,4 diol is present in the solution makes study of this compound difficult. Recent results seem to indicate that 2 butyne-1,4 diol favors the growth of the [211] fiber texture, or more exactly that it involves the disappearance of all orientations, except the [211] axis texture. These results obtained by a goniometric method of x-ray diffraction (15) are at the present time difficult to construe for the 2-butyne-1,4 diol concentrations higher than 5 mM. In this case, the brightening is effected by a reduction in all crystal dimensions, with conservation of the habits, at least down to crystallites too small to be observed on the replicas by the electron microscope.

In the presence of 2 butene-1,4 diol, the region of existence of the [110] texture is extended, initially at the expense of the [211] texture. The [110] texture exits at all current densities when the concentration of the additive attains 7.5 mM. The [110] oriented crystals are always large (16) and this fact can explain why the activity of ethylenic compounds in the electroplating bath went unnoticed by authors who only observed their brightening effects. The region of existence of the [110] orientation is separated in three sub-regions, and analogous separation is effected on the graphs of Fig. 3. These graphs are relative to three ethylenic al-

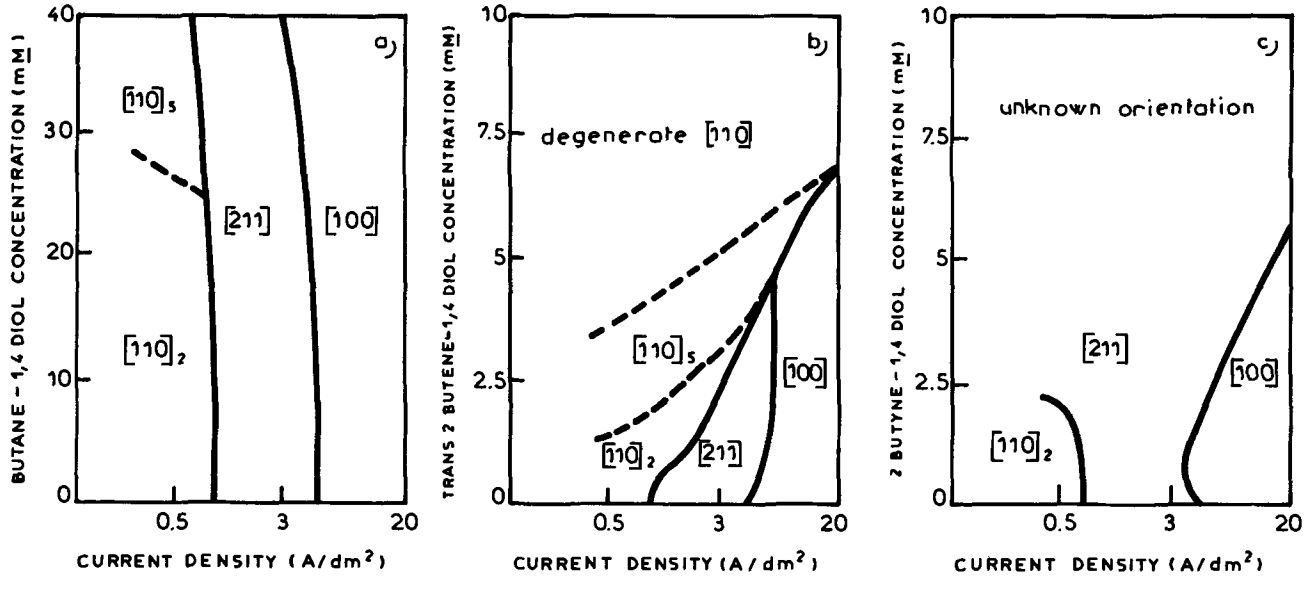

Fig. 2. Comparison between the texture axis of deposits obtained in presence of saturated compound (a), ethylenic homologue compound (b), and acetylenic homologue compound (c).

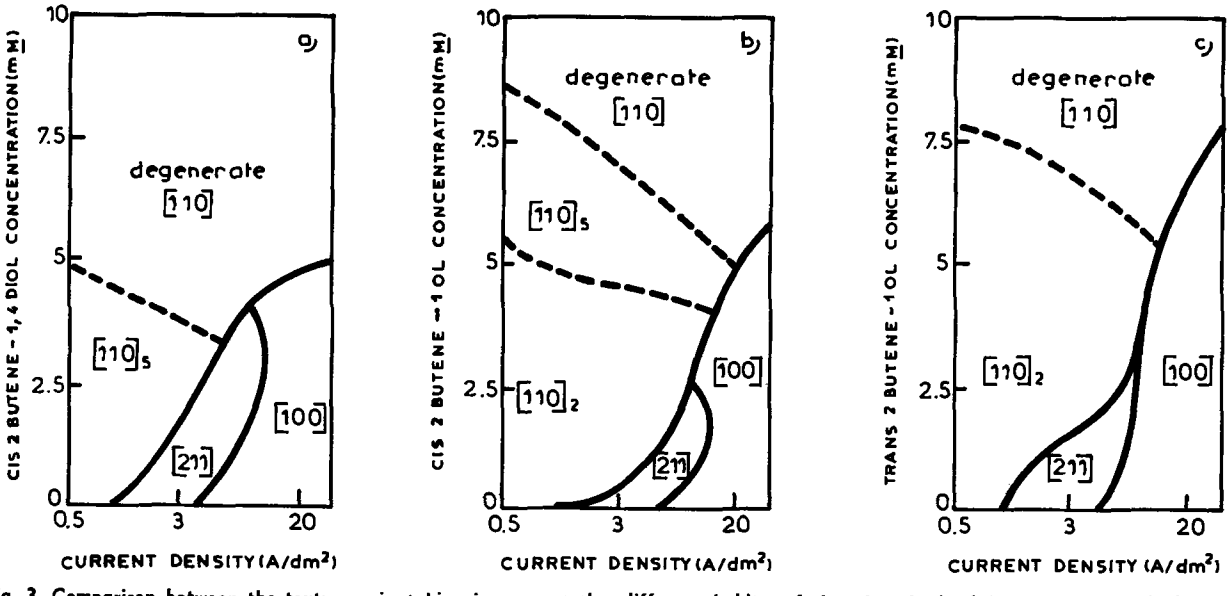

Fig. 3. Comparison between the texture axis, taking in account the different habits, of deposits obtained in presence of *cis* (b) and *trans* (c) monoalcohols, and with the corresponding *cis* diol (a)

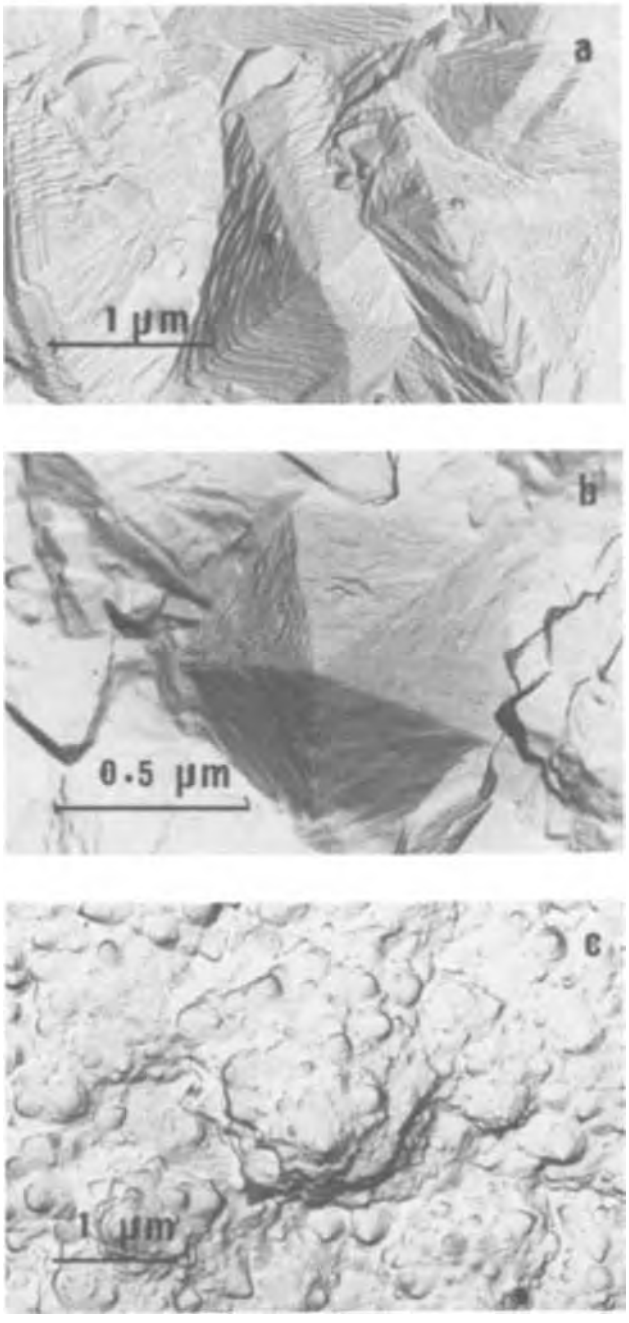

Fig. 4. Three typical habits of deposits with [110] axis fiber texture: two-fold symmetry (a), five-fold symmetry, (b) and cauliflower-like habit (c).

cohols, which evidently show the same effect in electroplating as does *trans* 2 butene-1,4 diol. However, the difference in the number and position of the functional groups around the double bond involves the difference of activity.

In the region marked $[110]_2$, the habit is constituted by large pyramids of two-fold symmetry formed around a twinning plane at the center of the grain (Fig. 4a). The angles between the faces [two (111) planes and two (100) planes] and the base of the deposit are 35° or 45°, respectively. The growth mode of these pyramids is similar to that of pyramids having a [211] axis, where the faces are placed symmetrically around twinning planes. Therefore, replacement of a [211] orientation by a $[110]_2$ does not constitute a significant structural change by the additive.

In the region marked $[110]_5$, the crystallites are arranged in a star around five twinning planes (Fig. 4b), the angles between the faces [(111) planes] with the basal plane are 35°. In a Watts solution without additives, at a pH equal to 4.5, this habit is only found at low overpotential. It characterizes a crystal mode produced by defects; the five-fold symmetry requires a minimal nucleation energy, as was shown in the case of vapor growth (17). In the last region marked "degenerate [110]," where the x-ray diffraction indicates only a weak [110] orientation, very small pyramids derived of five-fold symmetry pyramids are lumped to form irregular hummocks with a "cauliflower-like" appearance (Fig. 4c). The habit is no longer limited by crystallographic planes with simple indexes. This habit characterizes a very perturbed crystal growth.

The comparison between the activity of the four ethylenic alcohols shows a somewhat higher activity of the monoalcohols toward the dialcohols, and a higher activity of the *cis* compounds, toward the *trans* homologous compound: the Cm values and the σ values are lower for the *cis* compound than those for the *trans* homologue, at all current densities (16). The differences in σ are related to the formation of the several types of habits. In the presence of the *cis* isomer, the habit with five-fold symmetry and the disordered one occur at lower additive concentrations than for the *trans* one.

Figure 5 shows that a benzene ring presents the same type of activity toward the plating process as does ethylenic unsaturation. The similarity of the activity seems perhaps surprising; but, the enhancement of this activity in respect to that of ethylenic alcohol is in agreement with the results of Bockris and coworkers (18) that have shown in a similar situation (adsorption on mercury) that the order of increasing activity is butyl < phenyl < naphtyl.

The activity is further enhanced by conjugation with a double bond. The strong reactivity of the phenyl group masks the differences anticipated between the *cis* and *trans* isomers about the double bond.

Figure 6 shows that the three compounds present a different kind of activity from those already described, which must be due to the influence of the C=O unsaturation on the molecule-metal interactions. We shall not dwell on the case of the esters, whose presence leads to a rapid disappearance of the [211] texture zone of existence, with simultaneous preponderance of [100] and [110], followed by disorientation and varied habits. Examination of the habits and determination of σ values have shown, however, the formation of smaller crystallites in the presence of the *cis* compound, whose more accessible double bond favors the activity. In the presence of coumarine, on the other hand, the [110] texture is unequivocally favored, although weak. The habit is cauliflower-like, but it becomes flat enough for lesser concentrations than those of other ethylenic compounds.

Discussion

Using the growth of fiber textures in polycrystalline nickel deposits as an analytical criterion, we have clearly established the specificity of different unsaturations known to influence the course of electrodeposition. Whereas the acetylenic bond favors the [211] axis fiber texture, the ethylenic bond favors a [110] orientation, and the aryl-sulfone group favors a [100] orientation. In this work, we have particularly studied the role of some ethylenic compounds as addition agents in electrodeposition. Their action can be interpreted by an adsorption-desorption process, accompanied by hydrogenation of the adsorbed species before desorption. Our experimental results show that the neighboring of the unsaturated bonded groups can modify markedly the adsorption or desorption of the organic additives, and they are a matter for a number of reflections.

Comparison between cis and trans isomers.—The observed differences between the activity of *cis* and *trans* homologue alcohols or esters are easy to explain. The roughness of deposits, obtained in the presence of *cis* compounds are always lower than those obtained in the presence of *trans* homologues: the adsorption of

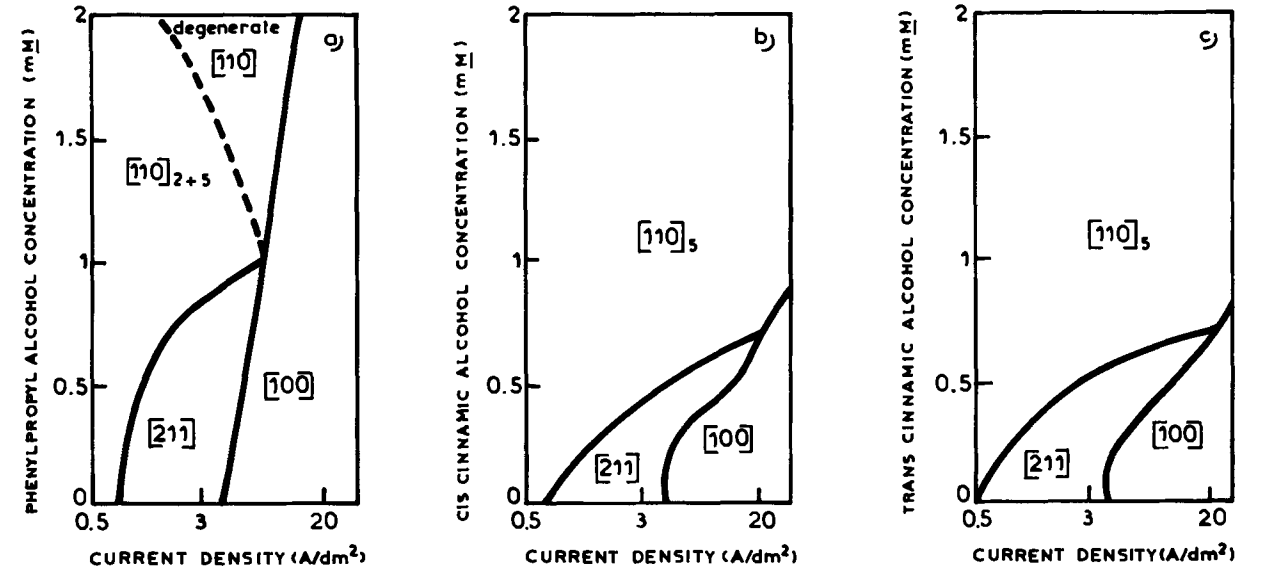

Fig. 5. Comparison between the role of a phenyl ring when it is found in a molecule having elsewhere a saturated side chain (a), an ethylenic side chain *cis* (b) or *trans* (c).

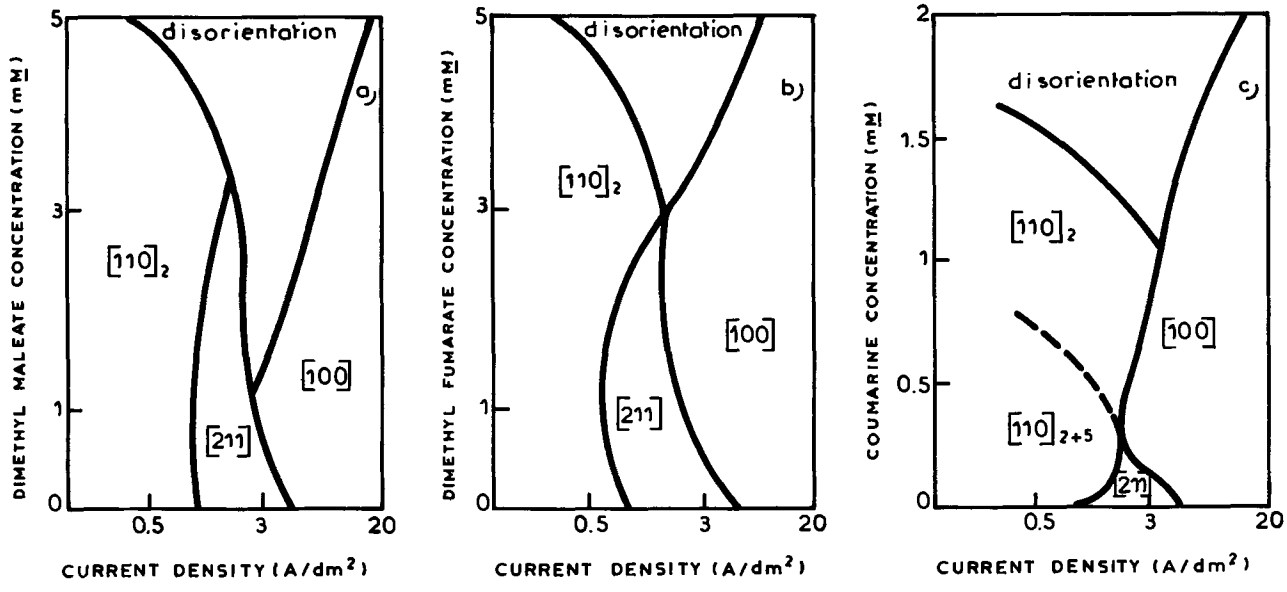

Fig. 6. Comparison between the role of a carbonyl group when it is associated to an ethylenic bond *cis* (a) or *trans* (b), and to a phenyl ring (c).

the *cis* isomer is facilitated by a relatively lower steric hindrance. The number of molecules lying on the surface is greater, thus more sites are occupied, and one observes formation of more crystallites of smaller size, limited in their lateral extension.

Role of hydroxy group.—Our present results seem to indicate that the hydroxy groups cannot, when they are alone, establish adsorption interactions with the cathode during the nickel electrocrystallization, which can lead to an alteration of texture. However, it is believed that butane-1,4 diol possesses some properties of a weak inhibitor in the corrosion of iron (19), and also that an addition agent behaves very much alike in both corrosion inhibition and electrocrystallization. Newman and colleagues (20) studied the role of butane-1,4 diol, 2 butene-1,4 diol, and 2 butyne-1,4 diol in the inhibition of cadmium and silver corrosion. They stated that the organic additives are oriented in one case parallel to the surface, and in the other case perpendicular to the surface. When the addition agent is adsorbed parallel to the surface, although the main interaction takes place between the unsaturated site and the cathode, the hydroxy group may establish some rather weak interactions. By this way, we cannot explain the higher activity of the monoalcohols toward the homologue dialcohols. We rather consider that the hydroxy group can interact with the constituents of the electrolyte, perturb the charge transfer reaction by substituting a complex metallic ion for the MOH^+ species normally discharged by the Heusler mechanism (21), and therefore modify the adsorption rate. These associations also could perturb the desorption rate. Examination of the habits tends to confirm the possibility of the discharge of complexed ions. The deposits obtained in the presence of monoalcohols have more frequently the $[110]_2$ habit. On the other hand, examination of the replicas obtained in the presence of aliphatic and cyclic saturated compounds shows a slight diminution of the crystallite size and a clearer appearance of the $[110]_5$ habit as one passes from butene-1,4 diol to *cis* 1,4 cyclohexanediol, then to *trans* 1,4 cyclohexanediol, and finally to *cis* 1,2 cyclohexanediol. This series of compounds is in a reasonable order for increasing the probability of complexing with the solution. It would seem that, in this case, a number of anions arrive complexed at the interface, where superficial crowding causes a slight diminution in the lateral extension of the crystallites.

Role of phenyl ring.—The observed modifications of the fiber texture suggest that the phenyl ring, when it is alone, is adsorbed by the same type of interactions as the ethylenic double bond. However, when a double bond is present in the molecule along with the phenyl group, the double bond has a higher probability of interaction with the metal than has the phenyl group. One supposes that the phenyl group activates the double bond by enhancing the π-electron density, but does not itself interact directly with the surface. Examination of the crystal habits permits further progress in the discussion of the phenomena. The deposits obtained in the presence of the cinnamic alcohols generally present a regular $[110]_5$ appearance, and then these alcohols perturb the crystal growth no more than the 2 butene diols/or ols. In contrast, the deposits obtained in the presence of phenyl propyl alcohol, even at low concentrations, have the cauliflower habit, characterizing an extensive crystallographic perturbation (even in the region marked $[110]_{2+5}$ on Fig. 5a, the habit is irregular enough). In this case the phenyl group only can interact with the surface. These major perturbations of the crystal form suggest that the phenyl group is flat on the surface. The size of this group is of the order of a unit cell on nickel, and it thus has a profound effect on the crystal formation. For the case of chemisorption of benzene in heterogeneous catalysis, different models have been proposed: benzene chemisorbed flat on the surface with six bonds (22), or perpendicular to the surface of catalyst with two bonds and rupture of the ring (23). But, for the case of electrocrystallization, the only experimental evidence is that the benzene ring is always found intact after electrolysis. Dubsky and Kozak (24) have studied the products of reduction and decomposition for a series of sulfone compounds. The authors found that the sulfur part is included in the deposit, while the undestroyed aromatic ring returns in the solution. The more probable model for the electrocrystallization then is the benzene molecule flat on the surface, adsorbed on nickel in the same way as an ethylenic double bond, but the following steps, hydrogenation and desorption, are not clearly explained at the present time.

Competition between unsaturations.—The interest in the study of the coumarin is that this study permits comparison between the interactions established by C=C and C=O with the cathode. The reduction product distribution studied by Rogers and Taylor (11) indicates that the interaction is preferentially located at the C=C unsaturation of the lactone ring, rather than at the C=O unsaturation. The melilotic acid (*i.e.*, 2 hydroxyphenylpropanoic acid), hydrogenation product of the C=C double bond in the lactone ring is always present in much greater quantity than o-hydroxyphenylpropanol, the reduction product of the carbonyl group (it is the principal product at low *p*H). One may therefore suggest that the influence of C=O and C=C unsaturations on electrodeposition follows the same mechanism of adsorption on nickel atoms, and then they are both hydrogenated, but that the carbonyl reduction at *p*H = 4.5 is more difficult, because this reaction requires the presence of more available H-adions than for ethylenic linkage.

Once again, in this case, the stability of the phenyl group is evident: inclusion of carbon-containing fragments has been extensively studied by tracer methods: Edwards and Levett (25) have been able to show that the rupture of a molecule of coumarin occurs in the lactone ring, the carbon atom of which is included in the deposit, while the aromatic ring is not destroyed and returns intact to the solution. It is likely that the melilotic acid and the other reduction products intervene in a second stage in a similar manner to that of phenyl propyl alcohol and reinforce formation of the [110] axis fiber texture. The presence in the molecule of coumarin of different groups able to adsorb on varied sites of the surface may be a reason for its very great activity on the electrodeposition process. Once again, it is shown that a phenyl group, when it is not alone in an otherwise saturated compound, cannot interact by itself with the metal surface but enhances the activity of the double bonds conjugated with it.

Role of hydrogen.—A last point of the discussion is the comparison of diagrams Fig. 2b, 3a, 3b, and 3c, with the *p*H overpotential diagram of Fig. 1. It reveals a remarkable similarity between the effect of increasing the concentration of organic compounds, or decreasing the *p*H, and especially in the disappearance of the [211] texture. The difference between the area covered by the organic molecules, and that covered by H-adions shows that it is not a simple effect of coverage but, rather, that of a modification of the charge transfer reaction. In fact, the reduction of the C=C unsaturation, by consuming substantial quantities of H-adions, displaces the equilibrium $H^+ + e \rightleftarrows$ H-adions and the reaction is driven to the right. The rate of this reaction may become as fast at *p*H = 4.5, as at lower *p*H in the absence of additives. This confirms that the hydrogen charge transfer reaction plays an important role in the formation of textures.

We must note that, in certain cases (coumarin and esters), we observe a slight increase in the *p*H of the electrolyte during the course of electrolysis: their reduction involves a consumption of a substantial quantity of H-adions, and evidently the boric acid is not able to furnish enough H^+ to adequately buffer the solution.

Specificity of adsorption.—In the previous discussion, we referred to adsorption without definition of the adsorption sites. However, the similarity with the catalysis phenomenon suggests that there is a possibly selective adsorption on the different crystallographic planes. DuRose (7) has tried to determine the adsorption sites, using spherical cathodes of monocrystalline nickel. Unfortunately, this method is questionable in that the adsorption is inferred from modifications in the aspect of the sphere surface in regions corresponding to simple crystalline orientations. Now, the greatest difficulty is that the initial plane (and the initial orientation) of the substrate for the deposit intervenes only in the first moments of nucleation, before the habit is constituted. After that, the interactions occur at the level of the growth-limiting faces, since the organic molecules are adsorbed on the crystal faces limiting the habit. Making deposits on a monocrystalline substrate is of interest only while growth figures limited by other planes have not appeared on the surface. On the other hand, the modification of aspect is not a good criterion and may correspond to very different phenomena: for example, the brightening can occur as a result of a process corresponding to distinct mechanisms of the modification of crystal growth. There may be a similar reduction in all dimensions of the crystallites, or there may be a reduction of the surface relief without a decrease of the grain size. There is sometimes also a degeneracy of the habits. Therefore, a direct method does not exist to determine the adsorption sites.

The determination of adsorption sites would allow the use of bond energy calculations, such as Bond's (26) relative to alcynes, olefins, and conjugated diolefins, to predict the most probable interactions between the unsaturated bond and a crystallographic face; the comparison between experimental data and energy calculations would permit a better understanding of the electrocrystallization mechanism. However, even in the simplest case of the catalysis, the results obtained by LEED (27) on the adsorption of ethylene and acetylene on nickel monocrystals do not agree with the theory. The LEED results show a greater catalytic activity for the (111) face than Bond's theory predicts. In electrocrystallization, the complexity of the interface is very much greater than in catalysis. The cathode-electrolyte interface can never be considered as a perfect and static plane, but it is in continuous evolution. Even

before the formation of the growth habit, and in the simplest case of an epitaxial growth on a monocrystalline face, the edges of the growth steps present the most favorable sites for adsorption, furthermore the appearance of dislocations and twinning create additional low-energy sites. The possibility of adsorption on a crystalline face depends on its perfection on an atomic scale, in a large measure.

The Ni^{++} adions, more or less hydrated or complexed, and H^+ migrate in company with molecular fragments toward their sites of discharge, or incorporation into the lattice. One does not know *a priori*, if the organic groups are strongly bound to a particular site, or if they remain mobile; this depends on the particular strength of the adsorption forces. In any case, the presence of these molecules or fragments (with a volume relatively large compared to that of an adion) should necessarily perturb the electrocrystallization process, and in certain cases of high concentrations, simply by a superficial crowding effect.

To conclude, we shall show that it is possible to describe the mode of action of an unsaturated compound without taking a position about the adsorption selectivity, but advancing the hydrogenation-desorption process, and the role of imperfections and low-energy sites.

Ethylenic compounds.—Adsorption is secured by the π-electrons of the carbon-carbon unsaturated linkage and by the establishment of localized bonds with nickel atoms, preferentially, to minimum energy sites such as twinning planes and dislocations. The cathode is thus covered partly with chemically bound organic molecules, and partly with relatively mobile adsorbed hydrogen, which can replace the metal in the organic molecule-metal linkage, and so permits the desorption of the former. The points liberated by this desorption are then very active sites for nucleation. The organic molecule acts as an intermediate, reinforcing the natural tendency to the crystalline growth from the surface defects at low overpotential, by improving these defects. It favors therefore the formation of a [110] axis. Adsorption is facilitated on the dense planes, *i.e.*, (111) against (100). The growth rate of the (111) faces is limited; the (100) faces must disappear, and the $[110]_2$ habit which involves (100) faces must also disappear in favor of the $[110]_5$ habit which involves only (111) faces. This process seems, finally, general enough, and other double bonds, C=O for example, and others not studied here, must act in this manner.

Acetylenic compounds.—The particularity of this class of compounds is to require a large quantity of adsorbed hydrogen in the reduction step. We suppose therefore that the rate of desorption is limited by the rate of hydrogen supply; the molecule stays a long time on the surface before desorption, involving a substantial blocking of the surface, *i.e.*, a great increase in the frequency of nucleation, as shown by the very small size of the crystallites observed with the electron microscope, and also a great increase of the surface coverage, as shown by the displacement of the cathodic overpotential. The nucleation intervenes, not at the place of the desorbed molecule as in the case of ethylenic compounds, but around the molecule adsorbed with formation of very numerous crystallites limited in their lateral extension.

Aryl-sulfonic compounds.—The mechanism is in this case different, as suggested by analysis of the decomposition products: a molecular rupture takes place, with phenyl returning into solution (it plays its activator role without directly interacting with the surface), and the sulfur-containing fragment incorporated in the deposit. This incorporation takes place along the denser direction. Organic fragments have been found along the >110< directions in the course of electrodeposition of the [100] textured nickel in the presence of sodium benzene sulfonate (28). Indeed, very strong interactions can be formed between the orbitals of sulfur and nickel, and rupture of the molecule occurs at the level of the phenyl sulfur bond. An essential difference with the preceding mechanisms is that, in the latter case, only adsorbed hydrogen atom is involved. This is in line with the kinetic measurements of Wiart (29) who has shown that 2 butyne-1,4 diol modifies the rate constant of the last step of the transfer reaction $NiOH\text{-adions} + NiOH^+ + 3e = 2Ni + 2\,OH^-$, which is influenced by the local pH. In contrast, it was shown experimentally that the presence of sodium benzene sulfonate does not modify the rate constant of the transfer reaction, and it brings only a slight change in the local pH.

We have shown that the organic molecule involved in a process of electrodeposition can, along its chemical structure, favor either a growth mode, perpendicular to the substrate, initiated from surface structural defects, or a lateral mode generally explained by a two dimensional nucleation theory. Then, the different theories of crystal growth being available for a particular growth mode, we understand why their fitting with the experiment is not often good. Very numerous parameters of the interface must be taken into account; we have shown that, at the present time, there is no experiment which allows a conclusion on the absorption selectivity of the organic molecules during an electrocrystallization process. We have pointed out the role played by the adsorbed hydrogen, and the modifications of the adsorption and desorption rates of the different species present on the interface.

and S. L. Chow and M. Schlesinger*

Department of Physics, University of Windsor, Windsor, Ontario, Canada

ABSTRACT

A comparative study of the transmission electron micrographs in the different stages of the autocatalytic plating process has been made. The comparison was made between conventional $SnCl_2/HCl$ sensitizer solution and a newly developed system based upon the incorporation of aged stannic component. Results have demonstrated an increase in catalytic site density of approximately one order of magnitude. This improved method has further resulted in the formation of finer and denser metal crystallites during the early stages of nucleation and growth.

In the art of plating on dielectric substrates, chemical treatment of the surface is an essential step required for the initiation of the autocatalytic (electroless) plating processes. During the chemical treatment procedure, sites are formed which provide a chemical path for the initiation of the plating process. At present, there are two basic procedures used in the formation of the catalytic sites: (*i*) sensitization (via acidic stannous chloride) followed by activation (via acidic palladium chloride), or (*ii*) a colloidal system (via palladium chloride in excess acidic stannous chloride). Although both of the above procedures are widely utilized, this investigation is concerned with modifications related to the first approach only.

In recent publications (1-4) it has been demonstrated that the effectiveness of conventional tin sensitizer solutions ($SnCl_2/HCl$) may be altered through proper solution modification. Specifically, the incorporation of aged stannic chloride solutions were found to provide the improvements in performance. During the

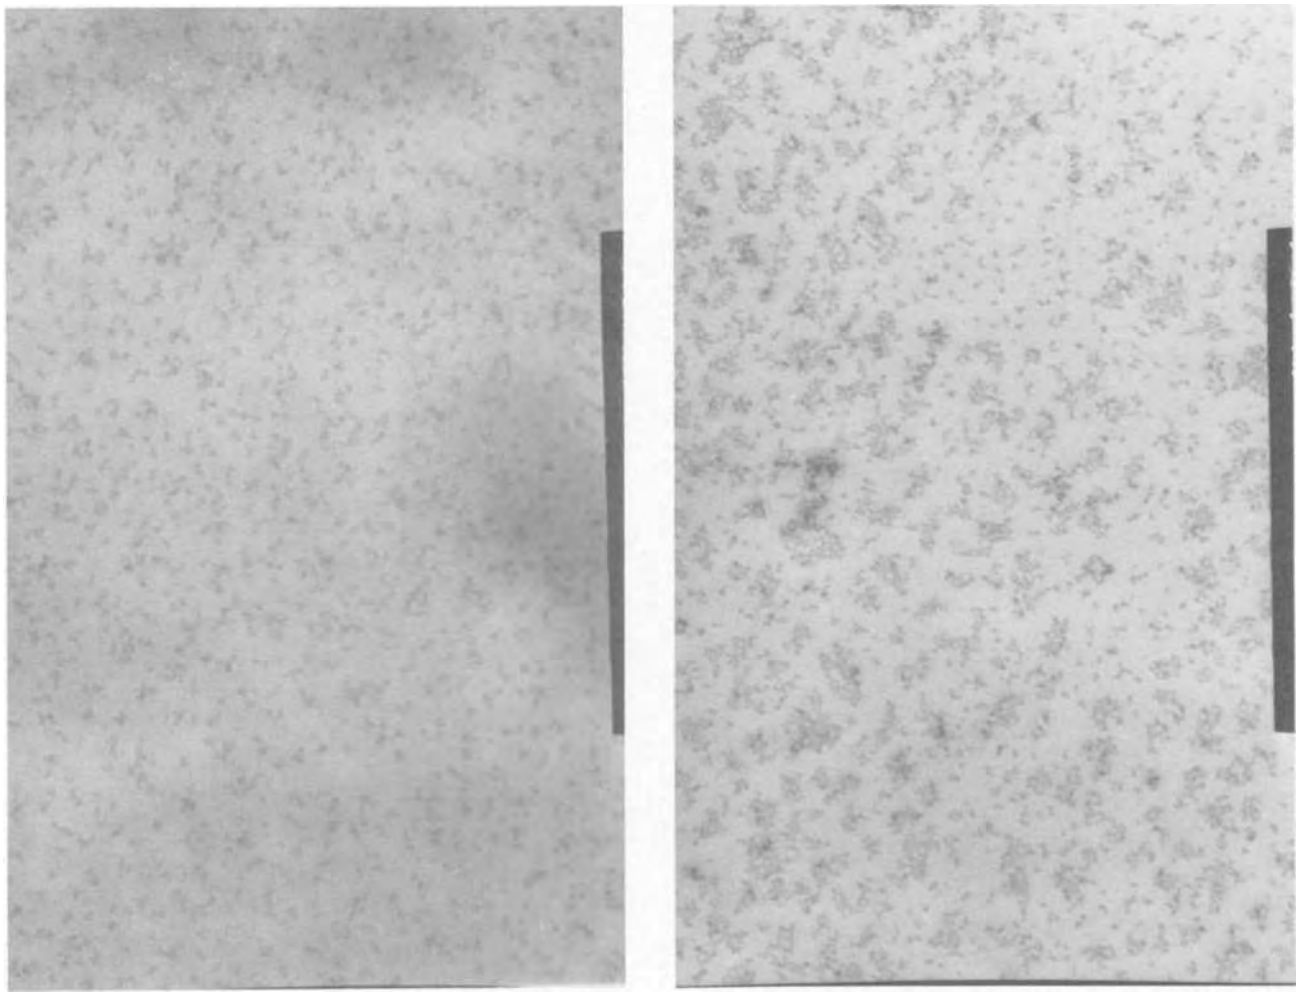

Fig. 2. Electron micrographs after the activation step on Formvar surface, at magnification 200,000× (1 cm = 500Å). A (left) conventional sensitizer; B (right), improved sensitizer.

aging process, a colloidal compound of tin (IV) was formed (1). It was also found (2, 3) that the aged stannic chloride solution may either be added to conventional tin sensitizers or used in a separate step prior to the immersion in conventional tin sensitizers. In either case, the same results were obtained by examining the uniformity of metallic coverage, by measuring the resulting surface through contact angle measurements (1-3), and by monitoring the concentrations of active components by radiochemical adsorption measurements (5). This development was of special significance in the metalization of hydrophobic substrates (Teflon, photoresists, etc.). Moreover, visual examination of thin films deposited onto hydrophilic surfaces showed also a greater degree of uniformity in comparison to films deposited by the use of conventional sensitizers.

Improvement in sensitizer performance was also obtained (7) through the aging of dilute acidic stannous chloride solutions. This procedure, which utilized an aging period of 1-2 weeks, is limited to solutions having a low acidity or chloride content. More recently (8), improvements in conventional sensitizers were also reported through the incorporation of colloidal tin or iron salts.

In examining the nucleation and growth of thin Ni-P deposits, Schlesinger *et al.* (9) have shown that the nucleation process is initiated at activation centers. The process of nucleation continues until the coalescence into a continuous layer takes place. The initial product derived from conventional sensitization ($SnCl_2$/HCl) appears to consist of particles approximately 20Å in diameter. These particles are agglomerated into clumps of an order of magnitude larger. The clumps themselves are randomly distributed on the surface. The activated surface shows particles of about 50Å in size. This is presumably a deposit of metallic palladium, although recent studies (5, 10, 11) have suggested that ionic palladium may be still present at the conclusion of the activation step.

Sard (12) has carried out similar studies with electroless copper films. His observations agree essentially with the previous findings by Marton and Schlesinger (9). The nucleation of Co-P deposits has been studied earlier to some extent by Frieze *et al.* (13). Their findings were corroborated by the above (9). With the development of the new sensitizing system (1-4), the question as to the actual microscopic processes responsible for both the conventional and improved sensitization became even more interesting. In the present work, Formvar surfaces were examined after being subjected to various treating solutions. The results of this work will show that the visual observation of more homogeneous metallic distribution is attributed to a more homogeneous distribution of sensitizer component on a microscopic scale.

Experimental Procedure

The main aim in the current investigation was to study the microstructure of the premetalizing stages in the electroless deposition procedure. The complete process of copper deposition was also included. The presensitizing solution was an "aged" (1 week at 25°C)

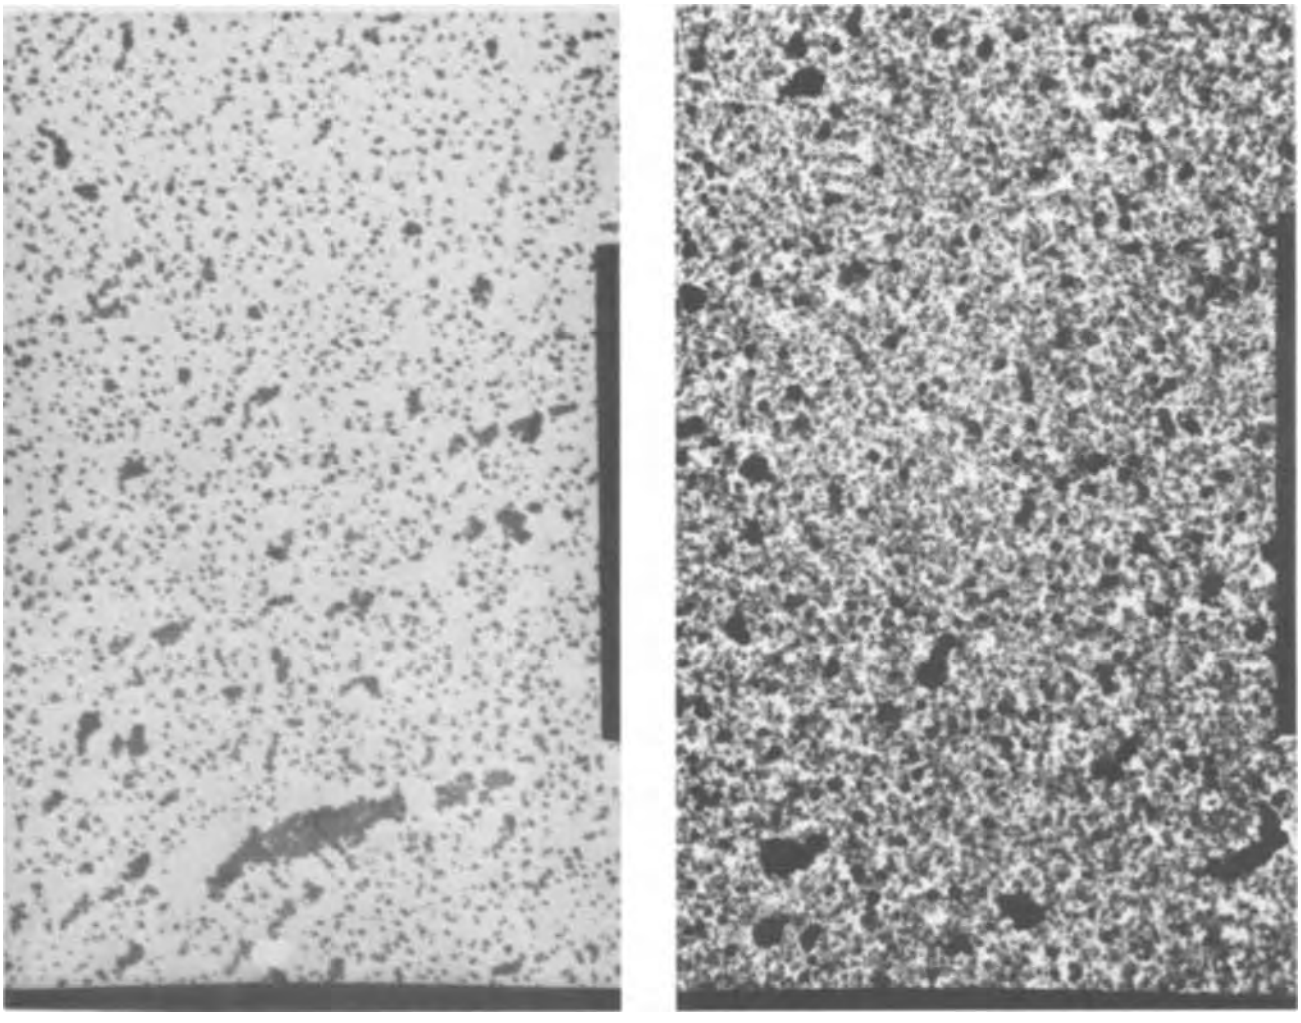

Fig. 3. Electron micrographs of a Formvar surface after 1 min immersion in electroless copper bath, at magnification 14,200× (1 cm = 7050Å). A (left), conventional sensitizer; B (right), improved sensitizer.

0.5M stannic chloride. Working solutions were made by 1:100 dilution using deionized water. The conventional sensitizer medium ($SnCl_2$/HCl) and activating solution ($PdCl_2$/HCl) were identical with those described previously (9). An identical procedure (9) of a 1 min deionized water rinse after each of the sensitizing and activating steps, was followed. In all cases, the sensitizer solutions were freshly prepared and used. The electroless copper metalizing bath was "bath B" described by Sard (12). All chemical treatments were carried out at room temperature.

All chemicals were reagent grade supplied by Fisher or Canlab, and were used without further purification.

Microscope slides glasses coated with Formvar (4g polyvinylformal in 1 liter of ethylene dichloride) were used as substrates. The coated Formvar was floated off the glass in distilled water. The samples were examined with a Hitachi HU-12 electron microscope operated at 100 kV.

Results and Discussion

In Fig. 1, the electron micrographs of tin-sensitized surfaces are presented. Figure 1A represents the micrographs of Formvar immersed for 1 min in freshly prepared conventional sensitizer. Figure 1B is the micrograph representing the Formvar surface after 1 min immersion in aged stannic chloride solution (presensitizer solution) followed by 1 min immersion in the same sensitizer solution used in Fig. 1A. Comparison of the results reveals a denser and a more uniform distribution of particles and clusters. The density of particles resulting from the improved procedure is about 10^{12} particles/cm^2. In comparison, the density resulting from conventional sensitizer is about 10^{11} particles/cm^2.

Identical electron micrograph results were obtained using the improved procedure whether the aged stannic chloride component was used prior to the conventional $SnCl_2$/HCl) sensitizer or mixed along with the sensitizer. This result, *i.e.*, that one may use the aged $SnCl_4$ prior to, or together with, the $SnCl_2$ sensitizer, is consistent with previous observations (1, 2, 5). It is consistent also with the model proposed (see below) to account for sensitization. It has also been observed that when diluted conventional sensitizer solutions are aged at room temperature for 1 week or more, they serve as effective presensitizing baths, rendering results similar to Fig. 1B.

Although the basic particles of Fig. 1 are about 20-30Å, it should be apparent that the improved sensitizer medium results in a decreased tendency for cluster formation. In fact, the clusters formed through the conventional approach are a few times larger in comparison with those obtained using the improved procedure. The results of Fig. 1B were independent of the tin (II) concentrations used.

Figure 2 represents the electron micrographs of Formvar surfaces at the conclusion of the activation step. Figure 2A represents the surface after 1 min immersion in sensitizer solution followed by 1 min immersion in activating solution. Figure 2B is the same except for the immersion for 1 min in the aged solution prior to the sensitizer solution. Here, too, the product of the improved procedure is denser in comparison with the conventional approach. Some tendency for clustering is evident in both cases.

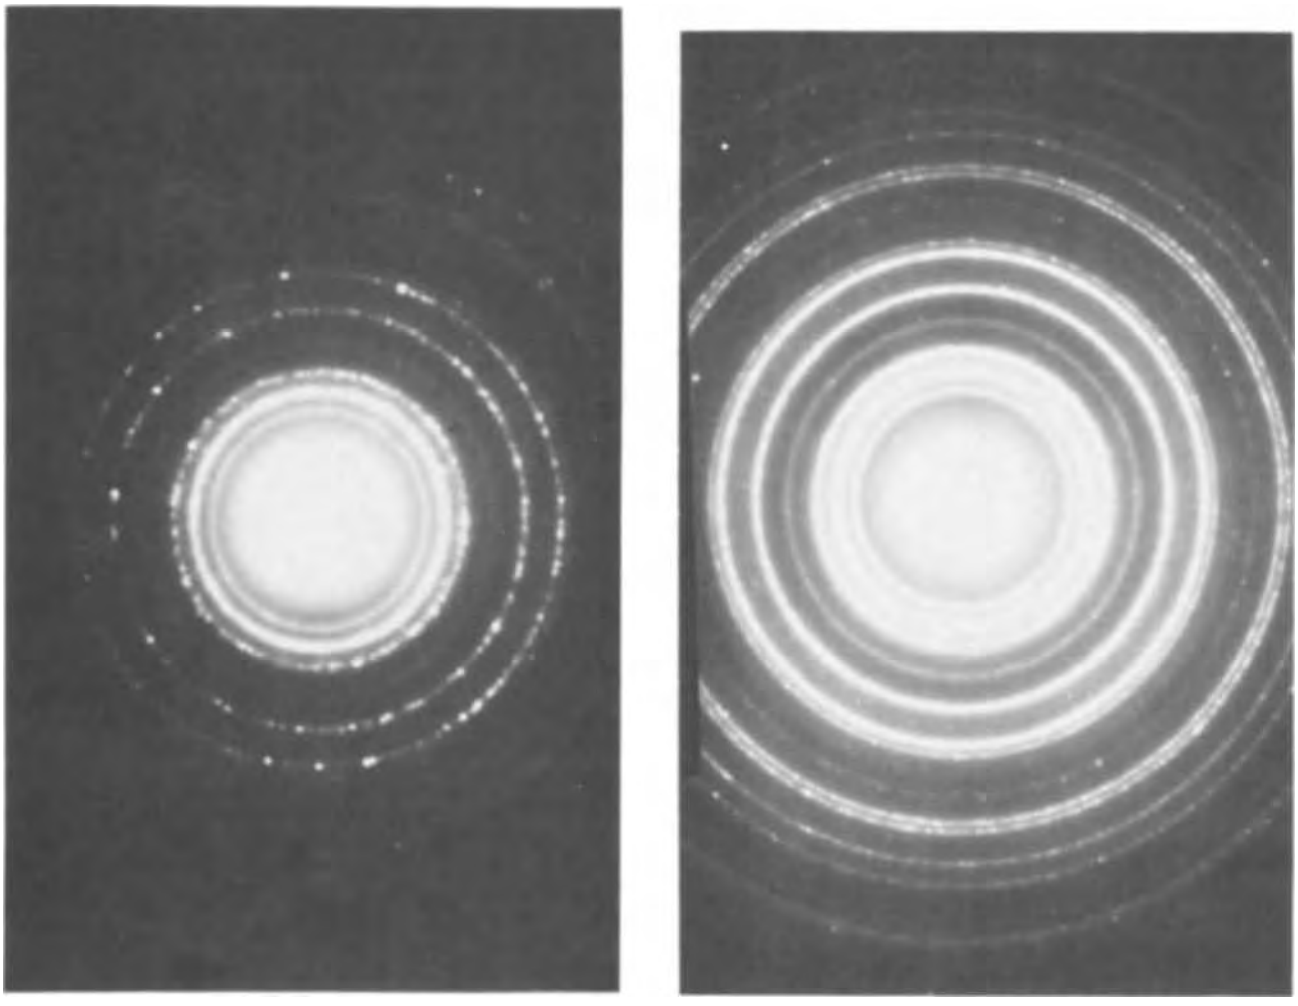

Fig. 4. Electron diffraction patterns corresponding to Fig. 3

Figure 3A represents the electron micrographs of electroless deposited copper using a conventional sequence, with 1 min immersions in each of the sensitizing, activating, and metalizing solutions. Figure 3B corresponds to a surface with the same treatment except for an immersion of 1 min in the aged solution, preceding the above treatment. Once again the finer and denser particle distribution is seen to result from the improved procedure. The finer size particles in Fig. 3B manifests itself in the corresponding diffraction patterns given in Fig. 4.

Preliminary analyses of the electron diffraction patterns corresponding to the micrographs presented in Fig. 1 and 2 indicate that the product of conventional sensitization is most probably hydrated stannic oxide. This is consistent with the previous findings (9, 14) and the model proposed by Cohen *et al.* (15) for the surface characteristics resulting from conventional sensitizer treatment. The surface product obtained by the improved method exhibits a diffraction pattern markedly different from that obtained using conventional sensitizers. It may well be argued that the chemical species responsible for this pattern is a polymeric substance of the type (1, 16)

$$(HO)_3 - Sn - [OSn - (OH)_2]_n - OH$$

or

$$(HO)_2 - Sn - [O_2Sn]_n - (OH)_2$$

where n is an integer, *i.e.*, 1, 2, 3, etc. This polymeric material was formed during the aging process.

It should be noted that three major experimental difficulties are inherent in the quantitative interpretation of the diffraction patterns: (*i*) the amount of material present on the surface is very small, and consequently, the intensity of patterns is rather low; (*ii*) the size of the "crystallites" present is such as to give diffuse patterns; and (*iii*) there is also the possibility of dehydration of the "hydrous Sn polymer" by the vacuum and/or irradiation of the electron beam.

Table I presents the derived d-spacing for the surface formed as a result of treatment with conventional and the improved sensitizers.

Conclusions

Although the improved sensitizer solution was initially aimed at achieving good plating uniformity of hydrophobic surfaces, the current results show significant improvements in hydrophilic substrates as well. The adsorbed sensitizer clusters and particles are more uniformly distributed on the surface in comparison to those obtained using conventional sensitizers. The density of adsorbed center is about 10^{12} centers/cm^2, which is approximately an order of magnitude greater in comparison with the results derived from conventional sensitizers on Formvar. No significant

differences were observed with respect to the basic particle size.

It was also confirmed that the results of the improved sensitization are independent of the specific procedure used in that specifically identical results were obtained whether the aged tin (IV) is used prior to conventional sensitizers or is incorporated into the same medium.

Following the activation step, it has been observed that the size of the clusters is increased; this trend is consistent with the behavior encountered with conventional sensitizers as well.

Examination of the electroless copper films in which deposition was interrupted during the early stage of nucleation and growth shows major differences. Similar differences would be expected for other electroless systems. The new sensitizer medium shows a greater degree of metallic coverage for the same immersion time in the electroless copper bath. This observation is not surprising in view of the fact that the improved sensitizer medium yields a greater number of active centers which are distributed more uniformly on the surface. From this observation, it is reasonable to speculate that thin films deposited by chemical plating will exhibit variations in physical properties such as conductivity, complex index of refraction, adhesion, etc., depending on the sensitizer solution used.

Measurement of the Potential of Zero Charge of Solid Electrodes by the Time-of-Contact Method

S. Efrima and E. Gileadi*

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

A new technique has been developed for the measurement of the potential of zero charge (PZC) of solid electrodes. The technique utilizes the repulsion between identically charged double layers (DL) and electrodes. This potential (or charge) dependent repulsion is shown to affect the time of contact (TOC) between two electrodes when one is struck by the other. It is shown that the TOC is a minimum at the PZC. Measurements on gold electrodes in perchloric acid solutions showed minima in the TOC near the potential +0.01V SCE. In sodium iodide solutions the minimum of TOC was shifted cathodically corresponding to the expected shift of the PZC resulting from specific adsorption of iodide. This technique, after several improvements, is suggested for measuring the PZC of solid electrodes.

The potential of zero charge (PZC) is a fundamental physical quantity in electrochemistry. It is very important in the research of the electric double layer, in studies of adsorption of charged and uncharged species on the electrode, and when treating kinetics of electrochemical reactions (1-4). Thus, it has an essential role in pure fundamental research as well as in applications of technology. Nevertheless, there is still no method to determine the PZC of solid electrodes unambiguously and with sufficient precision. For liquid electrodes there are several methods which are "thermodynamic" in the sense that they do not depend on any specific model of the system, and exact (5-8), and lately also some which are relatively easy to practice (9). They are based, in one way or the other, on the measurement of the surface tension. On solid electrodes such measurements are, of course, not as straightforward. One must then apply approximate thermodynamic methods [organic adsorption (10, 11), measurement of electrode elongations (12), electrode vibrations (13), and others], or go over to nonthermodynamic methods (capacity measurements, friction measurements, etc.).

The large spread of PZC values of solid electrodes which are reported in the literature (1, 2, 14-17) and which cannot be attributed entirely to differences in electrode pretreatments, indicates the unsatisfactory state of affairs in the PZC research. It is evident that further efforts in this field are needed. Below is a report of such an effort to develop a new method. It

Key words: potential of zero charge (PZC), gold electrodes, time-of-contact method.

is based on the measurement of the time of contact (TOC) between two electrodes constructed of the same metal and polarized to virtually the same potential, when one is struck by the other. Application of this method for the determination of the PZC on gold electrodes is described.

The principle of the method.—A schematic diagram of the apparatus is shown in Fig. 1. A rodlike electrode is suspended from a metal strip which acts as a spring. This electrode is pulled back by means of a small electromagnet. When released, the electrode at the end of the spring moves through the solution and hits the face of the planar electrode which is held at virtually the same potential. The time of contact (TOC) between the two electrodes is the quantity being measured in these experiments. This depends on the charge density q_M (and hence on the potential) of the two electrodes. As q_M increases more work must be expended to overcome the coulombic repulsion and bring the two electrodes together. This work will be done at the expense of the initial energy given to the moving electrode by the spring, so that the velocity of the moving electrode "just before making contact," will decrease as the absolute value of the charge increases. Hence at the PZC this velocity will be the greatest. The TOC is expected to decrease with increasing velocity, since the depth of penetration of the moving electrode into the planar electrode will be essentially independent of it. It may be concluded from the above qualitative reasoning that the TOC will be a minimum at the PZC and will increase with increasing rational potential on both sides.

Experimental

The mechanical system.—The mechanical system (Fig. 2) was built in and onto a large box constructed of Perspex (30 × 30 × 35 cm) which served the double purpose of establishing a base for the electrodes and ensuring an inert gas atmosphere. One of the side panels was easily removable. A round hole was bored into the top panel, through which a PVC rod (point 1), with a bore throughout its length (point 2), was pressure fitted. On the lower end of the PVC rod a cylindrical Teflon bar (point 3) could be attached with the aid of a sleeve (point 4). A gold pin (point 5) was pushed into the lower end of the Teflon bar. This gold pin screwed into a gold block (point 6) (8 × 10 × 5 mm), which was the stationary planar electrode. A brass rod passing through the bore (point 2) provided the electrical contact and contributed to the mechanical stability of this electrode.

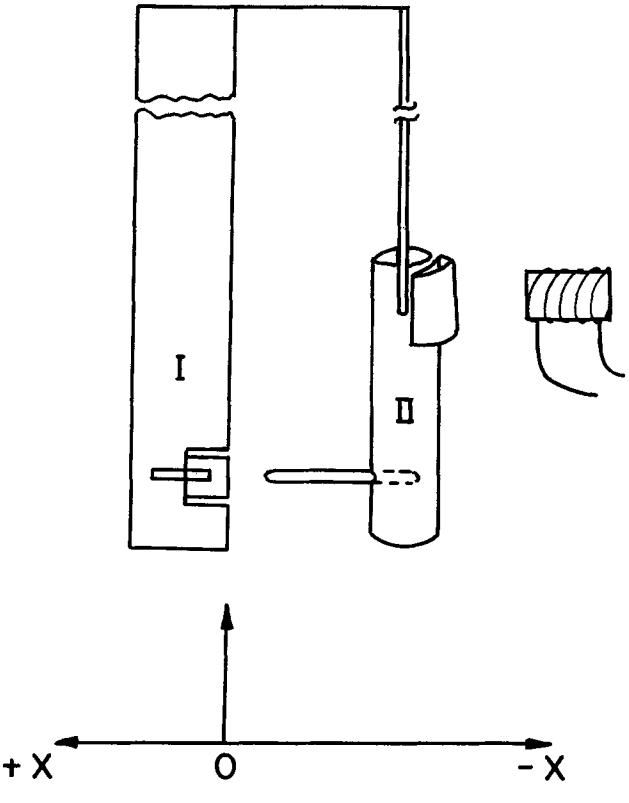

Fig. 1. A schematic diagram of the apparatus. I, Stationary electrode; II, moving electrode.

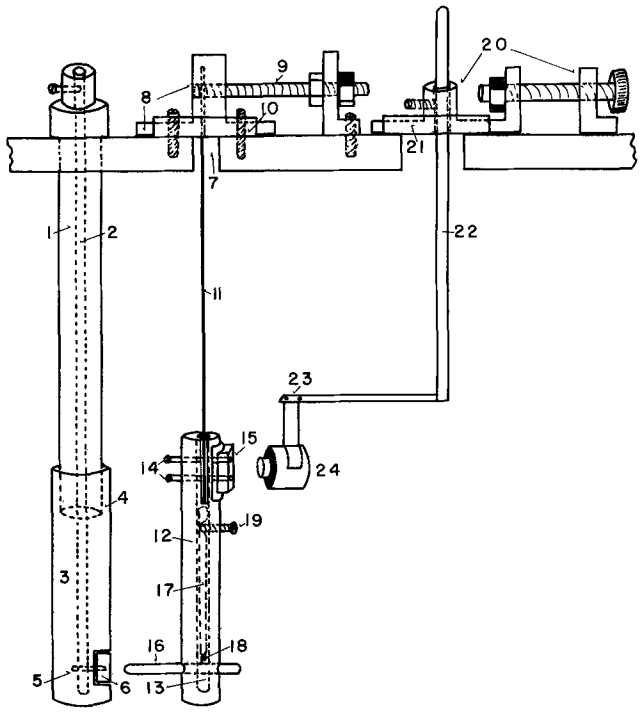

Fig. 2. Full scale diagram of apparatus

Not far from the first hole in the upper panel, another one was bored (point 7). This was a rectangular opening permanently covered by a metal device (point 8), which could move horizontally in tracks (point 10) by turning the nut (point 9). A steel band (point 11) serving as a spring was attached to the lower part of this device. The moving electrode was built of a Teflon rod (point 12) with a bore in the middle (point 13) almost all the way to the lower end. At that end a 3 cm long and 3 mm diameter gold rod (point 16) was inserted with pressure. Its point which faced the planar electrode was shaped as a truncated cone (the diameter of the small circle was ca. 0.5 mm). The upper end of the Teflon rod (point 12) was split in two, and the spring was inserted there and fastened by two screws (point 14), which screwed into an iron block (point 15). The electrical contacts of this electrode were conducted through the central bore. A brass rod (point 17) pressed a small spring (point 18) against the gold rod. The upper end of the brass was held tight by a small screw (point 19), to which the electric lead was soldered.

On the top panel of the Perspex box another movable device (point 20) with tracks (point 21) was built. It connected inside the box to a handle (point 22) carrying an electromagnet (point 24). When current passed through it the electromagnet could attract the moving electrode by the iron block (point 15). Stopping the current released the spring and the electrode moved forward to strike the planar electrode.

The two movable devices (points 8 and 20) were needed in order to control the velocity of the moving electrode. The Perspex box was kept on a special shock absorber to eliminate mechanical disturbances.

It was essential to ensure, as much as possible, the rigidity of the fixed electrode, the electromagnet setting, and the box. It was also important to ensure that the moving electrode should have freedom of motion

only in the forward and backward directions and should not be able to move sideways.

The electronic circuits.—There were two separate circuits. One provided current to the electromagnet; this current could be stopped by applying a voltage step for a controlled span of time. The time between current intermissions could also be controlled. Generally there were 3 sec for current intermission and 18 sec in between for the solution to calm down. In each cycle the direction of the current in the electromagnet was inverted to avoid residual magnetism in the magnetic core.

The second circuit controlled the potential of the electrodes and allowed the measurement of the TOC (Fig. 3). A potentiostat (Elron CHP-1) was used. The working electrode terminal was connected directly to the moving electrode and, through the resistance R_m, to the planar electrode. R_m was a 400 k-ohm helipot. The voltage on R_m was read on the y axis of an oscilloscope (Tetronix 564 with 3A3 and 3B3 plug-in units for the y and x axes, respectively).

Measurement of the TOC depends on the existence of a small residual current (*ca.* 0.5-1.0 μA/cm^2). The resistance R_m was set to give a potential drop of 8 mV between the moving and the stationary working electrodes. (This requires a different setting of R_m for each applied potential since the residual current depends on potential.) During contact there is no current through R_m and the potential across it drops to zero. This fast drop in potential is used to trigger the oscilloscope. When the electrodes detach, current again passes through R_m and the voltage assumes its previous value (Fig. 4). (The rise in the voltage is generally much slower than the fall.)

Cell, electrodes, and materials.—The cell was covered with a glass plate with a hole for the auxiliary electrode and openings for the working electrodes. The opening for the moving electrode was elongated, allowing enough free space for movement. The reference electrode was installed in a special compartment separated from the main cell by two fine sinters. An inert gas atmosphere was kept by flowing nitrogen into the Perspex box. Before beginning the measurements, nitrogen was passed through the solution for a period of about 1 hr. The nitrogen was cleaned first by passing it through an oven with copper files, through distilled water, through concentrated sulfuric acid, and again through water. The working electrodes were 99.99% pure gold. They were treated by abrading with alumina powder (0.05μ) until bright, then were rinsed with water, acetone, and again water in an ultrasonic cleaner. A platinum foil (*ca.* 2 cm^2) served as the counterelectrode and a saturated calomel electrode (Radiometer K-401) served as the reference electrode. All potentials are reported with respect to this electrode. Triple-distilled water was used to prepare solutions.

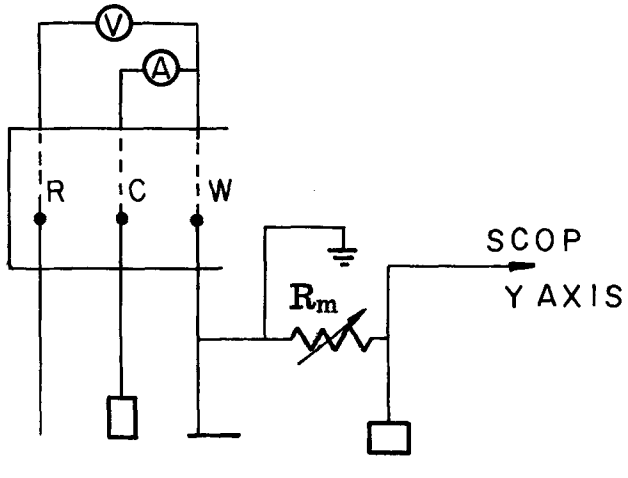

Fig. 3. Circuit for potential adjustment and TOC measurement

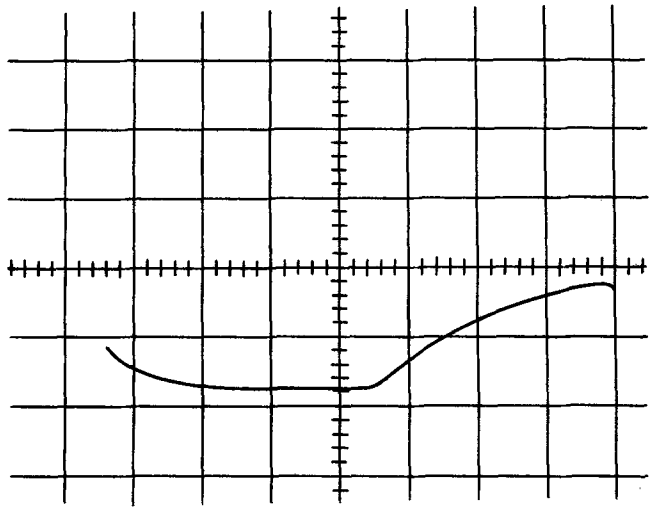

Fig. 4. An oscilloscope trace of the voltage on R_m during contact. The sudden rise marks the end of contact.

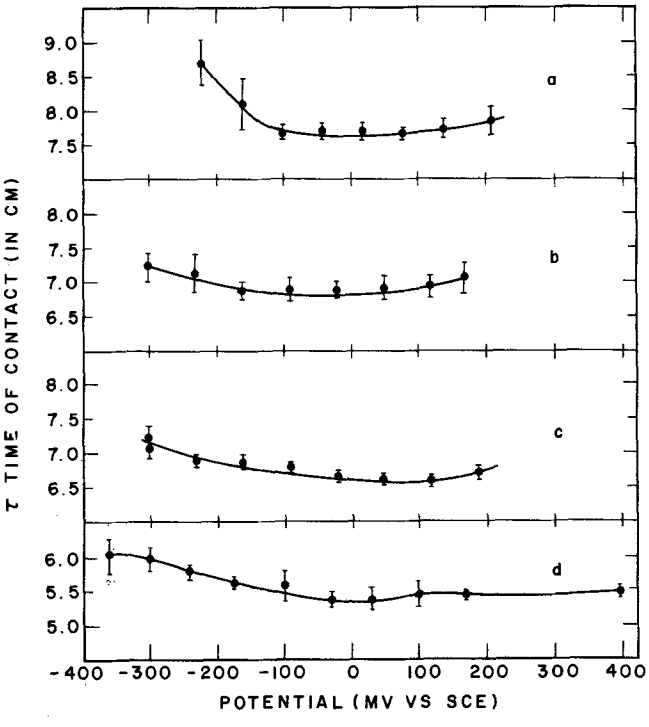

Fig. 5. TOC *vs.* potential curves measured in perchloric acid solutions. Time scale: a, 20 μsec/cm; b, 100 μsec/cm; c, 120 μsec/cm; d, 200 μsec/cm.

All chemicals were AR grade, used without further purification. Iodine solutions were prepared in water which was deaerated by bubbling nitrogen through it for 1 hr.

Results and Discussion

The variation of the TOC with potential was measured for gold electrodes in 1×10^{-3}M $HClO_4$ and in 5×10^{-3}M KI solutions with and without 5×10^{-4}M $HClO_4$.

The plots of the TOC *vs.* potential in 1×10^{-3}M $HClO_4$ showed rather wide minima (Fig. 5, a-d) in the range of -0.05 to $+0.10$V as seen in Table I.

The average value of the PZC in this solution is 0.01V. The limits of uncertainty are of the order of 0.05-0.1V. This result falls in the same region where most of the reported values of the PZC of gold (14, 16, 17).

In sodium iodide solutions we obtained minima which were generally sharper and clearer than in perchlorate solutions (Fig. 6, a-d). This corresponds

Table I. Minimum of TOC in perchloric acid solutions

No. of curve (see Fig. 5)	Potential of minimum (V)
a	0.00
b	−0.05
c	0.10
d	0.01

Table II. Minimum of TOC in sodium iodide solutions

No. of curve, see Fig. 6	Potential of minimum (V)
a	−0.28
b	−0.32
c	−0.23
d	−0.25

to the fact that in the case of specific adsorption, q_M changes more rapidly with potential. The average value of the PZC in this solution was −0.27V as seen in Table II, and shifted about 0.28V in the cathodic direction relative to the average observed in perchloric acid, in qualitative agreement with the shift expected for the PZC due to specific adsorption of anions.

It is important to note that the reproducibility in these experiments was not very high. There are many difficulties stemming from sudden, unpredictable jumps in the measured TOC which are probably caused by a change of the exact point of contact, or by a change of the surface structure of the electrodes at the point of contact under the influence of the blows. Notwithstanding this, almost all the results revealed the same general behavior; namely, a decrease in TOC when approaching the potential region where better runs yielded minima. These mechanical difficulties express themselves in the standard deviations which are rather large. The main factors which now limit the accuracy and reproducibility are mechanical, and improvements in this direction are feasible.

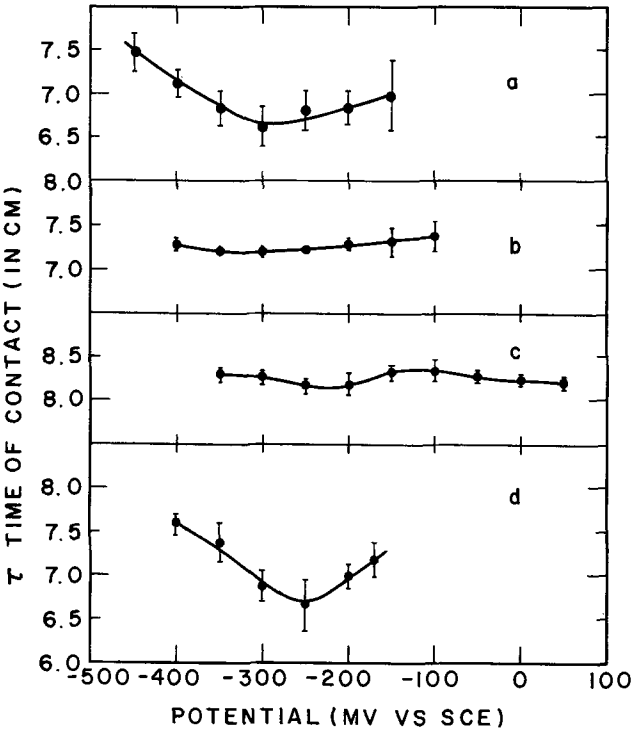

Fig. 6. TOC vs. potential curves measured in iodide solutions. Time scale: a, 380 μsec/cm; b, 150 μsec/cm; c, 100 μsec/cm; d, 400 μsec/cm.

Conclusions

It may be concluded that the time of contact between a moving and a stationary electrode can serve as a method for determining the potential of zero charge on solid electrodes. Measurements with the instrument described here are rather tedious, and limited in accuracy, but the measurement can be automated, and by further introducing small improvements in the mechanical construction, this may serve as a useful method for measurements of the PZC on solids.

Acknowledgments

The authors wish to thank Mr. Y. Drielinger for construction of the mechanical parts of the instrument and Mr. N. Tshernikovski for his assistance in the design of the electronic circuitry.

Financial support for this work by the Ford Foundation, under Grant No. 6/C/IV, is gratefully acknowledged.

ABSTRACT

Elementary processes for the reduction of thin films of silver chloride on silver have been investigated using rotating disk techniques. Experiments were carried out in 1, 2, and 4*N* solutions of KCl. The effective diffusion coefficients of the prevalent species of silver ion in 2 and 4*N* KCl are about 1.42 and 0.31 $\times$ 10^{-5} cm^2/sec, respectively. Reduction of thin AgCl films on Ag can be carried out at high rates, 100-200 mA/cm^2 at 300 mV overpotential, two orders of magnitude higher than that for the reduction of dissolved AgCl from bulk solution at 2000 rpm. A linear $i = \eta$ relationship and its independence of the state of charge suggest that liquid phase transport occurs, possibly followed by a rate controlling process of surface diffusion.

The silver/silver chloride electrode is an example of the class of battery electrodes which consists of a dispersed, sparingly soluble reactant within a continuous, conductive matrix. Electrodes of this class have a structure which is repeatedly encountered in practical batteries. Recent theoretical studies (1, 2) have indicated that a great variety of current density distributions may exist in such systems, *e.g.*, exhibiting maxima and/or minima in the discharge profile, depending on local conditions governing mass and charge transfer. Identification and evaluation of local conditions during electrode charge or discharge are consequently necessary not only for more accurate assessment of electrode behavior in terms of the developing theory, founded on firm experimental bases and corresponding closely to reality, but also to help ascertain conditions of the recently predicted current distributions. The present work on the reaction paths of reduction at silver/silver chloride electrodes was accordingly undertaken to provide information that may be of use in interpreting behavior of electrodes in this important class.

Summary of Reaction Paths

Sparingly soluble reactants.—In general, the processes governing the local mass and charge transfer can be represented by a diagram as shown schematically in Fig. 1. An element of the electrode structure is visualized as consisting of a metal which is partially covered with its salt and which is immersed in an electrolyte. The process of electrode discharge (metal ion reduction) can proceed along the paths indicated. The charge transfer process may occur at the metal/salt interface (path a), or at preferred sites of the metal/solution interface (path b). The first or film mode of transfer involves ion transport in the solid salt and is relatively simple to describe if the cation is the only species with a nonzero mobility in the solid salt phase (2). It is the second mode, the reduction of metal ions at the metal/solution interface, which may lead to unexpected distributions because of the several possible kinetic steps involved, including the dissolution rate, the diffusion flux, and various interfacial phenomena, such as adsorption, surface diffusion, and nucleation (crystallization). It is evident why a clear distinction between the numerous local complex paths is needed in order to avoid ambiguity and to allow a simple and clear development of theory.

A reasonably complete description of the isothermal operation of such electrodes, the so-called "solution-diffusion" model (1), requires the solution of five second-order partial differential equations. A considerable simplification can be made without seriously impairing the results through the use of a characteristic number, similar in many respects to the Thiele parameter (3-5). Dunning (2) showed that this characteristic number, λ^2/L^2 [N^2 in Nanis's (4) notation] contains the rate constants of a set of consecutive elementary steps, such as those shown in Fig. 1, and is of the form

$$\lambda^2/L^2 = A\kappa \sum_i k_i^{-1} \qquad [1]$$

where k_i is the rate or transport constant of the ith step, κ is the electrolyte conductivity, and A, a constant related to the electrochemical system. It is necessary to arrive experimentally at the numerical values of the coefficients in Eq. [1], or, at least to determine the relative magnitude of the steps involved in

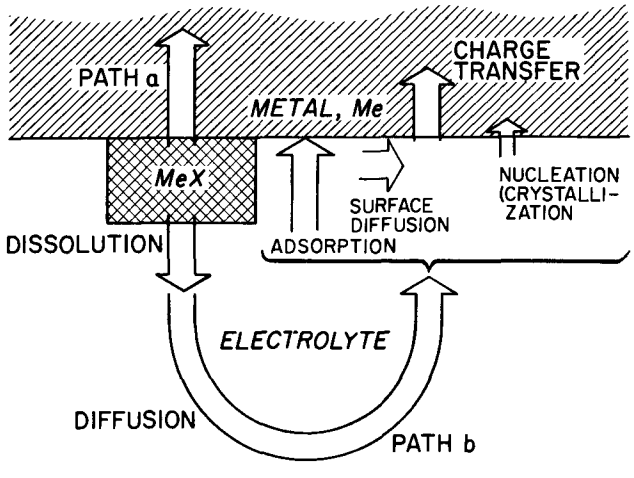

Fig. 1. Possible reaction paths for sparingly soluble reactant-conductive matrix electrode system. Path a: charge transfer at the Me/MeX interface. Path b: dissolution, diffusion, interfacial steps, and charge transfer.

Key words: porous electrodes, silver/silver chloride, batteries.

order to establish the governing or controlling steps for the "solution-diffusion" model (1, 2).

Ag/AgCl electrode.—The Ag/AgCl electrode has found practical applications in both primary and secondary batteries for operating conditions described as electrode discharge, electrode charge, or electrode cycling. Since an excess of Cl^- ions is formed on discharge while a deficiency results on charge in the vicinity of the reaction zone, variations in Cl^- ion concentration must be considered in the course of electrode analysis.

The set of elementary steps comprising the over-all discharge process, shown in Fig. 1, may also apply to the Ag/AgCl electrode. This set of events can be divided into two groups, those connected with the reduction via a solid-state path (path a) and those occurring via liquid phase (path b). Past work has been concerned primarily with the reduction of thick silver chloride films where reduction takes place at the Ag/AgCl interface, path a (6, 7). The detailed mechanism has not been definitely established although valuable microscopic observations were made by Jaenicke *et al.* (6) and Briggs and Thirsk (7), indicating that the reaction begins at the AgCl grain boundaries and the Ag/AgCl interface. Shortly after impressing external cathodic current, pores are formed in the thick layers of AgCl which are considered to be initially present in an essentially pore-free condition. Aleskovskii *et al.* (8) have recently presented evidence for the reduction of solid AgCl occurring via reduction of solvated silver ions. A quite different view, expressed by Dorosh and Galushko (9), implies that adsorbed hydrogen is required for the reduction of silver chloride on silver electrodes.

Conceivably, more than one reduction mechanism can operate, depending on experimental conditions such as thickness of the AgCl layer and its porosity, electrolyte concentration, and electrode potential. We shall only consider the reduction of films having physical dimensions on the order of 1 μm or less, *i.e.*, having physical dimensions compatible with the construction of a model AgCl electrode which has practical analogies in other battery systems and which is amenable to theoretical treatment.

Since thin silver chloride films are porous, it appears likely that the mechanism proposed by Aleskovskii *et al.* (8) should dominate the discharge process. The experimental work reported here is concerned with ascertaining the validity of this mechanism and with determining conditions under which it may operate in practical electrodes.

Experimental

In the experimental arrangement, a rotating disk silver electrode, 0.83 cm in diameter, centered in an epoxy cylinder, 2.43 cm in diameter, was employed. A Wenking, fast rise potentiostat and an Electronics Model C 612 galvanostat were used to impose the desired experimental conditions. The electrode response to a predetermined set of conditions was recorded on a Sargent MR recorder, a Tektronix Model 551 oscilloscope, or a Greibach Model 500 milliammeter, as applicable.

The electrolyte was an aqueous 1, 2, or 4*N* KCl solution prepared from triply distilled water and ACS reagent grade KCl, used as purchased. No additional purification was performed. The electrolyte in the electrolytic cell, approximately 500 cm^3 in volume, was continuously purged with nitrogen. All experiments were carried out at 22.5° ± 0.5°C in the deaerated solutions.

The sequence of experimental procedures to elucidate the reaction path and to assign relative importance of each step is suggested from an inspection of Fig. 1. The diffusion part of reaction path b was isolated and studied by observing silver ion transport from a bulk solution to the surface of the rotating disk. The bulk solutions were the various concentrations of KCl saturated with AgCl. Results were compared to experiments in which solid AgCl was previously formed on the electrode surface. The comparison provided insight into the effects of surface coverage by AgCl and dissolution kinetics limitations.

Results

Reduction of AgCl from KCl solutions.—Typical i-η curves for the reduction of silver ions from potassium chloride solutions saturated in AgCl are shown in Fig. 2. In particular, curves a and c together with curves b and d show the effect of Cl^- ion concentration and, therefore, total silver ion concentration, while curves a and b together with curves c and d indicate the influence of the speed of electrode rotation.

It is seen that in 2*N* KCl electrolyte, a diffusion-limiting current density, $i_l(2N, 100)$, is realized. As the speed of rotation is increased further, a limiting current density, $i_l(2N, 500)$, is again obtained. At still higher rotational speeds, when the current densities become appreciably higher, a deviation occurs from the usual form of the potential/current curve, namely, a relatively sharp break toward higher currents is recorded, segment AB, curve b, Fig. 2. With further increase in electrode rotation, this break is shifted to lower overpotentials, suggesting that a critical current density must be exceeded before the break occurs, about 0.5 mA/cm^2 in 2*N* KCl. The sharp increase in current density, together with the requirement of some minimum critical current density or time of electrolysis, is readily associated with the onset of an increase in electrode surface area by silver nucleation (10).

The situation remains qualitatively the same as chloride ion concentration is increased. However, the marked increase in current (electrode area) then coincided approximately with the occurrence of the mass transport limiting current density and partly obscured the plateau, Fig. 2, i_l (4*N*, 100) segments A'B' and A"B". A dense, whisker-like growth was noted on the electrode surface upon completion of the experimental run. This confirms the view that substantial increase in the electrode surface is responsible for current densities which exceed the diffusion-limiting values.

Formation of AgCl film.—Silver chloride films can be easily formed on a silver substrate in chloride solutions when an anodic (positive) overpotential is applied. The galvanostatic potential-time curve, shown in Fig. 3, exhibits typical characteristics for the formation of

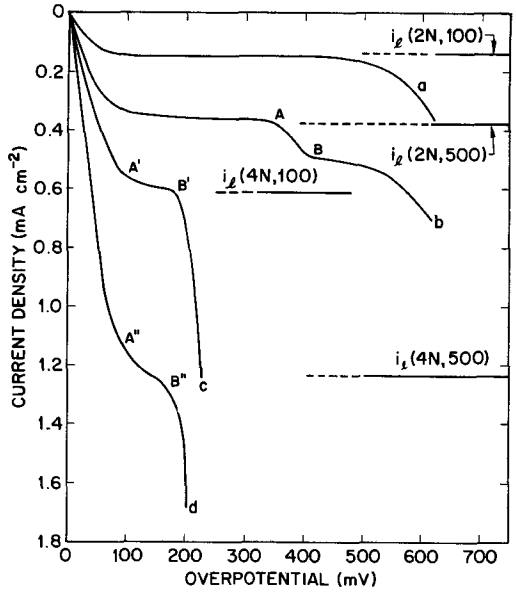

Fig. 2. Typical cathodic potential-current curves for selected chloride concentrations and electrode rotation. Curve a, 2*N* KCl + sat. AgCl, 100 rpm; curve b, 2*N* KCl + sat. AgCl, 500 rpm; curve c. 4*N* KCl + sat. AgCl, 100 rpm; and curve d, 4*N* KCl + sat. AgCl, 500 rpm.

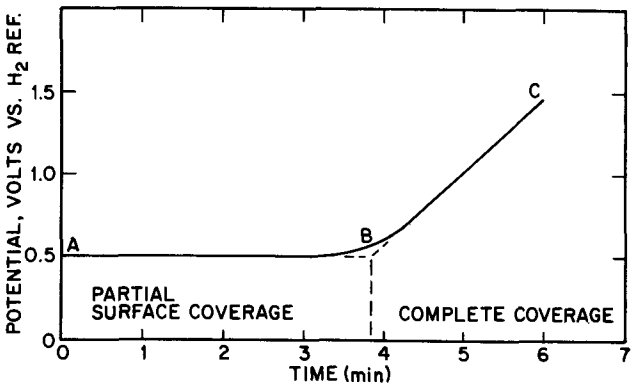

Fig. 3. Potential-time curve for galvanostatic (anodic) charging. Electrolyte, 1*N* KCl + sat. AgCl; charging current, 5.0 mA/cm².

an ion-conducting layer. The initial, flat portion, AB, corresponds to the formation of a porous film; the rising portion, BC, indicates a complete surface coverage with ohmic resistance proportional to film thickness (11), after 1.14 coulomb-cm^{-2} are passed.

The anodic films used in this investigation were formed at the rate of 0.5 μm/min, *i.e.*, at $i = 5$ mA/cm², and, assuming no porosity and 100% coulombic efficiency, their thickness did not exceed 2 μm. As a rule, thinner films were studied and, unless otherwise noted, the films were porous, being formed under conditions corresponding to the formation of fractional surface coverage, part AB, Fig. 3.

It was found that silver chloride films can also be obtained by simply immersing silver in a 1 or 2*N* potassium chloride solution saturated with silver chloride; no films were detected from 4*N* potassium chloride solutions saturated with silver chloride. Here, the mechanism of film formation is probably different than when anodic current is applied or, in the absence of applied current, when an oxidant, *e.g.*, Br_2, I_2, is added to the electrolyte (12). These solutions were purged with nitrogen to insure the absence of oxygen from the electrolytic solutions.

To differentiate between the various modes of film formation, the electroless films will be referred to as "charge accumulation" to distinguish them from the anodically formed films. The evidence presented in Fig. 4 and 5 suggests that transport of dissolved silver from bulk solution to the electrode surface governs the rate of electroless film formation. In particular,

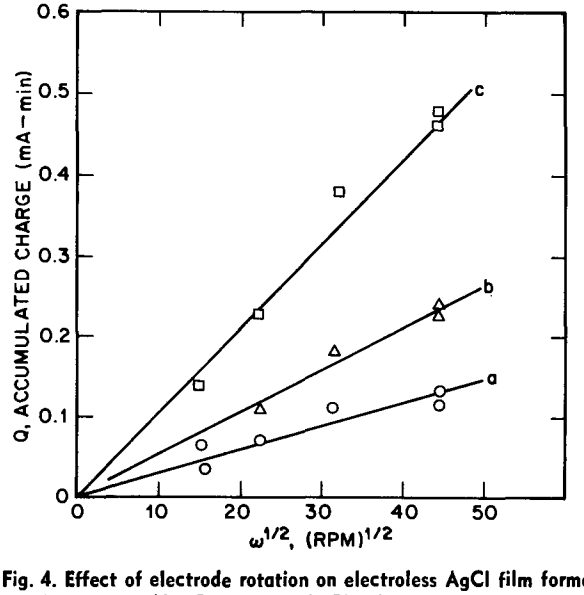

Fig. 4. Effect of electrode rotation on electroless AgCl film formation. Electrolyte, 1*N* KCl + sat. AgCl; charging time: 2, 4, and 8 min, curves a, b, and c, respectively.

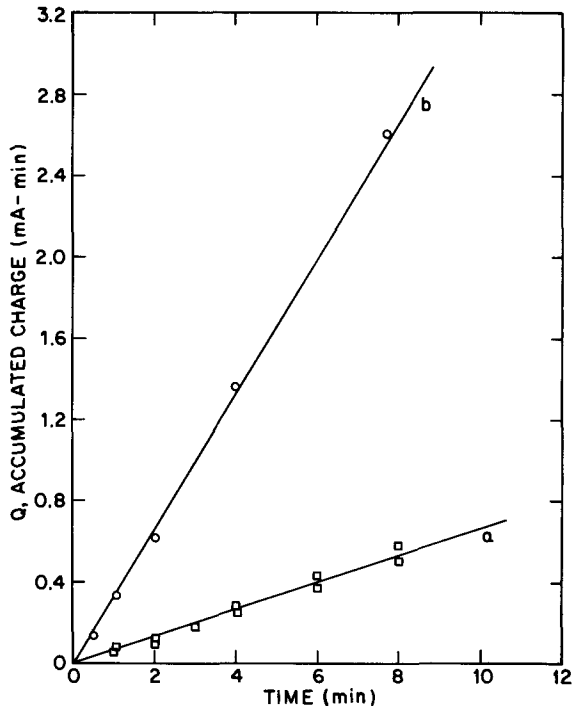

Fig. 5. Effect of chloride concentration on electroless film formation. Electrode rotation, 2000 rpm; curve a, 1*N* KCl + sat. AgCl; curve b, 2*N* KCl + sat. AgCl.

results of Fig. 4 clearly indicate the importance of diffusion in the charge accumulation, since the latter is shown to be proportional to the square root of rotational velocity. Results presented in Fig. 5 indicate that complex silver ions, $AgCl_{n+1}^{-n}$ with $n = 1, 2, 3$, are the diffusing species. This latter conclusion is reached by inspection of Table I, where it can be seen that the ratio of total silver in the form of various complexes, 5.9, agrees well with the ratio calculated on a basis of diffusional transport, 6.1, for 1 and 2*N* KCl, Fig. 5.

Reduction of thin AgCl films.—The determination of the reaction profile within a porous electrode structure requires the specification of the local current-potential relation, $i = f(\eta, c)$, where c is a relevant parameter, *e.g.*, concentration. The form of this expression can be derived if the reaction mechanism is known, alternatively, its form can be established experimentally.

Usually, steady-state values are employed to construct the current density-potential relationship. Here however, because in the course of measurements the stored active material is used up, it is advantageous to select some distinctive feature of the potentiostatically obtained *i-t* curves for the *i*-η plots.

The i-t curves.—The potentiostatically recorded *i-t* curves for the reduction of silver chloride films are shown in Fig. 6. The general shape of these curves

Table I. Concentration of $AgCl_{n+1}^{-n}$ in KCL + AgCl (sat.) solutions, 25°C

Species	Concentrations in normality, KCl		
	1*N*	2*N*	4*N*
Ag^{+}[a]	2.3×10^{-10}	1.2×10^{-10}	0.59×10^{-10}

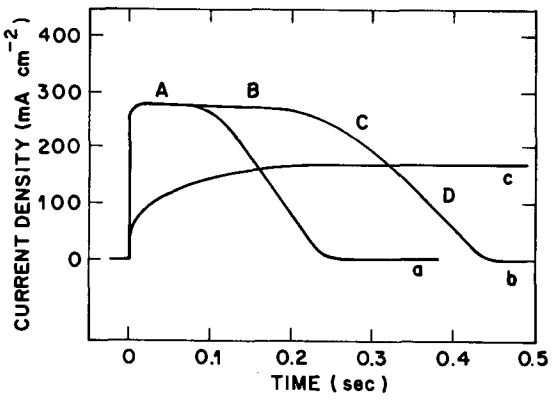

Fig. 6. Typical current-time curves for potentiostatic reduction of AgCl films. Curves a and b, thin films (thickness less than 2μm); curve c, thick films (thickness more than 2μm); electrolyte, 2*N* KCl + sat. AgCl; electrode rotation, 2000 rpm.

remained unchanged, as long as the AgCl film was porous, that is to say, as long as the charge on the electrode surface corresponded to the horizontal portion of the charging curve shown in Fig. 3.

It is seen that the *i-t* curves are characterized by a rapid attainment of a plateau, whose extent in time and height depend on the initial electrode charge and applied discharge potential, respectively. These curves, however, are not affected by externally imposed transport conditions, *i.e.*, electrode rotation. Also, their shape was essentially independent of the manner in which the film was formed, *i.e.*, whether the film was formed anodically, or the charge was accumulated by the electroless process from AgCl-saturated KCl solutions. However, if sufficiently large charge was placed on the electrode surface so that the film was no longer porous, then the *i-t* curve exhibited a gradual increase in the discharge current, cf. Fig. 6, curve c, until a more or less flat region was attained, followed by the decrease in the discharge current. Such behavior was also reported by Briggs and Thirsk (7).

The i-η curves.—The current potential plots, shown in Fig. 7 clearly display linear dependence for the plateaus of the *i-t* curves, examples of which are shown in Fig. 6. In particular, for overpotentials greater than *ca.* 50 mV they follow the relationship

$$i = a\eta + b \qquad [2]$$

with $a = 0.323$ ohm^{-1}/cm^2, $b = -7$ mA/cm^2; for 1*N* KCl, $a = 0.773$ ohm^{-1}/cm^2, $b = -45$ and -20 mA/cm^2 for 2 and 4*N* KCl, respectively.

For overpotentials less than 50 mV, higher order polynomials would have to be used to fit the experimental data. The linear dependence is maintained even when the electrode surface contains only a small fraction of the initial amount of AgCl. This situation is illustrated in Fig. 8, where the *i-η* curves for nearly discharged electrodes are shown. It is also seen that slopes of the *i-η* curves decrease with increasing electrode discharge. Thus, the form of above equation is retained, but now *a* becomes a function of the charge, *Q*, remaining on the electrode surface.

Discussion

Recently, the rotating disk electrode has been employed in the investigation of the passivation of metals (22) and also in the study of events occurring at the electrode surface during metal deposition (23). In this study, the rotating disk technique was used in an attempt to separate the elementary processes from the complex over-all reaction path. Thus, further insight into the mechanism for silver deposition and confirmation of an assumed reaction path was obtained through the analysis of the $i(\eta)$ *vs.* $\omega^{1/2}$ relationship.

Deviation from linearity occurred toward higher currents, Fig. 9, in the sense that the limiting current was exceeded many times over. This effect can be attributed to the formation of nuclei and dendritic-type growth into the boundary layer, and consequent increases in surface area of the rotating disk electrode.

Based on the limiting current plateaus in Fig. 2 and the limiting current slope shown in Fig. 9. (these are, in fact, independent data) the effective diffusion coefficient for the silver ions can be calculated by direct application of the Levich equation (17)

$$i_l = \frac{D^{2/3}\, n\mathbf{F}\, \omega^{1/2}\, c}{1.61\, \nu^{1/6}} \qquad [3]$$

The limiting currents are difficult to determine accurately because of the interference or disruption of the boundary layer due to formation, after a short time, of surface roughness or whisker-like growth. To within ±10%, the values are 1.4×10^{-5} and 0.31×10^{-5} cm^2/sec at 2 and 4*N* KCl, respectively, saturated with AgCl at 22.4°C. The large decrease in the effective diffusion coefficient is apparently due to the much larger proportion of $AgCl_4^{-3}$ present at the higher KCl concentration (see Table I).

Experimental evidence presented thus far (Fig. 2 and 9) indicates that silver diffusion from the bulk solution is the rate controlling process in depositing silver under some conditions. It also appears that nucleation phenomena must be included. The fact that the estimated mass transport limiting currents are exceeded under certain conditions must be considered in interpreting observed behavior.

The discharge current densities reported in Fig. 7 and 8, are about two orders of magnitude higher than those from AgCl-saturated KCl solutions, cf., Fig. 2. This observation suggests that the diffusion resistance for transport from the AgCl crystal to reaction sites is

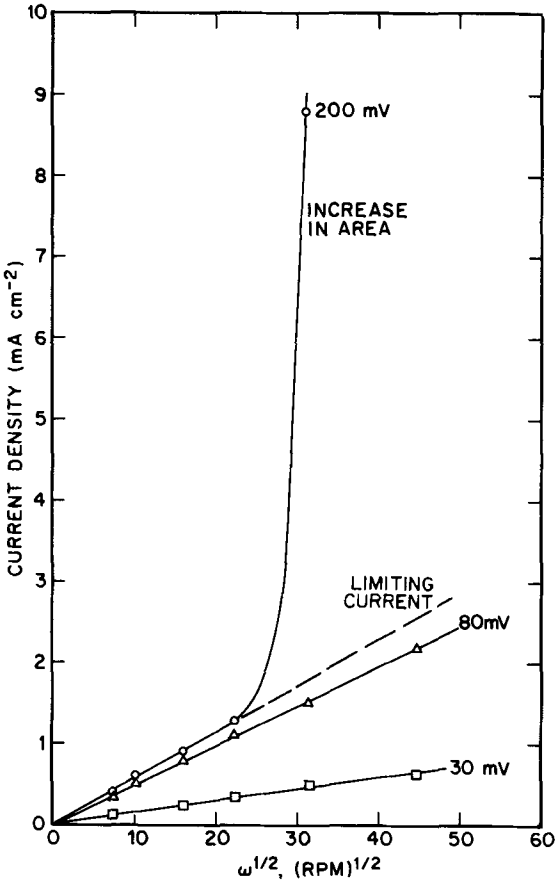

Fig. 9. Effect of overpotential and electrode rotation on cathodic current density. Electrolyte, 4*N* KCl + sat. AgCl; slope for dotted line showing diffusion transport for $D = 0.31 \times 10^{-5}$ cm^2/sec.

much less than diffusion resistance across the rotating disk boundary layer. The linear i-η relationship, Fig. 7 and 8, might be ascribed to the ohmic drop across a continuous nonporous film covering the electrode surface. This case seems unlikely because, if the ohmic-type resistance is ascribed to film thickness, resistance should decrease as the reaction progresses. Similarly, if the ohmic resistance is due to solid-state ion conductance followed by charge transfer at the metal/salt interface, the flat portion of the i-t curve (Fig. 6) could not exist, since the current density should increase as the film thickness decreases. This argument indicates that path a, Fig. 1, is unlikely under the observed conditions. Returning to path b, we consider metal deposition. In outline, the process of metal deposition consists of ions crossing the crystal-solution interface, liquid phase diffusion, surface diffusion to the growth center, and inclusion into the lattice. The linear dependence of the peak currents on overpotential (see Fig. 7) and the independence of the current peak heights (see Fig. 6) on the state of charge Q over a wide range can be explained by assuming that surface diffusion is the slow step. In surface diffusion, ions located within the Helmholtz layer will migrate to points just opposite the "growth sites" and traverse the Helmholtz layer at these points. That is to say, an inhomogeneous electric field is set up in a Helmholtz layer to guide the metal ions to their destination, resulting in a linear i-η relationship (18). The active metal area which is adjacent to the silver chloride crystals is assumed to be constant over a wide range of Q. Since the surface concentration of growth sites at the metal-liquid interface remains constant at fixed potential (19, 20), the independence of current peak heights on Q can then be accounted for.

The flat portion of the potentiostatic i-t curve, its magnitude and duration (see Fig. 6) provides additional clues for identification of the controlling steps in the reaction path. In accordance with Giles' concept (21) of the porous silver chloride film and the perimeter-advancement mechanism of reduction of thick AgCl films (6, 7), we may anticipate a movement of an Ag/AgCl perimeter during reduction and a surface diffusion to nucleation centers of fixed surface concentration. Eventually the patches of AgCl become small enough so that the electrode discharge rate drops as the resistance due to combined dissolution increases, and the resistance due to liquid phase diffusion increases. Qualitatively, these steps can explain both the linearity of the i-η curves, the shapes of the i-t curves, and the independence of the plateau current density of the i-t curves on Q.

The phenomenon of the "charge accumulation," that is, the film formation in the absence of impressed anodic potential or dissolved oxidants is of interest, both theoretical and practical.

The ratio of the rates of charge accumulation in 2 and 1*N* solutions (see Fig. 5) was found to be 5.9, which agrees rather well with the predicted ratio of 6.1 (see Table I) based on total silver content. It is to be noted that the proportions of the various species of silver complexes remain fairly constant between 1 and 2*N* KCl. However, on going to 4*N* KCl the proportion of $AgCl_4^{-3}$ increases dramatically. The self-charging characteristic was absent in 4*N* KCl saturated with AgCl. No self-charging was observed when no AgCl was present for any KCl concentration.

The explanation of the self-charging phenomenon, which may be of practical interest, is sought through an analysis of conditions and processes occurring within the metal/solution interphase (22). Consider Fig. 10 showing schematically the dynamic situation within the metal/solution interphase. The letters in parentheses in the figure indicate location of species and are as follows: (b) adsorbed, (c) the metal side of the diffusion layer, (d) the solution side of the diffusion layer, and (s) at the surface, not necessarily in the "adsorbed state."

In the absence of silver complexes in the bulk, only the equilibrium involving chloride ions exists for negatively charged species, set 1; the adsorption of water molecules is neglected and considered to be irrelevant for the present purpose. In the presence of silver complexes, however, additional competitive adsorption processes may enter, sets 2 and 3.

If the solubility of AgCl in the adsorbed state is less than in the bulk solutions, adherent "patches" of AgCl will form and at the same time produce an excess of adsorbed Cl^- ions, nCl^-. On the strength of evidence

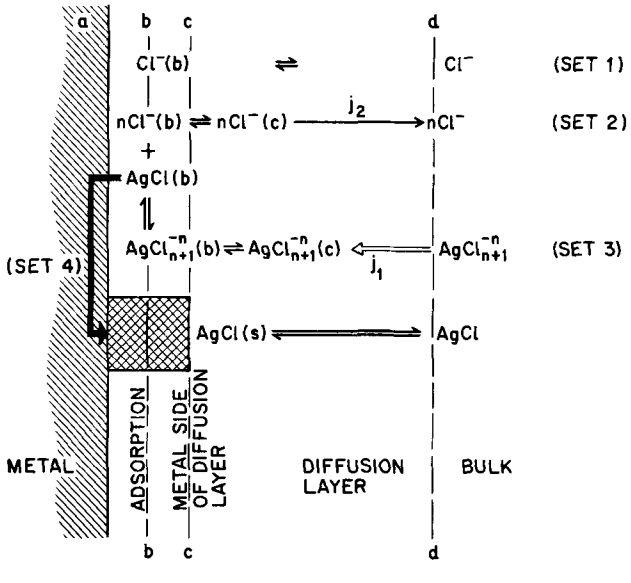

Fig. 10. Schematic representation of surface reactions and transport for saturated AgCl in KCl solutions, after Van Ryssel-berghe (22).

presented in Fig. 5, the rate of accumulation of silver chloride is governed by the transport of complex silver ions to the electrode surface, i_1, as indicated by the events of set 3, Fig. 10. The transport of charged species across any distance is equivalent to flow of current. Thus, in the absence of external current, electroneutrality condition requires a counterflow of species of the same charge or a co-current transport of species of opposite sign. The origin of these mass fluxes resides in the precipitation of silver chloride on the electrode surface. The precipitation of silver chloride from complex ions releases an excess of chloride ions, and a concentration gradient is established giving rise to the transport of Cl^- ions away from the electrode surface, j_2.

The adsorbed AgCl may form multiple layers on the solid surface, set 4, indicated as AgCl(s) which eventually attains equilibrium with bulk solution saturated with solid silver chloride. The nature of this transformation cannot be deduced on the basis of available information. Some inference, however, can be drawn from the detailed mapping of the potential within the metal/solution interphase (17).

In 4*N* KCl, saturated AgCl, the spontaneous formation of AgCl films did not occur, although the observations with 1 and 2*N* KCl, saturated AgCl, indicated that the rate of charge accumulation would increase with increase in silver complex ion concentration. The existence of an upper limit of chloride concentration for spontaneous film formation might be explained by the formation of different dominant complex species in the bulk solution and different species in the adsorbed state (see Table I and Fig. 10). The rates of electroless charge accumulation in 1 and 2*N* KCl solutions are almost constant for a period of ca. 30 min, after which they slowly diminish with time. These processes are of interest in battery technology because they may contribute to charge redistribution on cycling.

Conclusions

The identification and more precise description of some of the elementary processes occurring in silver/silver chloride porous electrodes have been investigated. The principal conclusions of this work are as follows:

1. The effective diffusion coefficient of silver ion in potassium chloride solution depends on the chloride ion concentration and is estimated to be 1.42 and 0.31 $\times$ 10^{-5} cm^2/sec at 22.4°C in 2 and 4*N* KCl, respectively.

2. The controlling step in the reduction of anodically formed AgCl films on Ag/AgCl electrodes in 2 and 4*N* KCl can be explained by surface diffusion to growth sites on the silver surface except when the state of surface charge is very small when the area of the silver chloride crystallites is small so that dissolution of AgCl becomes controlling.

3. Over a wide range of the state of charge, the local transfer current density is independent of the state of charge and is linearly dependent on local overpotential for the Ag/AgCl electrode.

4. At 1 and 2*N* KCl, AgCl from a saturated AgCl solution spontaneously precipitates on a silver surface. This did not occur in 4*N* KCl. This phenomenon may be of importance in redistribution of AgCl in AgCl/Ag porous electrodes on cycling.

5. The current densities possible with silver chloride crystallites on a silver electrode surface are much higher than when the limiting process is liquid phase transport from bulk solution to a rotating disk up to 2000 rpm, and suggest that high current densities are inherently possible in porous electrode structures because of the short diffusion paths.

6. Complete surface coverage by silver chloride during anodic oxidation in an aqueous solution of potassium chloride saturated with silver chloride occurred after the passage of 19 $\times$ 10^{-3} coulombs/cm. The onset of rapidly increasing polarization linearly with time, *i.e.*, with charge passed, is associated with this event.

Free Energy of Formation of Bi_2O_3, Sb_2O_3, and TeO_2 from EMF Measurements

D. Chatterji*,[1] and J. V. Smith

Metallurgy and Ceramics Laboratory, Aerospace Research Laboratories, Wright-Patterson AFB, Ohio 45433

ABSTRACT

The solid electrolyte cell technique was employed for the direct determination of the free energy of formation of Bi_2O_3, Sb_2O_3, and TeO_2 at temperatures above 520°C. The high-temperature free energy data obtained in the present investigation were used to calculate the thermodynamic properties for the three oxides at 298°K. The calculations depended in part on the accuracy of the published thermochemical data.

In recent years, considerable effort has been directed toward developing materials for thermoelectric devices. Alloys prepared from the tellurides of bismuth and antimony have been found to be promising for such applications. Therefore a research program has been initiated to determine the thermodynamic properties of Bi-Te and Sb-Te alloys using the solid oxide galvanic cell technique of Kiukkola and Wagner (1). The technique demands accurate free energy of formation data for Bi_2O_3, Sb_2O_3, and TeO_2. A literature search revealed that reliable values for thermodynamic properties, especially free energy of formation, are not available for these oxides. Therefore, we have used the cell technique for direct determination of the free energy change, $\Delta G°$, for the following formation reactions over the temperature ranges indicated:

$$520°\text{-}820°: \quad 2Bi\ (c) + 3/2\ O_2\ (g) = Bi_2O_3\ (c) \qquad [a]$$

$$520°\text{-}740°: \quad 2Sb\ (c) + 3/2\ O_2\ (g) = Sb_2O_3\ (c) \qquad [b]$$

$$520°\text{-}720°: \quad Te\ (c) + O_2\ (g) = TeO_2\ (c) \qquad [c]$$

Literature Review

Rossini *et al.* (2) critically reviewed all papers published before 1952 on thermodynamic properties of Bi_2O_3, Sb_2O_3, and TeO_2, and included the best available data in their compilation. The present discussion will be, therefore, restricted mainly to the papers published in the last two decades. However, some of the earlier work reviewd by Rossini *et al.* will be mentioned whenever required for the sake of comparison. Table I presents the data selected by Rossini and coworkers in a tabular form. It also includes the results of all later investigations to be discussed below.

Bi_2O_3.—The experimental data on the Bi-O system have been compiled by Hansen (3), Elliot (4), and Shunk (5). Two stable polymorphs of Bi_2O_3 are reported to exist; the low-temperature form, α-Bi_2O_3 transforms to the high-temperature form, δ-Bi_2O_3 at about 720°C. The melting point of δ-Bi_2O_3 is 825°C.

Mah (6) has determined the heat of formation of Bi_2O_3 by combustion calorimetry. He has also calculated the entropy and free energy of formation.

Sb_2O_3.—Elliot (4) and Shunk (5) have reviewed the available thermodynamic information on the Sb-O

system. Solid Sb_2O_3 occurs in two modifications, and the transformation temperature is reported to be 570°C. Sb_2O_3 melts at 655°C.

Using combustion calorimetry, Mah (7) has determined the heat of formation of Sb_2O_3, and calculated the entropy and free energy of formation. Gorgoraki and Tarasov (8) used adiabatic calorimetry to obtain heat capacity and enthalpy of Sb_2O_3. They calculated $S°_{298}$ values for the two modifications by graphical integration and extrapolation of their data to 0°K.

TeO_2.—The Te-O system has been reviewed by Elliot (4) and Shunk (5). TeO_2 prepared by precipitation from aqueous solution or oxidation of tellurium metal is reported to be tetragonal. The melting point of TeO_2 is 733°C.

Mezaki and Margrave (9) measured the heat contents of TeO_2 in a drop-type calorimeter over 446°-1146°K (173°-873°C). From an approximate fitting of the high-temperature heat content data with a Debye equation, they estimated $S°_{298}$ for TeO_2.

Schneider and Zintl (10) determined the heat of formation of TeO_2 by combustion of elemental tellurium in a bomb calorimeter. Gadzhiev and Sharifov (11) used the same technique but obtained a different $\Delta H°_{298}$ value (see Table I).

One of the earliest investigations of thermodynamic properties of TeO_2 deserves special attention. Schuhmann (12) in 1925 measured the emf of the cell

$$Te\text{-}TeO_2|HClO_4, H_2O|H_2, Pt$$

at 25° and 45°C, and directly measured the free energy of formation. He also estimated the heat of formation from the temperature dependence of free energy. This is the only direct free energy measurement to date for any of the three oxides under discussion.

Experimental Details

In the present investigation, the open-circuit emf of the following oxygen concentration cells were measured as a function of temperature

$$W, Bi\text{-}Bi_2O_3|0.85\ ZrO_2 + 0.15\ CaO|Air, Pt \quad [I]$$

$$W, Sb\text{-}Sb_2O_3|0.85\ ZrO_2 + 0.15\ CaO|Air, Pt \quad [IIa]$$

$$C, Sb\text{-}Sb_2O_3|0.85\ ZrO_2 + 0.15\ CaO|Air, Pt \quad [IIb]$$

$$W, Te\text{-}TeO_2|0.85\ ZrO_2 + 0.15\ CaO|Air, Pt \quad [III]$$

For cells of these types, the open-circuit emf (after necessary thermal emf corrections) is related to the equilibrium oxygen partial pressures at the two electrodes by the expression

$$E = \frac{RT}{4F} \ln [P'_{O_2}/P''_{O_2}];\ P'_{O_2} > P''_{O_2}$$

where P'_{O_2} = oxygen pressure at the reference electrode (air) = 0.21 atm; P''_{O_2} = oxygen pressure at the metal-metal oxide electrode for the experimental temperature, T; and all of the other symbols have their usual meaning.

Since the oxygen partial pressure for a metal-metal oxide equilibrium is related to the free energy of formation of the oxide, we obtain the following emf-free energy relations for the cells under consideration

$$\Delta G°_{Bi_2O_3} = -6FE_I + 1.5\ RT \ln (0.21) \quad [1]$$

$$\Delta G°_{Sb_2O_3} = -6FE_{II} + 1.5\ RT \ln (0.21) \quad [2]$$

$$\Delta G°_{TeO_2} = -4FE_{III} + RT \ln (0.21) \quad [3]$$

where the subscripts in $\Delta G°$ refer to the reactions [*a*], [*b*], and [*c*], respectively, and the subscripts in E refer to the cells [I], [IIa-IIb], and [III], respectively.

The cell assemblies used in the four experiments were similar. Figure 1 shows the main features of a typical set-up. The entire assembly was placed inside a quartz protection tube. The open end of the calcia-stabilized zirconia electrolyte tube was sealed to a vacuum manifold with epoxy. One end of a short platinum lead wire was brought out through the epoxy seal, and the other end was spot-welded to a tungsten lead wire (cells [I], [IIa], and [III]) or force-fitted to a graphite rod (cell [IIb]). For cell [I], the tungsten lead wire could be allowed to remain in contact with the $Bi\text{-}Bi_2O_3$ electrode for the entire duration of the experiment since no reaction between tungsten and bismuth was observed. This conclusion could be deduced from the fact that identical emf values were observed during repeated heating and cooling cycles.

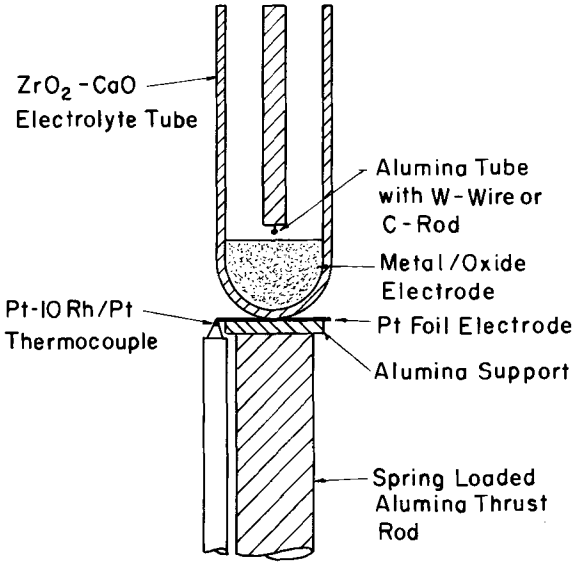

Fig. 1. Cell assembly (schematic)

Liquid antimony metal was found to slowly react with tungsten. It was therefore necessary to avoid prolonged contact between these two metals, or to seek a new lead element that would not react with liquid antimony. A minor modification in the cell design allowed us to raise or lower the tungsten lead wire into the $Sb\text{-}Sb_2O_3$ electrode only during emf measurements. This was accomplished by attaching a piece of soft iron to the tungsten wire, and moving the iron piece with an externally located magnet. This procedure prevented any appreciable tungsten dissolution from taking place. The cell where this technique was adopted is designated cell [IIa]. An alternative cell, denoted as cell [IIb], made use of a graphite rod as the lead element. The graphite rod was allowed to remain in contact with the molten electrode. As will be discussed later, the results obtained with cells [IIa] and [IIb] were consistent.

The reaction between tungsten and liquid tellurium was found to be rapid in agreement with earlier observations (13). Attempts to use graphite lead element were not successful since it quickly reduced TeO_2 to the liquid metal. It was, therefore, necessary to lower the tungsten lead wire into the electrode melt only when an emf measurement was desired, as in cell [IIa]. This procedure kept the electrode contamination to a minimum; the tungsten-content of the $Te\text{-}TeO_2$ electrode at the end of the experiment was found to be less than 30 ppm. The error in the free energy measurements due to electrode contamination is estimated to be less than 10 cal/mole.

In a typical experiment, the cell was placed in a wire-wound furnace at room temperature and assembled under a fume hood because of the toxic nature of the fumes involved in some of these systems. The metal-metal oxide electrodes were prepared by mixing the metal granules with the oxide powder in about 5:1 volume ratio. The mixture was then placed in the electrolyte tube and the tube closed off. The system was slowly heated to above 500°C, and the emf measurement was started. A DORIC integrating-type digital voltmeter (Model DS-100) was used to measure the

Table II. Details of electrode materials

open-circuit cell emf to a precision of 0.1 mV. The high input impedance of this voltmeter prevented loading of the cell and allowed reversible measurements. On reaching the desired temperature, the cell emf assumed a stable value within about half an hour. The emf remained constant to within ±1 mV for 24 hr or longer if allowed. The reversibility of the measured emf was checked frequently by shorting the cell for about 10 sec, and then allowing the emf to return to a stable value. The cell emf always returned to the original value within a minute. Once a constant cell emf was obtained for a controlled temperature, the set point of the controller (Tem-Pres Research Inc., Model CP-1V-M) was changed to a new value and the sequence of measurements was repeated. In the present investigation, the cell temperatures could be controlled to within ±2°C.

A typical experiment consisted of many heating and cooling schedules, and lasted from one to two weeks. The electrolyte tubes did not crack on thermal cyclings of this type.

The 15 m/o (mole per cent) CaO-stabilized ZrO_2 tubes were purchased from Zirconium Corporation of America. The tubes were 12 in. long with an outer diameter of 1/2 in. and wall thickness of 1/16 in. and were certified to be helium leak tested to 5×10^{-7} or less standard cubic centimeter per second at room temperature by the manufacturer. Tubes of this type from the same manufacturer have been shown to be acceptable as electrolyte materials for oxygen concentration cells (14).

Table II lists the electrode materials used in this study, their sources, and purity levels claimed by the suppliers.

Since the cells used in the present work employed dissimilar lead elements, the observed emf data had to be corrected for the thermal emf generated between tungsten and platinum (cells [I], [IIa], and [III]) or carbon and platinum (cell [IIb]). Couples of these types were, therefore, prepared and their thermal emf measured over wide temperature ranges. The system used to measure the thermal emf for the W-Pt couple is schematically shown in Fig. 2. Only minor modifications were necessary for the C-Pt couple. Thermal emf experiments were conducted in helium atmospheres to prevent the non-noble element from oxidation.

Results and Discussion

Figures 3, 4, and 5 present the emf-temperature data from cells [I], [IIa-IIb], and [III], respectively. Within the limits of experimental uncertainties, the emf-temperature plots are linear. It should be pointed out that for cells [I] and [III], the sample electrodes consisted of a liquid metal (Bi or Te) and a solid oxide (Bi_2O_3 or TeO_2). No phase transformations involving large heat effects (such as fusion) occurred in these cells over the temperature ranges selected. Linear emf-temperature plots are therefore expected for these cells. On the other hand, for cells [IIa] and [IIb], the sample electrode consisted of Sb(s) and Sb_2O_3(s) below 631°C, Sb(l) and Sb_2O_3(s) below 655°C but above 631°C, and Sb(l) and Sb_2O_3(l) above 655°C. The emf-temperature plots for these cells are thus expected to consist of three linear segments. However, the heat effects due to the melting of the metal and of the oxide tend to cancel each other. Moreover, the melting points of Sb and Sb_2O_3 are quite close (within 25°C). The emf-temperature plots for cells [IIa] and [IIb] thus appear as single straight lines over the entire temperature range.

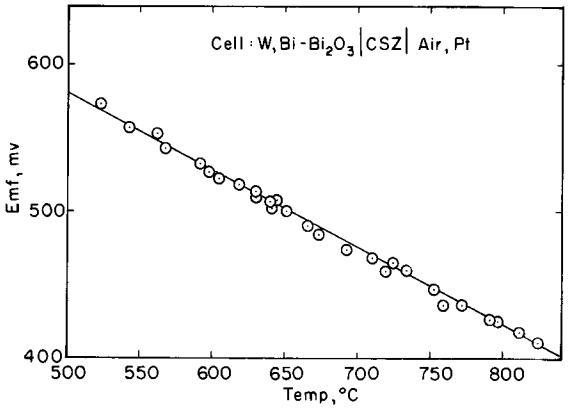

Fig. 3. Emf-temperature data from cell [I]

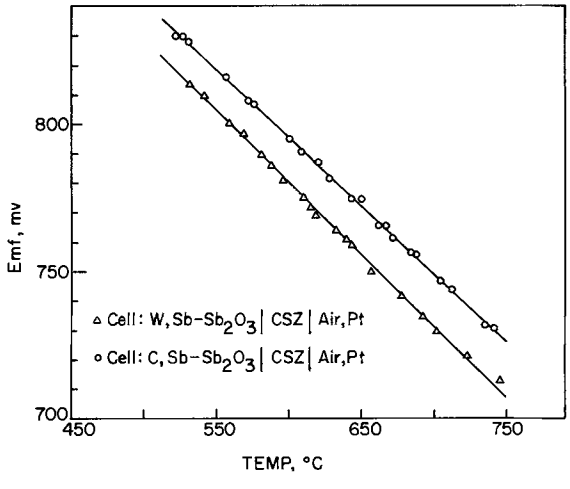

Fig. 4. Emf-temperature data from cell [11a] and cell [11b]. The difference in emf of the two cells is due to different lead wire combinations (W-Pt and C-Pt).

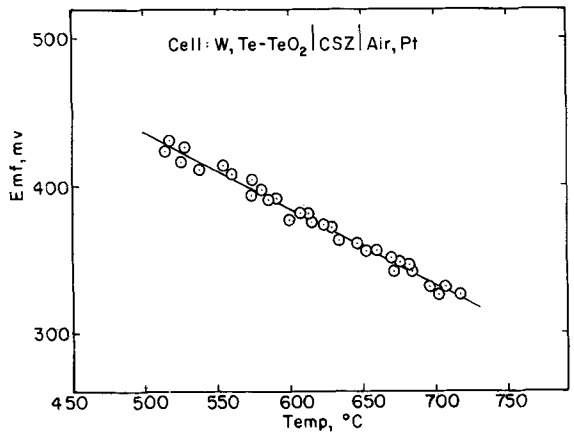

Fig. 5. Emf-temperature data from cell[III]

As mentioned earlier, the data presented in Fig. 3, 4, and 5 had to be corrected for thermal emf's due to dissimilar lead elements. The results of our thermal emf measurements on W-Pt and C-Pt couples are shown in Fig. 6 and 7, respectively. Table III presents the emf-temperature relationships for the cells under consideration before and after thermal emf corrections. It is obvious from Table III that the accuracy of the present emf measurements was high. The consistency between the cell [IIa] and cell [IIb] data is also good; at 900°K, the two sets of measurements agree within ±3 mV after necessary thermal emf corrections.

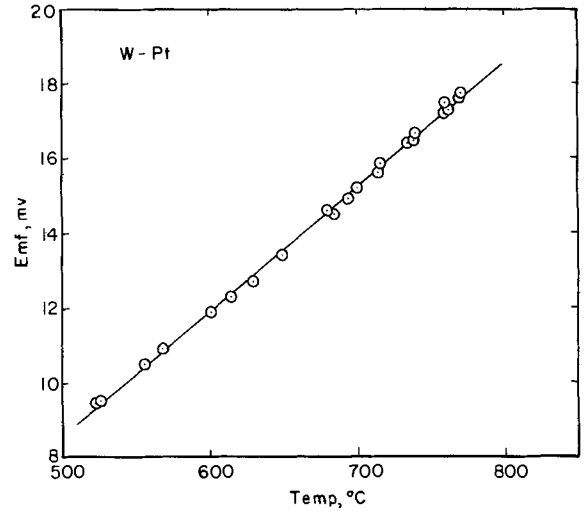

Fig. 6. Thermal emf of W-Pt couple as a function of temperature

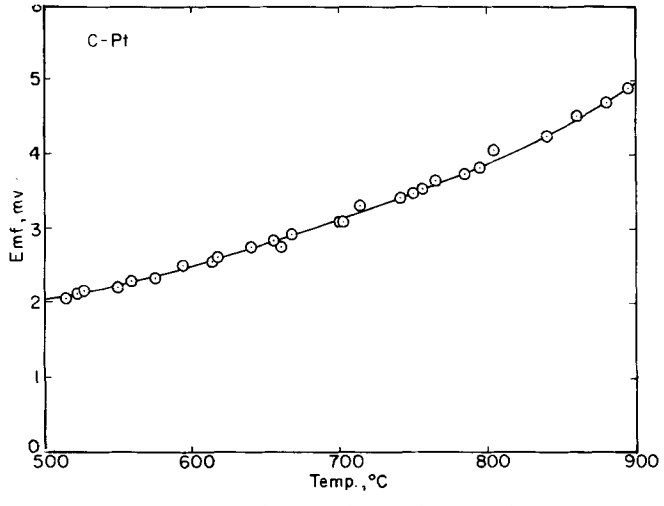

Fig. 7. Thermal emf of C-Pt couple as a function of temperature

Table III. EMF-temperature relationships for the cells under investigation

Cell No.	E (mV) = A-BT (K°) Emf data before thermal emf correction	Standard deviation	Emf data after thermal emf correction	Standard deviation
[I]	E = 989.0 − 0.529T	±0.6	E = 967.6 − 0.492T	±1.0
[IIa]	E = 1201.2 − 0.482T	±0.4	E = 1179.8 − 0.445T*	±0.5
[IIb]	E = 1197.9 − 0.461T	±0.3	E = 1195.6 − 0.455T*	±0.5
[III]	E = 835.7 − 0.517T	±0.7	E = 814.3 − 0.480T	±1.0

* E_{II} = 1/2 [$E_{[IIa]}$ + $E_{[IIb]}$] = 1187.7 − 0.450T ± 3.0 mV.

The corrected emf-temperature relationships given in Table III were used to obtain the following free energy-temperature expressions for the formation reactions [a], [b], and [c]

$$\Delta G^\circ_{Bi_2O_3} = -133{,}890 + 63.43T \pm 140 \text{ cal/mole}$$

$$\Delta G^\circ_{Sb_2O_3} = -164{,}340 + 57.62T \pm 400 \text{ cal/mole}$$

$$\Delta G^\circ_{TeO_2} = -75{,}120 + 41.18T \pm 100 \text{ cal/mole}$$

When a linear relation is found to exist between the free energy of reaction and the temperature, the slope of the line represents the entropy and the intercept the enthalpy of the reaction. The above equations, therefore, not only give reliable free energy values, but also offer working values for the enthalpy and entropy of formation for the three reactions at high temperatures.

It is possible to calculate standard thermodynamic properties for the three oxides under discussion from our high-temperature data. Such calculations are useful in providing a common basis for comparing results from different investigations. For such calculations to be of any real value, it is imperative that accurate heat capacity and heat of fusion data be available for the metals and oxides being studied. Unfortunately, only estimated heat capacity and heat of fusion values are available for some of our materials (15). Nevertheless, calculations were carried out for the three oxides taking all heat effects into account. Table IV presents the results of our extrapolation from the mean experimental temperatures. A comparison of our results with the available literature data (Table I) reveals large differences. The differences are too large to be totally attributed to the inaccuracy of published thermochemical data. Our calculated results are probably less accurate than the direct calorimetric measurements of Mah (6, 7), since our method is an indirect one. The high-temperature free energy values, however, are the first reported values obtained from direct experimental data.

Summary

The solid electrolyte cell technique has been successfully employed for the direct determination of the free energy of formation of Bi_2O_3, Sb_2O_3, and TeO_2 at temperatures above 520°C. Since the cells consisted of liquid metal-oxide electrodes, platinum lead wire was found unsuitable. The problem of electrode-lead wire interaction and methods used to minimize it have been discussed.

Table IV. Thermodynamic properties of Bi_2O_3, Sb_2O_3, and TeO_2 from the present investigation*

Property	Bi_2O_3 (s)	Sb_2O_3 (s)	TeO_2 (s)
ΔH°_{298}, kcal/mole	−131.6 ± 0.5	−158.1 ± 1.0	−72.0 ± 0.5
ΔS°_{298}, eu	−59.2 ± 2.0	−52.8 ± 3.0	−37.5 ± 3.0
S°_{298}, eu	41.4 ± 2.0	42.5 ± 3.0	23.4 ± 2.0
ΔG°_{298}, kcal/mole	−144.0 ± 1.0	−142.4 ± 2.0	−60.8 ± 1.0

* Heat capacity, heat of fusion, and standard entropy values needed in the calculations were obtained from the tables given by Kubaschewski *et al.* (15).

The high-temperature free energy data obtained in the present investigation were used to calculate the thermodynamic properties for the three oxides at 298°K. The calculations depended in part on the accuracy of the published thermochemicl data.

Formation and Surface Characteristics of Hydrous Metal Oxide Sols

Egon Matijević, Alexander Bell, Roger Brace, and Peter McFadyen

Institute of Colloid and Surface Science and Department of Chemistry, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

Methods for preparation of chromium(III), aluminum, and zirconium(IV) hydrous oxide sols consisting of spherical particles, and of copper(I) oxide sols of cubic particles, have been described. Under certain experimental conditions the particle size distribution is very narrow. Various properties of these sols are described and the mechanism of their formation and particle growth discussed.

Precipitation of metal hydroxides or, more appropriately, of metal hydrous oxides, is of continuing interest in various applications such as corrosion, water pollution, and catalysis. Although numerous studies have been initiated throughout the years attempting to elucidate the chemistry and physics of the formation of these systems, the results have been largely qualitative owing to the complex kinetics and equilibria involved. Numerous difficulties are encountered in the investigations of hydrous metal oxide precipitations. For example, the solids formed are generally amorphous; additional chemical reactions (hydrolysis, condensation, complexation, etc.) occur which may affect nucleation and particle growth; the extent of precipitation is highly dependent upon concentration, pH, temperature, and time (1). Furthermore, the particles produced are mostly of irregular shape and of broad size distribution. This makes it very difficult to characterize, on a quantitative basis, the particle formation, growth, surface properties, and sol stability (when the hydrous metal oxides appear in the colloidal state).

Ideally, the particles should be of simple shape (*e.g.*, spherical, cubic), of narrow size distribution ("monodispersed"), and stable enough so that their composition and properties, such as surface charge, might readily be determined. In addition, the electrolyte environment from which the particles are formed or in which they are suspended often contains complex solute species. These must be sufficiently inert (kinetically) to make their separation and identification possible, often via a variety of suitable analytical techniques (2).

Despite innumerable studies dealing with precipitation of various hydrous metal oxides, the methods for generation of hydrosols of these materials, uniform in size and shape, have only recently been described. "Monodispersed" chromium hydroxide sols consisting of spherical particles (3-5) and copper(I) oxide sols consisting of cubic particles (6) can now be reproducibly prepared over a range of modal size parameters. In addition to this work the preparation of "monodispersed" aluminum hydrous oxide sols having spherical particles will be described for the first time. Finally, preliminary work shows that zirconium hydrous oxide sols of spherical particles can also be produced. All these systems were obtained by aging of salt solutions of the corresponding metal ions at elevated temperatures in the presence of certain complexing anions. Many of the sols are of sufficient uniformity to show higher order Tyndall spectra (HOTS), which in the case of the chromium and aluminum hydrous oxides, permits a particle size distribution anal-

Key words: chronomal, electrophoresis, monodispersed sols, particle growth, penetrating anions, precipitation.

ysis and an estimation of the number concentration *in situ* from light-scattering measurements.

As well as describing the methods for the preparation of these "monodispersed" metal hydrous oxide sols and some of their characteristics, we will report here in greater detail recent studies on the kinetics of the formation and growth of the solids from chromium salt solutions. These shed some light on the mechanism of the hydrous metal oxide particle formation which has been hitherto very poorly understood.

Preparation of Metal Hydrous Oxide Sols of Narrow Size Distribution

Materials.—All chemicals were reagent grade and used without further purification. Generally, the stock solutions were filtered through Millipore filters (for Cr salt solutions, 1.2 μm; and for copper and aluminum salt solutions 0.2 μm), although for experiments involving Cr(III) solutes, filtration does not appear to be necessary to ensure reproducibility. An assay of all stock solutions was made by means of standard analytical methods. Water was distilled twice, the second time in an all glass apparatus. Pyrex culture tubes with Teflon-lined, screw-type caps were employed as reaction vessels.

Techniques.—Light-scattering data were obtained in a Brice-Phoenix photometer Model 2000. When possible, the particle size distribution was determined *in situ* from the polarization ratios of the scattered light using a method described earlier (7).

The histograms of all sols having particles of uniform shape and narrow size distribution were obtained from electron microscopy. Samples were prepared by placing a drop of the suspension on a collodion-covered copper grid and removing the liquid with a micropipette after several minutes. It could be shown that the size distributions determined by electron microscopy and by light scattering (in cases in which the latter technique was applicable) were in excellent agreement (8).

The change in light-scattering intensities was also employed to determine the precipitation boundaries. In the latter case, in a series of systems the concentration of the metal salt was kept constant whereas the *p*H was changed systematically in small increments. A plot of scattering intensity *vs.* *p*H showed a sharp increase at the *p*H at which solid phase first formed. The critical *p*H of precipitation for a given metal ion concentration was determined by extrapolation of the line of steepest slope to that of the homogeneous solutions.

Electrophoretic mobilities were measured in a microelectrophoresis apparatus with a van Gils cell.

The concentration of chromium in the dispersion medium after the removal of sol particles by filtration was determined by atomic absorption spectroscopy in a blue flame (9). Samples heated for 1 hr (and filtered) were used as standards.

All *p*H adjustments were made by means of glass-calomel combination electrodes. Where necessary the *p*H was measured at higher temperatures (75°C) and the combination electrode (Beckman 39500) was appropriately standardized with a KH-phthalate buffer.

Procedures.—The chemical composition, the morphological characteristics, and the surface properties of precipitated metal hydrous oxides depend on a number of experimental parameters, the most important among these being the concentration of the metal salt, the presence of complexing species (particularly of certain anions), *p*H, temperature, time of aging, method of mixing, and in some instances, the history of the solution preparation.

To illustrate some of these effects, with special reference to particle size and shape of the precipitated metal hydrous oxides, Fig. 1 gives a copper(II) sulfate concentration-*p*H precipitation domain (10). The systems on the left and right were aged for 18 hr at 25°C and 75°C, respectively. In region I (Fig. 1) solutions remain homogeneous; in region II (Fig. 1) a pale blue precipitate is formed consisting of the basic copper sulfate, $Cu_4(OH)_6SO_4$, whereas in region III (Fig. 1) the red-brown particles are tenorite, CuO. Dashed lines in Fig. 1 show calculated boundaries between regions I/II and II/III using corresponding equilibrium constants given by Barton and Bethke (11). The experimental and calculated boundaries for systems aged at 75°C (and then cooled to 25°C) are in reasonably good agreement whereas no such correlation was found for the systems aged at 25°C. Obviously, in the latter case the aging period was too short for the equilibrium to be established.

Also included in the various regions of the precipitation domain are the electron micrographs of the corresponding sols. The particle sizes and shapes change considerably with the concentration of the precipitating components and the temperature of aging. Quite uniform, oval-shaped particles were obtained by aging at 75°C solutions containing $CuSO_4$ and NaOH in the molar ratio of 1:2, these particles are shown in the electron micrograph at the extreme right of Fig. 1. They were not observed when a similar procedure was followed with $Cu(NO_3)_2$ in place of the copper(II) sulfate. However, using copper(II) nitrate solution to which sodium sulfate had been added, such that the sulfate concentration was equal to that of Cu^{2+}, very similar particles were again formed, strongly pointing to the role SO_4^{2-} ions play in their production.

Needless to say the precipitation domains obtained with solutions of salts of other metals show different boundaries because in each case the composition of the solid separated, and the composition of the solute complexes in the dispersion medium may vary considerably. Also the rates of formation and thermodynamic properties will differ.

The involved nature of metal hydrous oxide precipitation processes is most likely the reason that "monodispersed" sols containing particles of simple shapes (*i.e.*, spheres or cubes) have been reported only recently (3-6). It is therefore, even more remarkable that we have succeeded in the preparation of such sols of several metals. Significantly, certain conditions resulting in systems of narrow size distribution are similar in all cases. The metal salt solutions from which the sols form must be hydrolyzed, usually at elevated temperatures, for extended periods of time. More importantly these sols are produced only in the presence of certain coordinating or "penetrating" ions. In this regard, sulfate ions seem to play a special role, although preparations of monodispersed chromium hydroxide sols were successful also in the presence of phosphate ions (4). This would indicate that a similar mechanism underlies the formation of hydrous oxides of different metals, which, if resolved, would help in understanding many phenomena involving these materials.

Essential procedures for the preparation of metal hydrous oxide sols of narrow size distribution are given below.

Chromium(III) hydrous oxide sols were obtained if solutions of chrom alum or solutions containing chromium(III) nitrate and alkali sulfate were kept at 75.0° ±0.3°C for an extended period of time (from several hours to several days), after which the sample tubes were immersed in ice water and cooled to room temperature (3-5). An electron micrograph of such a sol is given in Fig. 2a. Uniform spherical particles could also be formed directly in the electron microscope if solutions of chrom alum were exposed to the electron beam in a "wet cell" (8, 12).

Similarly, aluminum hydrous oxide sols consisting of spherical particles uniform in size form upon aging at elevated temperatures of aluminum salt solutions. The latter contain either aluminum sulfate or aluminum nitrate to which sodium sulfate was added in concentrations approximating the aluminum sulfate

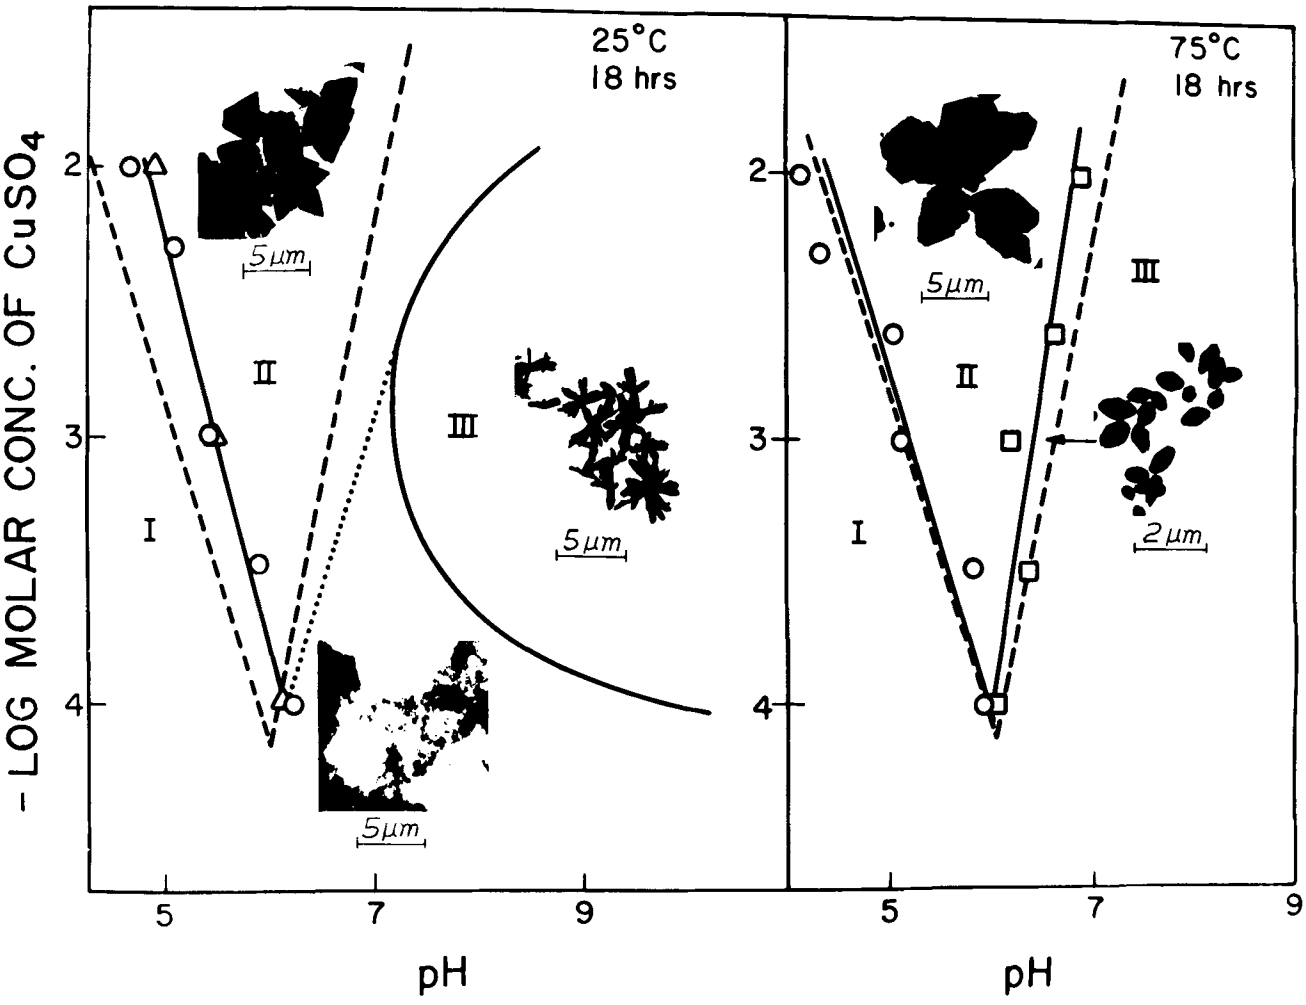

Fig. 1. Precipitation domains of copper sulfate as a function of pH for systems aged for 18 hr at 25°C (left) and at 75°C (right). Region I, homogeneous solution; region II, blue precipitate; region III, red-brown precipitate. Solid lines indicate boundaries between the various regions, the individual experimental data points being represented by the circle and the box symbols. (The triangles indicate data obtained with the ion-specific electrode.) The theoretical boundaries are indicated by the dashed lines; the dotted line indicates the boundary between the regions of large and small particles within region II at 25°C. The electron micrographs show particles typical of those formed thoughout the corresponding region except for the one at the extreme right, for which the preparation conditions are indicated by the arrow.

stoichiometry. The major difference as compared to the chromium hydrous oxides is in regard to the temperature of aging, which for aluminum salt solutions had to be in excess of ~90°C. Also in the latter case the rate of heating the solutions to the equilibrium temperature seemed to be important for the production of monodispersed sols. In the present work the rate of temperature rise was ~0.5°C/min during the first 2-3 hr of aging. In contrast, chromium salt solution, if chosen in proper concentrations, gave monodispersed sols regardless of how quickly they reached thermal equilibrium. An example of the aluminum hydrous oxide sols prepared as described above is shown in Fig. 2b.

The latest experiments indicate that similar sols can be obtained by hydrolysis of aluminum alkoxides at elevated temperatures if the pH and the sulfate concentrations are carefully adjusted.

Zirconium(IV) sulfate solutions on aging at 75°C also give sols containing spherical particles although in this case only sols of rather broad distribution have been obtained so far (Fig. 2c).

In all preceding cases the sols consisted of spherical particles. All attempts to produce similar copper hydrous oxide sols failed. However, it was possible to prepare copper(I) oxide hydrosols having cubic particles of narrow size distribution. Again the presence of complexing solutes seemed to be essential as such sols were obtained by reduction of an alkaline solution of copper tartrate complex (diluted Fehling's solution) with glucose (10). This reaction does not proceed stoichiometrically due to the changes in the sugar molecule caused by the alkaline medium (13) and the glucose concentration used actually was in excess in all cases. The solutions were mixed and heated rapidly until precipitation occurred (at about 92°C) and then cooled in an ice-water mixture. Typical particles are shown in Fig. 2d.

The conditions which will result in systems of narrow size distribution and uniform particle shape are rather restricted. As a rule such sols form over a narrow pH range just above the solubility boundary. By far the greatest effect on their appearance has been the concentration of the complexing solute, particularly of the sulfate ion. To illustrate this, Fig. 3 gives the reactant concentrations of a number of solutions containing aluminum and sulfate ions which were heated at 99°C for 40 hr in order to establish in which of these monodispersed sols are formed. At the end of the aging period systems designated by triangles showed no separation of the solid phase, whereas aluminum hydrous oxide separated in all other systems. Black circles (Fig. 3) designate sols exhibiting higher order Tyndall spectra (HOTS), which are most sensitive indicators for the presence of particles of rather narrow size distribution, particularly of spheres in the micron diameter range. It can be seen that "monodispersed" sols are obtained at aluminum ion concentrations from 2×10^{-4} to 6×10^{-3}F but only when sulfate ions were present to give an aluminum

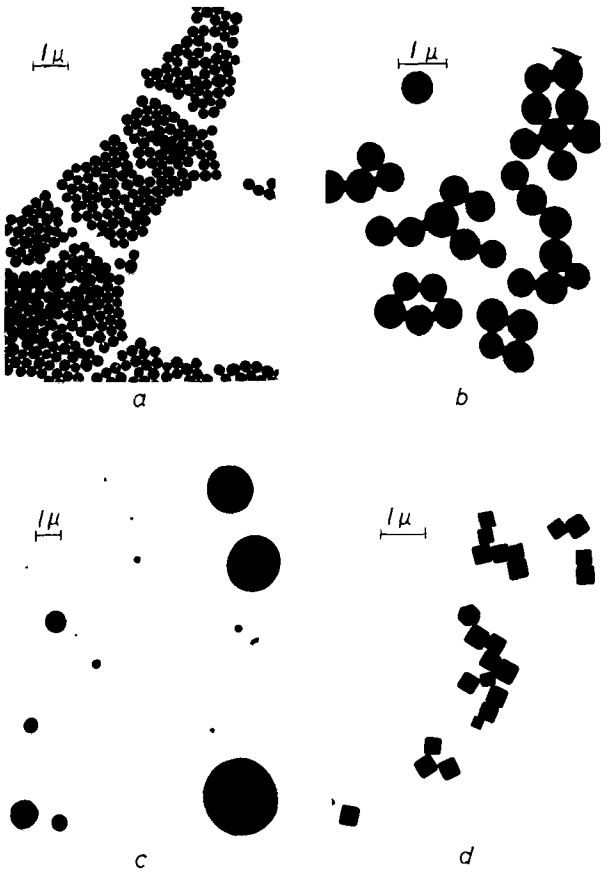

Fig. 2. Electron micrographs of various metal hydrous oxide sol particles obtained by aging of (a) chrom alum, 4 × 10^{-4}F, at 75°C; (b) aluminum sulfate, 1 × 10^{-3}F, at 99°C; (c) zirconium (IV) sulfate, 5 × 10^{-3}F, at 75°C; and (d) Cu_2O sol formed by reduction of Fehling's solution by glucose.

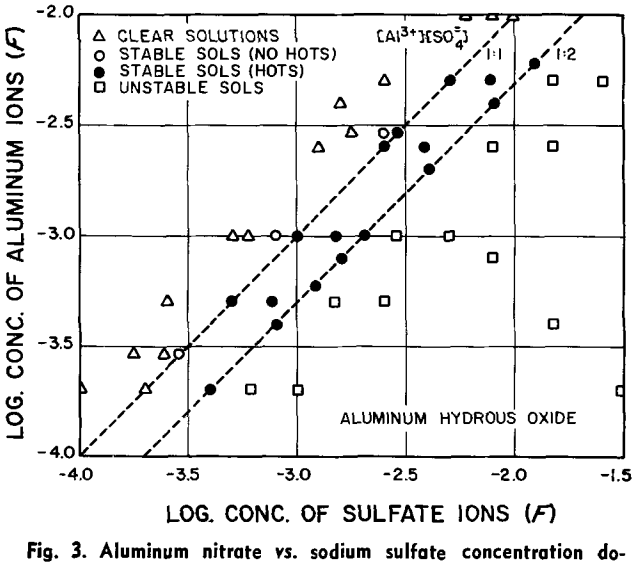

Fig. 3. Aluminum nitrate vs. sodium sulfate concentration domain of solutions aged for longer than 24 hr at 99°C resulting in △ no sol formation; ○ stable sols, small particles; ● sols showing HOTS; □ coagulated and settled sols.

to sulfate ratio between 1:1 and 1:2 (delineated by dashed lines). In larger excess of sulfate ions the particles grow considerably larger and in many cases flocculate and settle (indicated by squares). The pH in all systems showing HOTS was self-adjusted and upon aging and cooling of the sols to room temperature ranged from 3.1-3.5, the lower values being for systems of higher aluminum ion content. The great effect of pH on the formation of monodispersed metal hydrous oxides was demonstrated earlier with chromium hydroxide sols (4).

The size of the sol particles depends on the reactant concentrations. Again, in this regard, the complexing anion exhibits a considerable effect. Figure 4 (left) shows that the modal diameters of the spherical aluminum hydrous oxide particles increase with increasing sulfate concentration in the solution from which the sols are formed. Interestingly, at a given sulfate concentration the modal diameter does not seem to change if the aluminum ion concentration is varied over the narrow range which produces sols exhibiting HOTS. Similar observations have been made with the chromium hydroxide sols to be described in greater detail below.

The effect of the Cu^{2+} ion concentration on the edge length of cubes prepared by reduction of the Fehling's solutions is shown in Fig. 4 (right). In this case, the modal particle size is strongly affected by the metal ion concentration if the concentration of glucose is kept constant.

Properties of Monodispersed Metal Hydrous Oxide Sols

Because of their reproducibility and well-characterized morphology the metal hydrous oxides of narrow size distribution lend themselves uniquely to the study of their sol stability and of particle surface properties.

Whereas sol particles generated from solutions of chromium salts remain unchanged once formed, the aluminum hydrous oxide particles produced at higher temperatures (>90°C), slowly redissolve upon cooling to 25°C. The latter sols can, however, be permanently stabilized against dissolution if, after their formation, the pH is changed to ~10. No secondary precipitation of aluminum hydrous oxide takes place as the pH is made sufficiently high to complex excess aluminum ions in the form of solute aluminate species.

The pH of all sols prepared by aging as described earlier has been lower than the corresponding zero point of charge (ZPC); thus, the particles carry a positive charge. The surface charge can be readily altered by changing the pH of the medium. Consequently pH exercises a significant effect on sol stability. In general the sols coagulate when the pH is adjusted to be around the ZPC of a given system. However, they peptize completely if pH is sufficiently high or low to give strongly charged particles. Figure 5 shows the electrophoretic mobilities as a function of pH of three different sols. The ZPC of hydrous chromium and aluminum oxides are in agreement with the "best" values cited by Parks (14); the corresponding value

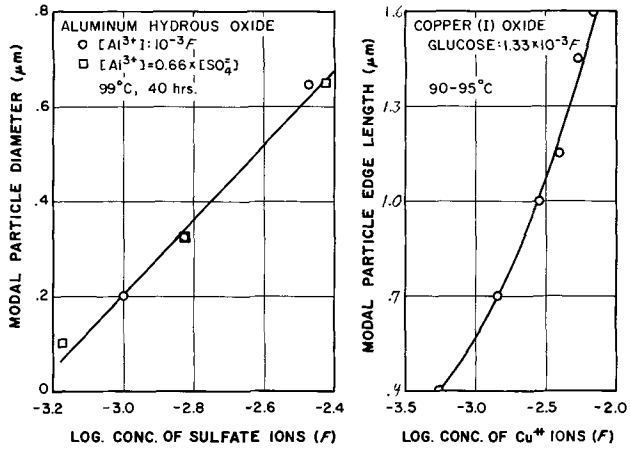

Fig. 4. Left, modal particle side of aluminum hydrous oxide sols formed by aging solutions containing 1 × 10^{-3}F Al (III) at 99°C in the presence of varying sulfate concentrations (○) and from a range of aluminum concentrations at a constant aluminum/sulfate ratio (□). Right, modal particle size of copper (I) oxide sols as a function of initial Cu(II) concentrations in the presence of constant initial concentration of glucose.

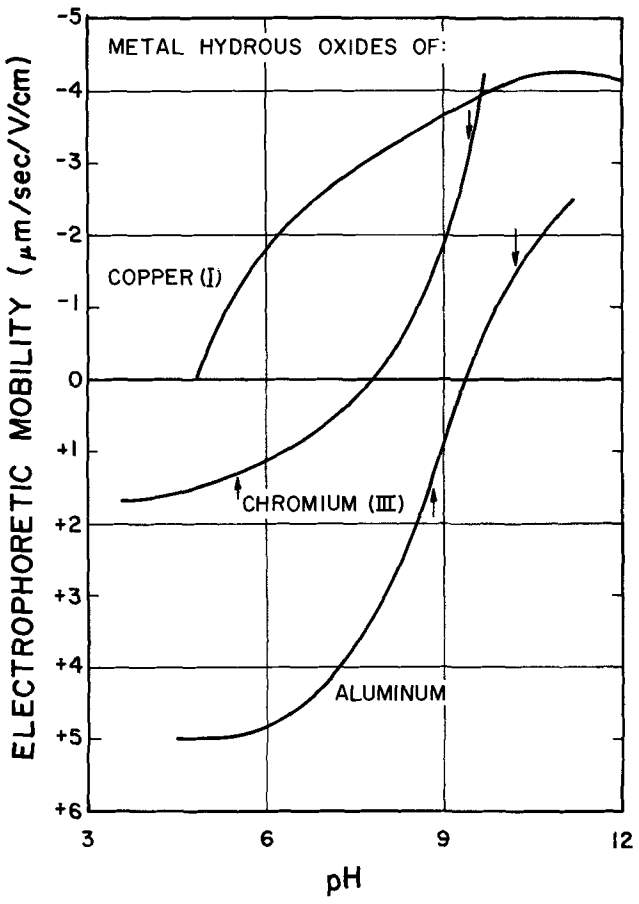

Fig. 5. Electrophoretic mobilities of monodispersed copper (I) oxide, chromium (III), and aluminum oxide particles as functions of pH at 25°C; between arrows, sols flocculate.

for copper(II) hydrous oxide is much lower than that reported elsewhere. Within the pH range indicated by arrows the chromium and aluminum hydrous oxide sols coagulate whereas outside of this range the sols remain stable.

Data for the aluminum hydrous oxide were obtained on a sol which was washed to remove the excess of reactant ions and then resuspended in solutions of different pH values. The original sol in the presence of sulfate ions showed much lower positive or higher negative mobilities as compared to the "washed" sol at the same pH values. The effect of sulfate ions is similar to that reported earlier on corundum in the presence of various anions (15). More recently, Alwitt showed a considerable influence of certain anions on the mobilities of pseudoboehmite (16).

The "monodispersed" sols could also be used to establish whether the particle size remains the same when pH, and consequently the charge, is changed. For this purpose the chromium(III) hydrous oxide sols are best suited since the light scattering could be used to establish the particle size distribution *in situ* with great precision (3, 8). A sol consisting of uniform, spherical, positively charged particles was prepared by aging chrom alum solutions at low pH and then the pH was increased sufficiently to give a stable sol of negatively charged particles. The size distribution was determined by light scattering before and after recharging. Both the modal particle diameter and the size distribution of chromium hydroxide sols remained essentially unchanged (Table I).

Kinetics of Formation and Growth of Chromium Hydrous Oxide Sols

The results described above showed that metal hydrous oxide sols of uniform size and shape may now be reproducibly prepared, although the conditions

Table I. Size distribution parameters and mobilities of a chromium hydroxide sol [4×10^{-4}M solution of $CrK(SO_4)_2$ aged for 21 hr at 75°C] at different pH

pH (25°C)	3.80	9.60
Particle diameter (μm)	0.314	0.318
Width of the size distribution, σ	0.12	0.10
Mobility (μm/sec/V/cm)	+1.48	−4.18

are somewhat restricted. These sols are suitable for the study of kinetics of particle formation and growth, since most theories apply to monodispersed systems of spherical particles. For this purpose chromium hydrous oxide seems to be most convenient since it is the least sensitive system to the changes in the experimental conditions (such as the rate of heating or the presence of impurities, etc.) leading to the formation of monodispersed sols. Also the complexes formed in chromium salt solutions are sufficiently kinetically inert (2, 5) to allow their identification.

Effect of sulfate ion concentration.—A previous study (5) described the change of particle diameter and of the content of soluble chromium species in a 4.0×10^{-4}F solution of chrom alum as a function of time of aging at 75°C. Here the effects of changing the sulfate concentration (added as sodium sulfate) at the constant concentration of chromium(III) nitrate on the formation of the hydrous oxide sols will be shown. In Fig. 6 the concentration of solute chromium is given as a function of time of aging the solutions at 75°C in the presence of three different sulfate concentrations and in the absence of this anion. It is apparent that with increasing content of sulfate ions the solution is more rapidly depleted of soluble chromium species.

Figure 7 shows that the pH at 75°C of the dispersion media for sols which have reached equilibrium (at 96 hr of aging) remains essentially constant at sulfate concentrations $<2 \times 10^{-3}$F but increases at higher sulfate additions. The latter indicates that sulfate ions are replacing hydroxyl groups in the basic chromium species formed during the aging process, which should influence the properties of the sols produced at elevated temperatures. Finally, Fig. 8 is a plot of the modal particle diameter of sols formed by aging 4.0×10^{-4}F chromium(III) nitrate solution at 75°C for 96 hr as a function of the initial sulfate concentrations. The nature of the particles formed is also indicated in this figure. At the lowest sulfate concentrations the particles are spherical but of broad size distribution. Because of polydispersity and small particle diameters, light scattering could not be applied for determination

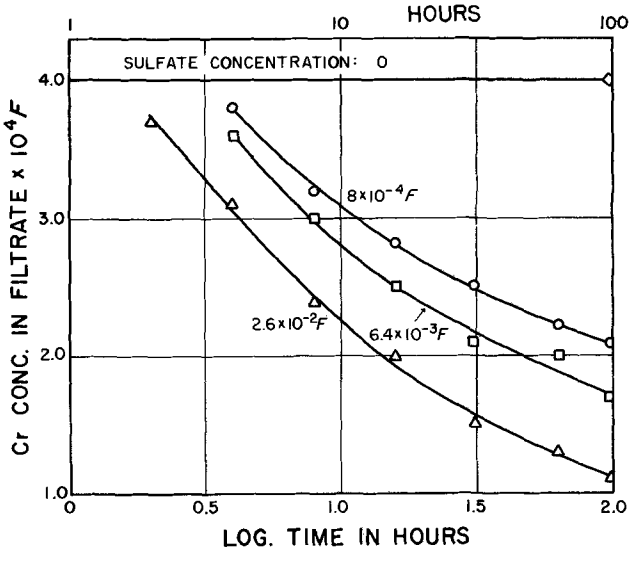

Fig. 6. Concentration of Cr (III) species remaining in solution after removal of sol particles from solutions containing three different sulfate concentrations each initially 4.0×10^{-4}F in Cr (III).

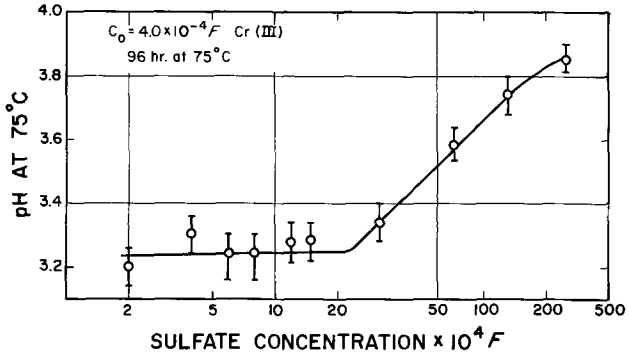

Fig. 7. The pH of the dispersion medium after 96 hr at 75°C as a function of sulfate concentration for solutions initially 4.0 × 10^{-4}F in Cr (III).

of the size distribution. Instead the electron microscopic results are given. At the intermediate sulfate concentrations the particle size distribution is sufficiently narrow for sols to show intense higher order Tyndall spectra (HOTS) and the particle size data are from the light-scattering analysis. At the highest sulfate concentrations studied the solids formed are aggregates of spherical particles. It is interesting to note that the onset of increase in pH (Fig. 7) and the formation of aggregates occur at approximately the same sulfate concentration. The aggregation apparently is caused by the lowering of the surface-charge density in the presence of higher concentrations of sulfate ions (as demonstrated by mobility measurements) and by the bridging of the particles by different coordinated chromium basic sulfate complexes which seem to form under these conditions (as indicated by the pH effects, Fig. 7).

These observations show the essential role which sulfate ions play both in the nucleation and in the growth process during the formation of chromium hydrous oxide sols. A more explicit mechanism of the particle generation will be possible once the chromium basic sulfate complexes are more precisely identified.

Growth mechanism.—When precipitation results in particles of uniform shape and size, and the number concentration remains nearly constant, the "chronomal" analysis (17) may be used to establish the growth mechanism. In principle this analysis permits dis-

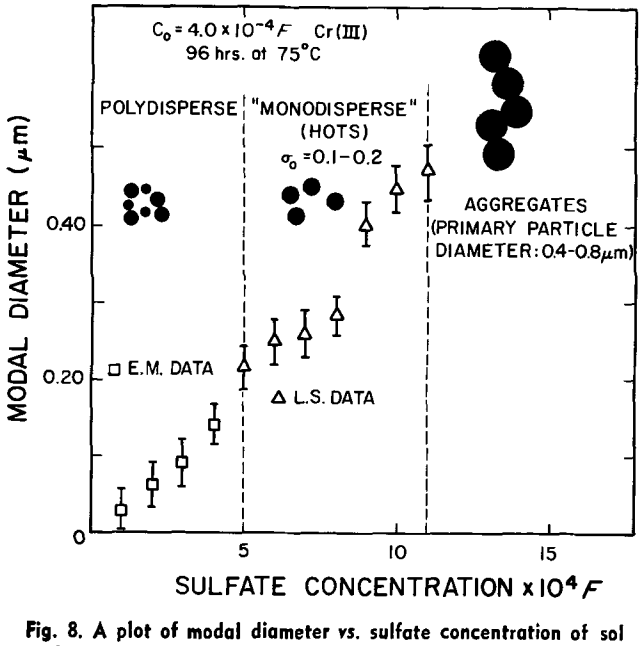

Fig. 8. A plot of modal diameter vs. sulfate concentration of sol particles formed in solutions aged at 75°C for 96 hr initially 4.0 × 10^{-4}F in Cr (III). E.M., electron microscopy; L.S., light scattering.

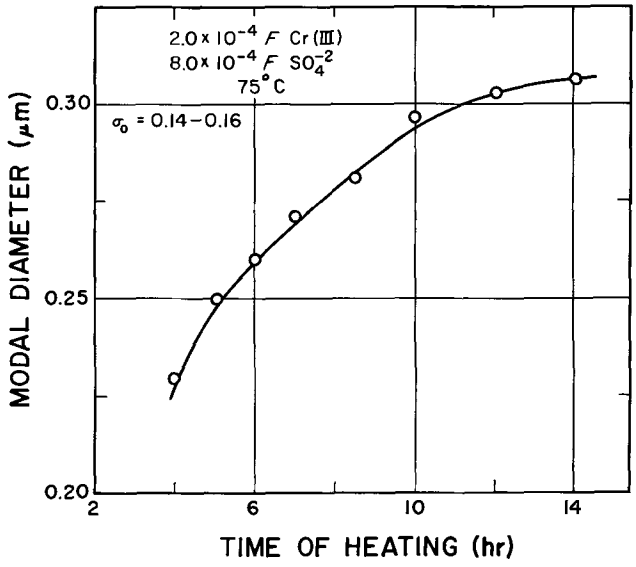

Fig. 9. Modal diameter of particles vs. time of aging at 75°C formed in solutions initially 2.0 × 10^{-4}F in Cr (III) and 8.0 × 10^{-4}F in SO_4.

tinguishing between diffusion controlled, polynuclear layer, and mononuclear layer growth.

The chromium hydrous oxide sols under certain experimental conditions meet the requirements necessary to apply the chronomals. For example, Fig. 9 shows the change of the modal particle diameter with time of sol generated by aging at 75°C a solution 2.0 × 10^{-4}F in chrom alum and 4.0 × 10^{-4}F in K_2SO_4. Assuming a constant particle composition (36% Cr) (5), throughout the entire period of particle growth shown in Fig. 9, a constant particle concentration of (2.0 ±0.5) × 10^8 cm^{-3} was calculated by means of the expression (18)

$$N = \frac{6\pi^2 w}{\rho\lambda^3} \cdot \left[\int_{\alpha_M \exp(-3\sigma_0)}^{\alpha_M \exp(3\sigma_0)} \alpha^3 p(\alpha)\, d\alpha \right]^{-1}$$

where w is the mass of particles per cm^3, ρ is the particle density (2.4 g/cm^3), $\lambda = 3.25 \times 10^{-5}$ cm, σ_0 is the distribution width parameter, and $p(\alpha)$ is the zeroth order logarithmic distribution function (19), α being the size parameter, $\alpha = 2\pi r/\lambda$, for which r is the radius of the spherical particle.

Nielsen (17) defines several chronomals, two of which are of interest in this work. The diffusion chronomal, I_D, is given as

$$I_D = \tfrac{1}{2} \ln [(1 - x)/(1 - x^{1/3})^3] - 3^{1/2} \tan^{-1} [3^{1/2}/(1 + 2x^{-1/3})]$$

where x is the degree of reaction (the ratio between the amount of substance that has reacted, and the total amount able to react, *i.e.*, solubility).

At time, t_D

$$t_D = K_D I_D$$

and

$$K_D = [48\pi^2 v N^2 (C_0 - S)]^{-1/3} D^{-1}$$

where v is the molar volume, D the diffusion coefficient, and $(C_0 - S)$ is the total amount reacted.

For the polynuclear controlled growth chronomal

$$I_P = \int_0^{X_P} X^{-2/3} (1 - X)^{-(m+2)/3} dx$$

where X is now defined as the fraction of the total initial species which has reacted to form the precipitate at time t_p. As above, $t_p = K_p I_p$ where

$$K_p \sim 0.6 r_1 [k_m v^{7/3} D^2 C_0^{(m+2)}]^{-1/3}$$

and r_1 is the equilibrium particle radius, k_m is a rate

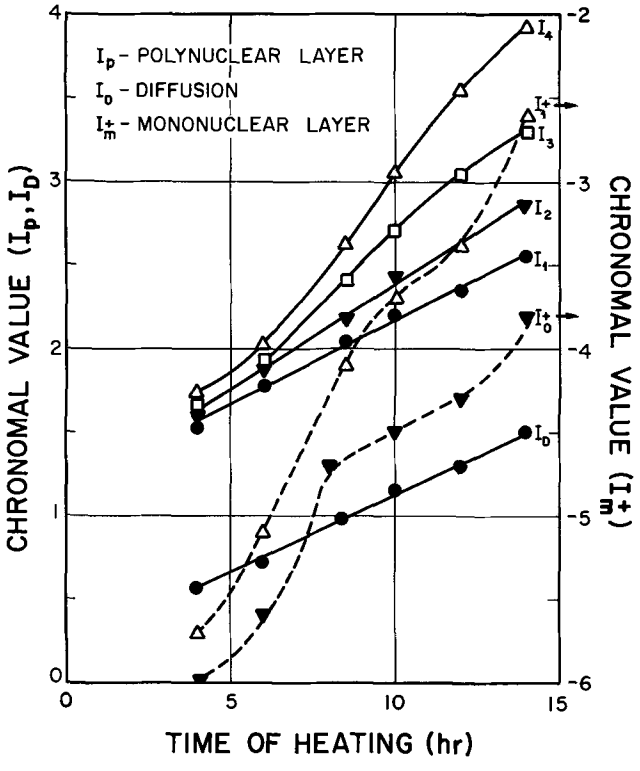

Fig. 10. Chronomal values assuming three different growth mechanisms designated by Nielsen as functions of time of aging at 75°C for solutions initially 2.0 × 10^{-4}F in Cr (III) and 8.0 × 10^{-4}F in SO_4^{-2} (see text).

constant, C_o is the initial concentration of the reacting species, and m is a constant.

For the chromium hydrous oxide sol described in this section, I_D and I_p, chronomals gave linear plots as a function of time (Fig. 10). Mononuclear controlled growth chronomals (I^+_m) did not give a linear relationship, and therefore, were not defined here.

To test whether a linear plot of a given chronomal properly indicates the growth mechanism, the diffusion coefficient, D, calculated from the corresponding K quantities, should have a reasonable value. In our case K_D did not yield a meaningful value for D over a wide range of values for the molar volume (the precipitate is amorphous). For example, assuming $v = \sim 50$ cm³/mole, $D = \sim 10^{-9}$ cm²/sec; a similar result is obtained using the expression $r(t) = [2Dv(C_o - S)t]^{1/2}$ which is valid for $v(C_o - S) << 1$ (1, 17). On the other hand, more reasonable values for D could be calculated from K_p values. It would appear that a polynuclear mechanism may be involved in the particular growth period studied although this is by no means certain; conceivably a compound growth mechanism might also be operative.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

LIST OF SYMBOLS

C	concentration at time t, mole/cm³
C_o	initial concentration, mole/cm³
D	diffusion coefficient of reacting species, cm²/sec
D_M	modal particle diameter, μm
K	factor converting a chronomal to time, sec
k_m	rate constant for nucleation controlled growth (units dependent upon m)
I	chronomal, dimensionless parameter proportional to time
I_D	diffusion chronomal
I^+_m	mononuclear layer chronomal
I_P	polynuclear layer chronomal
m	kinetic order of precipitation
N	particle number average concentration, cm^{-3}
p	kinetic order of polynuclear layer growth
$p(\alpha)$	zeroth order logarithmic distribution function
r	particle radius, cm or μm
r_1	equilibrium particle radius, cm
S	solubility of particles, mole/cm³
t	time, sec or hr
t_D	time of diffusional growth, sec
t_p	time of polynuclear layer growth, sec
v	molar volume of precipitating species, cm³/mole
w	mass per unit volume, g/cm³
x	degree of reaction
x_P	degree of reaction, polynuclear layer growth
α	particle size parameter
α_M	modal particle size parameter
σ_o	particle size distribution width parameter
λ	wavelength of scattered light in medium, cm
ρ	density of particles, g/cm³

A Theoretical Study of Bipolar Porous Electrodes

Richard Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

When electrical current passes through a porous metal diaphragm, the potential gradient in the electrolyte can serve to drive an electrochemical reaction provided that reactive species are present. One portion of the metal will act as an anode while the remainder will act as a cathode. A one-dimensional model is presented for determining how the reaction rate distribution is affected by system parameters including charge-transfer, resistance of the diaphragm, diffusion of solute species, and forced convection through the diaphragm. The results are presented in a series of dimensionless figures.

Nearly all current distribution studies have heretofore been conducted on electrodes of single polarity, either anodes or cathodes. A variety of important electrochemical systems, however, involve "bipolar" electrodes which are characterized by localized anodic and cathodic areas which coexist on adjacent regions of a single conductive surface. The following current distribution study has therefore been conducted in order to arrive at several features which are characteristic of one simple type of bipolar electrode.

The particular system under investigation involves a porous metal diaphragm of uniform porosity and thickness which is placed between two electrodes in a cell as shown schematically in Fig. 1. When current passes through the cell, a potential difference arises across the porous metal diaphragm so that electrochemical reactions may occur provided that reactive species are present. One portion of the diaphragm acts as an anode while the remainder acts as a cathode. Current, therefore, passes through the diaphragm both by ionic conduction in the electrolytic solution and by electronic conduction between anodic and cathodic regions.

Previous fundamental studies on bipolar systems have mostly focused attention on determining the current and potential distribution in a system of fixed anode/cathode geometry. In a series of publications, Waber *et al.* (1) calculated the primary and secondary current distribution in local cells having coplanar adjacent cathodes and anodes of known geometry ratio. Wagner (2) investigated the behavior of local cell action when the cathodic reaction was diffusion limited. Along different lines, Levich (3) employed concepts of convective diffusion to determine the rate of dissolution of inclusions of known size in both horizontal and vertical metal surfaces. In contradistinction to these studies, however, situations can arise where one has no *a priori* knowledge of which areas of a metal tend to be anodic or cathodic, or how the system properties influence the size of the anodic area. Analyses of bipolar systems which do not specify the size of the anodic or cathodic region are less common. For example, bipolar resistive wire electrodes have been analyzed by a linear network model (4), and bipolar electrochemical reactors have been treated as differential chemical reactors (5). Although no studies are known to exist which examine the behavior of bipolar porous electrodes, the following work is based on related analyses of porous battery electrode behavior (6). The simple model discussed below contains the salient features of many systems which exhibit bipolar behavior and, in addition, provides a basis for investigating more complex phenomena.

Derivation of the Model

The porous electrode under consideration is of uniform thickness, l, and is of uniform specific surface area throughout. Current enters the porous electrode in the solution phase at $y = 0$ and exits from the porous region at $y = l$. The concentration of reacting species is the same on both sides of the porous diaphragm.

Since rigorous calculations are cumbersome, several assumptions have been introduced: (*i*) The metal and void volumes of the porous diaphragm have a sufficiently fine structure that variations in potential and concentration occur along a single spatial dimension; the current distribution along each external surface is assumed to be uniform. (*ii*) Operation proceeds in the steady-state without structural changes, depletion, or insulation effects. (*iii*) Only one reversible electrochemical reaction occurs. (*iv*) The electrolyte is flooded with a nonreactive supporting electrolyte so that electrical migration of reactive species is not important. (*v*) Mass transfer limitations do not exist external to the porous diaphragm. (*vi*) Convection through the porous electrode takes place by forced plug flow along the same spatial direction as the flow of electrical current so that a one-dimensional analysis remains appropriate. Although these restrictions limit the applicability of the following model, they do not obviate the essential features which are of interest. As discussed in a later section, most of the assumptions may be altered to suit special circumstances without appreciable complication of the general procedures.

The transport equations which describe the model will be developed for an electrode reaction having the stoichiometric form

$$\sum_i \nu_i M_i^{z_i} = ne^- \qquad [1]$$

The reversible electrode reaction rate expression used in this investigation has concentration dependent forward and reverse rates

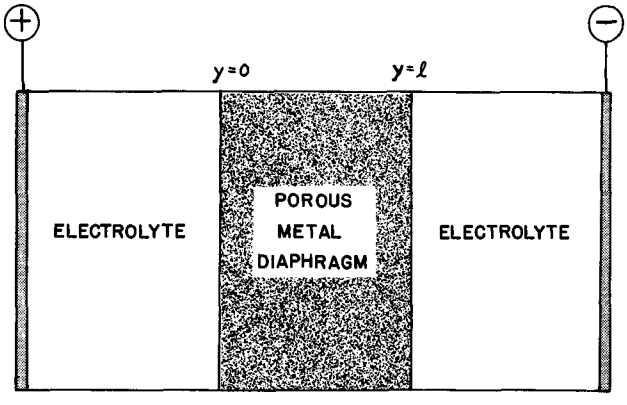

Fig. 1. Schematic diagram of bipolar porous metal diaphram

* Electrochemical Society Active Member.

Key words: current distribution, mathematical model, bipolar, porous electrode.

$$j(y) = i_0 \left[\frac{c_1(y)}{c_1^0} \exp\left(\frac{\alpha_a n\mathbf{F}}{RT} [\phi_s(y) - \phi_m(y)] \right) - \frac{c_2(y)}{c_2^0} \exp\left(-\frac{\alpha_c n\mathbf{F}}{RT} [\phi_s(y) - \phi_m(y)] \right) \right] \quad [2]$$

The notation is provided in the section on Symbols at the end of the paper. The four variables which appear on the right side of Eq. [2] (concentrations of both reactant and product species, potentials in both the electrode and solutions phases) are, in general, dependent on spatial position within the porous electrode; the four variables are to be determined by solving a set of equations as outlined in the following paragraphs.

In the solution phase, Ohm's law is

$$i_s(y) = -\kappa \frac{d\phi_s(y)}{dy} \quad [3]$$

The current in the solution, $i_s(y)$, varies with position since the electrochemical reaction acts as a sink

$$\frac{di_s(y)}{dy} = -aj(y) \quad [4]$$

The quantity "a" is the specific surface area in units of square centimeter surface area per cubic centimeter void volume. Combination of Eq. [2], [3], and [4] gives

$$\frac{d^2\phi_s}{dy^2} = \frac{i_0 a}{\kappa} \left[\frac{c_1}{c_1^0} \exp\left(\frac{\alpha_a n\mathbf{F}}{RT} [\phi_s - \phi_m] \right) - \frac{c_2}{c_2^0} \exp\left(-\frac{\alpha_c n\mathbf{F}}{RT} [\phi_s - \phi_m] \right) \right] \quad [5]$$

In a similar manner, Ohm's law may be applied to the passage of electronic current in the electrode phase

$$i_m = -\sigma \frac{d\phi_m(y)}{dy} \quad [6]$$

with the result

$$\frac{d^2\phi_m}{dy^2} = -\frac{i_0 aP}{\sigma(1-P)} \left[\frac{c_1}{c_1^0} \exp\left(\frac{\alpha_a n\mathbf{F}}{RT} [\phi_s - \phi_m] \right) - \frac{c_2}{c_2^0} \exp\left(-\frac{\alpha_c n\mathbf{F}}{RT} [\phi_s - \phi_m] \right) \right] \quad [7]$$

The group $[(aP/(1-P)]$ corresponds to the specific surface area in units of square centimeter surface area per cubic centimeter electrode volume.

The movement of reacting species within the electrode occurs by diffusion and by convection

$$N_i = -D_i \frac{dc_i}{dy} + vc_i \quad [8]$$

The anodic reactant concentration, $c_1(y)$, varies with position owing to the electrochemical reaction which acts as a sink so that

$$D_1 \frac{d^2c_1}{dy^2} - v\frac{dc_1}{dy} = \frac{\nu_1 i_0 a}{n\mathbf{F}} \left[\frac{c_1}{c_1^0} \exp\left(\frac{\alpha_a n\mathbf{F}}{RT} [\phi_m - \phi_s] \right) - \frac{c_2}{c_2^0} \exp\left(-\frac{\alpha_c n\mathbf{F}}{RT} [\phi_m - \phi_s] \right) \right] \quad [9]$$

Similarly, the anodic reaction product, $c_2(y)$, obeys the transport equation

$$D_2 \frac{d^2c_2}{dy^2} - v\frac{dc_2}{dy} = \frac{\nu_2 i_0 a}{n\mathbf{F}} \left[\frac{c_1}{c_1^0} \exp\left(\frac{\alpha_a n\mathbf{F}}{RT} [\phi_m - \phi_s] \right) - \frac{c_2}{c_2^0} \exp\left(-\frac{\alpha_c n\mathbf{F}}{RT} [\phi_m - \phi_s] \right) \right] \quad [10]$$

Equations [5], [7], [9], and [10] are sufficient for determining the four unknown variables which appear in Eq. [2]. Each of the differential equations contains all four unknown variables so that, in general, simultaneous integration is required. The model is completed by specification of the boundary conditions. At $y = 0$

$$\phi_s = \phi_{cell},\ c_1 = c_1^0$$

$$\frac{d\phi_m}{dy} = 0,\ c_2 = c_2^0 \quad [11]$$

while at $y = l$

$$\phi_s = 0,\ c_1 = c_1^0$$

$$\frac{d\phi_m}{dy} = 0,\ c_2 = c_2^0 \quad [12]$$

In order to render the calculations more compact, the following dimensionless quantities are defined

$$\mathrm{Y} = \frac{y}{l} \qquad \pi_i = \frac{D_i}{D_r}$$

$$\mathrm{C}_i(\mathrm{Y}) = \frac{c_i(y)}{c_r} \qquad \gamma_i = \frac{c_i^0}{c_r}$$

$$\Phi_m(\mathrm{Y}) = \frac{n\mathbf{F}}{RT}\phi_m(y) \qquad \beta = \frac{i_s^* l n\mathbf{F}}{\kappa RT}$$

$$\Phi_s(\mathrm{Y}) = \frac{n\mathbf{F}}{RT}\phi_s(y) \qquad J = \frac{alj}{i_s^*} \quad [13]$$

When these groupings are substituted into the equations which define the model, the following parameters arise

$$\xi = \frac{ai_0 l^2 n\mathbf{F}}{\kappa RT}$$

$$\chi = \frac{aPi_0 l^2 n\mathbf{F}}{(1-P)\sigma RT}$$

$$\Xi = \frac{i_0 a l^2}{n\mathbf{F} c_r D_r}$$

$$\zeta = \frac{vl}{D_r} \quad [14]$$

In dimensionless notation, the four equations which define the model can be arranged to the somewhat compact form

$$\Phi_s'' = \xi \left[\frac{C_1}{\gamma_1} \exp\left[\alpha_a(\Phi_s - \Phi_m)\right] - \frac{C_2}{\gamma_2} \exp\left[-\alpha_c(\Phi_s - \Phi_m)\right] \right] \quad [15]$$

$$\Phi_m'' = -\frac{\chi}{\xi}\Phi_s'' \quad [16]$$

$$C_1'' - \frac{\zeta}{\pi_1} C_1' = \frac{\nu_1 \Xi}{\pi_1 \xi}\Phi_s'' \quad [17]$$

$$C_2'' - \frac{\zeta}{\pi_2} C_2' = \frac{\nu_2 \Xi}{\pi_2 \xi}\Phi_s'' \quad [18]$$

Each "prime" superscript denotes differentiation with respect to the spatial variable Y. The boundary conditions given by Eq. [11] and [12] take on the form

$$\begin{aligned} &\text{at } \mathrm{Y} = 0: && \Phi_s = \Phi_a, && C_1 = \gamma_1 \\ & && \Phi_m' = 0, && C_2 = \gamma_2 \\ &\text{at } \mathrm{Y} = 1: && \Phi_s = 0, && C_1 = \gamma_1 \\ & && \Phi_m' = 0, && C_2 = \gamma_2 \end{aligned} \quad [19]$$

Once the four unknown variables are obtained, the current distribution along the porous electrode may be found from the dimensionless form of Eq. [2]

$$\beta J = \xi \left[\frac{C_1}{\gamma_1} \exp\left[\alpha_a(\Phi_s - \Phi_m)\right] - \frac{C_2}{\gamma_2} \exp\left[-\alpha_c(\Phi_s - \Phi_m)\right] \right] \quad [20]$$

Method of Solution

The solution of the Eq. [15]-[19], which describe the mathematical model, was carried out on a digital computer by a finite difference numerical procedure. Several computer programs were employed in order to examine the various cases presented below. In every case, the equations which describe the model were first linearized about a trial solution and then set into finite difference form. The set of tridiagonal matrices was then inverted (7) on an IBM 360 computer. Solutions to the nonlinear equations were subsequently obtained by iteration on the approximate linear solution; convergence was usually achieved within five iterations.

It may be noted that Eq. [15] becomes homogeneous when $\chi = 0$, that is, when the electrode conductivity is very large. The derivative boundary conditions on Φ_m will then no longer permit determination of the potential in the metal phase. In such cases, the boundary condition at $Y = 0$ was modified to

$$\Phi_m = \Phi_m^* \quad [21]$$

where Φ_m^* was chosen to be that value for which

$$\int_0^1 J\, dY = 0 \quad [22]$$

That is, the potential in the metal was chosen by inspection so that anodic and cathodic currents balance exactly.

Results and Discussion

Since the foregoing model contains a large number of system properties, it would be cumbersome to report detailed parameter studies for every possible case. Only a few features, which seem to be of special interest, have been chosen for discussion.

Effect of charge-transfer.—First consider the pristine situation when mass transport restrictions are altogether absent ($\Xi = 0$) and the electrode phase is of high conductivity ($\chi = 0$). Under these restrictions, the concentration of reacting species is uniform, and the potential in the metal is uniform. The system is described by Eq. [15] with the two appropriate boundary conditions, Eq. [19]. The potential in the electrode phase was chosen such that Eq. [22] was obeyed. The parameters under consideration are thus ξ, Φ_a, α_a, and α_c. Figure 2 illustrates how the electrochemical reaction rate varies along the porous diaphragm for various values of the parameter ξ. For small values of ξ, the reaction proceeds with difficulty (low i_0) so that current does not enter into the electrode phase; for large values, electrochemical reaction proceeds with ease so that a considerable amount of current flows in the electrode phase between anodic and cathodic areas. Fig. 3 provides a compilation of the current distributions for various values of the parameter ξ, as well as for two applied potentials across the diaphragm. The electrode reaction rate distribution depends on the value of applied potential, Φ_a, because the charge-transfer resistance is not constant but varies with Φ_a. For a given value of ξ, the current distributions shown in Fig. 3 have similar shapes which, in the interior regions of the diaphragm, are independent of the applied potential. For reactions having symmetric transfer coefficients ($\alpha_a = \alpha_c$) the reaction rate at the edges of the diaphragm is

$$J_{(Y=0 \text{ or } 1)} = 2\xi \sinh \frac{\alpha \Phi_a}{2} \quad [23]$$

Therefore, the current distributions for systems with different ξ or Φ_a than those provided in Fig. 3 may be

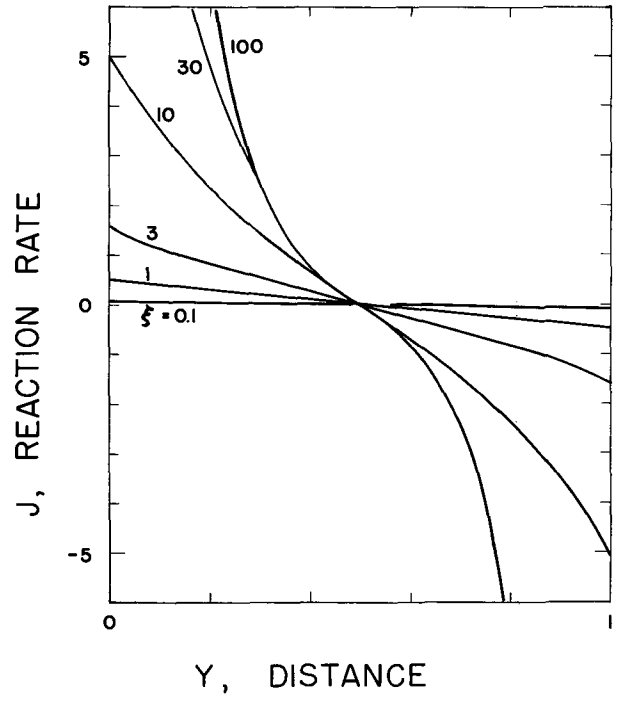

Fig. 2. Steady-state current density distributions within a bipolar porous electrode ($\alpha_a = \alpha_c = 0.5$, $\Phi_a = 1$, $\chi = \Xi = 0$).

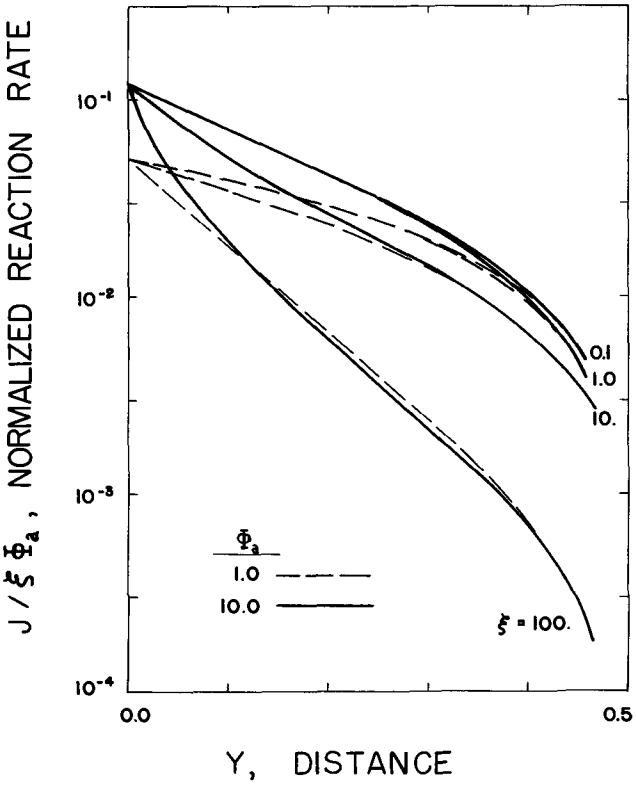

Fig. 3. Compilation of reaction rate distributions in bipolar porous electrodes ($\alpha_a = \alpha_c = 0.5$, $\chi = \Xi = 0$).

estimated by first computing $J_{(Y=0 \text{ or } 1)}$ from Eq. [23], and the interpolating between the appropriate lines in Fig. 3.

When the potential Φ_a is impressed across the diaphragm the magnitude of the current which flows will depend on the extent of electrochemical reaction taking place in the diaphragm as illustrated in Fig. 4. The quantity β_{avg}/Φ_a represents the over-all dimensionless conductivity of the diaphragm. The family of solid lines in Fig. 4 indicate that the over-all diaphragm conductivity increases as ξ increases; that is, electrochemical reaction permits passage of current through the

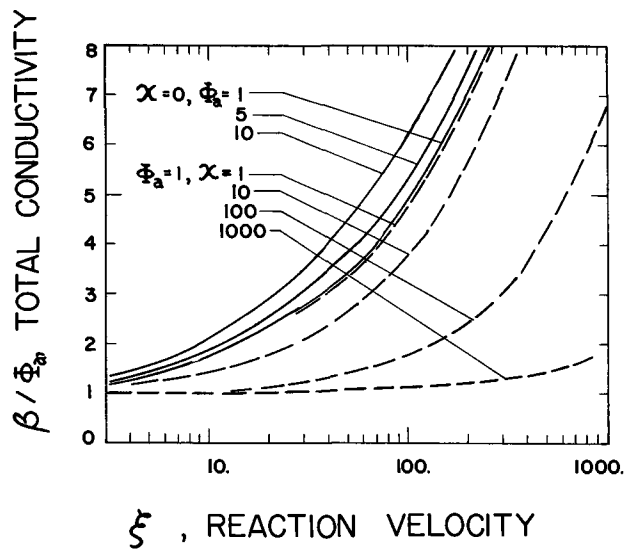

Fig. 4. Dependence of over-all electrode conductivity on system parameters ($\alpha_a = \alpha_c = 0.5$. $\Xi = 0$).

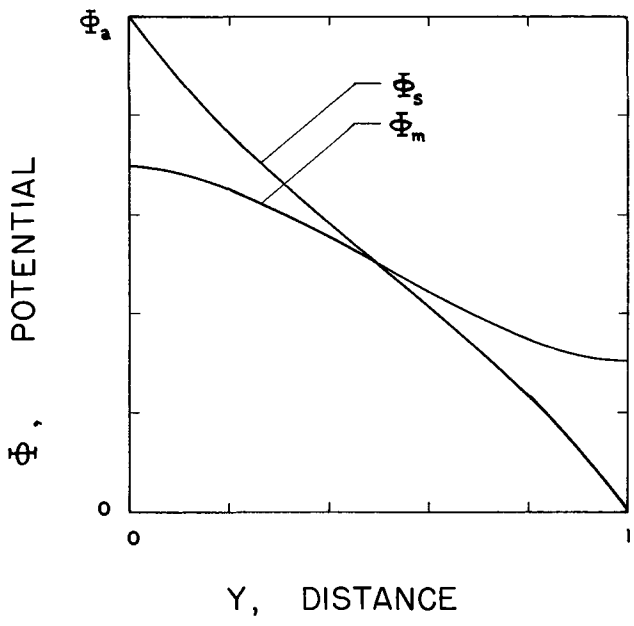

Fig. 5. Variation of potential in solution (Φ_s) and in metal (Φ_m) phases during electrolysis in a bipolar porous electrode ($\alpha_a = \alpha_c = 0.5$, $\Phi_a = 1$, $\xi = 10$, $\chi = 10$, $\Xi = 0$).

diaphragm in the electronic phase. At a given value of ξ, the over-all conductivity is somewhat potential dependent owing to the nonlinear reaction rate equation used in the present model. For the case $\Phi_a = 1$ and $\xi = 0.1$, it has been found that 98.7% of the current passes through the diaphragm in the electrolyte phase; on the other hand, with $\Phi_a = 1$ and $\xi = 100$, electrochemical reaction occurs to such a large extent that only 1.4% of the current flows in the electrolyte phase in the center of the diaphragm.

Effect of electrode resistance.—Now let us superimpose onto the foregoing pristine system the effect of finite electrode conductivity by increasing χ to nonzero levels; the potential in the electrode phase will no longer be constant. For the moment, however, Ξ will remain zero so that solute concentrations remain constant. The situation is modeled by Eq. [15] and [16] with the appropriate boundary conditions chosen from Eq. [19]. It was found that the most expedient method of integration was not to employ the two derivative boundary conditions on Φ_m but rather to chose the value of Φ_m on one side of the diaphragm such that Eq. [22] was obeyed.

Figure 5 illustrates how the potentials in the electrolyte and electrode phases vary with position within the diaphragm under the conditions $\xi = 10$, $\chi = 10$, $\Xi = 0$, and $\Phi_a = 1.0$. It is seen that potential gradients appear in both phases. The potential distributions in each phase exhibit inflection points since, by Eq. [15], their second derivatives change sign as one passes between electrode regions of opposite polarity. Figure 6 illustrates the effect of electrode resistance on the current distribution under the conditions of $\xi = 100$ and $\Phi_a = 1.0$. The electrode resistance tends to suppress electrochemical reaction by consuming a portion of the applied potential. The results shown by the dashed lines in Fig. 4 are helpful in estimating the effect of diaphragm resistance on over-all electrode conductivity. Even though the exchange current density may be very large (large ξ), it is clear that electrochemical reaction will tend not to occur if the metal has a sufficiently large resistance (large χ).

Effect of diffusion.—The importance of mass transfer limitations on electrode behavior is determined by the parameters Ξ and ζ. The first denotes the ratio of diffusion resistance to charge-transfer resistance insofar as it contains the ratio i_0/D_r; the quantity ζ provides the ratio of convective velocity to diffusive velocity. For the moment, consider pure diffusion control, that is, $\zeta = 0$. Further, let $\chi = 0$ so that the diaphragm is at a uniform potential. The system behavior is then deter-

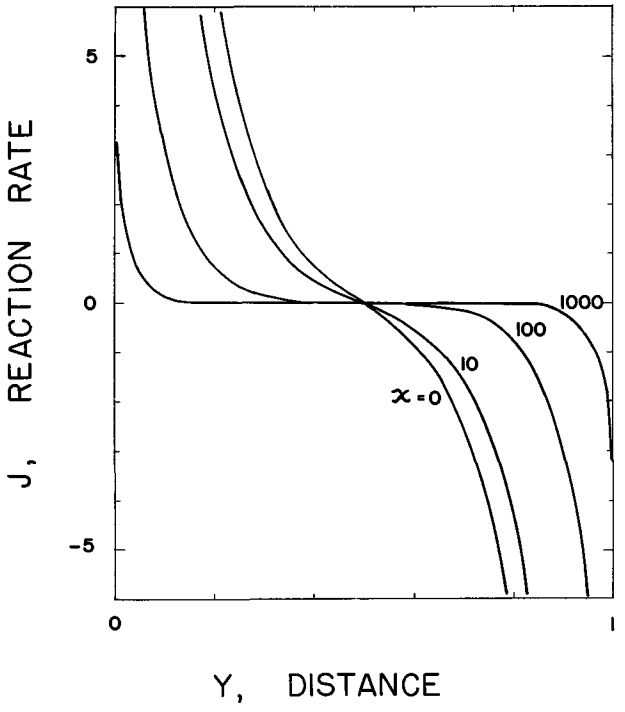

Fig. 6. Influence of electrode resistance on current density distribution in bipolar porous electrodes ($\alpha_a = \alpha_c = 0.5$, $\Phi_a = 1$, $\xi = 100$, $\Xi = 0$).

mined by Eq. [15], [17], and [18] along with the appropriate boundary conditions from Eq. [19]. As before, the potential in the metal is chosen such that Eq. [22] is obeyed.

When Ξ takes on nonzero values, concentration gradients may arise in the electrolyte if reaction rates are appreciable. The solid lines in the upper portion of Fig. 7 illustrate steady-state concentration profiles of the two reacting species for one particular set of conditions ($\xi = 10$, $\Xi = 1000$, $\Phi_a = 1$, $\chi = 0$). The concentration profiles are somewhat S-shaped since reactants consumed along the anodic region are generated by the reverse reaction along the cathodic region. An inflection point in the concentration profiles had been expected since the second derivatives in Eq. [17]

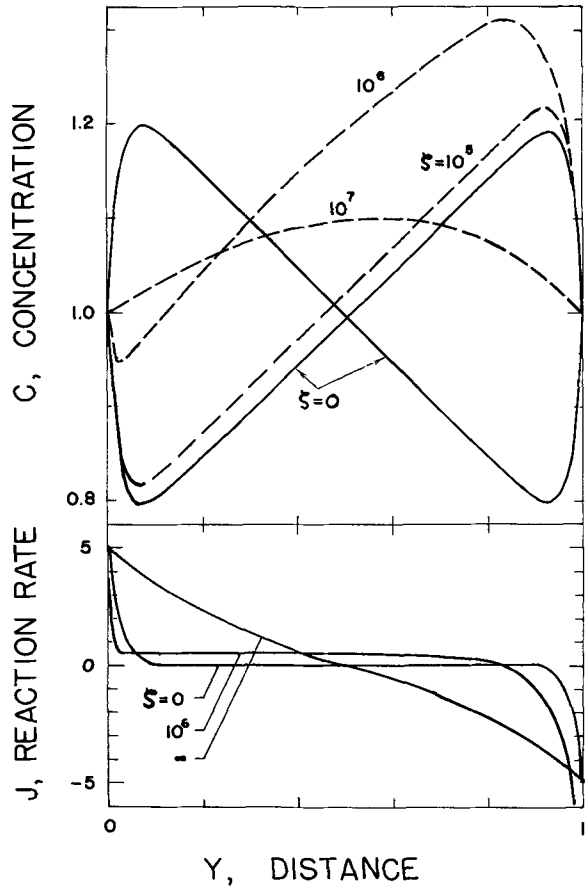

Fig. 7. Concentration and current distributions in a bipolar porous electrode under transport restrictions ($\alpha_a = \alpha_c = 0.5$, $\Phi_a = 1$, $\xi = 10$, $\chi = 0$, $\Xi = 1000$).

and [18] change signs as one passes between electrode regions of opposite polarity.

Naturally large concentration differences arise only if the electrochemical reaction proceeds at reasonably high velocities, that is for large ξ; otherwise, current merely passes through the diaphragm wtihout entering the metal phase and thus serving as a species sink. The existence of concentration differences, however, decreases the extent of electrochemical reaction by consuming a portion of the applied potential. Figure 8 illustrates how concentration overpotential acts to reduce the over-all conductivity of the porous diaphragm for the conditions $\Phi_a = 1$, $\chi = 0$, and $\zeta = 0$. The results shown in Fig. 8 are only weakly dependent on the applied potential in the range up to $\Phi_a = 10$. When Ξ takes on large values, the extent of electrochemical reaction is reduced and the reaction distribution becomes more uniform.

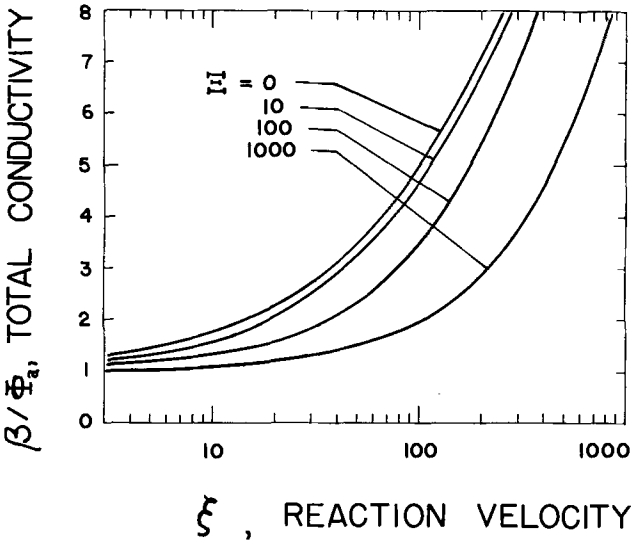

Fig. 8. Dependence of over-all electrode conductivity on system parameters ($\alpha_a = \alpha_c = 0.5$, $\Phi_a = 1$, $\chi = 0$).

Effect of electrolyte flow.—When mass transport limitations predominate electrode behavior, convection of electrolyte may naturally have a significant effect on performance. The parameter which determines the extent is ζ. The dashed lines in the upper portion of Fig. 7 illustrate the effect of forced flow on the concentration distribution of species C_1 which is consumed in the anodic regions. When ζ has the value zero, pure diffusion obtains and the concentration distribution is shown by the solid curve as mentioned previously. An increase in the value of ζ, corresponding to convection from right to left in the figure, distorts the concentration distribution as shown. At sufficiently high values of ζ the concentration distribution becomes uniform, that is, mass transport limitations are entirely removed. The lower portion of Fig. 7 illustrates the effect of convection on the electrochemical reaction rate distribution. Under pure diffusion control ($\zeta = 0$), the current distribution is symmetric and highly nonuniform. In the complete absence of mass transport effects ($\zeta = \infty$) the current distribution varies almost linearly with distance within the electrode. At intermediate levels (such as $\zeta = 10^6$), the current distribution is far from symmetric. For the example in Fig. 7, large local reaction rates are encountered in the (upstream) cathodic portion which, however, occupies less than 20% of the electrode volume. The cathodic reaction products are washed downstream onto the anodic surface where reaction occurs with remarkable uniformity over 60% of the electrode surface.

By relieving concentration overpotential, convection will increase the apparent diaphragm conductivity above the values for diffusion-controlled diaphragms as shown previously in Fig. 6. For the range of parameters reported in this investigation, it was found that pure diffusion behavior persisted for ζ values between 0 and 10^4. For values of ζ in excess of 10^7, on the other hand, the over-all diaphragm conductivity was within 1% of the value which corresponds to the absence of concentration overpotential. In all cases, convection affected electrode performance primarily in a narrow range of ζ between 10^5 and 10^6.

Conclusions

In the absence of concentration and electrode resistance effects, the electrochemical reaction distribution within the porous metal diaphragm depends solely on the parameter ξ. If ξ has a value greater than unity, electronic co-conduction via electrode reactions becomes appreciable. The effect of electrode resistance on electrode behavior is determined by the value of χ; if χ has a large value, the potential in the electrode phase varies with position. Similarly, the magnitude of the parameter Ξ determines the extent of concentration overpotential. The parameters χ and Ξ affect diaphragm behavior only insofar as they affect the electrochemical reaction; if ξ is small, electrochemical reaction does not occur, and the role of electrode resistance and concentration effects is of no concern.

The model presented above is based on a set of assumptions which naturally affect the applicability of the calculated results. For example, a potential difference across the porous diaphragm was chosen in this study for the driving force for occurrence of bipolar behavior. Other driving forces are possible. In order to investigate other systems having bipolar behavior, a significant number of the assumptions may be removed or substantially altered without appreciable complication of the over-all procedure. Several examples may be cited: assumption (*i*), concentration gradients often arise during high rate discharge of porous battery or fuel cell electrodes. After release of

the external load, the device proceeds to recover the terminal voltage by a process which depends in part on bipolar short-circuiting of the concentration gradients within the porous electrodes. Rate of recovery behavior may, thus, be investigated by removing assumption (*ii*) in favor of transient species conservation equations (8). Assumption (*ii*), many corrosion processes are driven by localized concentration, stress, or potential gradients which cause the metallic surface to become bipolar and thus corrode. Since at least two different electrochemical reactions are usually involved, assumption (*iii*) may be relieved in favor of, for example, oxygen reduction combined with iron dissolution/passivation kinetics. Assumption (*iii*), acid leaching of mineral ore pellets often takes place by corrosion-type reactions since many of the common sulfide and oxide ores are electronic conductors. Determination of leaching rates would, therefore, involve multiple bipolar reactions coupled, perhaps, with pore size variation considerations. Assumption (*iv*), electroless deposition processes consist of simultaneous corrosion-type reactions which have the net effect of depositing metal on an appropriately sensitized substrate. Bipolar concepts are involved in determining the local cathodic reaction rate, that is, the metal thickness distribution. Such studies are naturally of interest in improving quality control of electroless plating systems.

The bipolar porous electrode model described above, thus, provides a firm basis for further investigations on important electrochemical systems.

ABSTRACT

The galvanostatic operation of flooded porous electrodes employing metal/metal salt couples is analyzed. A model is developed for a single, circular pore configuration which accounts for the effects of differing equivalent volumes of the solid reactants. The model also includes effects of variation in solution properties and effects of complexing of the sparingly soluble salt with the bulk electrolyte anion. The $Cd/Cd(OH)_2$ couple in concentrated aqueous potassium hydroxide and the Ag/AgCl couple in concentrated potassium chloride solutions are considered. Overpotential is computed as a function of time for solid-film and solution-diffusion versions of the model. The solid film model shows a linear overpotential-time relationship and nearly uniform current distribution. The solution-diffusion model shows a variety of overpotential-time curves, based on different physical parameters. In general, anodic failure is caused by blockage of pores or by complete coverage of the metal surface by product crystallites. Cathodic failure is caused by low mass transport which leads to limiting currents in the electrode. The solution-diffusion model may generate extremely nonuniform current distributions, often with maxima inside the pore. These persistent nonuniform current distributions are important in terms of the analysis of cycling behavior.

Porous electrodes using sparingly soluble active species are common to most modern electrical storage cells. The negative plates in lead-acid batteries are porous structures containing lead and lead sulfate mixtures formed electrochemically from pastes pressed into lead alloy current collectors. The lead sulfate is sparingly soluble. Nickel-cadmium cells use sparingly soluble cadmium hydroxide and various nickel oxides and hydroxides on cadmium or nickel substrates. Sea water activated cells use the silver/silver chloride couple for the positive electrode reaction.

This study addresses itself to the formulation of a physical and mathematical model which describes the operation of flooded porous electrodes using a metal/sparingly soluble salt couple. Emphasis is on presenting an accurate description of the elementary processes believed to be the most important in establishing over-all electrode behavior. Comparison of critical aspects of the model to actual experimental observations is made insofar as such information is available.

Two specific examples of metal/salt couples have been considered. The first is cadmium/cadmium hydroxide in aqueous potassium hydroxide electrolytic solutions. Croft (1) and Farr and Hampson (2) have presented evidence supporting anodic film growth by ionic film transport as a controlling process. Dissolution and precipitation of a CdO intermediate has been proposed by Lake and Casey (3). Devanathan and Lakshmanan (4) suggest that a $CdOH^+$ ion is formed which may decompose into CdO and $Cd(OH)_2$. Armstrong *et al.* (5) found no CdO formed and that the primary product of oxidation was $Cd(OH)_2$. Croft (1) and Falk (6) also proposed that $Cd(OH)_2$ was formed directly on oxidation of Cd. Breiter and Weininger (7) suggested that a very thin layer of amorphous CdO could be formed. Yoshizawa and Takehara (8) proposed $HCdO_2^-$ as an intermediate in a sequence of elementary steps. Visco and Sonner (9) found that $Cd(OH)_3^-$ is formed on the dissolution of $Cd(OH)_2$ in KOH solutions from 2 to 15 molar. The results of Visco and Sonner make the Yoshizawa and Takehara sequence unlikely. Their observed third-order dependence of the equilibrium potential on OH^- activity can be explained by the mechanism proposed by Milner and Thomas (10) and by Okinaka (11).

$$Cd + 3\,OH^- \rightleftarrows Cd(OH)_3^- + 2e^-$$

$$Cd(OH)_3^- \rightleftarrows Cd(OH)_2 + OH^-$$

Okinaka concluded that in the active potential range the dissolution-precipitation mechanism is predominant. He also concluded that a thin film of CdO was responsible for the passivation of cadmium, rather than surface blockage by $Cd(OH)_2$ crystallites. In the passive region, continued growth was accomplished by ionic migration through the $Cd(OH)_2$ film which formed on top of the CdO film. Measurements of the conductivity of $Cd(OH)_2$ gave values of about 10^{-10} mho/cm. These results might be compared to $PbSO_4$ film results of 3.5×10^{-10} mho/cm found by Fleischmann and Thirsk (12). Okinaka (11) also estimated that the rate constant for the precipitation of $Cd(OH)_2$ was the order of 10^{-3} to 3×10^{-3} cm/sec.

The reduction of $Cd(OH)_2$ has been studied less than the oxidation of Cd even though this process is important in the charging of Ni-Cd cells. This is especially true with regard to possible hydrogen evolution in sealed cells. Croft (1) postulated that a direct solid-state mechanism was responsible for this process while Okinaka (11) found evidence for both solid- and solution-phase transport, with the contribution of the solution-diffusion mechanism increasing as the reduction progresses.

Will and Hess (13, 14) simulated a single pore by using a cadmium electrode covered with a thin (10-400μ) layer of electrolytic solution and arranged so that the counterelectrode was positioned side-by-side with the test electrode. Microscopic investigations of the resulting $Cd(OH)_2$ were interpreted as supporting the mechanism of solid-state ionic transport through passivating layers of $Cd(OH)_2$. It was noted that large

Key words: porous electrodes, current distribution, cadmium, cadmium hydroxide, silver, silver chloride, batteries, failure mechanisms.

particles of $Cd(OH)_2$ were formed on repeated cycling. This effect was concluded to be responsible for the decrease in capacity during the first ten cycles. A study by Bro and Kang (15) gives experimental data on the discharge profiles in an actual cadmium anode. These investigators sliced the electrode after discharge and were thus able to determine current distributions by differentiating the depth of discharge with respect to time. They also showed the effect of pore blockage by $Cd(OH)_2$ crystallites through an empirical correlation. It was found that the per cent coulombic efficiency dropped as the integral current density of a galvanostatic discharge was increased. Some polarization data were also presented. No theoretical treatment of the data was attempted.

Vermilyea (16) has classified films of silver halides on silver and oxide and hydroxide films on cadmium as "noncontinuous films." Some of the metal substrate is exposed and ions diffuse to and from the metal through openings in the overlaying salt or oxide. A review of metal electrodes with surface films is given by Vetter (17).

The mechanism of the growth of silver chloride on silver electrodes is apparently a function of applied current density. Lal *et al.* (18) found a purplish, probably polycrystalline deposit which formed at 1-2 mA/cm^2. Jaenicke *et al.* (19) obtained white films, with apparently lower specific resistance, formed at current densities greater than 20 mA/cm^2. They showed that these films were nonporous if thicker than 2-4μ. Thus liquid-phase silver ion transport was not important in anodic growth past this thickness. On the other hand, Giles (20) found that a series of intermediate, soluble complexes was formed on oxidation of silver single crystals in chloride-containing media. Lal *et al.* (21) observed periodic phenomena associated with the breakdown of the anodic film. Jaenicke *et al.* suggested that the cathodic process is cation migration along grain boundaries at large film thicknesses. After some time the film breaks down and a diffusion process in the electrolyte solution becomes predominant.

Lal *et al.* (18) found that the conductivity of AgCl depended on the current density during formation, rising with current density. The conductivity was reported to vary between 10^{-6} and 10^{-4} mho/cm. Apparently the solid-state transference number of the silver ion is nearly unity. Indira and Doss (22) have explained the high cation mobility on the basis of a stoichiometric excess of silver in the AgCl film formed electrolytically.

The rate of the electrochemical reaction in the Ag/AgCl couple seems large. Giles (20) proposed that the complexation dissolution reaction

$$Ag + nCl^- \rightleftarrows AgCl_n^{1-n} + e^-$$

takes place at a rate too fast to measure by faradaic impedance methods. The subsequent production of AgCl by chloride elimination would then be rate limiting. These results apply only to salt-free surfaces. As the surface becomes covered with AgCl crystals (phase formation takes place at about +25 mV overpotential), the overpotential of the electrode rises at constant current. Giles also observed large changes in the real surface area after formation and reduction of AgCl nuclei.

A review by de Levie (23) describes the features of many porous electrode models. Most porous electrode models employ a one-dimensional approach as discussed by Grens (24). Winsel (25) analyzed a single pore of constant conductivity with a highly conducting wall. He calculated some transient effects by integrating the local transfer current density over time and considering a finite amount of reactant to be available at each point in the electrode. Thus Winsel was able to show overpotentials which increased markedly as the amount of charge consumed approached the amount available.

Newman and Tobias (26) presented a steady-state analysis of a one-dimensional homogeneous mixture model of a porous electrode. They considered effects of a finite matrix resistance and variations in concentration. Austin and Gagnon (27) applied a similar analysis to their experimental data on Ag/Ag_2O electrodes and found good agreement. Grens (24) and Grens and Tobias (28) reported on analysis of transient effects in a porous electrode due to concentration changes in the pore solution. The transient mode was analyzed by a time-stepping method in which the results of computations for a previous step are used as the initial conditions of each time step.

The work by Alkire and co-workers (29, 30) was the first effort to account quantitatively for structural changes in a dissolving porous anode. They used dilute-solution theory with constant transport and solution properties. It was assumed that the solubility limit of the copper salt formed on anodic dissolution was not exceeded. Thus the effects of a sparingly soluble metal salt couple were not considered.

Dunning and Bennion (31) considered the effect of crystallites of active material on the charge and discharge process. The concept of a mass transfer coefficient describing transport between active metal sites and reactant salt crystallites was employed. Later Dunning *et al.* (32) extended that work to cover transient operation and cycling behavior. Even though constant solution properties and other idealizations were used, results of the model showed a redistribution of active-material conversion on repeated anodic and cathodic polarization.

The common assumptions underlying many theoretical porous electrode treatments have been analyzed by Grens (33). He stated that the assumption of concentration independent electrolytic solution properties is highly questionable. Changes in volume of metal and metal salt with time were not included.

In this work a model for the operation of a porous electrode with sparingly soluble reactants is developed. The effects of varying solution properties are included as well as convection arising from differing densities of reactant and product species. The effects of local mass transfer between salt crystallites and metal surface with considerable attention to the detailed physical and mathematical description of this process is investigated. In addition, the effect of complexing between active species and the bulk electrolyte, and the associated bulk electrolyte concentration dependence, has been considered. The behavior of the porous electrode is determined by a numerical solution of the combined continuity, transport, and kinetic equations which describe the system. The electrode polarization can be determined as a function of applied current density and time. The distribution of transfer current density and state of charge can be determined as a function of position and time. The results can suggest certain idealized modes of failure and performance limitations.

Development of a Single Pore Model

A one-dimensional approach is used in which variations in properties occur only along the y direction. At the origin is a current collecting backing plate or center of symmetry. The total electrode thickness is L. At values of y greater than L it is assumed that the solution has the properties of the bulk. The geometric cross section of a model pore is shown in Fig. 1. The solid, sparingly soluble salt is imagined as being a series of crystallites on the surface of the active metal. The radius r_3 limits the region in space allocated to an "average pore" and defines the pore as a system. The radius r_3 is a constant. The space between r_2 and r_3 defines the quantity of active metal within the space allocated to the pore. The radius r_2 is a variable and changes as the quantity of active metal within the pore varies. The space between r_1 and r_2 is the effective volume of solid, sparingly soluble salt within the pore. The inner radius r_1 defines the area available for transport in the solution phase in the y direction. The radius

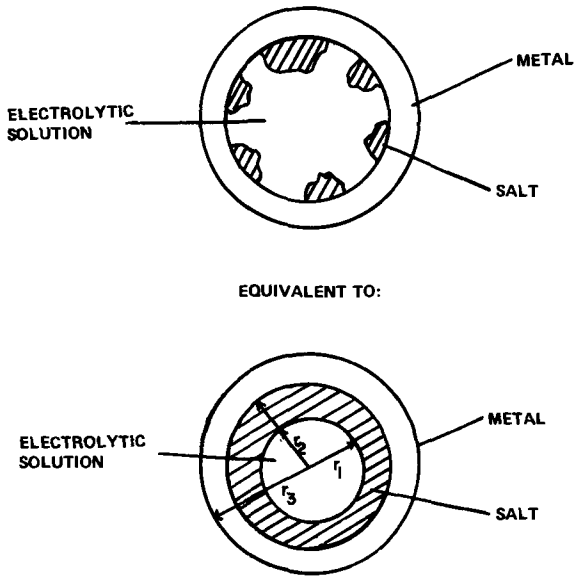

Fig. 1. Circular pore geometry

r_1 is a variable. This description is not to imply that the metal and salt are annular in shape. The radii, r_1, r_2, and r_3 are defined as bookkeeping artifacts to allow quantitative, mathematical treatment of the amounts of active metal and active salt as functions of time and position within the porous electrode.

The over-all, stoichiometric reaction representing the chemical process within the porous electrode is written

$$\sum_i s_i A_i^{z_i} = ne^- \qquad [1]$$

Examples are

$$Cd + 2\,OH^- - Cd(OH)_2 = 2e^-$$
$$Pb + SO_4^= - PbSO_4 = 2e^-$$
$$Ag + Cl^- - AgCl = e^-$$

The s_i are stoichiometric coefficients and can be positive or negative. The z_i are the charges on the species A_i and can be positive, negative, or zero. The n is the number of electrons transferred for the reaction as written and is a positive number.

The radius r_2 varies with time as the quantity of active metal varies. The local cathodic transfer current density, j, is a measure of the rate of appearance or disappearance of active metal. The two variables are related by the expression

$$\frac{dr_2}{dt} = \frac{-s_1 M_1}{n\mathbf{F}\rho_1} j \qquad [2]$$

The subscripts 1 imply the active metal. M_i is the molecular weight of species i, and ρ_i is the density of species i.

The variation of the radius r_1 depends on the relative rates of appearance and disappearance of the metal and salt. The relation between dr_1/dt and the transfer current density j depends on how both solid species vary with j. The relation is

$$\frac{dr_1}{dt} = -\sum_{\substack{\text{solid}\\ \text{species}}} \frac{s_i M_i}{n\mathbf{F}\rho_i} \frac{r_2}{r_1} j = A\frac{r_2}{r_1} j \qquad [3]$$

Equation [3] defines the constant A. The ratio r_2/r_1 appears because the quantities of salt and metal present are accounted for in terms of cylindrical geometry.

As the volume of solid species within the control element changes, the porosity or space available for liquid changes. In addition, the mass of liquid varies as liquid phase species also participate in the chemical reaction whose rate is characterized by j. As the relative volumes of liquid and solid change, the porous electrode "breathes," *i.e.*, a convective flow of the liquid into or out of the porous electrode is created. This bulk electrolyte solution convective motion can be described by an over-all continuity equation or molar balance on a control element

$$\frac{\partial}{\partial t}\left[\begin{pmatrix}\text{moles in electrolyte}\\ \text{solution phase}\end{pmatrix} + \begin{pmatrix}\text{moles in}\\ \text{solid phase}\end{pmatrix}\right] = \begin{bmatrix}\text{net increase in moles}\\ \text{due to convection}\end{bmatrix} + \begin{bmatrix}\text{net increase in moles}\\ \text{due to electrode reaction}\end{bmatrix}$$

In more mathematical terms, this relationship can be written as

$$\frac{\partial c_T}{\partial t} + \frac{2r_2}{r_1^2}\left(Ac_T - \frac{1}{\mathbf{F}}\right) j + \frac{1}{r_1^2}\frac{\partial}{\partial y}(r_1^2 c_T v^*) = 0 \qquad [4]$$

where c_T is the actual, total molar concentration in the liquid phase and v^* is the actual, molar average velocity in the liquid phase.

Two equations are needed to describe the concentration variations of water and electrolyte in the liquid phase. The first is the so-called species continuity equation

$$\frac{\partial}{\partial t}(c_+ \pi r_1^2) = -\frac{\partial}{\partial y}(\pi r_1^2 c_+ v_+) \qquad [5]$$

Here c_+ is the concentration of the positive ion and v_+ is the velocity of the positive ion. The positive ion is chosen for this balance since, for the electrodes being considered, the positive ion does not participate in the chemical reaction and no source term is needed in Eq. [5]. The species flux, c_+v_+, must be described as a function of the appropriate driving forces to complete the description of bulk electrolyte transport inside the porous electrode (34)

$$c_+ v_+ = -Dc_T\frac{dx_e}{dy} + \frac{i_2 t^*_+}{z_+\mathbf{F}} + c_+ v^* \qquad [6]$$

One can identify the diffusion, migration, and convection contributions to the electrolyte diffusion on the right-hand side of Eq. [6]. D is the diffusion coefficient for the electrolyte in water; x_e is the particle fraction of the electrolyte in the solution averaged across the pore diameter r_1; i_2 is the current density in the solution phase; and t^*_+ is the transference number relative to the molar average velocity, v^*.

The variation in potential in the solution, ϕ_2, and the variation of potential in the matrix phase, ϕ_1, must be described and related to the current density in the solution, i_2, and the current density in the matrix phase i_1. The simple form of Ohm's law does not hold in the solution phase; there must be a correction for variations in electrolyte activity, a_e, where, for example, a_e is the mean molal activity coefficient $\gamma_\pm$ times the molality

$$i_2 = -\kappa\frac{d\phi_2}{dy} - \frac{\kappa t^0_+}{\mathbf{F}}\nu RT\frac{d\ln a_e}{dy} \qquad [7]$$

Here κ is the conductivity of the electrolyte solution and ν is the number of ions per electrolyte molecule. It is assumed that there are no concentration variations within the matrix and that Ohm's law holds

$$i_1 = -\sigma\frac{(r_3^2 - r_2^2)}{r_3^2}\frac{d\phi_1}{dy} \qquad [8]$$

Here σ is the specific conductance of the matrix. The geometric terms are there to correct i_1 from an area basis of the whole volume element to that for the metal phase alone between r_2 and r_3. The current density i_2 is applied to the solution alone, by definition. This un-

usual variation in definitions is for mathematical convenience.

The two current densities, i_1 and i_2, are related to the over-all or total current density I through the conservation of charge

$$I = i_1 + \frac{r_1^2}{r_3^2} i_2 \qquad [9]$$

The physical and mathematical model developed up to here is similar to one presented earlier (32). In the earlier model, the detailed description of the transport of the active, sparingly soluble salt was handled using a single, constant transport coefficient and redox overpotential expression. In this study a more detailed description of the transport of the active salt and the effect of crystallization resistance and complexing are added. Two possible situations for transport of the active salt species to and from the salt lattice are described. The first is simply to assume that the salt completely covers the metal and ions arrive at the metal-salt or salt-electrolytic solution interfaces by solid-state transport through the salt film. If the transference number of the solid salt cation is unity, the film model simply means adding a series resistance to the surface overpotential. The redox expression relating the transfer current density to the surface overpotential between the matrix and solution, $\phi_1 - \phi_2$, is

$$j = -i_o \left\{ \exp\left[\frac{-\alpha_a \mathbf{F}}{RT} \left(\phi_1 - \phi_2 + \frac{j}{\kappa'} r_2 \ln \frac{r_2}{r_1} \right) \right] - \exp\left[\frac{-\alpha_c \mathbf{F}}{RT} \left(\phi_1 - \phi_2 + \frac{j}{\kappa'} r_2 \ln \frac{r_2}{r_1} \right) \right] \right\} \qquad [10]$$

Here i_o is the exchange current density, and α_a and α_c are transfer coefficients. The κ' is the specific conductance of the solid electrolyte film. The geometric term $r_2 \ln r_2/r_1$ accounts for the film thickness and the cylindrical geometry.

The solution-diffusion model assumes that the sparingly soluble salt must dissolve into the electrolytic solution and then diffuse in the liquid phase to the metal surface, or *vice versa*. It is possible that a rate-limiting step occurs at the salt interface due to limitations on how rapidly the salt ions can get out of or into the crystal, so-called crystallographic overpotential. There can also be a rate-limiting step in transport through the solution. The fraction of the metal surface exposed to the liquid electrolytic solution is defined as θ. The over-all mass transfer coefficient is k_m^* defined so that

$$j = n\mathbf{F}k_m^* c_{eq}(1 - c_0/c_{eq}) \qquad [11]$$

where c_0 is the active salt concentration at the metal surface and c_{eq} is the equilibrium concentration of the active salt in the electrolytic solution. The c_{eq} is assumed to depend on local electrolytic solution concentration through a complexing reaction of the form

$$MX_n + X^- = MX^-_{n+1} \qquad [12]$$

where MX_n is the active salt and X^- is the anion of the electrolyte in the liquid electrolyte solution. The species MX^-_{n+1} is the form in which the active metal ion moves through the solution. The equilibrium concentration of the complex MX^-_{n+1} c_{eq}, depends on the concentration of species X^- and the equilibrium constant, K, associated with the reaction [12]. This dependence of c_{eq} on the electrolyte concentration, c_e, and the equilibrium constant have been included in the mathematical calculations.

The over-all mass transfer coefficient, k_m^*, is related to the mass transfer and crystallographic resistances as follows

$$\frac{1}{k_m^*} = \frac{1}{k_m^o \dfrac{1 - 2\theta}{\ln\left(\dfrac{1-\theta}{\theta}\right)}} + \frac{1}{(1-\theta)k_{xtal}} \qquad [13]$$

Here k_m^o is twice the mass transfer coefficient when θ equals 1/2. The expression $(1 - 2\theta)/\ln((1 - \theta)/\theta)$ adjusts the mass transfer coefficient as it is expected to vary depending on the surface area of metal, θ, or surface area of active salt, $1 - \theta$, exposed. The term $(1 - \theta)k_{xtal}$ is the coefficient for the kinetics of dissolution (or deposition) of the salt.

The surface overpotential could be treated as a potential-dependent resistance for mass transfer in series in Eq. [13]. In this study it has been treated separately. The surface overpotential $(\phi_1 - \phi_2)$ and transfer current density are assumed to be related through a concentration-dependent expression of the form

$$j = -\theta i_o \left\{ \exp\left[\frac{\alpha_a \mathbf{F}}{RT} (\phi_1 - \phi_2) \right] - \frac{c_o}{c_{eq}} \exp\left[-\frac{\alpha_c \mathbf{F}}{RT} (\phi_1 - \phi_2) \right] \right\} \qquad [14]$$

Here i_o is the exchange current density when MX_{n-1}^- is at the concentration c_{eq}. The terms α_a and α_c are transfer coefficients.

It is convenient to define a new variable

$$C_1 \equiv c_0/c_{eq}$$

and substitute Eq. [14] into Eq. [11], rearrange terms and get

$$C_1 = \exp\left[\frac{(\alpha_a + \alpha_c)\mathbf{F}}{RT} (\phi_1 - \phi_2) \right] + \frac{(1 - C_1) n\mathbf{F} k_m^* c_{eq}}{\theta i_o} \exp\left[\frac{\alpha_c \mathbf{F}}{RT} (\phi_1 - \phi_2) \right] \qquad [15]$$

If just the first term on the right side is considered, Eq. [15] is seen to reduce to the Nernst equation. The second term on the right side accounts for the nonzero electrochemical kinetic contribution to the overpotential. If k_m^* is small and i_o is large, this contribution will be small under most conditions. However, even for k_m^* small and i_o large, the electrochemical kinetic overpotential becomes dominant as θ goes to zero.

A final but important aspect of the model is the relation between θ, the fraction of the active metal surface exposed, and the state of charge. Before this relation can be expressed, the maximum charge storage per unit volume must be established. There are two factors which may be limiting. First, the amount of active metal may limit the maximum charge, Q_{cm}. For example, when all the cadmium in a $Cd/Cd(OH)_2$ electrode is consumed, that will end the discharge. When the active metal is limiting, Q_{cm} can be expressed as

$$Q_{cm} = n\mathbf{F} \frac{\rho_M}{M_M} \left(1 - \frac{r_{2o}^2}{r_{3o}^2} \right) \qquad [16]$$

Here ρ_M and M_M are density and molecular weight respectively, of the active metal. The r_{2o} and r_{3o} are the initial or fully charged radii r_2 and r_3 (when active salt is converted entirely to metallic form).

A second limitation on the maximum charge per unit volume, Q_{cm}, might be the complete choking or filling of the pore by the active salt MX_n. The salt loading capacity limitation on Q_{cm} is then given by the expression

$$Q_{cm} = Q_{cmo} + n\mathbf{F} \frac{r_{1o}^2}{r_{3o}^2} \frac{1}{\left(\dfrac{M_{MX_n}}{\rho_{MX_n}} - \dfrac{M_M}{\rho_M} \right)} \qquad [17]$$

Here Q_{cmo} is the initial amount of active material, MX_n. The second term on the right side represents the additional MX_n that can be formed from the metal before the pore becomes completely plugged or "choked solid."

The value of Q_{cm} is calculated using both Eq. [16] and [17]. The smaller value of Q_{cm} is selected for use.

It may be that the charge storage is further limited by passivation, *i.e.*, θ going to zero before the maximum charge Q_{cm} is realized. A new charge parameter Q^* is defined

$$Q^* = \lambda Q_{cm} \qquad [18]$$

The coefficient λ represents the fraction of the theoretical maximum of charge per unit volume which can be realized prior to the metal surface becoming completely covered by salt and passivated. (Thus far, the film and solution diffusion models have not been combined. In this solution-diffusion model, the electrode cannot operate once θ goes to zero.)

The relation between θ and the state of charge, Q_c/Q^*, is assumed to be described by the expression

$$\theta = 1 - \left(\frac{Q_c}{Q^*}\right)^p \qquad [19]$$

Here p is essentially a fitting parameter. However, using simple geometric arguments it can be shown that for $p = 0$, film-type passivating active salt deposits are implied. For $p = 2/3$ cubic salt crystals are implied. As p gets very large, long needle-like crystals of the active salt are implied.

This completes the physical and mathematical description of the porous-electrode models. Of necessity, some aspects of the model are still rather highly idealized, and all possible processes are not included. For example, temperature effects are not included. Such effects could have a large effect on the parameter p as well as migration of various species within the pores. However, it is hoped that the more detailed description of transport of active species inside the porous structure will bring the mathematical modeling closer to actual electrode behavior and help in visualizing and describing quantitatively the effects of various processes.

Results of Calculations and Discussion

Details of the computational problem and a copy of the computer program are presented elsewhere (35). The equations have been solved for a few selected operating conditions and parameters. The use of an effective, efficient matrix inversion technique is most important to realizing solutions for a minimum cost. The method described by Newman (33, 34) has been used. Additionally, proper linearization of the nonlinear terms in the equations has been found to reduce greatly run time and therefore cost. Time-dependent results were achieved using the pseudo-steady-state approximation. This approximation means assuming time-independent behavior and solving the steady-state, ordinary differential equations. The steady-state solution is then used to predict the electrode conditions for one time increment later, *i.e.*, new values of r_1, r_2, and Q_c. A new steady-state solution is then found, and so on. The dr_i/dt terms are related to the transfer current, j, and are thus retained, in effect, while still eliminating the explicit time dependence. The actual concentration dependence of the physical properties of the binary solution was used, except t_+° was assumed constant. The exchange current density, i_o, was assumed to be directly proportional to the electrolyte concentration c_e. The correlations of solution properties are based on the work of Chapman, Newman, and Nisancioglu (38-40).

Several results are presented to illustrate a few of the features of this physical and mathematical description of porous electrodes of the second kind. Using input parameter characteristics of the cadmium electrode, overpotential as a function of time has been predicted for mass transfer, crystallization, and electrochemical kinetic rate-controlling steps as shown in Fig. 2. The initial decline in overpotential for crystallization rate control results because of initial lack of nuclei on which the product $Cd(OH)_2$ can precipitate. This leads to large supersaturation initially and higher overpotential. As more sites for $Cd(OH)_2$ precipitation are produced, the level of supersaturation decreases, and the overpotential decreases. Somewhat similar arguments apply to the solution-phase mass transfer; however, the effect is much less pronounced. In each case, the consuming of reactant, cadmium in this case, and blocking of the cadmium surface slowly forces the reaction zone back into the electrode. The resulting increase in resistance in the electrolytic solution causes the observed rise in electrode overpotential. In all cases, a limiting current condition finally terminates the discharge.

In all cases studied for the $Cd/Cd(OH)_2$ electrode, the transfer current is initially high near the front, *i.e.*, the interface with the bulk electrolyte, and "eats" its way back into the electrode as cadmium is consumed. The electrochemical kinetic resistance will always become controlling as the cadmium surface becomes blocked (recall the discussion of Eq. [15]). In Fig. 3, the dimensionless reaction distribution as a function of position is shown at various states of discharge for the electrochemical resistance controlling. The quantity AJ is the dimensionless current density corrected to the outer radius of the pore and defined as $AJ = -j2\pi r_2 L/I\pi r_3^2$. The shapes of the curves in Fig. 3 match quite well with similar experimental data on actual $Cd/Cd(OH)_2$ electrodes presented by Bro and Kang (15).

Although it has been possible to match Bro and Kang's (15) result with the mathematical model at 2 mA/cm² over-all current (35), the overpotential predicted by the solution-diffusion model at 50 mA/cm² is much lower than observed by Bro and Kang. Using the film model, a reasonably good fit of predicted and experimental overpotential time behavior is achieved for a salt-film specific conductance of 3.5×10^{-8} mho/cm, as shown in Fig. 4. However, although the solution-diffusion model predicts a cutoff, *i.e.*, sudden increase in overpotential indicating the electrode is discharged, no such sharp cutoff is predicted by the film model. This result suggests that a combination of the solution-diffusion and film-transport mechanisms in parallel

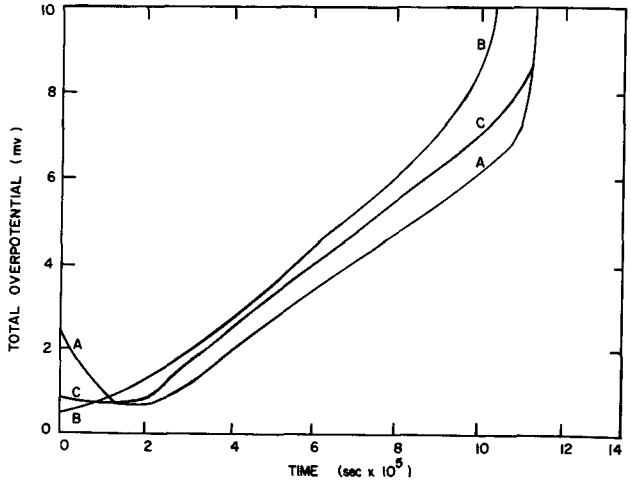

Fig. 2. Overpotential-time curves for a cadmium anode, solution diffusion model, current density 2 mA/cm². Input parameters: $r_1 = r_2 = 6.9 \times 10^{-4}$ cm, $r_3 = 8.93 \times 10^{-4}$ cm, $L = 0.508$ cm, $x_e^\circ = 0.11$, $K = 2 \times 10^{-5}$, $\lambda = 0.7$, $p = 2/3$, $\alpha_a = \alpha_c = 1$. Curve A, crystallization rate control, $k_m^\circ = 1.437$ cm/sec, $k_{xtal} = 1.47 \times 10^{-2}$ cm/sec, $nFc_{eq}/i_o = 0.696$ sec/cm. Curve B, electrochemical kinetic control, $k_m^\circ = k_{xtal} = 1.437$, $nFc_{eq}/i_o = 68.29$. Curve C, mass transfer control, $k_m^\circ = 1.47 \times 10^{-2}$, $k_{xtal} = 1.437$, $nFc_{eq}/i_o = 0.696$.

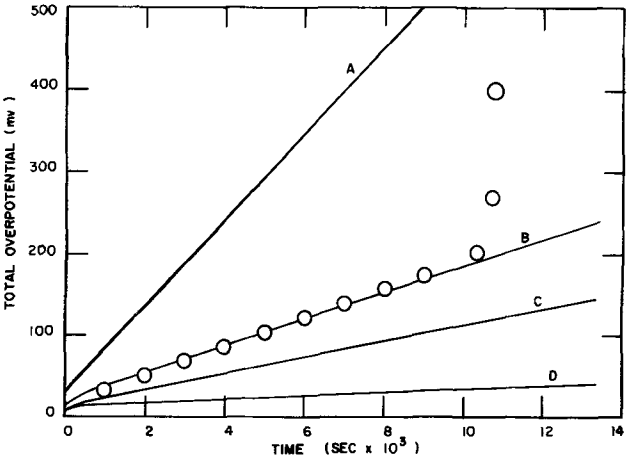

Fig. 4. Overpotential-time curves for cadmium anode at 50 mA/cm^2. Film model for various film conductances; curve A, 10^{-8} mho/cm; curve B, 3.5×10^{-8}; curve C, 10^{-7}; curve D, 10^{-6}. Circles are experimental data of Bro and Kang (16). Physical input parameters are the same as in Fig. 2. Exchange current density is 100 mA/cm^2.

or even series may be required to describe actual electrodes more accurately. Our conclusion here is similar to the explanation proposed by Nagy and Bockris (41) for the zinc-zinc oxide electrode behavior. Additionally the role of CdO may need to be more clearly understood and included as an explicit part of the model.

The model can be used to predict many combinations of current, overpotential, concentration, reaction rates, maximum power, etc., as functions of position, time, and cycling. However, only one more effect will be shown here to illustrate the type of information the mathematical model can produce.

It is generally to be expected that for a uniform state of charge or discharge, *i.e.*, Q_c uniform at different values of y, and a highly conducting matrix, the reaction distribution will be shifted toward the front of the electrode due to resistance losses in the electrolytic solution. This nonuniform reaction distribution is generally expected to become more nonuniform at higher

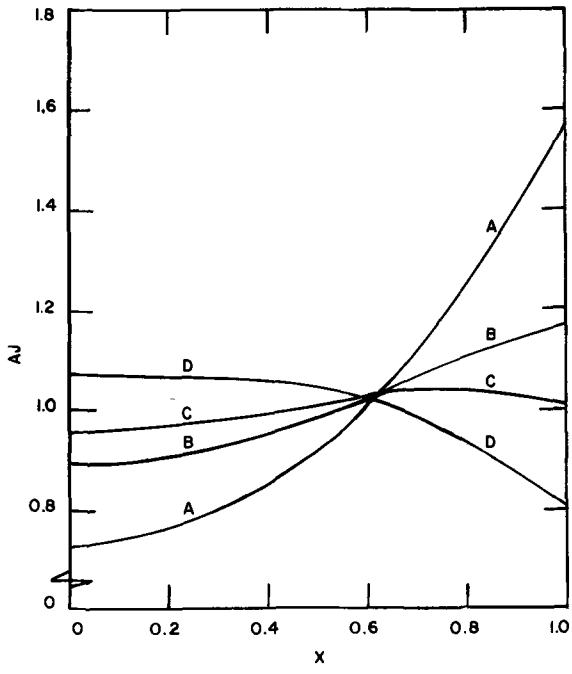

Fig. 5. Initial current distribution in Ag/AgCl cathode at various current densities. Curve A, 1 mA/cm^2; curve B, 7 mA/cm^2, curve C, 10 mA/cm^2; curve D, 15 mA/cm^2. Input parameters: $r_1 = 5.0 \times 10^{-4}$ cm, $r_2 = 7.2 \times 10^{-4}$ cm, $r_3 = 10^{-3}$ cm, $L = 0.1$ cm, $x_e^o = 0.02$, $K = 1.735 \times 10^{-5}$, $\lambda = 0.90$, $p = 2/3$, $\alpha_a = \alpha_c = 1/2$, $k_m^o = 0.1$ cm/sec, $k_{xtal} = 10^3$, $i_o = 1$ mA/cm^2.

currents. This effect is one explanation for lower charge utilization at higher currents or power levels. Using parameters characteristic of the Ag/AgCl electrode, the possible behavior was observed, as shown in Fig. 5. As the current was increased, the reaction distribution became more uniform, and at the highest current density explored, 15 mA/cm^2 in this sequence of runs, the reaction rate was higher toward the back. This behavior can lead to uniform utilization of active material and implies a continual high energy density at high power. The effect is caused by the complexing phenomena incorporated into the mathematical model in Eq. [11] through [15]. At higher cathodic currents, the electrolyte concentration, KCl in this case, increases toward the back of the electrode. The increased Cl^- concentration increases the concentration of the active complex, MX^-_{n+1}. This increased concentration, c_{eq}, increases the mass transfer, crystallization, and electrochemical rates. Thus, the back of the electrode may become a favored reaction zone in spite of the solution resistance losses. The proper use and control of this complexing phenomenon could lead to improved battery design and performance.

The current distribution as a function of position for various states of discharge at 40 mA/cm^2 is shown in Fig. 6 to illustrate further the effect of the complex formation on Ag/AgCl electrode behavior.

A final example of the predictive capability of the mathematical model for the Ag/AgCl electrode is the variation of the discharge efficiency or energy storage capability with applied current as shown in Fig. 7. A higher mass transfer coefficient, k_m^o, is seen to increase utilization efficiency at high currents. The discharge was at constant current in each case. The electrode was assumed to be discharged when the overpotential began to rise very rapidly and the numerical computations would no longer converge. Error bars are used at intermediate points because coarse time grids were used. Accurate convergence and fine time steps became expensive and time consuming under these conditions. However, the end points at 0% discharge efficiency are accurately determined, since they correspond to the limiting currents at the initial charge conditions.

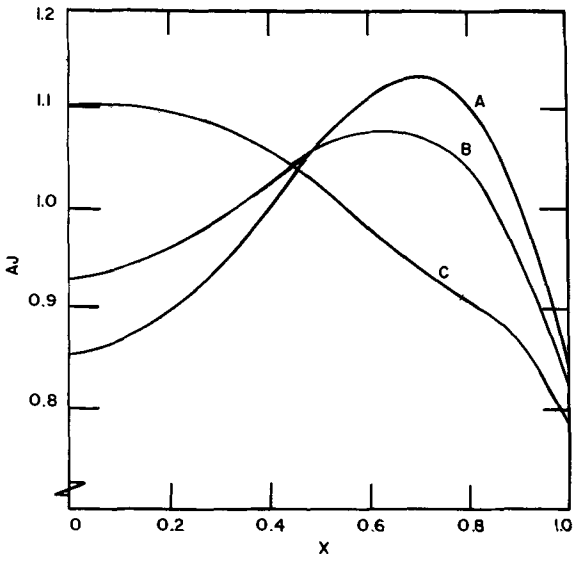

Fig. 6. Current distribution in Ag/AgCl cathode, 40 mA/cm², at various times. Input parameters same as Fig. 5 except k_m^o = 0.3 cm/sec. Curve A, initial; curve B, 1000 sec; curve C, 2000 sec.

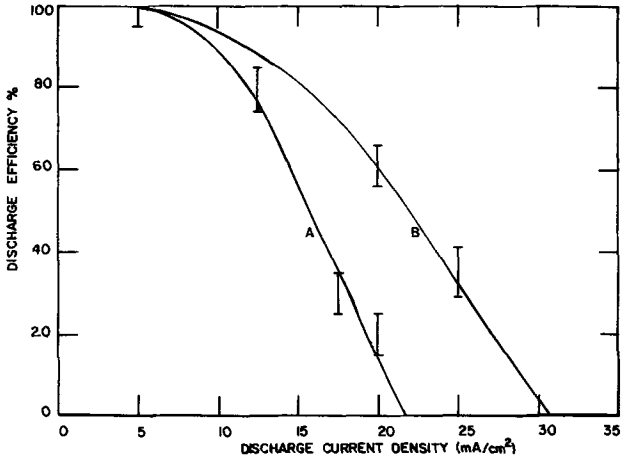

Fig. 7. Discharge efficiency as a function of discharge current density for Ag/AgCl cathode. Input parameters same as Fig. 5 except i_o = 100 mA/cm². Curve A, k_m^o = 0.10 cm/sec; curve B, k_m^o = 0.12 cm/sec.

Conclusions

A key to the validity and applicability of the models is the extent to which the local overpotential expressions approximate conditions inside the operating porous electrode. Apparently, the general behavior of a cadmium anode is best approximated by the solution-diffusion model at low current densities and the film model at higher current densities. The formation of a CdO layer may explain this result. A combination of the film and solution-diffusion models would be a logical extension of this work.

Solution-diffusion model results are very sensitive to the magnitude of k_m^o. Possibly further interpretation and investigation of this parameter can explain the failure of some systems to give higher energy and power densities. The results of this study show that cathodic failure is caused by low mass transport which leads to limiting currents in the electrode. Anodic failure is, in general, caused by blockage of pores or by complete coverage of the metal surface by product crystallites. All these effects are closely related to the magnitude and functional dependence for the mass transfer coefficient k_m^*.

Dunning *et al.* (31) calculated current distributions without considering the effects of concentration variations or of complexing reactions. By considering these effects, the present solution-diffusion model predicts that a peak in current distribution may occur at initial polarization and that the middle of a porous cathode may be exhausted before the front face. This effect has not been previously observed and suggests that experiments could be performed to look for it.

The film model presented here is simpler than the solution-diffusion model. It does not predict such subtle but important phenomena as variations of useful energy density with discharge current. Unless the films are very thin or highly conductive, the film model represents the mode of operation of passivated electrodes which, hopefully, is a condition not often encountered in battery operation. For highly conducting films, a more nearly correct model may involve competing or series solution-diffusion steps or more complex solid-state diffusion processes than those discussed here. The nickel oxide or lead dioxide electrodes may be in the latter classification.

Only a few computer results have been presented compared to the many possible performance predictions possible. The nonuniform current distributions predicted by all models lead to nonuniform reactant conversion. On cycling [see also Ref. (32)], these effects propagate and can ultimately lead to some sort of failure. The programs can keep accurate account of the state of charge. Battery performance (current-voltage curves for example) can be determined as a function of state of charge and possibly improved methods can be developed to determine more easily the state of charge for real batteries.

The usefulness of models and predictions of the type presented here is predicated on the faithful description of actual, physical processes. An important next step is experimental validation and improved descriptions of the elementary processes in real batteries.

SYMBOLS

A_i	chemical symbol for species i
A	a structural parameter for the metal salt system, cm³/coulomb
a_e	activity of the electrolyte solution
AJ	a dimensionless reaction rate in the electrode, $-2jr_2L/Ir_3^2$
C_1	ratio of surface concentration to bulk saturation concentration of active species
c_T	total concentration $\Sigma_i c_i$, mole/cm³
c_i	concentration of species i, mole/cm³
c_{eq}	equilibrium concentration of complex species, mole/cm³
c_o	concentration of active species at the metal surface, mole/cm³
D	diffusion coefficient of the electrolyte, cm²/sec
e^-	symbol for the electron
$\mathbf{F}$	Faraday's constant, 96,500 coulombs/equivalent
I	superficial applied current density, A/cm²
i_1	superficial current density in metal phase, A/cm²
i_2	actual current density in solution phase, A/cm²
i_o	exchange current density, A/cm²
j	local (internal) cathodic current density, A/cm²
K	dissolution constant for complexation reaction
k_m^*	combined mass transfer and crystallization rate constant, cm/sec
k_m^o	mass transfer coefficient, cm/sec
k_{xtal}	a crystallization rate constant, cm/sec
L	total electrode thickness, cm
M_i	molecular weight of species i
MX_n	chemical symbol for a metal salt
n	number of electrons transferred in the electrode reaction as written
n	number of anions in a salt MX_n
N_i	flux of species i, mole/cm² sec
p	an adjustable parameter characterizing internal

crystal morphology
Q_c amount of charge stored at a point within the electrode, coulombs/cm³ of electrode
Q_{cm} the maximum amount of active material salt possible to store in the pore, coulombs/cm³
Q^* effective amount of active material available, coulombs/cm³
r_1 inner radius available for solution phase conduction, cm
r_2 inner radius of metal, cm
r_3 outer radius which defines over-all electrode area, cm
RT gas constant multiplied by the absolute temperature, joules/mole
s_i stoichiometric number for species i
t time, sec
t_+^* transference number of cation referred to molar average velocity
t_+° transference number of cation referred to solvent velocity
v^* molar average velocity, $\sum_i c_i v_i / \sum_i c_i$, cm/sec
v_i velocity of species i in solution, cm/sec
x_e particle fraction of the electrolyte, $c_e/(c_o + 2c_e)$
x dimensionless distance from backing plate, y/L
y dimensionless coordinate, cm
z_i charge number of species i

Greek symbols

α_c a kinetic parameter
α_a a kinetic parameter
θ microporosity of crystallite-surface system
κ specific conductance of electrolytic solution $ohm^{-1}\ cm^{-1}$
κ' conductivity of the solid film $ohm^{-1}\ cm^{-1}$
λ an adjustable parameter corresponding to the fraction of Q_{cm} reached before blocking of the surface occurs
ν number of ions per molecule of dissolved electrolyte (equals 2 for a 1-1 electrolyte)
ρ_i density of solid species i, g/cm³
σ conductivity of metal, mho/cm
ϕ_1 potential in metal phase, V
ϕ_2 potential in solution phase, V

On the Displacement Reaction in the Concentration Cells Involving Liquid Zinc and Cadmium Alloys

Z. Moser and K. Fitzner

Institute for Metal Research, Polish Academy of Sciences, Kraków, Poland

ABSTRACT

The equilibrium constant of displacement reaction $Zn + CdCl_2 \rightarrow Cd + ZnCl_2$ occurring in the concentration cell $Zn(l)\,|ZnCl_2$ in $(LiCl\text{-}KCl)_{eut}(l)\,|Zn\text{-}Cd(l)$ has been determined on the basis of the following parameters: (*i*) $\Delta F^{o}{}_{T}$ of the displacement reaction assuming ideal solutions for the salt and metal phases; (*ii*) data of dilute solutions of zinc in cadmium; (*iii*) thermodynamic properties of dilute solutions of $ZnCl_2$ and $CdCl_2$ in LiCl-KCl eutectic obtained in this paper from formation cells.

In this case of dilute solutions of zinc in cadmium the influence of displacement reaction is visible in the values of zinc activity coefficients at $X_{Zn} = 0.01$ molar fraction resulting in deviations from the linear dependence of $\ln \gamma_{Zn}$ *vs.* X_{Zn}. Investigations enabled the calculation of the correction for the measured emf values, which when taken into account prove the linear character of $\ln \gamma_{Zn}$ *vs.* X_{Zn} over the range $X_{Zn} = 0.01\text{-}0.1$ molar fraction in Zn-Cd system.

Investigations on dilute solutions of zinc carried out to determine the self-interaction parameter $\epsilon_{Zn}{}^{Zn}$, defined by Wagner (1), show that the dependence of $\ln \gamma_{Zn}$ *vs.* X_{Zn}, which is linear for dilute solutions, deviates from a linear relationship for some systems as $X_{Zn} \rightarrow 0$. The typical linear dependence of $\ln \gamma_{Zn}$ *vs.* X_{Zn} is illustrated in Fig. 1 by the Zn-Pb system (2), and deviations from a linear behavior as $X_{Zn} \rightarrow 0$ by the Zn-Cd (3) and Zn-In (4) systems. These deviations from linearity may be explained by a displacement reaction of the type

$$Me + ZnCl_2 = Zn + MeCl_2 \qquad [1]$$

(where Me = Cd, In, or Ga) occurring between $ZnCl_2$ in the metal salts and the metal of an alloy electrode of a concentration cell.

The closer Zn and the metal of the alloy electrode are to each other in the electromotive series, the further the equilibrium of reaction [1] lies to the right. Wagner (5) has assumed that the occurrence of reaction [1] is connected with the difference in standard-free energy of the formation of the metal chlorides. If the absolute value of the difference $\Delta F^{o}{}_{ZnCl_2} - \Delta F^{o}{}_{MeCl_2}$ is less than 7000 cal, the influence of the displacement reaction should be taken into account, and the range of the concentration of the components experimentally determined. Pursuing their considerations, Wagner and Werner (6) calculated the error resulting from reaction [1] in an experimentally determined activity.

Key words: concentration cell, displacement reaction, equilibrium constant, dilute $ZnCl_2$ and $CdCl_2$ solutions, formation cell, curve of equilibrium compositions.

However, the method of calculating the error given in (6) is unsatisfactory if the cation of the metal salt acting as a charge carrier changes in valency in the temperature range of the cell operation, as is the case with the gallium salts (7).

The present paper is an attempt to determine the composition of the alloy and the temperature range over which reaction [1] may occur by taking into consideration the metal-salt equilibrium.

The results of the investigations obtained for the Zn-Cd system are discussed, and the equilibrium of the reaction

$$Zn + CdCl_2 \rightarrow Cd + ZnCl_2 \qquad [2]$$

is determined.

From Fig. 1 in a paper by us (3) it appears that the displacement reaction occurs within the temperature range 773°-873°K, consequently our calculations have been made for three different temperatures: 773°, 823°, and 873°K. Utilizing the dependence

$$\Delta F^{o}{}_{T} = -2F\,(E^{oT}{}_{ZnCl_2} - E^{oT}{}_{CdCl_2}) \qquad [3]$$

and the data obtained by Hildebrand and Wachter (8),

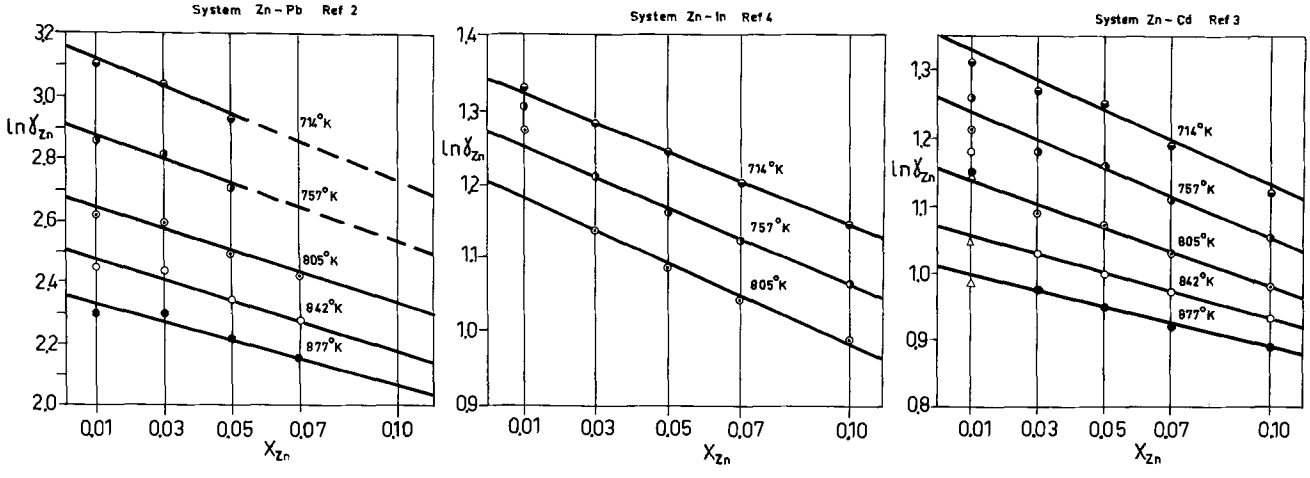

Fig. 1. Dependence $\ln \gamma_{Zn}$ *vs.* X_{Zn} for the Zn-Pb, Zn-Cd, and Zn-In systems. For the Zn-Cd system the graph includes points Δ calculated from corrected emf values.

Table I. The values of equilibrium constant of displacement reaction [2]

T°K	ln K	K
773	5.11502	166.5
823	4.66912	106.6
873	4.27116	71.6

Lorenz and Velde (9), and Lantratow and Alabyszew (10), which allows the following relationships to be determined

$$E^{\circ}_{ZnCl_2} = 1.9178 - 0.000696t \pm 0.0022V \quad [4]$$

$$E^{\circ}_{CdCl_2} = 1.6990 - 0.000599t \pm 0.0037V \quad [5]$$

(where t is the temperature in °C) the equilibrium constant K of reaction [2] was calculated and is summarized in Table I, and the dependence of ln K on temperature was determined to be

$$\ln K = \frac{5659}{T} - 2.208 \quad [6]$$

Use was made of the fact that reaction [2] occurs in the concentration cell in the solution LiCl-KCl which appears in excess relative to $ZnCl_2$ and $CdCl_2$. These solutions may be regarded as a solvent thus allowing the determination of the thermodynamic properties of $ZnCl_2$ and $CdCl_2$ in the eutectic LiCl-KCl for each metal chloride separately (1), since theoretical considerations show only slight differences in the activity coefficient on transition from a ternary to a quaternary system for dilute solutions. The concentration range of Zn in Cd, X_{Zn} — 0.01 — 0.09, permits the metal phase to be regarded in a similar way. Thus when $X_{Zn} \to 0$ in the system Zn-Cd we assume limiting values γ°_{Zn} instead of γ_{Zn}. Similarly when $X_{ZnCl_2} = X_{CdCl_2} \to 0$ in the salt phase the values $\gamma^{\circ}_{ZnCl_2}$ and $\gamma^{\circ}_{CdCl_2}$ may be assumed instead of γ_{ZnCl_2} and γ_{CdCl_2}.

Considering the negligible mutual solubility of the metals in salts, then $X_{Zn} + X_{Cd} \cong 1$ and $X_{CdCl_2} + X_{ZnCl_2} \cong 1$, thus the equilibrium constant of reaction [2] may be expressed in the form

$$\left(\frac{X_{[Cd]}}{1 - X_{[Cd]}}\right)\left(\frac{1 - X_{(CdCl_2)}}{X_{(CdCl_2)}}\right) = K\left(\frac{\gamma^{\circ}_{CdCl_2}}{\gamma^{\circ}_{ZnCl_2}}\right)\gamma^{\circ}_{Zn} = K'(T) \quad [7]$$

or in the form

$$\left(\frac{X_{[Cd]}}{1 - X_{[Cd]}}\right)\left(\frac{1 - X_{(CdCl_2)}}{X_{(CdCl_2)}}\right) = K \quad [8]$$

if it is assumed that the metal and the salt phases are both ideal solutions. It follows from Eq. [7] and [8] that to calculate the equilibrium composition of the phases the following are necessary:

(*i*) The calculation of the equilibrium constant of reaction [2] from the free-energy change, ΔF°_T, of that reaction according to formula [3].

(*ii*) Experimental determination of limiting activity coefficients of zinc in dilute solutions of zinc in cadmium. These values are available elsewhere (3) where the following formula was given

$$\ln \gamma^{\circ}_{Zn} = \frac{1131}{T} - 0.31 \quad [9]$$

which takes into account only those points having a linear dependence (Fig. 1). (The deviation from this linear dependence at $X_{Zn} = 0.01$ molar fraction is caused by the displacement reaction [2].)

(*iii*) Experimental evaluation of $\gamma^{\circ}_{ZnCl_2}$ and $\gamma^{\circ}_{CdCl_2}$ in dilute $ZnCl_2$-LiCl-KCl and $CdCl_2$-LiCl-KCl solutions obtained in this paper.

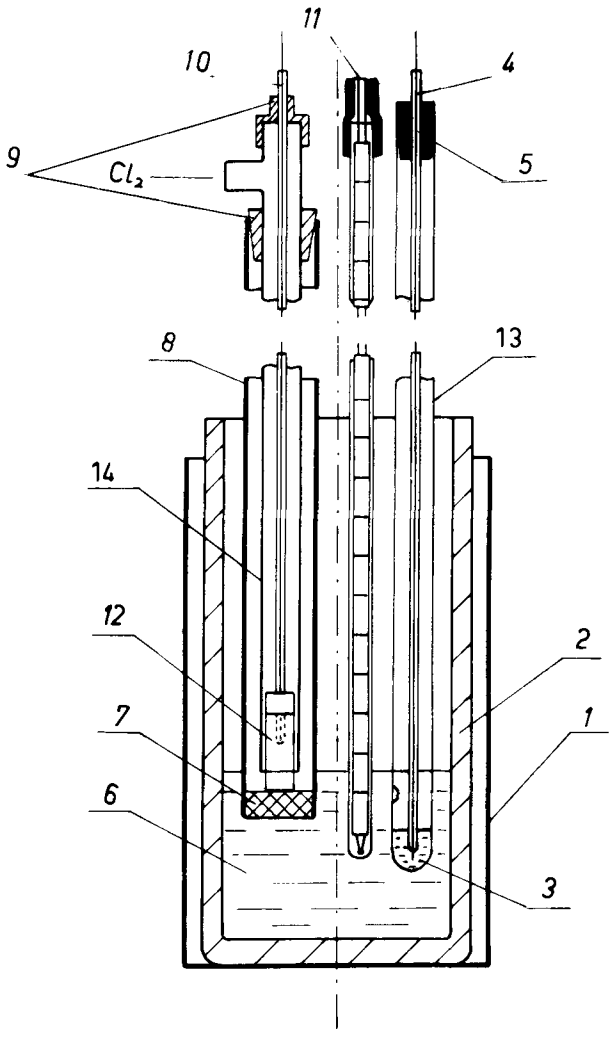

Fig. 2. Scheme of the experimental cell

Experimental

The investigation of the thermodynamic properties of $ZnCl_2$ and $CdCl_2$ were carried out using the reversible formation cells

$$Zn(l) \mid ZnCl_2 \text{ in } (LiCl\text{-}KCl)_{eut.}(l) \mid Cl_2(g)$$

$$Cd(l) \mid CdCl_2 \text{ in } (LiCl\text{-}KCl)_{eut.}(l) \mid Cl_2(g)$$

over the concentration range 0.01-0.09 X_{ZnCl_2} and X_{CdCl_2} molar fractions. The scheme of the cell is shown in Fig. 2. A crucible (point 2) made of silica and containing liquid salts (point 6) was placed in an alumina tube (point 1). The following were immersed in the liquid salts:

(*i*) A high-melting glass tube (point 13) closed at one end in the bottom of which was placed the liquid metal (point 3), Zn or Cd. An electrode made of tungsten wire (point 4) passing through the rubber stopper (point 5) of the tube (point 13) was introduced into the metal;

(*ii*) A Pt-PtRh thermocouple (point 11) was placed in a quartz tube enabling temperature measurements to ±2°C.

(*iii*) A diaphragm (point 8), with a sintered alundum cement plug (point 7) at the bottom, contains the chlorine electrode made of a high-melting glass tube (point 14), a graphite rod (point 12), and a Pt wire (point 10). Seals (point 9) were made of Teflon.

The preparation of the electrode and the diaphragm have been described elsewhere (11-12). The cell was placed in an ordinary resistant furnace with a longitudinal temperature gradient of ±2°C.

Temperature and emf were recorded on a Pye potentiometer having an accuracy of 0.01 mV.

Procedure

The eutectic LiCl-KCl mixture obtained by evaporating a water solution, was dried under vacuum for about 70 hr while the temperature was increased. The dried mixture was next placed in a crucible (point 2, Fig. 2) located in an operating furnace. The required amount of $ZnCl_2$ or $CdCl_2$ was added and the salts melted under an HCl atmosphere. After melting, HCl was passed through the melt for about 1 1/2 hr followed by argon for about 1 hr. The crucible was placed in the measurement furnace in an alumina sheath (point 1) and the cell arranged as shown in Fig. 2. Measurements were made for temperatures increasing or decreasing at a constant rate. The results of measurements were corrected for the thermoelectric emf between the tungsten and the platinum which were used as the leads from the electrodes. The composition of salts for the particular runs were determined analytically after a series of measurements had been completed.

The results of the measurements are given in Fig. 3 and 4 and show a linear dependence of emf on temperature. Applying the least squares method, the experimental data in the case of the $ZnCl_2$-LiCl-KCl system may be presented by the following equations for the $ZnCl_2$-LiCl-KCl system

$$X_{ZnCl_2} = 0.010 \quad E = 2.1299 - 0.000441t \pm 0.0041V \quad [10]$$
$$X_{ZnCl_2} = 0.023 \quad E = 2.1202 - 0.000490t \pm 0.0039V \quad [11]$$
$$X_{ZnCl_2} = 0.036 \quad E = 2.1088 - 0.000501t \pm 0.0037V \quad [12]$$
$$X_{ZnCl_2} = 0.050 \quad E = 2.0934 - 0.000512t \pm 0.0038V \quad [13]$$
$$X_{ZnCl_2} = 0.077 \quad E = 2.0907 - 0.000544t \pm 0.0041V \quad [14]$$

and for the $CdCl_2$-LiCl-KCl system

$$X_{CdCl_2} = 0.010 \quad E = 1.8646 - 0.000422t \pm 0.0047V \quad [15]$$
$$X_{CdCl_2} = 0.024 \quad E = 1.8354 - 0.000429t \pm 0.0039V \quad [16]$$
$$X_{CdCl_2} = 0.038 \quad E = 1.8264 - 0.000466t \pm 0.0038V \quad [17]$$
$$X_{CdCl_2} = 0.050 \quad E = 1.8256 - 0.000471t \pm 0.0038V \quad [18]$$
$$X_{CdCl_2} = 0.073 \quad E = 1.8062 - 0.000466t \pm 0.0037V \quad [19]$$

where t is the temperature in °C. The deviations given for E at each concentration in Eq. [10]-[19] are the sum of the standard deviation of the emf and the correction for the oscillation of chlorine pressure about 1 atm.

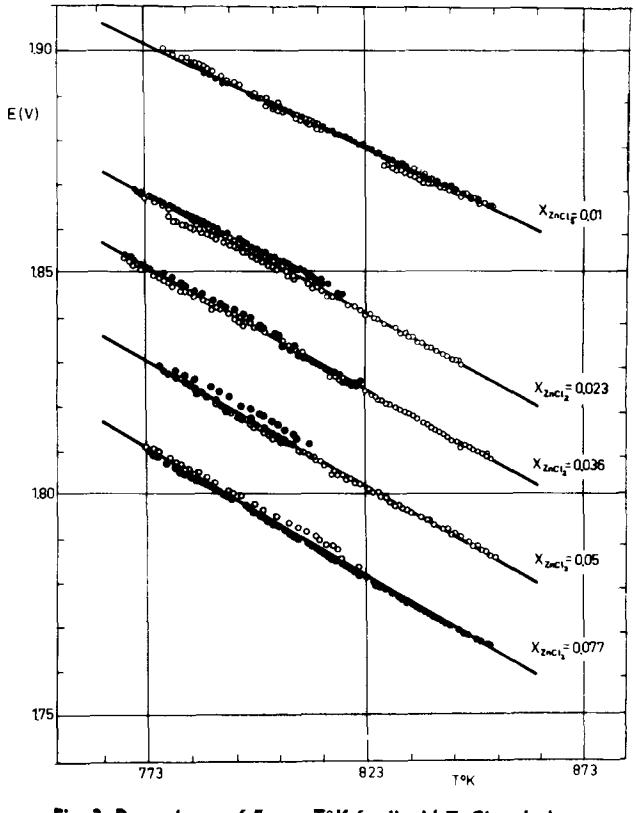

Fig. 3. Dependence of E_V vs. T°K for liquid $ZnCl_2$ solutions

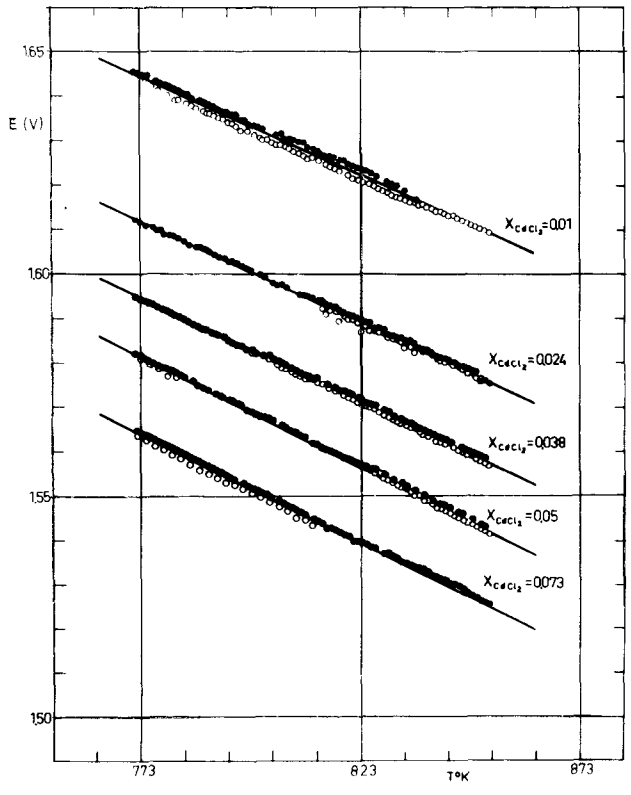

Fig. 4. Dependence E_V vs. T°K for liquid $CdCl_2$ solutions

Employing the relation

$$E_i - E^\circ_i = -\frac{RT}{nF} \ln a_i \quad [20]$$

where E°_i is the standard cell potential obtained with pure $ZnCl_2$ or $CdCl_2$, E_i is the emf value of the formation cell for the $ZnCl_2$-LiCl-KCl or $CdCl_2$-LiCl-KCl system, T is in °K, R is the ideal gas constant = 1.986 cal/deg, n is the electrochemical valency, $\mathbf{F}$ is Faraday's constant = 23,066 cal/V, and a_i is the activity of $ZnCl_2$ or $CdCl_2$. The ln γ_i was calculated for the particular salt compositions taking into account Eq. [10]-[19] and assuming $P_{Cl_2} = 1$ atm, and $n = 2$.

The results of the calculations are presented in Fig. 5 and 6. It was found that within the concentration range 0.01-0.1 molar fraction they may be described by a linear dependence as in the case of the metal systems. The calculated values $\gamma^\circ_{ZnCl_2}$ and $\gamma^\circ_{CdCl_2}$ for $X_{ZnCl_2} = X_{CdCl_2} = 0$ are given in Table II.

To verify the obtained results at a temperature of 773°K the activities calculated from [20] were compared with those determined experimentally by Yang and Hudson (13). Figure 7 shows the good agreement obtained between both sets of data.

Discussion

Equations [6] and [7] were transformed so that assuming the composition of the metal phase, it was possible to calculate the respective concentrations of the salt phase. The obtained results are given in Fig. 8 for the temperatures 773° and 873°K along with the data of Lorenz and Schulz (14) and Jellinek and Siewers (15).

To determine the composition of the metal phase, starting from which the reaction [2] may occur in the

T°K	$\gamma^\circ_{ZnCl_2} \times 10^2$	$\gamma^\circ_{CdCl_2} \times 10^2$
773	0.346	4.538
823	0.451	5.586
873	0.572	6.730

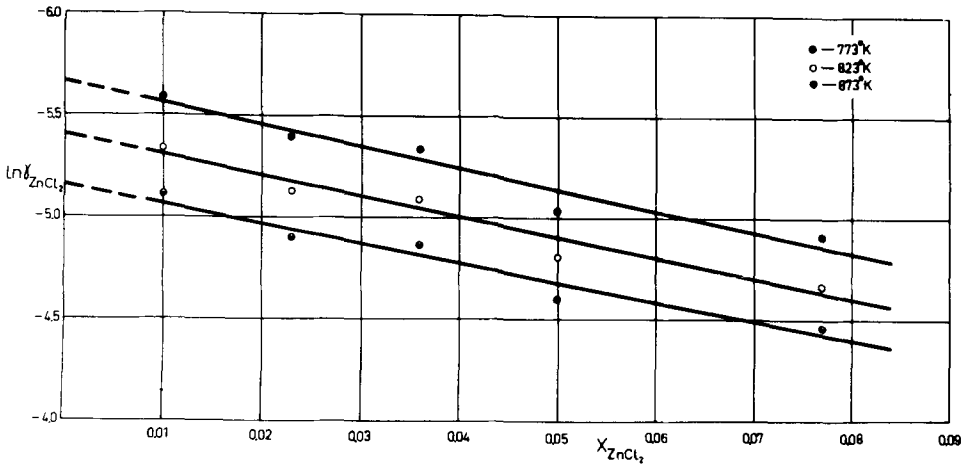

Fig. 5. Dependence ln γ_{ZnCl_2} *vs.* X_{ZnCl_2} for liquid $ZnCl_2$ solutions.

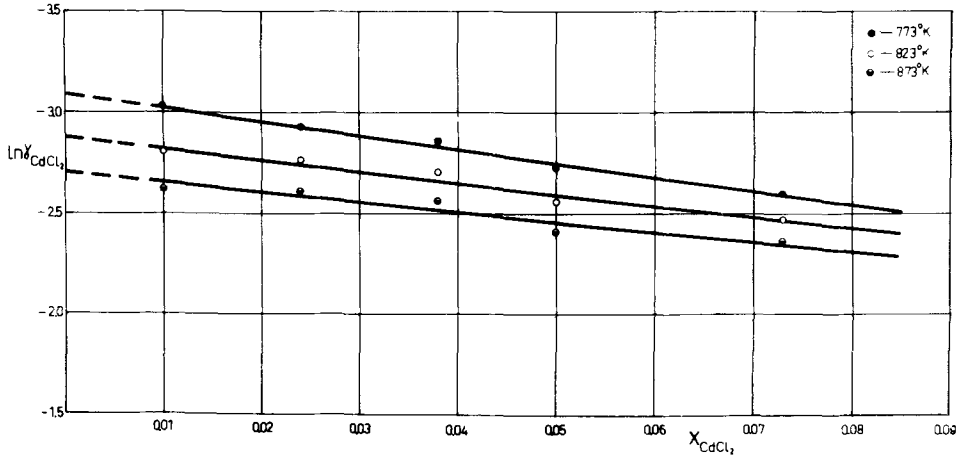

Fig. 6. Dependence ln γ_{CdCl_2} *vs.* X_{CdCl_2} for liquid $CdCl_2$ solutions.

cell, we assume that it corresponds to the extreme point of the curve of equilibrium composition in the coordinates $X_{CdCl_2} - X_{Cd}$ turned clockwise 45°. At this point the change in the metal-phase composition given by dX_{Cd}, corresponds to the change in the salt-phase composition dX_{CdCl_2}, which is defined by the condition

$$\frac{dX_{CdCl_2}}{dX_{Cd}} = 1 \qquad [21]$$

When the condition of reaction [21] is exceeded, the change in the metal-phase composition, given by dX_{Cd}, results in a great change in X_{CdCl_2} which corresponds to the formation of $CdCl_2$ in the salt phase as a result of reaction [2]. From Eq. [21] and [7] we obtained

$$X_{[Cd]} = \frac{\sqrt{K'}}{1 + \sqrt{K'}} \qquad [22]$$

which allowed the determination of the metal-phase composition (alloy electrode) for a given temperature.

The results are shown in Fig. 9 and this dependence may be presented by the equation

$$X_{[Cd]} = -9 \times 10^{-5}T + 1.058 \qquad [23]$$

Assuming that the lowest zinc concentration of the alloy electrode used in the investigations is $X_{Zn} = 0.01$, it is possible by means of Eq. [23] to determine the temperature, starting from which, as a result of reaction [2], the composition of the alloy electrode will be changed, the change eventually influencing the emf measurements. The temperature, 756°K, is in very good accordance with the plot ln γ_{Zn} *vs.* X_{Zn} for the Zn-Cd system in Fig. 1.

As can be seen from Fig. 8, the obtained results differ both from the experimental data obtained by Lorenz and Schulz (14) and from those of Jellinek and Siewers (15). It does not seem likely that the errors these

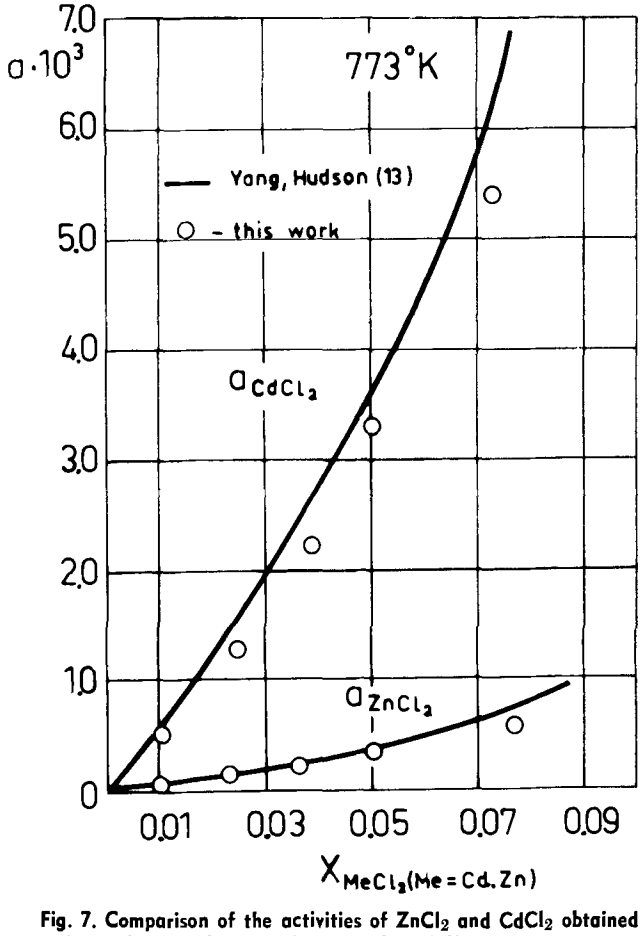

Fig. 7. Comparison of the activities of $ZnCl_2$ and $CdCl_2$ obtained experimentally with the data given elsewhere (13).

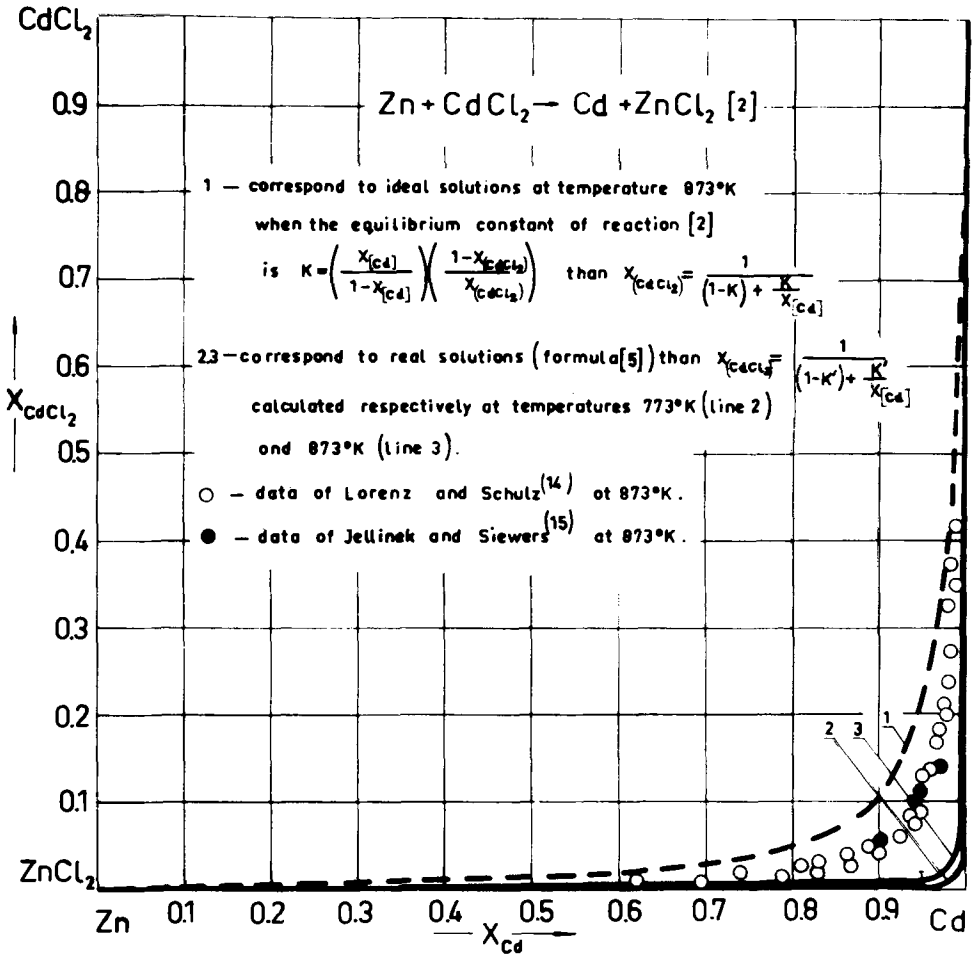

Fig. 8. Curve of the equilibrium composition of a displacement reaction compared with the ideal solutions and the data from literature.

authors (14, 15) may have made, resulting mainly from chemical analysis or poor dehydrating of salts, can account for these differences.

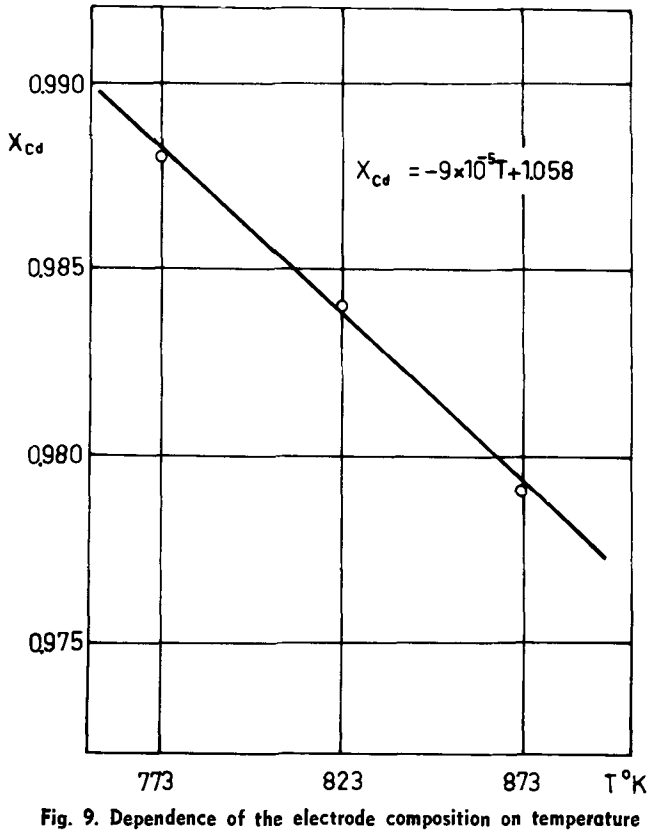

Fig. 9. Dependence of the electrode composition on temperature in the case of liquid Zn-Cd solutions.

In these papers (14, 15) the salt phase consisted of the solutions $ZnCl_2$-$CdCl_2$, while in our cell we were concerned with the $ZnCl_2$-$CdCl_2$-LiCl-KCl system, where $ZnCl_2$ and $CdCl_2$ are present only in small quantities, hence we consider that the main reason for the translocation of the curve is the eutectic LiCl-KCl. Assuming the salt phase is an ideal solution, from Eq. [7] $K' = K$, and $\gamma^{\circ}_{Zn} = 192.6$ at 873°K and we obtain almost the same values as in the papers (14, 15) in Fig. 8. This proves both the influence of the eutectic on the translocation of the curve of equilibrium composition and the fact that the solution $ZnCl_2$-$CdCl_2$ is ideal.

Conclusions

The investigations carried out prove the influence of the displacement reaction [2] on the emf of the concentration cell Zn(l) | $ZnCl_2$ in $(LiCl\text{-}KCl)_{eut}$(l) | Zn-Cd(l) and cause the value of the zinc activity coefficient at $X_{Zn} = 0.01$ for the higher temperatures to have considerable error. The displacement reaction [2] limits the applicability of the concentration cell method to $X_{Zn} = 0.01$ and a temperature of 756°K in the case of dilute zinc solutions in cadmium; in determining the linear dependence of ln γ_{Zn} *vs.* X_{Zn} the results at $X_{Zn} = 0.01$ molar fraction were not, therefore, taken into consideration.

Investigations on the equilibrium constant of reaction [2] and Eq. [28] for the dependence of the metal-phase composition *vs.* temperature enabled the calculation of the correction for the concentration $X_{Zn} = 0.01$ yielding agreement with the results for the higher zinc content. For this purpose a correction δ was introduced in the measured emf values at the temperatures 805°, 842°, and 877°K (Fig. 1). This correction was $\delta = \left(\frac{dE}{dX}\right)_T (X'_{Zn} - 0.01)$ where $X'_{Zn} = (1 - X_{[Cd]})$ and $X_{[Cd]}$ is calculated from Eq. [23]. After recalculation of the emf values at $X_{Zn} = 0.01$ corrected in this manner, the linear dependence of ln

γ_{Zn} *vs.* X_{Zn} was obtained over the whole range X_{Zn} = 0.01-0.1 molar fraction.

When undertaking experiments using the emf method of concentration cells it would appear necessary to determine experimentally the range of concentration of components and temperatures thus enabling the exclusion of the influence of various factors such as the displacement reactions between the components of electrodes and those of the electrolytes.

Acknowledgment

The authors are indebted to W. Ptak for assistance in the interpretation of the experimental results. This paper was presented at the 23rd I.S.E. Meeting in Stockholm, Sweden, 1972.

Manuscript submitted Aug. 16, 1972; revised manuscript received Feb. 16, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Technical Notes

Electrical Conductivity and Structure of Molten Binary $LiF-AlF_3$ and $NaF-AlF_3$ Mixtures

K. Matiašovský and V. Daněk

Institute of Inorganic Chemistry, Slovak Academy of Sciences, Bratislava, Czechoslovakia

The study of the electrical conductivity of molten salts is one of the indirect methods which is used for determination of the structure of molten salts and of the interaction of the constituents in molten mixtures. The changes in the composition of a molten mixture are frequently accompanied by structural changes which affect the character of the dependence of the electrical conductivity on composition. Consequently, an analysis of this dependence should provide some information regarding the ionic species and their arrangement in the melt. Supplementary information, *i.e.*, that concerning the formation and decomposition of complex ions, the character of the bond cation-anion, and the character of the conductivity, cationic, anionic, electronic, etc., can be obtained from an analysis of the dependence of the activation energy, calculated from the temperature dependence of the electrical conductivity on the composition.

The shape of the isotherms of the electrical conductivity of binary mixtures is principally determined by two factors: (*i*) by the formation of new chemical compounds and consequently by the formation of new complex ions; and (*ii*) by the values of the electrical conductivity of the components and the newly formed compounds.

A theoretical interpretation of the concentration dependence of equivalent conductivity for simple binary mixtures was presented by Markov and Shumina (1). It should be pointed out that this theory, even when considering the structural aspect, represents rather a method of interpretation of the experimental data than a genuine picture of the structure of the melt. In molten salts generally only ions and not molecules are present, hence the conception of Markov and Shumina is to be considered also from this aspect. Their theory is based on the assumption that the electrical conductivity of a mixture of molten salts varies with temperature similarly to the case of pure components. In this respect, some general character of the dependence of the electrical conductivity on the composition, indicating the interaction of components in an ideal solution, could be expected. Considering this assumption, Markov and Shumina derived a relation for the dependence of the equivalent conductivity of a mixture of molten salts on the conductivity

$$\lambda_{mix} = x_1^2 \cdot \lambda_1 + x_2^2 \cdot \lambda_2 + 2x_1x_2 \cdot \lambda_2 \qquad [1]$$

where λ_i is the equivalent conductivity, ohm^{-1}-cm^2, and x_i is the mole fraction, with the presumption that $\lambda_1 > \lambda_2$. Thus for the calculation of the equivalent conductivity of a molten binary mixture according to Eq. [1], only the equivalent conductivities of the components at the same temperature must be known.

This problem was treated more generally by Kvist (2), who proposed for the equivalent conductivity of mixtures with one common ion and n interacting ions the equation

$$\lambda_{mix} = \lambda_1 \cdot x_1^n + \lambda_2(1 - x_1^n) \qquad [2]$$

For $n = 2$, Eq. [2] is transformed to Eq. [1].

In this work, the equivalent conductivity of the molten binary $LiF-AlF_3$ and $NaF-AlF_3$ mixtures was

Key words: conductivity, activation energies, molten salts.

calculated on the basis of experimental data and the values determined were compared with the theoretical ones calculated using Eq. [1]. On the basis of the experimentally determined values, the activation energies of the equivalent conductivity of the above mixtures at 1000°C were calculated. An analysis of the dependence of the equivalent conductivity and of the activation energy on the composition makes it possible to draw some qualitative conclusions on the structure and the character of the current transport as well as on the interaction of constituents in the above binary mixtures.

Calculation

The equivalent conductivity of both the molten components and of the molten binary mixture was calculated on the basis of the previously published experimental data on the specific conductivity and density (3-5) according to the equation

$$\lambda = \frac{\kappa \cdot M_e}{\rho} \qquad [3]$$

where λ is the equivalent conductivity, ohm^{-1}-cm^2, κ is the specific conductivity, ohm^{-1}-cm^{-1}, M_e is the mean equivalent weight of a mixture defined by the relation

$$M_e = \sum_i \frac{M_i \cdot x_i}{n_i} \qquad [4]$$

where M_i is the molecular weight, x_i the mole fractions of the components, and n_i is the number of the positive and negative charges of the cation and anion, respectively, and ρ the density, $g\text{-}cm^{-3}$.

Regarding the formation, in the system investigated, of a congruently melting compound of the type M_3AlF_6, which partially dissociates according to the equation

$$M_3AlF_6 = MAlF_4 + 2MF \qquad [5]$$

the presence of the products of dissociation in the melt has to be considered. In the calculation of the equivalent weight of the molten mixture the equilibrium concentration values of the constituents presented by Matiašovský *et al.* (6) were used. Assuming the primary dissociation of Na_3AlF_6 with the formation of $3Na^+$ cations and AlF_6^{3-} anion, for cryolite the value $n = 3$ was considered.

The values of the equivalent conductivity of molten LiF-AlF_3 mixtures at 900° and 1000°C, calculated with regard to the presence of LiF, Li_3AlF_6, and $LiAlF_4$ in the melt, are presented in Fig. 1. In Fig. 2, the calculated values of the equivalent conductivity of the molten NaF-AlF_3 mixtures at 1000° and 1100°C are presented.

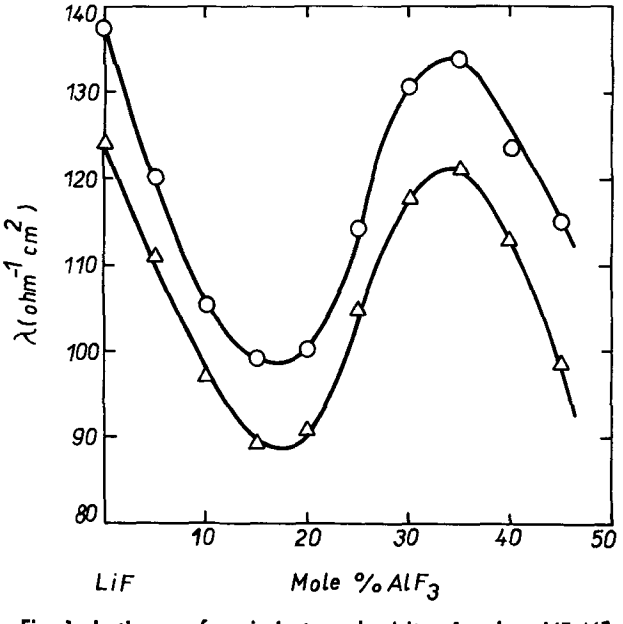

Fig. 1. Isotherms of equivalent conductivity of molten LiF-AlF_3 mixtures. ○, 1000°C; △, 900°C.

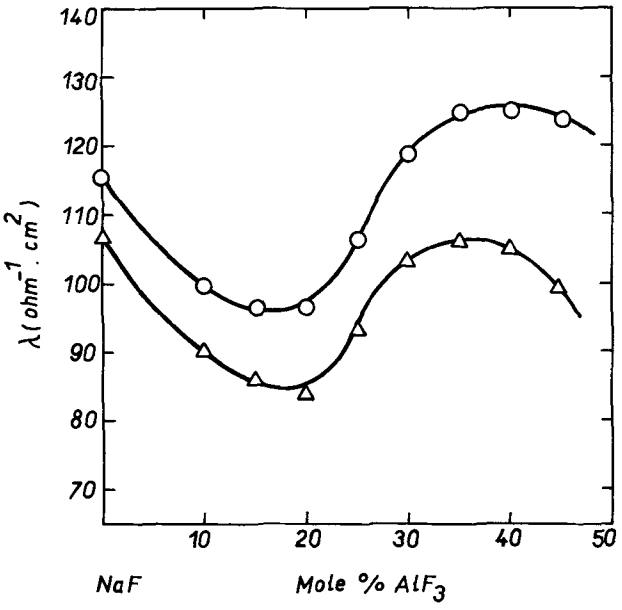

Fig. 2. Isotherms of equivalent conductivity of molten NaF-AlF_3 mixtures. ○, 1100°C; △, 1000°C.

The activation energies of the equivalent conductivity were calculated according to the equation

$$E_\lambda = R \ln (\lambda_2/\lambda_1)/(1/T_1 - 1/T_2) \qquad [6]$$

The values of the activation energies of the equivalent conductivity of the LiF-AlF_3 and NaF-AlF_3 mixtures at 1000°C are plotted in Table I. The dependence of the activation energy of the equivalent conductivity on the concentration in the above systems is presented in Fig. 3 and 4. The activation energy of the equivalent conductivity was found to be practically independent of the temperature in the temperature region investigated.

Discussion of Results

In the system LiF-AlF_3, the components react to form congruently melting lithium cryolite, Li_3AlF_6 (mp = 782°C) (7). According to the phase diagram, no other compound is formed in this system (7). However, in a series of papers the formation of $LiAlF_4$ was suggested (8-11). The existence of the complex AlF_4^- anion in the liquid phase was confirmed also by Malinovský and Matiašovský (12) on the basis of cryoscopic measurements in the system Li_3AlF_6-KCl. Hence, with regard to the investigated concentration range in the study of the specific conductivity and density of LiF-AlF_3 mixtures, this system can be divided in two partial systems: LiF-Li_3AlF_6 and Li_3AlF_6-$LiAlF_4$.

Similarly, in the system NaF-AlF_3, the analogous partial systems, NaF-Na_3AlF_6 and Na_3AlF_6-$NaAlF_4$, were considered. In the concentration range investigated, congruently melting sodium cryolite, Na_3AlF_6, (mp = 1006°C) is formed (13). The compound $NaAlF_4$

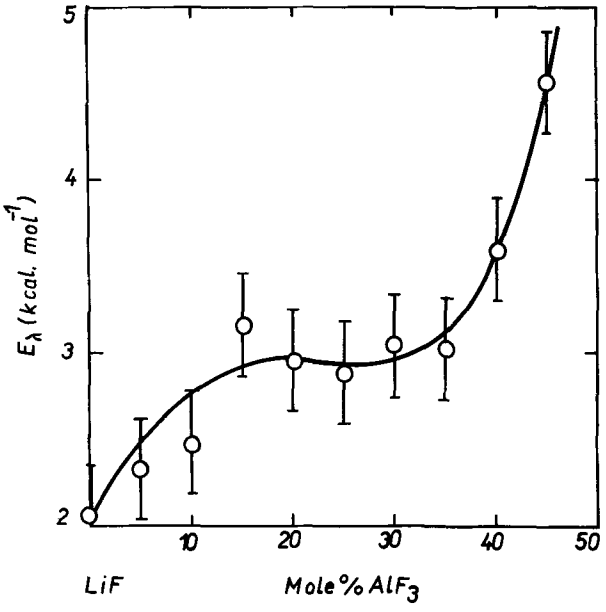

Fig. 3. Activation energy of equivalent conductivity of molten LiF-AlF$_3$ mixtures.

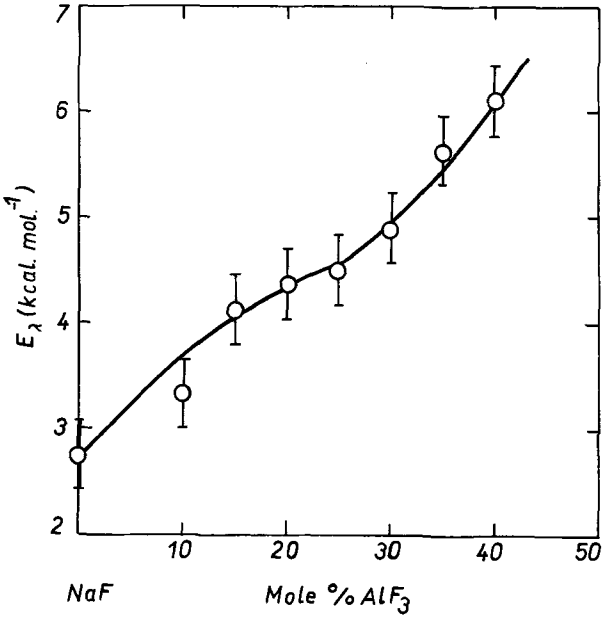

Fig. 4. Activation energy of equivalent conductivity of molten NaF-AlF$_3$ mixtures.

was first identified by Howard (14) by means of chemical analysis and x-ray powder diffraction of quenched vapors over the melt corresponding to the equimolar composition NaF · AlF$_3$. The existence of the complex AlF_4^- anion in molten cryolite was later confirmed by cryoscopic (15) and spectroscopic (16) measurements, and by investigations of the structure and the density (17) as well as on the electrical conductivity of cryolite close to the melting point (18, 19).

Besides Na_3AlF_6 and $NaAlF_4$, in the system NaF-AlF$_3$ the incongruently melting compound $Na_5Al_3F_{14}$, chiolite, is formed. However, this compound is not stable and decomposes by a peritectic reaction at 739°C (20). It was confirmed spectroscopically that at 1030°C there are no complex $Al_3F_{14}^{5-}$ anions in the melt (16). Therefore, this compound was not considered in the calculation of the equivalent conductivity of molten NaF-AlF$_3$ mixtures.

The course of the isotherms of the equivalent conductivity of molten MF-AlF$_3$ mixtures (Fig. 1 and 2) indicates significantly the character of interaction of the components. The inflection point on the isotherms corresponds to the formation of the complex compound M_3AlF_6. The decrease of the conductivity with increasing MF concentration in the partial system MF-M_3AlF_6 is due most probably to the suppression of the dissociation of the complex AlF_6^{3-} anion according to the scheme

$$AlF_6^{3-} = AlF_4^- + 2F^- \qquad [7]$$

effected by the introduction of F^- anions in the form of MF into the melt. The Li^+ and Na^+ ions, respectively, occupy the interstitial positions between the large AlF_6^{3-} and AlF_4^- complex anions and for this reason their positive influence on the increase of the electrical conductivitly is thus limited. It can be assumed that the minimum in the isotherms of the equivalent conductivity of the MF-M_3AlF_6 mixtures may be ascribed to the combined influence of both factors. The prevalent participation of cations in the current transport is evident only in the range of high MF concentrations. The course of the dependence of the activation energy of the equivalent conductivity on the composition in the investigated system agrees with the above assumption. From a comparison of the course of the isotherm at 1000°C with the isotherm calculated according to Eq. [1], it follows that the character of the interaction of components is in contradiction with the simplifying assumptions made by Markov and Shumina (1).

An entirely different isotherm shape of the equivalent conductivity was determined in the partial system M_3AlF_6-$MAlF_4$. This isotherm shape is very rare in the literature. Qualitatively, it can be explained by the simultaneous influence of several factors. First, it is the decrease of the relaxation influence of the F^- anions resulting in an increased conductivity caused by the prevalent cationic transfer. In the range of high $MAlF_4$ concentrations, the concentration of the particles taking part in the current transport is decreased which causes decreased electrical conductivity. Both these factors manifest themselves by a maximum on the isotherm of the equivalent conductivity in the M_3AlF_6-$MAlF_4$ partial systems.

From the course of the dependence of the activation energy of the equivalent conductivity of the MF-AlF$_3$ mixtures it follows that the activation energy generally increases in the entire concentration range, the inflection point corresponding to the formation of the compound M_3AlF_6. The course of the dependence confirms the conclusions on the character of the conductivity and on the interaction of the components.

Finally it should be said that in the case of such complicated systems as those of the type MF-AlF$_3$, only qualitative conclusions can be made. This scarcity of experimental data is due mainly to deficiencies in the theoretical aspects in the field of the chemistry and electrochemistry of fused salts.

Electrochemistry of Nematic Liquid Crystals

M. Voïnov* and J. S. Dunnett

Battelle Geneva Research Centre, 1227-Carouge, Genève, Switzerland

Dynamic scattering in nematic liquid crystals has mostly been investigated with a view to making passive display devices. The devices work on a-c or d-c excitation. However low voltage d-c operation is desirable to make the display compatible with battery power sources. Several theories have been proposed to explain dynamic scattering (1, 2). It seems to be generally accepted that the current carriers in liquid crystals are ions (3, 4), and it would thus be surprising if there were no electrolysis at the potentials necessary to cause scattering.

Although it is generally felt among specialists in the field that degradation of liquid crystals under d-c excitation is due to parasitic electrochemical reactions, we are not aware of any investigation of these materials from the point of view of electrochemistry. Furthermore we propose that electrochemical reactions are not only parasitic but that they are essential to the operation of the liquid crystal device.

We have measured current-voltage curves for 10 μm thick layers of Merck's nematic phase *NV* sandwiched between two pyrolytic tin oxide electrodes (R = 1 k-ohm/□) deposited on flat glass plates. Merck's nematic phase *NV* is a mixture in undisclosed proportions of four compounds

$$R_1\,C_6H_4\,N(O)N\,C_6H_4\,R_2$$

where

$$R_1 = CH_3O, \quad R_2 = C_4H_9 \qquad [I]$$

$$R_1 = C_4H_9, \quad R_2 = CH_3O \qquad [II]$$

$$R_1 = CH_3O, \quad R_2 = C_2H_5 \qquad [III]$$

$$R_1 = C_2H_5, \quad R_2 = CH_3O \qquad [IV]$$

The characteristics of nematic phase *NV* are described in Merck's brochure (5).

We have also made measurements on a 12 μm thick cell containing a 1:1 mixture of p-methoxybenzilidene-p'-butylaniline with p-ethoxybenzilidene-p'-butylaniline (MBBA-EBBA). The cathode of this cell was vapor deposited aluminum and the anode tin oxide ($R \simeq$ 200 ohm/□), both supported on glass plates.

The current-voltage curve for nematic phase *NV* is shown in Fig. 1A. After correction for the high resistance of the cell estimated from the resistivity quoted by the manufacturer, the curve is seen to be characteristic of electrolysis (Fig. 1B). Two waves are apparent, the first at about 1V and the second at 2V. The current due to the first wave reaches a limiting value of 2 μA/cm^2 at about 1.7V, well before the start of the second wave.

Figure 1C shows the optical transmittance of the cell against applied voltage. The onset of scattering also occurs at a corrected voltage of about 1.7V (Fig. 1D), the tension at which the current reaches the plateau. Scattering reaches saturation before the second wave begins, that is over a span of only 1.3V once correction for the ohmic drop has been made.

The current-voltage curve (Fig. 2A) for the MBBA-EBBA mixture is less easy to interpret. After correction for the ohmic drop, several inflections become apparent in the ascending branch (Fig. 2B). The well-defined first wave, I, is presumably due to some impurity whilst the inflection at 1.5V, II, is possibly caused by the electrolysis of water which is more likely to be present in this hygroscopic mixture than in nematic *NV*. The main "scattering" wave, III, appears to commence at 3.8V although, as with nematic *NV*, visible scattering does not occur much below the inflection point at 4.5V, IV. We assume that this corresponds to the current plateau observed with nematic *NV*, possibly obscured in the case of the MBBA-EBBA mixture by some further electrochemical reaction. As with nematic *NV*, scattering increases rapidly above 4.5V, to reach saturation by 6V.

The descending branch recorded for the MBBA-EBBA mixture is also interesting. The current at corresponding voltages is lower than that for the forward curve and there are no well-defined inflections. This indicates that the products of electrolysis are only weakly or not at all electroactive, so that the stock of depolarizer in the cell is seriously depleted on continued electrolysis.

Discussion

An electrochemical mechanism can explain many well-known features of the behavior of nematic liquid crystals. First, it has been reported that the current increases with cell thickness at constant field. Now in the steady state, for an electrochemical reaction (8)

$$V = E_o + \eta(i) + l\rho i \qquad [1]$$

where the symbols are defined at the end of the paper.

Neglecting $\eta(i)$, which is reasonable for electron exchange reactions in high resistivity, nonaqueuos solvents, we have

$$i = V/l\rho - E_o/l\rho \qquad [2]$$

Thus at constant field, V/l, Eq. [2] correctly predicts the increase of current with the thickness of the sample. Of course, such a mechanism requires that there be sufficient ions in the solution to neutralize the space charge on the electrodes. This is consistent with the observation that for satisfactory operation, liquid crystals must possess a finite electrical conductivity. The current carrying ions are not necessarily the same as the electroactive species which may themselves be uncharged. Using the results of Heilmeier *et al.* (3) on anisylidene-p-aminophenylacetate (APAPA) and Eq.

* Electrochemical Society Active Member.

Voltage scan rate, 8 mV/sec; cell thickness, 10 μm.

[2] we calculate reasonable values $E_0 \simeq 3.4$V and $\rho \simeq 4 \times 10^{10}$ ohm-cm.

Other features which can be interpreted electrochemically are the so-called rise and decay times. The time constant for relaxation of a steady-state concentration gradient (8) gives the observed dependence of the decay time on the square of the sample thickness. Furthermore the rise time has been reported to be inversely proportional to the current (3) and to the square of the applied tension (9, 10). For electrochemical reactions limited by diffusion and driven by a constant current, the interface concentrations of the reacting species vary in a well-known fashion (11). It can be shown that the time which elapses before this interface concentration becomes smaller or higher than a given value is inversely proportional to the square of the current. This is the basic equation in voltametry at controlled current (11)

$$i\tau^{1/2} = \text{constant} \qquad [3]$$

Because of the high resistance of liquid crystal devices the total tension, at voltages higher than the threshold tension, can be approximated by Ohm's law so that

$$\tau_{rise} \simeq R/V^2 \qquad [4]$$

in agreement with the experimental results (9, 10).

An intriguing aspect of nematic liquid crystals is that they can sustain direct current excitation for over 1000 hr before failure. For example, Sussman has shown (12) that, in a cell containing 0.5×10^{-5} M/cm² p-methoxybenzilidene-p'-aminophenylacetate

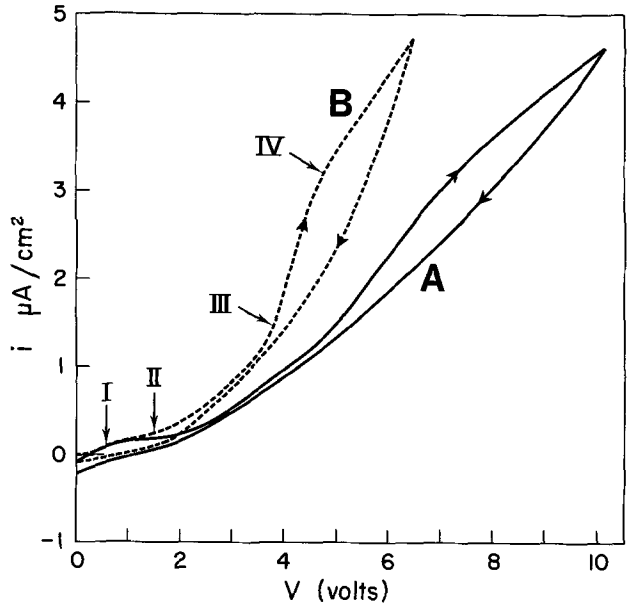

Fig. 2. MBBA-EBBA mixture. A, As measured; B, corrected for ohmic drop. Voltage scan rate, 10 mV/sec; cell thickness, 12 μm; resistivity of liquid crystal, 6 x 10^9 ohm-cm.

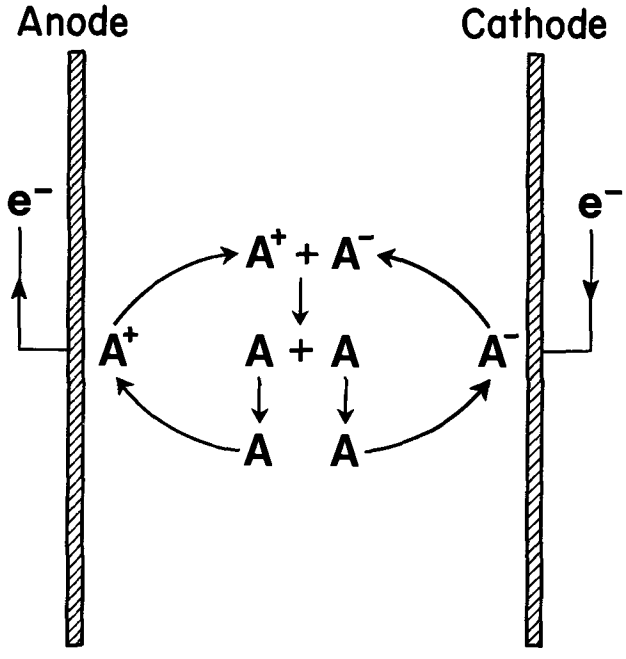

Fig. 3. Proposed scheme of cell reactions showing formation of ions, A^+, A^-, and regeneration of molecules, A.

(APAPA), it is possible to pass about 12.5 coulomb/cm² before 50% failure of the device. To electrolyze completely the APAPA contained in the cell 0.5 coulomb/cm² would be sufficient, assuming a one-electron process though the number of coulombs to electrolyze the impurities in the cell would be much smaller. Thus there must be at least partial regeneration of the APAPA or of other electroactive species if the long life under d-c excitation is to be explained. To this end, we propose that the ions created from the electrolysis of neutral molecules on the electrodes diffuse or migrate to the center of the cell where they react giving back the original molecules which, in turn, diffuse back to the electrodes to be electrolyzed again. This cyclic process is shown schematically in Fig. 3. One would expect these two opposing flows of ions and molecules to eventually cause turbulence. Failure of the device would be brought about if some of the recombination reactions at the center of the cell did not give back the original molecules, possibly because of alternative reactions with impurities or with the liquid crystal material itself.

There has been some speculation in the literature as to whether the work functions of the electrode material have any influence. According to our electrochemical mechanism these have no role to play in the scattering phenomenon.

The mechanism is essentially the same under a-c excitation. In this case two separate and independent recombination regions exist, as each electrode acts, alternately, as anode and cathode.

Acknowledgment

We wish to thank Dr. B. Zega for the liquid crystal cells and helpful discussions.

Authors' note.—After we submitted this note, a paper on electrochemistry of liquid crystals by A. Lomax, R. Hirasawa, and A. J. Bard was published [*This Journal*, **119**, 1679 (1972)]. The results in that paper are not inconsistent with our own conclusions.

Manuscript submitted Nov. 15, 1972; revised manuscript received Feb. 12, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Brief Communication

Antimony in the Lead-Acid Battery

Don E. Swets

Research Laboratories, General Motors Corporation, Warren, Michigan 48090

It is well known that antimony, which is alloyed in the grids of the lead-acid battery to improve their castability, corrosion resistance, and strength, affects the properties of the battery in various ways. Of particular interest is its apparent beneficial effect on the cycle life of the positive plate. This beneficial action has been the subject of much research (1) and various mechanisms have been proposed to explain it. For example, it has been suggested that antimony is responsible for maintaining a minimum concentration of αPbO_2 during cycling, which in turn stabilizes the plate structure. If this is so, the function of antimony may be to nucleate new αPbO_2 crystals during charge or to passivate already existing αPbO_2 during discharge.

In an effort to shed further light on this proposed mechanism we have studied the crystal structures of α and β PbO_2 and certain AB_2O_6 compounds to which they are related. [This approach was also suggested by Burbank (2) in a recent publication.] More specifically, we were interested in determining if the compound $PbSb_2O_6$ could reasonably be expected to grow epitaxially onto αPbO_2 (or vice versa) and passivate (or nucleate) it.

Key words: battery, nonantimonial, αPbO_2, βPbO_2, antimony.

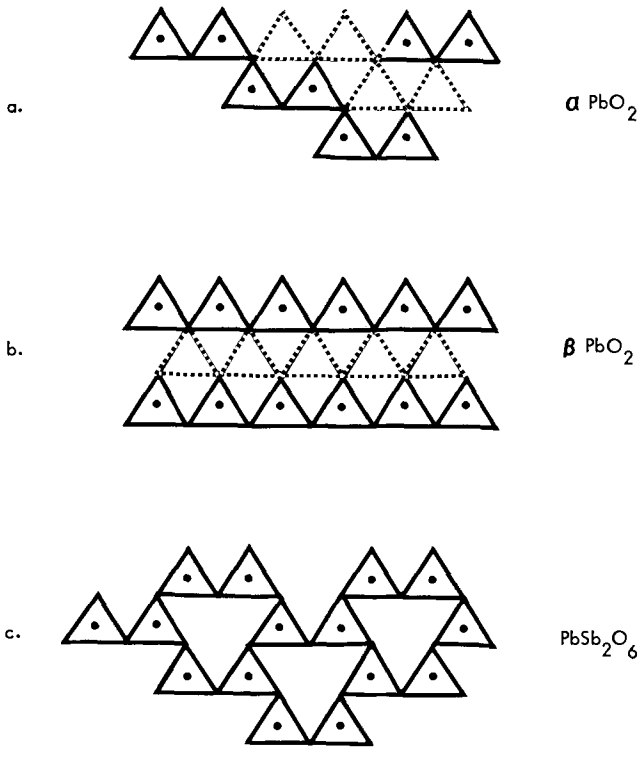

Fig. 1. In this figure the octahedra containing a metal ion are represented by triangles as viewed perpendicular to layers of close-packed oxygen. The metal ions filling octahedral holes in a given plane halfway between oxygen layers are represented by dots. The dashed triangles represent filled octahedra at higher or lower levels. a) αPbO_2; b) βPbO_2; c) $PbSb_2O_6$.

Alpha-PbO_2 is isostructural with columbite, (Fe, Mn)Nb_2O_6 whereas βPbO_2 has the structure of cassiterite, SnO_2. In both of these structures the cations are octahedrically coordinated to six oxygen ions but the pattern of cation-filled octahedra is different for the two types. Simply stated, the filled octahedra form zig-zag chains in αPbO_2 and linear chains in βPbO_2. This concept is illustrated schematically in Fig. 1.

In making the list of columbite type compounds for Table I we have taken three unit cells of αPbO_2 stacked along the a_o axis and written $PbPb_2O_6$ instead of $3PbO_2$ for comparison with the other columbite compounds. Similarly we have written $3\alpha PbO_2$ as $PbPb_2O_6$ for comparison with a series of compounds isostructural with the mineral tapiolite $FeTa_2O_6$. Wyckoff (3) describes this structure as a superlattice on cassiterite with three cassiteritelike units stacked end on end. In this group several of the compounds contain SbO_6 octahedra in linear chains.

Another family of structures is typified by lead metantimonate, $PbSb_2O_6$. In this structure the Sb^{5+} ion is again octahedrally coordinated to oxygen with the filled octahedra lying in sheets perpendicular to the C_o axis in a hexagonal pattern (see Fig. 1). The layers of octahedra are separated by the large Pb^{2+} ions. Magneli (4) lists several compounds with this structure (which we have included in Table I) and points out that the $(Sb_2O_6)^{2-}$ sheets are only slightly influenced by the bivalent cations between them. He also notes that, for this structure to form, the bivalent cations must be rather large; with smaller ions metantimonates will have the structure types columbite or mossite (similar to tapiolite).

Thus, in summary, there is a series of AB_2O_6 compounds whose structures are related in that they all contain BO_6 octahedra but fall into three separate types. In the columbite structure only one compound is listed in which Sb^{5+} is the *B* ion and in this case the *A* ion radius is 0.80Å, quite close to Pb^{4+} at 0.84Å.

Table I. AB_2O_6 crystals with the columbite, tapiolite, or lead metantimonate structure

Crystal	*A* ion radius (Å)	
$PbPb_2O_6$ (αPbO_2)	0.84	Columbite
$FeNb_2O_6$	0.76	
$MnNb_2O_6$	0.80	
$CdNb_2O_6$	0.97	
$CoNb_2O_6$	0.78	
$MgNb_2O_6$	0.65	
$NiNb_2O_6$	0.78	
$ZnNb_2O_6$	0.74	
$MnSb_2O_6$	0.80	
$PbPb_2O_6$ (βPbO_2)	0.84	Tapiolite
$FeTaO_6$	0.76	
$CeSb_2O_6$	0.78	
$FeSb_2O_6$	0.76	
$MgSb_2O_6$	0.65	
$NiSb_2O_6$	0.78	
$ZnSb_2O_6$	0.74	
$BaSb_2O_6$	1.35	Lead metantimonate
$CaSb_2O_6$	0.99	
$CdSb_2O_6$	0.97	
$HgSb_2O_6$	1.10	
$PbSb_2O_6$	1.20	
$SrSb_2O_6$	1.13	

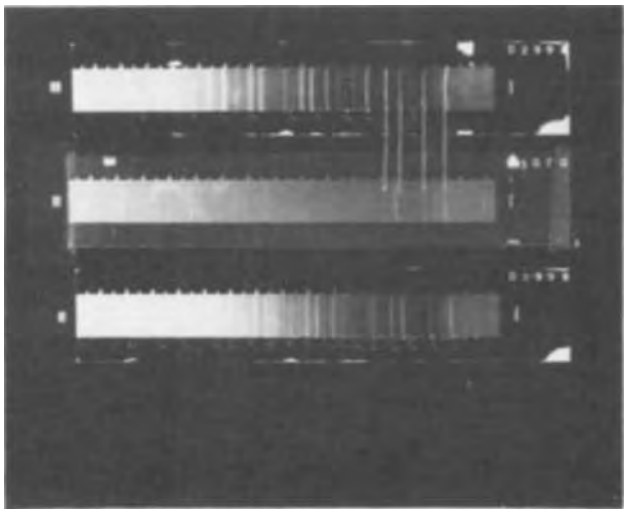

Fig. 2. X-ray patterns for 1) $PbSb_2O_6$; 2) old battery-active material residue after PbO_2 removal; and 3) residue from a cycled minicell to which $PbSb_2O_6$ had been added.

In the tapiolite group there are several compounds with Sb^{5+} all with *A* ion less than 0.80Å, and in the $PbSb_2O_6$ group all the *A* ions are greater than 0.97Å. So with SbO_6 octahedra the preferred structure is apparently determined by the *A* ion size. Burbank and Ritchie (1) suggested that Sb^{5+} ions may occupy vacant Pb^{4+} octahedral sites in the PbO_2 lattice. If this is true then from the relation between ion size and preferred structure one might speculate that, as Pb^{4+} (with ionic radius 0.84) is reduced to Pb^{2+} (with ionic radius 1.20Å) during discharge, some $PbSb_2O_6$ forms (along with the $PbSO_4$) and either nucleates new αPbO_2 crystals on subsequent charging, or passivates the surface of already existing αPbO_2 and prevents it from reacting in the next discharge.

Efforts to prove by experiment that antimony improves positive life via the compound $PbSb_2O_6$ have not been conclusive. Over 200 miniature three-plate batteries with various amounts of $PbSb_2O_6$ (or other materials, such as Nb_2O_5) added to the positive plate were cycle-life tested in a period of 2 yr. No significant difference in cycle life was found; however, the $PbSb_2O_6$ (which we synthesized according to the method of Magneli) had relatively large particle size, perhaps too large for nucleating αPbO_2. In another approach, some old batteries, which had failed in automotive use, were cut open; the positives were removed, and lead dioxide was removed from the plates. Care was taken to avoid breaking off pieces of the grid which was quite fragile. The PbO_2 was digested in HNO_3 and H_2O_2 to obtain a small residue which was analyzed by x-ray diffraction. In one out of five attempts a pattern was obtained which contained the major lines of our synthesized $PbSb_2O_6$ as shown in Fig. 2. Other materials were also present in the residue.

Whereas this result and the argument from comparing crystal structure give some credence to the concept that antimony acts in the positive plate via the compound lead metantimonate, it is not the intent of the author to imply that absolute proof or a final answer has been given, but rather to suggest another approach to a rather difficult and complex problem.

Selected Properties of Pyrolytic Ta_2O_5 Films

W. H. Knausenberger

Bell Telephone Laboratories, Incorporated, Whippany, New Jersey 07981

and R. N. Tauber

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

Pyrolytic Ta_2O_5 films, in thicknesses up to 30,000Å, were produced by the $TaCl_5$-CO_2-H_2 reaction at 900°C. These films were characterized by use of transmission electron microscopy, electron microprobe analysis, measurement of dielectric, and optical properties. It was found that the films were orthorhombic Ta_2O_5 (β-Ta_2O_5) with a fine grained structure. The films did not etch appreciably in hydrofluoric acid. Ellipsometric measurements indicated that the films had an index of refraction of 2.20 ± 0.03 at 5461Å. In addition, certain areas of the films exhibited slight optical absorption. The optical energy gap was found to be 4.20 eV. The dielectric constant and the loss tangent of the pyrolytic Ta_2O_5 films were measured over the temperature range 78°-488°K and the frequency interval 1-100 kHz and exhibited a surprisingly strong temperature dependence. These results and the electron microprobe results indicate the films are not stoichiometric.

Tantalum pentoxide (Ta_2O_5) has played a very active role in electronic applications for over a decade. Ta_2O_5 has been used in thin film form long before the much studied thin film materials such as SiO_2, Si_3N_4, and Al_2O_3 came into positions of importance for applications such as integrated circuit (IC) passivation and insulated gate, field effect transistor gate dielectrics. It has been found for the latter materials that high-temperature (600°-1000°C) chemical vapor deposition (CVD) produced films with properties generally considered more desirable than those of films produced by other methods. In electronic applications Ta_2O_5 is usually produced anodically, or sometimes thermally, but pyrolytic Ta_2O_5 has not been used, nor its properties investigated. This paper reports selected details on the preparation and properties of Ta_2O_5 films produced by CVD.

Film Deposition

The general subject of oxide film preparation by CVD has been well-treated by Powell *et al.* (1). Pyrolytic Ta_2O_5 has been produced by Peacock (2) through the reaction of $TaCl_5$ vapor, H_2 gas, and CO_2 gas at 900°C, and by Wang *et al.* (3), through the reaction of tantalum alcoholate vapor, helium, and oxygen at 450°C. The properties of the films produced by the former reaction were not investigated, and those of the latter reaction were described as amorphous and annealable to polycrystalline β-Ta_2O_5 fter 30 min at 800°C.

The reaction between $TaCl_5$ vapor, H_2, and CO_2 at 900°C was used to prepare the films for this study. The presumed over-all reaction is

$$2TaCl_5 + 5H_2 + 5CO_2 \xrightarrow{900°C} Ta_2O_5 + 6CO + 10HCl$$

Key words: tantalum oxide, chemical vapor deposition, insulators, dielectric properties, optical properties.

The deposition apparatus, shown schematically in Fig. 1, is a modified version of the one reported by Tauber, Dumbri, and Caffrey (4) for the pyrolytic deposition of zirconium dioxide. The substrate rests on a molydenum susceptor, which is heated inductively at 480 kHz, The susceptor is rotated by a specially designed harmonic drive. The gases are carefully metered through Brooks rotometers and are carried through stainless steel lines to the deposition chamber. The $TaCl_5$ vapor is transferred to the chamber by passing hydrogen through a heated saturator. A schematic of the stainless steel saturator is shown in the enlarged section of Fig. 1. The carrier gas is forced to take a tortuous path over six layers of $TaCl_5$. It is assumed that the carrier is saturated with the vapor. All lines past the saturator are heated approximately 60°C above the saturator temperature, in order to prevent recondensation of the $TaCl_5$ prior to its arriving at the heated substrate.

All depositions were made at a substrate temperature of 900°C. The substrate usually used was 3-10 ohm-cm n-type (100) silicon, with the occasional use of fused silica disks, thermally grown SiO_2 on Si, and 0.001 ohm-cm silicon for special purposes. The typical concentrations by volume used were 0.02% $TaCl_5$ and 0.15% CO_2 with the remainder hydrogen. The total H_2 flow rate was 3270 cm³/min. These conditions yielded a deposition rate of approximately 300 Å/min.

Film Properties

General

The films deposited by the above procedure were clear, hard films of good quality which formed a tenacious coating on the substrate. Films as thick as 30,000Å deposited on polished silicon or fused silica showed no evidence of cracking, even when quenched to −195°C.

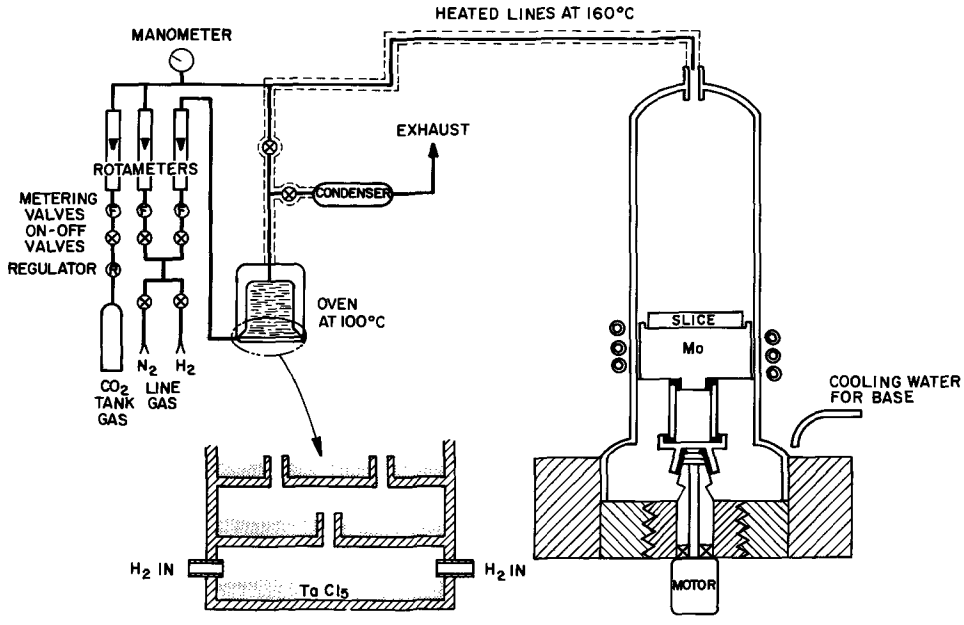

Fig. 1. Schematic representation of deposition equipment.

The characteristic ring interference color pattern revealed nonuniformity in the thickness of the films on the order of ±10%. Ellipsometric (5) and ultraviolet-visible reflection spectra (6) measurements indicated the center of the deposit to be the thickest area; no attempt was made to improve the thickness uniformity of the film.

Structure Identification

Transmission electron microscopy and electron diffraction analysis.—Pyrolytic Ta_2O_5 does not appear to etch appreciably, even in concentrated HF. Thus, in order to produce a thin sample for transmission electron microscopy, a 1000Å Ta_2O_5 film was pyrolytically deposited on a 1000Å thick layer of thermally grown SiO_2 on a silicon substrate. A long-term etch (15 hr) in 49% HF sufficed to undercut the Ta_2O_5 and lift it from the substrate. The etchant was then diluted and the film specimens were removed on a fine copper grid.

The specimens were examined in a Philips 300 Electron Microscope at an accelerating potential of 100 kV. Figure 2 is a transmission micrograph made at a magnification of 74,500 times. A well-defined and relatively uniform grain structure is observed with a 600Å average grain size.

Figure 3 shows an electron diffraction pattern of the same area. The film is crystalline and the pattern indexes to orthorhombic Ta_2O_5 (β-Ta_2O_5) (7). However, the line positions are such that one cannot rule out the presence of a small amount of Ta. The indexing is summarized in Table I.

Electron microprobe analysis.—The stoichiometry of a 5000Å pyrolytic Ta_2O_5 film deposited on silicon was studied by electron microprobe by the technique described by Colby (8). A Materials Analysis Corporation electron microprobe was used. The accelerating voltage was 5 kV, the beam current 0.4 μA, and the x-ray emergence angle 38.5°. The depth of analysis was approximately 1000Å, calculated from an assumed density of 8.70 g/cm^3. The elements analyzed were Ta, O, and Si, the latter being included to insure that the electron beam was not penetrating the film. Eight spots in regular increments of width from the center of the outer edge of the slice were analyzed. The result of analysis in depth on five of the spots is presented in Table II. Note the fact that the average oxygen to tantalum ratio is 2.37 ± 0.05, which is somewhat smaller than the 2.50:1 expected for stoichiometric Ta_2O_5. One can expect a slight overestimation of the amount of Ta present since the standard sample, of necessity, has on it a thin oxide layer on the order of 20-50Å thick. However, it is doubtful that this can be responsible for so large a difference. The comparison of a pyrolytic film on a relative basis with a film of known stoichiometry should allow the resolution of this question. Therefore, a Ta_2O_5 sample was prepared

by anodizing a sputtered β-Ta film at 120V in 0.01% citric acid with a 1 mA/cm^2 current density. The Ta_2O_5 film formed in this manner is reported to be stoichiometric (9). This film was analyzed by electron microprobe at the same time the pyrolytic Ta_2O_5 film was reanalyzed. The oxygen to tantalum ratio in the anodic film was 2.55 ± 0.05 and the average ratio in the pyrolytic film remained 2.37 ± 0.05. The over-all conclusion of this analysis is that the pyrolytic film, as examined across the width of the slice, is slightly oxygen deficient and not stoichiometric Ta_2O_5.

Infrared absorption and reflection study.—The specimens analyzed were 5000Å thick pyrolytic Ta_2O_5 films deposited on 50 ohm-cm silicon slices approximately 0.63 mm thick. Both the absorption and reflection spectra were obtained on a Beckman IR-12 double beam infrared spectrophotometer with appropriate attachments. The instrument scans in the wave-number range of 4000-200 cm^{-1}, but no peaks were observed above 1200 cm^{-1}.

The absorption spectrum obtained in this study is shown in Fig. 4. Two prominent and eight minor peaks were observed. McDevitt and Baun (10) have reported the absorption spectrum of β-Ta_2O_5 pressed powder in a Nujol mull over the wave-number range of 700-240 cm^{-1}. The peaks of the present study in that wave-number range roughly coincide with their three reported peaks, with a finite shift in positions having taken place. Sidorov (11), in an investigation of the absorption of β-Ta_2O_5 in the wave-number range of 1041-576 cm^{-1}, observed two peaks which coincide with peaks of the present study. Table III presents a comparison of results. Kihara-Morishita *et al.* (12) showed that the position of the prominent peaks is very sensitive to the voltage of anodization in making anodic films, and thus presumably to small differences in structure. Hence, from the *IR* absorption spectrum we can conclude that the deposited film is similar to β-Ta_2O_5 reported in the literature.

The infrared reflection spectrum (IRRS) obtained from the same specimens is seen in Fig. 5. Kihara-Morishita *et al* (12), recently reported the IRRS of

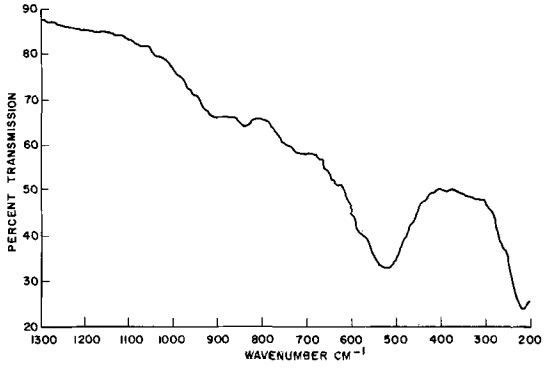

Fig. 4. Infrared transmission spectrum of Ta_2O_5

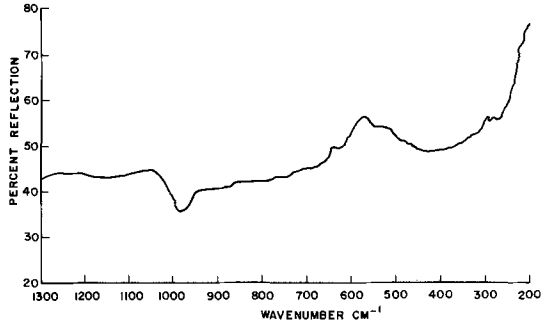

Fig. 5. Infrared reflection spectrum of Ta_2O_5

anodic tantalum oxide films in the wave-number range of 4000-7000 cm^{-1}. Two of their three reported peaks were observed in the present study, as seen in the comparison of results in Table IV. From the reflection spectrum it can be seen that the deposited films of the present study are related to but not identical to anodic tantalum oxide.

Optical Properties

Optical constants.—The index of refraction, n, of the pyrolytic Ta_2O_5 deposited on 1¼ in. diameter polished silicon slices was measured as a function of radial distance from the center of the slice by ellipsometry at 5461Å. The Ta_2O_5 film was assumed to be nonabsorbing. During this examination some concentric areas were observed, in which n was consistently 2.20 ± 0.03, as well as other concentric areas where the index of refraction had anomalously large values and changed strongly as a function of position. The value of n = 2.12-2.20 and 2.32-2.37 are found in the literature (13) for the two axes of β-Ta_2O_5 at 6710Å. Correction to 5461Å with the dispersion relationship reported for Ta_2O_5 (14) yields n = 2.23-2.31 and 2.43-2.48, in fair agreement for one of the axes with the present result of 2.20 ± 0.03. The anomalous values of n and their sensitivity to position indicate the film is absorbing in those areas.

Ellipsometry can be used for explicit measurements of an absorbing film (*i.e.*, a film with nonvanishing extinction coefficient) at the expense of adding an additional unknown parameter. If it is assumed that $k = 0$ in an absorbing film, ellipsometry will overestimate the value of n. However, once n in the nonabsorbing portions of the film is known the thickness and extinction

coefficient of the film at all other points on the film can be obtained from the measured ellipsometric parameters Δ and Ψ by a method described elsewhere (15). Table V presents the optical constants calculated from Δ and Ψ, which were measured in approximately 2 mm increments across the slices.

The optical constant of the silicon substrate is taken to be $4.05-0.28i$ (5). Note the small amount of absorption in the Ta_2O_5 film that suffices to cause such a drastically different apparent n if it is assumed $k = 0$. For example, at spot 1 there is an apparent shift of 0.56 in n from neglecting the extinction coefficient of 0.044. The Drude ellipsometry equation (16), on which the program used for the present calculations is based, assumes an ideally homogeneous and optically isotropic substrate and film. Thus one cannot determine from ellipsometry whether the absorption in the film is isotropic through its depth, or whether it occurs in a specific region of the film, *e.g.*, at the substrate-film or film-ambient interfaces. The extinction coefficient k (where the absorption coefficient α is related to k by $\alpha = 4\pi/k\lambda$) which is listed in Table V is an average number applying to the whole depth of the film.

Optical energy gap.—The energy gap measurement samples were prepared by depositing Ta_2O_5 on fused silica disks. Absorbance *vs.* wavelength measurements in the wavelength region of 2000-7500Å were made on a Perkin-Elmer 202 UV-VIS double beam spectrophotometer. There was only one absorption peak observed, and this was assumed to be due to the fundamental energy gap absorption. The absorption coefficient α was calculated as a function of photon energy from this in the neighborhood of the absorption edge.

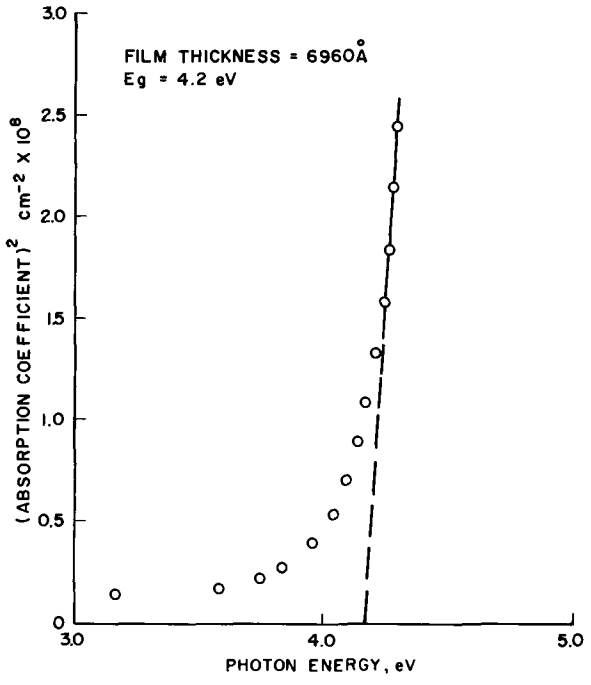

Fig. 6. (Absorption coefficient)^2 as a function of photon energy, $h\nu$, for Ta_2O_5.

This yielded values of α on the order of 10^4 cm^{-1}, which are indicative of direct optical transitions. Fan (17) has shown that for direct allowed transitions α is related to the photon energy by

$$\alpha = A(h\nu - E_g)^{1/2}$$

where A is a constant and E_g, the bandgap energy. Figure 6 shows α^2 as a function of energy. Extrapolation to $\alpha = 0$ yields an energy gap of 4.20 eV. This is well within the range of 3.58 eV reported for both α and β-Ta_2O_5 from conductivity measurements (18), and values of 4.5 and 4.6 eV from reflectivity and absorption measurements (19, 20).

Electrical Properties

Ta_2O_5 films approximately 1000Å thick were pyrolytically deposited on 0.001 ohm-cm silicon and aluminum dots 2.0×10^{-3} cm^2 in area were vacuum evaporated at a pressure less than 10^{-6} Torr. A 2000Å sheet of Al was evaporated as a back contact. The specimens were mounted in a temperature chamber and electrical connection was made using spring loaded contacts. The capacitance and loss tangent were measured in a temperature interval of 78°-488°K and a frequency interval of 1×10^3 to 1×10^5 Hz. Measurements of loss tangents at frequencies down to 1×10^2 Hz were made, but could not be continued through the whole temperature range because of excessively large loss tangent values. The measurements were performed on a General Radio Type 1615-A capacitance bridge using a three-terminal probe.

Dielectric constant.—The dielectric constant was calculated from the capacitance measured as outlined above and from the Ta_2O_5 film thickness measured by ellipsometry and the reflectivity minima in the ultraviolet and visible spectrum. Figure 7 shows the results as a function of temperature for the frequencies 1×10^3, 2×10^3, 1×10^4, and 1×10^5 Hz. At room temperature and 100 kHz the apparent dielectric constant is 44.0. To the authors' knowledge there are no published data on the dielectric constant of crystalline β-Ta_2O_5 available in the literature to make comparison with the present results. However, Pavlovic (21) reported the dielectric constant of β-Ta_2O_5 ceramic to be 24.1 at room temperature and 100 kHz. Gerstenberg found an average value of dielectric constant for anodic films of 21.7 (22). There is clearly a strong tempera-

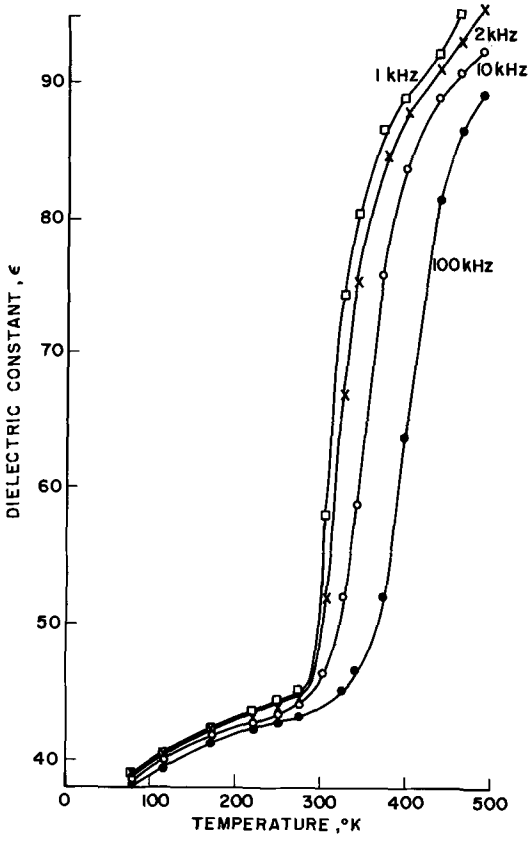

Fig. 7. Dielectric constant, ε, as a function of temperature with frequency as a parameter.

ture dependence which manifests itself above 290°K and suggests the existence of ionization sites in the Ta_2O_5 film. Smyth *et al.* (23), in their investigation of the effects of heat-treatment and reanodization on anodic Ta_2O_5 films, found strong temperature dependence under conditions in which there were oxygen vacancies in the film. An oxygen vacancy would contain two electrons, whose ionization would be temperature dependent. Thus the data presented in Fig. 7 indicates that the film investigated is probably not stoichiometric.

Loss tangent.—The loss tangent was calculated directly from the General Radio Type 1615-A capacitance bridge readings. Figure 8 presents these data as a function of temperature for the frequencies 1×10^3, 2×10^3, 1×10^4, and 1×10^5 Hz. At room temperature and 100 kHz, the loss tangent is 0.025, in contrast to Pavlovic's (22) value of 0.0001 for β-Ta_2O_5 ceramic. In this case also a strong temperature dependence, as in the case of the dielectric constant, could be attributed to the ionization of oxygen vacancies.

Acknowledgments

The authors would like to thank R. E. Caffrey for his encouragement throughout the course of this work. Thanks are also due to D. R. Wonsidler for his assistance with the microprobe analysis, L. P. Adda for assistance in measuring the dielectric properties, J. Drobek for assistance with electron microscopy, and D. Gerstenberg for helpful discussions.

Manuscript submitted Sept. 25, 1972; revised manuscript received Feb. 7, 1973. This was Paper 170 presented at the Miami Beach, Florida, Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Measurement of Film Thickness from Lattice Absorption Bands

C. J. Mogab

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Many compound semiconductors and insulators exhibit characteristic infrared lattice absorption bands which can be quantitatively described by classical dispersion theory. When the dispersion parameters are known, the thickness of an absorbing film on a nonabsorbing substrate can be determined from a measurement of the lattice absorption. For thin films the dispersion parameters can differ from the values appropriate to bulk single crystals; however, it is shown that the parameter most susceptible to variation can be obtained directly from the measured absorption band without knowledge of the film thickness. It is also shown that the integrated optical density (the area under the band plotted as optical density *vs.* wave number) is a linear function of thickness when the refractive index of the substrate is unity, but departs from linearity as the substrate refractive index increases. The appropriate equations and a method for determining film thickness from a measured absorption band are given. The discussion is illustrated by data for thin SiC films on Si substrates.

Of the many techniques available for the measurement of film thickness (1), the use of infrared lattice absorption bands has received comparatively little attention despite the fact that it is a potentially useful technique for a variety of compound semiconductors and insulators of practical importance. Nakayama and Collins (2) used the optical density at the peak of the 9.3 μm infrared band of SiO_2 to determine the thicknesses of thin SiO_2 films on silicon substrates. This was accomplished by calibration against the Vamfo method (1) for several films in excess of 2400Å with a linear interpolation of the peak optical density between 2400Å and zero thickness assumed valid. In another study of SiO_2 films on Si, Pliskin and Esch (3) pointed out that the peak optical density is not a linear function of thickness and suggested the integrated band intensity (the area under a plot of optical density *vs.* wave number) as a more suitable function for linear interpolation. They measured the integrated optical density and film thickness, the latter quantity by use of the Vamfo technique, and observed a linear relation between these quantities over the range of their thickness measurements. Choudhury and Formigoni (4) attempted to determine the thickness of β-SiC films on Si substrates by comparing the transmission at the peak of the 12.6 μm band to the values expected for unsupported films on the basis of the dispersion parameters for β-SiC determined by Spitzer *et al.* (5).

In the course of a study of the growth of very thin epitaxial films of SiC on Si crystals (6), we have found it necessary to resort to infrared lattice absorption measurements in order to determine film thickness. More conventional methods such as ellipsometry at 5461Å failed to provide accurate thickness values due, we believe, to the peculiar topology of these films which allowed some scattering of visible light. In a survey of the literature we were unable to find any basis for the interpretation of infrared measurements insofar as the determination of film thickness is concerned. Moreover, in most instances where infrared measurements had been used for this purpose, we felt that an improper interpretation of these measurements was made leading to erroneous thickness values.

This paper considers the use of infrared lattice absorption measurements as a means for thickness determination for films for which the lattice absorption can be described in terms of classical dispersion theory (7) and which are supported on a substrate that is transparent within the region of the absorption band.

Key words: films, thickness, infrared, absorption.

(A partial listing of the many compounds exhibiting lattice absorption bands which can be quantitatively described by classical dispersion theory is given in Table I). In particular, the use of linear interpolation or extrapolation from calibration measurements, for materials whose dispersion constants are unknown, and the appropriate methods for dealing with film materials, for which dispersion parameters are available from measurements on bulk crystals, are discussed. Calculations and experimental data for β-SiC films on silicon substrates are used to illustrate the discussion.

As with most thickness measuring techniques, this method has certain advantages and limitations which will dictate its applicability for specific situations. It is contactless and nondestructive and does not require that the film be transparent in the visible, or that there be a step in the film; requirements which must be met in order to use several of the most widely employed techniques (1). Further, it does not depend on interference within the film and thus in certain instances can be used to measure thicknesses well below the minimum value at which interference techniques are applicable. Since infrared is used the method can be useful for films having rough (nonspecular) surfaces, on the scale of visible light, but negligible roughness in comparison to infrared wavelengths. Its main limitations are that it requires a substrate which is transparent in the region of the absorption band and, as will be discussed, the high and low frequency dielectric constants of the film material must be known or an auxiliary method of thickness measurement must be available for calibration. In addition the method involves a comparatively complicated analysis, although no more so than for ellipsometry. Consideration of the foregoing remarks suggests that this method may be most useful for opaque semiconductor films and possibly also for insulator films having sufficiently rough surfaces to preclude the use of simple techniques employing visible light.

Theory

The classical dispersion theory (7) for a single resonance considers the interaction of monochromatic radiation of wave number w with a collection of charged oscillators undergoing damped harmonic motion with a resonant wave number w_0. The frequency dependence of the complex dielectric constant as deduced from this theory is

$$\epsilon_1 = \epsilon_\infty + 4\pi\rho \frac{1-\nu^2}{(1-\nu^2)^2+\gamma^2\nu^2} \quad [1]$$

$$\epsilon_2 = 4\pi\rho \frac{\gamma\nu}{(1-\nu^2)^2+\gamma^2\nu^2} \quad [2]$$

where ϵ_1 and ϵ_2 are the real and imaginary parts of the dielectric constant, ϵ_∞ is the high frequency dielectric constant, $\nu = w/w_0$, γ is a dimensionless damping constant, and ρ is a dimensionless parameter reflecting the strength of absorption. ρ is related to the static (low frequency) dielectric constant, ϵ_0, by

$$\rho = (\epsilon_0 - \epsilon_\infty)/4\pi \quad [3]$$

The parameters ϵ_∞, ρ, γ, and w_0 are referred to as the dispersion parameters and completely determine the optical properties, n, k, in the region of the absorption band (n and k are the real and imaginary parts of the refractive index) since

$$\left.\begin{aligned}\epsilon_1 &= n^2 - k^2\\ \epsilon_2 &= 2nk\end{aligned}\right\} \quad [4]$$

If the dispersion parameters are known for a specific film, the thickness of that film on a transparent substrate can be determined from a transmission measurement as described in the Appendix. A desirable alternative to computation of the thickness would be direct calibration of the integrated optical density against an independent thickness measuring technique, and subsequent use of linear interpolation or extrapolation over the thickness range of interest, as suggested by the work of Pliskin and Esch (3). The validity of this approach is discussed below.

The equations describing the transmission of a thin absorbing film on a transparent substrate (see Appendix) are sufficiently cumbersome that no direct relation between optical density and film thickness can be obtained from them. In order to arrive at simplified relations, an unsupported film, exhibiting a single lattice resonance,[1] is considered here. The applicability of these simplified relations to films on substrates is then tested by direct numerical computation using the exact equations as given in the Appendix and values of the dispersion parameters for β-SiC as determined by Spitzer *et al.* (5), which are representative of materials having a single lattice resonance.

A first-order approximation to the transmission, T,[2] of an unsupported film of thickness, d, valid when $2\pi wd\sqrt{n^2+k^2} << 1$, gives

$$\frac{1}{T} = 1 + \beta\epsilon_2 + \frac{1}{4}(\beta\epsilon_2)^2 + \frac{1}{4}[\beta(\epsilon_1 - 1)]^2 \quad [5]$$

where $\beta = 2\pi wd$. Substitution of Eq. [1] and [2] in [5] yields

$$\frac{1}{T} = 1 + \mathbf{F}(\nu) \quad [6]$$

with

$$\mathbf{F}(\nu) = \frac{4\pi\rho}{D}\left[\beta\gamma\nu + \frac{\beta^2}{2}(\epsilon_\infty - 1)(1-\nu^2) + \pi\rho\beta^2\right] + \frac{\beta^2}{4}(\epsilon_\infty - 1)^2 \quad [7]$$

where $D = (1-\nu^2)^2 + \gamma^2\nu^2$. Equations [6] and [7] describe the transmission in the vicinity of the absorption band. For typical dispersion parameters (see Table I) the last term in Eq. [7] is negligible over the entire band, and since ν is near unity throughout the band, Eq. [7] can be rewritten

$$\mathbf{F}(\nu) \simeq \frac{C}{(1-\nu)^2 + (\gamma/2)^2} \quad [8]$$

where

$$C = \pi^2\rho[2\gamma w_0 d + 4\pi^2\rho(w_0 d)^2] \quad [9]$$

The optical density is defined by

$$OD = \log(1/T) \quad [10]$$

Figure 1 illustrates computed absorption bands, plotted as optical density *vs.* reduced wave number (w/w_0), for a 600Å film of β-SiC on substrates of various refractive indexes. Note that the effect of increasing the substrate refractive index is to enhance the transmission; this results mainly from a reduced reflectivity at the film-substrate interface.

Substitution of Eq. [6] and [8] in [10] gives

$$OD \simeq \log\left[1 + \frac{C}{(1-\nu)^2 + (\gamma/2)^2}\right] \quad [11]$$

According to Eq. [11] and [9] the optical density has a maximum at $\nu = 1$ given by

$$OD_{max} = \log\left(\frac{\gamma^2 + 4C}{\gamma^2}\right) = 2\log\left(1 + \frac{4\pi^2\rho w_0 d}{\gamma}\right) \quad [12]$$

Expansion of Eq. [12] in powers of $w_0 d$ indicates that the peak optical density is linear in $w_0 d$, for typical values of ρ/γ, only up to values of $w_0 d$ corresponding to negligible absorption. From the exact equations it can be shown that the peak optical density becomes linear in thickness when $4\pi k w_0 d > 2$ where k is the value of the imaginary part of the film refractive index at the resonant frequency. For typical materials, the latter criterion implies that the peak optical density is linear in thickness only for thicknesses corresponding

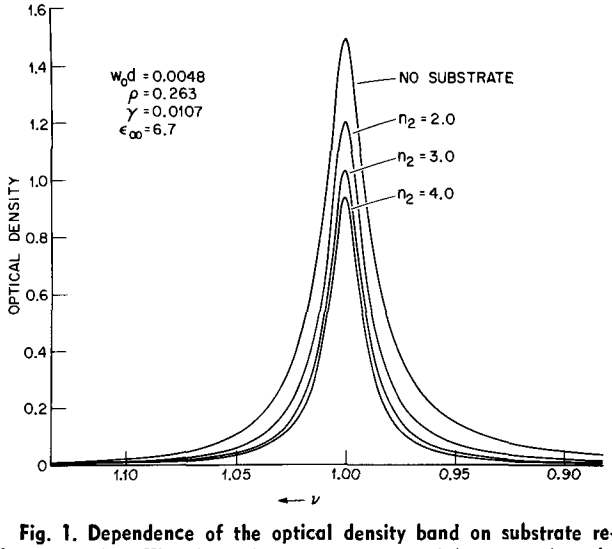

Fig. 1. Dependence of the optical density band on substrate refractive index. The dispersion parameters used in computing the band are those for β-SiC as reported in Ref. (5).

[1] Multiresonance absorption processes are described by equations analogous to [1] and [2]

$$\epsilon_1 = \epsilon_\infty + \sum_j 4\pi\rho_j \frac{(1-\nu_j^2)}{(1-\nu_j^2)^2 + \gamma_j^2\nu_j^2}$$

$$\epsilon_2 = \sum_j \frac{4\pi\rho_j\gamma_j\nu_j}{(1-\nu_j^2)^2 + \gamma_j^2\nu_j^2}$$

where ν_j and ρ_j are the dispersion parameters associated with the jth resonance. An extension of the discussion presented here to materials exhibiting multiresonance lattice bands will be evident.

[2] Throughout this paper it is assumed that the transmission, T, in the region of an absorption band is normalized relative to any observable background.

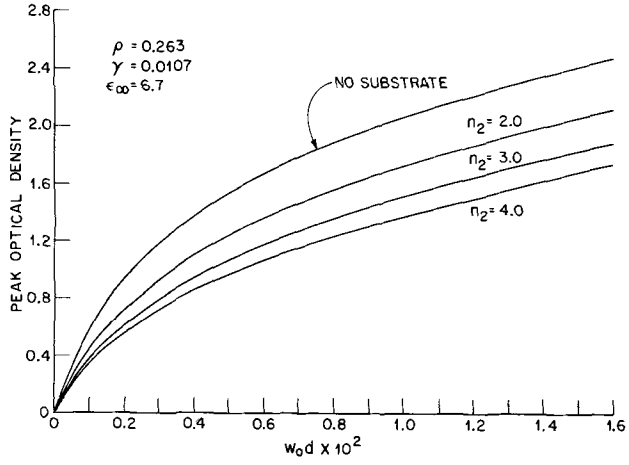

Fig. 2. Dependence of the peak optical density on film thickness and substrate refractive index for β-SiC films having the dispersion parameters given in Ref. (5).

to substantial absorption. Thus over the range of thicknesses where transmission measurements can be employed with high accuracy, the peak optical density is not a linear function of thickness. This is demonstrated in Fig. 2 for the case of β-SiC films having dispersion parameters as determined by Spitzer *et al.* (5). Accordingly, linear interpolation of peak optical density *vs.* thickness, as used by Nakayama and Collins (2), is certain to lead to considerable error.

The integrated optical density, A, can be obtained from Eq. [11] as

$$A = \int (OD)\, d\nu \cong \frac{1}{2.303} \int_{-\infty}^{\infty} \ln\left[1 + \frac{C}{(1-\nu)^2 + (\gamma/2)^2}\right] d\nu \quad [13]$$

and carrying out the integration with use of Eq. [9]

$$A = 4\pi^3 \rho w_0 d/2.303 \quad [14]$$

Thus, within the first-order approximation, which is expected to be valid even for the thickest films that can be measured, the integrated optical density is linear in thickness and independent of the damping constant γ when the film is unsupported. The validity of this conclusion. when a substrate is present, has been tested by use of the exact equations. Figure 3

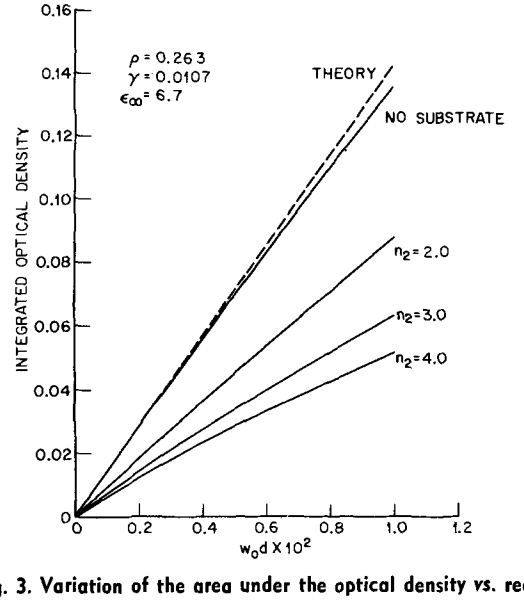

Fig. 3. Variation of the area under the optical density *vs.* reduced wave number (w/w_0) band with thickness and substrate refractive index. The dashed line represents Eq. [14].

shows the dependence of the integrated optical density on film thickness for a series of substrate indexes. The dashed line represents Eq. [14] while the solid lines correspond to numerical integrations of the exact equation for optical density. In carrying out the numerical integrations, infinite limits cannot be used thus leading to an error due to neglect of the band "wings" (see Fig. 1). If fixed limits are used (as was done here) this error increases with film thickness. For the "no substrate" case the error can be calculated exactly and can be shown to account for the divergence between the theoretical line and the "no substrate" curve in Fig. 3. As is evident from Fig. 1, for a given film thickness the wing correction is smaller the larger the substrate index. Accordingly, while the curves for $n_2 > 1$ in Fig. 3 are slightly in error for $w_0 d \gtrsim 0.004$, due to neglect of the wing correction, making this correction will not impart linearity to the curves since the maximum possible correction is given by the departure of the "no substrate" curve from the dashed line. We conclude, therefore, that the integrated optical density is strictly linear in thickness only when $n_2 \to 1.0$. However, it can be seen from Fig. 3 that, except for rather high substrate indexes, comparatively little error is involved in use of linear interpolation or extrapolation of the integrated optical density. The linearity observed by Pliskin and Esch (3) for SiO_2 films on silicon substrates ($n_2 \simeq 3.4$) probably results from the fact that the ρ value for the 9.3 μm band of SiO_2 is likely to be considerably smaller than the values indicated in Table I,[3] (this causes the initial linearity evident in Fig. 3 to be retained to higher $w_0 d$ values) and may also result in part from their inclusion of the small 8 μm shoulder on the 9.3 μm band in the integration. The effect of the damping constant on the computed areas was also tested. For the "no substrate" case the area was independent of γ as predicted by Eq. [14]. however for $n_2 \gtrsim 2.0$ there was a very slight dependence of the integrated optical density on γ, which if neglected would lead to a maximum error in derived thickness estimated to be about 5%.

One other noteworthy feature of the optical density band obtainable from Eq. [9] and [11] is that the band half-width (the width of the band at half the peak intensity) is not independent of film thickness as might customarily be assumed. In fact for the unsupported film

$$\Delta\nu = [\gamma(4\pi^2 w_0 \rho d + \gamma)]^{1/2} \quad [15]$$

where $\Delta\nu$ is the half-width. Figure 4 illustrates the effect of the substrate refractive index on the half-width of the optical density band, again for the case of β-SiC films.

In contrast to the behavior of the optical density function, it can be seen from Eq. [6] and [8] that the function $(1/T - 1)$ has a Lorentzian shape with a half-width equal to γ independent of the film thickness. It also has a maximum at the resonant frequency, however, both the peak height and the area under the peak are quadratic in thickness as can be deduced by the use of Eq. [6], [8], and [9]. Direct numerical computation of the half-width of the $[(1/T) - 1]$ function for several test cases, including the full range of dispersion parameters and substrate refractive indexes which might normally be encountered in practice indicates that the half-width is in fact equal to γ, well within probable experimental error, up to the maximum measurable thicknesses. Consequently an experimental plot of $[(1/T) - 1]$ *vs.* wave number can be used to obtain γ (and w_0) directly. This is significant because the damping "constant" is expected to be structure-sensitive.

[3] The films measured by Pliskin and Esch (3) were presumably amorphous. The author knows of no determination of the dispersion parameters for vitreous SiO_2, however for quartz, which exhibits multiresonance bands, Spitzer and Kleinman (11) report $\rho = 0.053$ for the 9.3 μm band.

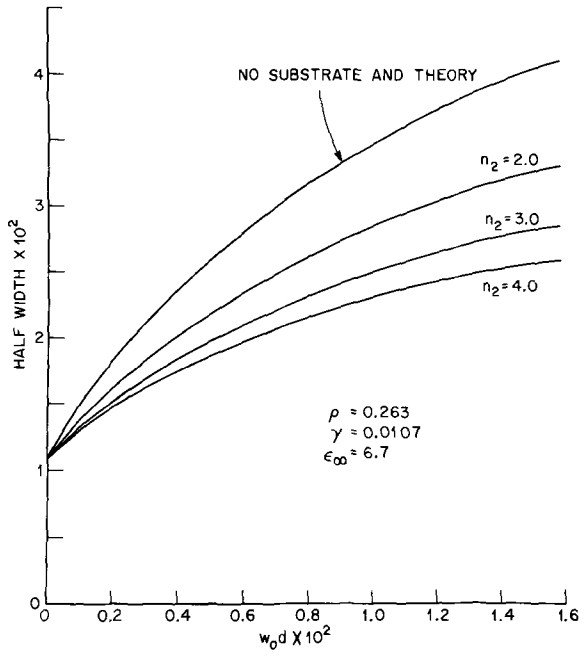

Fig. 4. Dependence of the half-width of the optical density band on film thickness and substrate refractive index.

Discussion and Comparison to Experiment

When the dispersion parameters for a particular material are available from the literature, it is imperative that their applicability be checked, when measurements are to be made on films, because of the anticipated structure-sensitivity. Once the appropriateness of a set of constants is confirmed, a simple measurement of peak optical density suffices for the determination of thickness. As an example of the error involved in applying published constants without regard to their validity, Fig. 5a compares experimental data for a thin epitaxial β-SiC film grown on Si with an absorption band computed from the dispersion parameters of Spitzer *et al.* (5) using a film thickness chosen to match the experimental peak height. (The carbide film was grown by reaction of C_2H_2 with a (111) silicon crystal. The absorption band was recorded on a Perkin-Elmer Model 621 grating spectrophotometer). It is evident from this comparison that the published dispersion parameters are not applicable to this film; varying the film thickness for the computed curve will vary its breadth as per Eq. [15] but will also change the peak height. When the experimental data of Fig. 5a were plotted as $(1/T) - 1$ *vs.* wave number it was found that the resonant frequency was identical to the value determined by Spitzer *et al.* but the damping constant γ was considerably larger ($\gamma = 0.0211$). Using this new damping constant and retaining the literature values for the other dispersion constants, a film thickness was found which resulted in a match between the computed and measured peak height and half-width. A new band was then computed which gave a good match to the experimental data as shown in Fig. 5b. The thickness determined in this way was 930Å which is to be compared to the 470Å film which matches only the peak height using the published damping constant.

To further emphasize the structure-sensitivity of the damping constant Table II lists the experimentally determined values of γ and w_0 for several β-SiC films grown on silicon under different conditions of time, temperature, and C_2H_2 pressure. Note that, even for films grown at the same temperature and C_2H_2 pressure, the damping constant varies with growth time and, therefore, with thickness. The large values of γ (compared to those of Spitzer *et al.*) shown here are not peculiar to the author's SiC films; similar values can be deduced from the data of Choudhury and Formigoni (4) for SiC films formed by reaction of

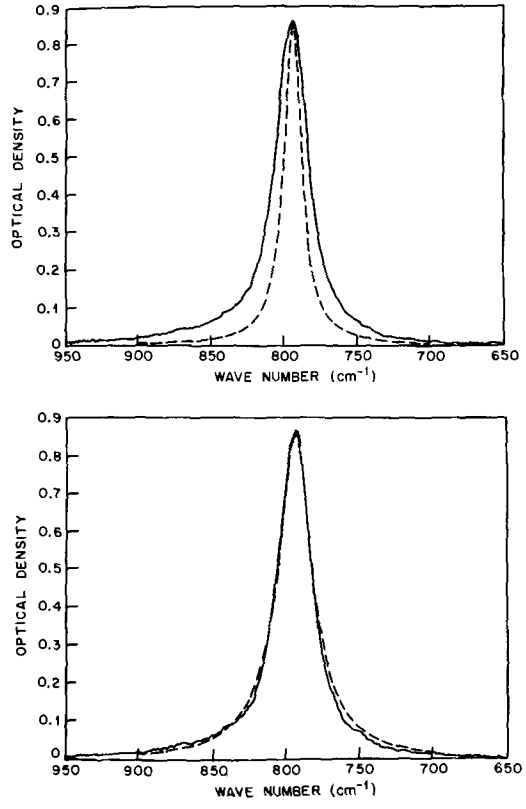

Fig. 5. (a, top) Comparison of an experimental absorption band (solid line) for a thin β-SiC film on silicon to a band (dashed line) computed from published dispersion parameters (Ref. 5) which matches the experimental peak intensity. (b, bottom) Comparison of measured and computed bands when the correct damping constant is used.

CH_4 with silicon. The reason for the variability of the γ parameter is open to conjecture, but whatever the case, the error involved in not accounting for it can be substantial.

One must also consider the possibility of variation of the parameters ρ and ϵ_∞. Unfortunately, if the film thickness is unknown there is no way to determine these parameters uniquely from a transmission measurement, or, for that matter, from a combination of transmission and reflection measurements. From Eq. [15] and [12] it can be seen that the width and intensity of the absorption band are independent of ϵ_∞, but depend directly on the product ρd. Indeed, using the exact equations as given in the Appendix it is found that large changes in ϵ_∞ have very little effect on the computed absorption bands. For example, changes in the bulk value of ϵ_∞ for SiC by factors of two and one-half lead to nearly imperceptible differences in the computed bands, over the wave number region where a fit to a measured band would be made. More importantly, variation of ϵ_∞ mainly affects the wings of the band and thus the thickness derived by matching

Table II. Observed values of damping constant and resonant frequency for thin β-SiC films on silicon

Sample	Growth temperature (°C)	C_2H_2 pressure (Torr)	Growth time (hr)	γ	w_0 (cm^{-1})
10-1	955	$5\cdot10^{-7}$	2	0.0283	794
10-2	955	$5\cdot10^{-7}$	4	0.0238	794

10-4	955	$5\cdot10^{-7}$	8	0.0193	794
11-1	1000	$5\cdot10^{-7}$	2	0.0286	793
11-2	1000	$5\cdot10^{-7}$	4	0.0242	793
11-3	1000	$5\cdot10^{-7}$	6	0.0184	793
11-4	1000	$5\cdot10^{-7}$	8	0.0156	793
2-1SH	950	$1\cdot10^{-6}$	1	0.0261	793
2-2SH	950	$1\cdot10^{-6}$	2	0.0245	793
2-3SH	950	$1\cdot10^{-6}$	0.5	0.0305	794
2-4SH	950	$1\cdot10^{-6}$	5	0.0193	793

the peak region is not influenced by the choice of ϵ_∞. Thus values of ϵ_∞ obtained from the literature can be used with impunity. On the other hand, Eq. [15] and [12] imply that, given the correct values of w_0 and γ, one can fit an experimental band (as in Fig. 5b) by choosing any combination of values for ρ and d which give the correct product. Using the exact equations it is found that the wings of the band vary for different choices of ρ and d such that ρd is maintained constant. However, within the realm of typical experimental error one could fit a measured band using a rather wide range of thicknesses depending on the value of ρ selected.

In the simple Lorentz theory the parameter ρ is given by

$$\rho = \frac{Ne^2}{4\pi^2 m_r \nu_0^2} \qquad [16]$$

where N is the oscillator concentration, m_r is the reduced mass, ν_0 is the resonant frequency, and e is the effective charge. Thus, for a given material, ρ is essentially a measure of the oscillator density and can reasonably be expected to be considerably less structure-sensitive than the damping constant which reflects local interactions between an oscillator and its surroundings. For single-phase films whose densities and/or lattice parameters are not appreciably different from their bulk values, ρ can be expected to be approximately the same as the bulk value. Where some independent method exists, for example, determination of film thickness by some other technique, one can, of course, use the lattice absorption data to obtain the value of ρ.

Since the band intensity depends only on the product ρd, it follows that, if ρ is constant from film to film, but not necessarily equal to the bulk value, one can still obtain an accurate relative measure of thickness by using the bulk ρ value. Figure 6 is a plot of film thickness *vs.* growth time for several films of β-SiC grown under various conditions which were expected to yield a linear growth rate. The thickness values were determined by fitting the 12.6 μm absorption band

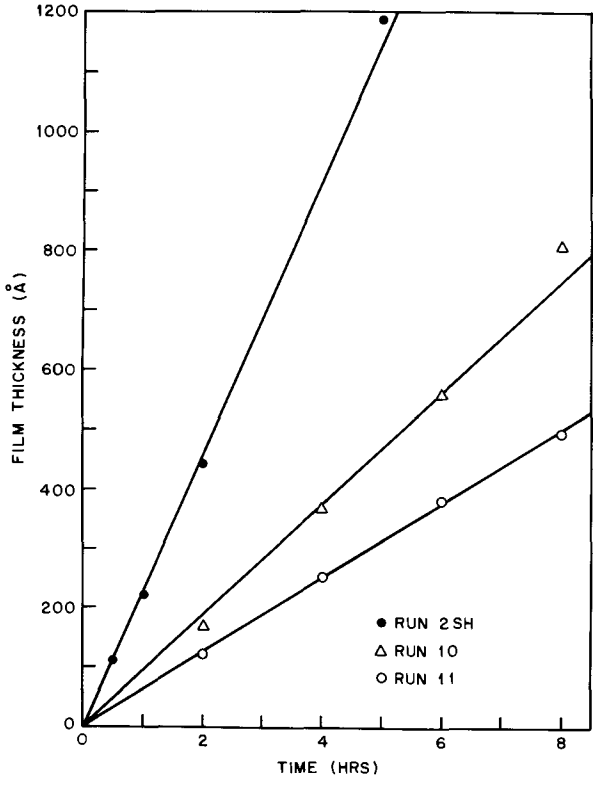

Fig. 6. Dependence of film thickness, determined from the experimental absorption bands, on film growth time for several films having variable damping constants (see Table I).

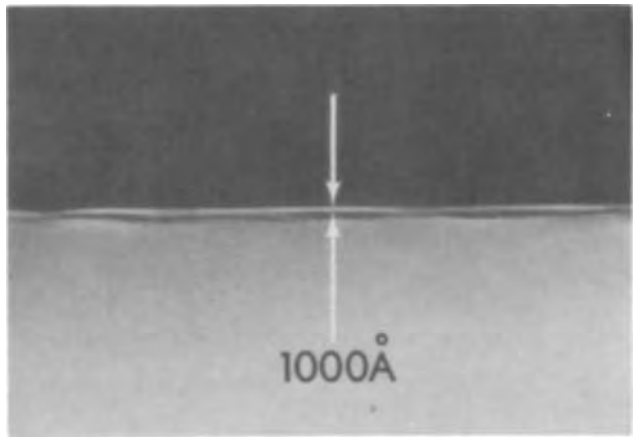

Fig. 7. Scanning electron micrograph of cleaved silicon substrate with a thin SiC film on the surface viewed edge-on. The film is delineated by the vertical arrows.

using experimentally determined values of γ and w_0 and the ρ (and ϵ_∞) value of Spitzer *et al.* (5). The values of γ vary widely for these films (see Table I) but the ρ value is apparently essentially constant, as evidenced by the reasonable fit to a straight line.

As noted at the beginning of this paper, we initially attempted determination of the thicknesses of our SiC films by the ellipsometric technique. These measurements generally gave results which were obviously affected by light scattering; the surfaces of the films were often not specular at visible wavelengths. Consequently, ellipsometry could not be used to check the infrared values. In lieu of a more sensitive technique, we endeavored to obtain a check on the thicknesses derived from the infrared bands by cleaving several samples and viewing the film-substrate composite edge-on in a scanning electron microscope. Within the resolution of this instrument. a good correspondence between the infrared and scanning microscope measurements was found. As an example, Fig. 7 illustrates a typical observation of a film on its substrate as seen edge-on. The thickness of this film, as determined from an infrared measurement, was 930Å. The interesting topological details evident in Fig. 7 (note particularly the film-substrate interface) will be discussed elsewhere (6).

Summary and Conclusions

Fundamental lattice absorption bands can be used to determine film thickness when the dispersion parameters are known. The damping constant and resonant frequency can be obtained directly from transmission measurements. If the high and low frequency dielectric constants are known no additional information is needed. However, the structure sensitivity of the dispersion constants, particularly the damping constant, requires that caution be exercised in deriving film thicknesses from measured absorption bands by the use of published dispersion constants. When the dispersion parameters are not available, the integrated optical density appears to be the most suitable function for linearization when direct calibration against an independent thickness measuring technique is to be used to generate a standard curve for subsequent thickness measurements.

APPENDIX

The relations needed to derive film thickness from measured transmission bands are given here together with a brief discussion of a useful computational scheme. The thickness range over which measurements can be made is also estimated.

When a film-covered, transparent substrate is compared to an uncoated, but otherwise identical substrate in a double beam spectrophotometer (at normal incidence) the observed transmission, T_{obs}, is given by

$$T_{obs} = \frac{T_f(1 + R_f')}{1 - R_f'R_s'} \qquad [A\text{-}1]$$

provided the substrate is thick enough to suppress interference effects.[4] If n_2 is the substrate refractive index

$$R_s' = \left(\frac{n_2 - 1}{n_2 + 1}\right)^2 \qquad [A\text{-}2]$$

T_f and R_f' are given by (13)

$$T_f = \frac{n_2\{(1 + g_1)^2 + h_1^2\}\{(1 + g_2)^2 + h_2^2\}}{e^{2\alpha_1} + (g_1^2 + h_1^2)(g_2^2 + h_2^2)e^{-2\alpha_1} + C\cos 2\gamma_1 + D\sin 2\gamma_1} \qquad [A\text{-}3]$$

$$R_f' = \frac{(g_2^2 + h_2^2)e^{2\alpha_1} + (g_1^2 + h_1^2)e^{-2\alpha_1} + A\cos 2\gamma_1 - B\sin 2\gamma_1}{e^{2\alpha_1} + (g_2^2 + h_2^2)(g_1^2 + h_1^2)e^{-2\alpha_1} + C\cos 2\gamma_1 + D\sin 2\gamma_1} \qquad [A\text{-}4]$$

where

$$g_1 = \frac{1 - n_1^2 - k_1^2}{(1 + n_1)^2 + k_1^2}$$

$$h_1 = \frac{2k_1}{(1 + n_1)^2 + k_1^2}$$

$$g_2 = \frac{n_1^2 - n_2^2 + k_1^2}{(n_1 + n_2)^2 + k_1^2}$$

$$h_2 = \frac{-2n_2k_1}{(n_1 + n_2)^2 + k_1^2}$$

$$\alpha_1 = \frac{2\pi k_1 d}{\lambda};\ \gamma_1 = \frac{2\pi n_1 d}{\lambda}$$

$$A = 2(g_1g_2 + h_1h_2);\ B = 2(g_1h_2 - g_2h_1)$$

$$C = 2(g_1g_2 - h_1h_2);\ D = 2(g_1h_2 + g_2h_1)$$

here n_1 and k_1 are the real and imaginary parts of the film refractive index, d is the film thickness, and λ is the vacuum wavelength. n_1 and k_1 are computed from Eq. [1], [2], and [4]. The complexity of these expressions necessitates the use of a computer for obtaining the thickness. Two cases can be distinguished: (*i*) the dispersion parameters are known and are independent of film thickness and preparation conditions, (*ii*) the values of γ and/or w_o vary from film to film. In the former case, Eq. [1], [2], [4], and [A-1]-[A-4], are used to obtain a standard plot of peak height (*e.g.*, peak optical density) *vs.* thickness. In the latter case, the values of γ and w_o can be obtained from the experimental data by plotting $(1/T_{obs}) - 1$ *vs.* wave number as discussed in the text. Using known values of ρ and ϵ_∞ the thickness is then determined, by trial and error, so that the height of the $(1/T_{obs}) - 1$ peak is matched to any desired degree of accuracy. The height of this peak for an unsupported film is given by $4C/\gamma$ which allows for an initial estimate of d. For $n_2 > 1$ this initial estimate will be less than the actual thickness. As an alternative to plotting $(1/T_{obs}) - 1$, trial and error adjustments of both γ and d can be made until the peak height and half-width of an experimental optical density *vs.* wave number curve are matched. It can easily be shown that for fixed ρ, ϵ_∞, and w_o there is a unique pair (γ,d) which provides a match.

Applicable thickness range.—Assuming the availability of a spectrophotometer capable of measuring optical density from 0.1 to 2.0, Eq. [12] can be used to estimate the minimum and maximum film thicknesses which can be measured

$$d_{min} \approx 3 \times 10^{-3}\left(\frac{\gamma}{\rho w_o}\right) \qquad [A\text{-}5]$$

$$d_{max} \approx 2 \times 10^{-1}\left(\frac{\gamma}{\rho w_o}\right) \qquad [A\text{-}6]$$

These estimates are too small for substrate refractive indexes exceeding unity. As an example for β-SiC films, using the dispersion parameters in Table I and Eq. [A-5] and [A-6], the minimum and maximum detectable thicknesses are 15 and 1025Å, respectively, whereas, using the same dispersion parameters, for β-SiC films on Si substrates ($n_2 = 3.42$) films of 40 and 2400Å thickness correspond to the assumed limits on measurable optical density. Note that for typical γ/ρ values (see Table I) the measurable thickness range is determined primarily by the resonant frequency; lower resonant frequencies requiring proportionately larger film thicknesses to produce a given optical density.

Manuscript submitted Dec. 21, 1972; revised manuscript received March 8, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

[4] The minimum thickness necessary to suppress interference depends on the substrate refractive index, n_2, and the resolution of the spectrometer used, $\Delta w(cm^{-1})$. Then $d_{subs} > (2\ n_2\Delta w)^{-1}$ cm will eliminate interference.

Resistivity and Photoluminescence of Zn(S,Se):I Annealed in Liquid Zinc

Lyuji Ozawa and H. N. Hersh

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

The resistivity and photoluminescence of Zn(S,Se):I single crystals annealed in liquid Zn at several temperatures have been studied. The change in resistivity with annealing temperature had a characteristic activation energy of 16 kcal/mole and was independent of the S:Se ratio suggesting that Zn is diffusing into the crystal. The photoluminescent spectra was not changed by annealing; however, the room temperature photoluminescence efficiency increased as Zn diffused in and decreased when Zn diffused out. It was concluded that diffused Zn only contributes to the resistivity and the thermal quenching centers. In addition it was found that excess iodine gave an additional yellow luminescent band centered at 2.23 eV (560 nm).

The photoluminescence of zinc sulfoselenide crystals, Zn(S,Se):halogen, as a function of ZnSe concentration is of basic interest in understanding II-VI compound semiconductors because ZnSe is isoelectronic with GaAs and Ge. From a practical point of view, the phosphor ZnSe:Cu:Br has been proposed as a possible red color TV phosphor (1) and is an electroluminescent material (2, 3); yellow-emitting Zn(S,Se):Cu:Br has been shown to be a brighter electroluminescent phosphor than ZnS:Mn:Cu and has been used in an EL TV display panel (4).

The majority carriers of ZnSe at room temperature are electrons. The resistivity of n-ZnSe as-grown single crystals is high but is lowered by annealing in Zn (5). Cu_2Se-ZnSe and Cu_2S-ZnS emit a brilliant d-c electroluminescence (6, 7). Stringfellow and Bube have measured the photoluminescence and excitation spectra at 85°K and the thermally stimulated luminescence of n-ZnSe(SA) annealed in Zn (8). They concluded that the fact that the center lies 0.5-0.6 eV above the valence band is an intrinsic defect.

In this work the resistivity and photoluminescence of Zn(S,Se):I single crystals before and after annealing in Zn were studied. This report will describe first the effect of annealing on Zn(S,Se):I crystals as determined by the change in resistivity, thus confirming that Zn diffuses into the crystals. Then the photoluminescence of Zn(S,Se):I crystals as-grown and annealed will be described.

Experimental

The Zn(S,Se):I single crystals were grown by an iodine transport technique (9, 10) from the amorphous powder mixture; the ZnSe powder was a vacuum deposition grade from the Apache Chemical Company and the ZnS powder was a luminescent grade from RCA. The crystals did not grow under conditions of excess Zn but only grew in an excess Se and S. X-ray diffraction analysis indicated that all Zn(S,Se) crystals formed solid solutions over the whole range of composition within 2% error from the expected composition.

The crystals, about 5g, were cut into slices along the <111> plane and were polished by carborundum (1μ grit size) to 0.5 mm thickness. These sliced pieces were used in the study of the photoluminescence and resistivity.

The crystals (about 100 mg) were placed in a quartz capsule (1 cm^3) which was evacuated to 5×10^{-6} Torr by means of an ion pump and were heated in liquid Zn (1g) with iodine (20 mg) at desired annealing conditions. Iodine was introduced into the evacuated capsule with vapor transport techniques. Then the crystals were taken out of the liquid Zn and cooled to room temperature. The samples were washed with alcohol in order to remove the excess ZnI_2 and I_2 from the crystal surface. Ohmic contact was made using indium which was rubbed onto the fresh cleaved surface; the crystals were then heated at 350°C for 2 min in nitrogen atmosphere. All of the resistivity measurements were made at room temperature.

The photoluminescent spectra at room temperature and liquid-nitrogen temperature were measured using a Bausch and Lomb grating monochromator (1300 lines/mm). A high pressure Hg-lamp plus Corning filter (7-60) was used as the excitation source. Correction of the spectral response to the combination of the monochromator and photomultiplier was made with a standard tungsten lamp.

Results and Discussion

Resistivity.—The change in the resistivity of ZnSe:I crystal as a function of temperature and time of annealing was essentially similar to the change in the resistivity of Zn(S,Se):I crystals. For this reason, the resistivity of ZnSe:I crystal is primarily discussed and then the difference of the Zn(S,Se):I crystals is described.

The resistivity of the as-grown ZnSe:I crystal was 7 ± 1 kohm-cm. This resistivity decreased upon annealing in an atmosphere of Zn. The resistivity of the ZnSe:I crystals annealed in Zn alone (either in Zn vapor or in liquid Zn) was about twice as high as the resistivity of the samples in Zn and iodine. Annealing in Zn vapor alone yielded transparent ZnSe plates but annealing in liquid Zn resulted in opaque plates due to the rough surface formed when a part of the crystal dissolved in liquid Zn.

The solubility of ZnSe in liquid Zn is shown in Fig. 1. These experimental determinations were done by a weight-loss method with a controlled weight of ZnSe and Zn in a controlled volume. The ZnSe samples were heated for 7 days at the given temperatures. The experiments at temperatures below 600°C were difficult because a small amount of Zn adhered to the surface of the ZnSe crystal when the ZnSe crystal was taken out from liquid Zn. The solubility markedly increased above 1000°C. Etch pit patterns were observed under a microscope on the surface of the annealed crystals.

The resistivities of ZnSe crystals as a function of the temperature and time of annealing in liquid Zn and iodine are shown in Fig. 2. Three to five samples were made for each annealing condition to check the variance (which is given by the vertical lines in the figure). The resistivity of the annealing samples at a given temperature decreased with annealing time and finally reached the constant value which is shown in Fig. 2. The annealing time required to reach a constant re-

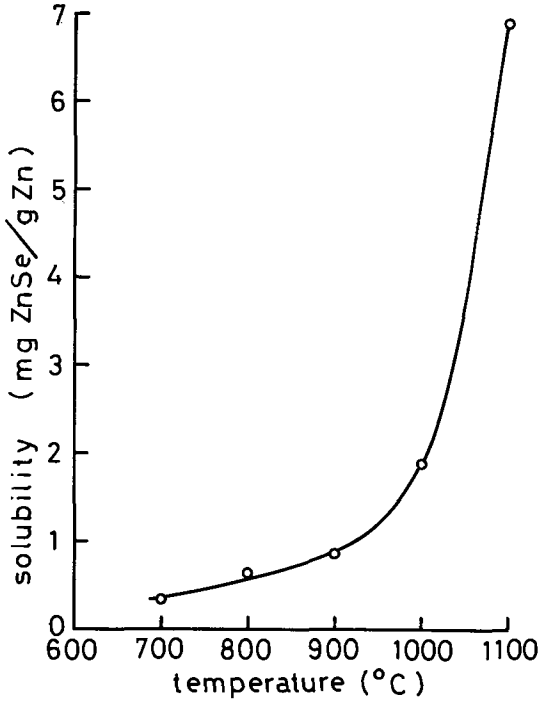

Fig. 1. Solubility of ZnSe in liquid Zn

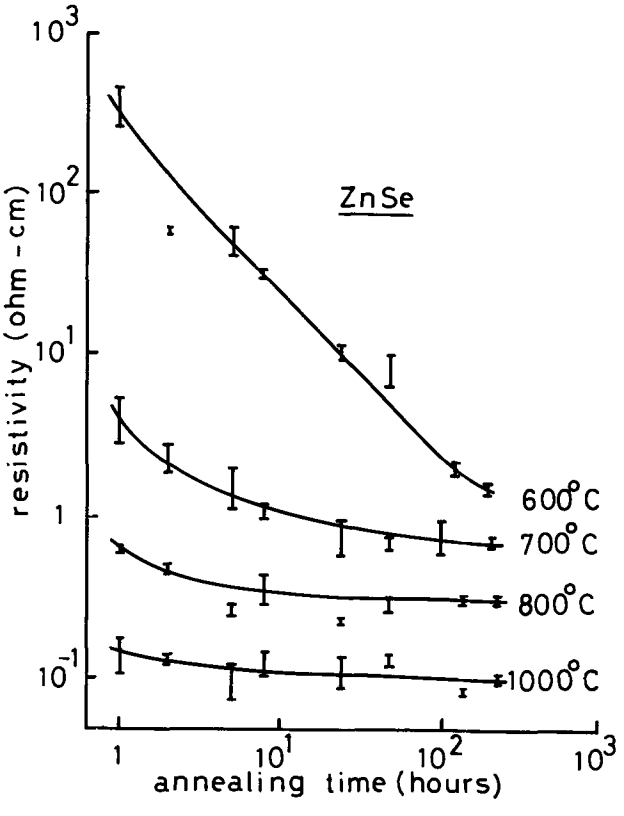

Fig. 2. Resistivities of ZnSe:I annealed at various temperatures and lengths of time.

sistivity decreased with an increase in the annealing temperature: 100 hr at 700°C, 20 hr at 800°C, and 10 hr at 1000°C.

It is assumed that the ZnSe crystals which were annealed for 160 hr reach the characteristic resistivity at a given annealing temperature. The logarithm of this resistivity is plotted against reciprocal temperature ($1/T$°K) in Fig. 3. It may be seen that there is an exponential relationship between the resistivity and reciprocal temperature, indicating that the resistivity follows a diffusion equation. Therefore, it is believed that the resistivity of the annealed ZnSe

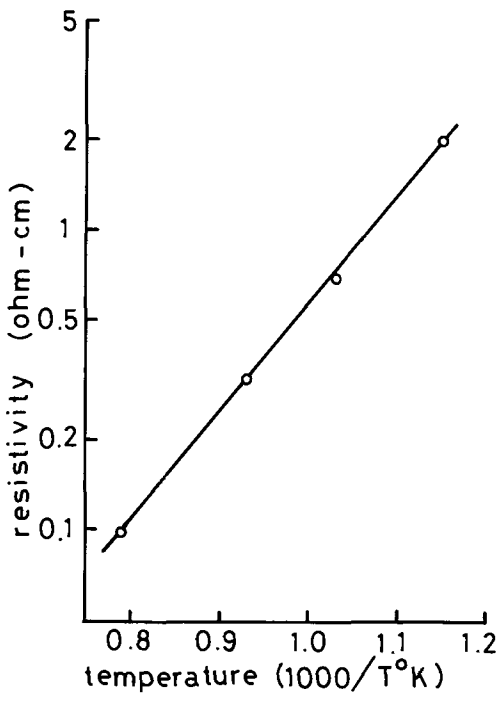

Fig. 3. Exponential relationship between resistivity of ZnSe:I and reciprocal annealing temperature. Activation energy was calculated at 16 kcal/mole.

crystal decreases in proportion to the amount of Zn diffused into ZnSe crystal, and activation energy is required to diffuse Zn into ZnSe:I crystal. This energy is determined from the slope to be 16 kcal/mole.

When the annealed crystals were heated in vaccum (5×10^{-6} Torr), the resistivity of the crystals became greater with an increase in the heating temperature and length of time. The change in the ZnSe resistivity by the heating at 1000° and 800°C in the absence of Zn and iodine is shown in Fig. 4. Since the resistivity of the annealed ZnSe crystal is proportional to the amount of Zn diffused into ZnSe, the increase in the resistivity must be due to an out-diffusion, of which the amount depends on vapor pressure and capsule volume. Since the capsule was kept at constant volume (1 cm^3), the amount of out-diffusion at equilibrium that was required for 20 min at 1000°C and for 100

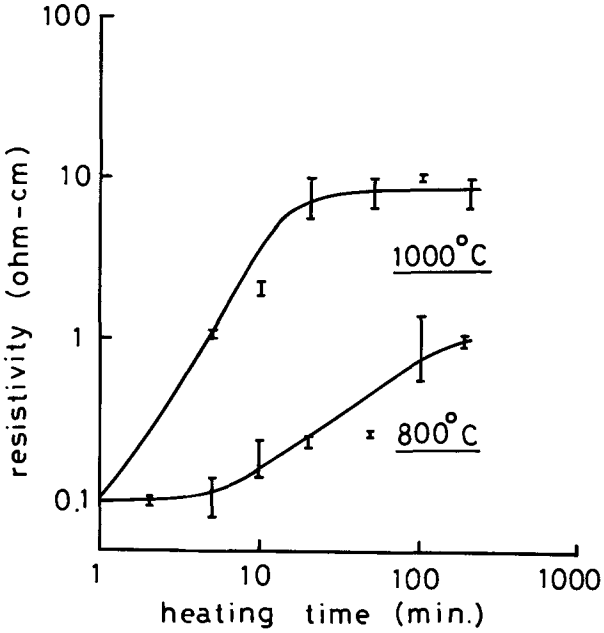

Fig. 4. Change in resistivity of annealed ZnSe:I by heating in vacuum, 5×10^{-6} Torr.

min at 800°C depended on the heating temperature. As a result of this out-diffusion, the room temperature photoluminescence of the annealed ZnSe:I crystal was diminished.

The activation energy required to diffuse Zn into the Zn(S,Se):I crystals was the same as into the ZnSe:I. The resistivity at a given temperature, however, differed. The resistivities of Zn(S, Se):I crystals annealed at 800° and 1000°C as a function of the amount of ZnSe in the Zn(S,Se) solid solution are shown in Fig. 5. It was found that an exponential relationship between the resistivity and mole per cent (m/o) of ZnSe was maintained at the annealing temperature from 600° to 1000°C. The reason why the resistivity exponentially increases with ZnS content is not understood as yet.

Photoluminescence.—To make sure that Zn diffused into the Zn(S,Se):I crystals, the annealed crystals were made by heating at 1000°C for 160 hr in liquid Zn and iodine. These samples were used to study the photoluminescence.

The photoluminescent spectra of as-grown Zn(S,Se):I crystals are shown in Fig. 6. The same spectra were also obtained with polycrystalline Zn(S,Se):I phosphor which were prepared by the firing at 950°C for 3 days with iodine. The photoluminescent intensity of ZnSe:I at room temperature was too weak to measure.

It may be seen that the room temperature spectra of Zn(S,Se):I (not ZnS:I) monotonically shifted to longer wavelengths with an increase in ZnSe content. At liquid-nitrogen temperature, the spectral behavior differs somewhat from that at room temperature: the short wavelength side of the spectra of Zn(S,Se):I containing above 60 m/o ZnSe did not move to longer wavelengths. The luminescent spectra of ZnSe:I seem to give the key to this spectral behavior. When the ZnSe:I crystal was annealed in Zn and iodine, a yellow photoluminescence was obtained; in Zn alone an orange photoluminescence was obtained.

The photoluminescent spectra at 77°K are shown in Fig. 7. Upon annealing in liquid Zn alone, spectrum (1) with center wavelength at 2.02 eV (614 nm) was always obtained. Spectrum 1 was also obtained with ZnSe:Br powder, prepared by using a small amount of NH_4Br (0.5 weight per cent (w/o). Spectrum 2, considerably broader than spectrum 1, was obtained with ZnSe:I crystals as-grown and/or annealed in liquid Zn and iodine. Spectrum 3, shown with dashed lines, was detected by subtracting spectrum 1 from spectrum 2. The center wavelength of spectrum 3 was 2.23 eV (560 nm). Spectrum 1 and spectrum 3 were completely Gaussian, as shown in Fig. 8 in which the photoluminescent spectra were plotted on a normal distribution graph. The position and distribution of the yellow luminescent band of ZnSe:I is very closely

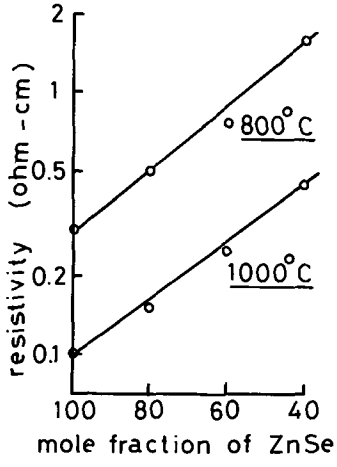

Fig. 5. Exponential relationship between resistivity of Zn(S,Se): I crystals annealed and ZnSe amount in Zn(S,Se) solid solution crystals.

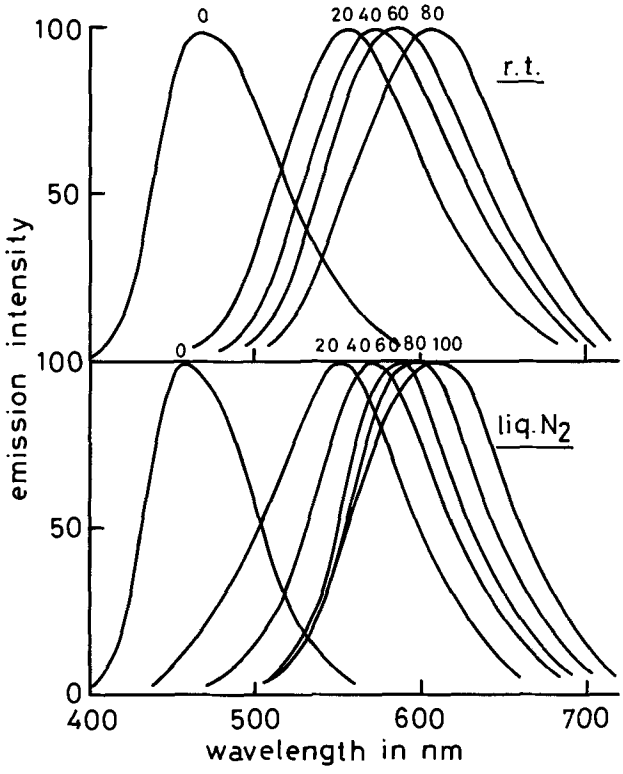

Fig. 6. Photoluminescent spectra of Zn(S,Se):I at room and liquid-nitrogen temperatures. The number above each spectrum indicates ZnSe m/o in Zn(S,Se) crystal.

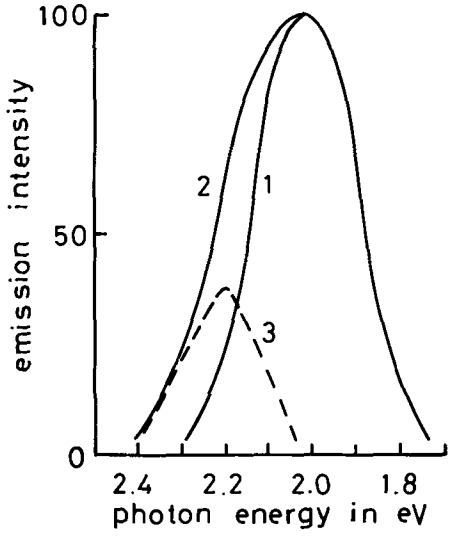

Fig. 7. Photoluminescent spectra of ZnSe:I at 77°K. Details in text.

matched to that of ZnSe:Ag:I. But the yellow luminescent band is not the Ag luminescent band. The intensity of the ZnSe:Ag:I band changes with Ag concentration and is quenched at room temperature and furthermore this Ag band completely disappears upon annealing in liquid Zn, whereas the yellow band of ZnSe:I emits at liquid-nitrogen temperature and does not diminish upon annealing in liquid Zn and iodine. The yellow band is also observed at room temperature in the samples annealed in liquid Zn and iodine. In addition, chemical determination of Ag in the samples indicated that Ag concentration was less than 10 ppm, suggesting that the intensity of the Ag band was weak.

Figure 9 shows the 2 photoluminescent spectra of ZnSe:I, annealed lightly in liquid Zn (for 3 hr at 1000°C) and annealed in ZnI_2 vapor for a long time (7 days). The yellow luminescent band was markedly enhanced by the annealing in ZnI_2 vapor and this luminescence is not quenched at room temperature.

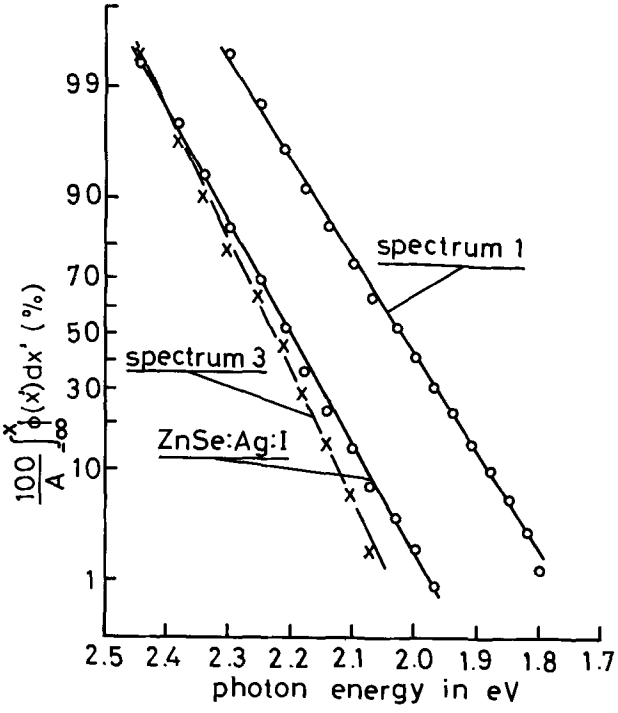

Fig. 8. Photoluminescent spectra of ZnSe:I and ZnSe:Ag:I plotted on normal distribution graph. A in ordinate is $\int_{-\infty}^{\infty} \phi(x')dx'$ and is 1.0 for normal distribution.

It is inferred from all these results that excess iodine is somehow responsible for the yellow luminescent band centered at 560 nm.

The room temperature luminescent spectra of Zn(S,Se):I crystals annealed in liquid Zn and iodine coincided with the spectra of as-grown Zn(S,Se):I crystals at liquid nitrogen temperature as indicated in Fig. 6. Considering that the position of the yellow luminescent band of ZnSe:I is at 560 nm, this yellow luminescent band seems to be contributing to the spectra of Zn(S,Se):I crystals containing more than 60 m/o ZnSe. It is inferred therefore that the yellow luminescent band of ZnSe:I appears in the spectrum of Zn(S,Se):I crystals containing more than 60 m/o ZnSe, and that spectral position is independent of the composition of host crystal. It is possible that the center of the yellow luminescent band involves molecular iodine.

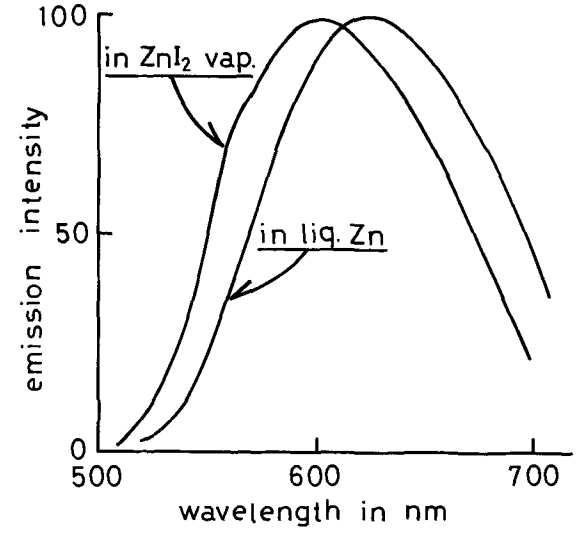

Fig. 9. Photoluminescent spectra of ZnSe:I crystals annealed lightly in liquid Zn for 3 hr at 1000°C and in ZnI_2 vapor for 7 days at 1000°C.

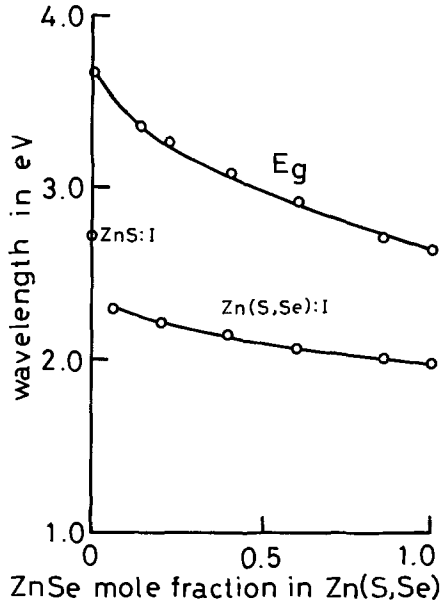

Fig. 10. Bandgap and peak wavelengths of Zn(S,Se):I annealed in liquid Zn alone at 900°C for 7 days.

The bandgap, E_g, and the peak position of the photoluminescent spectra of self-activated Zn(S,Se):I crystals annealed in liquid Zn alone are shown in Fig. 10. The bandgap was determined from the optical absorption spectra of Zn(S,Se):I single crystals. When a small amount of ZnSe was introduced into ZnS crystal to make a Zn(S,Se) solid solution, the blue luminescent band of ZnS "jumped" to the green spectral region and then monotonically shifted to longer wavelengths with an increase in ZnSe amount (11). The jumping of the blue luminescent band of ZnS to green does not happen in (Zn,Cd)S solid solution [in which the luminescent band monotonically shifts over the whole composition range (12)]. The results on Zn(S,Se):I, indicate therefore, that the self-activated center in Zn(S,Se):I crystal differs from that of ZnS:Cl, which is known to be a pair consisting of a vacancy and a halogen ion occupying the nearest neighbor site (13). The luminescent center of Zn(S,Se) crystals should be identical to that of ZnSe but not to that of ZnS

At 77°K, the identical photoluminescent spectrum and intensity were detected with the ZnSe:I crystals before and after annealing at 1000°C. Under this annealing condition, Zn surely diffused into ZnSe crystal, resulting in the change in the resistivity of the crystal. This diffused Zn did not affect the luminescent center. It is inferred, therefore, that the luminescent center of ZnSe:I may be an intrinsic defect, as suggested by Stringfellow and Bube (8).

Brilliant room temperature photoluminescence of ZnSe:I was always observed with the annealed samples. This room temperature photoluminescence diminished after heating in vacuum (Zn diffused out from the crystal). It is inferred from the results on annealing in liquid Zn that the diffused Zn occupies sites that form thermal quenching centers (resulting in the improvement of room temperature photoluminescence).

Other annealing effects were also observed; the impurities, such as Ag and Cu which were ubiquitous impurities in ZnSe, were removed from the crystals (14). The determination of Cu and Ag concentration in the annealed samples were made by atomic absorption spectrometry. The excess iodine in ZnSe:I crystal as-grown was also removed from the crystal by the annealing. The absorption spectra of ZnSe:I crystals before and after annealing at 1000°C for 7 days are shown in Fig. 11. The absorption spectrum of the annealed sample coincided with the absorption spectrum of the ZnSe crystal obtained from Eagle Picher.

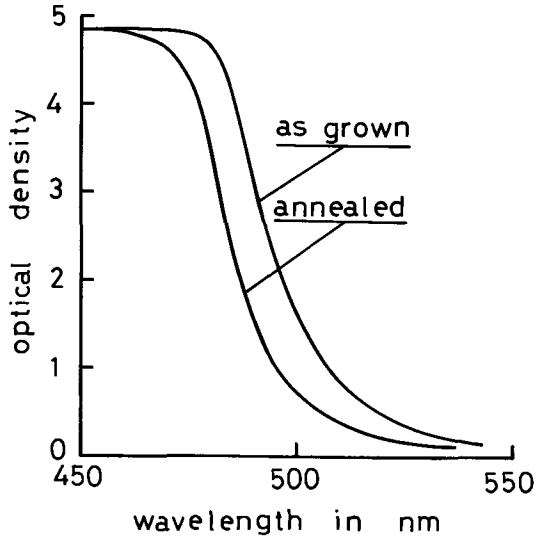

Fig. 11. Transparent spectra of ZnSe:I crystals before and after annealing at 1000°C for 7 days.

It is possible to say that Zn(S,Se):I crystals are purified by the annealing in liquid Zn; the Zn reduces the concentration of impurities and the crystal defects which form the temperature quenching centers; it also decreases the resistivity. On the other hand, the luminescent centers are not affected by annealing in Zn.

Summary

By the annealing in liquid Zn, Zn diffuses into ZnSe crystal with an activation energy 16 kcal/mole as determined by the change in resistivity at the annealing temperature. The activation energy required to diffuse Zn into Zn(S,Se) crystals is the same as the activation energy required to diffuse Zn into ZnSe. The actual resistivity at the given temperature, however, depends on the S:Se ratio in solid solution crystals. An exponential relationship between the resistivity and m/o of ZnSe was found. The photoluminescent spectra did not change upon annealing in liquid Zn and iodine but the luminescence at room temperature, which was diminished by heating the crystal in vacuum, was improved. A yellow luminescent band centered at 2.23 eV was found in samples having excess iodine.

Efficient Mn(IV) Emission in Fluorine Coordination

A. G. Paulusz

Osram (GEC) Research Laboratories, The General Electric Company Limited, Hirst Research Centre, Wembley, England

ABSTRACT

The efficiency of Mn(IV) luminescence in fluorine coordination is discussed in the context of the chemical bonding in the MnF_6^{2-} center. It is possible that the lower degree of σ-antibonding in the e_g orbitals, and the greater degree of π-antibonding in the t_{2g} orbitals, compared with the effect observed in oxides, contributes to a high efficiency and quenching temperature of the emission. The excitation and emission spectra of Mn(IV) in K_2SiF_6, K_2GeF_6, and K_2TiF_6 are presented and compared.

The luminescent center in transition-metal ion-activated phosphors consists of the transition-metal ion itself together with its directly coordinated anions. This is often an octahedral or a tetrahedral group and is the same center treated by the ligand field theory. When this group is represented in the well-known configurational coordinate model of the center, (*e.g.*, Fig. 1) it is convenient to identify the configurational coordinate with the actual transition metal/anion separation so that changes in bond length can be represented by displacements of the potential curves along the configurational coordinate axis (1). It seems to be generally recognized that the bond lengths in such centers can change in the excited state, depending on the electron transition involved. For example, Orgel has explained the Stokes shift of Mn(II) activated phosphors by noting that the electron transition which occurs on excitation, $t_{2g}^3e_g^2 \rightarrow t_{2g}^4e_g^1$, involves a transition from an antibonding e_g orbital to a nonbonding t_{2g} orbital (2) The center is thus more tightly bound in the excited state than in the ground state with a corresponding decrease in the manganese-oxygen bond length. The excited state potential curve is shifted, relative to the ground-state curve, to a smaller internuclear separation on the configurational coordinate diagram and this can account for the observed Stokes shift.

As well as introducing a Stokes shift between emission and absorption, the relative displacement of the ground and excited state potential curves can also en-

Key words: luminescence, phosphors, fluorides, emission spectra, excitation spectra.

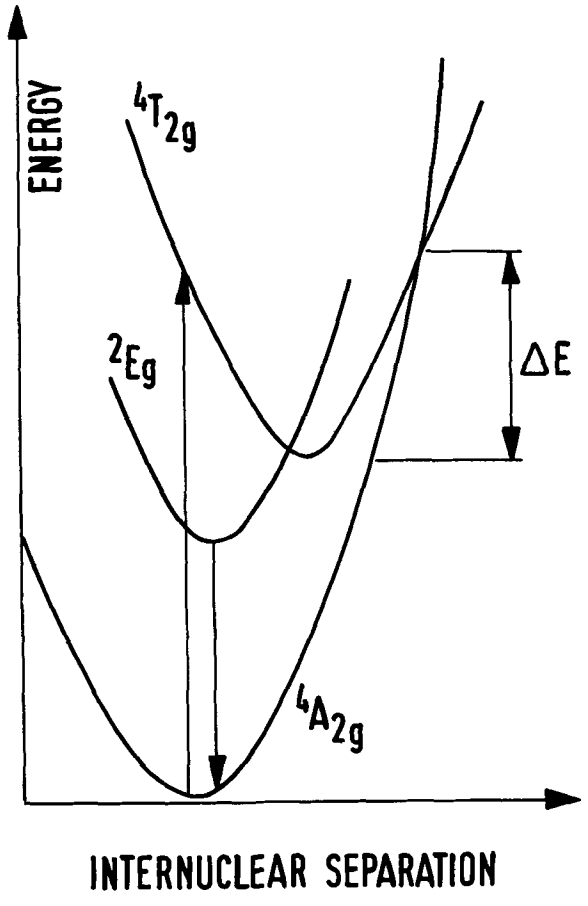

Fig. 1. Schematic configurational coordinate diagram of a d^3 center. Only one of the excited states ($^4T_{2g}$) derived from the electron configuration $t^2_{2g}e_g$ is shown.

hance nonradiative processes by lowering the energy of the crossover point of the curves. Furlani, for example, has suggested this as the reason why only a few cases of emission from d^6 ions, such as Co(III), have been reported (3). The excitation transition ($t_{2g}^6 \rightarrow t_{2g}^5 e_g^1$) involves the promotion of an electron to an antibonding e_g orbital with a corresponding increase in the cobalt-ligand bond length. The shift of the excited-state potential curve in this case is apparently sufficient to prevent efficient radiative processes except in a few cases.

In the case of d^3 ions in octahedral coordination the emitting level (^2E_g) derives from the same t_{2g}^3 electron configuration as the ground state. The transition to the ground state, $^2E_g \rightarrow {}^4A_{2g}$, only involves the net spin change $S = \frac{1}{2}$ to $S = 3/2$, so that the potential curves are not displaced relative to each other. This is illustrated in Fig. 1 which gives a schematic representation of a typical d^3 center. Several workers have noted that this fact may account for the emission of this center being comparatively well known, as in V(II), Cr(III), and Mn(IV) for example (3, 4). Emissions from other isoelectronic ions such as Re(IV) (5) and Mo(III) (6) have also been reported recently.

On the other hand, the emission of d^3 ions is most effectively excited by irradiation into the broad spin allowed bands $^4A_{2g} \rightarrow {}^4T_{2g}$ and $^4A_{2g} \rightarrow {}^4T_{1g}$ and not by direct excitation of the ^2E_g level. The excited states $^4T_{2g}$ and $^4T_{1g}$ derive from the electron configuration $t_{2g}^2 e_g^1$, *i.e.*, with an electron occupying an antibonding e_g orbital, and the excited-state curves are therefore displaced to greater internuclear separations on the configurational coordinate axis as shown in Fig. 1. In fact single crystal studies of Re(IV) in Cs_2ZrCl_6 have indicated that the rhenium-chlorine bond length increases about 7% in the excited state (7) and a similar increase probably occurs in other d^3 centers.

Because nonradiative processes can occur from the excited $^4T_{2g}$ state, either before energy is transferred to the emitting ^2E_g state, or subsequently after thermal repopulation of the $^4T_{2g}$ state, it is clear that the relative shift of the ground and excited state curves will be important for d^3 centers as well, although perhaps not so critical as in the cases mentioned earlier in which the displaced curve represents the emitting state itself.

It is well known that the activation energy, ΔE, is related to the quenching temperature, of the luminescence (8) and it is clear from Fig. 1 that the greater the displacement of the $^4T_{2g}$ curve relative to the ground-state curve $^4A_{2g}$, the lower will be ΔE and hence the quenching temperature. The activation energy is associated with the excited-state curve, and not the emitting level in this case, because as we have noted, nonradiative processes can occur from the $^4T_{2g}$ state. If the displacement could be restricted, a higher value of the quenching temperature might be obtained. Since the displacement is due to the difference in antibonding character between the e_g and t_{2g} orbitals it is possible that this could be minimized in materials in which the e_g orbitals become less strongly antibonding or alternatively in which the t_{2g} orbitals become more strongly antibonding. In the molecular orbital theory the t_{2g} orbitals are nonbonding and the e_g orbitals strongly antibonding if only σ-interactions are considered. On the other hand if π-interactions are also included the t_{2g} orbitals become π-antibonding (9).

Orgel has suggested that ligands occupying an early position in the spectrochemical series (9) have weaker σ-antibonding effects than later members (10). Thus, more favorable conditions for the luminescence of d^3 ions might very well be obtained in materials other than oxides in which the ligands occupy an early position in the spectrochemical series. The position of oxygen in the spectrochemical series is variable and in oxides will depend upon the crystal structure and the nature of other ions in the lattice, but in general we might expect the halides, for example, to be somewhat less σ-antibonding than oxygen ions. In oxide lattices particularly, the t_{2g} π-antibonding interaction is also dependent on crystal structure and the polarizing effect of more distant ions in the lattice. The CN^- ligand will however provide quite strong π-antibonding effects (9) and it is interesting to note that a higher quenching temperature is observed in $K_3Cr(CN)_6$ than in other Cr(III) complexes (11) and also that the only reported emissions from Co(III) have been in cyanide complexes (12). In the case of these complexes, however, a relatively high value of the crystal field parameter, 10 Dq, is also observed and this must also contribute to the efficiency of the radiative process.

Blasse has suggested a more physical way to limit the displacement of the excited-state curve: if the activator is substituted at a lattice site somewhat too small to accommodate it easily, the surrounding anions will be forced apart by the intruding ion even in the ground state so that further expansion of the center in the excited state will be strongly resisted by the lattice (13).

Mn(IV) Centers.—The application of these suggestions to Mn(IV) is particularly interesting because comparatively few cases of efficient emission above room temperature have been reported.

We shall consider first the question of the size of the manganese site. The radius of the ion is not known exactly (Pauling gives a radius of 0.52Å and Goldschmidt 0.54Å) but it is certainly very small. The smallest ions which regularly form octahedral groups in oxides are arsenic ($r = 0.47$Å), aluminum ($r = 0.50$Å), and germanium ($r = 0.53$Å), but unfortunately these ions are not significantly smaller than Mn(IV) itself. Nevertheless, it is interesting that the most efficient Mn(IV) emissions above room temperature have indeed been observed in arsenates, aluminates, and germanates. Examples are: $Mg_6As_2O_{11}$ (14), $6Al_2O_3 \cdot 6Li_2O \cdot As_2O_5$ (15), Al_2O_3 (8), alkaline earth aluminates (8, 16), AlN (17), $LiMgAlO_3$ (18),

'Mg_4GeO_6' (19), $LiMgGeO_4$ (18), $3Li_2O$, $8GeO_2$ (18). Smaller ions such as silicon (r = 0.41Å) and phosphorus (r = 0.34Å) are not found in octahedral coordination in oxides. In fluorides, however, octahedral coordination seems to be preferred, such groups as SiF_6^{2-} and PF_6^- being well known. The reason for this is probably partly a steric effect (the F^- ion is slightly smaller than O^{2-}) and also the greater electronegativity difference between the central ion and the ligands as Pauling has suggested. In any case the conditions for compressing the Mn(IV) into a small lattice site are easily available in fluorophosphates and fluorosilicates.

Turning next to the question of chemical bonding in the Mn(IV) center, the small size and instability of the manganese ion place severe restrictions on the type of material which might be considered. Strong π-antibonding effects might be expected in cyanides, as in the case of Cr(III), however these materials are likely to be unstable. A cyanide complex of Mn(IV), apparently $K_2Mn(CN)_6 \cdot 2KCN$, has in fact been reported (20), but we have not succeeded in preparing this compound by the method described. On the other hand weaker σ-antibonding interactions than generally observed in oxides may be observed at the other end of the spectrochemical series in halides. Again the small size and instability of Mn(IV) restrict the possibilities, but the F^- ion seems to be an exception. The MnF_6^{2-} group is quite stable out of contact with water and might be further stabilized in suitable fluoride or oxyfluoride lattices.

Finally we should remark that we have only considered the case of octahedrally coordinated Mn(IV) as the emission from the tetrahedrally coordinated ion has not been definitely observed.

Thus consideration of both the chemical bonding in the Mn(IV) center and the size of the ion lead to the conclusion that efficient emission above room temperature may be observed in fluorides. These considerations led us to examine Mn(IV) activated fluorosilicates. In order to check the importance of the manganese site size we also prepared Mn(IV) activated fluorogermanates and fluorotitanates, and we report here on the luminescence spectra of K_2SiF_6, K_2GeF_6, and K_2TiF_6 containing Mn(IV).

Experimental

The materials were prepared by recrystallizing mixtures of K_2MnF_6 and the host lattice material (K_2SiF_6, K_2GeF_6, or K_2TiF_6) from 40% aqueous hydrofluoric acid. The K_2MnF_6 was prepared by the method of Bode *et al.* (21): 100 volume hydrogen peroxide was added dropwise with constant stirring to an ice-cold 40% aqueous hydrofluoric acid solution of KHF_2 saturated with $KMnO_4$. As soon as the yellow precipitate of K_2MnF_6 began to form it was rapidly filtered off on polythene ware, washed with acetone, and then purified by recrystallizing from 40% HF.

The chemical purity of the materials was examined by x-ray fluorescence analysis and the purity of phase checked by x-ray diffraction. K_2SiF_6 crystallizes with a cubic K_2PtCl_6 structure while the other materials have a hexagonal β-$(NH_4)_2SiF_6$ lattice.

The excitation and emission spectra were measured at 90° and 300°K using a double prism Hilger D300 monochromator fitted with a trialkali photomultiplier (EMI 9558 QA). A 150W xenon lamp was used for excitation in the ultraviolet and a tungsten halogen lamp at longer wavelengths. The brightness of the phosphors as a function of temperature was measured with a Gamma Scientific Telephotometer (Model 2000) focused onto a plaque of the material which could be heated in a small enclosure in order to get a measure of the quenching temperature.

Results and Discussion

The brightness of the phosphors increases slightly with temperature up to about 200°C and then quenches very rapidly. Following Kröger (8) we have obtained the temperature at which the emission intensity has fallen to half its maximum value and called this $T_{1/2}$. The values are given in Table I. The quenching temperatures increase as the radius of the site at which Mn(IV) substitutes decreases, as expected from the model proposed by Blasse (13). On the other hand the quenching temperature also increases with the value of the crystal field parameter, 10 Dq. We have found that there is a fairly general relationship between the value of 10 Dq and $T_{1/2}$ in Mn(IV) luminescence, such that high values of 10 Dq are associated with high quenching temperatures (22), so that this fact could also explain the observed relationship. The two effects need not however be entirely independent because the small Mn(IV) site in K_2SiF_6 will in any case tend to increase the value of 10 Dq because of a compression effect. Reinen has demonstrated that this is the case for Cr(III) in oxides (23). A comparison of $T_{1/2}$ values in the series is complicated by the fact that the compounds are not isomorphous. Although the manganese is surrounded by an octahedron of fluoride ions in each case, K_2SiF_6 is cubic with a structure related to CaF_2 while the other two materials are hexagonal with a layer type structure resembling CdI_2 (24). In K_2TiF_6 where the manganese occupies a site almost 0.2Å larger than itself a relatively high quenching temperature of 450°K is observed. This is about 100°K higher than typical values of $T_{1/2}$ in oxides with about the same value of the crystal field parameter (20-21 kK) (22) and this suggests that other factors beside the radius of the Mn(IV) site are also important in this case.

Table I. Quenching temperature, site radius, and crystal field parameter of Mn(IV) in fluoride hosts

Host material	Radius of Mn (IV) site (Å)	10 Dq (kK)	$T_{1/2}$ (°K)
K_2SiF_6	0.41	22.12	490
K_2GeF_6	0.53	21.28	470
K_2TiF_6	0.68	21.19	450

The quantum efficiency of the phosphors has not been accurately measured but is estimated to be about 80%. The brightness of K_2SiF_6:Mn(IV) is up to two and a half times that of the well-known phosphor magnesium fluorogermanate [$Mg_4GeO_5F_2$:Mn(IV)]. It seems reasonable to suggest that the high efficiency and quenching temperature are connected with the fluorine coordination of the manganese, and that this could be associated with a smaller displacement of the excited-state ($^4T_{2g}$) curve than usually observed, due to the weaker σ-antibonding character of fluorine compared with oxygen.

The excitation spectra of the materials are interesting and show a well-resolved vibrational structure, as do a number of other transition-metal ions in fluorine coordination. The excitation spectra of the three phosphors are shown in Fig. 2.

The intense band peaking between 450 and 470 nm in the first spin allowed transition $^2A_{2g} \rightarrow {}^4T_{2g}$. In all three materials this consists of a number of components, with a spacing of 500-600 cm^{-1}, which are most clearly resolved in K_2SiF_6. Recent studies by Pfeil of the complex Cs_2MnF_6 have shown that the symmetric stretching (a_{1g}) mode of the MnF_6^{2-} group occurs at 608 cm^{-1} in the ground state (25). The structure of this band can therefore be understood as a vibronic progression of this fundamental frequency combined with an unsymmetrical vibration of the MnF_6^{2-} group (probably the e_g mode), superimposed on the electronic transition. The fact that the energy separation of the components is less than 608 cm^{-1} can be attributed to the weakening of the manganese-fluorine bond in the excited state due to the presence of an electron in the antibonding e_g orbitals. The true value of the crystal field parameter, 10 Dq, is given by the energy of the zero phonon transition in the spectrum (10). Unfortunately we have not succeeded in identifying this component and so we have taken the peak at the center of

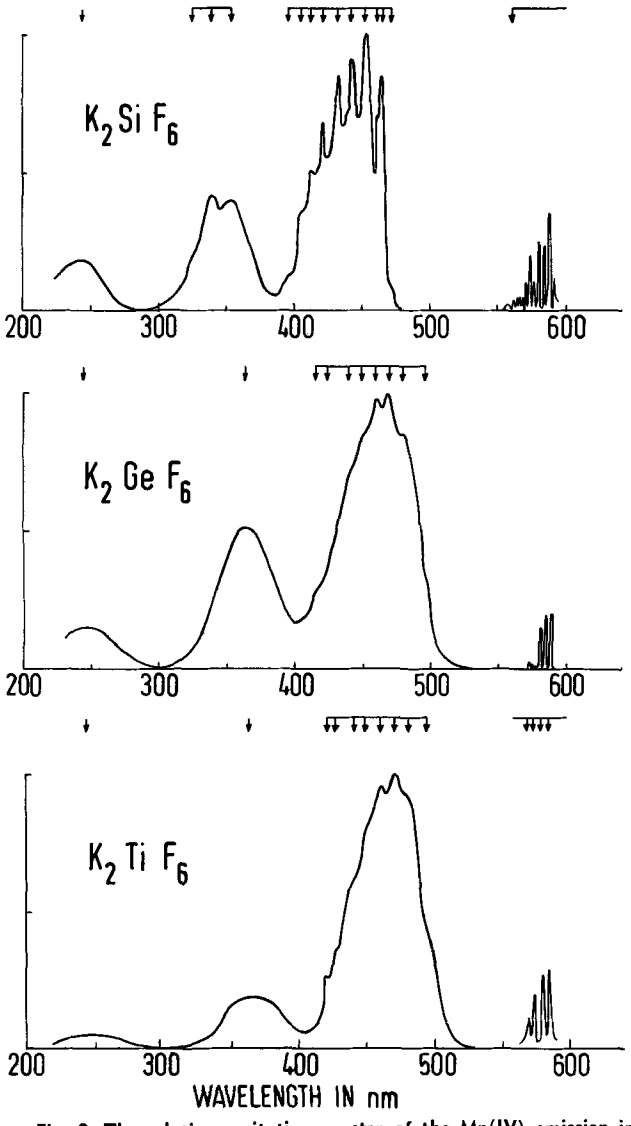

Fig. 2. The relative excitation spectra of the Mn(IV) emission in fluoride lattices containing 1 mole per cent Mn(IV) at 90°K. The ordinate represents relative radiant power per unit input power and is marked in arbitrary units.

the band to give a rough measure of 10 Dq. Although this is not correct it does allow a comparison to be made with other Mn(IV) phosphors where the absence of structure forces us to use the peak of the band as a measure of 10 Dq in any case.

The second broad excitation band between 340 and 360 nm is the $^4A_{2g} \rightarrow {}^4T_{1g}$ transition. In the case of K_2SiF_6 there is some structure in this band too. The component at 339 nm (29.5 kK) becomes much more prominent at 300°K. Apart from a slight broadening this is not detectable in the spectra of the other materials. Reisfeld *et al.* have recently discussed the absorption spectrum of Cs_2MnF_6 (26), and commenting on possible sources of splitting in the spin-allowed absorption bands have concluded that this could be due either to a vibronic progression, as observed in the first band, or a Jahn-Teller splitting assisted by a spin-orbiting coupling effect. The resolution of this band in these materials does not seem adequate to warrant further discussion of these possibilities at this stage.

There are two possible assignments of the third band near 240 nm. This could be either a fluorine-manganese charge-transfer band, or the third spin-allowed transition, $^4A_{2g} \rightarrow {}^4T_{1g}(^4P)$, of the manganese ion. The transition to $^4T_{1g}(^4P)$ is a two-electron transition, the state arising from the electron configuration $t_{2g}{}^1e_g{}^2$ (9), so that in the absorption spectrum of Cr(III), for example, it tends to be weaker than the first two spin-allowed bands. Because two electrons occupy the antibonding e_g orbitals the excited $^4T_{1g}(^4P)$ state is expected to be even further displaced along the configurational coordinate axis than the $^4T_{2g}$ and $^4T_{1g}$ states, and energy absorbed by the level is likely to be dissipated by a completely nonradiative process. This explains why this band is never observed in Mn(IV) excitation spectra (18). The absorption spectrum of Cs_2MnF_6 (26) and the diffuse reflectance spectrum of K_2MnF_6 (27) show an intense absorption at about 255 nm which has been assigned to a transition from a π-type antibonding orbital on a fluorine ion to the nonbonding t_{2g} orbitals on the Mn(IV) ion. We assign the band in these excitation spectra to the same transition although it is shifted to progressively higher energies in the titanate, germanate, and silicate, respectively.

It is interesting to note that the energy of the corresponding charge-transfer band in oxides should be at lower energies because the oxygen ion is, in general, less stable than the fluorine ion. In oxides however excitation into this band does not always lead to emission. In the case of K_2TiF_6 too, only very weak excitation is observed. A possible explanation of this is as follows. Blasse has argued that in the course of excitation into a charge-transfer band an electron is transferred from an orbital on an anion to an orbital predominantly localized on the central ion. There is thus a build up of charge on the central ion in the excited state which has a screening effect, lowering the effective positive charge of the central ion. As a result the anions relax slightly to a greater internuclear separation (13). The result of this relaxation is to shift the potential surface of the charge-transfer state relative to the ground-state curve so as to reduce the activation energy ΔE. This effect is minimized when the manganese occupies a small lattice site, so the intensity of the charge-transfer excitation band decreased in the order $K_2SiF_6 > K_2GeF_6 > K_2TiF_6$ as the radius of the Mn(IV) site increases. In oxides the charge-transfer absorption is expected at longer wavelengths, and the displacement of the potential curve to lower energies decreases ΔE so that effective excitation of the center in this band cannot be achieved even when the manganese enters comparatively small lattice sites. In a number of other centers too it is known that if the charge-transfer band lies at low energies luminescence may not be observed (28).

A number of narrow excitation bands can be observed in the region of 580 nm. These are most clearly resolved in K_2SiF_6 and have not previously been reported in a Mn(IV) excitation spectrum. An enlarged version of this part of the spectrum is shown in Fig. 3. We assign these bands to vibronic levels of the ^2E_g and $^2T_{1g}$ states. These transitions are not usually observed

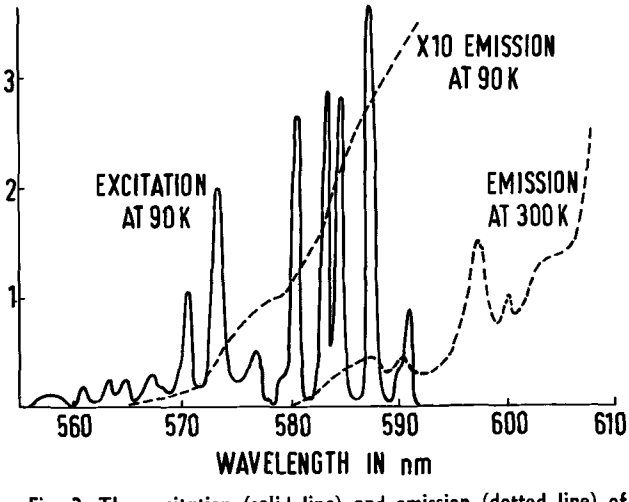

Fig. 3. The excitation (solid line) and emission (dotted line) of K_2SiF_6:0.01 Mn(IV) at 90°K in the region 18-18 kK. The excitation is plotted against the same ordinate as in Fig. 2 and the emission is plotted on an arbitrary scale.

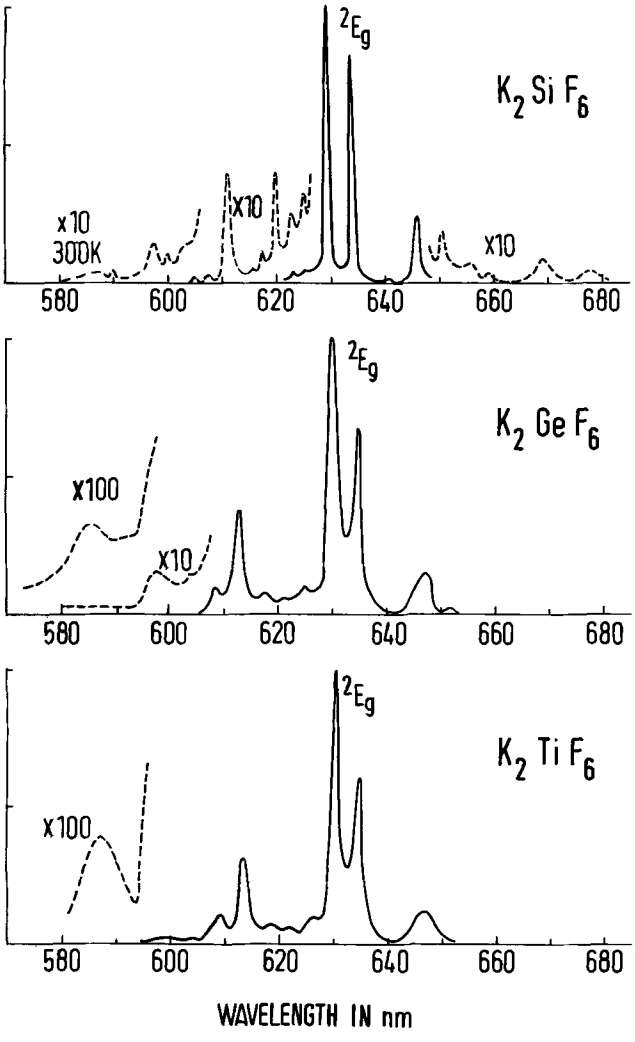

Fig. 4. The emission spectra of Mn(IV) in fluoride lattices containing 1 mole per cent Mn(IV) at 90°K. The ordinate represents relative radiant power per constant bandwidth and is marked in arbitrary units. The weak emission at shorter wavelengths is shown on an enlarged scale (dotted line).

in Mn(IV) absorption and excitation spectra because the tail of the $^4T_{2g}$ band extends into this region making them difficult to detect. A partial analysis of this structure indicates that not all these lines can be attributed to vibronic levels associated with the $^4A_{2g} \rightarrow {}^2E_g$ transition and that some must belong to the $^2T_{1g}$ state (18). The $^2T_{1g}$ state itself appears to be ~800 cm above ^2E_g; however more complete data are required before all these transitions can be satisfactorily explained.

The emission spectra of the materials are shown in Fig. 4. This must be assigned to transitions between the vibronic levels of the ^2E_g and $^4A_{2g}$ states. For electric dipole radiation the $^2E_g \rightarrow {}^4A_{2g}$ transition is forbidden in the octahedral MnF_6^{2-} ion, but may gain intensity by the activation of odd vibrational modes in the center. As in Cs_2MnF_6 (25) the most intense line at ~629 nm (15.891 kK) can be assigned to the transition to the $\nu_6(t_{2a})$ vibrational level of the ground state. The next most intense lines at ~634 nm (15.775 kK) and 646 nm (15.473 kK) are due to transitions to the $\nu_4(t_{1u})$ and $\nu_3(t_{1u})$ levels, respectively. The zero phonon line is rather weak at room temperature but can be identified as the transition at ~623 nm (16.124 kK) in the 90°K spectrum. The strong transitions to ν_6, ν_4, and ν_3 are separated from the zero phonon line by 233, 349, and 651 cm^{-1}, respectively, and these figures are in reasonable agreement with vibrational frequencies already observed in Cs_2MnF_6 (229, 334, and 616 cm^{-1}, respectively) (25). A higher quality spectrum is required before any attempt can be made to comment in more detail on the other lines in the spectrum.

Mn(IV) phosphors and complexes can also show a broad diffuse transition, mostly in the infrared peaking at about 750 nm, due to a Stokes-shifted emission from the $^4T_{2g}$ state (22) but this was not observed in these fluorides. The reason is that the relatively high value of the crystal field probably places the emitting ^2E_g level at a significantly lower energy than the $^4T_{2g}$ state. A similar effect is noticed in the emission of Cr(III) materials (29).

The first absorption band of Mn(IV) in oxides is typically observed at 20°-21°kK but it is not always certain that this is due to the $^4A_{2g} \rightarrow {}^4T_{2g}$ transition of Mn(IV) because there is often an equilibrium between Mn(IV) and Mn(III) ions (16). In these excitation spectra however there is no doubt that the excitation spectra must be attributed to Mn(IV) alone, and the value of the crystal field parameter, 10 *Dq*, is therefore interesting as it is derived from one of the few spectra where the assignment is least in question. It is well known that attempts to calculate the value of 10 *Dq* from considerations of electrostatic interactions, as in the crystal field model, lead to a negative value of 10 Dq. This only becomes positive with a value in reasonable agreement with experiment when σ-bonding interactions are included in molecular orbital calculations. The value of the parameter is thus largely a reflection of σ-bonding interaction in the center. The magnitude of 10 *Dq* is however also affected by π-bonding interactions. Low lying π-orbitals on the ligands tend to reduce the magnitude of 10 *Dq* to a lower figure than would be observed with σ-bonding alone. On the other hand high lying π-orbitals have the opposite effect, tending to increase 10 *Dq* [*e.g.*, see Ref. (32)]. These considerations allow some of the features of the chemical bonding in the Mn(IV) center to be connected with the luminescence. In fact π-bonding interactions may be quite important in these materials. ESR studies of MnF_6^{2-} in K_2GeF_6 have indicated that this is possible (33) and so the relatively small displacement of the excited-state potential curves of Mn(IV) centers in fluorides may be due to a combination of a generally low σ-antibonding effect in the e_g orbitals together with a greater π-antibonding effect in the t_{2g} orbitals.

Conclusions

These complex fluoride phosphors provide much more information than has been available previously on Mn(IV) luminescence spectra.

The relatively high value of the quenching temperature in K_2SiF_6 may very well be due to the small silicon site which compresses the Mn(IV) ion. This restricts the expansion of the center in the excited state, and at the same time causes a relatively high value of 10 *Dq* to be observed, and both these effects favor a high quenching temperature. On the other hand the high efficiency and quenching temperature, only 40°K lower in K_2TiF_6, suggest that the manganese-fluorine bonding is also important in determining the properties of these phosphors. The earlier position of F^- in the spectrochemical series than O^{2-} probably results in a weaker σ-antibonding effect in the e_g orbitals, and it also seems likely that π-antibonding in the t_{2g} orbitals is important. The difference in antibonding character between the t_{2g} and e_g orbitals is thus less in the MnF_6^{2-} center than in the $Mn(O^{2-})_6$ center so that the relaxation of the group in the excited state is minimized.

If the compression of the Mn(IV) ion is of importance the effect is likely to be enhanced in rigid ionic lattices which contain small highly charged ions (13). The comparatively large number of small doubly charged magnesium ions in the commercial phosphors $Mg_6As_2O_{11}$ (14) and Mg_4GeO_6 (19) [more accurately $Mg_{28}Ge_{10}O_{48}$ (34)] is noteworthy in this connection. Clearly this condition has not been very well satisfied in the potassium compounds reported here. However,

efficient Mn(IV) emission is also observed in other complex fluorides, and we hope to report details of the preparation and properties of these materials later.

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Epitaxial layers of single-crystal $In_{1-x}Ga_xP$ have been deposited on GaP substrates by an open-tube vapor-growth technique. The dependence of alloy composition on the deposition temperature and the relative amounts of In and Ga transported have been established. The effects of substrate preparation, reaction temperatures, deviations from equilibrium, and gas-phase mixing on achieving material with controlled composition, purity, doping, and homogeneity have been investigated. *In situ* vapor-grown p-n junction structures employing Se and Zn as the respective n- and p-type dopants have been prepared with sufficient perfection to permit fabrication of efficient visible-light-emitting diodes and injection lasers.

Because of its direct band structure to energies as high as about 2.2 eV (1, 2), $In_{1-x}Ga_xP$ has recently received considerable attention as a luminescence source for efficient coherent and spontaneous emission throughout the red, orange, and yellow portions of the visible spectrum. Despite considerable efforts in the synthesis of the alloy, the quality of the material prepared to date has limited the performance of light-emitting diodes to well below expectations. For example, until recently, external quantum efficiencies for visible electroluminescence have been limited to typical values of 1 to 5 $\times$ 10^{-4} at room temperature (3-5), undesired low-energy emission peaks frequently have been large (6), and p-n junctions of sufficiently high quality to support laser emission have been difficult to fabricate (7). Many of the problems in the synthesis of homogeneous material may be directly related to the relatively large lattice mismatch between the compounds which constitute this alloy. The large separation of the solidus and liquidus curves in the temperature-composition phase diagram (8) of $In_{1-x}Ga_xP$ results in a large segregation of GaP for melt-growth, making the preparation of bulk alloys of uniform composition difficult. The large segregation

coefficient (4) also complicates liquid-phase epitaxial growth of $In_{1-x}Ga_xP$. Very little work has been done on the vapor-phase growth of this material.

Earlier work by Nuese, Richman, and Clough (6) demonstrated that epitaxial layers of $In_{1-x}Ga_xP$ could be prepared across the entire alloy system by an open-tube vapor-growth technique. However, diodes fabricated from this material yielded very low electroluminescence efficiencies ($\sim 10^{-6}$), perhaps due to crystal strain and compositional inhomogeneity. In this work, we report the development of vapor-growth techniques for preparing $In_{1-x}Ga_xP$ with controlled composition, doping, homogeneity, purity, and crystalline perfection. From such material, electroluminescent diodes and lasers have been obtained (9) with luminescence properties that are significantly improved relative to those of previous vapor-grown material, and which are comparable to the best reported (3) for this alloy system.

Vapor-Growth Technique

The apparatus used to prepare $In_{1-x}Ga_xP$ alloys is shown schematically in Fig. 1 and is similar to that used earlier (6). The use of separate quartz tubes to contain the In and Ga sources allows independent control of the HCl concentrations over each of the metal sources. Mass spectrometric analysis (10) of the gases in the growth tube has shown that HCl reacts with Ga and In metals to form monochlorides of these metals according to the reaction

$$y\,M(l) + HCl(g) = y\,MCl(g) + (1-y)HCl(g) + \frac{y}{2}H_2(g) \quad [1]$$

Here M is In or Ga and y is the mole fraction of HCl consumed in the reaction. The metal monochlorides are carried in hydrogen into the mixing zone where they mix, but do not react, with gaseous phosphine, the source of phosphorus. The reduced temperature in the deposition zone, where the substrate is positioned, allows the reaction between gases to give $In_{1-x}Ga_xP$ as an epitaxial film and HCl as the gaseous by-product (10) according to the reaction

$$MCl(g) + P^*(g) + H_2(g) = MP(s) + HCl(g) \quad [2]$$

Here, P* represents PH_3 and the products of the decomposition of PH_3, namely P_2 and P_4. The provisions for *in situ* n- and p-type doping using H_2Se and Zn vapor, respectively, are also shown in Fig. 1. For p-n junction formation, the dopants are sequentially introduced during growth, thereby eliminating the need for an extra high-temperature processing step.

An important feature of this system is the ability to uniformly and controllably grade the alloy composition between the substrate and the terminal alloy in order to minimize strain and reduce dislocations due to lattice-constant mismatch. This is particularly important in $In_{1-x}Ga_xP$ because the lattice parameters of the end components differ by almost 8%. Compositional grading previously has been shown to lead to enhanced electroluminescence in vapor-grown $GaAs_{1-x}P_x$ p-n junctions (11).

Choice of Growth Temperature

Since unknown background contaminants might introduce trapping states, nonradiative recombination centers, or compensating impurities, it is desirable to first achieve background concentrations as low as possible before introducing controlled amounts of dopants. Therefore, several temperatures and temperature profiles were examined in order to determine the optimum conditions for high-purity $In_{1-x}Ga_xP$ epitaxial growth. Three representative crystals grown under various growth conditions together with their mass spectrometric analyses and electrical properties are listed in Table I. Here, we see that the lower temperatures used for the three zones in Fig. 1 have led to significantly reduced background doping concentrations. In addition, note the correlation in each case between the free electron concentration (determined by Hall measurements) and the concentration of Si (determined by mass spectrometric analysis), suggesting that Si is the predominant electrically active impurity. This is consistent with the observation that Si is the predominant donor impurity in other III-V compounds such as AlAs (12, 13) and GaAs (14) prepared by similar vapor-growth techniques.

Substrate Preparation and Characterization

The $In_{1-x}Ga_xP$ epitaxial layers in this work were typically deposited on liquid-encapsulated Czochralski-grown (referred to as LEC) GaP substrates oriented 3° off the <100> direction toward the <010> direction. These layers were graded in alloy composition from GaP at the substrate to the final desired composition, which usually was between 50 and 65 m/o (mole per cent) GaP.

The GaP wafers were first chemi-mechanically polished using a bromine:methanol:phosphoric acid solution (15) (later referred to as BMP etch) to remove work damage. A bromine-methanol solution has been found to be particularly effective in revealing work-damaged areas which can remain after insufficient etching. The photomicrographs in Fig. 2 show a wafer prior to the test for work damage (Fig. 2a) and after etching for 2 min in bromine-methanol (Fig. 2b). Note how this etchant reveals minute surface damage. The white areas (in contrast to the light scratches) are artifacts of the bromine-methanol etching procedure and occur only when the solution contains trace amounts of moisture.

As a standard procedure in our substrate preparation, we performed a second chemical etching treatment

shortly before insertion into the vapor-growth system. A hot (80°C) Caro's acid ($5H_2SO_4:H_2O_2:H_2O$) etch was used for 5 min, followed by a hot (50°C) BMP etch. It should be noted that the etching rate for both the Caro's etch and the BMP etch are highly dependent on the temperature of the etchant, as indicated in Fig. 3. We have found that etching rates of greater than 5 μm/min (obtained at elevated temperatures) cause both etchants to become preferential, resulting in etch pits and nonplanar surfaces. Best results have generally been attained for etching rates of 0.6 μm/min for the Caro's etch and 1.5 μm/min for the BMP etch, which occur at 80° and 50°C, respectively.

We also have found that the BMP etch should be used immediately after the Caro's acid etching of the substrate. For example, a 24-hr delay between the use of the two etchants resulted in the appearance of pits after a 5 min BMP etch (50°C). These pits most likely originate from an oxide or other surface contaminant from the ambient in the interval between the etching steps. If the wafers are used immediately after chemi-

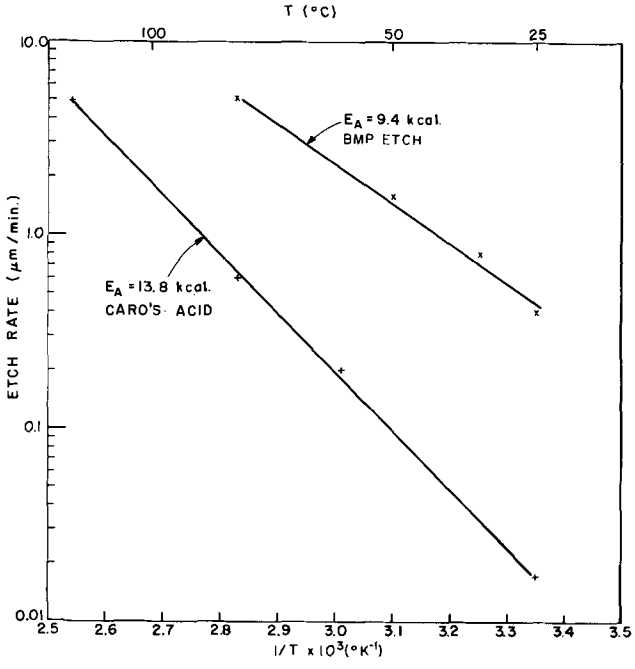

Fig. 3. Etch rate of Caro's acid and the BMP etch on <100>-oriented liquid-encapsulated GaP substrates as a function of etchant temperature.

mechanical polishing, single-crystal epitaxial layers are obtained; however, if a 24-hr delay occurs prior to growth, the layers are inevitably polycrystalline. These results suggest that removal of surface contamination is important for achieving high-quality single-crystal epitaxial layers.

Control of Composition

Since earlier work (6) on the vapor growth of $In_{1-x}Ga_xP$ has shown that the composition of the alloy depends strongly on the ratio of the HCl flow rates to the In and Ga sources (HCl_{In}/HCl_{Ga}), precision electronically activated gas-flow controllers were employed for each of the metal sources. However, to achieve reproducible control of alloy composition, it is necessary not only to have constant flow rates to the metal sources, but also to be certain that the conversion of HCl to the respective metal chlorides remains fixed with time. Both the Ga and In conversion have been examined in detail, the results of which are presented below.

Gallium source.—From mass spectrometric investigations (16) of the amount of HCl reacted during the transport of Ga for various hydrogen carrier flow rates, it is possible to calculate the per cent HCl reacted for various linear velocities (since the reaction temperature and the effective cross-sectional area of the metal zone tube are known).[2] If the length of the Ga boat is also known, the linear velocities can be expressed in terms of a "residence time," *i.e.*, the amount of time the HCl is in contact with the metal source boat. Using the mass spectrometric data (16) the dependence of the unreacted amount of HCl on residence time is plotted in Fig. 4 for a reaction temperature of 800°C. Here, the equilibrium (10) fraction of HCl not converted to GaCl is also shown. In the present work, an effective Ga zone tube cross-sectional area of 2.1 cm^2 and a flow rate of 600 cc/min are employed, resulting in a linear velocity of 16.7 cm/sec. Since two 15-cm boats are used in series in the gallium source zone in our experiments, the residence time is 1.7 sec. If the conditions employed in our work are similar to those reported for the mass-spectrometric studies (16), we would expect equilibrium to be approached rapidly with increasing residence time, as indicated in Fig. 4.

It should be noted that the smaller diameter tube used in the present case [1.7 cm *vs.* 2.5 cm used in the earlier study (16)] further increases the equilibration

[2] The effects of the displacement of the metal boats and the expansion of the carrier gas at reaction temperature on the linear velocities and residence times of the gases within the metal zone have been taken into account in the calculations reported here.

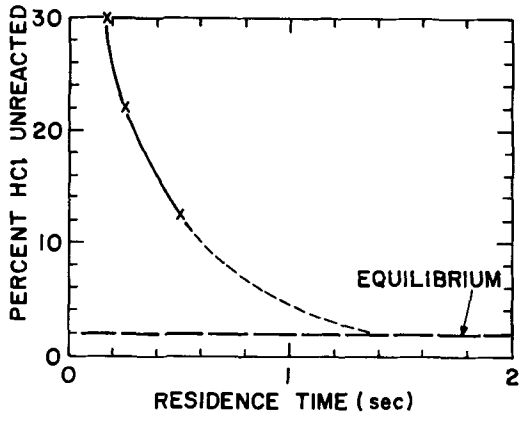

Fig. 4. Percentage HCl unreacted as a function of residence time, the amount of time the HCl is in contact with the Ga metal source boat.

rate in the Ga zone, since the ratio of the surface area of the Ga to the volume of gas above the boat must be somewhat higher than previously.

To experimentally determine the precise amount of HCl converted with the geometries employed here, the number of moles of Ga consumed (as determined by the weight difference of the boats before and after a series of six 3-hr runs) was compared to the number of moles of HCl passed over the source (measured by precision gas flowmeters). These findings, presented in Table II, assume that only reaction [1] leads to the transport of Ga. The calculated per cent conversion of 97.8% is in excellent agreement with values expected for equilibrium conversion of HCl to GaCl and, therefore, verifies that equilibrium is attained in the Ga zone under the experimental conditions employed. Note also that the second boat converts less than 3% of the total HCl entering the Ga zone, in approximate agreement with the curve in Fig. 4 for residence times between 0.85 and 1.7 sec. The data in Table II and the curve in Fig. 4 also indicate that small changes in the residence time should not cause large changes in the amount of GaCl formed.

Indium source.—Despite the fact that x-ray diffraction and electron microprobe findings indicated reasonable uniformity of composition, a gradual shift in alloy composition for runs employing essentially the same growth conditions was observed over a 15-hr period required to grow four to five samples, as illustrated in Fig. 5. Differences by as much as 15 m/o InP were observed. The fact that the percentage of InP decreased monotonically with time in Fig. 5 suggested a depletion of In as the source of the change; incomplete reaction

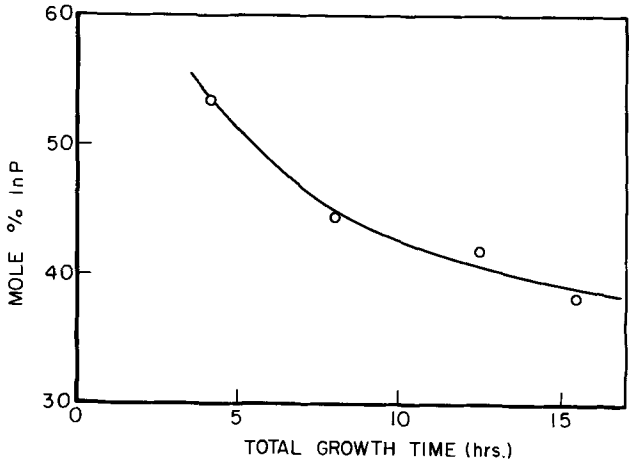

Fig. 5. Variation of composition for a series of $In_{1-x}Ga_xP$ epitaxial layers employing the same growth conditions. The HCl flow to the In source was 50 cc/min.

Table II. Number of moles of gallium consumed determined by the weight difference of the boats before and after a series of six 3-hr runs

between In and HCl as the In source depleted would then cause a decrease in InCl concentration in the deposition zone. In addition, since HCl is a by-product of the deposition reaction [2], the composition would be further changed by the extent to which the unreacted HCl suppresses deposition of InP. Upon increasing the In source contact with the HCl either by increasing the volume of In or by using deflection baffles, reproducible compositions and compositional profiles have been achieved.

Experiments similar to those described for Ga concerning the per cent conversion of HCl to InCl also were carried out. The data in Table III are based on 50 cc/min of HCl to the In source, 600 cc/min of H_2 carrier, and an effective cross-sectional area of 7.8 cm^2, yielding a linear velocity of 7.5 cm/sec. Note that the final boat contributes only about 2% of the total HCl converted. The per cent conversion of 96% is in good agreement with that expected (10) for complete equilibrium in the In zone according to reaction [2]. The discrepancy between the 96% reported here and a value of only 80% measured in earlier work (10) can be attributed to the differences in the experimental conditions employed, in particular, the use of baffles and a larger In source in the present investigation.

One feature common to many of our earlier layers (which were graded from a GaP substrate) was a "lag" in alloy composition observed in the initial stages of the compositional grading (the first 10 μm of growth for the crystal in Fig. 6a), which would be expected to generate large concentrations of lattice-misfit dislocations. Analysis of the In source after the series of vapor depositions indicated a solubility of about 2 to 3% of InCl in the In metal. Consequently, the strong nonlinear variation in alloy composition at the onset of the grading was thought to be due to slow saturation of the In source with InCl. By allowing the metal source to become saturated prior to initiation of the grading schedule, it has been possible to eliminate such deviations, as illustrated in the microprobe profile of Fig. 6b.

Dependence of Alloy Composition on HCl Ratio and Deposition Temperature

The incorporation of InP in vapor-grown $In_{1-x}Ga_xP$ is strongly dependent on both the deposition temperature and the relative ratio of the HCl flows in the respective metal zones, as shown in Fig. 7. This results, in part, from the large difference in the free energy of formation, $\Delta G°_f$, of InP(s) and GaP(s). Under the range of experimental temperatures employed, the free energy of reaction is large and negative for the deposition of GaP. Therefore, the conversion of GaCl to GaP is nearly complete. But for InP the free energy of reaction is only slightly negative and then becomes

Table III. Number of moles of indium consumed determined by the weight difference of the boats before and after a series of runs

Boat	Moles In consumed ($\times 10^2$)	Moles HCl consumed ($\times 10^2$)	Per cent conversion to InCl
1	27.78		
2	19.79		
3	4.73		
4	1.07		
Combined	53.37	55.49	96.2

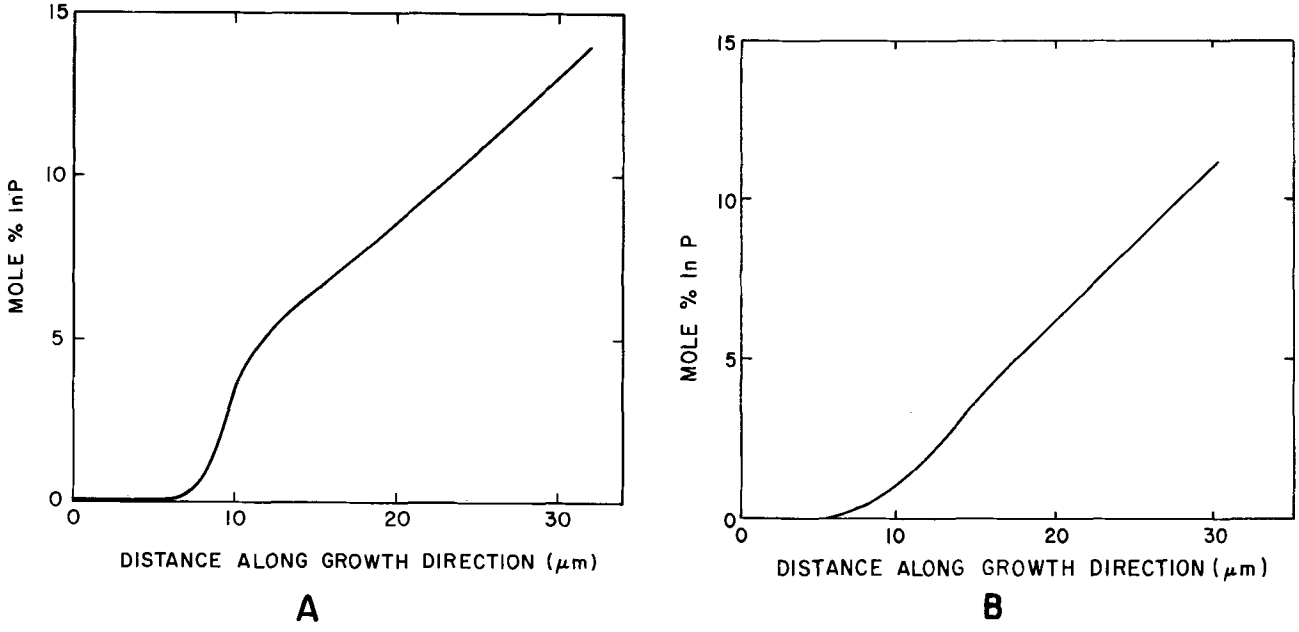

Fig. 6. Microprobe profile of the mole fraction of InP in the initial $In_{1-x}Ga_xP$ deposition for (A) incomplete saturation of the In sources with InCl, (B) complete saturation of the In sources with InCl.

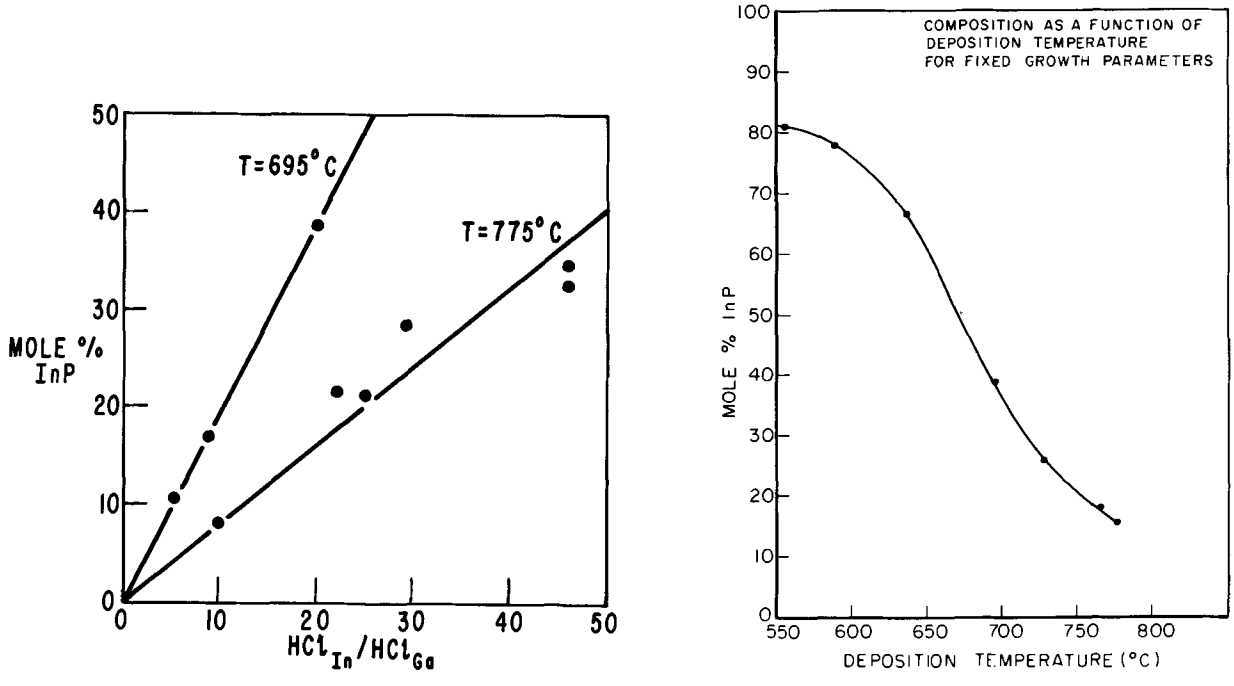

Fig. 7. Dependence of the mole fraction of InP in the $In_{1-x}Ga_xP$ alloy on (A, left) the ratio of the HCl flow rate over the In and Ga sources, and (B, right) deposition temperature.

positive with increasing temperature. As a result, only a small fraction of InCl is converted to InP under the experimental conditions employed, and the conversion becomes less efficient with increasing temperature.

Ban and Ettenberg (10) have carried out an elegant analysis of the deposition of $In_{1-x}Ga_xP$ alloys in our vapor-growth system, which takes into account the activity of the InP and GaP in the deposition reaction [2]. The close agreement between their equilibrium calculations and our experimentally determined data reported in that work indicates that equilibrium is closely approached, not only in the reaction between the Group III metals and HCl, as we have shown earlier, but also in the deposition under the experimental conditions used in this work.

Origin of Hillock Formation in Vapor-Grown $In_{1-x}Ga_xP$

Although hillock formation has been a minor problem in the vapor growth of several III-V compounds, such formation has been particularly severe in the $In_{1-x}Ga_xP$ epitaxial layers. For this reason, an investigation was carried out to determine the source of the surface imperfections. We have found that hillocks can originate from loose deposits which form on the walls of the quartz tube during growth, fall onto the substrate, and thereby create sites for heterogeneous nucleation. Therefore, by orienting the wafers vertically and parallel to the gas flow, the hillock density was substantially reduced.

In addition to the effect of substrate orientation, several observations during the course of our investigation suggested that ambient gas leaks are the origin

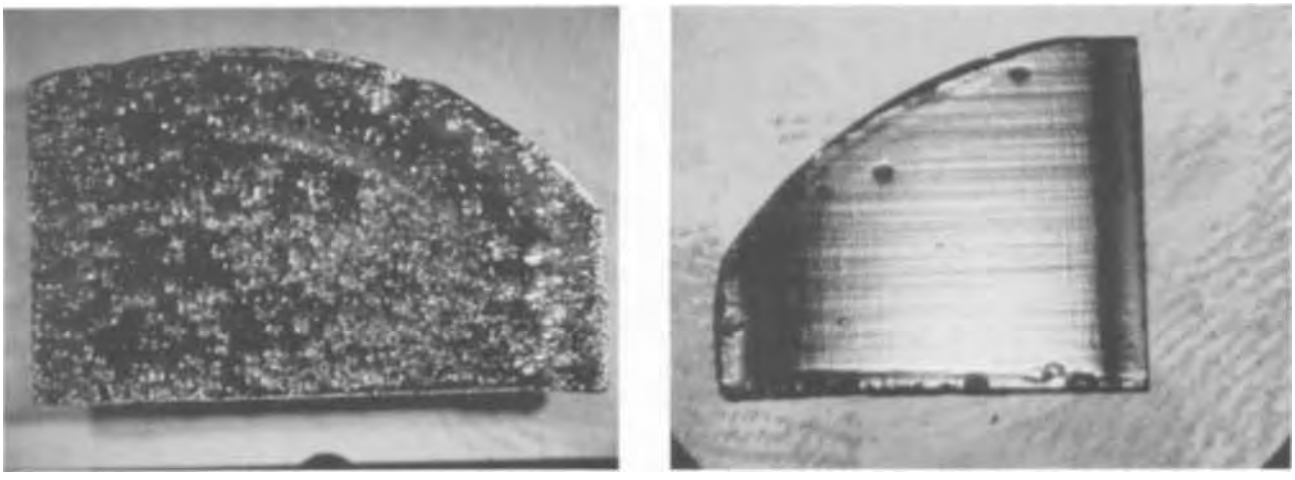

Fig. 8. Photomicrographs of the surface morphology of an $In_{1-x}Ga_xP$ epitaxial layer (A, left) grown in the presence of an ambient gas leak and (B, right) grown in the absence of an ambient gas leak.

of many of the hillocks. Most notably, upon ensuring that our growth system was leak tight, the hillock density was observed to decrease appreciably. To confirm this observation, a very small quantity of ambient gas to approximate a pinhole leak was intentionally introduced into the vapor growth system during the deposition of $In_{1-x}Ga_xP$ epitaxial layers. Figure 8 shows the surface morphology of wafers grown with and without the intentional leak. It is apparent that small ambient leaks can have a catastrophic effect on the crystal surface appearance. We also should mention that no correlation has been seen between hillock density and crystallographic orientation for GaP substrates oriented 0°, 2°, 3°, 4°, and 5° off {100} toward {010}, in contrast to Blakeslee's findings (17) on vapor-grown GaAs.

Under suitable growth conditions using a substrate free of work damage, a vertical substrate orientation, and a growth system free of leaks, large area macroscopically defect-free epitaxial layers can be routinely obtained. The surfaces of $In_{1-x}Ga_xP$ layers deposited on GaP substrates are comparable in appearance to high-quality epitaxial layers of GaP deposited on GaP substrates, as shown in Fig. 9. One notable difference between the $In_{1-x}Ga_xP$ and GaP surface structure is the presence of a grid network in the case of the $In_{1-x}Ga_xP$. This is related to the orthogonal array of dislocations (18) introduced during the compositional grading between the GaP substrate and the $In_{1-x}Ga_xP$ alloy.

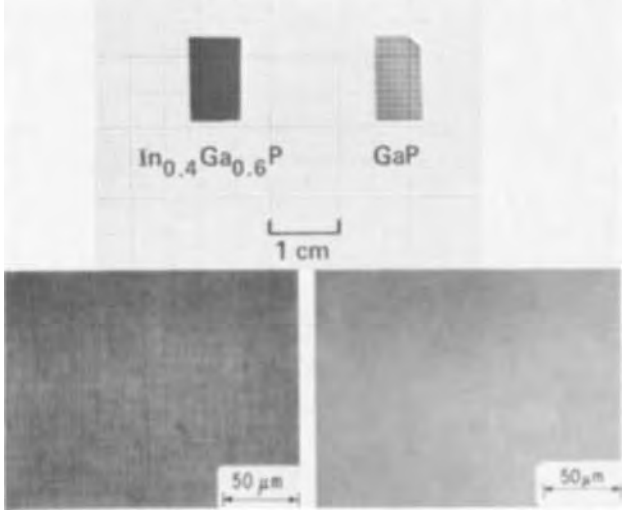

Fig. 9. Photograph of $In_{0.4}Ga_{0.6}P$ and GaP epitaxial layers deposited on GaP substrates with the vapor-growth refinements discussed in the text.

P- and N-Type Doping of $In_{1-x}Ga_xP$

Semi-insulating substrates are frequently used for the deposition of epitaxial layers because their high resistance allows Hall measurements to be made without removal of the substrate. Since semi-insulating GaP substrates were not available, a series of $In_{0.49}Ga_{0.51}P$ layers which were Zn- and Se-doped over a wide range of carrier concentrations were epitaxially deposited on <100>-oriented Cr-doped GaAs substrates. To minimize problems associated with lattice mismatch between the $In_{1-x}Ga_xP$ and GaAs, an alloy composition of 51 ± 1 m/o GaP [3] was chosen. In Fig. 10 the electron and hole concentrations determined by standard Hall measurements on the $In_{0.49}Ga_{0.51}P$ are plotted as a function of the zinc and H_2Se partial pres-

[3] Room-temperature lattice matching between GaAs and $In_{1-x}Ga_xP$ occurs at $x = 0.515$.

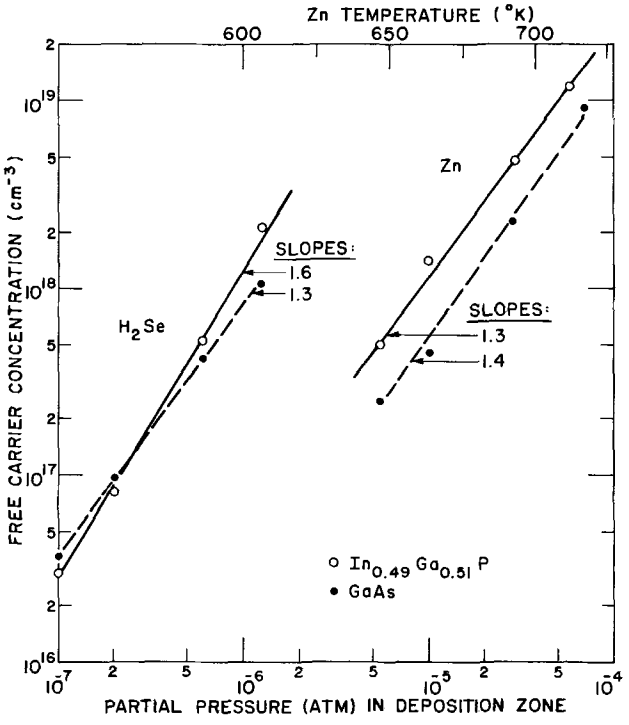

Fig. 10. Hole and electron concentrations in Zn- and Se-doped vapor-grown layers of $In_{0.49}Ga_{0.51}P$ and GaAs grown under similar growth conditions as a function of the zinc and H_2Se partial pressure in the deposition zone. Also shown above the Zn data are the temperatures of the Zn source.

sures in the deposition zone. Also included in Fig. 10 are the carrier concentrations for Zn- and Se-doped GaAs layers deposited under similar growth conditions.

The amount of Zn incorporated into the epitaxial layers was determined by the temperature of an elemental Zn source placed in an auxiliary sidearm to the main deposition chamber (see Fig. 1). In Fig. 10, the Zn partial pressures were calculated under the assumption that the elemental Zn and the hydrogen carrier gas have equilibrated in the Zn sidearm. This has been independently confirmed by measurements of the amount of Zn vaporized with time and the amount of hydrogen flowing over the source.

In general, the carrier concentration is a factor of two to three higher in Zn-doped $In_{0.49}Ga_{0.51}P$ than in GaAs. Since the ionization energy of Zn in these two compounds is not sufficiently large [$E_A \sim 59$ meV in $In_{0.5}Ga_{0.5}P$ (19, 20) and ~ 26 meV in GaAs (21)] to limit the carrier concentration at room temperature, the differences must represent the extent to which Zn is introduced into the respective materials, presumably due to differences in thermodynamic properties or the kinetics by which the impurity is incorporated during the growth processes.

In order to determine if equilibrium is achieved during the incorporation of Zn into our vapor-grown layers, the expected dependence of hole concentration on Zn partial pressure under equilibrium conditions can be independently established and compared with the experimental data of Fig. 10. At thermal equilibrium, the incorporation of Zn into both GaAs and $In_{0.49}Ga_{0.51}P$ can be described by the equation

$$Zn(g) = Zn^- \text{ (crystal)} + h^+ \qquad [3]$$

Since $[Zn^-] = [h^+]$, $[h^+]$ can be expressed in terms of the equilibrium constant, K_{eq}, for reaction [3] and the zinc partial pressure, P_{Zn}, in the deposition zone by the equation

$$[h^+] = (K_{eq} P_{Zn})^{1/2} \qquad [4]$$

Since the slopes of log $[h^+]$ *vs.* log P_{Zn} shown in Fig. 13 are 1.2 and 1.4 for the incorporation of Zn into $In_{0.49}Ga_{0.51}P$ and GaAs, respectively, we must conclude that thermal equilibrium is not established during the deposition process.

For the case of Se-doping, no empirical data exist on the decomposition of H_2Se in our growth system. The partial pressures in Fig. 10 were therefore calculated by assuming the absence of all polyatomic species of Se. Because of the strong dependence of carrier concentration on H_2Se partial pressure, an electronic gas flowmeter was used in conjunction with a micrometer needle valve to achieve reproducible doping of the layers. The incorporation of Se appears to be almost the same for GaAs and for $In_{0.49}Ga_{0.51}P$ over the donor concentrations measured. The slopes of 1.6 and 1.3 for n-type $In_{0.49}Ga_{0.51}P$ and GaAs, respectively, in Fig. 10 indicate that, like Zn incorporation, equilibrium is not achieved during the incorporation of Se. Comparison of the data for Se- and Zn-doping in Fig. 10 show that the incorporation of Se is over an order of magnitude higher than that of Zn at the same dopant partial pressure.

The smooth monotonic curves of Fig. 10 show that Zn- and Se-doping can be well controlled over a relatively wide range of carrier concentrations. Such control has been found to be essential for attaining optimum electroluminescence performance from vapor-grown $In_{1-x}Ga_xP$ p-n junctions (19). Finally, it should be noted that the background doping concentration for both $In_{0.49}Ga_{0.51}P$ and GaAs samples which were not intentionally doped was found to be about 2×10^{15} cm^{-3}.

Alloy Homogeneity

Independent evaluations by a variety of experimental techniques indicate that alloy homogeneity may be an important parameter governing the perfection and luminescence properties of vapor-grown $In_{1-x}Ga_xP$. We have explored this possibility by examining the near-bandgap photoluminescence half-width, x-ray line broadening, optical transmission, and bulk electrical properties of our layers, the results of which are presented below.

Near-bandgap photoluminescence half-width.—In a ternary III-V alloy, the width of the near-bandgap luminescence peak can be increased due to alloy inhomogeneity occurring within the volume of the crystal responsible for the luminescence. Such effects were reported for early $GaAs_{1-x}P_x$ crystals (22), where broadened spontaneous electroluminescence spectra were correlated with an inability to attain laser operation. Similar effects have been observed in our vapor-grown $In_{1-x}Ga_xP$ layers, where a general relationship has been noted for a large number of samples between narrow spontaneous emission spectra and efficient photoluminescence. To confirm this relationship quantitatively, and to separate the effect of doping on the half-width, a series of Zn-doped $In_{0.47}Ga_{0.53}P$ layers with acceptor concentrations of only 4×10^{17} cm^{-3} were prepared over a period of a few weeks. For these samples, room-temperature photoluminescence measurements, shown in Fig. 11, indicated a range of spectral half-widths between 55 and 110 meV. Since the spectral half-width at such low acceptor concentrations is only weakly dependent on doping (23, 24), small unintentional doping variations could not account for the range of half-widths shown in Fig. 11. We, therefore, conclude that the increased half-widths shown here are due to compositional inhomogeneities, and that such inhomogeneities can lead to reductions in the photoluminescence efficiency by as much as three orders of magnitude. The fact that compositional inhomogeneity does exist in our vapor-grown layers, and that it can significantly affect the optical and electrical properties of our material is further corroborated by independent measurements described below.

X-ray line broadening.—Despite the fact that x-ray diffraction patterns of our vapor-grown $In_{1-x}Ga_xP$ layers are typically well resolved in the back reflection into $K\alpha_1$ and $K\alpha_2$ doublets, notable differences are seen be-

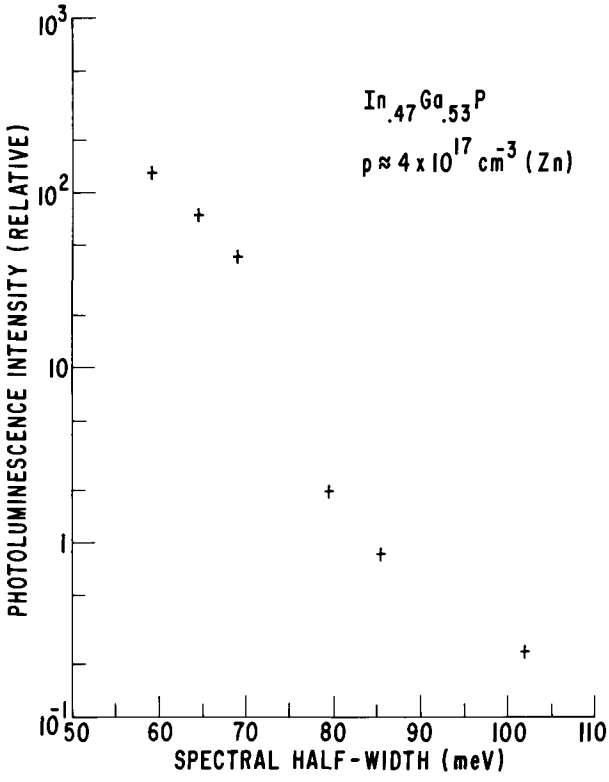

Fig. 11. Variation of the near-bandgap photoluminescence intensity as a function of the spectral half-width for a variety of p-type $In_{0.47}Ga_{0.53}P$ layers grown epitaxially on GaP substrates.

tween the $In_{1-x}Ga_xP$ layers and InP or $GaAs_{1-x}P_x$ deposited by this vapor-growth technique. These differences are summarized in Table IV. The lattice constants were calculated using the highest angle reflection, the (711), except for InP for which the (642) reflection was chosen. The range in lattice constant was estimated from the maximum and minimum diffraction angle of the x-ray diffraction line, and, therefore, is a measure of line broadening. Note that the $In_{1-x}Ga_xP$ samples as a class have the least sharply resolved x-ray lines. In addition, in a few samples, efforts were made to homogenize the InCl and GaCl vapor by the use of baffles in the center zone. Samples 10624 and 20202 have somewhat less broadened lines than samples 20014 and 20005, which is attributed to more thorough mixing of the metal chlorides in the former samples. A clear correlation also was observed between the $In_{1-x}Ga_xP$ line broadening and the near-bandgap photoluminescence intensity, with the better-mixed chlorides consistently resulting in the higher photoluminescence intensities.

Optical transmission.—The optical transmission of several wafers was evaluated. Three representative layers, together with the optical density of the substrate on which they were grown, are plotted as a function of wavelength in Fig. 12. The optical density data have not been corrected for reflection losses. Since the refractive index of GaP ($n = 2.97$) is close to that of InP ($n = 3.3$), we can assume that for GaP-rich alloys the optical density should be close to that for the GaP substrate. Note that there are significant differences in the absorption depending on the degree of mixing of the InCl and GaCl. When the chlorides are mixed, the transmission properties are not far from those of the GaP substrate. The differences in the transmission properties at 9000Å between samples with mixed and unmixed chlorides are almost 40%. This loss would represent a significant attenuation of near-bandgap emission for an electroluminescent structure. Although the mechanism responsible for the increased absorption in the less homogeneous alloys is unknown, two possible causes are refractive index fluctuations and scattering at misfit dislocations.

Electrical properties.—Since the electron mobility is expected to be relatively large for direct energy-gap alloy compositions away from the direct-indirect transition, it should be a sensitive test for the crystalline quality of our layers. A series of Se-doped n-type $In_{0.49}Ga_{0.51}P$ layers were epitaxially deposited on Cr-doped GaAs substrates, as described earlier. Shown in Fig. 13 is the electron mobility of these samples as a function of free-electron carrier concentration both for the case of mixed and unmixed metal chlorides. Although the scatter in the data precludes interpolation of a precise curve, it is apparent that the electron mobilities are consistently higher where the metal chlorides are mixed. This is to be expected since chloride mixing has been shown earlier in this work to lead to more homogeneous alloys. Although the mobility of 1750 cm^2/V-sec at 2×10^{15} cm^{-3} is the highest we have measured in our vapor-grown layers, and is comparable to our results reported elsewhere (20), it is significantly smaller than a value of 2950 cm^2/V-sec at 1.8×10^{17} cm^{-3} reported by Clark (25) for vapor-grown InP deposited on InP substrates, or a value of 2560 cm^2/V-sec at 1.2×10^{17} cm^{-3} determined for Se-doped InP vapor deposited on InP in this work.

The alloy composition, $x = 0.51$, for these samples differs sufficiently from that at the direct-indirect transition ($x \sim 0.7$) (6) to minimize a mobility reduction due to subsidiary indirect conduction-band minima. In addition, since previous mobilty measurements in $GaAs_{1-x}P_x$ (26) indicate that alloy scattering is not prevalent over the direct-bandgap compositional range, the fact that our $In_{0.49}Ga_{0.51}P$ values are significantly lower than that of InP suggests that other scattering processes, perhaps those related to strain or residual inhomogeneity, still exist in the vapor-grown $In_{1-x}Ga_xP$.

Luminescence Properties

As a result of increasing the crystalline perfection of the vapor-grown layers, the resultant radiative properties have been considerably improved, particularly by a large-scale enhancement of the near-bandgap photoluminescence and a concomitant reduction in low-energy infrared emission. $In_{1-x}Ga_xP$ p-n junctions have

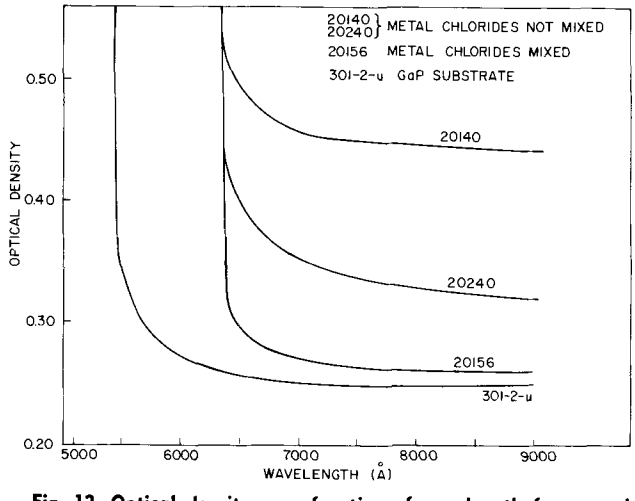

Fig. 12. Optical density as a function of wavelength for several $In_{1-x}Ga_xP$ epitaxial layers which employ mixed and unmixed metal chlorides compared to the GaP substrate on which they were grown.

been prepared *in situ* on GaP substrates by using H_2Se and Zn vapor, as described previously. The electroluminescence emission spectra of diodes prepared from these structures also is primarily bandgap with very weak impurity peaks. This is in sharp contrast to diodes made from earlier vapor-grown (6), solution-grown (27), and melt-grown (27) material prepared in our laboratories. External efficiencies of the vapor-grown diodes have been found to be on the order of 5 to 10 $\times 10^{-4}$ for unencapsulated diodes which emit in the range of 6100-6600Å at room temperature. Brightness values as high as 310 ft-lumens/A-cm^2 were calculated (9) for these diodes. In addition, laser diodes emitting at wavelengths as short as 6105Å with threshold current densities of 4000-6000 A/cm^2 at 80°K have been fabricated (9). Further description and analysis of the luminescence properties of our vapor-grown material as well as a detailed description of the electroluminescent diode characteristics are presented in a companion paper (23).

Summary and Conclusions

An open-tube vapor-growth technique which employs separate transport of the metals as chlorides and PH_3 as the source of phosphorus has been used to deposit single-crystal epitaxial layers of $In_{1-x}Ga_xP$ on GaP substrates. Using precision electronically activated gas-flow controllers, the dependence of composition on deposition temperature and on the relative HCl flows over the metal sources has been determined. Comparison of previously determined kinetic and thermodynamic data with experimental findings in this work show that equilibrium is attained in the metal and deposition zones.

The purity of the vapor-grown layers depends on the growth and reaction temperatures employed. The orientation of the wafer with respect to the gas stream as well as the elimination of ambient gas leaks are found to be important in obtaining large-area macroscopically defect-free epitaxial layers. Evaluation of the photoluminescence half-width, x-ray line broadening, optical transmission, and electron mobility values indicate that alloy homogeneity may be one of the most important parameters governing the perfection and luminescence properties of vapor-grown $In_{1-x}Ga_xP$.

$In_{1-x}Ga_xP$ p-n junctions have been prepared *in situ* by using H_2Se and Zn vapor as the source of donor and acceptor impurities, respectively. Photoluminescence spectra of the as-grown layers consist primarily of an intense near-bandgap peak and a weak low-energy infrared peak which is typically 10-100 times weaker in integrated intensity. Electroluminescence diodes fabricated from the vapor-grown junctions have yielded external quantum efficiencies of up to 0.1% (unencapsulated) and brightness values as high as 310 ft-lumens/A-cm^{-2} for red and orange emission at room temperature.

ABSTRACT

$In_{1-x}Ga_xP$ epitaxial layers, prepared by an improved vapor-phase growth technique, have been evaluated by photoluminescence measurements and by transmission electron microscopy. Maximum photoluminescence intensities for Se- and Zn-doped $In_{1-x}Ga_xP$ layers ($0.5 \lesssim x \lesssim 0.6$), are observed at carrier concentrations of 1×10^{17} and 3×10^{18} cm^{-3}, respectively. At higher concentrations, a severe degradation in the photoluminescence intensity occurs, concurrent with the appearance (by TEM) of precipitates in concentrations of about 10^{14} cm^{-3}. For Zn-doped $In_{1-x}Ga_xP$, the precipitate has been identified as Zn_3P_2 from its electron diffraction pattern. The luminescence spectra from the vapor-grown layers at 300°K consist of a high-energy peak, attributed to band-to-band recombination, and a low-energy peak, located 0.4 to 0.5 eV less than bandgap. The low-energy peak increases with Se donor concentration and with alloy composition, x, but is typically orders of magnitude less intense than the bandgap peak. Electroluminescent p-n junctions prepared with optimum donor and acceptor concentrations have yielded external quantum efficiencies between 5 and 10×10^{-4} (unencapsulated) for emission between 6150 and 6600Å. From such junctions, laser diodes have been fabricated which emit orange coherent radiation between 6105 and 6150Å with threshold currents as low as 4000 A/cm² (at 77°K).

Visible-light-emitting junctions previously have been prepared (1) in vapor-grown $In_{1-x}Ga_xP$ layers both by Zn-diffusion techniques and by the sequential introduction of donor and acceptor impurities during growth. The performance of the junctions prepared by either technique was poor in the early vapor-grown material (1), as evidenced by low quantum efficiencies of 10^{-5}-10^{-6} and large infrared contributions to the electroluminescence spectra. Nonetheless, the attractiveness of direct energy gaps approaching 2.2 eV (2-4) and a high-brightness capability (5) in this alloy system have prompted a renewed examination of vapor-grown $In_{1-x}Ga_xP$ for electroluminescent diodes.

In the first part of our recent study (6), refinements in the $In_{1-x}Ga_xP$ vapor-growth technology have been described which result in epitaxial layers with significantly improved compositional homogeneity and crystalline perfection, as well as reduced impurity contamination relative to our earlier vapor-grown layers. In the present paper, we treat in detail the optimization of donor and acceptor concentrations used for the vapor-grown p-n junctions, and describe the photoluminescence and electroluminescence characteristics of these structures. We will further show that such optimization can lead to $In_{1-x}Ga_xP$ spontaneous-light-emitting diodes with room-temperature external quantum efficiencies of 10^{-3} between 6100 and 6600Å, and laser diodes which emit coherent orange radiation at 80°K with threshold current densities between 4000 and 6000 A/cm².

Photoluminescence

Although the ultimate objective of our research program has been the fabrication of efficient electroluminescent diodes of $In_{1-x}Ga_xP$, we have relied heavily on a photoluminescence evaluation of both n- and p-type material prior to p-n junction formation, since this simple and rapid technique has been found to reveal a considerable amount of information about the luminescence characteristics of the material. In addition, as we will indicate later in this paper, a strong and consistent correlation has been observed between the "quality" of a particular $In_{1-x}Ga_xP$ layer based on a photoluminescence evaluation and the ultimate performance of similarly prepared junction structures evaluated as electroluminescent diodes.

Our photoluminescence measurements utilize the 5145Å radiation from a pulsed (2W peak power) argon laser, which is focused to a spot size on the order of 0.25 mm. For our apparatus, approximately 0.5W (peak power) of 5145Å radiation is absorbed in the sample after the laser beam is passed through an interference filter and reflected from the shiny surface of the semiconductor. The power absorbed per unit area is about 1000 W/cm², which, for an assumed absorption coefficient of 10^{-4} cm^{-1}, results in a carrier generation rate of 2×10^{25} electron-hole pairs/cm³-sec. For a typical electroluminescent junction, a current density of about 400 A/cm² would be required[2] to generate electron-hole pairs at this rate; hence our pulsed laser source is clearly capable of pumping the semiconductor samples to relatively high excitation levels. A duty cycle of about 0.1% is used to avoid heating effects at this power density.

The as-grown surface condition of the epitaxial layers was found to be sufficient to allow photoluminescence measurements to be taken without first treating the surfaces. In cases where a bromine-methanol-phosphoric etch (6) was used to remove selected portions of the $In_{1-x}Ga_xP$ layers, the photoluminescence characteristics were not altered appreciably by the etching process. This observation is consistent with the relatively low surface recombination velocity previously reported for solution-grown $In_{1-x}Ga_xP$ (7).

Typical photoluminescence emission spectra at room temperature are shown in Fig. 1 for a heavily and lightly doped n-type sample of vapor-grown $In_{1-x}Ga_xP$ with x equal to 0.56 and 0.53, respectively. In both cases, the high-energy near-bandgap peak is shown to dominate the emission spectra, although a broad low-energy infrared peak is also evident at an energy position about 0.4-0.5 eV less than bandgap, especially for the more heavily doped sample. Some of the character-

istics of the near-bandgap peak and the low-energy infrared peak in Fig. 1 are discussed further in a subsequent section of this paper.

Optimization of Donor and Acceptor Concentrations

The refinements in the growth conditions discussed in the first portion of our study (6) would be expected to reduce the introduction of undesired nonradiative recombination centers into the vapor-grown layers. In this section, we describe experiments designed to determine the optimum donor and acceptor concentrations for efficient radiative recombination. The enhancement of the radiative recombination rates which arises due to such an optimization should contribute to a further improvement in the luminescence conversion processes, resulting in brighter electroluminescent diodes.

In order to optimize the impurity concentrations for our vapor-grown $In_{1-x}Ga_xP$, a series of n- and p-type epitaxial layers with selected donor (Se) and acceptor (Zn) concentrations were deposited on single-crystal GaP substrates. For these samples, the alloy composition in the epitaxial layer was graded smoothly between the GaP substrate and the desired final portion of the epitaxy (where $x \sim 0.5$-0.6) at a rate of typically 1-2% InP/μm. The carrier concentrations were determined by standard Hall measurements taken on $In_{1-x}Ga_xP$ layers similarly deposited on semi-insulating Cr-doped GaAs substrates. The manner in which the carrier concentrations were controlled has been described previously (6).

For each of the Se-doped samples, photoluminescence spectra similar to those in Fig. 1 were obtained at room temperature. The relative intensity of the dominant near-bandgap high-energy peak was then plotted as a function of the measured electron concentration, as shown in Fig. 2. For electron concentrations between 10^{16} and 10^{17} cm^{-3}, the photoluminescence intensity increases approximately linearly, as expected. However, for concentrations increasing between 10^{17} and 2×10^{18} cm^{-3}, the photoluminescence intensity falls off by about two orders of magnitude. The maximum intensity occurs at a value of about 1×10^{17} cm^{-3}, which is appreciably lower than the optimum concentrations we have observed for electroluminescence in vapor-grown layers of GaAs (8) or $GaAs_{1-x}P_x$ (9), or that for cathodoluminescence in solution-grown samples of GaAs (10).

The reduction in the photoluminescence intensity at moderately large donor concentrations in Fig. 2 correlates well with a surface degradation observed microscopically, as illustrated in the photomicrographs of Fig. 3a and b. Here, the surface appearance of a Se-doped $In_{1-x}Ga_xP$ layer with a donor concentration of 8×10^{16} cm^{-3} (sample I in the photoluminescence data of Fig. 2) is compared with that for a similarly prepared $In_{1-x}Ga_xP$ layer doped with Se to a concentration of 5×10^{17} cm^{-3} (sample II in Fig. 2). The surface of the more heavily doped sample appears to be decorated orthogonally along <110> directions, although the preponderance of this structure is unidirectional (*i.e.*, lies in the horizontal direction in Fig. 3b). This is in sharp contrast to the unblemished surface of the more lightly doped sample. Surface imperfections such as those apparent in Fig. 3b were observed on n-type vapor-grown $In_{1-x}Ga_xP$ layers only when doped with Se to concentrations greater than about 5×10^{17} cm^{-3}.

Samples I and II of Fig. 2 also were examined by transmission electron microscopy (TEM). For this evaluation, the epitaxial layers were first thinned to 25 μm by chemical-mechanical polishing, after which they were further thinned to about 0.2 μm by an ion plasma etching technique (11). An RCA EMU-3G transmission

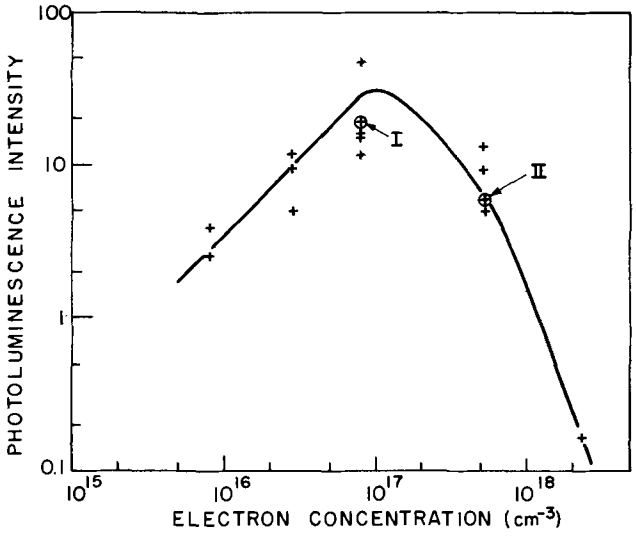

Fig. 2. Room temperature photoluminescence intensity vs. free electron concentration for Se-doped vapor-grown layers of $In_{1-x}Ga_xP$ with $x \sim 0.5$-0.6. Electron concentrations were determined from Hall measurements. Microscope evaluation of samples I and II are illustrated in Fig. 3.

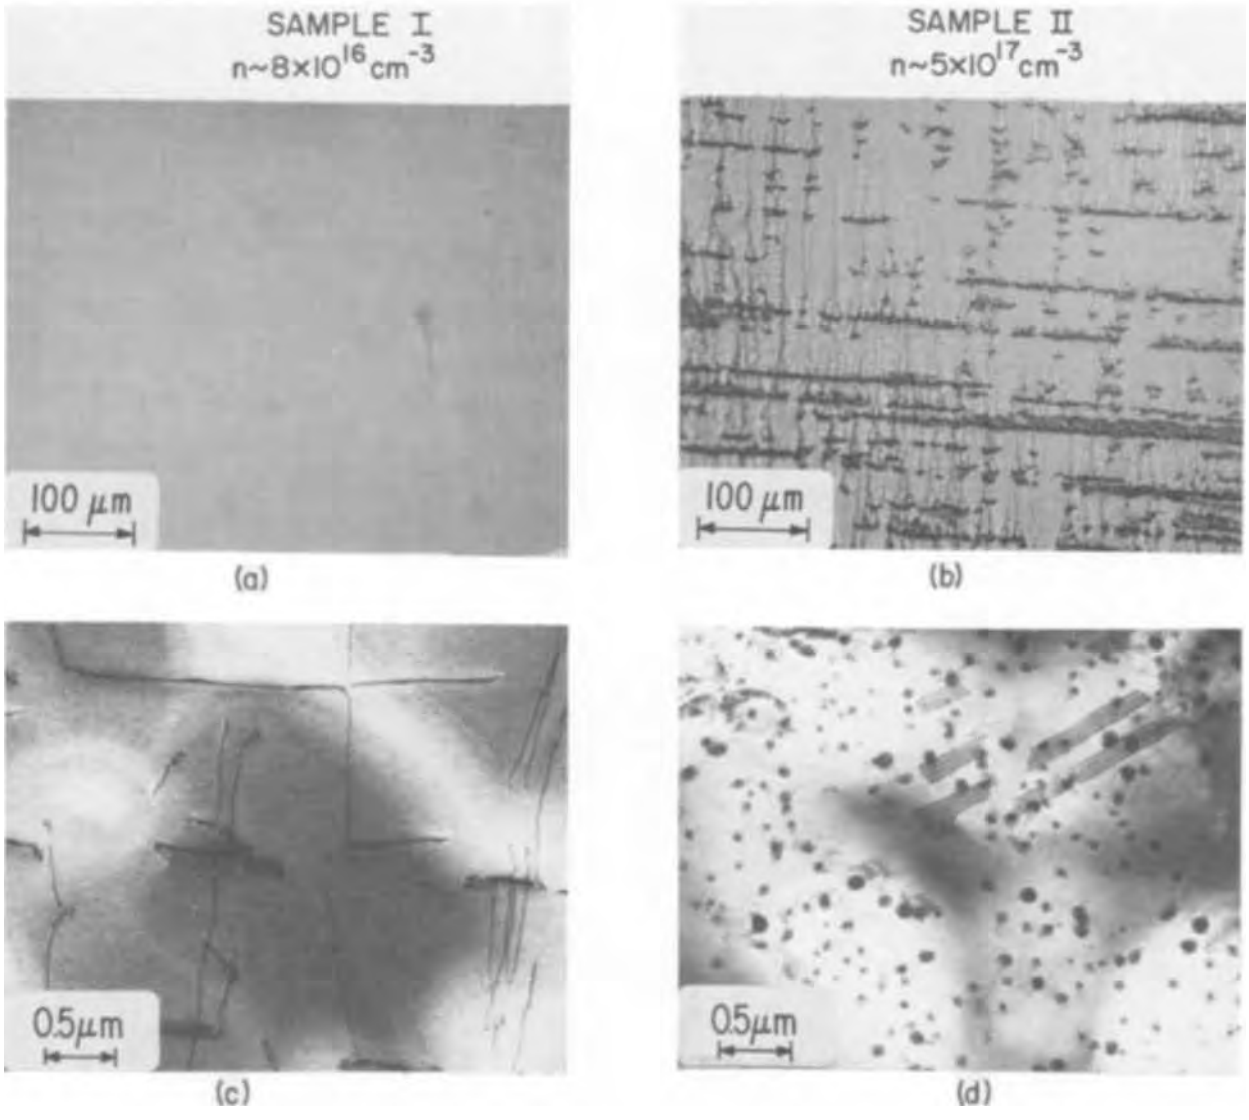

Fig. 3. Optical photomicrographs (a and b) and transmission electron micrographs (c and d) of Se-doped $In_{1-x}Ga_xP$ layers. For sample I, $n \sim 8 \times 10^{16}$ cm^{-3}. For sample II, $n \sim 5 \times 10^{17}$ cm^{-3}. The photoluminescence response of samples I and II are indicated in Fig. 2.

electron microscope was then used to determine the imperfection morphology of the $In_{1-x}Ga_xP$ layers. For each of the samples discussed in this paper, the electron beam was transmitted through the crystal in a direction parallel to the [100] growth direction.

In Fig. 3c we illustrate a transmission electron micrograph taken from sample I ($n = 8 \times 10^{16}$ cm^{-3}). The portion of the epitaxial layer illustrated here was located in the uppermost region of the compositional grading layer (just prior to the junction-containing constant-composition region), which accounts for the expected orthogonal array of "grading" or misfit dislocations (12). More importantly, however, is the fact that there is no evidence of second-phase precipitates in sample I, which is in sharp contrast to the numerous imperfections of this type illustrated in Fig. 3d for the more heavily doped $In_{1-x}Ga_xP$ specimen (sample II). The dark circular particles in Fig. 3d are thought to be precipitates, since their contrast was found to reverse when standard dark-field imaging was employed. The precipitates in Fig. 3d are as large as 700Å and occur with a density of about 10^{14} cm^{-3}. Positive identification of the precipitates could not be made, however, since no extra spots appeared in the electron diffraction pattern for sample II; hence the nature of the precipitates is unknown.

Also shown in Fig. 3d are stacking faults, which occur with a linear density of about 3×10^3 cm^{-1}. The projection of these faults on the (100) plane (as shown in Fig. 3d) was found to be predominantly parallel to one of the two orthogonal [011] directions, much as was the surface structure shown in Fig. 3b.

In previous luminescence studies with other III-V compounds (8-10, 13), a decrease in the luminescence efficiency at high donor concentrations has been attributed to the generation of nonradiative recombination centers associated with precipitation of the dopant impurity. In particular Ga_2Te_3 precipitates have been identified at Te concentrations greater than about 3×10^{18} cm^{-3} in GaAs layers prepared by liquid-phase epitaxy (13). At this stage of our investigation, we cannot conclusively specify whether the precipitates or the stacking faults, or both, in Fig. 3d are responsible for the photoluminescence degradation observed at moderately large Se concentrations. However, based on the presence of stacking faults in three of the four samples ultimately described in this section, even in a lightly doped p-type sample where no photoluminescence or surface degradation was observed, we suspect the precipitates as the primary cause of the degradation found at moderately large Se concentrations. The stacking faults may be related to residual work damage in the substrates.

In order to similarly examine the effects of Zn doping concentrations on the photoluminescence characteristics, a series of eight Zn-doped $In_{1-x}Ga_xP$ layers ($x \sim 0.5$-0.6) with acceptor concentrations between 5×10^{17} cm^{-3} and 1×10^{19} cm^{-3} were deposited epi-

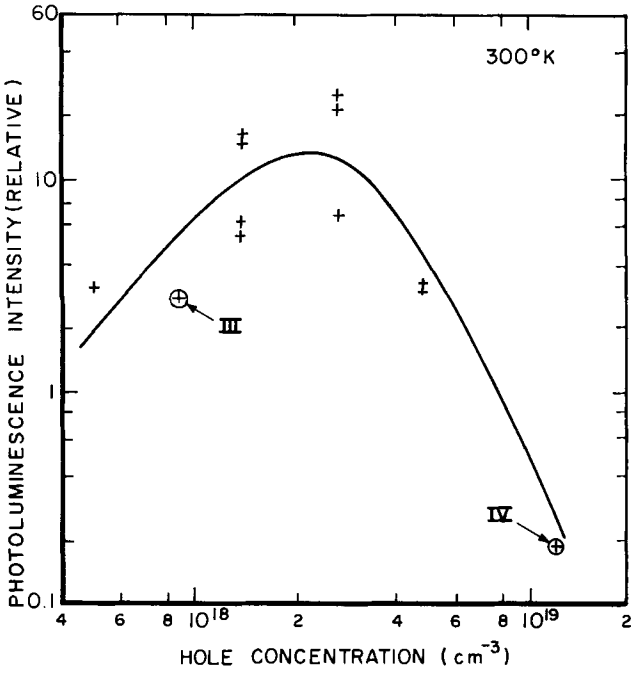

Fig. 4. Room temperature photoluminescence intensity vs. free hole concentration for Zn-doped vapor-grown layers of $In_{1-x}Ga_xP$ with $x \sim 0.5$-0.6. Hole concentrations were determined from Hall measurements. Microscopic evaluation of samples III and IV are illustrated in Fig. 5.

taxially on GaP substrates. The near-bandgap photoluminescence intensity for these samples is illustrated in Fig. 4 as a function of the measured $In_{1-x}Ga_xP$ hole concentrations. As shown here, the photoluminescence intensity increases with increasing Zn concentrations between 5×10^{17} and 3×10^{18} cm^{-3}, but drops by nearly two orders of magnitude for Zn concentrations increased further to values as large as 1.2×10^{19} cm^{-3}. At the optimum acceptor concentration of 3×10^{18} cm^{-3} the photoluminescence intensity was comparable in magnitude to that for the Se-doped $In_{1-x}Ga_xP$ layers doped to the optimum donor concentration of about 1×10^{17} cm^{-3}.

From the photoluminescence data of Fig. 4, it is clear that diffusion conditions which result in large Zn concentrations near the p-n junction should be avoided in vapor-grown $In_{1-x}Ga_xP$. The fact that Holonyak and co-workers (14) have found that improved electroluminescent junctions can be prepared in melt-grown $In_{1-x}Ga_xP$ by utilizing an In(90%)-Zn(10%) source (to reduce the surface concentration of Zn in the diffused wafer) is consistent with our data, and suggests that the doping dependence of the luminescence efficiency shown in Fig. 4 may be applicable to p-type $In_{1-x}Ga_xP$ prepared by other crystal growth techniques.

As was the case for the Se-doped $In_{1-x}Ga_xP$ layers, the fall-off in the photoluminescence intensity at high Zn carrier concentrations was accompanied by a degradation of the surface appearance of the epitaxial layers, as shown in Fig. 5a and b. Here, the surface appearance of a lightly Zn-doped $In_{1-x}Ga_xP$ vapor-grown layer (sample III in the photoluminescence data of Fig. 4) is compared with that for a similarly grown layer doped with Zn to a carrier concentration of about 1×10^{19} cm^{-3} (sample IV in Fig. 4). The surfaces are very similar to those previously illustrated for small and large donor concentrations in Se-doped $In_{1-x}Ga_xP$ layers. Notably, the heavy Zn-doping in Fig. 5b has resulted in an orthogonal array of disturbances which lie parallel to both [011] directions in the (100) planes, but the surface of the sample with lighter Zn doping ($\sim 1 \times 10^{18}$ cm^{-3}) is not perceptibly disturbed.

To determine the cause of the surface deterioration and the photoluminescence degradation at high Zn doping concentrations, the two samples illustrated in Fig. 5a and b also were examined by transmission electron microscopy. A transmission electron micrograph of the Zn-doped constant-composition layer of sample III ($p = 1 \times 10^{18}$ cm^{-3}) is shown in Fig. 5c. The inclined dislocations observed here are typical of a vapor-grown constant composition layer that has been deposited above a compositional grading region. The specimen also was found to contain stacking faults whose density was 1×10^3 cm^{-1} and whose intersections with the (100) specimen surface were parallel to both the [011] and [01$\bar{1}$] directions. In this sample there was no evidence for precipitates, which was also the case for the lightly doped (Se) n-type $In_{1-x}Ga_xP$ layer discussed previously (Fig. 3).

Sample IV was also Zn-doped, but with a carrier concentration of 1×10^{19} cm^{-3}. A transmission electron micrograph of this sample is shown in Fig. 5d. The black circular features are precipitates, which have a diameter of about 500Å and a density of 1×10^{14} cm^{-3}.

The precipitated phase in Fig. 5d was identified as Zn_3P_2 from an electron diffraction pattern obtained from the same region of the specimen as that shown in Fig. 5d. In addition to the normal 100 matrix spot pattern, additional spots (sometimes defining portions of rings) also were seen, due to the presence of the precipitates. The interplanar spacings (d-spacings) of the extra reflections are presented in Table I. Here, we see that the observed values of the d-spacings agree with the reported values for tetragonal Zn_3P_2 to better than 3%. Dark-field imaging of the extra spots and partial rings was observed to cause contrast reversal of the precipitates in Fig. 5d, showing that the extra reflections arise from the precipitates.

It is reasonable to assume that the Zn_3P_2 will be oriented in the $In_{1-x}Ga_xP$ matrix so as to minimize the misfit energy at the interface between the precipitate and the matrix. In order to determine this orientation, we have compared the observed values of d for Zn_3P_2 with the calculated d-spacings for the $In_{1-x}Ga_xP$ sample IV ($x = 0.48$; $a_0 = 5.667$Å). From such a comparison, we find equivalent values for d_{220} of $In_{0.52}Ga_{0.48}P$ and d_{400} of Zn_3P_2: for d_{200} of $In_{0.52}Ga_{0.48}P$ and d_{220} of Zn_3P_2, and for d_{011} of $In_{0.52}Ga_{0.48}P$ and d_{002} of Zn_3P_2. These correspondences indicate that the Zn_3P_2 tetragonal crystals can be incorporated into the $In_{0.52}Ga_{0.48}P$ with minimal misfit strain with one unit cell of Zn_3P_2 replacing four unit cells of $In_{0.52}Ga_{0.48}P$. We should stress, however, that the orientation of the Zn_3P_2 described here is based on the lattice parameter for $In_{1-x}Ga_xP$ at $x = 0.48$, the composition of sample IV. At significantly different alloy compositions, the precipitates could not be expected, *a priori*, to orient identically.

Finally, stacking faults also were seen in sample IV, whose traces on (100) were parallel to both [011] and [01$\bar{1}$]. The faults were observed in approximately

equal densities (1×10^4 cm^{-1}) in each of these directions.

A summary of the photoluminescence intensity, surface appearance, and TEM evaluation of samples I through IV is given in Table II. From this table (or from Fig. 3 and 5), it is clear that precipitates are formed at moderate-to-large donor and acceptor concentrations in Se- and Zn-doped vapor-grown $In_{1-x}Ga_xP$. Table II also illustrates the strong correlation between the presence of the precipitates and a degradation in the surface appearance and the photoluminescence efficiency of the layers. Since the density of the precipitates for both the Se- and Zn-doped $In_{1-x}Ga_xP$ is about 10^{14} cm^{-3}, the mean separation between precipitates is only 0.2 μm, which is probably much smaller than the minority carrier diffusion lengths. Hence, it is not surprising that the precipitates would have an adverse effect on the recombination processes. It is not clear why these dopants have such adverse effects on the crystalline perfection at the somewhat modest doping concentrations observed here. We speculate that the incorporation of the dopants to date is limited by the relative perfection of the crystalline lattice during vapor-growth. In this regard, the present epitaxial layers are known to be somewhat strained by the observation of bowing in the substrate-epitaxy composite following growth, and by the ease with which the structures cleave on thinning with standard lapping and polishing techniques. Since the radiative recombination lifetime is inversely proportional to the active carrier concentrations, it is important that future efforts be concerned with increasing the

donor and acceptor concentrations that can be incorporated into the $In_{1-x}Ga_xP$ layers without adversely affecting their crystalline perfection.

Spectral Characteristics

In an earlier section, we illustrated (Fig. 1) typical photoluminescence spectra for n-type $In_{1-x}Ga_xP$, and showed that the emission contained two spectral peaks, a narrow intense near-bandgap peak in the visible region of the spectrum and a weak but broad infrarad peak located 0.4-0.5 eV less than the bandgap energy. In this section, we examine some of the parameters which have been found to affect the properties of both types of peaks.

Near-bandgap emission.—The dependence of the near-bandgap photoluminescence peak on alloy composition (as determined by x-ray diffraction measurements) for our recent vapor-grown samples is illustrated in Fig. 6. For $In_{1-x}Ga_xP$ layers with x less than about 0.60, the data closely follow the quadratic equation

$$E(x) = 1.35 + 0.735x + 0.70x^2 \quad [1]$$

which was previously obtained by Stringfellow (15) from photoluminescence measurements on $In_{1-x}Ga_xP$ layers prepared by liquid-phase epitaxy. For values of x greater than about 0.6, the peak energy tends to fall below the value given by Eq. [1], in closer agreement to the quadratic dependence noted by Lorenz and Onton (3). The departure from Eq. [1] noted in Fig. 6 near $x = 0.6$ is very similar to that recently observed by McVittie (16) for liquid-phase $In_{1-x}Ga_xP$. A higher energy peak noted by Mabbitt *et al.* (17) when high-purity (six 9's) In and Ga were used as the sources was not observed for our vapor-grown $In_{1-x}Ga_xP$, even though the purity of our metal sources was also as high as can be obtained commercially (six 9's).

The highest energy value observed for our photoluminescence peaks was 2.238 eV at an alloy composition of $x = 0.752$. This data point and another at $x = 0.743$ lie slightly below the curves in Fig. 6, probably

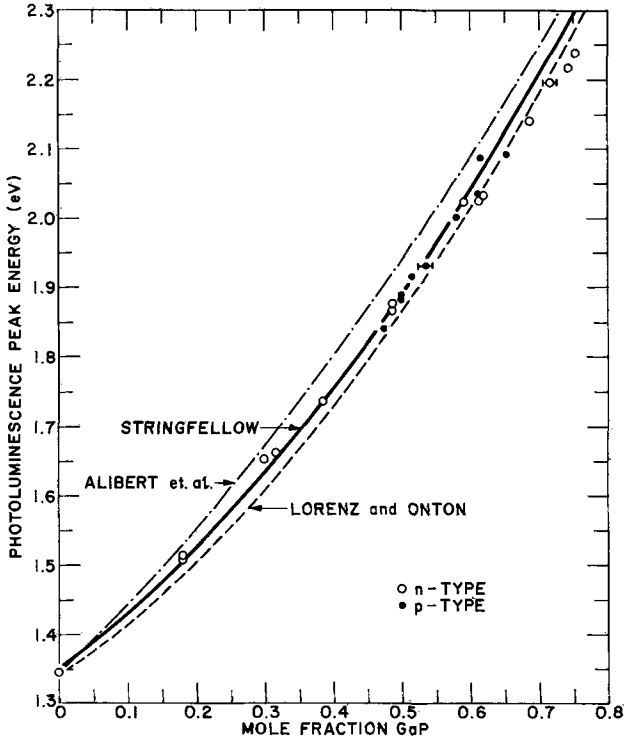

Fig. 6. Photoluminescence emission peak at 300°K for $In_{1-x}Ga_xP$ vapor-grown layers vs. mole fraction GaP in alloy. The solid curve is from photoluminescence measurements on LPE epitaxial $In_{1-x}Ga_xP$ by Stringfellow (15), and is given by Eq. [1] in the text. The upper and lower curves are from Ref. (34) and (3), respectively.

due to distortion caused by the lower energy indirect conduction band minima at these compositions. Direct bandgap recombination has been similarly observed (18, 19) in alloys of $GaAs_{1-x}P_x$ that have compositions slightly on the indirect side of the direct-indirect transition. The phenomenon occurs because of the more efficient recombination from the direct bandgap minimum and the small but finite electron population in the direct conduction band minimum, even when its energy is higher than that of the subsidiary indirect minima.

The fact that the photoluminescence energy at 300°K is approximately the same for both n-type (Se) and p-type (Zn) $In_{1-x}Ga_xP$ is surprising since the donor and acceptor ionization energies in vapor-grown $In_{0.49}Ga_{0.51}P$ have been found to differ substantially (~59 meV for Zn; ~8 meV for Se) (20, 21), and since radiative transitions involving these impurity states would be expected to predominate in extrinsic material. The electroluminescence spectra are indeed shifted to lower energies by typically 30-50 meV relative to the photoluminescence spectra, however, this shift is due to selective high-energy absorption of the junction emission, as evidenced by the fact that photoluminescence peaks on the n- and p-sides of p-n junction structures do not differ substantially in energy, consistent with the trend in Fig. 6. These results suggest that band-to-band or exciton recombination processes (rather than conduction band-acceptor transitions) occur in the p-type vapor-grown layers, perhaps as a result of the relatively light doping concentrations employed here. The fact that the dominant radiative recombination at room temperature is band-to-band in p-type $In_{1-x}Ga_xP$ has been confirmed by Bachrach and Hakki (22) for liquid-phase layers and by Kressel *et al.* (21) for vapor-grown layers.

The emission energy and the spectral half-width of the near-bandgap peak also would be expected to vary significantly with doping concentration due to the interaction of the impurity atoms at high doping concentrations. In a ternary alloy, such as $In_{1-x}Ga_xP$, the dependence of the peak emission energy on doping concentration is difficult to ascertain due to difficulty in precisely controlling the nominal composition of the alloy during crystal growth. However, the spectral broadening which occurs due to the smearing of the conduction or valence band edges with donor or acceptor states, respectively, can be evaluated, even when the alloy composition varies slightly from wafer to wafer. In Fig. 7 we illustrate this dependence for the series of Se-doped (n-type) and Zn-doped (p-type) $In_{1-x}Ga_xP$ vapor-grown layers that were used for the optimization of the photoluminescence intensity on donor and acceptor concentrations (Fig. 2 and 4, respectively). Two effects are apparent here. First, for a given carrier concentration, the half-widths span a range of values (*e.g.*, the half-widths vary between 80 and 100 meV for Se-doped $In_{1-x}Ga_xP$ samples doped to a carrier concentration of 5×10^{17} cm^{-3}). This spread is almost certainly due to fluctuations in the compositional homogeneity of the layers, as discussed in more detail in the first paper (6) of our recent study. Second, for both n- and p-type samples, the spectral half-widths of our vapor-grown $In_{1-x}Ga_xP$ increase more rapidly with doping than do the half-widths previously reported for n- (10, 23) and p-type (10) GaAs at room temperature. At low doping concentrations, the half-widths of our samples are close to those for lightly doped GaAs (40 meV).

Although the GaAs curves in Fig. 7 were taken with electron beam excitation, the difference in penetration depths (2-4 μm for the electron beam excitation, 0.5-1 μm for our laser excitation) for our photoluminescence and the previous cathodoluminescence would not be able to account for the differences illustrated in Fig. 7. To confirm this, photoluminescence measurements also were taken on a series of about 10 vapor-grown Zn-doped GaAs layers for which Hall measurements had

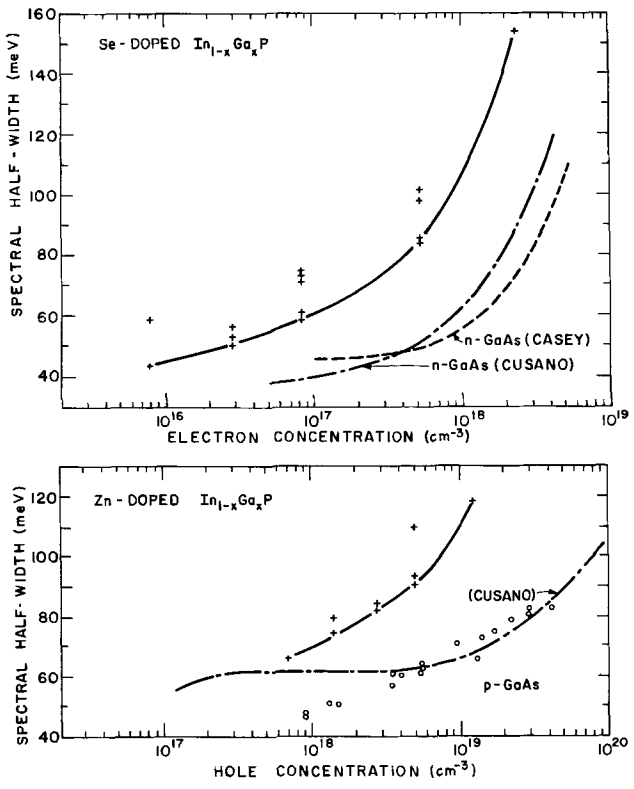

Fig. 7. Spectral half-width at room temperature vs. free carrier concentration for Se-doped (top) and Zn-doped (bottom) $In_{1-x}Ga_xP$ with $x \sim 0.5$-0.6. The dashed curves in the top figure are from cathodoluminescence measurements by Cusano (10) and by Casey and Kaiser (23). The open circles in the bottom figure are from our photoluminescence measurements on Zn-doped vapor-grown GaAs.

been previously taken.[3] As indicated by the round data points in the bottom graph of Fig. 7, photoluminescence measurements taken with the same apparatus as that used for the $In_{1-x}Ga_xP$ show that the disparity in the dependence of spectral half-width on impurity concentration for p-type $In_{1-x}Ga_xP$ and GaAs is genuine. It remains for us to determine whether this difference is fundamentally related to the structure of the energy bands and impurity states in $In_{1-x}Ga_xP$ or to residual inhomogeneity in our present vapor-grown layers.

Low-energy emission.—In an early section of this paper, we illustrated (Fig. 1) that the photoluminescence spectra contained a broad infrared peak located 0.4-0.5 eV below the near-bandgap peak. A low-energy peak such as this is undesirable since the radiation responsible for it is not visible to the eye, and hence does not contribute to the useful brightness of the electroluminescent diode. In addition, the significant breadth of the low-energy peak (~1600Å) magnifies its contribution to the total (integrated) radiative emission. Fortunately, the intensity of the low-energy emission has a sublinear dependence on current density (or incident photon density for the case of photoluminescence) which is characteristic of deep energy states where the recombination rate is proportional to the concentration of a single carrier (rather than both electrons and holes) (24). Hence, the low-energy peak tends to saturate at moderate injection levels.

In our early $In_{1-x}Ga_xP$ vapor-grown material (1), the broad low-energy emission usually dominated the photoluminescence or electroluminescence spectra. However, as the crystalline perfection of the material has improved throughout the course of our recent investigation (6), the peak intensity of the near-bandgap emission has been found to increase by orders-of-magnitude relative to that of the low-energy emission.

[3] The samples were prepared by R. E. Enstrom, J. R. Appert, H. F. Gossenberger, M. Ettenberg, and T. Zamerowski, of RCA Laboratories.

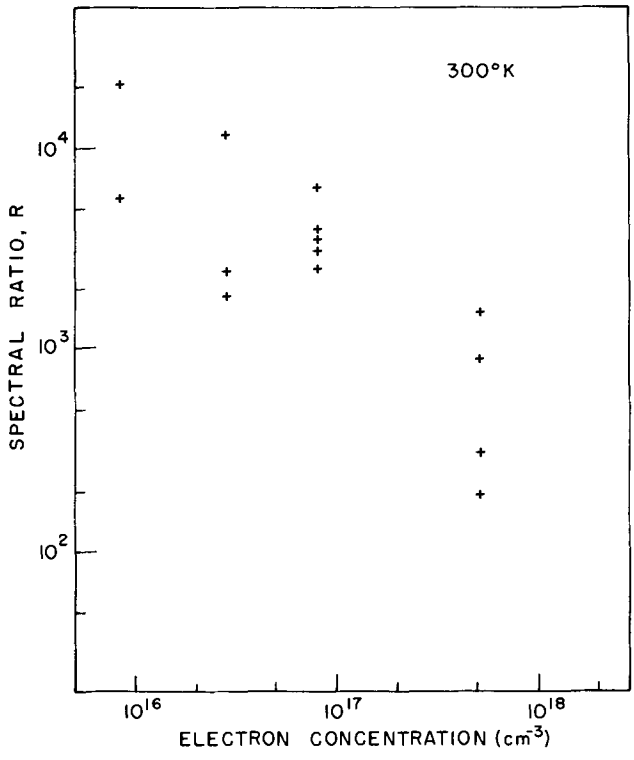

Fig. 8. Photoluminescence spectral ratio R (intensity of near-bandgap peak divided by intensity of low energy peak) vs. free electron concentration for vapor-grown n-type samples of $In_{1-x}Ga_xP$ with $x \sim 0.5$-0.6.

Defining a spectral ratio, R, as the amplitude of the near-bandgap peak divided by the amplitude of the low-energy peak, values of R as large as 20,000 have been observed in the photoluminescence spectra of our recent material. It should be made clear that the spectral ratios used throughout this section do not take into account the integrated response of the two peaks. Ratios based on integrated responses would be about eight times smaller than used here due to the breadth of the low-energy peak.

It is not surprising that the spectral ratio R has increased to some extent with the improvements in crystal quality, since any increase in the radiative efficiency of the material is reflected more strongly in a two-carrier near-bandgap recombination process than in a single-carrier low-energy process (25). However, even a three-order-of-magnitude increase in the radiative efficiency would increase R by only a factor of about 30;[4] hence, the extremely large spectral ratios described above reflect, at least in part, a real reduction in the centers responsible for the low-energy emission relative to those responsible for the near-bandgap emission.

Although we have not conclusively determined the origin of the low-energy emission, several of its predominant characteristics have been established, and are described here. First, from an examination of a large number of n- and p-type vapor-grown samples, we have found that the peak of the infrared emission occurs at about the same energy (at any particular alloy composition) for both conductivity type layers, but that the peak is usually more prominent in the n-type layers. In addition, the magnitude of the low-energy emission (relative to the near-bandgap emission) increases with increasing Se donor concentration, as indicated by the decreasing spectral ratio illustrated in Fig. 8. For the most lightly doped samples here, the low-energy emission was so weak that it was not readily discernible from the background noise. However, ratios of 5000-20,000 were estimated as the mini-

[4] In ref. (25) we show that Mayberg and Black's analysis (24) of band-to-band and low-energy recombination processes result in an expression relating R to the radiative quantum efficiency, η, by an equation R = (constant) η^m, where m is a constant whose value is typically ½.

mum values possible for R, based on the magnitude of the background noise (at the expected wavelength for the low-energy emission) under our most sensitive detection conditions. The data of Fig. 8 show that the spectral ratio varies between a value of about 200 at high Se doping levels to about 20,000 at low donor concentrations. No correlation was observed between the intensity of the infrared peak in p-type material and the Zn acceptor concentration. The dependence of R on the Se concentration strongly suggests that the low-energy emission is the result of a transition between a Se donor state (or a defect related to the incorporation of Se) and a deep-level state which, as yet, is unidentified.

The spectral ratio also was found to vary significantly with alloy composition, as shown in Fig. 9. Although the intensity of both the near-bandgap and the low-energy peaks for these samples varied widely due to differences in their crystalline perfection, the ratio of the intensities, R, decreased monotonically over nearly three orders-of-magnitude for $In_{1-x}Ga_xP$ alloys with x increasing between 0.45 and 0.72. The general trend responsible for this variation was a strong decrease in the near-bandgap peak due to the direct-indirect transition and a relatively unchanging low-energy peak. A similar decrease in R with increasing alloy composition, x, has recently been observed for our melt-grown $In_{1-x}Ga_xP$ samples (26), although for this material much smaller ratios R were observed at any particular value of x (*i.e.*, low-energy peaks were much more intense for the melt-grown material). The stronger low-energy emission for the melt-grown material is consistent with increased contamination (perhaps O_2), since significantly higher growth temperatures (950°-1050°C) and longer growth times (2-4 weeks) are needed for $In_{1-x}Ga_xP$ prepared in this fashion.

It is not clear whether the decrease in R with increasing alloy composition (Fig. 9) is related to the electronic parameters of the $In_{1-x}Ga_xP$ alloy system or to the chemistry of preparing the alloys with differing composition. It should be noted, however, that the low-energy emission also has been observed to become more important for vapor-grown layers of $GaAs_{1-x}P_x$ with GaP-rich alloy compositions (19).

Electroluminescent Diodes

Most of the Zn-doped layers prepared for the optimization of the acceptor concentration were deposited epitaxially as the uppermost layer of a p-n junction structure, so that the junction electroluminescence characteristics could be compared with the photoluminescence from the Zn-doped layers. For electroluminescent diode fabrication, the GaP substrate was thinned to within about 125 μm of the $In_{1-x}Ga_xP$ epitaxial surface by standard lapping and polishing techniques. Ohmic contacts were evaporated to the structure in the form of a Ag-In-Zn film to the p-type epitaxial layer and as an array of Au-Sn, followed by Ag, dots to the n-type GaP substrate. Individual diodes about 1 mm square were cleaved from the wafer and mounted on a TO-5 transistor header with the p-type epitaxial layer adjacent to the header. Au wires 1.5 mils thick were ultrasonically bonded to the Au-Sn, Ag dots to complete device fabrication.

The junction radiation from such structures was directed primarily through the uppermost surface of the GaP substrate. This geometry is particularly attractive for light-emitting diodes since the emission energy from the $In_{1-x}Ga_xP$ junction is much less than the bandgap energy of the GaP substrate, thereby allowing the junction radiation to pass through the substrate with very little absorption. A similar technique, employing a large-energy-bandgap "window," previously was used to enhance the external efficiency of $GaAs_{1-x}P_x$ vapor-grown electroluminescent diodes (9).

For the series of electroluminescent diodes discussed below, the donor concentration was held at about 8×10^{16} cm^{-3}, which was close to optimum for photoluminescence efficiency in the n-type $In_{1-x}Ga_xP$. The thickness of both the n- and p-type vapor-grown layers was held at about 10 μm. The external quantum efficiencies for the series of $In_{1-x}Ga_xP$ diodes were measured with a silicon solar cell placed in close proximity to the uppermost emitting surface of the electroluminescent diodes. A d-c current density between 5 and 10 A/cm^2 was used for the efficiency results described in this paper.

In Fig. 10 the relative electroluminescence efficiency of the vapor-grown p-n junctions is plotted as a function of the Zn doping in the uppermost p-type epitaxial layer. Also shown for comparison is the relative near-bandgap photoluminescence intensity for the p-type layer as a function of the Zn doping concentration

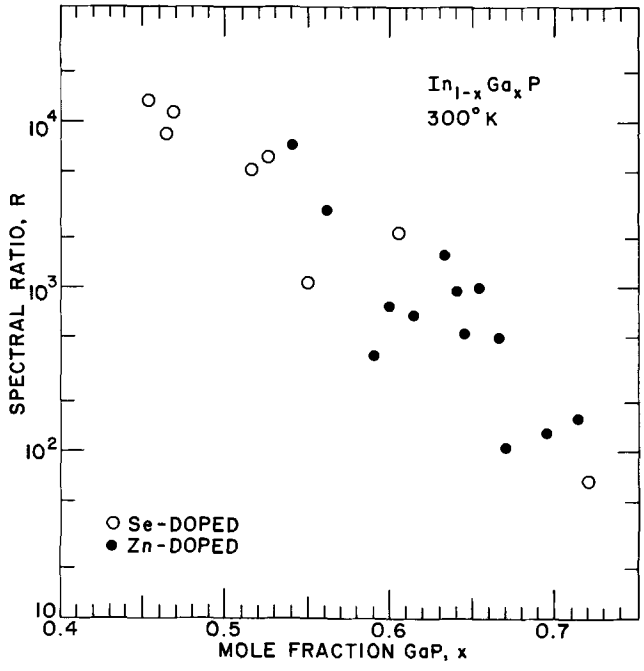

Fig. 9. Photoluminescence spectral ratio R *vs.* mole fraction GaP, x, for n- and p-type $In_{1-x}Ga_xP$ at 300°K.

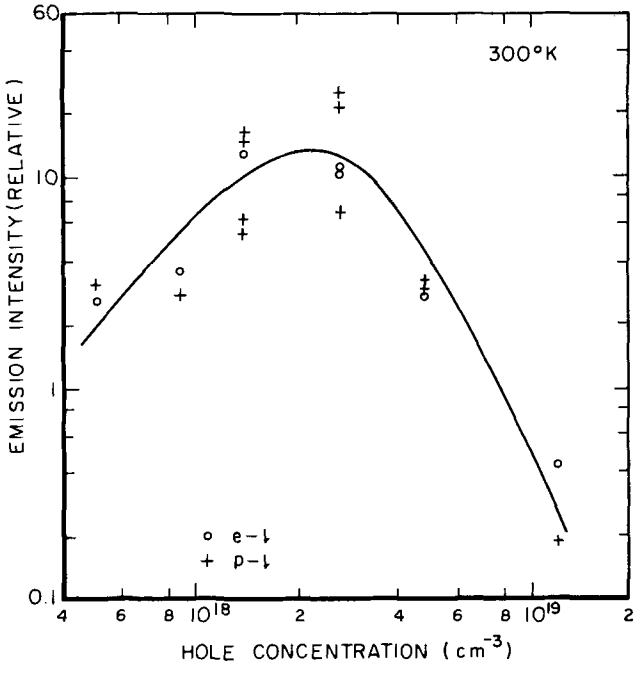

Fig. 10. Photoluminescence intensity of Zn-doped layers (from Fig. 4) and electroluminescence intensity of vapor-grown p-n junctions *vs.* hole concentration in p-type $In_{1-x}Ga_xP$ layers. $x \sim 0.5$-0.6. $T = 300$°K. Emission intensities are relative values.

(previously illustrated in Fig. 4). From Fig. 10 we see that the electroluminescence efficiency has a maximum value at the same Zn acceptor concentration ($\sim 3 \times 10^{18}$ cm^{-3}) as that which results in the maximum photoluminescence intensity. In fact, from the similarity in the shape of the electroluminescence and photoluminescence dependences on the Zn concentration, it is clear that the dominant electroluminescence emission originates on the p-side of the junction, which is the origin of the p-type photoluminescence. In addition, from the manner in which both the photoluminescence and electroluminescence intensities drop off at large Zn concentrations, it is apparent that the deterioration of the surface perfection and the presence of Zn_3P_2 precipitates previously noted also significantly limit the performance of the $In_{1-x}Ga_xP$ p-n junctions.

The p-n junctions prepared with donor (Se) and acceptor (Zn) concentrations that were optimum for maximum photoluminescence intensities also yielded electroluminescent diodes with the highest external quantum efficiencies that we have yet attained for $In_{1-x}Ga_xP$. As illustrated in Table III, external efficiencies of 5 to 10 $\times$ 10^{-4} were obtained for unencapsulated diodes from several different vapor-grown structures that emitted in the range of 6100-6600Å at room temperature. With simple plastic encapsulation, the external efficiencies increased by about a factor of two, as expected, to values of about 10^{-3}. For all of the structures listed in Table III (with the single exception of sample 8-13, DE) the spectral ratio R (near-bandgap to infrared peak intensity) was between 50 and 500 at a d-c current density of 10 A/cm^2, illustrating that the emission spectra consisted primarily of the desired near-bandgap emission. It should be noted, however, that the spectral ratios observed in the electroluminescent diodes and entered in Table III were somewhat smaller than those observed in the photoluminescence spectra of either n- or p-type $In_{1-x}Ga_xP$ (see for example Fig. 7). This probably is due to the fact that the carrier generation levels are higher for the optical excitation than for the junction excitation, and due to the known saturation of low-energy peaks at high excitation levels.

Visually, the brightest diode of those listed in Table III was sample 8-24, D3, for which an estimated brightness (per unit current density) of 317 ft-lumens/A-cm^2 was calculated (27). This value is close to the best reported for an $In_{1-x}Ga_xP$ p-n junction at room temperature [320 ft-lumens/A-cm^{-2}, similarly calculated (5) for a Zn-diffused p-n junction in melt-grown $In_{1-x}Ga_xP$ (28)]. The fact that the vapor-grown diodes are prepared from large-area single-crystal epitaxial layers significantly enhances their ease of fabrication and device yield compared to those prepared infrequently and nonreproducibly from unoriented polycrystalline melt-grown ingots of $In_{1-x}Ga_xP$.

The forward- and reverse-bias I-V characteristics of p-n junction structures prepared with optimum impurity concentrations and the recent refinements described in our vapor-growth process (6) were found to be very free of leakage currents, as shown in Fig. 11. In contrast, the characteristics of most previous melt-grown or vapor-grown junctions were dominated by large leakage currents typically on the order of

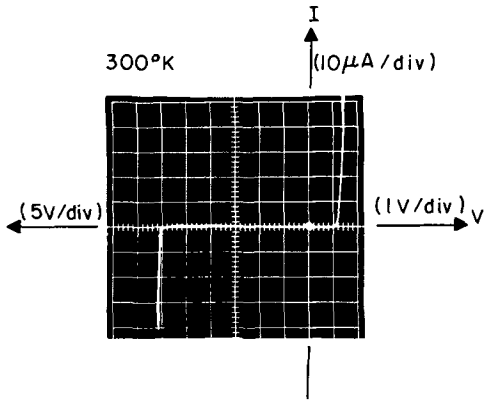

Fig. 11. I-V characteristics at room temperature for vapor-grown $In_{1-x}Ga_xP$ electroluminescent diode (sample 8-24, D3). Diode area is $\sim 10^{-2}$ cm^2. Note that the origin has been displaced three squares to the right of center.

milliamperes at comparable voltages, and "soft" low-voltage reverse breakdown characteristics indicative of junction imperfections. The sharp avalanche breakdown at 30.5V corresponds to a donor concentration of 8.2×10^{16} cm^{-3}, based on Sze and Gibbon's (29) relationship[5] between breakdown voltage, energy bandgap, and doping concentration for an abrupt semiconductor p-n junction. This value is in good agreement with the intended "optimum" donor concentration of Fig. 2, which was used for the fabrication of this series of diodes. At forward-bias currents significantly larger than those of Fig. 11, a series resistance of several hundred ohms was observed, which is attributed primarily to resistive contacts to the GaP substrate. For $In_{0.5}Ga_{0.5}P$ vapor-grown junctions deposited, instead, on GaAs substrates, the series resistance was eliminated, and both the current and the light intensity followed a relationship of the form exp(qV/1kT) at current densities greater than about 10^{-2} A-cm^2. Such a dependence is indicative of classical injection over a junction barrier, and is similar to that observed in our vapor-grown $In_xGa_{1-x}As$ p-n junctions (30).

Injection Laser Diodes

Prior to our investigation, Holonyak and co-workers (31) had demonstrated that melt-grown crystals of $In_{1-x}Ga_xP$ could support laser emission to wavelengths as short as 5800Å at 77°K when the bulk crystals were excited optically. However, only a single report of laser action in $In_{1-x}Ga_xP$ p-n junctions had been made (14), this being for melt-grown material into which a p-n junction was formed by Zn diffusion. For such junctions, the threshold currents were very high (67,000 A/cm^2 at 77°K) even for InP-rich alloys where the emission was in the infrared (at 7600Å). The difficulty in previously obtaining lasers was clearly related to the lack of good crystalline perfection at the semiconductor p-n junction.

The laser diodes that we prepared have been described elsewhere (27). For completeness, we merely note here that the vapor-grown laser diode structures were identical to those described in the previous section, and were prepared with the optimum donor and acceptor concentrations described in this work, after making the improvements in the crystalline perfection discussed in the preceding paper (6). The characteristics of the vapor-grown $In_{1-x}Ga_xP$ lasers are summarized in Table IV, which is taken from Ref. (27). To our knowledge, the emission at 6105Å is the shortest wavelength that has yet been reported from a p-n junction laser diode, and is the first example of orange coherent emission from such a device. The threshold current densities of 4000-6000 A/cm^2 indicated in Table

[5] $V_B = 60\ (E_g/1.1)^{3/2}\ (N_d/10^{16})^{-3/4}$, where V_B is the breakdown voltage, E_g is the energy bandgap, and N_d is the doping concentration on the more lightly doped side of an abrupt semiconductor p-n junction.

Table IV. Emission wavelength and threshold current density at 80°K for short-wavelength-emitting p-n junction lasers

Material	Emission wavelength (A)	J_{th} (A/cm²)	Reference
$In_{1-x}Ga_xP$	6105, 6130, 6145	5.9×10^3	27
$In_{1-x}Ga_xP$	6180	4.1×10^3	27
$Al_xGa_{1-x}As$	6280	$6 \times 10^{3*}$	32
$GaAs_{1-x}P_x$	6350	2.5×10^5	33

* For close confinement heterojunction structure with 2 μm active region.

IV compare favorably with those from $GaAs_{1-x}P_x$ and $Al_xGa_{1-x}As$ at short emission wavelengths, and demonstrate that the 6100Å emission is not limited severely by loss of carriers to the subsidiary indirect conduction band minima. The direct band structure of $In_{1-x}Ga_xP$ should ultimately be capable of providing yellow coherent emission from p-n junctions at wavelengths as short as about 5700Å at 77°K.

Conclusions

A photoluminescence evaluation of Se and Zn doping in $In_{1-x}Ga_xP$ with $x \sim 0.5$-0.6 has been carried out for improved vapor-grown layers deposited epitaxially onto GaP substrates. The near-bandgap photoluminescence intensities at 300°K reach their maximum values at a Se donor concentration of 1×10^{17} cm^{-3} and at a Zn acceptor concentration of 3×10^{18} cm^{-3}. At larger doping concentrations, the photoluminescence intensities decrease drastically due to the introduction of second-phase precipitates. For heavy Zn doping, tetragonal Zn_3P_2 precipitates have been identified, which tend to fit into the lattice of $In_{0.52}Ga_{0.48}P$ by replacing four unit cells.

The near-bandgap photoluminescence emission peak for our vapor-grown layers ($0 \leq x \leq 0.6$) approximately follows the quadratic relationship previously determined by Stringfellow (15). For alloy compositions with $0.6 < x < 0.74$, the peak energy values lie somewhat lower than predicted by the quadratic equation. Spectral broadening of the near-bandgap emission is observed for carrier concentrations larger than about 1×10^{17} cm^{-3} for n-type $In_{1-x}Ga_xP$ and 7×10^{18} cm^{-3} for p-type $In_{1-x}Ga_xP$. The extent of the broadening in the present vapor-grown samples is more severe than it is in GaAs. A low-energy infrared peak located approximately 0.4-0.5 eV less than bandgap is enhanced for alloys with increased GaP concentrations and in n-type material with increased Se donor concentrations, but under all conditions is extremely weak in intensity compared to that of the desired near-bandgap peak.

Vapor-grown p-n junctions prepared with the optimum Se and Zn carrier concentrations yield room-temperature electroluminescence efficiencies between 5 and 10×10^{-4} at wavelengths between 6100 and 6600Å. From the improved $In_{1-x}Ga_xP$ vapor-grown junctions, laser diodes capable of providing coherent orange emission (6105Å at 80°K) with threshold current densities between 4000 and 6000 A/cm² have been fabricated (27).

Solid-Solid Vacuum Diffusion Processes in Silicon

R. Gereth, A. Kostka, and K. Kreuzer

AEG-Telefunken, Semiconductor Division, Heilbronn, Germany

ABSTRACT

Two diffusion techniques are described making use of doped silicon wafers as the diffusion source. The processes are carried out either in an evacuated capsule or inside a high vacuum furnace. Using the capsule technique, boron and phosphorus layers in silicon have been produced, with sheet resistances ranging from approximately 20-4000 ohms/□, and junction depths between approximately 0.3 and 15 μm. Good uniformity and reproducibility of results were obtained, with relative variations below 3% across one wafer, from wafer to wafer, and from run to run. In a series of boron diffusions, the high vacuum technique yielded results comparable to the capsule technique. It offers more experimental flexibility but requires masking layers other than SiO_2 for the production of planar devices.

The exact and reproducible control of doping profiles is a fundamental requisite for the fabrication of advanced semiconductor devices. Standard diffusion processes in open systems do not always fulfill these requirements. Especially, shallow diffused layers and/or low surface concentrations are extremely difficult to obtain using an open doping system. In addition, during each predeposition step included in open diffusion runs, the semiconductor body is heavily stressed by the rather high impurity concentrations arising from these processes. Crystal structure damage, such as local lattice defects caused by impurity clusters, or dislocation networks caused by partial stress release (1, 2) are the consequences. These defects lead to an appreciably lower electrical quality of the diffused area and its surroundings.

Some of the problems can be overcome by diffusion techniques keeping dopant concentrations well below the saturation value during the high temperature step. Several successful attempts have been made in recent years using capsule diffusion (3, 4), diffusion from doped glasses (5), boron nitride source, or ion implantation (6). This paper deals with two modifications of the sealed capsule process proposed by Armstrong and Duffy (3).

Using doped silicon wafers instead of powder for the diffusion source (4) offers advantages in the handling of the source and the means of surface concentration adjustment by variation of the active source area inside the capsule. Details of this method are reported in the first part of this paper.

Limitations of the capsule diffusion technique arising from insufficient mechanical stability and chemical impurity of the capsule material may be overcome by replacing the capsule with a high vacuum furnace. The features of this technique are described in the second part of this paper.

Sealed Tube Diffusion

Experimental procedure.—Doped silicon source wafers and silicon wafers to be diffused are placed inside an evacuated capsule which is inserted into the diffusion furnace. The basic quartz components employed are shown in Fig. 1. The capsule and the sealing plug are both fabricated from a quartz tube. Typical dimensions of the capsule are 300 mm length, 45 mm diameter, and 2 mm quartz thickness. The quartz wafer carrier exhibits individual grooves approximately 1 mm apart to take up the wafers. All quartz parts are cleaned in an HF-HNO_3-HCl-mixture, rinsed in distilled water, and dried in a furnace of 400°C for 1 hr.

The source wafers are cut, lapped, and polished from a silicon rod doped with the desired material up to the desired level. They may be used for a large number of diffusion processes. During each process, however, doping material concentration is reduced by outdiffusion from a region below the surface. In order to guarantee reproducible source conditions, the source wafers are immersed into a silicon etch to remove the depleted layer before each new diffusion run. As a rule of thumb, a layer thickness twice the produced junction depth is normally etched off. Immediately before capsule loading, both the source wafers and the wafers to be diffused are immersed in a dilute HF etch to remove all traces of surface oxide, because this oxide is able to mask the diffusion resulting in lower surface concentrations and shallower junction depths.

For the diffusion run, the wafers are put into the previously cleaned quartz carrier. The entire assembly is then placed in the quartz tube, which is evacuated to better than 10^{-5} Torr, heated for 30 min at approximately 500°C to drive off all water residues, and sealed by collapsing the outer tube upon the inner one. The whole capsule is put into the diffusion furnace, which must have a thermal flat better than 1°C over the entire length of the capsule. Poor thermal flats result in nonuniform diffusion and in damage to the silicon surface (7).

The geometrical arrangement of the wafers within the capsule has some influence on the diffusion results. A series of experiments revealed the following evidence. If all the wafers are placed at a distance of approximately 1 mm from each other, no variation in results occurs by deliberately changing the positions of the wafers in the capsule. On the other hand, bringing source and test wafers into intimate contact resulted in a certain increase in measured sheet resistances. The observations are in good agreement with the theory of vacuum diffusion processes (8). The transport mechanism in the gas phase is essentially controlled by the total pressure in the sealed tube at

† The terms used are defined: T = diffusion temperature, t = diffusion time, C_o = source concentration, Φ = ratio of source wafer area to total silicon area, ρ_s = diffused sheet resistance, x_j = diffused junction depth, C_s^* = diffused surface concentration, calculated from ρ_s and x_j after Irvin (9) assuming erfc profile, * = no erfc profile because of concentration dependent diffusion coefficient.

the diffusion temperature. In order to achieve a homogeneous mixture of dopant atoms, silicon atoms, and residual gas molecules over all the capsule, the value of the mean free path of all the particles needs to be considerably lower than the distance between the wafers. For the closely stacked arrangement, this condition obviously is not fulfilled. Since the sticking probability of the silicon and dopant atoms on the silicon surfaces is high (4), this geometry results in an impediment of the particle flow out of and into the narrow space between the stacked wafers.

Results.—The capsule wafer diffusion has been applied to diffuse boron and phosphorus into silicon over a wide range of parameters; *i.e.*, source concentration C_o, diffusion temperature T, and diffusion time t. After diffusion, junction depth x_j and sheet resistance ρ_s of the layer in the test wafer were measured. Typical results are shown in Table I. The test wafer surface concentrations C_s^* were calculated from the measured values of x_j and ρ_s using the curves published by Irvin (9) assuming an erfc-profile. The actual surface concentrations C_s may deviate from the calculated values C_s^* becuse of a non-erfc nature of the profile. Theoretical considerations (8), however, show that the difference between the actual and an erfc profile is small provided that the surface concentration is low enough thus allowing the application of a concentration-independent diffusion coefficient, and that the diffusion time is long compared to the duration of the effects mentioned below. For diffusions exhibiting junction depths above 1 μm (deep diffusions), the second condition is fulfilled.

For all experiments with a source concentration $\leq 2.10^{19}$ cm^{-3} we found the relation $C_s^* \leq C_o$. Sealed tube diffusions using a powder source experimentally (3) and theoretically result in $C_s = C_o$ and an erfc profile (*i.e.*, $C_s^* = C_s$). The major reasons for the fact that a wafer source produces results with $C < C_o$ and

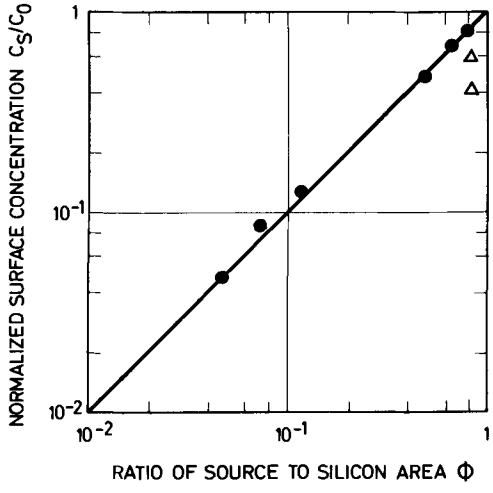

Fig. 2. Normalized surface concentration vs. ratio of source area to total silicon area inside the capsule. C_o = source doping level.

a profile slightly different from erfc (*i.e.*, $C_s^* \approx C_s$) are theoretically analyzed in a separate publication (8) and are shown to be (*a*) the finite area of the source wafers, (*b*) the influence of the capsule walls on the exchange process, and (*c*) the sorption limited rate of exchange during the first stage of the diffusion process.

Effect (*a*) is independent of diffusion time, effect (*b*) and, more rapidly, effect (*c*), vanish with increasing diffusion times. Of course, there are other possible mechanisms that could affect materials exchange in the capsule. The above-mentioned effects, however, are necessarily involved, and their consideration proved to be sufficient for the explanation of our results. This does not exclude minor influences of other processes. As a demonstration of effect (*a*), Fig. 2 shows the results of a couple of diffusion experiments with varying surface area of the source wafers. In all cases, the surface concentration C_s in the test wafer is a certain fraction of the homogeneous source wafer doping C_o. This fraction C_s/C_o has been plotted *vs.* the controlling parameter Φ, denoting the ratio of source wafer area to total Si area in the chamber. Theoretically (8), for deep diffusions, the dependence is linear, $C_s = \Phi C_o$, illustrated by the straight line. The dots are experimental values for deep diffusions. The triangles refer to shallow diffusions. The deviations from the theoretical line may be explained by effects (*b*) and (*c*) and are discussed in detail in the section on Shallow layers below.

The diffused layers produced by the wafer source technique are fully comparable with those produced by the powder source method. In order to examine the uniformity and reproducibility, the series of diffusion runs represented in Table II has been carried out. For

† The terms used are defined: Δ = standard deviation of measured sheet resistances from their mean value ρ_s, other symbols defined in Table I.

each series, the source concentration and surface ratio were kept constant. In all cases, the maximal standard deviations from the mean value of the sheet resistances of the diffused layers are below ±3% across one wafer, within the wafers of one diffusion run, and from run to run. This excellent value of uniformity and reproducibility was observed both for blanket diffusions and diffusions into silicon wafers utilizing SiO_2-masked planar structures.

Shallow layers.—The trend in modern devices goes to shallower structures having junction depths below 1μ. Therefore, a series of experiments was performed concerned with the extension of vacuum diffusion processes into the submicron range (10). Of course, this requires either very short diffusion times, which are difficult to control, or relatively low diffusion temperatures, typically 1100°C and below. The first exploratory experiments at 1100°C yielded remarkable deviations from the results expected from the simple model assuming constant surface concentration $C_s = \Phi C_0$. In addition, an influence of the extent of the quartz surface inside the capsule became apparent. For example, doubling the quartz surface inside the capsule yielded a remarkable increase in the diffused sheet resistance. This experiment indicated a direct influence of the inner capsule walls on the material exchange between source and test wafers. In order to evaluate its magnitude under different diffusion conditions, the following series of diffusions has been carried out: phosphorus was diffused at 1100° and 1150°C, boron was diffused at 1050°, 1100°, and 1200°C. For each series, the diffusion time was varied within wide limits. The results are plotted in Fig. 3 and 4. The straight lines indicate the results expected from the constant surface concentration mode. Measured sheet resistances and junction depths (dots) show a systematical deviation from the straight lines, with an increase in the deviation for shorter diffusion times and lower diffusion temperatures.

Qualitatively and quantitatively, the results can be explained through effect (b) mentioned above, an absorption of doping material by the quartz walls of the capsule in the initial stage of the diffusion process. After a certain time saturation of the walls will occur and the exchange of material will no longer be affected.[1] This is the reason for the decrease of the deviation with increasing diffusion time. At higher temperature, saturation of the inner wall surface proceeds faster because of the higher vapor pressures and diffusion constants involved. This is the reason for the decrease of the deviation with increasing temperature. In addition to its time and temperature dependence, the wall coverage effect can be shown to be proportional to the parameter Φ_w denoting the ratio of wall surface to Si surface inside the capsule. Further theoretical details are discussed in a separate paper (8). The experimental conditions of the diffusion series are in accordance with the assumptions on which the theoretical treatment is based. The open circles in Fig. 3 and 4 represent the values calculated by the theory using the set of parameters listed in Table III. The

[1] Radio tracer experiments (11) revealed the expected quantity of phosphorus at the inner quartz walls.

† The terms used are defined: ϕ_w = ratio of inner capsule wall surface to total silicon area, $S_{\infty w}$ = wall saturation coverage, t_w = rise time for wall coverage effect, and other symbols defined in Table I.

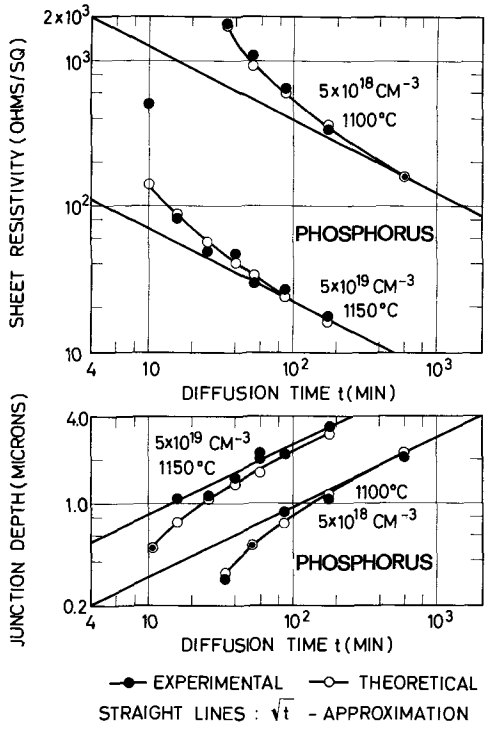

Fig. 3. Results of phosphorus-sealed capsule diffusions

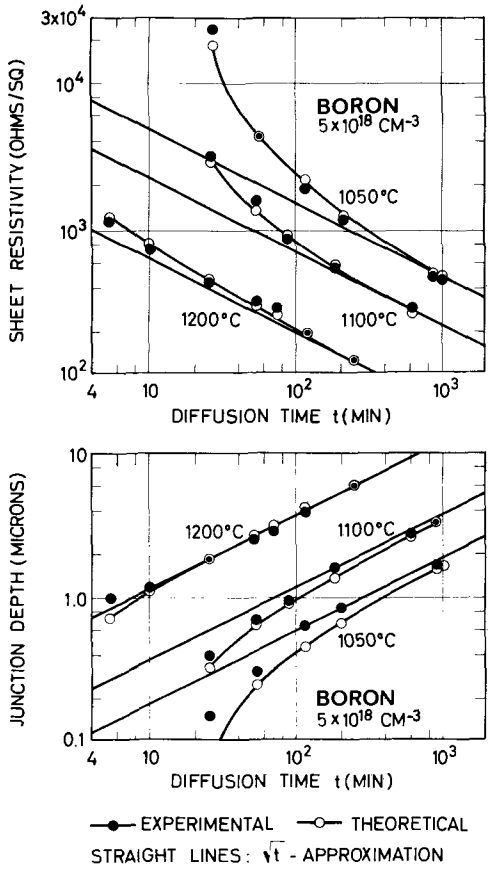

Fig. 4. Results of boron-sealed capsule diffusions

values of sheet resistance have been derived from the concentration profiles using Irvin's (9) relations between concentration and conductance. For the $5 \cdot 10^{19}$ cm^{-2} phosphorus series, the results give only qualitative information since a fictitious value of $1 \cdot 10^{20}$ cm^{-3} for the source doping had to be introduced in order to obtain some accordance with the measurements. This is a consequence of the concentration dependence of the diffusion coefficient which was not accounted for in the theoretical treatment.

In Table III, the quantities $S_{\infty w}$ and t_w denote, respectively, the saturation coverage of the capsule walls and the rise time of the saturation process. The quartz coverage values $S_{\infty w}$ necessary to fit the experimental points all lie well below one monolayer (approximately 10^{15} cm^{-2}). Because of the proportionality to Φ_w, one method to reduce the wall coverage effect for a given diffusion time and temperature is the reduction of Φ_w by increasing the silicon surface inside the capsule. On the other hand, while working under conditions of quartz influence, reproducibility of results can only be guaranteed by keeping Φ_w and $S_{\infty w}$ constant. The first condition is accomplished by using a constant number of wafers in a quartz capsule of definite size for every reproduction run. The second condition may be approximated by using a standardized quartz cleaning procedure that will result in defined quartz surface properties. Minor fluctuations, however, cannot be avoided.

Limitations.—The limitations of the capsule diffusion technique are principally governed by the capsule properties. Maximum operating conditions, such as temperatures and times, are limited by the values quartz can sustain without softening causing a collapse of the capsule. A typical set of values is 20 hr at 1200°C for an industrial grade quartz. Backfilling the capsule with inert atmospheres could extend the range of application. Lower limits in time and temperatures are given by the problematics involved in heating the capsule for a short period of time and by the rapid increase of the quartz adsorption effect for short times and low temperatures. The usable source doping concentration range is limited by the maximum available doping concentration in silicon single crystals for wafer diffusion. The lower concentration limit is set by the impurities always present in the quartz material. During the diffusion step they are partly released from the inner surface of the walls and transported to both test and source wafers, where they cause undesired doping or contamination of the material. Using an industrial grade quartz tube, n-type impurities up to surface concentrations of $2 \cdot 10^{17}$ cm^{-3} were found in test wafers after a test diffusion step without source wafers in the capsule.[2] A high purity quartz material did not show this effect, but mechanical stability of such capsules was insufficient. The limitations arising from quartz material properties may be overcome by replacing the quartz capsule with a high vacuum furnace, as described in the following section.

High Vacuum Diffusion

Experimental procedure.—Doped silicon source wafers to be diffused are placed inside a high vacuum furnace (see Fig. 5) for the diffusion process. The diffusion chamber, 7,[3] is represented by an electrically heated high temperature furnace installed inside the bell jar of a standard high vacuum apparatus. The diffusion chamber has a diameter of 25 cm and a height of 6 cm. It is heated by two meander-shaped carbon plates, 4, each plate located between two quartz disks, 3. Several tantalum sheets, 6, and a water cooling system, 1 + 2, act as heat shields. The wafers are placed in any kind of wafer carrier, 8, suitable for the specific experiment. During the diffusion process both the diffusion chamber and the carrier remain connected to the vacuum system. In this way, a pressure gradient is established which protects the wafers inside the chamber against impurities from the outside.

Source and test wafers cleaned and etched as described in the previous section, are positioned alternately and in direct contact with each other. The sandwich-type arrangement is necessary in the high vacuum furnace in order to avoid thermal etching of the silicon surfaces caused by evaporation and pump-away

[2] Investigations of Fränz and Langheinrich (11) suggest that the n-type doping of the test wafers was caused by an Sb contamination of the quartz material.

of the material. A typical diffusion cycle does not require more time than a sealed capsule diffusion run. After evacuating the bell jar (down to approximately $5 \cdot 10^{-7}$ Torr at room temperature, and 10^{-5} Torr at 1200°C) and heating up the diffusion furnace, diffusion temperature is controlled by a variable transformer during the diffusion time. The sensing thermocouple, 5, located inside the black body arrangement easily allows absolute temperature recordings. Cool down is initiated by switching off the furnace supply. In the lower temperature range, a more rapid cooling of the diffusion furnace can be achieved by introducing inert gases (*e.g.*, argon) in the bell jar up to approximately atmospheric pressure.

Material exchange.—In contrast to capsule diffusion processes, high vacuum diffusions are carried out in an open vacuum system. Although a good thermal flat (~±2°C) is maintained inside the symmetrical black body arrangement of the furnace, evaporating material can arrive at and stick to the cooler region of the diffusion furnace, or escape from the diffusion chamber. Because of the steady pump-away of material by maintaining the pressure in the chamber in the high vacuum range, no equilibrium pressure of silicon or dopant is established. Since the mean free path of the evaporating particles exceeds the chamber dimensions, the particles move in straight lines, and the material exchange is defined by the geometrical arrangement of the surfaces. This becomes evident from an experiment illustrated in Fig. 6. Two test wafers are packed together in close contact, one of them covering only half the area of the other. A source wafer is facing them approximately 5 mm apart. After the diffusion cycles only the nonmasked part of the rear test wafer has

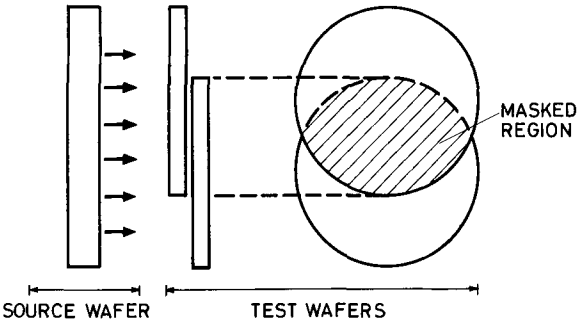

Fig. 6. Straight line material transport during high vacuum diffusion.

Fig. 7. Effect of thermal evaporation from a silicon surface partly covered by another wafer.

been doped. The masked area has been effectively shielded from the source by the front test wafer.

Another consequence of straight line movement and pump-away is thermal etching of open surfaces inside the chamber. Uncovered mirror smooth polished surfaces of Si wafers show heavily damaged surfaces with a strong etch pit pattern after the diffusion step (Fig. 7). Knopp (7) pointed out that the etch pit density of silicon treated in a poor vacuum was much greater than in a high vacuum ($<10^{-6}$ Torr). The enhancement of thermal etching at higher ambient pressure is due to the formation and subsequent evaporation of volatile SiO. This effect is of even greater importance if SiO_2 is used as a localized diffusion mask in high vacuum diffusion processes. At diffusion temperatures, Si and SiO_2 interact forming the rapidly evaporating SiO phase (12, 13). Figure 8 shows the results of such

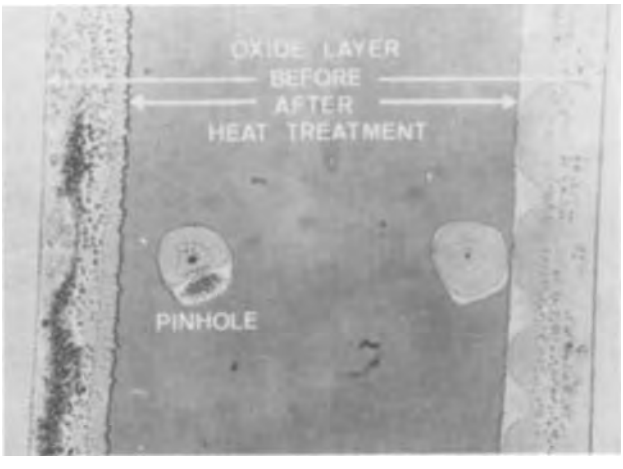

Fig. 8. Effect of silicon monoxide evaporation from silicon-silicon dioxide interfaces.

an experiment at 1200°C for approximately 1 hr. The oxide layer was about 50μ wide, the SiO_2 thickness was 1μ. After diffusion the masking oxide had vanished from the interface between the free silicon surface and the SiO_2 window edges. Because of the same effect, pinholes in the masking oxide lead to widened circles in the middle of Fig. 8.

In order to avoid the silicon evaporation effect, it is necessary to use a closely stacked face-to-face arrangement (sandwich arrangement) of source and test wafers within the high vacuum furnace. The escape probability of the evaporating material from the surfaces directly contacting each other into the outside is greatly reduced. In this way, blanket diffusions applicable, *e.g.*, in the mesa technology, can be carried out resulting in negligible damage to the surfaces, the only exception being a narrow region along the circumference of a wafer. The problem of SiO evaporation from planar device structures may be overcome by using any masking material that does not interact with the underlying silicon, such as Si_3N_4.

Results.—The influence of diffusion temperature on results has been investigated by a series of boron diffusions lasting 1 hr at various temperatures between 1000° and 1200°C. From the theory (8) one gets a value of $\Phi = 0.05$ for the sandwich arrangement of the wafers used, leading to a surface concentration in the test wafer which is half the value of source doping. This result should be independent of temperature if an unhindered material exchange takes place between the facing surfaces. Within experimental error this is indeed the case as can be seen from Table IV. The surface concentration in the test wafers has been evaluated assuming an erfc profile. The maximum deviations from the mean value of measured sheet resistance of the diffused layers are approximately ±4% across one wafer and within the wafers of one run, and approximately ±5% from run to run. These figures are comparable with the results reported for the sealed tube experiments.

Limitations.—Unlike the behavior of capsule diffusion, limitations in the applicability of high vacuum diffusion are not defined by the properties of the material surroundng the gas phase. The principal condition for this is the restriction of material exchange between wafer surfaces directly facing each other in the closely stacked sandwich arrangement.

With the exception of planar devices, which are difficult to handle because of SiO evaporation, limits of the high vacuum diffusion technique arise mainly from the equipment. With the present apparatus, short diffusion times (in order of 10 min) are excluded because of slow cool-down rates. On the other hand, there seems to be no upper limit of diffusion time as encountered with capsule diffusion processes. Diffusion temperatures may be chosen deliberately within the practical range.

Conclusions

Two different diffusion methods employing doped silicon wafers as diffusion source are described, one using an evacuated capsule, the other a high vacuum furnace as the diffusion chamber. Both methods have been proved to be highly reproducible and applicable over a wide range of diffusion parameters. Good control

of results is extended into low concentrations and shallow layers. Doped silicon wafers as diffusion source are attractive because they are readily available in any laboratory or production area dealing with silicon planar technology. The additional equipment for carrying out the diffusion experiments stays within reasonable limits. No extra capital budget has to be allocated for the purchase of an elaborate apparatus.

Acknowledgments

The authors are indebted to Dr. R. Dahlberg who designed the high vacuum diffusion chamber and initiated the high vacuum diffusion experiments. They also acknowledge the contribution of R. Lorenz, who carried out a part of the capsule diffusion experiments. This work has been supported by the German Bundesministerium für Wissenschaft und Forschung.

A Physical and Mathematical Approach to Mass Transport in Capsule Diffusion Processes

A. Kostka, R. Gereth, and K. Kreuzer

AEG-Telefunken, Semiconductor Division, Heilbronn, Germany

ABSTRACT

A mathematical model based on the various physical processes occurring in a multiphase system is developed to allow the calculation of material exchange in capsule diffusion processes. The influences of three main effects on this exchange are considered: the finite ratio of source to sink surfaces, the limited rate of exchange at the beginning of the process due to the sorption processes at the surfaces, and the disturbance of the exchange process by doping material adsorption at the capsule walls. The first effect is independent of time and offers a simple means of concentration control. The influence of the other two effects on diffusion results is more complicated and may be calculated using a computer program.

Experimental conditions of the early work on capsule diffusion allowed the results to be explained on the basis of diffusion from constant surface concentrations. For capsule diffusion processes using a powder source (1), the constant surface concentration was assumed to be equal to the source doping, which could be verified by experiment. Processes employing doped semiconductor wafers as sources (2, 3) produced surface concentrations appreciably lower than the source doping, especially for short diffusion times or low diffusion temperatures. In order to understand and control these effects, the following work has been carried out. In the first part a review of the various physical processes occurring in the capsule is given. The second part deals with a straight-forward mathematical description for every case and the mass transfer equations resulting from the combination of these different processes. Finally, some characteristic properties of the solution are evaluated.

System Components and Transport Mechanisms

Capsule diffusion processes (1-3) have been carried out in sealed and evacuated quartz tubes loaded with doped and undoped silicon material. The doped source is represented either by a powder (1) or by a wafer (2), the undoped sink is formed by the wafers to be diffused.

Key words: material exchange, solid-gas-solid transport, closed system.

The physical system considered in the present work consists of four components, namely, source, sink, capsule walls, and the gas phase inside the capsule. The treatment, however, is not restricted to the special materials silicon and quartz. It may be easily applied to other semiconductor and capsule materials by switching to the appropriate material constants

The whole system is kept at an over-all constant elevated temperature. During the process, an exchange of all material components existing in the capsule takes place depending on the different surface desorption and readsorption rates. The gas phase, therefore, consists of the gaseous state of each introduced component, together with the residual gas desorbed from the solid components during heat-up.

The material exchange in the described system is controlled by the following mechanisms: (*a*) diffusion inside the solid components, (*b*) sorption (evaporation and condensation) at the solid surfaces, and (*c*) transport in the gas phase. The physics and mathematics of process (*a*) may here be regarded as well known, whereas processes (*b*) and (*c*) require some further considerations.

Sorption effects at solid surfaces generally are rather complex in nature, and the material properties in-

volved in most systems are hardly known. However, a straightforward linear approximation of thermal desorption and physical adsorption reveals the influence of sorption parameters on the capsule diffusion process.

Thermal evaporation of semiconductor and doping atoms from the source and sink crystal surfaces is determined by the temperature and the corresponding activation energy, which is closely related to the binding energy, and has been measured, *e.g.*, for silicon (4).

Condensation rates are mainly controlled by the sticking probability and the particle concentration in the gas phase. The sticking probability is a widely unknown function of material parameters, such as the binding mechanism, surface coverage, and contaminants. Any contaminated or chemically modified surface conditions may effect a drastic reduction of the amount of material exchange caused by a reduction in sticking probability. In order to guarantee process reproducibility, wafer cleaning and capsule evacuation have to be carried out in a way that prevents the wafer surfaces from contamination or reactive gaseous material during the high temperature process.

Under certain circumstances, the inner surfaces of the capsule wall play an important role in the exchange process by adsorbing doping material from the gas phase. The adsorption process will be considered to take place during the initial phase of the diffusion run, lasting until saturation of the walls is achieved.

Material transport in the gas phase is determined by the total pressure. In the high pressure range, realized by an inert gas backfill into the capsule, it has been shown (1) that pressures exceeding 10 Torr result in a restriction of material exchange, presumably by coverage of the surfaces with foreign atoms and reduction of sticking probability. On the other hand, at pressures below 10^{-2} Torr the mean free path of the gas particles exceeds the capsule dimensions. The absence of collisions in the gas phase results in a straight line movement exhibiting shadow effects. A slice shielded from the source by another slice will not be doped (3). Consequently, in order to get a homogeneous mixture in the gas phase independently from the geometrical arrangement of the wafers, the total pressure in the capsule has to be high enough to guarantee at least a couple of collisions for an impurity atom on its way from source to sink. This is roughly the case for pressures exceeding 0.1 Torr. Because of the extremely uniform doping achieved in capsule diffusions, it can be concluded that the total pressure in the capsule will be between 0.1 and 10 Torr, most likely around 1 Torr. Since the vapor pressures of semiconductor, doping, and wall material normally are orders of magnitude smaller (5) than this value, the main part of the gas phase material must be some residual gas desorbed from the surfaces during heat-up of the capsule. It is an interesting feature of capsule diffusion that this overwhelming part of the gas phase does not influence the surface conditions of source and sink in a deleterious manner. One would expect this residual gas to consist of the air components H_2O, O_2, N_2. Nitrogen has been shown to cause no harm up to pressures of 10 Torr (1). Oxygen and H_2O, however, are highly reactant molecules causing silicon oxidation and monoxide evaporation (6) until the saturation pressure is reached.

If the amount of oxidizing material in the capsule exceeds a certain value, *e.g.*, as a result of poor pumping or ineffective water outbake, an oxide layer on the semiconductor surfaces will be formed and will act as a diffusion barrier for the doping atoms. Material exchange is drastically reduced in most of those cases.

Transport Equations and Solution

In this section, a mathematical approach to the different transport processes is made. The transport equations are then summarized and the combined problem is solved. In order to simplify the mathematical treatment, the following idealizations will be made: (*a*) diffusion in the wall material is negligible; (*b*) diffusion in source and sink follows the diffusion equation with a concentration independent diffusion coefficient; (*c*) sorption processes may be described by linear approximations involving constant activation energies and sticking probabilities; (*d*) a homogeneous gas phase transmits the material instantaneously, without taking up a significant part of it; and (*e*) adsorption of doping material at the capsule walls may influence, but not dominate, the exchange process.

All of these assumptions may be verified by a proper choice of capsule material (*a*), doping concentrations in the semiconductor material (*b*), total pressure in the gas phase (*d*), and diffusion time and temperature. For the usual cases with moderately doped silicon in quartz capsules, the validity of assumptions (*a*) through (*e*) may easily be shown (2, 3).

Evaporation.—The particle current density j_e evaporating from a solid surface is dependent on the surface particle density S (per square centimeter) and the activation energy of desorption Q via an Arrhenius formula

$$j_e = SA_0 \exp(-Q/kT) = SA \qquad [1]$$

where A_0 is a material dependent factor of proportionality, k denotes the Boltzmann constant, and T is the absolute temperature. Q is taken to be concentration independent following assumption (*c*). Calculating the dopant evaporation rate from a doped semiconductor surface and relating it to that of the semiconductor atoms (subscript s) results in

$$j_e = ca_sA_s \cdot \frac{A_0}{A_{0s}} \exp(\Delta Q/kT) = ca_sA_s\epsilon \qquad [2]$$

with c being the dopant surface concentration, and a_s the mean atomic distance in the crystal. ΔQ represents the difference of activation energies $Q_s - Q$, which is assumed to be small compared to Q_s since the binding mechanism acting between semiconductor atoms and substitutionally located dopant atoms is essentially the same as between semiconductor atoms themselves. Therefore, ϵ is a factor of proportionality which is only slightly temperature dependent. It denotes the ratio of evaporation probabilities of dopant and semiconductor atoms, respectively.

Condensation.—The particle current density j_c of atoms hitting a surface from the gas phase and sticking to it is

$$j_c = nP(kT/2\pi m)^{1/2} = nPC \qquad [3]$$

with n being the gas phase particle density, P the sticking probability, and m the particle mass. P is taken to be concentration independent following assumption (*c*).

Wall coverage.—The influence of the walls will be described by a process of coverage with dopant atoms following an exponential saturation characteristic

$$S_w = S_{\infty w}(1 - \exp(-t/t_w)) \qquad [4]$$

The wall coverage S_w approaches the saturation value $S_{\infty w}$ with a rise time t_w. The functional dependence of Eq. [4] may only be expected under the condition of constant gas phase dopant particle density. This is the case only in a system free of wall adsorption, or with small adsorption at the walls compared with the total material exchanged between source and sink according to assumption (*e*). Both t_w and $S_{\infty w}$ are regarded as experimental parameters.

Combined problem.—The physical background of the solution is the following: from the laws of sorption and Fick's diffusion laws one gets continuity equations for the dopant material currents at the solid surfaces. Together with a materials balance describing the conservation of the over-all doping material in the system, they form boundary values coupling the system of

partial differential equations for the doping concentrations $c_i(x, t)$ in source ($i = 1$) and sink ($i = 2$). The space and time coordinates are x and t, the surface is situated at $x = 0$, and the diffusion starts at $t = 0$. The diffusion equations are written

$$\dot{c}_i = Dc_i'' \quad (i = 1, 2) \qquad [5]$$

with the point and prime denoting time and space derivation, respectively.

Continuity equations.—At the surfaces of source and sink, material current is described by two different models: diffusion at the bulk side of the surface, and sorption at the gas phase side. In order to find an uncomplicated mathematical expression for the connection of these processes, the assumption is made that every particle at the surface of the semiconductor material takes part in both the diffusion and the sorption processes. This implies that the influence of the ionization process which has to occur before the doping atom will diffuse, or any other electrical influence based on surface space charge layers, may be ignored.

Under these conditions a pile-up of nondiffusing doping material at the surface is prohibited. The particle current densities resulting from diffusion and sorption on both sides of the surface have then to be equal at the surface

$$-Dc_i' = nPC - \epsilon a_s A_s c_i \quad (\text{at } x = 0,\ i = 1, 2) \qquad [6]$$

In Eq. [6], the left-hand term represents the well-known dopant diffusion current density. The right-hand terms represent dopant condensation and evaporation currents after Eq. [2] and [3], respectively.

Materials balance.—The materials balance is based on the assumption that the gas phase does not take up considerable amounts of doping material according to assumption (d) which can be justified for the case of doped silicon in quartz capsules (2). Consequently, the total material currents out of source, sink, and walls sum up to zero

$$F_1Dc_1' + F_2Dc_2' - F_w\dot{S}_w = 0 \quad (\text{at } x = 0) \qquad [7]$$

F denotes the various areas of source (subscript 1), sink (subscript 2), and wall (subscript w). $\dot{S}_w$ represents the time derivative of the wall surface coverage which is equal to the net dopant current density onto the wall.

Initial values.—The initial values depend on the doping conditions of source and sink wafers. For ease of calculation and because of the practical interest we choose the case of homogeneously doped source and undoped sink, that is

$$c_1 = c_o = \text{const} \quad (\text{for all } x \text{ at } t = 0)$$
$$c_2 = 0 \qquad [8]$$

Solution.—The coupled system of Eq. [5]-[8] can be uncoupled and solved under the condition that the term $\dot{S}_w$ in Eq. [7] does not depend significantly on the solution itself. This is the case with Eq. [4] for S_w.

Introduction of the surface ratios $\Phi = F_1/(F_1 + F_2)$ and $\Phi_w = F_w/(F_1 + F_2)$ together with two auxiliary functions

$$d = c_1 - c_2$$
$$m = \Phi c_1 + (1 - \Phi)c_2 \qquad [9]$$

and Eq. [4] into Eq. [5]-[8] results in

$$\dot{d} = Dd''$$
$$d = c_o \quad (\text{at } t = 0)$$
$$d' = \epsilon a_s A_s d/D \quad (\text{at } x = 0) \qquad [10]$$

and

$$\dot{m} = Dm''$$
$$m = \Phi c_o \quad (\text{at } t = 0)$$
$$m' = \Phi_w S_{\infty w} \exp(-t/t_w)/Dt_w \quad (\text{at } x = 0) \qquad [11]$$

The solution of Eq. 10 yields (3, 7)

$$d = c_o(\text{erf}(x/2\sqrt{Dt}) + d^*)$$
$$d^* = \exp(t/t_s + x/\sqrt{Dt_s}) \cdot \text{erfc}(\sqrt{t/t_s} + x/2\sqrt{Dt})$$
$$t_s = D/(\epsilon a_s A_s)^2 \qquad [12]$$

A solution of Eq. [11] is not directly available by using elementary or otherwise tabulated functions. It has to be evaluated numerically from the following integral form

$$m = \Phi c_o - \Phi_w S_{\infty w} m^*$$
$$m^* = \frac{1}{t_w\sqrt{\pi D}} \int_o^t \exp\left(-\frac{\tau}{t_w} - \frac{x^2}{4D(t-\tau)}\right) \frac{d\tau}{\sqrt{t-\tau}} \qquad [13]$$

with help of a computer program. The validity of this solution is verified by insertion. The concentration profiles c_1 and c_2 existing in the source and sink crystals after the diffusion process are now easily achieved by the inversion of Eq. [9] and the introduction of d and m from Eq. [12] and [13]. They are given by

$$c_1 = \Phi c_o + (1 - \Phi)\, c_o(\text{erf}(x/2\sqrt{Dt}) + d^*) - \Phi_w S_{\infty w} m^*$$
$$c_2 = \Phi c_o(\text{erfc}(x/2\sqrt{Dt}) - d^*) - \Phi_w S_{\infty w} m^* \qquad [14]$$

Discussion

The concentration profiles described by Eq. [14] differ from the approximate solution

$$c_1 = c_o$$
$$c_2 = c_o \text{ erfc}(x/2\sqrt{Dt}) \qquad [15]$$

one would get if the sink surface concentration were kept constant and equal to the source doping c_o (diffusion from constant source). One geometrical and two physical effects are responsible for the difference:

(a) The finite surfaces of source and sink limit the maximum concentration achievable at the sink surface to the value Φc_o which is lower than the source doping c_o.

(b) sorption processes at source and sink surfaces limit the rate of material exchange especially in the first stage of diffusion, reducing the concentration in the sink through function d^*.

(c) sorption processes at the capsule wall effect a loss of doping material until saturation of the wall, again reducing the concentration both in source and sink through the term $\Phi_w S_{\infty w} m^*$.

One may note that for the extreme case of a source of infinite surface (powder, $\Phi = 1$) with infinite sorption rates ($d^* = 0$) and negligible wall adsorption ($S_{\infty w} = 0$), Eq. [14] will transform into Eq. [15].

Inserting $x = 0$ into Eq. [14] yields the variation of surface concentrations c_s in source and sink with time. It is determined by the correction functions d^* and m^*, and the relative magnitude of the constants involved. The time dependences of d^* and m^* are illustrated in Fig. 1 for a representative relation between t_s and t_w. For $t > t_w$ and $t > t_s$, both corrections decrease proportionally to the square root of diffusion time. The influence of m^* exhibits a maximum at times around t_w. The corresponding time dependence of surface concentrations is shown in Fig. 2. The dashed lines refer to the case of negligible influence of the walls on the exchange process ($S_{\infty w} = 0$ in Eq. [14]). Because of the sorption limited exchange at times shorter than t_s, the surface concentration in the sink gradually rises from 0 and later saturates at the equilibrium value Φc_o. During the same initial time interval lasting approximately $10t_s$, the surface concentration in the source falls from its initial value c_o down to the equilibrium value Φc_o. The solid lines in Fig. 2 represent the case of considerable adsorption at the capsule walls. The correction term $\Phi_w S_{\infty w}\, m^*$ is also shown for comparison by

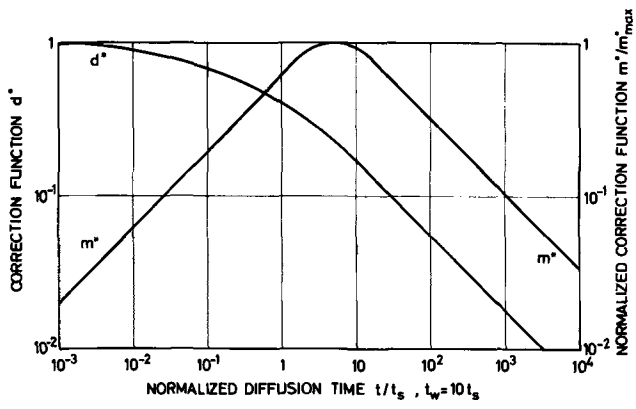

Fig. 1. Variation of the correction functions d^* and m^* with time

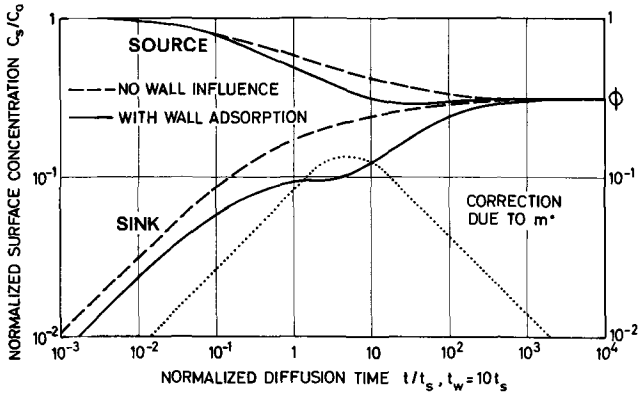

Fig. 2. Variation of normalized surface concentrations in source and sink with time. The correction due to m^* is inserted for comparison.

the dotted line. The result is a marked dip in the concentration curves at times around t_w.

For appreciably longer times, the deviation from Φc_0 rapidly vanishes. Therefore, after diffusion times longer than approximately $10t_w$, a constant surface concentration of the value Φc_0 may be assumed as a boundary condition of the diffusion process, resulting in a nearly undisturbed complementary error function profile.

The absolute values of the characteristic time constants t_s and t_w usually depend on material properties and temperature. The temperature dependence of t_s may be derived from that of D and A_s via the definition of t_s in Eq. 12. For silicon, t_s decreases with temperature, varying from some minutes to some seconds between 1050° and 1200°C. The values of ϵ, which are necessary to calculate t_s, range between 10 and 100 and have been found by fitting the theory to experimental results (3). In the same way, for a quartz capsule t_w is shown to decrease with temperature, with absolute values somewhat higher than t_s mentioned above. For silicon in quartz capsules, therefore, it is possible to avoid deviations from the erfc-solution by using high-temperature, long-time diffusions. For a successive prediction of results achieved by diffusions leading to shallow profiles with junction depths in the submicron range (3), however, the more rigid solutions of Eq. [14] have to be used, since these diffusions are low-temperature and short-time processes.

ABSTRACT

The concentration of nitrogen and oxygen in semiconductor silicon and their solubilities in silicon at its melting point have been measured by charged particle activation analysis and infrared spectrophotometry. It has been found that: (*i*) commercial semiconductor silicon contains less than 1×10^{15} atoms/cm^3 of nitrogen in the un-ionized state; (*ii*) the solubility in solid silicon is $4.5 \pm 1.0 \times 10^{15}$ atoms/cm^3 for nitrogen and $2.75 \pm 0.15 \times 10^{18}$ atoms/cm^3 for oxygen; and (*iii*) the solubility in liquid silicon is about 6×10^{18} atoms/cm^3 for nitrogen and $2.20 \pm 0.15 \times 10^{18}$ atoms/cm^3 for oxygen. Thus, the equilibrium distribution coefficient has been determined to be about 7×10^{-4} for nitrogen and 1.25 ± 0.17 for oxygen. The solubilities of the two elements are compared with those of other elements, especially carbon, and are discussed thermochemically.

After maximum purification of any semiconductor material or metal, carbon, nitrogen, or oxygen almost always constitutes a major portion of the remaining impurity. These light elements are abundant in nature, but a reliable determination of their sub-ppm level cannot be carried out with ease. We reported previously on the concentration and behavior of carbon in semiconductor silicon as studied by charged particle activation analysis (1). Similar studies have been made for nitrogen and oxygen. Infrared spectrophotometry was also used for oxygen, after calibration by activation analysis. As is well known, the activation analysis gives the total oxygen concentration, but the spectrophotometry is sensitive only to oxygen forming the Si-O-Si bonding in silicon crystal. In this paper, (*i*) the concentration range for nitrogen and oxygen in commercial semiconductor silicon is presented, (*ii*) the solubilities of the two elements in solid and liquid silicon at its melting point are given, (*iii*) the physical states of the two elements in solid silicon are discussed, and (*iv*) the solubilities of carbon, nitrogen, and oxygen in silicon are treated thermochemically.

Experimental

Sample preparation.—Commercial semiconductor silicon of various origins and specifications was collected as the sample. In order to obtain polycrystalline silicon rods of anomalous nitrogen contents, monosilane was decomposed thermally in the presence of ammonia. Also, elementary silicon in various stages of the monosilane process at Komatsu Electronic Metals Company was taken to be analyzed. For the measurement of the maximum solubility of the two elements, pure silicon was doped with each of them up to the saturation concentration at the melting point of silicon.

For the measurement of the solid solubility of nitrogen, a silicon rod (30 mm diameter) was cut into hemicylinders and a sufficient quantity of Si_3N_4 was sandwiched between them. A molten zone (10 mm in length) with various velocities was then passed through several parts of the sandwich, in an atmosphere of argon containing several per cent of nitrogen. In the zone-melting, the melt was always covered with small particles of silicon nitride. To determine the solubility of nitrogen in liquid silicon, silicon with Si_3N_4 powder was kept just above its melting point in an evacuated quartz ampoule and was then suddenly cooled to give silicon grains (2-4 mm diameter).

For the oxygen doping, the result of Kaiser and Breslin was used (2). In an atmosphere of oxygen, a molten zone was made, kept immobile for 10 min, and then caused to travel in a part of a silicon rod. Several parts of the same rod were zone melted with various velocities to provide the sample for solubility measurements. Also, the molten zone was cooled suddenly for the measurement of the solubility of oxygen in liquid silicon; the solidification rate was of the order of 100 mm/min.

Activation analysis.—The reactions of $^{14}N(p,\alpha)^{11}C$ and $^{16}O(^3He,p)^{18}F$ were used for the activation analysis of nitrogen and oxygen, respectively. Detailed descriptions of the charged particle activation analysis for carbon, nitrogen, and oxygen in semiconductor silicon are given in a separate paper (3). Careful examination of the accuracy in the oxygen determination, however, showed that the result of the given method involving the chemical separation of ^{18}F should be corrected by a factor of $1.19 + 0.03$. This correction is due mainly to the coprecipitation of $PbCl_2$ with $Pb^{18}FCl$, which results in an overestimation of carrier recovery and thus an underestimation of oxygen content (4). In the present study, oxygen concentrations over 2×10^{17} atoms/cm^3 were usually determined nondestructively, and the correction was applied to the results of the separation-involving method.

This activation analysis has as its lower limit of sensitivity 1×10^{14} atoms/cm^3 for nitrogen and 5×10^{14} atoms/cm^3 for oxygen. Uncertainty in the determination of nitrogen is estimated to be 10 and 30% for concentrations of 1×10^{17} and 1×10^{15} atoms/cm^3, respectively. For oxygen, the accuracy is slightly better than for nitrogen in concentrations over 5×10^{15} atoms/cm^3 but is poorer in those under 2×10^{15} atoms/cm^3.

For granular samples a technique different from that described in Ref. (3) should be used in the charged particle bombardment. A cavity ($30 \times 20 \times 3$ mm) was made in an aluminum block and was covered by a pure silicon plate (200 μm thick). The sample grains were put in the cavity and bombarded by the charged particles through the plate. After the removal of the surface contamination by etching under controlled conditions, the induced annihilation activity was measured nondestructively and its decay followed. This

Key words: solubility, equilibrium distribution coefficient, infrared spectrophotometry of O, phase diagram of N-Si, phase diagram of O-Si, concentration of N and O in Si.

technique gives slightly poorer accuracies than the value described above.

Infrared spectrophotometry of oxygen.—The absorbance of the oxygen absorption peak at 1108 cm^{-1} was measured at room temperature by a popular spectrophotometer of grating type (Japan Spectroscopic Company Model IR-G). After examination of measurement conditions, the spectrophotometer was set as follows: beam cross section, 10 × 5 mm; scanning velocity, 600 cm^{-1}/hr; mechanical slit width, 0.6 mm (observed spectral half-width, 38 cm^{-1}). The sample thickness after a mirror-polishing with the aid of diamond paste was selected to be 2, 5, or 10 mm with uncertainty of ±5 μm. An ultrapure silicon, after being ascertained by activation analysis not to contain more than 3×10^{15} atoms/cm^3 of oxygen, was used as the reference sample. Throughout the present study, care was taken to the possible inhomogeneous distribution of oxygen within a single silicon slice (5).

Since a number of different values have been reported for the absorptivity of oxygen in silicon (5-11), we first examined it using various silicon samples of known histories. Their absorbances were measured and then they were analyzed by activation analysis. [The absorptivity is defined by the relation of $10^{-abc} = 10^{-A} = T/T_0$, where a is the absorptivity, b is the sample thickness, c is the concentration, and T and T_0 are the transmittance for the sample and for the pure matrix itself, respectively, after the correction of multiple reflection. Thus, the absorption coefficient is equal to (ln 10) ac.]

The results for as-grown samples are shown in Fig. 1 (for lower oxygen concentration range) and Fig. 2 (for higher oxygen concentration range), together with the calibration curve used in the present study. Two other calibration curves are also shown in Fig. 2. The ever-reported results for the comparison between infrared absorption and activation analysis (6, 9-11), vacuum fusion (5, 7, 8) of the lithium-diffusion method (9) can be grouped into two categories, one corresponding to an absorptivity of 0.073 ± 0.010 (cm · atomic ppm)$^{-1}$ (5-7) and the other giving considerably lower absorptivities. Our calibration curve belongs to the former. Many of our experimental plots in Fig. 2 lie in the upper side of our own calibration curve, which is the extrapolation from the experimental plots in Fig. 1. A discussion for the justification of our curve and for the explanation of the upward deviation of the experimental plots in Fig. 2 is given in a later section.

As low as 5×10^{15} atoms/cm^3 of oxygen can be detected by this spectrophotometry at room temperature, when a reliable reference sample is available. Its precision is better than activation analysis for concentrations over 2×10^{16} atoms/cm^3. The effect of surface

oxygen was examined by treating sample slices with various reagents under 200°C; no notable change of the absorbance has been observed.

Measurement of the effect of nitrogen on conductivity.—The resistivity of semiconductor silicon crystals of various nitrogen contents was measured by the usual method. Nitrogen was then removed from the crystals by three zone passes, and the change in the resistivity was measured. Further, the concentration of phosphorus and boron were determined by the melt-back technique (12), and their contribution to the resistivity of the zone-melted sample was subtracted in order to determine the effect of nitrogen on the resistivity.

Results and Discussion

Nitrogen and oxygen content of semiconductor silicon.—Nitrogen content of commercial semiconductor silicon was found to be always less than 1×10^{15} atoms/cm^3 and usually in the range of 1×10^{14} and 5×10^{14} atoms/cm^3. Oxygen contents of various kinds of semiconductor silicon have already been reported in our previous paper together with the carbon content (1). Most of the float-zone crystals contained from 2×10^{15} to 2×10^{16} atoms/cm^3 and Czochralski crystals usually had from 2×10^{17} to 1×10^{18} atoms/cm^3 of oxygen. It is clear that the oxygen content of the silicon single crystal depends on the condition of the crystal formation but scarcely on the starting material.

Solubility and equilibrium distribution coefficient of nitrogen.—Nitrogen was found to be distributed almost uniformly throughout the entire part of the sample prepared by zone-melting the Si_3N_4-inserted rod, except at its tail-end portion, as is shown in Fig. 3. In the

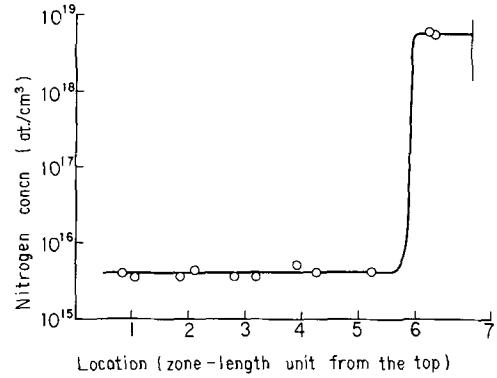

Fig. 3. Nitrogen distribution in a silicon rod after a passage of a nitrogen-saturated molten zone. Zone velocity: 0.4 mm/min.

zone-melting, the liquid phase was always saturated with nitrogen. The resultant solid silicon, however, could contain a slightly higher concentration of nitrogen than its solid solubility at the melting point of silicon, because the solid-liquid boundary might have been dendritic and thus the growing solid phase would have captured a small fraction of the liquid phase. In fact, the nitrogen concentration in the solid was found to depend on the zone-traveling velocity, as is shown in Fig. 4. The solid solubility at the melting point of silicon can be obtained by the extrapolation of the curve in Fig. 4 to zero velocity; it is $4.5 \pm 1.0 \times 10^{15}$ atoms/cm^3.

Nitrogen solubility in liquid silicon at its melting point was determined by the use of the suddenly solidified sample; it was found to be about 6×10^{18} atoms/cm^3. This value agrees fairly well with the value of around 10^{19} atoms/cm^3 reported by Kaiser and Thurmond (13). Almost the same nitrogen concentration was observed at the tail-end portion of the sample from the Si_3N_4-inserted rod when this portion was solidified rapidly. The equilibrium distribution coefficient of nitrogen between solid and liquid silicon, which is equal to the ratio of nitrogen solubility in solid silicon to that in liquid silicon at its melting point, has thus been determined to be about 7×10^{-4}.

From the above information, the phase diagram of the N-Si system in the extremely low nitrogen concentration range can be drawn. It is shown in Fig. 5. The lowering of the melting point (ΔT) was calculated from the relation

$$\Delta T = x(1 - K_{eq})RT_m^2/L \qquad [1]$$

where x is the concentration of the solute in the liquid phase in mole fraction, K_{eq} is its equilibrium distribution coefficient, R is the gas constant, and T_m and L are the melting point and the molar heat of fusion, respectively, of the solvent (for silicon, $T_m = 1683$°K and $L = 12.1 \pm 0.4$ kcal/mol). This equation is an integrated form of Clapeyron's equation and is valid for dilute solutions obeying Raoult's law. Among various silicon nitrides, Si_3N_4 is regarded as the stable form when contacted with silicon at its melting point (13). In the single-crystal formation of silicon, impurity nitrogen is removed very easily, because not only

is its distribution coefficient so small but also it evaporates so readily from a silicon melt (14).

Solubility and equilibrium distribution coefficient of oxygen.—The total oxygen concentration in silicon crystals obtained by solidification of the oxygen-saturated melt at various rates is shown in Fig. 6. For each rate, from 4 to 11 wafers were cut out of the zone-melted rods and analyzed by activation; the mean value of the result is indicated in Fig. 6 with standard deviation. The infrared-sensitive oxygen concentration is also shown in Fig. 6, although only the total concentration is necessary for the determination of the solubility. The solubility of oxygen in solid silicon and liquid silicon at its melting point can be given as the total oxygen concentration for the crystals solidified from the oxygen-saturated melt at an infinitely low rate and an infinitely high rate, respectively. Thus, although some arbitrariness may be seen in drawing the smooth curve in Fig. 6, the following constants have been obtained: (*i*) solubility of oxygen in solid silicon at its melting point, $2.75 \pm 0.15 \times 10^{18}$ atoms/cm^3; (*ii*) solubility of oxygen in liquid silicon at its melting point, $2.20 \pm 0.15 \times 10^{18}$ atoms/cm^3; and (*iii*) equilibrium distribution coefficient of oxygen in silicon, 1.25 ± 0.17.

The phase diagram of the O-Si system in the extremely low oxygen concentration range is shown in Fig. 7. The raising of the melting point was calculated by Eq. [1] for K_{eq} equal to 1.25. The stable oxygen silicide in contact with silicon is known to be SiO at the melting point of silicon but to be SiO_2 at somewhat lower temperatures (15). Oxygen in silicon forms a peritectic mixture and cannot be removed by segregation. Oxygen, however, evaporates easily from a silicon melt as SiO, and the oxygen content of the usual float-zone crystals is highly dependent on the conditions of atmosphere in the zone-melting.

Infrared-insensitive oxygen.—As is seen in Fig. 6, silicon crystals made from oxygen-saturated melt usually contained infrared-insensitive oxygen, with its quantity increasing with the decrease of the solidification rate. The upward deviation of the experimental

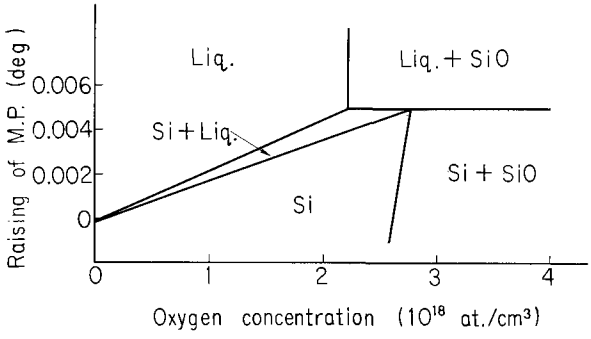

Fig. 7. Phase diagram of O-Si system in extremely low oxygen concentrations.

plots in Fig. 2 can be explained also by the presence of infrared-insensitive oxygen. The nature of this infrared-insensitive oxygen is thought to be aggregates of oxygen (16). The aggregation process and the solid solubility of oxygen in silicon have been studied by many workers (16-18). It has been reported that the aggregation proceeds fairly rapidly over 1000°C and that oxygen in heat-treated silicon is partly aggregated when its concentration is relatively high. Also from our observation on the change of the infrared absorbance in heat-treatment, it can be guessed that the aggregation proceeds to a notable extent after a melt of a relatively high oxygen content is solidified at a usual rate in industrial zone-melting or Czochralski process. Although the rate of aggregation depends on many factors, it is quite natural that the lower the solidification rate and the higher the total oxygen concentration, the larger the aggregated fraction, when other factors are the same. A tendency of the concenration dependence can be observed in Fig. 2.

The experimental relationship between the total and infrared-sensitive oxygen concentration in Fig. 1 is denoted by a straight line, indicating the absence of any notable amount of oxygen aggregate in this low concentration range. This gives a justification of our calibration curve, although many experimental plots in Fig. 2 lie on the upper side of it. The infrared-insensitive fraction, however, has been found mostly to be less than 20% of the total oxygen in as-grown silicon crystals.

Effect of nitrogen on semiconductor property.— The resistivity of an N-type crystal containing nitrogen up to the saturation concentration at the melting point 4.5×10^{15} atoms/cm^3, was found to be 37 ohm-cm, showing the existence of 1.4×10^{14}/cm^3 of free electrons. By the melt-back technique, boron content was found to be about 2×10^{12} atoms/cm^3. Thus, even when the free electrons were entirely due to the nitrogen, the ionization degree of nitrogen should be less than 4%. The phosphorus content of the original crystal was calculated from the measured resistivity of the zone-melted crystal by the use of its reported effective distribution coefficient which was regarded as 0.35 for our solidification rate of about 0.5 mm/min; it was 1.1×10^{14} atoms/cm^3. Therefore, the number of free electrons in the silicon crystal excluding those derived from the phosphorus atoms amounts to only about 1% of the number of nitrogen atoms. When the evaporation of phosphorus in zone-melting is taken into account, the ionization degree of nitrogen should be less than 1%.

A still higher resistivity (7000 ohm-cm) was reported by Kaiser and Thurmond for silicon crystals grown from a nitrogen-saturated melt (13). They calculated the distribution coefficient of nitrogen to be less than 10^{-7} on the assumption that the nitrogen was totally ionized in silicon, although they did not rule out the possibility of the presence of un-ionized nitrogen. Now the existence of un-ionized nitrogen has been proved, and the distribution coefficient of less than 10^{-7} has been shown to be incorrect.

Comparison of the solubility and distribution coefficient.—A summary of the solubilities of carbon, nitrogen, and oxygen in solid and liquid silicon at its melting point (or more correctly at the eutectic or peritectic point) and their equilibrium distribution coefficients is given in Table I. The solubilities of the three elements in liquid silicon are of the same order and are considerably lower than those of many metallic elements, which are soluble up to 10^{20}-10^{22} atoms/cm^3 (19). The solubility in solid silicon, on the other hand, is markedly different among the three elements. Oxygen is more soluble than many refractory metals in solid silicon but less soluble than many metals of low melting points (with a few exceptions such as zinc), and nitrogen is one of the least soluble elements (19). The distribution coefficients of elements within a given group of the Periodic Table have been known to increase with the decrease of atomic number (19). This rule, however, does not hold true for carbon and nitrogen, which have smaller distribution coefficients than silicon and phosphorus.

Explanation of the low solubilities and the small distribution coefficients.—The low solubilities can be explained by the following two properties of the three elements: (*i*) they form stable silicides of vast dissociation energies (SiC, Si_3N_4, and SiO), and (*ii*) they are significantly smaller than silicon in atomic size. The small distribution coefficients of carbon and nitrogen can also be explained by the latter.

As is well known, the solubility in general can be given by the relation of

$$[M] = \exp[\Delta S/R] \exp[-\Delta H/RT] \qquad [2]$$

where $[M]$ is the solubility of a solute M in mole fraction, S is the entropy of solution, R is the gas constant, ΔH is the heat of solution, and T is the absolute temperature. Since H for a solid solution implies the energy necessary for the rupture of its crystal lattice, the following tendency is regarded as existing naturally and has actually been observed (19): the larger the heat of vaporization of the solute substance, the higher its ΔH and consequently the lower its solubility. For the present three elements when dissolved in the atomic state, the heat of dissociation of the stable silicide into silicon bulk, and monatomic gas of carbon, nitrogen, or oxygen should be regarded as equivalent to the heat of vaporization for a usual metallic solute substance. The heats of dissociation calculated by the use of thermochemical tables (15, 20) are shown in Table I. They are as large as the heat of vaporization of a refractory metal (*e.g.*, Zr, 146; Nb, 172; W, 203; Re, 186 kcal/mol at 25°C), and this can be the major reason for the low solubilities. Oxygen in liquid silicon may be in the molecular state of SiO, because its heat of vaporization is about 70 kcal/mol (15). However, this molecule is so different from silicon in atomic size and shape that its solubility should be low, as is shown by the elastic model theory cited just below.

The replacement of an atom in its own crystal by a foreign atom of a different size introduces a strain

energy into the crystal, which is a component of ΔH. The strain energy ($[E^{st}]$) for a substitutional impurity in silicon has been shown to be given by the relation of

$$[E^{st}] = 22 \times 10^{20} (\Delta r)^2 \text{ cal/mol} \quad [3]$$

where Δr is the disparity of tetrahedral radius (in angstroms) between silicon and the impurity (21). Among various theories treating the solubility or alloy formation, the elastic model theory emphasizes the role played by the disparity of atomic size (22). This theory shows that: the greater the disparity, the less the mutual solubility both in liquid and solid solution and also the less the distribution coefficient. The tetrahedral radii and atomic radii of the three elements are shown in Table I. For silicon they are both 1.17Å. Since even thallium, lead, and bismuth are larger than silicon by only about 3Å in tetrahedral radius, the disparity between silicon and the three elements should be considered to be remarkable. Although this theory is regarded as not always reasonable (22), it can explain the small solubilities of the three elements and also the small distribution coefficients of carbon and nitrogen.

Since nitrogen in solid silicon is not ionized, it is probably not substitutional. The much higher ionization potential of nitrogen (14.54 eV) than the ionization potentials of other Group V elements (P, 11.0; As, about 10; Sb, 8.46; Bi, about 8 eV) can be an additional cause of the undetectably low concentration of ionized substitutional nitrogen.

Numerical value of ΔH and ΔS.—It would be worthwhile calculating ΔS in Eq. [2] by the use of the solubility in Table I and of the reported ΔH. For carbon in liquid silicon, Scace gave 59 kcal/mol for ΔH (23); thus ΔS is obtained as about 17 cal mol^{-1} deg^{-1}. For carbon in solid silicon, the value of ΔH reported by Bean and Newman (18) agrees closely with our result (24), the latter being 55 ± 4 kcal/mol. It thus follows that $\Delta S = 88 \pm 2.6$ cal mol^{-1} deg^{-1}. Two different values have been reported for ΔH of oxygen in solid silicon: 22 ± 2 kcal/mol by Hrostowski (17) and 38 ± 4 kcal/mol by Bean and Newman (18). The former and the latter give -6.4 ± 1.5 cal mol^{-1} deg^{-1} and 3.0 ± 2.5 cal mol^{-1} deg^{-1}, respectively, for ΔS. We followed their experiment; our result is closer to the former than to the latter. The smaller ΔH of oxygen than that of carbon makes oxygen more soluble in solid silicon than carbon in spite of its very small ΔS.

Anomalous distribution coefficient of oxygen.—Oxygen in solid silicon is known to be interstitial, forming a Si—O—Si bonding. The small size and the bivalent nature with its own bond angle of oxygen atom are considered favorable for oxygen to be in this state. This can be the reason for the higher solid solubility of oxygen than that of carbon and nitrogen and also of its anomalous distribution coefficient. From the electronic configuration of nitrogen atom, the formation of a Si—N—Si bonding in silicon crystal is regarded as the least probable.

Acknowledgment

The authors would like to express their thanks to the Cyclotron Group of the Institute of Physical and Chemical Research for their bombardment services in the activation analysis.

Interface Reactions of B_2O_3-Si System and Boron Diffusion into Silicon

E. Arai, H. Nakamura, and Y. Terunuma

Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo, Japan

ABSTRACT

The interface reactions of the B_2O_3-Si system were studied by infrared spectroscopy, electron and x-ray diffraction, etc.

The compound, which was produced at the B_2O_3-Si interface in the temperature range of 900°-1200°C closely resembled SiB_4 or SiB_6 in the diffraction measurements. The growth rate of silicon oxide, produced in the interface in an oxygen atmosphere, was several times as fast as that in a nitrogen atmosphere. These growth rates are much faster than the ordinary growth rate of silicon oxide in a dry oxygen atmosphere. From these data, the rate constants of growth of silicon oxide were estimated, assuming the relationship of the parabolic oxidation.

Comparing these results with the doping amount of boron in silicon, it was confirmed that the rate-determining step of the transfer of boron into silicon was classified by whether the above Si-B compound was present or not.

Although a number of authors have studied the diffusion of boron into silicon, no detailed measurements concerning the reactions of the glass-silicon interface have been involved (1-4). The purpose of the present work is to study the reactions of the interface.

There are many diffusion sources for diffusion of boron into silicon, *i.e.*, boron tribromide (BBr_3), boron nitride (BN), and diborane (B_2H_6) as the gas phase diffusion sources, and boron doped oxide as the solid or liquid phase diffusion source. By using all of these sources, boron oxide is formed on the silicon surface. It is reduced to elemental boron reacting with silicon as follows

$$B_2O_3 + \frac{3}{2}\,Si \rightleftarrows 2B + \frac{3}{2}\,SiO_2 \qquad [1]$$

and the reduced boron diffuses into silicon.

The two significant problems for diffusion of boron into silicon are the influence of oxygen gas in the atmosphere and the growth condition and the properties of the compound insoluble in a fluoric acid, which is produced in the glass-silicon interface for high boron doping.

This insoluble compound has been studied by Busen *et al.*, using an ellipsometer and it was assumed to be a Si-B phase from the facts that the refractive index of this compound was between 1.6 and 1.7, which was larger than that of boro-silicate glass, and it could be converted to a substance which was removed by standard glass etches by means of a low-temperature oxidation (2, 3). Further, it has been known that the growth rate of this compound is depressed as the oxygen concentration in the atmosphere increases. Therefore, the following reactions are also expected

$$x\mathrm{Si} + y\mathrm{B} \rightleftarrows \text{Si-B compound} \qquad [2]$$

$$\text{Si-B compound} + O_2 \rightleftarrows SiO_2 + B_2O_3 \qquad [3]$$

The doping amount of boron into silicon decreases with increase of the oxygen concentration in the atmosphere and this effect is more marked at a low temperature. Therefore, it is assumed that the silicon surface under the glass is oxidized by the oxygen in the atmosphere, by the reaction

$$Si + O_2 \rightleftarrows SiO_2 \qquad [4]$$

This paper identifies the insoluble compound and reports on a study of its electrical resistivity and its growth condition. Also, measurement was made of the growth rate of silicon oxide at the interface and of the amount of boron doped into silicon by changing the oxygen concentration in the atmosphere and the diffusion sources.

From these measurements the rate-determining step of the transfer of boron into silicon is estimated.

Key words: B_2O_3-Si system, Si-B compound, SiB_4, SiB_6, silicon oxidation, boron diffusion.

Experimental Procedure

BN (source I) and B_2H_6-O_2 gas system (source II) were used as the diffusion sources from gas phase, and boron doped oxide (source III) and pure boron oxide (source IV) were used from the solid or liquid phases. The boron doped oxide (source III) and pure boron oxide (source IV) were deposited on silicon wafers, using the oxidation of SiH_4 and B_2H_6 at 400°C and also that of $(CH_3O)_3B$ at 550°C. The deposition rate of the latter system was about 0.2-0.3 μ/min and the deposition time was 20 min, unless otherwise noted. It should be noted that measurements of the deposition rate of pure B_2O_3 are not satisfactory in accuracy because of a strong tendency to absorb water.

The silicon samples used were 100-200 ohm-cm and 1-2 ohm-cm resistivity, n-type with a mirror-polished (111) surface. The former wafers were used only to measure the infrared absorption spectra.

The insoluble compound produced in the interface was studied by infrared spectroscopy, and electron and x-ray diffraction. To correct for the lattice absorption bands of silicon in an infrared transmission examination, a bare companion wafer of approximately the same thickness was always used in the reference beam of the double beam spectrophotometer. The electrical resistivity of the compound was obtained from the resistance and the thickness of the compound, which were determined by the difference of the sheet resistivity and the weight before and after the removal of the layer, assuming the density of this layer to be 2.55 g/cm^3, which was given by Brosset as that of SiB_4 (5) or to be 2.43 g/cm^3, given by Cline as that of SiB_6 (6).

The growth rate of silicon oxide in the interface during the diffusion of boron into silicon was obtained from the changes of the absorption band of the Si-O at 9.2μ. The sheet resistivity of the diffused layer was measured after removal of the insoluble compound, which was changed to a soluble compound by means of a wet oxygen oxidation (saturated with 95°C water) at 800°C for 5 min. The surface concentration of boron in silicon was determined by differential conductance measurements. The procedure consisted of successively measuring the sheet resistivity of the wafer followed

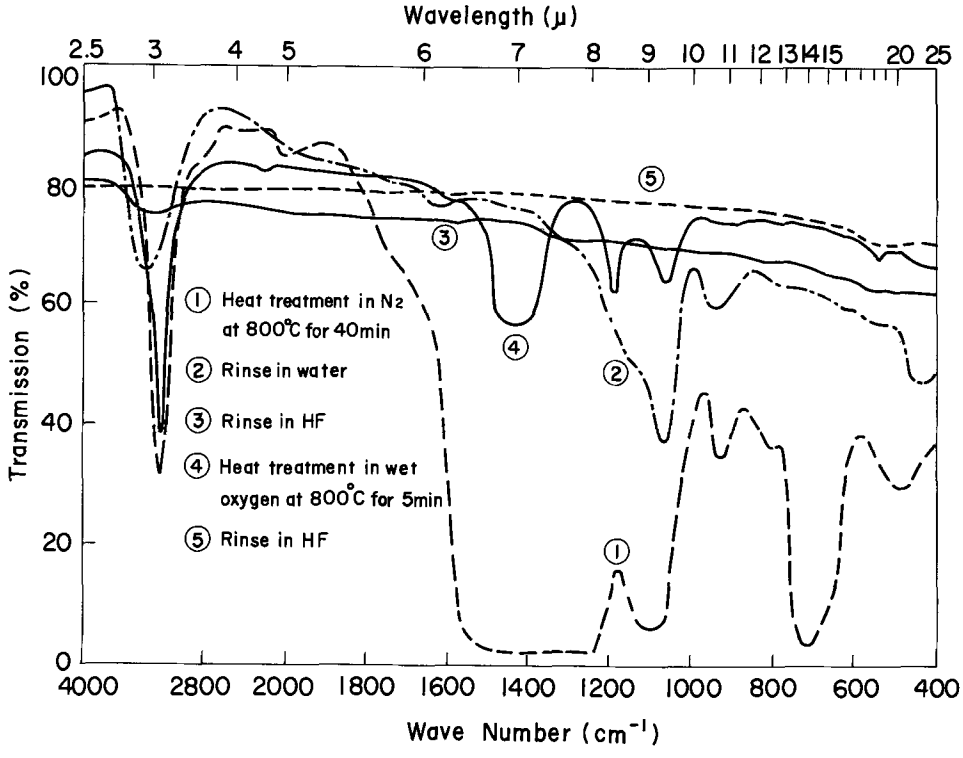

Fig. 1. Changes of absorption spectrum obtained after successive various treatments for source IV.

by the removal of a silicon layer of controlled thickness. Sectioning of the diffused layer was made by anodically growing an oxide of 350Å thickness, corresponding to a consumption of a 140Å silicon layer. The oxide was subsequently removed by etching in a buffered HF solution.

Experimental Results

Identification and properties of the insoluble compound.—The insoluble compound produced in the B_2O_3-Si interface has been assumed to be a Si-B compound by many authors (1, 2) but no direct identification of it has been accomplished. The layer was verified to be a Si-B compound by infrared spectroscopy as follows. Figure 1 shows the infrared absorption spectra for the sample of source IV obtained after successive treatments involving (curve 1) heating in nitrogen gas at 800°C for 40 min, (curve 2) rinse in water to remove the pure B_2O_3 unreacted, (curve 3) rinse in an HF solution to remove the SiO_2 produced in the interface, (curve 4) exposure to wet oxygen at 800°C for 5 min, and (curve 5) rinse in an HF solution to remove the unresolved layer which was oxidized.

Since the spectrum of curve 1 in this figure has the large and broad band of B-O at about 7μ, it is supported that a large amount of B_2O_3 remained unreacted. In the spectrum of curve 2 the band of the B-O disappears completely but the bands of the Si-O at 9.2μ and of the Si-O-B at 10.8μ remained unchanged (7, 8). No absorption band is observed in the spectrum of curve 3 but the insoluble layer is visible on the silicon surface. The absorption bands of the B-O at 7μ, Si-O at 9.2μ, and B-OH at 8.4μ appear again in the spectrum of curve 4. There are no absorption bands in the spectrum of curve 5 and the surface became hydrophobic for the first time. From these experimental results, it is concluded that the insoluble layer is a Si-B compound, which is easily oxidized in a wet oxygen atmosphere at a low temperature and changed to the mixed SiO_2-B_2O_3 system containing water. Since the Si-B compound and SiO_2 are produced by heat-treatment in the interface of the system, which at first consists of a B_2O_3 layer deposited on Si, the system is separated in three successive layers of B_2O_3, SiO_2, and Si-B compound in order on the Si specimen, where SiO_2 contains boron because of the presence of the Si-O-B absorption band.

To identify the Si-B compound, reflection-electron and x-ray diffraction were utilized. X-ray diffraction was carried out with a diffractometer using V-filtered CrKα radiation. Figure 2 shows the electron diffraction patterns of the Si-B compound which were produced by source IV, after heat-treatment at 900°, 1100°, and 1200°C for 4.5 hr and by source II at 1100°C for 10 min. The lattice constants and the relative intensities obtained by the electron and x-ray diffraction are summarized in Table I. The lattice constants were measured in the range from 2θ = 20°-35° for specimens produced below 1100°C and 20°-55° for those at 1200°C in the x-ray diffraction. Table I also shows the data on SiB_4 and SiB_6.

The electron diffraction maxima in Fig. 2 are not sharp and the error due to the broadness of the peaks is 10%. From these broad peaks it is expected that samples never experience the extended heating required to crystallize completely.

Although the measured values in the present work do not always coincide with all maxima of SiB_4 or SiB_6 (orthorhombic and cubic structures) (6, 15) in Table I, the compound produced below 1100°C for source IV is similar to orthorhomic SiB_6, and that produced at 1100°C for source II and at 1200°C for source IV is similar to cubic SiB_6 or SiB_4 in the diffraction maxima.

According to the Si-B phase diagram, reported by Elliot, silicon is in an equilibrium state with SiB_4 below 1269°C and with SiB_6 above 1269°C (9). On the other hand, Brosset *et al.* indicated that SiB_4 can be formed by sintering in the 1200°-1370°C temperature range, although the compound is metastable, only being transitory to the formation of the stable SiB_6 in this temperature range (5). Rizzo and Bidwell reported that B and SiB_4 free of SiB_6 were produced at 1100°C, using the reaction between Si and molten B_2O_3, and the structure of SiB_4 was rhombohedral (16). These experimental conditions are the same as in the present work except for sintering.

From these results and discussions, the Si-B compound obtained in the present work is expected to be SiB_4 and/or SiB_6. More detailed measurements must be carried out to identify the compound completely.

The electrical resistivity of the Si-B compound was measured and was found to be 0.01-0.03 ohm-cm. The samples were prepared at 950°, 1050°, and 1150°C, using source IV. No definite relationship could be

found between the electrical resistivity and the time or temperature of heat-treatment. This value is smaller than the electrical resistivity of the SiB_6 single crystal, 0.2 ohm-cm, reported by Cline (6). It is not possible, from these measurements, to conclude a reason for this low resistivity.

Measurements of growth rate of silicon oxide produced at interface.—The growth rate of silicon oxide at the silicon-glass interface was measured by the changes of the infrared absorption band of the Si-O at 9.2μ. Specimens were prepared by heat-treatment at 700°, 800°, and 900°C in a nitrogen and an oxygen atmosphere, using source IV. An example of the changes of infrared absorption spectrum by the heat-treatment at 800°C in an oxygen gas is shown in Fig. 3. From this figure, it is found that the peak height of the Si-O band at 9.2μ and the Si-O-B band at 10.8μ increase with time, but that the broad band at about 7μ hardly changes. Figure 4 shows the changes of the absorption amount of Si-O band at 9.2μ with the time of the heat-treatments in a nitrogen gas at 700°, 800°, and 900°C and in an oxygen gas at 900°C. The absorption amount of the Si-O band and the thickness of the silicon oxide, which was made from the ordinary oxidation of silicon in a dry oxygen gas at 900°C are also shown in this figure. It should be noted that the measured values are the sum of the absorption amount and thickness of the silicon oxide produced in both surfaces of the specimens. From this figure, it can be seen that the silicon oxide produced in an oxygen atmosphere is about 3 times as great as that in a nitrogen atmosphere and 70 times as great as that made from the ordinary oxidation of silicon in a dry oxygen gas at 900°C; the silicon oxide is produced in proportion to the square root of the time of heat-treatment within the time measured.

Influence of Si-B compound on boron diffusion.—The surface concentration and sheet resistivity of the boron

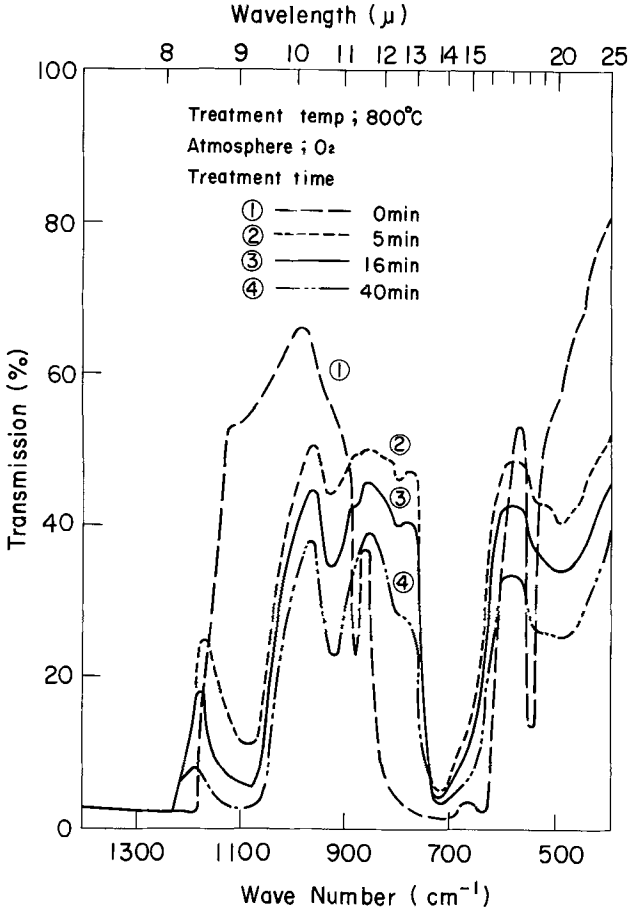

Fig. 3. Changes of absorption spectrum of B_2O_3-Si system in an oxygen atmosphere at 800°C for source IV.

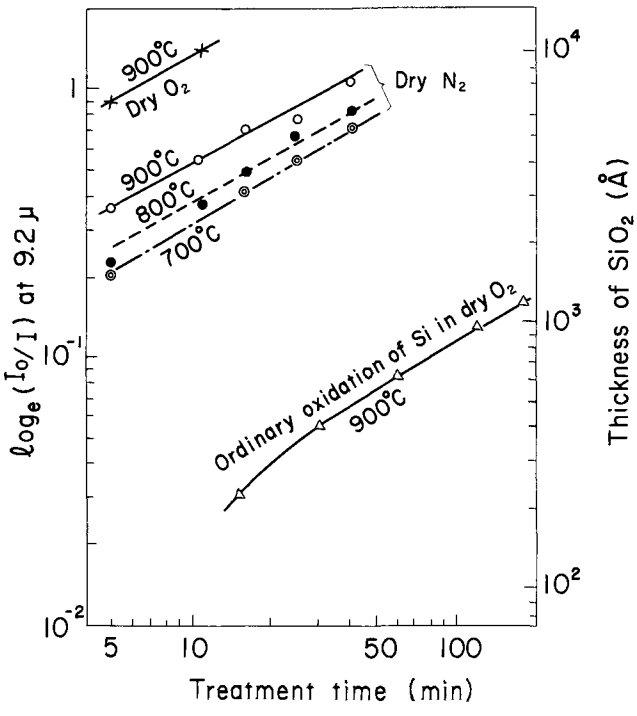

Fig. 4. Dependence of absorption amount of Si-O band at 9.2μ on time of heat-treatment for source IV.

diffused layer in silicon were measured, varying the molar per cent of B_2H_6 in the gaseous reactants for the deposition of the doped oxide (source III and IV). In this measurement, the thickness of the doped oxide was constantly maintained at 0.2μ and the specimens were heated at 1050°C for 15 min in a nitrogen atmosphere. The results are shown in Fig. 5. From this figure, it is found that the surface concentration increases with the molar per cent of B_2H_6 up to about 12%, then it saturates above that, indicating that the solid solubility of boron in silicon at 1050°C is about 2×10^{20} cm^{-3}. This is in good agreement with the experimental value given by Vick and Whittle (1).

Further, it is found that the sheet resistivity decreases with the molar per cent B_2H_6 up to about 12%, then increases gradually. The B_2O_3 content in the doped oxide at 12 mole per cent (m/o) B_2H_6 in the gaseous reactants is expected to be about 12 m/o from the measurements of the ratio of the 7μ B-O and 9μ Si-O infrared absorption peaks, using the data in Ref. (4).

It is interesting that the sheet resistivity at the 100% B_2H_6 (100% B_2O_3) largely depends on the quantities of B_2O_3, *i.e.*, the thickness of B_2O_3 and increases with

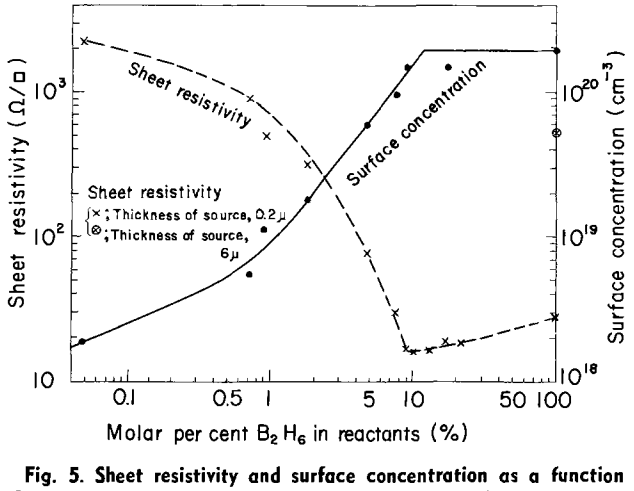

Fig. 5. Sheet resistivity and surface concentration as a function of molar per cent B_2H_6 in reactants Samples were heat-treated at 1050°C for 15 min in a nitrogen atmosphere using sources III and IV.

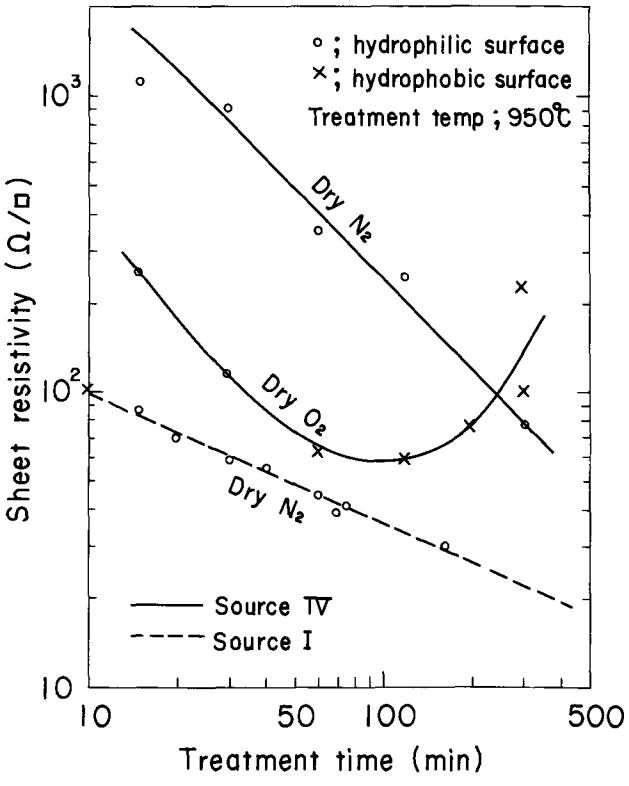

Fig. 6. Dependence of sheet resistivity and presence of the Si-B compound on time of heat-treatment at 950°C for sources I and IV.

it, as shown in the figure. After diffusion and removal of the doped oxide, the hydrophilic nature, characteristic of the presence of the Si-B compound, was observed all over the surface, when the molar per cent B_2H_6 exceeded about 12%. This value coincides with the molar per cent where the surface concentration saturates and the sheet resistivity turns over.

Figure 6 shows the dependences of the sheet resistivity on the time of heat-treatment. Samples were heat-treated at 950°C in nitrogen and oxygen atmospheres for source IV, and in a nitrogen atmosphere for source I. It is also shown in this figure whether the Si-B compound was present or not on the silicon surface, which was determined by the hydrophilic nature of the silicon surface.

In case of source IV, heated in a nitrogen atmosphere, the thickness of the compound increased rapidly with time up to 1 hr and was saturated beyond it, as shown in Fig. 7. These measurements were carried out after oxidizing the Si-B compound in the wet oxygen atmosphere in place of measuring the thickness of the Si-B compound directly. It was impossible to determine the thickness of the Si-B compound for source I in a nitrogen atmosphere and for source IV in an oxygen atmosphere because it was too thin to measure.

From Fig. 5-7 it is found that the doping amount of boron in silicon decreases as the growth rate of the Si-B compound increases and its growth rate is depressed in the oxygen atmosphere. Further, it was also confirmed experimentally that it took more time for the Si-B compound to disappear in the oxygen atmosphere when the quantities of B_2O_3 are increased.

Influence of oxygen on sheet resistivity.—The doping amount of boron into silicon depends markedly on the oxygen concentration in the atmosphere. A comparison was made of the doping amount of boron for source I where a small amount of the Si-B compound is produced in the silicon surface, with that for source IV where a large amount of the Si-B compound is produced. A plot of the sheet resistivity *vs.* the oxygen concentration in the atmosphere is given in Fig. 8. From this figure, it is found that a region of the oxygen concentration, where the sheet resistivity is constant,

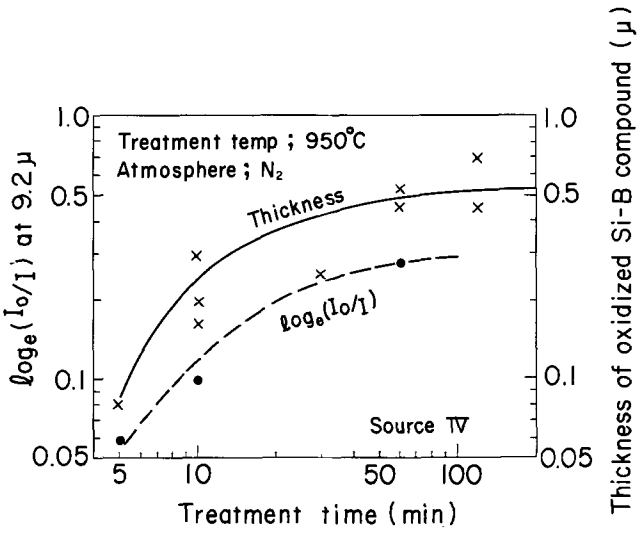

Fig. 7. Growth amount of Si-B compound *vs.* time of heat-treatment at 950°C in a nitrogen atmosphere for source IV. Samples were measured after oxidizing the Si-B compound.

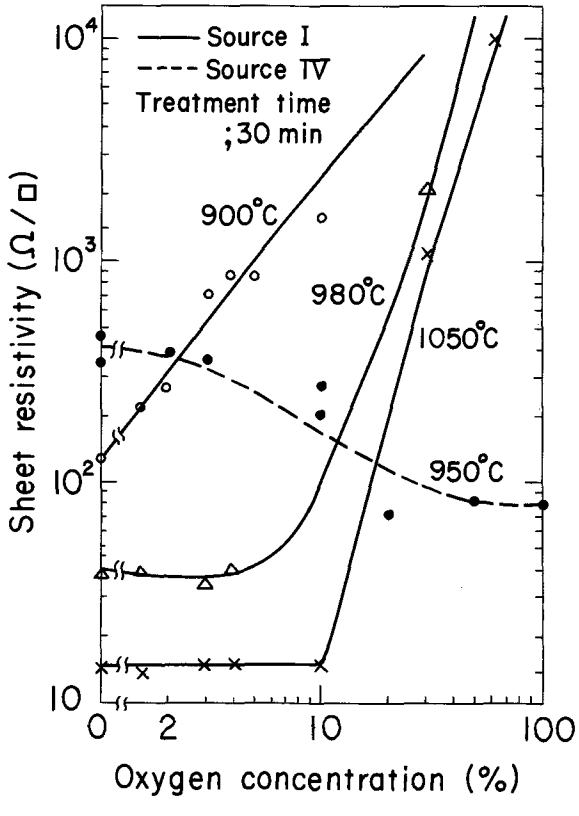

Fig. 8. Dependence of sheet resistivity on oxygen concentration in the atmosphere for sources I and IV.

increases with the temperature of heat-treatment and the sheet resistivity increases with the oxygen concentration rapidly beyond the constant regions for source I. It was confirmed that the surface concentration of the diffused layer coincided with the solid solubility of boron in silicon in these constant regions. On the other hand, it is found in this figure that the sheet resistivity decreases with the oxygen concentration in the case of source IV. In this case, it was also confirmed that the thickness of the Si-B compound decreased with the oxygen concentration and the dependence of the sheet resistivity on the oxygen concentration became similar to that of source I, if the thickness of the deposited B_2O_3 (in source IV) was decreased below 1μ.

To investigate the effect of an oxygen atmosphere upon the diffusion of boron in more detail, the follow-

ing experiment was carried out. Boron was diffused using the B_2H_6-O_2 gas system (source II) where the B_2H_6 and O_2 gases in the atmosphere were removed, leaving N_2 gas only to flow after time t_G, keeping the total diffusion time constant (t = 30 min). The results are shown in Fig. 9a and 9b. As seen in Fig. 9a, only 3 min for t_G is long enough to obtain the largest amount of diffused boron in this system at 800°C and the amount is rather decreased with a longer t_G. If the above data are plotted against time t-t_G, as shown in Fig. 9b, it is found that the sheet resistivity decreases parabolically with time after removal of the doping gases. This fact indicates that the diffusion of boron does not occur when the doping gas stream is flowing. On the other hand, the amount of diffused boron at 900° and 1100°C increases with t_G gradually or is maintained constant, as shown in Fig. 9a.

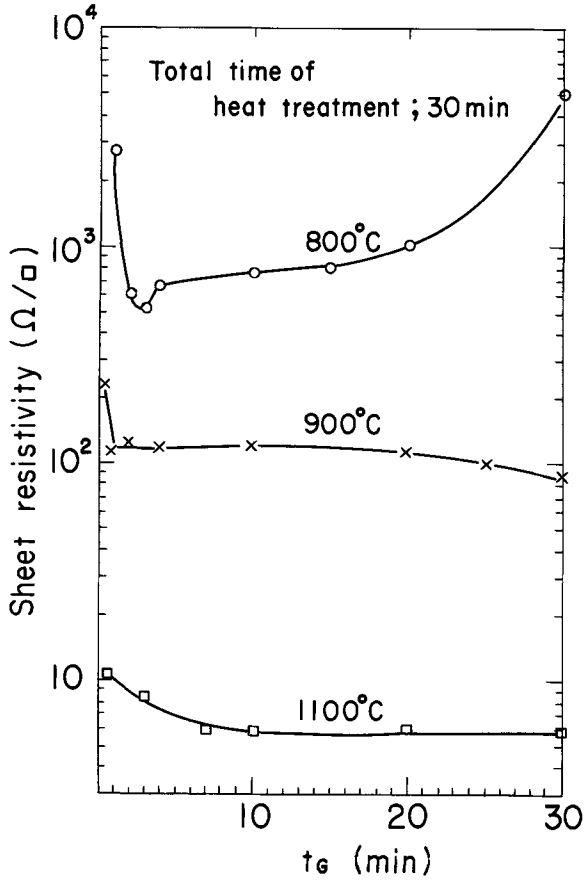

Fig. 9a. Dependence of sheet resistivity on t_G at 800°, 900°, and 1100°C for source II (B_2H_6-O_2 gas system, B_2H_6; 250 ppm, O_2; 0.2%). Total time of heat-treatment, t, is 30 min.

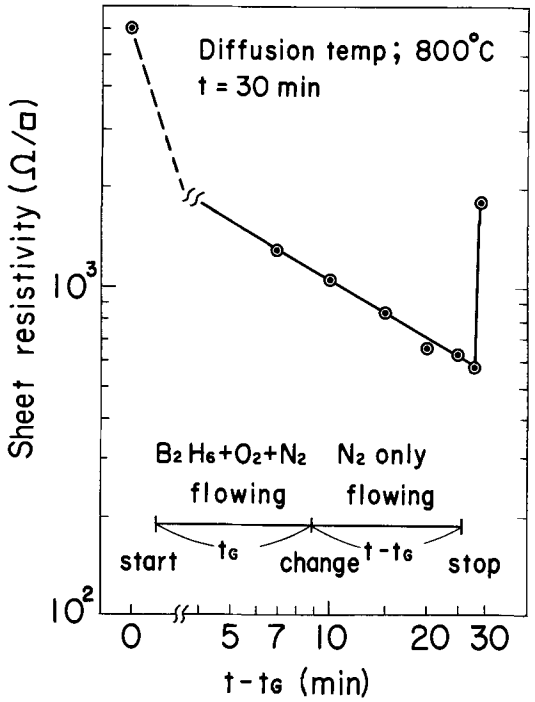

Fig 9b. Sheet resistivity as a function of t-t_G at 800°C for source II, obtained from the data of Fig. 9a.

From these experiments it is assumed that the oxygen in the atmosphere greatly depresses the doping amount of boron into silicon at a low temperature in case of source I or II which supply a small amount of B_2O_3 on the silicon surface.

Discussion

Role of oxygen in interface reaction.—The growth rate of SiO_2 in the silicon-glass interface for source IV is promoted by the oxygen in the atmosphere, as shown in Fig. 4. In order to interpret these results, we must consider the interface reactions of Eq. [1], [3], and [4].

From this figure, it is expected that the growth rate of SiO_2 is limited by the diffusion process resulting in the parabolic relationship

$$w = Kt^{1/2} \qquad [5]$$

where w is the SiO_2 thickness, t is the heat-treatment time, K is the rate constant.

Further, it is expected that the diffusing species which can limit the growth rate of SiO_2 are B_2O_3 in glass in a nitrogen atmosphere, and B_2O_3 and/or oxygen in glass in an oxygen atmosphere. If the growth rate of SiO_2 is given by the sum of the growth rate of SiO_2 as follows, we have

$$w = Kt^{1/2} + K't^{1/2} \qquad [6]$$

instead of Eq. [5] where K and K' are the growth rate constants due to the diffusion of B_2O_3 and oxygen in glass, respectively (*i.e.*, the first term in Eq. [6] corresponds to the reaction of Eq. [1] and the second term to that of Eq. [3] or [4]).

Table II shows the rate constants of the parabolic oxidation calculated by Eq. [6], using the data from Fig. 4. From these data, it is found that K' is about 40 times as much as the ordinary oxidation rate constant for silicon at 900°C and the activation energy of K is about 0.2-0.3 eV. The former result can be explained by the fact that the borate glass presents very little resistance to the diffusion of oxygen, comparing with pure SiO_2 (10). The activation energy of K is expected to be a half of that of the viscosity of a mixed SiO_2-B_2O_3 system, because K is in proportion to the square root of the diffusion coefficient of B_2O_3 in glass and the diffusion coefficient of B_2O_3 is in inverse proportion to the viscosity of the glass. The activation energy of the viscosity of the above glass is 0.65 (B_2O_3: 100%) to 1.3 (B_2O_3:50%) eV (11) and a half of these values is a little higher than the activation energy of

Table II. Relationship of parabolic oxidation rate constants for interface reactions of B_2O_3-Si system

Source	Ambient	Temp. (°C)	Rate const. K (Å)	Rate const. K' (Å)	$K+K'$ (Å)
Source IV	dry N_2	700	761	—	761
Source IV	dry N_2	800	904	—	904
Source IV	dry N_2	900	1225	—	1225
Source IV	dry O_2	900	1225	1837*	3062
Source II		800			~87**
Ordinary oxidation of Si	dry O_2	800	—	17	17
	dry O_2	900	—	45	45

* This value was obtained by substracting the value of K at 900°C in dry N_2 from the total rate constant, $K+K'$ at 900°C in dry O_2.

** This value was calculated from the data of Ref. (14), assuming the parabolic relationship.

K. Thus far, it is not possible to explain the difference between these two values of the activation energy.

If we use diffusion sources such as source I or II the growth of SiO_2 in the silicon surface is not parabolic, as reported by one of the authors (14), and it is expected that the rate-determining step of the interface reaction of Eq. [1] is the deposition of B_2O_3 on silicon, but not the diffusion of B_2O_3 in glass.

Si-B compound growth conditions.—The diffusion current of boron per unit area, $J(t)$, which enters through the surface of the silicon, is given by

$$J(t) = N_0 \sqrt{\frac{D}{\pi t}} \qquad [7]$$

if the diffusion sources are assumed to be infinite (12), where N_0, D, and t are the surface concentration, diffusion coefficient of boron in silicon, and diffusion time, respectively. $J(t)$ decreases in inverse proportion to the square root of the diffusion time and becomes the maximum value, $J_M(t)$, when N_0 reaches the solid solubility of boron in silicon. According to Fig. 6, however, the sheet resistivity decreases more rapidly for source IV than for source I in a nitrogen atmosphere. It is also seen that the sheet resistivity decreases in inverse proportion to the square root of the diffusion time for source I and is lower than that for source IV. Further, the amount of Si-B compound produced in case of source IV was larger than that in case of source I. Considering the composition ratio of Si to B in the Si-B compound and the solid solubility of boron in silicon to be of the order of 10^{20} cm^{-3}, the Si-B compound is expected to be an approximately infinite diffusion source, even if the amount of the compound is very small.

From these considerations, it is expected that the Si-B compound grows under the conditions of Eq. [2] when the production rate of the elemental boron produced under the conditions of Eq. [1] is much more than $J_M(t)$ and it decreases in the opposite case, decomposing it to the diffusion source; the boundary of silicon and the Si-B compound moves to the silicon side in the generation process and to the Si-B compound side in the degeneration process. The production rate of the elemental boron produced in the interface is controlled by the diffusion of B_2O_3 in the vicinity of the interface, as described in the previous section. The liquidus curve in the phase diagram of the B_2O_3-SiO_2 system is fairly flat or very sensitive to the concentration of the SiO_2 at a low temperature (13). Further, the viscosity of this system is very high and becomes higher with the concentration of SiO_2. The samples, therefore, never experience the time required to reach the equilibrium value shown in the phase diagram below liquidus because SiO_2 continues to grow under Eq. [1] and/or [4] during the drive-in process. This effect apparently corresponds to the movement of the liquidus curve of the glass to the side of B_2O_3. From the above discussions, it is expected that the reasons why the growth of the Si-B compound is depressed in an oxygen atmosphere at a low temperature are the promotion of the growth rate of SiO_2 and the high viscosity of this glass.

Boron diffusion rate-determining step.—Based on the above discussions of the growth of SiO_2 and Si-B compound in the interface, the roles of oxygen on the doping amount of boron and the rate-determining step of the transfer of boron into silicon are discussed.

One of the authors reported that boron diffused more quantitatively and more uniformly, and that the growth rate of SiO_2 in the glass-silicon interface was lower in the B_2H_6-CO_2 gas system than in the B_2H_6-O_2 gas system at 800°C. He explained this fact in terms of the oxygen concentration in the atmosphere (14).

From Fig. 8 and 9 (a and b) and Ref. (14) the reason for the doping amount of boron into silicon being depressed in an oxygen atmosphere at a low temperature is expected to be that the temperature dependence of diffusion coefficient of B_2O_3 or oxygen in glass is less than that of the diffusion coefficient of boron in silicon, *i.e.*, the values of the activation energy of Eq. [1], [3], and [4] are smaller than that of the diffusion coefficient of boron in silicon. Therefore, it is concluded that the diffused layer of boron in silicon or the Si-B compound is oxidized and, in case of a small amount of source, such as source I or II, the diffused amount of boron in glass is rapidly decreased with the growth of SiO_2 at a low temperature. On the other hand, in the case of a large amount of source, such as source III or IV, the doping amount of boron is not always depressed if the diffused amount of boron in glass is not decreased with the growth of SiO_2 even at a low temperature, *i.e.*, if the production rate of elemental boron under Eq. [1] is large enough to compensate for the growth rate of SiO_2 under Eq. [3] or Eq. [4].

From the above experimental results and discussions, it is concluded that the rate-determining step of boron into silicon is classified by the presence or absence of the Si-B compound. In the presence of the Si-B compound in the interface, the rate-determining step is the diffusion of boron in silicon, whether the compound is generated or degenerated. In this case, the surface concentration of boron in silicon agrees with the solid solubility of boron.

In the absence of the Si-B compound, the rate-determining step is the diffusion of boron in glass. The diffusion process of boron in B_2O_3-Si system is shown in Fig. 10. The reproducibility and uniformity of boron diffusion into silicon, therefore, depends strongly on the interface reaction, which is controlled by the amount of B_2O_3 and the oxygen concentration in the atmosphere.

Conclusion

1. The compound insoluble in a HF solution produced at the interface in the 900°-1200°C temperature range is supposed to be SiB_4 or SiB_6 from the diffraction measurements. The electrical resistivity of the insoluble compound is 0.01-0.03 ohm-cm.

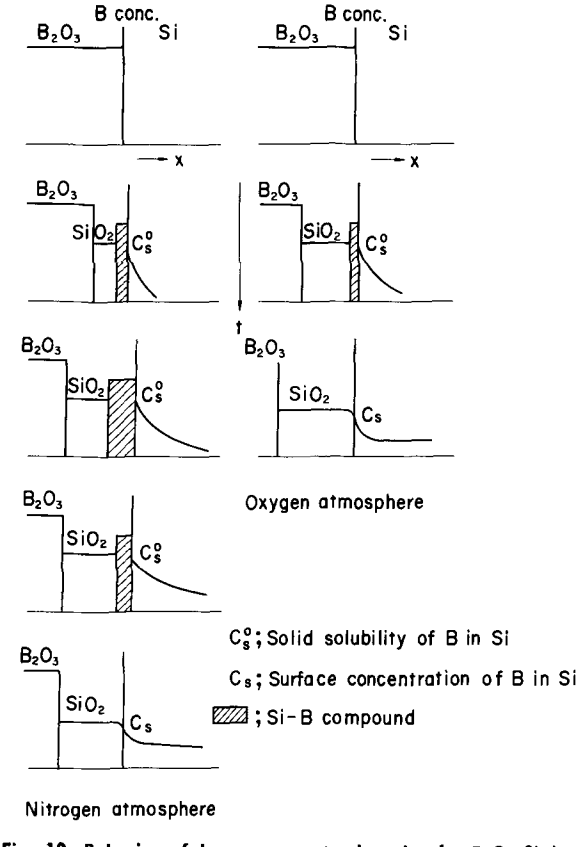

Fig. 10. Behavior of boron concentrations in the B_2O_3-Si interface during heat-treatments.

2. The Si-B compound grows when the production rate of the elemental boron by the interface reaction of Eq. [1] is much more than the maximum diffusion current of boron in the interface and degenerates in the opposite case, decomposing to the diffusion source.

3. The reasons for the growth of the Si-B compound being depressed in an oxidizing atmosphere at a low temperature are due to the increase in the growth rate of SiO_2 and to the high viscosity of the mixed SiO_2-B_2O_3 glass.

4. The growth rate of SiO_2 by Eq. [1] in the silicon-glass interface is rate determined by the diffusion of B_2O_3 in glass in large excess of source, such as source IV, and by the deposition of B_2O_3 on silicon in the case of the diffusion source from gas phase, such as source I or II.

5. The growth rate of SiO_2 by Eq. [3] or [4] in an oxygen atmosphere in the interface of B_2O_3-Si system is very much faster than its ordinary growth rate. This fact is explained by assuming that the diffusion coefficient of oxygen in SiO_2, produced in the interface, becomes larger when the SiO_2 contains boron.

6. The rate-determining step of the transfer of boron into silicon is classified by the presence or absence of the Si-B compound. If the compound is present, it is the boron diffusion in silicon, and if not, it is that in glass.

Flame Emission Analysis of Potassium Contamination in Silicon Slice Processing

William R. Knolle

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania 19604

ABSTRACT

A study of potassium contamination in semiconductor processing was undertaken to determine its extent and magnitude in processing chemicals and slice-handling tools. Simple methods of preventing contamination of silicon and silicon dioxide from chemicals and tools were investigated. To this end a flame photometric technique has been developed to detect routinely less than one part per billion (ppb) of potassium in solution. Potassium contamination of reagent grade chemicals commonly used in silicon device processing is generally less than 500 ppb which is comparable to levels of sodium contamination. However, Triton X-100 surfactant solution and 30% hydrogen peroxide contain several orders of magnitude more sodium than potassium. Pyrex dishware yields minimal amounts of potassium whereas significant amounts of sodium are leached from Pyrex by chemicals. It is shown that potassium levels on both bare and oxidized silicon slice surfaces from a basic or acidic treatment can be reduced to $<2.3 \times 10^{12}$ atoms/cm^2 by a 10 min overflow rinse of deionized water and by using slice-handling tools and spin drier surfaces which have been rinsed with deionized water for short times immediately prior to use. Potassium is shown to be mobile at high temperatures and presents the same unwanted electrical instability in silicon dioxide as does sodium.

Sodium contamination of semiconductor materials and its deleterious effect on the desired electrical stability of devices is well known. Little attention has been paid to the other alkali elements such as potassium. Potassium is the seventh most abundant element in the earth's crust (sodium is the sixth) (1) and is present in man as is sodium (2). The diffusion coefficient of potassium in silica is about an order of magnitude smaller than that for sodium (3). This is also the case for the diffusion coefficients in silicon at room temperature (4). Possible evidence of potassium contamination of chemically etched silicon has been found (5).

Presented in the following sections are the method of analysis used to detect potassium in the ppb range, sources of potassium contamination of silicon slices due to routine chemical treatment and slice handling, and ways to reduce the potassium contamination. Also pre-

Key words: silicon processing, MOS devices, flame photometry, potassium contamination, sodium contamination.

sented are the results of temperature-bias drift, capacitance-voltage (C-V) measurements made on intentionally potassium-contaminated MOS testers.

Method of Analysis

Trace amounts of potassium in chemicals were determined by emission flame photometry. An Instrumentation Laboratory Model 153 Atomic Absorption Spectrometer was used in the flame emission mode. The grating of the spectrometer has a blaze angle (6) that optimizes the efficiency of the grating at a wavelength of 250 nm; therefore the grating does not efficiently pass light of 766.5 nm—the detection wavelength for potassium. By inserting a 766.5 nm narrow bandpass filter between the flame and the grating, and using the grating as a mirror instead of as a monochromator, the best signal-to-noise ratio was obtained (7). Potassium standards in the ppb range were prepared by successive dilutions of a stock solution. The solutions were contained in polypropylene volumetric flasks that had been soaked in dilute HF for several hours and then finally rinsed with deionized water. The deionized water used in preparing the standards was passed through a set of Barnstead demineralizers and finally a 0.30 μm Millipore filter. The potassium level of this water was less than 1 ppb. See Fig. 1 for the response of the instrument to 3 different potassium standards used to calibrate the instrument's output. A least squares analysis of the instrument's response in Fig. 1 as a function of potassium concentration yields a line with a slope of 9.35 units/ppb and a correlation coefficient of 0.99991.

The silicon slices used in this work for potassium contamination were 10 ohm-cm, n-type, 0.85 in. in diameter, and 0.005 in. thick. Generally, determination of potassium contamination of silicon and silicon-dioxide-covered silicon surfaces was done on several samples and an average value of potassium contamination reported. This averaging over several slices that have received the same chemical treatment was necessary in sodium analyses where accidental contamination of a sample due to a high concentration of sodium was easily possible (8). Therefore the same precaution of averaging data was adopted for the potassium analysis. In order to calculate the minimum amount of potassium detectable under this analytical condition, a procedure according to Gabriels was followed (9). Accordingly, five 2 ml samples of dilute HF were dispensed from the same stock solution and analyzed for potassium. The calculated standard deviation multiplied by a statistical factor yields 1.1 ng of potassium as a workable detection limit in the 2 ml samples. The detection limit for sodium calculated in this way was 0.10 ng of sodium (8).

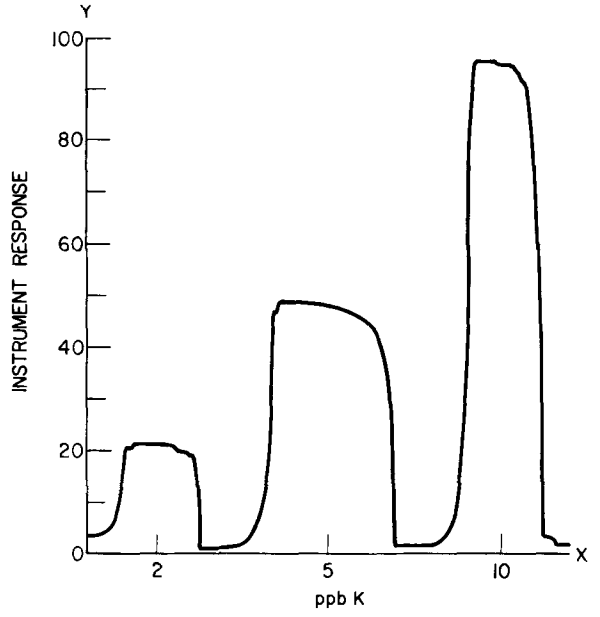

Fig. 1. Strip chart recorder tracing of potassium standards

Potassium in Processing Chemicals

Some chemicals commonly used in silicon semiconductor device processing were checked for potassium. Several of these chemicals were repackaged into polyethylene containers before use. Seven milliliters of each were diluted to 100 ml in a clean polypropylene volumetric flask and the resulting solution aspirated into the flame and analyzed for potassium. The results are presented in Table I. Each value represents the average of measurements on 4 different batches. Also tabulated is the amount of sodium present. The sodium was detected by emission flame photometry with the grating used as a monochromator. Stringent precautions were taken to avoid spurious sodium contamination (8). Hydrochloric acid was very low in both sodium and potassium. A basic peroxide solution used for slice cleaning (1:1:4 by volume of 30% H_2O_2, conc NH_4OH, and H_2O) (10) was high in both sodium and potassium, the sodium coming from the H_2O_2 and the potassium from the NH_4OH.

Contamination of Silicon and Silicon Dioxide by Chemicals

A group of 9 bare silicon slices was treated with hot basic (adjusted to $pH \sim 12$ by addition of NH_4OH) 0.01M KCl solution (~391 ppm potassium) for 20 min and then rinsed in overflowing deionized water. This work was done in a clean bench in order to minimize particulate contamination of the slices. A Fluoroware basket was used to contain the slices. The basket design allowed a flow of solution around the slices sufficient to help prevent any particulate adherence to the silicon slice surface. The flow of water in this work was set at 4 volume changes per min for the Pyrex dish used to contain the Fluoroware basket. Specifying the number of volume changes per min is preferable to specifying only the rinse time since flow rate may vary from process to process. The slices were monitored for residual potassium on their surfaces as a function of rinse time. At periodic intervals a slice was removed from the rinse vessel and placed in 2 ml of dilute HF dispensed from a Nalgene polyethylene automatic constant volume pipettor. The silicon slice and HF were held in a polypropylene container that had been soaked in dilute HF for several days and prior to use was rinsed again in dilute HF followed by copious amounts of deionized water. The dilute HF was allowed to equilibrate with the silicon slice for 5-10 min and at the end of this equilibration time the silicon slice was removed and the solution capped until analysis. This method was found necessary to prevent any spurious sodium contamination during sodium analysis (8) and so was used in the potassium analysis. Similarly, bare silicon slices were treated with hot acidic (adjusted to $pH \sim 3$ by addition of HCl) 0.01M KCl solution and monitored for residual potassium. The data are presented in Fig. 2. Each point represents the average for 3 slices. The results show that potassium contamination from chemicals used to clean the slices may be rinsed from bare silicon slices with overflowing deionized

Table I

Reagent	Sodium ppb	Potassium ppb
H_2O_2	995	9
0.5% Triton X-100*	412	3
H_2SO_4*	220	176
Methanol*	174	74
HNO_3	87	100
HF	19	76
HCl	15	17
NH_4OH*	7	320

Each point represents the average potassium contamination for 3 slices. The overflow water rinse yielded 4 volume changes per minute of the Pyrex dish used to contain the solution.

water. This same result has been found for sodium contamination (8).

A group of silicon-dioxide-covered silicon slices was treated with boiling basic peroxide solution (1:1:4 H_2O_2, NH_4OH, and H_2O by volume) for 15 min and monitored for residual potassium as a function of rinse time. The data is presented in Fig. 3. Similarly, potassium from acidic peroxide solution was rinsed off silicon-dioxide-covered silicon slices within 8 min (to a detection limit of 6×10^{12} atoms of potassium/ml). This is in contrast to sodium from a basic solution on oxidized silicon where an acid rinse prior to overflowing deionized water was necessary to reduce sodium contamination to the detection limit (8).

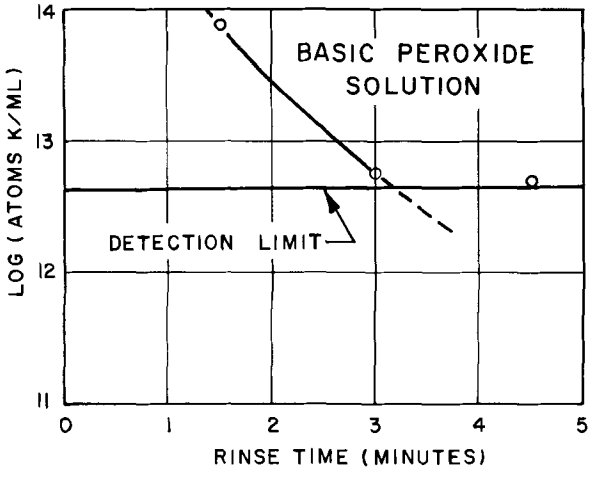

Fig. 3. Desorption of potassium from oxidized silicon slices. The slices were contaminated by immersion in a hot 0.01M KCl solution for 15 min. Each point represents the average contamination for 3 slices .The overflow water rinse yielded 4 volume changes per minute of the Pyrex dish used to contain the solution.

Contamination by Chemicals from Glassware

Two Pyrex beakers were degreased with hot trichloroethylene, rinsed with methanol, and overflow-rinsed with deionized water for 10 min. They were then treated with hot aqua regia for 10 min and finally overflow-rinsed with deionized water for 10 min. This treatment reduced the potassium contamination that may have previously been on the beakers to the detection limit of $<5.7 \times 10^{12}$ atoms of potassium/ml. Then 25 ml of deionized water were placed in each beaker and allowed to stand for 1 hr. At the end of this time the water was analyzed for potassium. No potassium above background level could be detected ($<5.7 \times 10^{12}$ atoms of potassium/ml). In contrast, the amount of sodium leached from Pyrex glass beakers similarly treated was $49 \pm 30 \times 10^{12}$ atoms of sodium/ml (8). The level of potassium contamination of chemicals from glassware is at least an order of magnitude lower than the sodium contamination.

Potassium on Slice-Handling Tools

Several stainless steel vacuum chucks that were routinely used for silicon slice handling were checked for possible potassium contamination. The chucks were dipped into 15 ml of deionized water in a polypropylene container for 15 sec. This treatment is meant to simulate the actual practice of submerging the vacuum chuck into solution in order to remove the silicon slice. Of the 5 chucks checked, only one showed any measurable potassium transferred to 15 ml of deionized water in 15 sec. This was 9.8×10^{14} atoms of potassium compared to 20×10^{14} atoms of sodium for the most sodium-contaminated vacuum chuck found in routine use (8). When a vacuum chuck rinsed with dilute HCl and then deionized water for 30 sec was wiped dry with Twill Jean cloth, no potassium above the detection limit was observed ($<8.6 \times 10^{13}$ atoms of potassium compared with 105×10^{13} atoms of sodium transferred to 15 ml of deionized water in 15 sec) (8).

A stainless steel vacuum chuck cleaned with dilute HCl and deionized water and then touched with 3 ungloved finger tips for 3 sec yielded 311×10^{13} atoms of potassium in 15 ml of deionized water in 15 sec compared with 1680×10^{13} atoms of sodium transferred to deionized water (8). A simple deionized water rinse in flowing water for 30 sec of the finger-touched chuck appeared to remove most of the easily transferrable potassium from the surface of the chuck ($<8.6 \times 10^{13}$ atoms of potassium transferred to deionized water). Again, potassium contamination appears to be an order of magnitude lower than sodium contamination.

MOS Measurements

Electrical instability of semiconductor devices due to potassium contamination of silicon dioxide has not been extensively investigated (11). In order to see if potassium presents any electrical instability similar to sodium, silicon slices with 10,000Å of thermally grown oxide were prepared and purposely contaminated with potassium and MOS capacitance-voltage measurements made.

Seven oxidized silicon slices were immersed in 125 ml of 10 ppm KCl solution whose sodium contamination level was 0.5 ppb above the deionized water reference level. The sodium analysis of the potassium solution was made to assure that there was no inadvertent contamination of the slice by sodium ions. The slices were heated below boiling for 20 min in a quartz beaker and were then spun dry on a clean Teflon-coated spin drier (8). Five of them were analyzed for surface potassium by flame photometry. Each of the 5

slices was immersed in 2 ml of dilute HF in order to etch the first 400Å of oxide considered to be representative of the oxide surface. The first 400Å of oxide yielded a surface concentration of $47 \pm 10 \times 10^{13}$ atoms of potassium/cm^2. In order to differentiate between the temperature-bias drift of potassium and that of the residual sodium contamination, 6 other slices from the same oxidized lot were immersed in a hot 64 ppb sodium solution for 20 min and spun dry. This solution contained over 50 times more sodium than the potassium solution did and so the slices immersed in the 64 ppb sodium solution should have higher mobile charge if potassium is immobile. Five of the 6 sodium-contaminated slices were analyzed for surface sodium by flame photometry. The slices contained less than 7.5×10^{13} atoms of sodium/cm^2 on the surface as detected by flame photometry. As a control, one slice was left untreated and so should have lower mobile charge than the sodium-contaminated slice. The 4 slices then had gold field plates of 0.060 in. diam evaporated onto them.

The MOS testers were temperature-bias-drifted at several temperatures for 5-10 min and $+9 \times 10^5$ V/cm, then cooled quickly to room temperature under bias, and capacitance-voltage measurements made. The results are presented in Fig. 4 where log Q_{FB}/q *vs.* temperature is plotted for the control, the sodium-contaminated, and the potassium-contaminated slices. Each point is the average measurement of 3 or 4 MOS testers.

From Fig. 4 it is apparent that Q_{FB}/q for the potassium-contaminated samples is higher than for the sodium-contaminated samples. The difference between Q_{FB}/q for the control slice and Q_{FB}/q at 275°C for the sodium-contaminated slice (2.3×10^{11} electronic charge/cm^2) is similar to the amount of mobile charge found by Yurash and Deal (12) when oxidized slices were rinsed in 64 ppb sodium solution and blown dry with N_2 gas ($\sim 2.9 \times 10^{11}$ mobile electronic charge/cm^2). The C-V curves for the potassium-contaminated slices resembled those for the sodium-contaminated and control slices except for the much larger flat-band voltage shift. No evidence was found for a thousandfold difference in mobility between sodium and potassium movement in the stressed MOS testers as has been previously reported (11).

It is interesting that the amount of potassium and sodium detected on the contaminated oxide surfaces

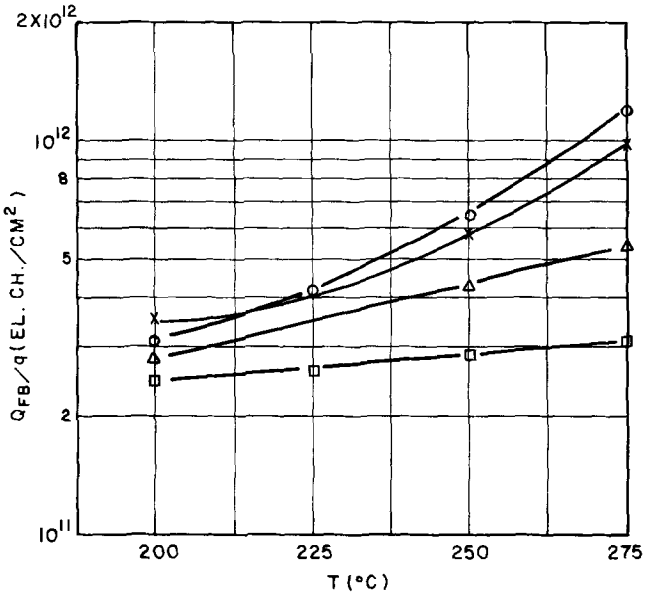

Fig. 4. Plot of Q_{FB}/q *vs.* temperature; 0.060 in. diameter, evaporated-gold field plates bias-drifted at $+9 \times 10^5$ V/cm. X, Potassium-contaminated slice, 5 min drift; ○, potassium-contaminated slice, 10 min drift; △, sodium-contaminated slice, 10 min drift; and □, control slice, 5 min drift.

by flame photometry is greater than the amount of mobile charge calculated from the C-V measurements. A possible explanation for this difference may be the manner in which the contamination is introduced, namely by immersion of the oxidized slices in a solution of the alkali metal salt. While the slice is in solution alkali metal ions may exchange with hydrogen ions that are present in silanol groups (≡Si-OH) on the surface of the oxidized slice, in addition to adsorption of molecules of the alkali metal salt onto the surface. It would not be expected that all of the exchanged alkali metal ions would drift under bias since some may be more tightly bound to the lattice than others. When a slice is contaminated by evaporation of the residue from one drop of a dilute aqueous solution of the alkali metal salt (11), only molecules will be deposited on the slice surface; hence the exchange mechanism for contamination is not possible in this case.

From the MOS tester results it is concluded that at high temperatures potassium contamination of devices will lead to electrical instability similar to that attributed to sodium (13).

Conclusions

Emission flame photometry may be used to routinely detect potassium in concentrations of less than 1 ppb in solution. A practical detection limit of 1.1 ng of potassium in 2 ml of solution is easily achieved when determining potassium contamination of silicon surfaces. For a silicon slice of 0.85 in. diameter, 1.1 ng of potassium corresponds to a detection limit of 2.3×10^{12} atoms of potassium/cm^2.

With respect to silicon slice processing, potassium is found in chemicals to about the same extent as sodium. However, 30% H_2O_2 and 0.5% Triton X-100 surfactant solution are two orders of magnitude lower in potassium than sodium. Potassium contamination of chemicals from Pyrex is minimal whereas significant amounts of sodium are leached out of Pyrex. Potassium can be easily rinsed from bare silicon, oxidized silicon, and stainless steel vacuum chucks with overflowing deionized water. This is in contrast to sodium contamination of oxidized silicon where a dilute acid treatment prior to a deionized water rinse was necessary to reduce sodium contamination to the detection limit (8). Potassium is easily transferred to solutions and slice-handling tools by ungloved hands; to avoid potassium contamination clean gloves are necessary.

Potassium contamination of semiconductor devices is to be avoided since potassium evidently is mobile at high temperatures. By proper handling and treatment the amount of potassium may be kept below the detection limit of 2.3×10^{12} atoms/cm^2.

Electrical Properties of Vapor-Deposited Silicon Nitride Films Measured in Strong Electric Fields

P. K. Chaudhari, J. M. Franz, and C. P. Acker

IBM System Products Division, Essex Junction, Vermont 05452

Recently, silicon nitride films have received considerable attention (1-3), mainly for passivating silicon, constructing diffusion masks, and use as gate insulators. The physical and electrical properties of deposited films have been found to vary with reactant composition during growth, temperature, and method of deposition (4-6).

Studies of the electrical conductivity of silicon nitride films in strong electric fields can give information concerning the mechanism of the increase of conductivity, the existence and location of trap levels, and dielectric constant.

Experimental

The substrates used for this study were mechanically polished 2 ohm-cm, p-type silicon. Just before loading into the reactor, the substrates were chemically etched in fresh, concentrated HF and rinsed in deionized water. An rf-heated, horizontal tube reactor was used for the silicon-nitride deposition.

A 4μ, 2 ohm-cm boron-doped epitaxial layer was deposited at 1135°C by reacting silicon tetrachloride and diborane in hydrogen. The temperature was then reduced to 925°C during the hydrogen purge cycle and silicon nitride was deposited using 150:1 ammonia-silane ratio in a hydrogen ambient. The deposition rate was approximately 100 Å/min. The MIS structures for electrical measurements were formed by evaporating aluminum field plates, 30-mil diam over the silicon nitride through a metal mask. Aluminum was also evaporated on the backside of the silicon for contact. The thickness of the nitride films studied ranged from 175 to 500Å. The thickness and the index of refraction were measured ellipsometrically.

Results and Discussion

Physical Properties.—Optical measurements were made on samples deposited on silicon blanks by the same process as the samples for electrical measurements. Transmittance curves obtained in the range 2.5-40μ using a Beckman Model IR-12[1] spectrophotometer indicate a broad absorption peak in the range 10-12μ with a minimum at 11.6μ. This absorption is due to the Si-N bond and agrees with that reported by Bean *et al.* (6). No peaks due to SiO, SiH, or NH were observed. Etch rates of 0.7 and 1.1 Å/sec were obtained at 50°C for 10:1 and 5:1 buffered etch, respectively, in good agreement with Bean *et al.* The dielectric constant of the silicon nitride films was obtained by measuring the capacitance of MIS structures at 1 MHz, under bias conditions corresponding to strong accumulation of the silicon surface. The electrode area was measured by photographing the electrode with a calibrated scale. The average value of the dielectric constant so determined was 7.

Key words: dielectric, thin film, d-c conductivity, silicon nitride.

High Field Conductivity

The current flow through the silicon nitride films was measured using a Keithley Model 602C electrometer. A hot-stage probe chamber with nitrogen ambient was used for all the measurements in the range 300°-500°K. Special care was taken to ensure that conduction measurements were made under steady-state conditions. The current was measured as a function of bias at various temperatures. Current measurements made on 4 or 5 capacitor dots per wafer indicated a considerable scatter in absolute magnitudes. However, least square fit of the ln σ *vs.* $E^{1/2}$ plots yielded rather consistent values for slope and convergence point (to be discussed below). A representative plot of ln σ *vs.* $E^{1/2}$ at various temperatures for Al-Si_3Ni_4-Si, 324Å thick, 30 mil diam is represented in Fig. 1. Figure 2 shows ln σ against $1/T$ for different field strengths. It is well established (7-9) that for fields in excess of 10^4 V/cm, many dielectric films exhibit current-voltage characteristics of the form

$$\sigma \sim \exp - \left[\frac{q\phi}{K_B T} - \beta_F E^{1/2} \right] \qquad [1]$$

which is evidence of either Schottky or Poole-Frenkel (P-F) effect (10). β_F in Eq. [1] is given by

$$\beta_F = \frac{q}{K_B T} (q/\alpha\pi\epsilon_0\epsilon_n)^{1/2} \qquad [2]$$

where $\alpha = 1$ for P-F effect and 4 for Schottky. Here σ is the conductivity, E is the field in V/cm, ϵ_0 is the vacuum permittivity, K_B is Boltzmann's constant, q is the electronic charge, T is the temperature in degrees Kelvin, ϵ_n is the relative dielectric constant for the insulating film, and ϕ is the potential barrier or the depth of the trap level. In Fig. 1 the curves clearly show that the conductivity obeys Eq. [1]. The slope of

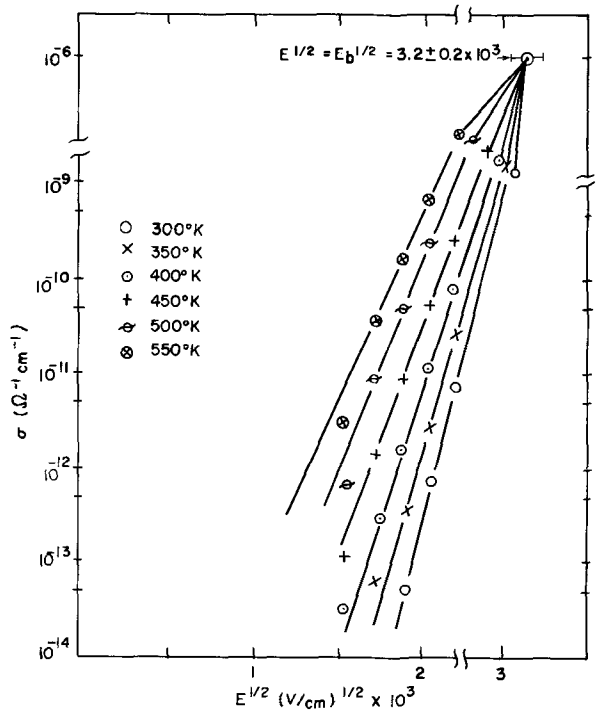

Fig. 1. Conductivity plotted vs. the square root of the electric field for a 324Å thick silicon nitride film, at various temperatures.

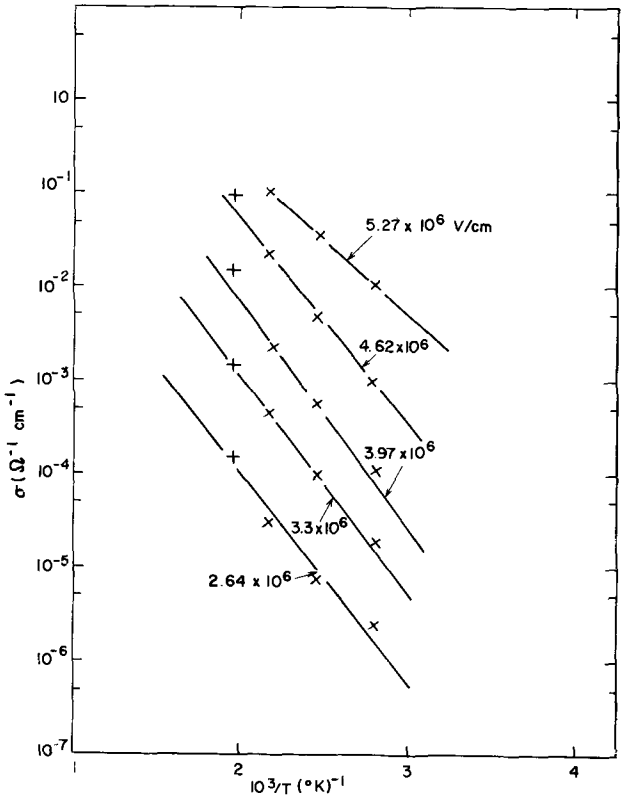

Fig. 2. Conductivity plotted against the inverse of the temperature for a 324Å thick silicon nitride film, at various fields.

the straight lines decreases with increasing temperature, as expected for either of these mechanisms. The slopes β_F obtained from Fig. 1 are plotted against $1/T$ as shown in Fig. 3. Note that not only an increase in β_F with decreasing temperature is observed, but also a rather good proportionality, $\beta_F \sim 1/T$, in the temperature range 300°-500°K, which is in good agreement with Eq. [2]. By equating the slope of Fig. 3 to Eq. [2], $\alpha\epsilon_n = 3.6 \pm 0.2$. The refractive index of the silicon nitride films measured by ellipsometer is $n =$

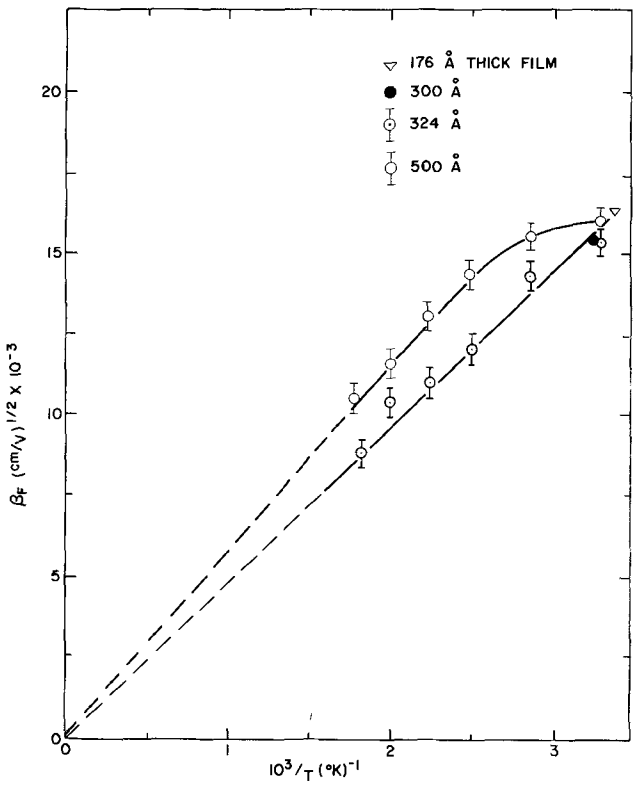

Fig. 3. Temperature dependence of the P-F coefficient β_F obtained from Fig. 1.

1.98 that yields $\epsilon_n = n^2 = 4$, and hence $\alpha = 1$ in Eq. [2]. It therefore appears that Fig. 1 represents a bulk-limited conduction obeying the P-F law. The discrepancy in the value of ϵ_n obtained from the data and that obtained from the ellipsometer measurement is consistent with the concept of an increased effective temperature at high electric fields, as proposed by Jonscher and Ansari (11) and observed experimentally in SiO (11), amorphous carbon films (12), and aluminum-doped SiO (13). Room-temperature data on 176, 300, 324, and 500Å thick films also gave similar values for β_F. However, 500Å films yield higher values of β_F for higher temperatures (see Fig. 3). This anomalous effect has been observed, in scribed silicon nitride samples, by Brown *et al.* (2).

Barrier lowering due to P-F effect.—The ln σ *vs.* $E^{1/2}$ straight lines extrapolated in the high-field region meet at $E^{1/2} = E_B^{1/2}$, indicating a temperature independent conductivity at E_B. This field corresponds to complete removal of the coulombic barrier due to the P-F effect, and is given by $E_B \sim 1 \times 10^7$ V/cm. It is interesting to note that this value agrees with the field strength for electrical breakdown of thicker silicon nitride films (14). Following the same procedure, Fig. 1 of Ref. (2) gave a value of $E_B = 1.05 \times 10^7$ V/cm.

Trap levels.—Consistent with the P-F effect, Eq. [1] is evidence of field-enhanced thermal emission from a localized level or trap level located at ϕ eV below the conduction band. The depth of the trap level is determined by Eq. [3] by equating the exponent to zero and using $E = E_B$. The trap level so determined is found to be $\phi = 1.1 \pm 0.2$ eV below the conduction band. This value also agrees with that obtained from the slope of ln σ *vs.* $1/T$ plot. Kendall (15) reports, from thermally stimulated current work, a definite trapping level in nitride between 0.50 and 0.90 eV. Sze (14) also reports a level located at $\phi = 1.2 \pm 0.3$ eV. ϕ and ϵ_n were calculated from values of E_B and β_F found using computer fit of the data. The uncertainty in E_B and β_F is thus reflected in the uncertainty in ϕ and ϵ_n. These uncertainties in E_B and β_F are indicated in the figures (see Fig. 1 and 3) as error brackets. This

uncertainty includes also a sample-to-sample variation in these parameters.

Data by Kendall (15) indicates the presence of small crystalline regions in his films of silicon nitride and suggests that these regions are responsible for the deep trap levels. However, transmission electron microscopic examination of films similar to those studied here do not show evidence of crystallinity and are found to be essentially amorphous. Hence it is postulated that the origin of the deep-seated traps may be more closely related to structural defects. This is supported by the measured etch rates of about 1 Å/sec at 50°C, indicating the likely presence of excess of silicon.

Acknowledgments

The authors are grateful to Dr. A. LeBlanc for encouragement and support during the early part of this investigation. The authors also wish to acknowledge S. D. Warley and N. R. Rapoport for making many measurements.

Chemical Vapor Deposition of a TiC Coating on a Cemented-Carbide Cutting Tool

M. Lee and M. H. Richman

Division of Engineering, Brown University, Providence, Rhode Island 02912

Chemical vapor deposition has been used to deposit coatings of titanium carbide on steel and more recently on cemented carbides. The kinetics of the coating process and the coating growth morphology have also been the subject of many earlier reports (1-3). Ever since titanium-carbide-coated, cemented-carbide cutting tools became popular in manufacturing operations, this subject has attracted increased attention from the cutting tool industry.

Direct deposition of the carbide onto a heated surface from a gaseous mixture of volatile titanium tetrachloride, hydrogen, and some hydrocarbon or carbon tetrachloride is a widely used process. Although much is known about the kinetics of this process, some questions still remain unanswered. The most notable problem is the effect of the substrate material and its structure on the growth morphology of the coating. This information must be understood in order to produce consistently satisfactory cutting tools.

While it is generally believed (3) that pyrolysis of the hydrocarbon is the controlling mechanism in the coating process, some questions concerning the growth morphology of the coating remain to be answered. A particularly interesting question is to what extent the hydrocarbon pyrolysis affects the growth morphology of the titanium carbide.

A series of machining experiments relating the performance of the coated cutting tools to the thickness and type of the TiC coating has already been carried out (4) and it is the intent of this paper to present such information regarding the chemical vapor deposition of TiC coatings as may be useful to carbide manufacturers.

Experimental Procedure

The chemical vapor deposition system used in this research is shown schematically in Fig. 1.

Key words: carbide cutting tool, titanium carbide coating, chemical vapor deposition.

Either methane or toluene is used as the hydrocarbon. Gas flow rates are controlled by standard tube-type flow meters equipped with an extrasensitive needle valve, calibrated for each gas species, and corrected for the pressure gradient across the meter. Toluene is carried into the system by hydrogen, and the partial pressure of toluene in hydrogen is controlled by varying the temperature of the liquid toluene bath.

Titanium tetrachloride is introduced into the system by bubbling hydrogen through liquid $TiCl_4$; the concentration of $TiCl_4$ vapor in the system is fixed throughout this research. The total gas pressure inside the coating system is maintained at 1 atm. Any back pressure caused by bubbling the exit gas through an oil trap (depth approximately 2 cm) and a water trap (depth approximately 10 cm) does not signifi-

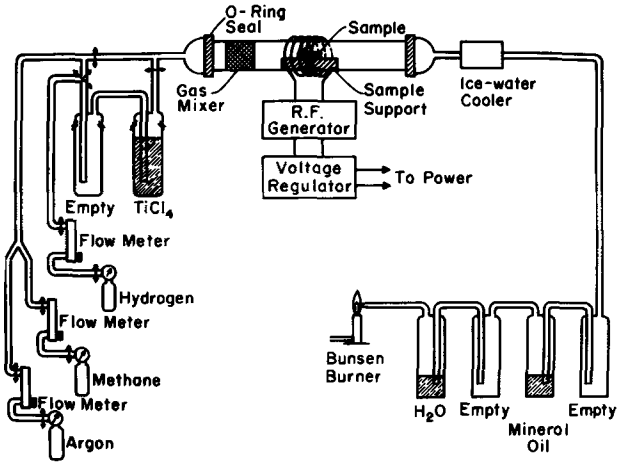

Fig. 1. TiC coating system

cantly increase the total pressure beyond 1 atm. Although the system pressure is an important independent variable in the chemical vapor-deposition process, atmospheric pressure is used throughout this research because of the quality of the coatings which were deposited at this pressure.

Radio-frequency surface heating is used to maintain the tool being coated at the proper temperature. The TiC coating deposited on the surface of the substrate tool changes the heating characteristics of the system, but constant temperature is maintained by continuous adjustment of the power input. A micro-optical pyrometer is used to monitor the substrate temperature, and all necessary corrections are made for the emissivity and the reaction tube wall.

A 32 mm ID Vycor tube equipped at both ends with silicon-rubber o-ring compression seals is used as the reaction chamber. To avoid any influence of the support material on the structure and properties of the coating, the tools to be coated are placed in the center of the chamber on a TiC-coated alumina support. In addition, the tools have a positive rake angle and all metallurgical examinations are performed at the cutting tip which is located at the top of the tool—the face distant from and in no way in contact with the support. While the latter condition would not negate any carbon transport due to eddy currents caused by thermal convection, the former condition would insure a uniform and constant substrate. The tool surface is also deliberately decarburized and η-phase formed before the TiC deposition. Therefore any tendency for η formation where the substrate does not contact the TiC or η suppression where the substrate does contact the TiC would be negligible in this study. A silica-wool trap at the inlet end of the reaction chamber causes the reactant gases to mix and also filters out any dust. A preheating attachment is also used in some cases to bring the temperature of the reactant gas mixture close to the substrate temperature before the gas reaches that point in the chamber. This eliminates the development of a temperature gradient across the tool surface due to any chilling effect of the cold gas on the hot tool. It was also considered that the concentration gradient in the gas mixture across the reaction surface might result in a nonuniform coating but such an effect would be minor. The coating system is baked prior to each run at a temperature over 150°C but below the softening temperature of silicon rubber and purged with argon for at least 1 hr in order to remove air and, especially, water vapor from the system.

Surfaces of the substrate tools are prepared in three different ways: (*i*) cleaning in a highly concentrated bath of boiling KOH; (*ii*) deeply etching the surface with 10% ferricyanide and 10% KOH solution in water which exposes the clean crystalline-carbide grains; and (*iii*) heating the tools in a flow of hydrogen gas which produces a thin silvery white film of continuous η-phase on the surface.

The tools are plated with a thick copper layer and sectioned on a diamond wafering machine. The thickness of the coating is measured metallographically on a section which has been etched with an aqueous solution of 10% potassium hydroxide. Examination of coating and coating-substrate interface structure is performed with an optical metallograph and electron microscopes (JEM 30 and JEM 7). Two-stage carbon replication is used for electron microscopy. All of the coated tools are investigated by x-ray diffraction to identify the crystal structure of the coating and any impurities in it.

Results and Discussion

The dependence of the growth rate on the substrate temperature is shown in Fig. 2. The substrate tool used was WC + 6% Co and the total coating time for each tool was 90 min. The time dependence of the coating growth rate is linear except for a short initial induction period of less than a minute. The waiting

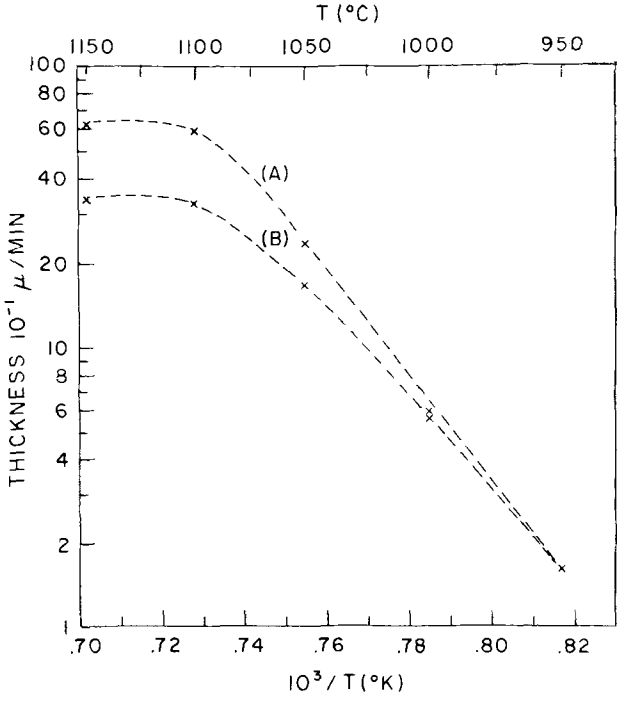

Fig. 2. Arrhenius plot of coating rate. Curve (A), 1500 cm³/min. H_2 saturated with toluene at −18°C; curve (B), 1000 cm³/min. H_2 saturated with toluene at −18°C.

time used for average rate determination is 90 min in each case. The hydrocarbon used for the particular experiment, the results of which are represented in Fig. 2, is toluene carried into the system by hydrogen bubbled through a toluene bath at -18°C. It may be seen from this data that the deposition rate is relatively independent of flow rate when the substrate temperature is below 1100°C, whereas transport of the reactant and the product materials become rate limiting when the temperature exceeds 1100°C.

The growth morphology of the coating is very strongly dependent upon the surface state of the substrate tools. When deeply etched tools with clean crystalline-carbide grains projecting from their surfaces are used as the substrate, three distinct types of deposit structure are observed. (*i*) When the coating temperature and the hydrocarbon concentration in the reactant gas mixture are relatively low, whiskers often form. (*ii*) At an intermediate temperature (*e.g.*, 1050°C) and with a moderate concentration of hydrocarbon, large well-defined crystal growth is often seen. (*iii*) At high temperature, *i.e.*, at the upper edge of the kinetic-controlled (or the transport-restricted) region, a coarse polycrystalline film is formed. The boundaries between these three regions are not definite. There is often considerable overlap because both the temperature and the hydrocarbon concentration are independent variables. At a fixed temperature (*e.g.*, 1050°C), depending on the amount of hydrocarbon in the system, different coating structures can be produced.

When as-ground tools are used after having been cleaned in a bath of boiling KOH, the results are mixed. Sometimes a crystalline form of coarse titanium carbide is deposited, but in most cases a continuous polycrystalline film of fine grain size would form. However, the tool surface is deliberately decarburized to a slight degree by heating in a flow of hydrogen until a thin film of very smooth silvery white η-phase is formed at the surface. The coating deposited on this η-phase layer at a temperature between 950°C and 1150°C with sufficient[1] hydrocarbon in the gas mixture is always a strong continuous film with ultrafine grain size. A typical coating formed under these

[1] About 18% by volume of methane in the total gas mixture is sufficient for the system used here.

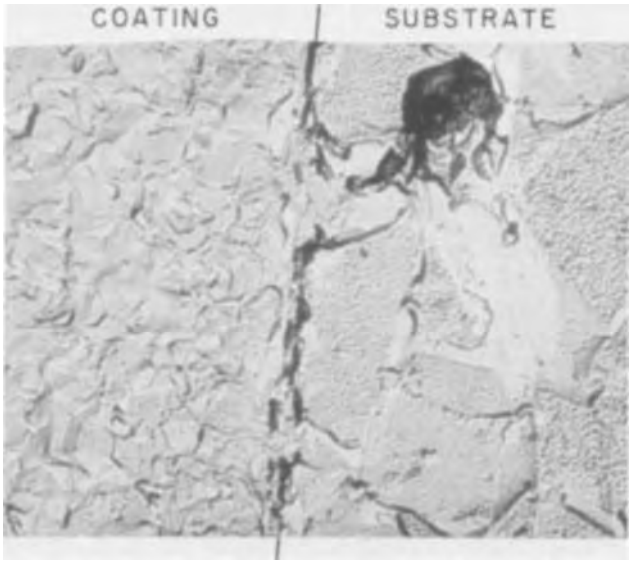

Fig. 3. An electron micrograph of tool-coating interface taken by double-stage carbon replication. Substrate tool: WC + 6% Co; hydrogen reduced surface; coated at 1050°C; rate of $TiCl_4$, saturated H_2 flow, 500 cm^3/min; rate of methane flow, 28 cm^3/min. 14,200×.

conditions is shown in Fig. 3. Although the η-phase is not desirable in cutting tools, it seems to be a necessary condition for good coating.

If a thick coating is deposited at a high rate, the coating consists of an array of large columnar grains oriented normal to the substrate surface. It is also found that the presence of some air or water vapor in the coating system would drastically change both the growth rate and the coating structure. Very fine titanium dioxide (TiO_2) particles which had formed in the gas phase provide extra nucleation sites, increase the growth rate of the coating, and result in a bimodal coating structure. The structure of a thick coating deposited with some air in the system is shown in Fig. 4.

The dependence of the film growth rate on the concentration (Fig. 5) changes with the hydrocarbon content of the reactant gas mixture. This agrees well with previously published reports (3). Along with the coating temperature, the hydrocarbon concentration has a considerable influence on the deposition rate.

An activation energy for the coating process may be estimated from the linear portion of Fig. 2. It varies from 84 ~ 94 kcal/mole depending upon the data obtained. This variation is due to the many sources of possible error mentioned above. It does,

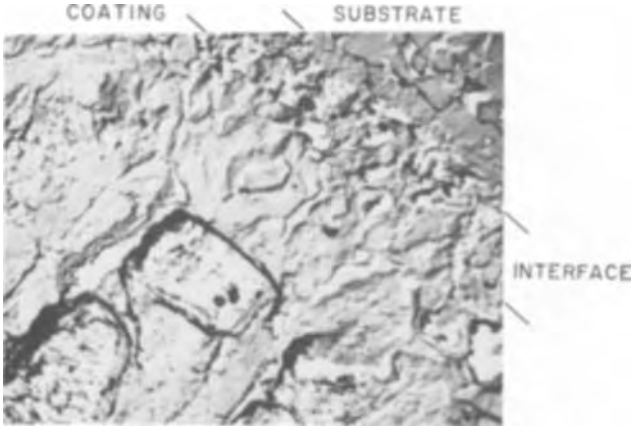

Fig. 4. An electron micrograph of a coating structure with large carbide particles grown from oxide nuclei within a continuous-carbide matrix. 2800×.

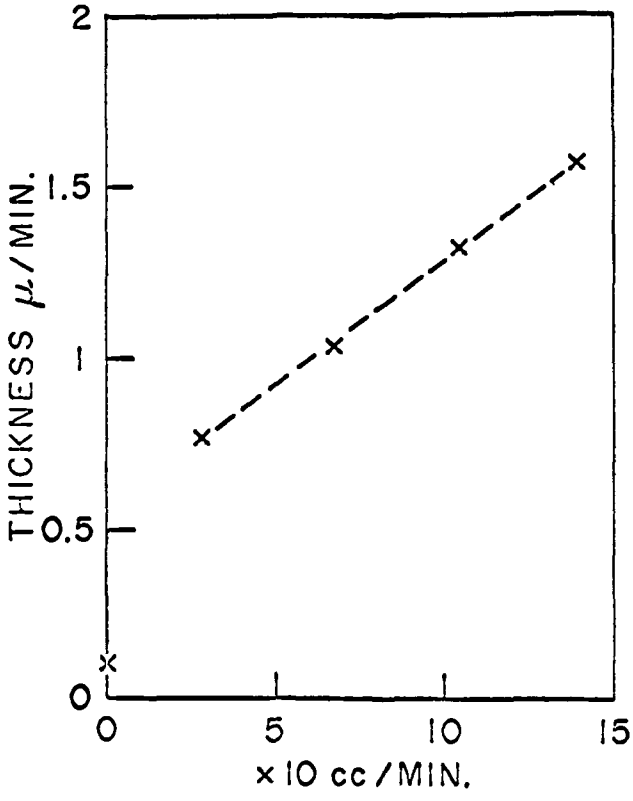

Fig. 5. Coating thickness as a function of hydrocarbon flow rate. Temperature: 1050°C, rate of $TiCl_4$-saturated (at room temperature)-hydrogen flow: 500 cm^3/min.

however, agree reasonably well with the reported activation energy of 90 cal/mole for the deposition of pyrolytic carbon from toluene (5). This may mean that within this surface-controlled region, it is the dissociation of carbon from the hydrocarbon molecules rather than the absorption and desorption of the reactant and the product gases that is the rate-controlling step and that different hydrocarbon gases could show different TiC deposition activation energies equivalent to their dissociation energies. Takahashi *et al.* (1, 2) found from their investigation that the TiC deposition rate changes if different hydrocarbon species are used in the coating process even though all other coating parameters are identical. They reported that methane showed the slowest deposition rate while propane and ethane showed much higher deposition rates. The reported activation energy of pyrolytic graphite deposition from methane is 103 kcal/mole (6). For propane decomposition it is 28 kcal/mole (7) and for ethane, 72 kcal/mole (8). According to these activation energies, methane would be expected to produce TiC at the slowest deposition rate. However Takahashi (1) also reported that the deposition rate is lower with propane than with ethane even though the latter has the higher hydrocarbon dissociation activation energy. It seems that some more study is definitely needed in this area.

It is also quite possible that the morphology of the TiC deposition may be controlled by pyrolytic graphite deposition from the hydrocarbon involved. Takahashi *et al.* (2) have also determined the orientation of their whiskers by the Laue technique and found the <111> axis of the cubic crystal to be the growth direction. They often found a large TiC crystal of hexagonal prism shape. The similarities between Takahashi's TiC whisker growth and the most common type of graphite whiskers indicates that the growth morphology of graphite whiskers may have a direct bearing on the growth morphology of TiC whiskers.

A series of microhardness measurements (Vickers hardness number with a 50g load) was taken on titanium-carbide coatings deposited with different con-

Table I. Microhardness of the coatings and the tools

Materials	Vickers hardness kg/mm²	Remark or Reference
WC + 6% Co	1550-1750	Substrate tools used
WC + 6% Co	1550-1700	Schwarzkopf and Kieffer (10)
Coating 1	2550	CH_4, 140 cm³/min
Coating 2	2350	CH_4, 105 cm³/min
Coating 3	2250	CH_4, 68 cm³/min
Coating 4	2150	CH_4, 28 cm³/min
$TiC_{0.8} \sim TiC_{1.0}$	1900 ~ 2900	William and Lye (9)

The test load used was 50g.

centrations (flow rates) of hydrocarbon in the coating system. The hardness values are listed in Table I for the coating rates shown in Fig. 5 as a function of hydrocarbon flow rate. The microhardness increases as the hydrocarbon concentration in the reactant gas increases. Oxygen or nitrogen impurities in the coating could affect the hardness but the samples were very carefully controlled so that, other than hydrocarbon concentration, all conditions were identical. There are two possible causes for this variation in hardness. (*i*) When the hydrocarbon concentration in the coating system is high, the degree of supersaturation and, therefore, the nucleation rate increases. The coatings deposited under these conditions would have a finer grain size than coatings deposited under other conditions. (*ii*) Titanium carbide usually has some carbon deficiency (as compared to its stoichiometric composition) and according to Williams *et al.* (9), the hardness of the carbide increases linearly as the carbon deficiency decreases.

The hydrocarbon concentration in the coating system is a critical factor which must be understood in order to assure high quality coating production. The coating system must provide the high degree of supersaturation needed to deposit a strong and hard continuous film. However, when the CH_4 flow rate exceeded 35% of the $TiCl_4$-saturated H_2 flow rate, x-ray diffraction analysis indicated the presence of some free graphite in the coating.

A thin layer of TiC could be formed on the surface of the carbide tool without any hydrocarbon in the coating system. In such cases, however, the surface of the tool is degraded (Fig. 6) and the growth rate is very low (Fig. 5).

Conclusions

Each individual coating system will show some difference in the kinetic data due to differences in the gas flow pattern. The following conclusions can serve as a useful reference for coating systems utilizing chemical vapor deposition of titanium carbide from a gas mixture of titanium tetrachloride, hydrogen, and some hydrocarbon.

1. The substrate temperature should not exceed 1200°C. Higher temperature tends to create a grain-growth problem and causes cobalt to diffuse into the coatings and it was observed (4) that coatings of this type do not perform well in cutting applications. At temperatures in excess of 1200°C, the growth rate is too high and control of the coating thickness is difficult.

2. Surface preparation of the substrate tool is very important for good coating production. A slight decarburization and creation of a thin smooth layer of η-phase on the surface insures the optimum coating structure for machining applications with excellent consistency.

3. Control of the hydrocarbon concentration and flow rate is a key to the production of well-coated tools. Selection should be made based on the information regarding the pyrolysis of each hydrocarbon species and an optimum hydrocarbon flow rate must be determined for each coating system. The pyrolysis of hydrocarbon is not only the controlling chemical reaction of the process, but also some evidence tends to indicate that the morphology of the titanium carbide coating depends on the morphology of pyrolitic graphite deposition.

4. It is also noteworthy that deposition of some titanium carbide is possible without any hydrocarbon in the system. Tungsten carbide reacts with $TiCl_4$ and forms double (TiW) carbide but this degrades the substrate tool surface.

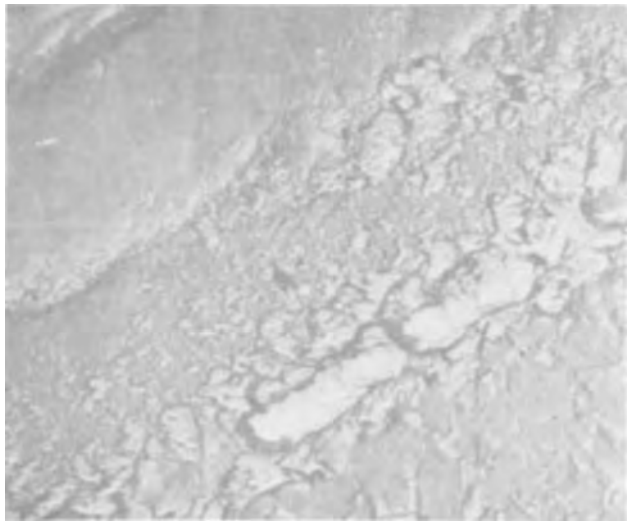

Fig. 6. A tool coated without hydrocarbon in the coating system. The lower right-hand corner is the tool and the upper left-hand corner is a layer of plated copper for preservation of the edge during metallographic preparation. The TiC layer is not very continuous nor does it adhere well to the substrate. 3550×.

Emission of Eu^{3+} in Some Calcium Germanates

T. J. Isaacs and A. A. Price

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

In a three-component fluorescent lamp, the optimum Spectral Power Distribution (SPD) for artificial white light consists of spectral colors which emit near 450, 540, and 619 nm when both luminosity and color rendering index are important (1). When Eu^{3+} is used as an activator and substituted into a site having a linear crystal field term (*i.e.*, lacking inversion symmetry), the $^5D_0 \rightarrow {}^7F_2$ transition is allowed and emission at approximately 610 nm is produced (2). Strong emission at this wavelength has been obtained when Eu^{3+} has been substituted in such hosts as Y_2O_3.

We decided to look at Eu^{3+} emission in compounds containing Ca^{2+} in noncentric sites to see if essentially single-line emitting phosphors would be produced. Dicalcium germanate fit our conditions, and it proved to have a very promising spectrum when activated with Eu^{3+}. We then made the other compounds in the system $CaO\text{-}GeO_2$ which have been reported in the literature and studied their spectra when activated with Eu^{3+}. The compounds selected had $CaO:GeO_2$ ratios of 3:1, 2:1, 3:2, 1:1, 2:3, 1:2, and 1:4. A summary of experimental information of other investigators relating to these compounds is as follows:

An olivine-type calcium germanate ($\beta = Ca_2GeO_4$) was probably the first crystalline compound synthesized in the system $CaO:GeO_2$ (3). A high-temperature polymorph (α) was subsequently found which was at first believed to have the olivine structure (4), but was later thought to be similar to the high-temperature Ca_2SiO_4 (5, 6).

Several new compounds in this system (as well as Ca_2GeO_4) were reported and their fluorescence with some activators (Pb, Ti, Mn) given (7). These compounds were $CaGeO_3$, $CaGe_2O_5$, and $Ca_2Ge_3O_8$. The existence of the last mentioned compound was questioned by Eulenberger *et al.* (8) who found that the x-ray diffraction powder pattern which they obtained for a material of this composition was identical to that of their $CaGe_2O_5$ and similar to $CaTiSiO_4$. X-ray diffraction studies of single crystals of $CaGeO_3$ indicated that it has the same structure as β-wollastonite (9).

Eulenberger *et al.* also reported synthesizing $CaGe_4O_9$ (10) and later postulated two modifications with this composition (8).

Tricalcium germanate (Ca_3GeO_5) was synthesized at high temperatures (approximately 1500°C), but this compound was found to be unstable when cooled slowly; it broke down into Ca_2GeO_4 and CaO (5, 8). Polymorphism in this compound was studied by Hahn and Eysel (11), who found two modifications (monoclinic and triclinic) at room temperature. They reported inversion temperatures of 750°, 1030°, and 1160°C. Only one form of Ca_3GeO_5 was observed in a study of the system $CaO\text{-}GeO_2$, and it was found to break down to Ca_2GeO_4 and CaO at 1320°C (12). The compound $Ca_3Ge_2O_7$ was also reported in this work.

Experimental Details

Spectrographic grade starting materials ($CaCO_3$, GeO_2, Eu_2O_3) from Johnson-Matthey were used to make the compounds. The reactions tended to go slowly and, therefore, fluxes were employed. We used Na_2CO_3, B_2O_3, and CaF_2, the last mentioned being one used elsewhere (7). We obtained our best results when we used Na_2CO_3 as the fluxing agent; the reactions were more nearly complete than with the other agents under our conditions of synthesis. Sodium carbonate also served the purpose of being a source of a univalent ion (Na^+) for charge compensation of the Eu^{3+} ion in the Ca^{2+} site. Other charge compensators in this site were K^+ (as K_2CO_3) and Li^+ (as Li_2CO_3), but the best results were obtained with Na, a finding which could be predicted as its ionic radius (1.10Å) is nearer to those of Ca (1.08Å) and Eu^{3+} (1.03Å) than are those of K (1.46Å) and Li (0.82Å) (13).

We also substituted trivalent ions (Al, As, or Sb) for Ge^{4+} to effect charge compensation (instead of substituting a univalent ion in the Ca^{2+} sites) in some of the runs. No improvement in performance was seen, and in fact the Na substituted runs gave the highest intensity of luminescence.

The Eu^{3+} content was varied from 0.25 to 7 mole per cent (m/o) with the optimum amount generally being from 1 to 2%. The amount of compensator was usually the same percentage as the europium.

Samples were fired at temperatures ranging from 1150°C for most of the materials to 1480°C for Ca_3GeO_5 and α-Ca_2GeO_4 as these compounds can only be synthesized at high temperatures and are stable only at these temperatures.

The initial syntheses were done in open boats in air or oxygen atmospheres, but single-phase materials often were not obtained because of volatilization of GeO_2, even when an excess of GeO_2 was used. We also fired mixtures of stoichiometric composition in sealed platinum capsules in our attempts to produce single-phase material, but we often did not obtain the desired compounds. The runs synthesizing Ca_3GeO_5 and α-Ca_2GeO_4 were made with the material in sealed capsules to enable us to quench them quickly in ice water in order to freeze in the high-temperature equilibrium.

X-ray powder diffraction patterns using the Debye-Scherrer method were taken of all the materials, both to identify them and to ascertain that they were essentially single phase. Exposure times were in the order of 9 hr.

Emission spectra were determined at room temperature on a double-beam monochrometer system of the type described by Riedel (14). The relative intensities of the main emission peaks in the different samples were also determined on this instrument. Over-all brightness was measured with a "spectra" brightness meter.

Results and Discussion

The compounds which we were successful in obtaining in a single phase along with the per cent of the total emission in the range 460-730 nm which appeared at 611 nm (in samples containing 1% Eu^{3+}) are given in Table I along with a standard $Y_2O_3:Eu^{3+}$ containing 7% Eu^{3+}. These were the only compounds which we could positively identify as being the materials we sought or as being new single phases.

Results of attempts to make the other compounds mentioned in the literature were at best ambiguous. When we tried synthesizing $CaGe_2O_5$, we obtained a material which had an x-ray powder pattern corresponding to $Ca_2Ge_3O_8$ plus $CaGe_2O_5$ as given in the literature. The same results were seen for materials

Table I

Compound	% of total emission at 611 nm line
$Y_2O_3:Eu^{3+}$	57
β-$Ca_2GeO_4:Eu^{3+}$	58
α-$Ca_2GeO_4:Eu^{3+}$	25
$CaGeO_3:Eu^{3+}$	28
$Ca_3GeO_5:Eu^{3+}$	23

Key words: calcium germanates, emission, europium, phosphor, brightness.

of composition $CaGe_4O_9$. Even the addition of extra GeO_2 to the firing mixture and/or the use of sealed tubes did not produce the materials we sought. These compounds have been made in the past by repeated firings with intermittent grinding and it is possible that there were losses of germania as a result of these treatments which could have led the various authors (7-9, 12) to erroneous conclusions about the compositions of their materials.

The low-temperature (β) form of $Ca_2GeO_4:Eu^{3+}$ proved to be an essentially single line emitter (Fig. 2), with an emission spectrum very similar to that of $Y_2O_3:Eu^{3+}$ containing 7% Eu_2O_3 (Fig. 1). It has its main peak at 611 nm, and approximately 58% of the total Eu^{3+} emission is concentrated in this line. The half-width of this line is approximately 1-3/4 times as wide as that of $Y_2O_3:Eu^{3+}$. The transition producing this peak is assigned to $^5D_0 \rightarrow {}^7F_2$. The brightness, however, was only about 25% that of our standard $Y_2O_3:Eu^{3+}$. We varied the Eu^{3+} concentration from 0.25 to 9% and found that there was little variation in intensity between 0.5 and 7%, with the greatest intensity being at 1%. This was the best of the 5 phosphors we made.

A more complex spectrum was obtained for α-$Ca_2GeO_4:Eu^{3+}$ (Fig. 3). Once again the main peak is at 611 nm, but there are also significant peaks at 700 nm, between 611 and 630 nm, and between 580 and 600 nm. Its brightness is poor compared with Y_2O_3:Eu, and too little of its emission is at 611 nm for it to be a satisfactory red phosphor.

The spectrum for $CaGeO_3:Eu^{3+}$ also shows significant peaks at 600 nm, between 611 and 630 nm, and between 580 and 600 nm as well as its main peak at 611 nm. This material too is not a good red phosphor for the reasons given above.

The spectrum for $Ca_3GeO_5:Eu^{3+}$ shows a number of peaks between 560-700 nm (Fig. 5), and it too is a poor red phosphor.

The spectral energy distribution for β-$Ca_2GeO_4:Eu^{3+}$ is quite good, but its efficiency is poor. Examination of reflectance of this material and of $Y_2O_3:Eu^{3+}$ shows that the reflectivity of $Ca_2GeO_4:Eu^{3+}$ was in the range 40-50% at 254 nm, while that of $Y_2O_3:Eu^{3+}$ was in the range 10-20%. We checked reflectivity to see if the

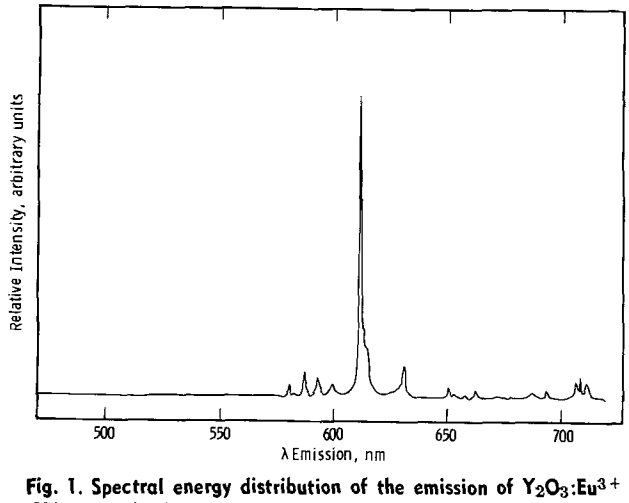

Fig. 1. Spectral energy distribution of the emission of $Y_2O_3:Eu^{3+}$ at 259 nm excitation.

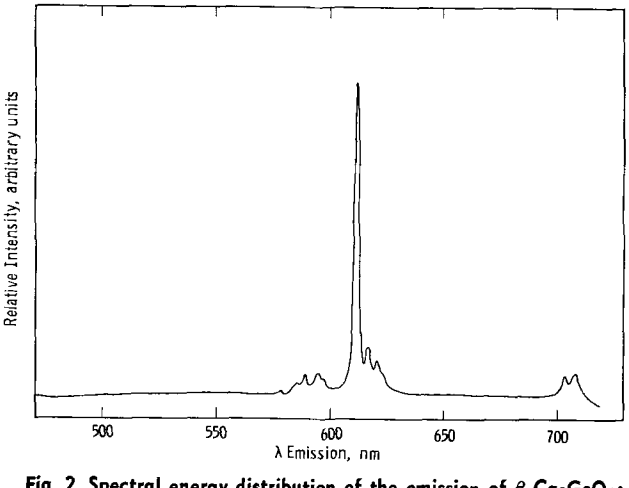

Fig. 2. Spectral energy distribution of the emission of β-$Ca_2GeO_4:Eu^{3+}$ at 259 nm excitation.

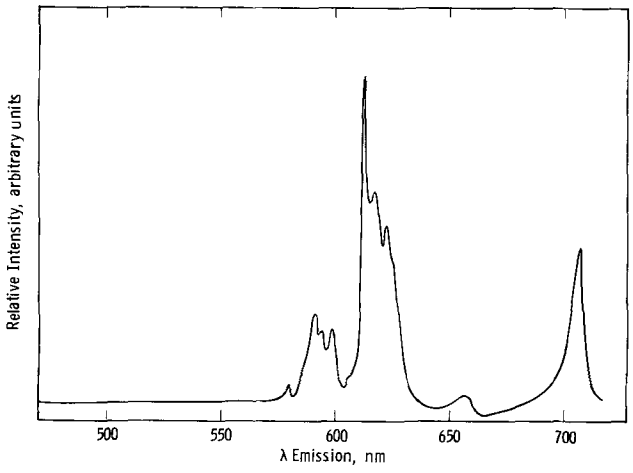

Fig. 3. Spectral energy distribution of the emission of α-$Ca_2GeO_4:Eu^{3+}$ at 259 nm excitation.

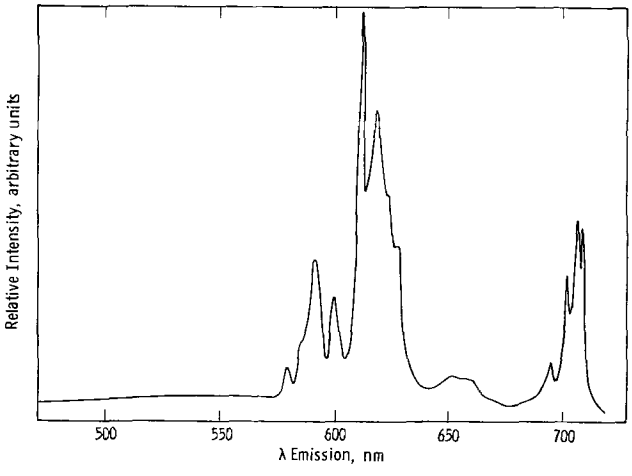

Fig. 4. Spectral energy distribution of the emission of $CaGeO_3:Eu^{3+}$ at 259 nm excitation.

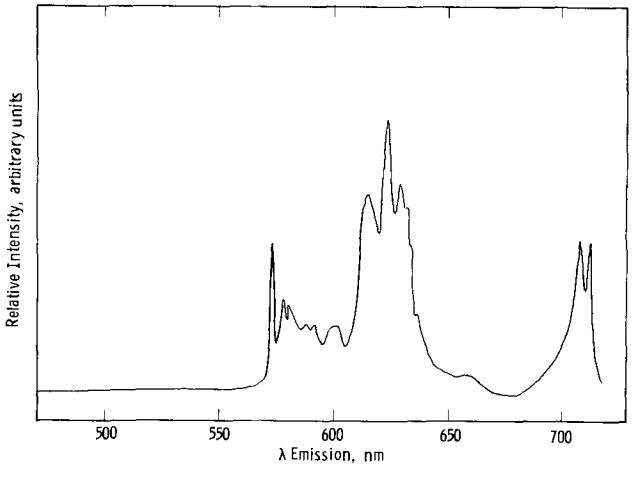

Fig. 5. Spectral energy distribution of the emission of $Ca_3GeO_5:Eu^{3+}$ at 259 nm excitation

low brightness was due to lack of absorption, but the difference in reflectivity was not great enough to explain the much poorer performance of Ca_2GeO_4: Eu^{3+}.

There are two Ca sites in this compound, one of which, ($\bar{1}$), has inversion symmetry, and the other, (m), has no inversion symmetry and has a linear crystal field term. The emission spectrum (Fig. 2) would indicate that much of the Eu^{3+} went into the (m) site, but it is possible that some of the Eu^{3+} may have entered the ($\bar{1}$) site.

If we assume structures analogous to corresponding silicates, then each of the other compounds which we made had one Ca site. It was noncentric and had a linear crystal field term, yet the emission spectra were poor. This result was somewhat unexpected as we expected to find a higher percentage of light in the 610 nm line where there was a single Ca site which was noncentric and had a linear term. A possible explanation for our results could be differences in charge compensation in these materials.

Acknowledgments

We wish to thank R. Williams for taking the emission spectra, and Dr. W. D. Partlow for obtaining reflectance data and, along with Dr. R. Warren, for reviewing the manuscript.

The Effect of Oxide Thickness on Threshold Voltage of Boron Ion Implanted MOSFET

R. B. Palmer,* C. C. Mai,* and M. Hswe
Mostek Corporation, Worcester, Massachusetts 01606

The greatest interest in the application of ion-implantation to MOS integrated circuit fabrication has been the ability to shift threshold voltages and to produce depletion-mode devices as well as enhancement-mode devices on the same chip (1-3). By applying ion-implantation techniques, the threshold voltage of enhancement-mode devices and the pinch-off voltage or the drain to source current, I_{DSS}, for depletion-mode devices may be adjusted to almost any desired value independent of substrate resistivity, gate dielectric, and metalization.

In the fabrication of MOSFET's by using the ion implantation technique to adjust the threshold voltage, V_T, the impurity ions are usually implanted through a thin oxide layer, *i.e.*, gate oxide. The effect of the oxide thickness on threshold voltage shift, ΔV_T, was studied and is reported in this paper.

Experimental Procedure

N-type silicon slices of 9-15 ohm-cm resistivity and <111> orientation were used as substrates. A standard P-channel MOSFET fabrication process was employed (1). Different thickness of thermally grown SiO_2 in the range of 600-2000Å were used as gates, and boron ions were implanted through these oxide layers. The implantations were carried out at 44 keV with two sets of doses: (*i*) 4×10^{11} ions/cm^2 for enhancement-mode devices and (*ii*) 2×10^{12} ions/cm^2 for depletion-mode devices. During the implantations, one-half of each slice was protected from the boron beam by a thin aluminum strip in order to provide both implanted and unimplanted devices on every slice. The unimplanted devices provide the reference value of V_T so that more accurate determination of the threshold shift may be determined. After implantation the slices were annealed at 950°C for 10 min in order to achieve essentially complete activation of the implanted boron species, and to eliminate the radiation damage.

An MOS test transistor with a channel length of 20 mils and width of 20 mils was used as a vehicle for measuring the threshold voltage (V_T at 1 μA) and drain-to-source current I_{DSS}. The latter was measured with a drain-to-source bias of 10V and 0V bias from gate-to-source. The relatively large values of W and L were chosen in order to minimize the effects of slight variations normally produced during fabrication on the parameters in question.

Effect of Oxide Thickness

Figure 1 shows the threshold voltages of the unimplanted and the implanted enhancement MOSFET's.

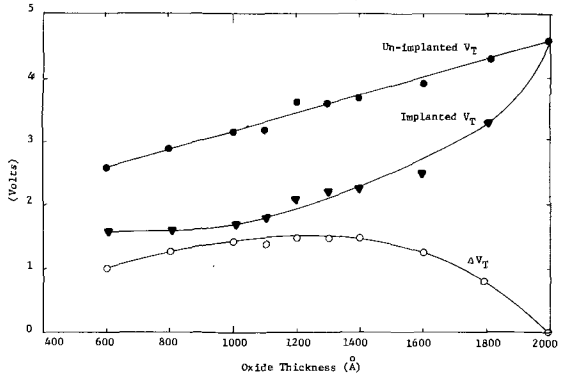

Fig. 1. Threshold voltage as a function of oxide thickness for an implanted dose of 4 X 10^{11} boron ions/cm^2 at 44 keV.

* Electrochemical Society Active Member.
Key words: ion-implantation, threshold voltage, MOSFET.

Also plotted at the bottom of the figure is the shift in threshold voltage as a function of oxide thickness. The boron implantation dose was approximately 4×10^{11} ions/cm^2. The graph shows that ΔV_T equalled 1V for 600Å of oxide and increased with increasing oxide thickness. ΔV_T appeared to remain relatively constant from 1000 through about 1400Å, and then gradually decreased. As the oxides became thicker than 2000Å, ΔV_T was effectively 0, *i.e.*, the additional implantation had no effect on the threshold voltages. The variation of the implanted thresholds with oxide thickness may be explained as follows. For oxides thicker than 2000Å, the implanted boron ions have insufficient energy to penetrate the oxide to reach the SiO_2-Si interface. As the thickness decreases, boron ions begin to reach this interface and counterdope the silicon surface. The channel resistivity is effectively increased, resulting in the reduction in V_T. The number of ions reaching the interface and slightly beyond increases with decreasing gate oxide thickness.

Figure 2 shows the same kind of plot for the more heavily implanted devices. The dose was approximately 2×10^{12} ions/cm^2. All of the MOSFET's became depletion-mode devices with the exception of those having 2000Å thick gate oxides. The pinch-off voltages were determined by extrapolation and the ΔV_T's were calculated. It is interesting to note that the curve of ΔV_T is very similar to that shown in Fig. 1. It may be concluded that for these implantation conditions the effect of implanted boron ions on V_T is essentially the same except for the magnitude of the V_T shifts.

The maximum threshold shift resulting from a given ion dose can be expressed as $V = qN_I/C_o$ (4) where N_I is the implanted dose and C_o is the oxide capacitance. However, V_T's measured in this study were observed to be lower than these maximum values. The percentage ratio of ΔV_T (observed) and ΔV_T max (calculated) is plotted in Fig. 3 as a function of oxide thickness. It is shown that this ratio decreases as oxide thickness increases (curve A). It is interesting to note that for an oxide thickness of 1000Å, the ratio is about 80%, which may be interpreted to mean that at least 80% of the boron ions penetrated the oxide layer and came to rest in the silicon near the SO_2-Si interface. This interpretation is consistent with the data of Swanson and Meindl (5) obtained by computer calculation of the LSS depth-penetration theory.

To calculate the depth distribution of boron in silicon can be very difficult for the SiO_2-Si structure, due to the unknown energy and vector distribution of boron ions at the SiO_2-Si interface (6). For a simple approximation, one can calculate the relative stopping power of SiO_2 and silicon and convert the thickness of SiO_2 into an equivalent thickness of silicon (7, 8). By applying this technique, the projected range of boron at 44 keV has been calculated as a function of oxide thickness, and is plotted (curve B) in Fig. 3. It can be seen that R_p is inversely proportional to

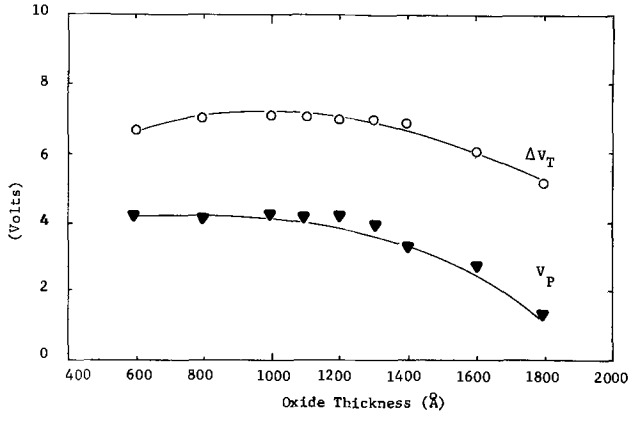

Fig. 2. Threshold voltage as a function of oxide thickness for an implanted dose of 2 X 10^{12} boron ions/cm^2 at 44 keV.

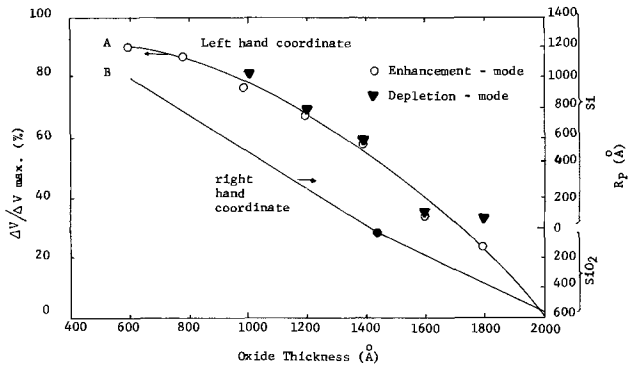

Fig. 3. (A) Left-hand coordinate, the ratio of ΔV to ΔV max as a function of oxide thickness. (B) Right-hand coordinate, R_p as a function of oxide thickness.

oxide thickness, decreasing linearly from 600 to 1440Å where the peak of the distribution is right at the SiO_2-Si interface. The slope then changes slightly and R_p remains in the SiO_2. The difference in slope is due to the small difference in ion stopping power between SiO_2 and Si.

From Fig. 1 it can be seen that at oxide thickness range of 600-800Å the V_T of the implanted devices remained constant at 1.6V regardless of the variation in oxide thickness. Since in this region, V_T changes at the same rate as ΔV_T, they are approximately compensated by each other. At the other extreme, at oxide thickness from 1600-1800Å, V_T is increasing while ΔV_T is decreasing. From a mass production point of view, one wishes to obtain constant V_T irrespective of the small unavoidable variation of oxide thickness. From the above data, we have demonstrated that for any particular energy level, there is an optimum oxide thickness range that can provide better V_T control. For boron ion implantation at 44 keV, the optimum oxide thickness is 600-800Å, which correlated to a R_p of from 900 to 1100Å inside silicon. For different oxide thicknesses, one should change the energy to obtain the same R_p, if constant V_T is desired.

Effect of Boron Projected Range

To demonstrate the importance of boron depth distribution on V_T, another experiment has been done as follows:

A number of slices having gate oxides of 1250Å were implanted with 5×10^{11} ions/cm^2 at energies between 24 and 84 keV. It was found that at 24 keV, ΔV_T was only 0.15-0.2V as shown in Fig. 4. The values of ΔV_T increased with increasing energy until 55 keV. From 55 to 84 keV the value of ΔV_T was essentially constant. This would imply that an energy of 60-70 keV would be most suitable for threshold shifting of devices having 1250Å gate oxides. Similar data have been reported by MacPherson (4).

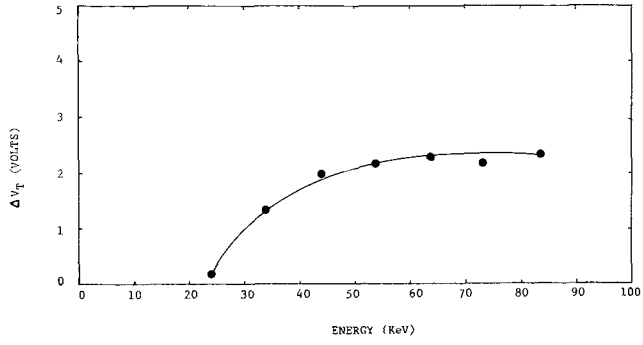

Fig. 4. Threshold shift as a function of implanted energy for an oxide thickness of 1250Å.

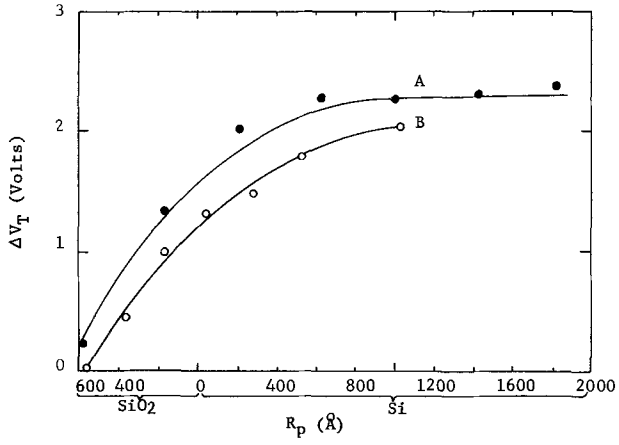

Fig. 5. Threshold shift ΔV_T as a function of boron ion project range R_p: Curve A, for energy of 24-84 keV with fixed oxide thickness of 1250Å; curve B, for fixed energy at 44 keV with oxide thickness from 600 to 2000Å as normalized to 1250Å.

These data are compared to those of Fig. 1 for the boron projected range R_p. ΔV of Fig. 4 and normalized ΔV_T to oxide thickness of 1250Å of Fig. 1 was plotted in Fig. 5 as a function of R_p. It was shown that both curves have the same trend, *i.e.*, ΔV_T increases with R_p and starts to saturate when R_p reaches about 600-800Å inside silicon. This phenomenon can be interpreted as follows. When R_p is deeper than 600-800Å, even though more boron penetrates the silicon dioxide layer, some of the boron ions are situated too far from the SiO_2-Si interface to cause a shift in threshold voltage. From the above study, it can be concluded that to obtain a constant ΔV_T, one can either adjust the oxide thickness with fixed implanted energy, or adjust the energy with fixed oxide thickness to place the R_p in the optimum location.

Summary and Conclusion

The effect of oxide thickness on threshold shifting by ion implantation has been reported. It has been found that for a particular implant energy, there is an optimum oxide thickness range for which a relatively constant V_T can be obtained. It has also been shown that for a given range of oxide thickness, there is an optimum energy which should be used to insure minimum variation in V_T.

Brief Communication

Reliability of NiCr "Fusible Link" Used in PROM'S

R. S. Mo and D. M. Gilbert

Xerox Corporation, El Segundo, California 90245

A fast integrated circuit Programmable Read Only Memory is useful in digital applications not only as a ROM, but as a universal logic element. However, because of its potentially wide usage and the complexity of the device, its reliability is a matter of concern. The usual IC reliability can readily be estimated (1). Some reliability data of the NiCr fusible link is presented in this communication.

The reliability of the NiCr fuses may be treated in two parts: the first part deals with the life of an unblown fuse; the second part deals with the reliability of a blown fuse. The test results reported here are based on six runs of a special test chip from a major vendor as well as samples from other vendors. The test chip is designed such that each fuse is individually accessible. Furthermore, chip temperature is controlled by built in temperature sensor and heater elements. The sample size is approximately 10,000 fuses from kit parts and an equal number from PROM's.

Key words: memory, nichrome, reliability, fuse.

The Fuse

The fuses studied are a NiCr film, approximately 350Å thick, vacuum deposited on a silicon dioxide substrate. Aluminum contacts are deposited over each end of the NiCr film and a 1 μm glass passivation layer covers the resulting structure. The film composition is approximately 65% Ni, 35% Cr with a sheet resistivity of 70 ohms per square.

The Unblown Fuse Life Test

The test fuses are "blown" by stressing with constant current and constant temperatures until they fail. The failure data under each condition was plotted using several distributions. The best fit, however, was obtained using the Weibull distribution (2, 3). The Wei-

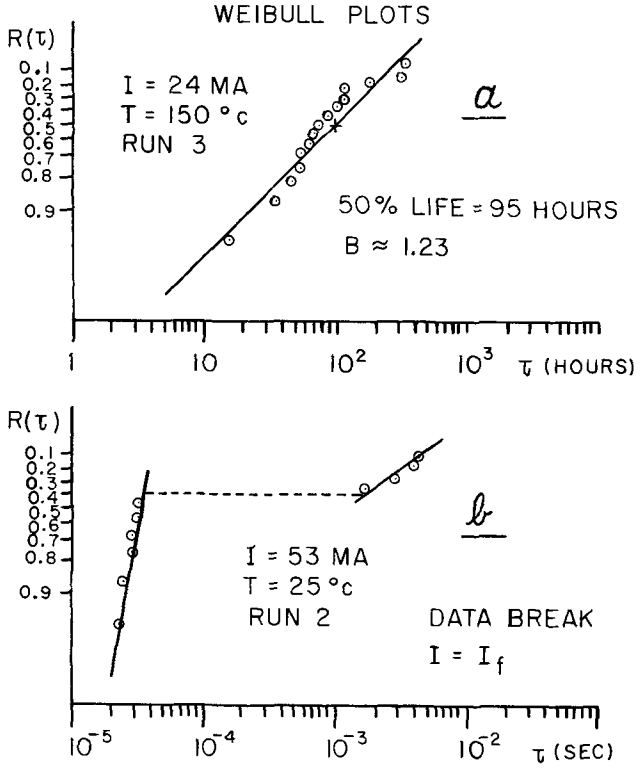

Fig. 1. Weibull plots. (a) For relatively low stresses, where the fuse temperature does not reach melting point, the failure times follow the Weibull distribution. (b) At a high current stress, a data break is observed. This indicates different failure mechanisms. Energy calculations show fuses melt above this break point.

bull density function is

$$f(t) = [\beta(t-\gamma)^{\beta-1}/\alpha] \exp[-(t-\gamma)^{\beta}/\alpha] \quad [1]$$

This expression may be rewritten as

$$\ln\ln[1/R(t)] = \beta \ln(t-\gamma) - \ln\alpha \quad [2]$$

where $R(t) = 1 - \int_0^t f(t)dt = 1 - F(t)$

At each stress level, the failure data was reduced to the form of Eq. [2] and plotted. The resulting "Weibull Plot" was used to estimate the 50% lifetimes. Good fits are obtained with $\gamma \simeq 0$ (time translation factor), and β (shape factor) varies from about 0.7 to 1.5 (Fig. 1a).

The Weibull plots in the very fast blow, high current region show a data break as shown in Fig. 1b. This indicates a different failure mechanism, and from energy calculations, it can be shown to correspond to melting of NiCr. Failure time here is a function of the fuse thermal capacity, thermal time constant, heat of fusion, and input power, and is in the μsec region. Blow times in the region of msec and longer are due to a different mechanism, possibly localized oxidation. By knowing the current at which this data break occurs, the "fusion current" I_f is obtained. I_f is the current required to raise the fuse temperature to the NiCr melting point (~1400°C).

Knowing I_f, the fuse temperature can be calculated at any given stress current I

$$T = [T_c + (I/I_f)^2(1400 - T_{cf})(1 - 1400c)]/$$
$$[1 - c(I/I_f)^2(1400 - T_{cf})] + 273 \quad [3]$$

where T = fuse temperature, T_c = chip temperature, T_{cf} = chip temperature at which I_f is measured, and c = fuse T.C.R. Equation [3] assumes that the T.C.R. is essentially constant throughout the temperature range.

Taking the 50% life estimates at various stress levels from the Weibull plots and comparing these with the calculated fuse temperatures at each of these stress levels, the failure times are observed to obey the Arrhenius equation

$$L = Ae^{\phi/kT} \quad [4]$$

where A = constant, k = Boltzmann constant, ϕ = activation energy, T = calculated fuse temperature, and L = 50% lifetime.

Figure 2 shows the data obtained from four different runs. Run 4 showed abnormally high T.C.R. and low activation energy. The other 3 runs show consistent life projections. Analysis using electron microprobe showed run 4 to have different composition and thickness. It is evidently the result of abnormal process variations. From Fig. 2 the 50% life at 110°C is estimated at 3×10^5 yr. The failure percentage of 1024-bit PROM's in 10 yr may also be estimated: ~1.0% for $\beta = 1$.

The Blown Fuse Reliability

"Healing" or relinking of a blown fuse is found to be possible. The conditions which encourage the heal phenomena are slow blowing and current limited voltage bias across a blown fuse, as well as elevated temperatures.

Figure 3 shows scanning electron micrographs of a fuse blown with a slow ramp voltage source. The "whiskers" are believed to be important in the relinking process, as shown in the figure.

Under normal PROM pulse blowing conditions, the blowing time is usually in the microsecond regions. Tests on fuses blown in this range have never shown healing under normal operating bias voltage (4.5V) and temperature (110°C). Figure 4 is an SEM picture of a fuse blown in that time region. For the marginal cases where the current density at the fuse neck is less than 4×10^7 A/cm^2, and the blowing time is in the region of several milliseconds, the fuses may heal. Heal probabilities as high as 3% have been observed for such fuses at 150°C in 500 hr. Almost all the heals occur in the first two hours. (One fuse healed in ~300 hr.) Healed fuses in these cases have $R \simeq 1K$ and will reblow with $i < 1$ mA.

The evidences so far suggest that unless circuit design takes into account the fuse requirements, healing can definitely occur. The desirable conditions for no healing are: blow current density $\geq 4 \times 10^7$ A/cm^2, such that blow time is <10 μsec; the bias voltage across

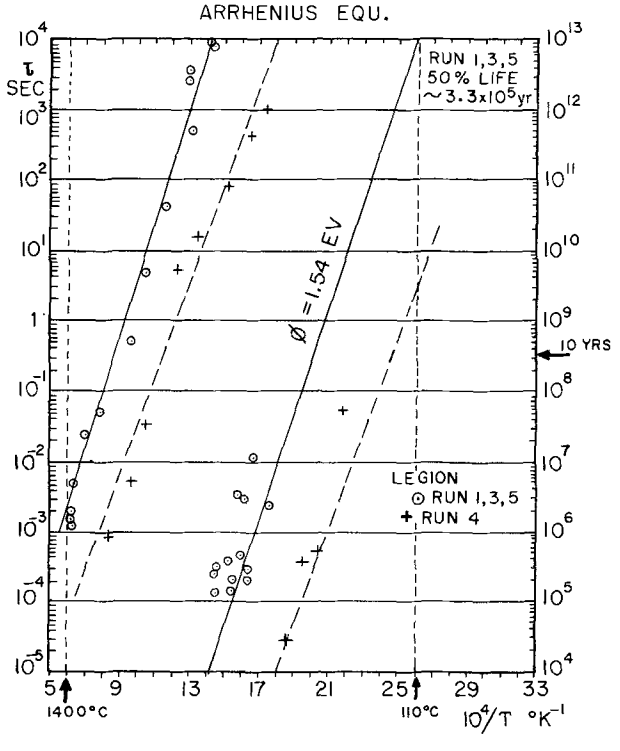

Fig. 2. Arrhenius equation. Fifty per cent life obeys the Arrhenius equation. The life for normal fuses is adequate.

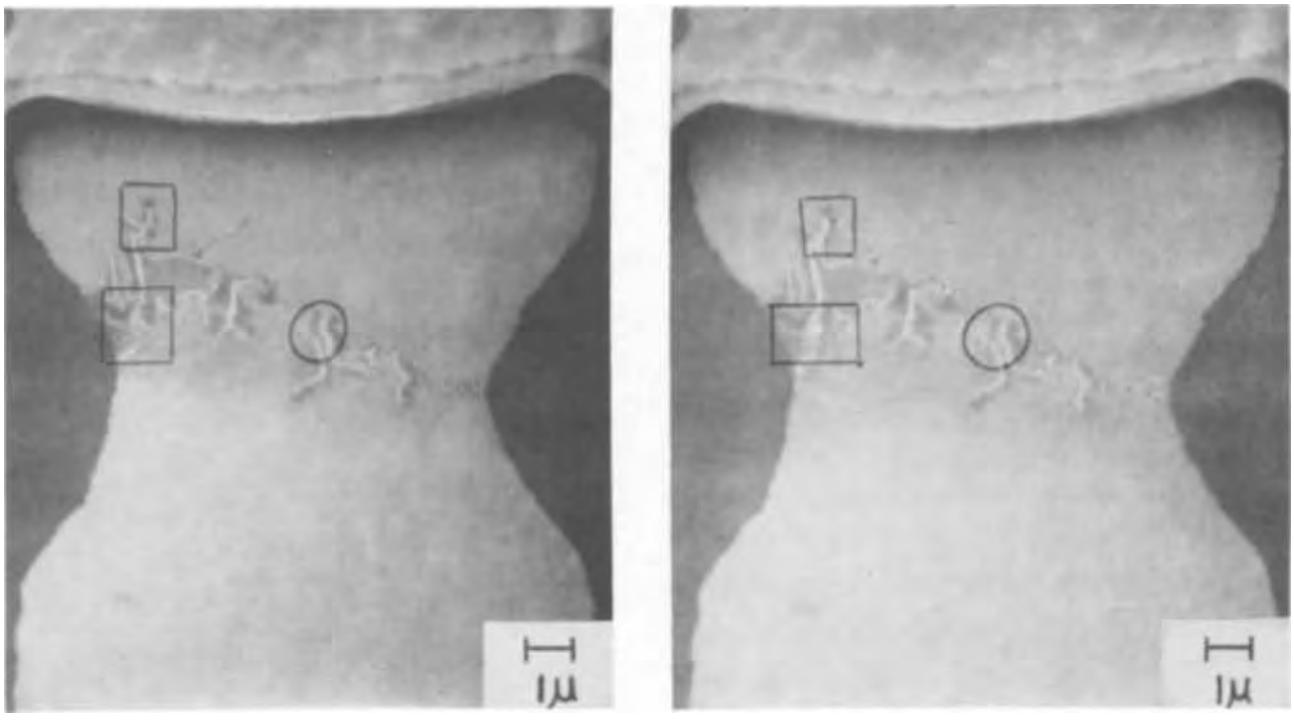

Fig. 3. Fuse blown by slow V-ramp; left, healed fuse; right, same fuse, reblown. The fuse was healed, examined, and then reblown. The marked areas show differences in pattern. Square boxes indicate healed areas reopened by reblowing. Circled area shows growth of conductive strand, though contact was not made.

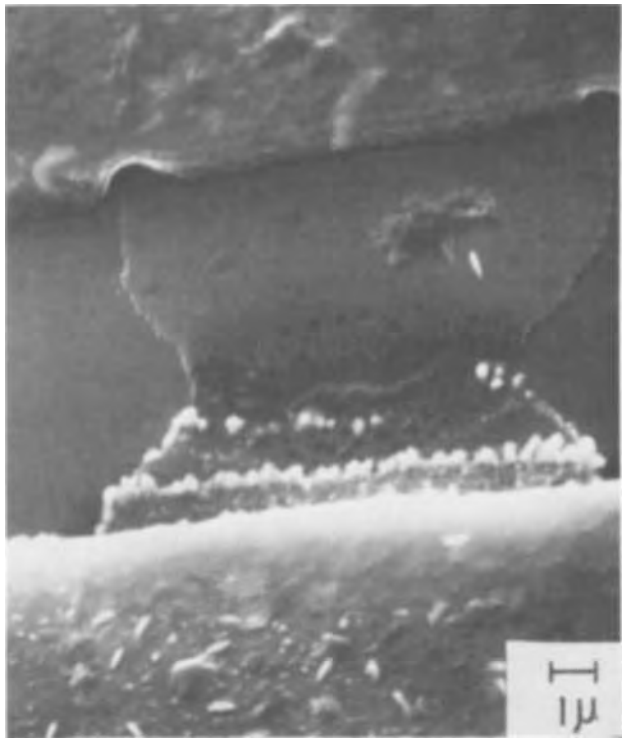

Fig. 4. Fuse blown by fast pulse. This fuse was blown with current density of $\sim 4 \times 10^7$ A/cm^2. Blowing time was < 4 μsec. Such fuses have not been observed to heal.

the blown fuse is low, preferably <1.0V; and the sense circuit has a threshold such that >1 mA conduction through the fuse is needed for detection. The fact that most heals occur quickly also suggests a burn-in after programming may be most useful.

Conclusion

It is shown here that the fuse failure times for a given stress obey the Weibull distribution, and the failure times are temperature dependent, obeying the Arrhenius equation. Excepting for certain grossly abnormal fuse runs, the unblown fuse life is generally adequate though by no means negligible, for a 1024 bit PROM. For the blown fuses, healing can occur. No heal model is available yet. However, it is established that the heal problem can be greatly reduced if proper blowing conditions as well as circuit biasing and sensing conditions are achieved.

A Model for Discharge of Storage Batteries

Dimitri Gidaspow

Institute of Gas Technology, Chicago, Illinois 60616

and Bernard S. Baker*

Energy Research Corporation, Bethel, Connecticut 06801

ABSTRACT

The common porous electrode model has been rederived to include the transformation of one solid phase into another, for example, lead into lead sulfate. Differential mass balances for the solid porous reactant and the solid product yielded new dimensionless groups which characterize the structural changes that occur during discharge or charge of storage batteries. Effects of fraction of active material, exchange current and molar density ratios on overpotential at a constant current were investigated numerically. The trends agree well with the empirical correlation of Shepherd.

At the present time no comprehensive electrode model exists for batteries of any kind (1-4). Discharge data are related to discharge duration by purely empirical equations of the type $I^n t = C$, where I is current, t is time, and n and C are constants having no physical significance, as for instance in a recent paper on lead-acid batteries (5). A more comprehensive empirical equation is that developed by Shepherd (6). It takes into account the consumption of the active material and in this respect is not purely empirical. Shepherd's equation correctly describes discharge curves for many batteries over a range of current densities. His polarization coefficient and electrical internal resistance, however, have no physical meaning because they are some lumped parameters for two electrodes with at first no electrical resistance in the metal or solution phases (Eq. 7), with an afterthought correction for a resistance (Eq. 8).

The first theoretical attempt at predicting overpotentials as a function of time that can be applied to a single electrode of a battery has recently appeared (7). The authors use the common, steady-state, one-dimensional porous electrode equations combined with a mass transport of an active species given by a mass transfer coefficient that must be determined empirically. To handle time-dependent phenomena Dunning, Bennion, and Newman (7) assume that their mass transfer coefficient is some reasonable function of the amount of active material present in any part of the electrode. Their approach apparently allows them to predict a failure caused by an internal mass transfer limitation with a sparingly soluble reactant, although they do not cite any experimental studies in support of their conclusions. Their model cannot predict failure by blockage of pores that is commonly observed in lead acid batteries (1) and in the recent study of cadmium electrodes (8).

In this paper we are proposing a model that describes the time variation of charge and discharge of a battery for given electrode kinetics and initial structure of electrodes. The structure of the porous electrodes changes with the state of charge or discharge, with pores opening or closing depending on the molar volumes of solid reactants and products. The shape of our calculated overpotential *vs.* fractional capacity utilized curves agree with Shepherd's correlations. A quantitative comparison has not been made, because his discharge data are for two electrodes and because we found that structural parameters that are usually different for the negative and positive electrodes markedly influence the overpotential curves. We present numerical results for constant current operation of a single electrode of a battery.

As in the study of Dunning, Bennion, and Newman (7) we consider the electrode to be one dimensional. We therefore do not consider effects such as shape changes that are two or three dimensional. We also present numerical results only for the case of linear polarization which is claimed to be (9) valid for alkaline nickel-cadmium batteries and should be valid in general at low current densities. The principal contribution of this paper is believed to be the analysis of battery failure by chocking near the front of the electrode.

Description of the Model

Consider generation of current in a porous electrode such as treated by Ksenzhek (10), Pschenichnikov (11), and particularly by Tobias and co-workers (12, 13). However, unlike in the previous studies (7, 13), assume that in the porous electrode a consumable solid-fluid reaction takes place. The reaction could be the formation of lead sulfate in the positive plate of a sulfuric acid lead battery

$$PbO_2 + 2H^+ + H_2SO_4 + 2e \rightarrow PbSO_4 + 2H_2O \quad [1]$$

the reaction of lead in the negative plate

$$Pb + SO_4^{=} - 2e \rightarrow PbSO_4 \quad [2]$$

or the reaction of cadmium to form an insoluble product in the cadmium electrode

$$Cd + 2\,OH^- - 2e \rightarrow Cd(OH)_2 \quad [3]$$

* Electrochemical Society Active Member.

Key words: porous electrode, solid-state reaction, current distribution, pore plugging, molar volumes, integral equation.

In each case, in a well-designed electrode, the solid reagent, be it lead or cadmium, is sufficiently finely dispersed to be accessible to the electrolyte. As the reactions proceed to the right, there is less and less solid reagent to produce current. Furthermore the solid products occupy considerably more space forcing the electrolyte out of the electrode. The ratios of molar volumes of solid products to solid reactants for Eq. [1]-[3] are 1.9, 2.7, and 2.3, respectively (14). This causes a decrease of the effective conductivity of the electrolyte in the pores of the electrode and possible blocking of the pores.

To easily handle this physical reality, assume that at any point in space in the electrode we have the following phases: the solid reactant, called S, the solid product called P, electrolyte, binder, and a metal support that acts as a conductor which is electrically connected to a metal backing. Such a continuum approximation should be valid for a well-designed electrode of a high surface area, as discussed by Gidaspow (15). Then on an inert free basis the volume fractions of S, P, and the electrolyte add up to one

$$\epsilon_S + \epsilon_P + \epsilon = 1 \qquad [4]$$

A current balance on an element of volume $A\Delta x$, as shown in Fig. 1, is

$$[I\epsilon A]_x^{x+\Delta x} = -\int_x^{x+\Delta x} ia\epsilon_S A dx \qquad [5]$$

where i is the rate of production of current per unit area by chemical reaction and a is the surface to volume ratio for the solid reagent. The current flux I is related to the electrical conductivity of the solution, K by Ohm's law

$$I = -K\frac{\partial V_S}{\partial x} \qquad [6]$$

where V_S refers to the voltage in the solution phase as for example in the model of Newman and Tobias (12). Application of the mean value theorems to [5] and the usual limiting process yield the partial differential equation for the solution potential

$$\frac{\partial}{\partial x}\left(K\epsilon\frac{\partial V_S}{\partial x}\right) = ia\epsilon_S \qquad [7]$$

In general i is a function of potential differences and concentrations in the fluid phases of reactants and products. For constant concentrations in the porous electrode a commonly (12) used form is

$$i = i_0\left\{\exp\left[-\frac{n\mathbf{F}}{2RT}(V_m - V_S)\right] - \exp\left[\frac{n\mathbf{F}}{2RT}(V_m - V_S)\right]\right\} \qquad [8]$$

where i_0 is the exchange current density, V_m the metal potential, and the other symbols have their usual meaning. Sometimes (6) for discharge of storage batteries a linear relation seems applicable. For $(V_m - V_S)/(RT/n\mathbf{F}) << 1$ relation [8] becomes

$$i = i_0\left(\frac{n\mathbf{F}}{RT}\right)(V_S - V_m) \qquad [9]$$

Although a specific form of current-polarization relation will be used in this study, the theory presented here is not restricted to any particular electrode kinetics.

It was already shown by Gidaspow (15) that for the reaction

$$A(f)^{-n} + S(s) - n(e) \rightarrow \gamma P(s) \qquad [10]$$

a mass balance on S yields the differential equation for the volume fraction of S

$$\rho_S\frac{\partial\epsilon_S}{\partial t} = -\left(\frac{iM_S a}{n\mathbf{F}}\right)\epsilon_S \qquad [11]$$

when the thickness of the electrode remains constant. Similarly a mass balance on P yielded

$$\rho_P\frac{\partial\epsilon_P}{\partial t} = \left(\frac{iM_P\gamma a}{n\mathbf{F}}\right)\epsilon_S \qquad [12]$$

Since expansion or contraction occurred at the expense of the fluid phase, the volume fraction of liquid is obtained by difference as

$$\epsilon = 1 - \epsilon_S - \epsilon_P \qquad [13]$$

Initial distributions of S and P can be chosen to be functions of electrode thickness. They are ϵ_{SO} and ϵ_{PO}.

Two boundary conditions are needed for the second-order differential Eq. [7]. At the metal backing, solution ends. Therefore at

$$x = L, \quad \frac{\partial V_S}{\partial x} = 0 \qquad [14]$$

To compare calculated results to discharge data, consider the case of constant current discharge. Then for a discharge current density I_0, expressed on an inert free basis, at the solution end we have at

$$x = 0, \quad -K\epsilon\frac{\partial V_S}{\partial x} = I_0 \qquad [15]$$

The electrode overpotential $V_S(t,0) - V_S(t,L)$ is one of the quantities we want to obtain. Note that V_m does not enter into this potential difference.

The case of prescribed potential at $x = 0$, when using the linear relation [9] corresponds exactly to the case of a first-order reaction for concentration obtained by Gidaspow (15). All results presented for concentration are applicable to the potential difference in this case. However, since such operation is uncommon we will proceed only with the constant current case. The model is, of course, applicable to time-dependent operation, as long as changes are slow enough for the double-layer capacity effects to be negligible. Changes in concentration can be accounted for by the use of diffusion equations of the type solved by Gidaspow (15) coupled with the problem presented here. When the metal reagent carries most of the current, an equation for metal potential of the type of Eq. [7] must be added to the system. In this study, however, the conductivity of the metal phase is assumed to be so high that the metal is at the potential of the metal backing plate.

We would like to add that while potentiostatic studies of batteries are rare, as already noted by Sanghi and Fleischmann (16), they provide an excellent means to study rates of electrochemical reactions. Since the rate constants controlling electrochemical reactions are chiefly potential dependent, they can be kept constant during study by this procedure. In this way we obtain an analogy between concentration and potential. We thus expect the rates to behave similarly with potential, as was observed with concentration by Onischak and

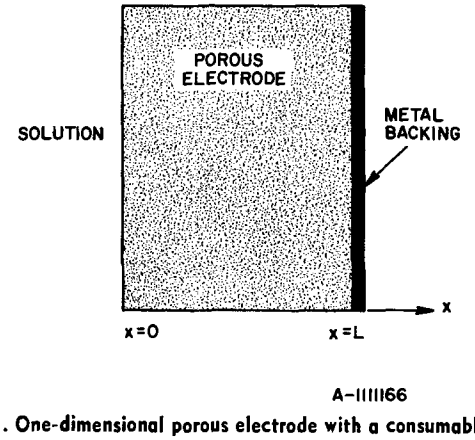

Fig. 1. One-dimensional porous electrode with a consumable solid

Gidaspow (17). Indeed Fleischmann and Thirsk's (18) Equation 1 is analogous to Gidaspow's Equation 12 (15). Furthermore, Fleischmann and Thirsk observed maxima in rates with time for the reverse reaction given by Equation 2 for which pores tend to open up leading to an initial increase in rate. Such limited electrochemical rate studies with consumable solid reactions provide additional support for the form of the rate expression chosen in this study.

Dimensionless Equations

For the case of linear polarization, as expressed by Eq. [9], the potential distribution in the electrode is governed by

$$\frac{\partial}{\partial \bar{x}}\left(\epsilon \frac{\partial Y}{\partial \bar{x}}\right) = \phi^2 \epsilon_S Y \qquad [16]$$

In Eq. [16], Y is the difference of solution minus metal potentials scaled by the current drawn, as shown below

$$Y = \frac{V_S - V_m}{\left(\frac{i_0 L}{K}\right)} \qquad [17]$$

The boundary condition given by Eq. [15] dictated this choice of scale factor.

The group

$$\phi^2 = \frac{i_0 n \mathbf{F} a L^2}{RTK} \qquad [18]$$

is a dimensionless exchange current. It is called ϕ^2 due to its analogy to the Thiele modulus in the concentration problem (15).

The boundary conditions (BC) for Eq. [16] become, in dimensionless form

$$\text{BC 1: } \frac{\partial Y(t,1)}{\partial \bar{x}} = 0 \qquad \text{BC 2: } \epsilon \frac{\partial Y(t,0)}{\partial \bar{x}} = -1 \qquad [19]$$

Equation [11] dictates that the dimensionless time, $\bar{t}$ be expressed as

$$\bar{t} = \left(\frac{i_0 M_S a L}{RTK\rho_S}\right)(I_0 t) = \epsilon_{SO}\phi^2\left(\frac{I_0 t M_S}{\epsilon_{SO} L \rho_S n \mathbf{F}}\right) = \epsilon_{SO}\phi^2 t_f \qquad [20]$$

with

$$t_f = I_0 t / Q$$

where t_f is the fraction of theoretical capacity utilized at time t, since $Q = \epsilon_{SO} L\rho_S n\mathbf{F}/M_S$ is the initial number of coulombs per unit area of electrode on an inert free basis. Discharge data are usually plotted *vs.* $I_0 t$ or *vs.* $I_0 t/Q$.

In Eq. [16], ϵ_S is determined by the integrated form of Eq. [11] which is

$$\epsilon_S = \epsilon_{SO} \exp\left[-\int_0^{\bar{t}} Y dt\right] \qquad [21]$$

and ϵ is given by

$$\epsilon = (1 - E\epsilon_{SO} - \epsilon_{PO}) + (E - 1)\epsilon_S \qquad [22]$$

where E is the ratio of molar volumes of solid product to solid reactant times the stoichiometric coefficient γ.

Integral Equation Representation

To solve this nonlinear system of partial differential equations it is best to reformulate the system in terms of integral equations. Integration of Eq. [16] using boundary condition [2] gives

$$Y = \phi^2 \int_0^x \frac{dz}{\epsilon} \int_0^z Y \epsilon_S dx' - \int_0^x \frac{1}{\epsilon} dz + C_2 \qquad [23]$$

where C_2 is an integration parameter. To obtain C_2 apply an integral of zero to one to Eq. [16]. This procedure gives

$$\epsilon \frac{\partial Y}{\partial x}\Big]_0^1 = \phi^2 \int_0^1 \epsilon_S Y dx' \qquad [24]$$

Then using both boundary conditions we obtain

$$\phi^2 \int_0^1 \epsilon_S Y dx' = 1 \qquad [25]$$

Equation [25] says that we draw current at a constant rate. Using this equation and applying an integral of zero to one to Eq. [23], C_2 is determined to be

$$C_2 = \frac{1}{\int_0^1 \epsilon_S dx'}\left[\frac{1}{\phi^2} - \phi^2 \int_0^1 \epsilon_S dx \int_0^x \frac{dz}{\epsilon} \int_0^z Y \epsilon_S dx' + \int_0^1 \epsilon_S dx \int_0^x \frac{1}{\epsilon} dz\right] \qquad [26]$$

Equation [23] is now a functional equation of the form

$$Y = G(Y) \qquad [27]$$

It is solved simultaneously with the integral Eq. [21] by iteration and marching in time similarly to the procedure already discussed by Gidaspow (15). As a first guess in the iteration procedure the exact analytical solution for zero time, shown in the next section, was used. In this manner the simple iteration

$$Y_{n+1} = G(Y_n) \qquad [28]$$

where the subscripts denote iterates worked for parameters investigated in this study. Improved iteration was only infrequently resorted to.

The fraction of theoretical capacity utilized, t_f, can be obtained from the dimensionless time, $\bar{t}$, using the relation $\bar{t} = \epsilon_{SO}\phi^2 t_f$ derived in the previous section. It can be also obtained by material balance as follows. By definition we have

$$t_f = \int_0^1 \frac{\epsilon_{SO} - \epsilon_S}{\epsilon_{SO}} d\bar{x} \qquad [29]$$

Substitution of Eq. [21] gives

$$t_f = 1 - \int_0^1 \exp\left[-\int_0^{\bar{t}} Y dt\right] d\bar{x} \qquad [30]$$

Such a calculation served as a check on possible accumulation of errors. It was obtained in a natural way from the quantity of solid product formed, given at any x by the equation

$$\epsilon_P - \epsilon_{PO} = E(\epsilon_{SO} - \epsilon_S) \qquad [31]$$

The fractional capacity utilized calculated in this manner always agreed with that calculated from the dimensionless time, $\bar{t}$. To minimize expenditure of computer time, the interval zero to one was divided into only ten or twenty parts, since the computer time increased as the cube of the ratio of subdivisions. With ten subdivisions it took only a few minutes on the small IBM 1130 to generate a complete time profile. For small ϕ^2, results were sufficiently accurate for graphical representation even with such a coarse grid.

Zero Time Solution

At zero time, that is before any capacity of the battery is used up, the system of partial differential equations reduces itself to the simple boundary value problem

$$\frac{d^2Y}{d\bar{x}^2} = \phi^2 \frac{\epsilon_{SO}}{\epsilon_0} Y$$

$$\text{BC 1: } \frac{dY(1)}{d\bar{x}} = 0 \qquad \text{BC 2: } \epsilon_0 \frac{dY(0)}{d\bar{x}} = -1 \qquad [32]$$

where

$$\epsilon_0 = 1 - \epsilon_{SO} - \epsilon_{PO}$$

Its solution is

$$Y = \frac{1}{\phi\sqrt{\epsilon_{SO}\epsilon_0}\tanh\phi\sqrt{\epsilon_{SO}/\epsilon_0}}\cosh\phi x\sqrt{\epsilon_{SO}/\epsilon_0} - \frac{1}{\phi\sqrt{\epsilon_{SO}\epsilon_0}}\sinh\phi x\sqrt{\epsilon_{SO}/\epsilon_0} \quad [33]$$

By Taylor series expansion we can obtain some useful approximations. Equation [33] shows that for small ϕ, that is for thin cells, Y becomes very large. Y is roughly given by $1/\phi^2\epsilon_{SO} - x/\epsilon_0 - x^2/\epsilon_0$. This shows that for small ϕ^2 we must obtain Y correct to a large number of significant figures in order not to lose all accuracy in calculating the potential difference $Y(0) - Y(1)$. This overpotential can be approximated by the formula

$$Y(0) - Y(1) = \frac{1}{2\epsilon}\left(1 - \frac{1}{24}\phi^2\epsilon_{SO}/\epsilon_0\right) \quad [34]$$

for

$$\phi^2\epsilon_{SO}/\epsilon_0 < 1$$

Formula [34] shows that for $\phi^2 < 1$ and reasonable ϵ_{SO}, the overpotential is not a function of the electrode kinetics. Roughly we have

$$\frac{V_S(0,0) - V_S(0,L)}{\left(\frac{I_0 L}{K}\right)} = \frac{1}{2\epsilon_0} \quad [35]$$

The electrode kinetics which appears in the dimensionless exchange current ϕ^2 is only a correction to the dominant behavior which is governed by the conductivity and the structure of the electrode. Values of ϕ^2 much larger than one result in a high localization of the reaction near the solution face and are not desirable. Such cells are much too thick. A value of ϕ^2 near one is not unreasonable as seen from the hypothetical example below. Let

$i_0 = 10^{-5}$ A/cm^2 $\qquad \frac{nF}{RT} = 40$ volts^{-1}

$a = 10^4$ cm^{-1}

$K = 10^{-1}$ mho/cm $\qquad L = 0.1$ cm

Then ϕ^2 becomes equal to 0.4. Note that by having chosen a simplified form of polarization relation we were able to obtain a number of significant conclusions which may have escaped us had we tried to solve a more realistic problem at the start.

Numerical Results and Discussion

Several kinds of information can be derived from the model. In Fig. 2 the distribution of reactant is shown as a function of electrode thickness for different states of discharge starting with zero for reference purposes and rising to 95% discharge. We assumed there was no solid product initially for all cases studied and chose the values of E and ϵ_{SO} such that pores never ultimately close completely. In Fig. 3 the void fraction distribution is indicated by solid lines for this case. The voids are filled with electrolyte in the model and therefore the curves indicate how the electrolyte conductivity changes with depth into the electrode. The dashed curves in Fig. 3 are for such a sufficiently high value of E that pores ultimately close. This leads to incomplete discharge. Only slightly over 56% of the theoretical capacity can be utilized when half the volume of the electrode on an inert free basis is made of the active material. Clearly such an electrode should never be built and those with experience in the field avoid the use of such high percentages of active solid material.

Constant current battery discharge data with respect to a reference electrode can be obtained in the laboratory as a function of discharge time. Figures 4-6 show such overpotentials *vs.* discharge times for various hypothetical electrodes. We note that the plots agree with the empirical correlation of Sheperd (6), as much as one can expect of a correlation that averages the negative and positive electrodes. Specifically Shepherd's Equation 8 can be rewritten in our notation as

$$\frac{V_S(t,0) - V_S(t,L)}{I_0 K_{Sh}} = \frac{1}{1 - \frac{I_0 t}{Q}} + N/K_{Sh} \quad [36]$$

where K_{Sh} is the K used by Shepherd and N is his N. The left side of Eq. [36] corresponds to our dimensionless overpotential in the plots. The independent variable is identical with Shepherd's. Our plots have the basic shape indicated by Eq. [36], except that Shepherd's correlation predicts an infinite overpotential for complete utilization only. Our model predicts high overpotentials for less than complete utilization, for poorly constructed electrodes.

Figure 4 shows the large effect played by the expansion ratio, E. The values indicated are quite realistic, since E for the negative plate of a sulfuric acid

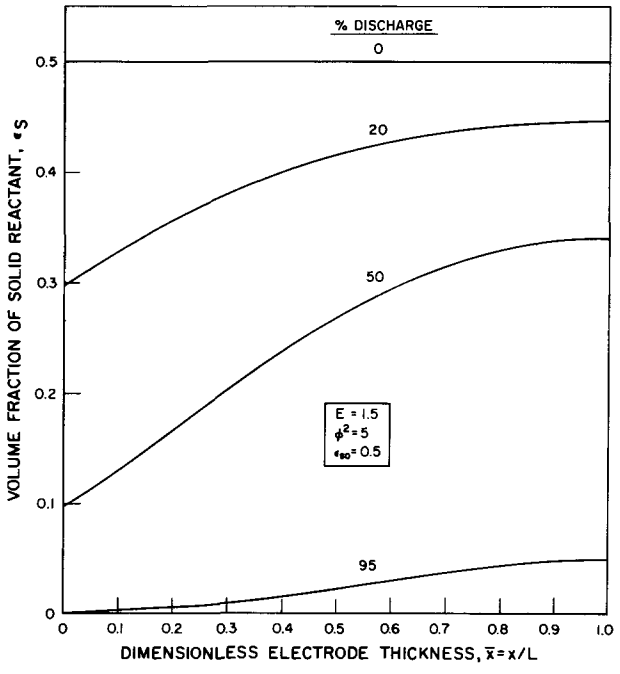

Fig. 2. Distribution of active material during discharge

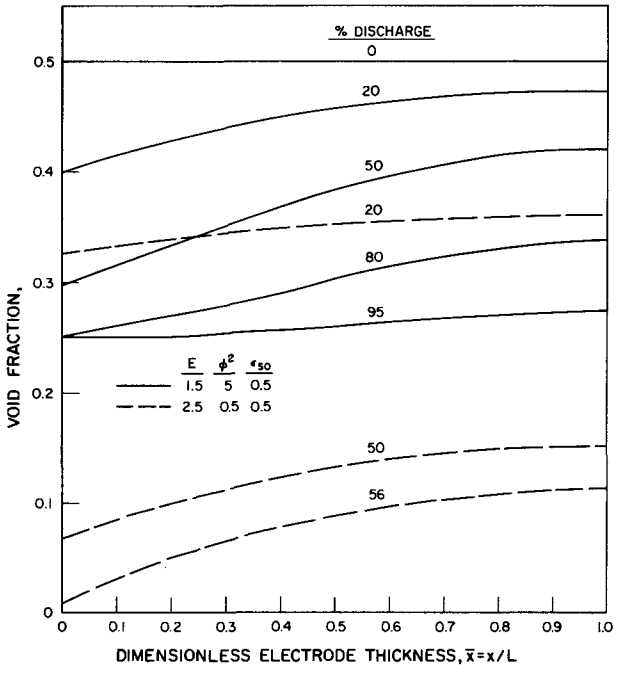

Fig. 3. Distribution of electrolyte with incomplete (——) and complete (– –) pore closing.

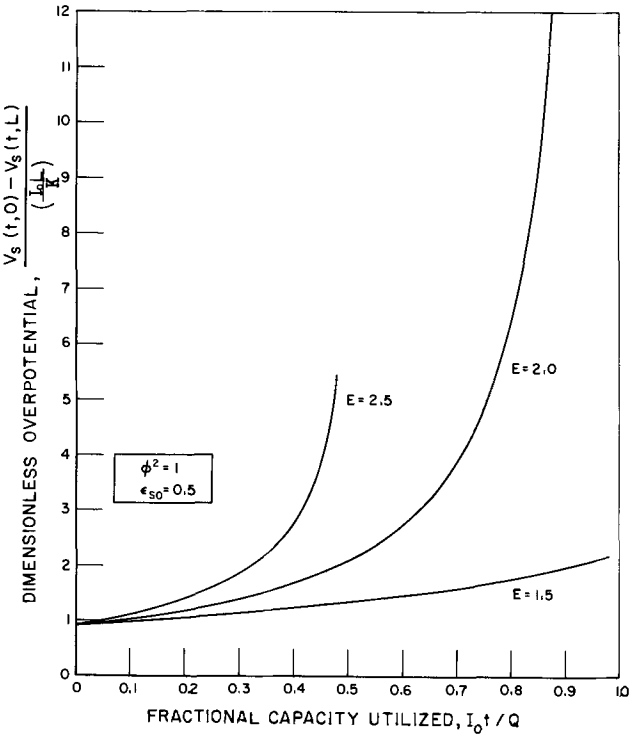

Fig. 4. Effect of expansion ratio on overpotential

battery is 2.7. Thus if half the plate were made of lead ($\epsilon_{so} = 0.5$ in the figure) no more than about 30% of the theoretical capacity could be utilized.

Figure 5 shows the effect of the initial fraction of active material on overpotential. For a uniformly accessible case (15) pores will close completely when the product of ϵ_{so} and E reaches unity. For $E = 2.5$ in Fig. 5 this occurs at $\epsilon_{so} = 0.4$. The performance of the hypothetical battery shown is poor at this value and beyond. No one would build such a plate. Our result, however, has nothing to do with hard won experience. The agreement with the facts shows the validity of the transport phenomena approach.

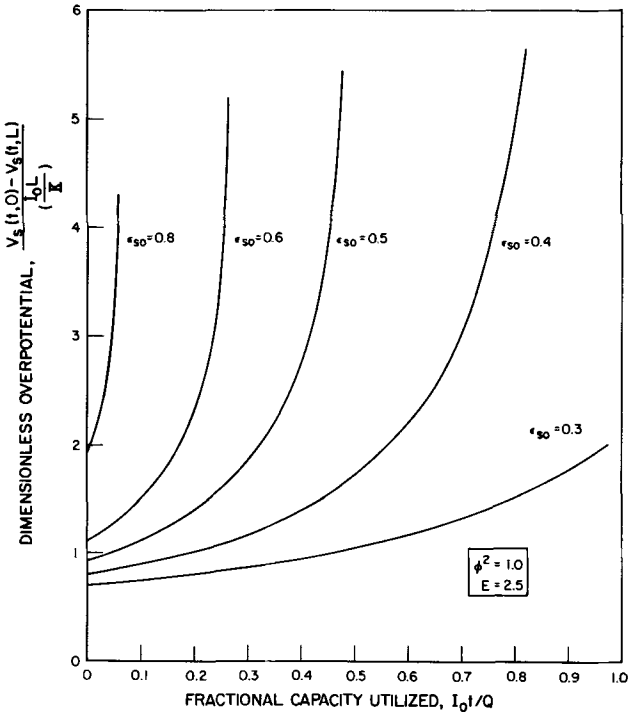

Fig. 5. Effect of initial fraction of active material on overpotential with a high expansion ratio, E, and unit dimensionless exchange current, ϕ^2.

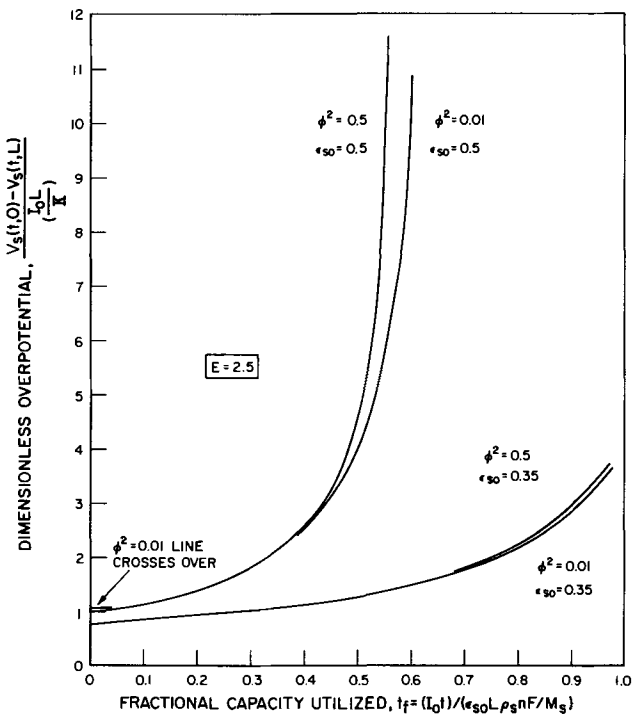

Fig. 6. Effect of dimensionless exchange current, ϕ^2, on overpotential for two initial fractions of active material.

Figure 6 shows the effect of the dimensionless exchange current on overpotential, that is it shows the role played by the electrochemical kinetics. In the linearized polarization curve real kinetics entered only through the exchange current, i_0. In dimensionless quantities it appeared only in ϕ^2. Figure 6 shows that at least for values of ϕ^2 less than one electrochemical kinetics plays only a small role. To verify this surprising conclusion we had developed the approximate solution for zero time presented in the previous section. In view of this result we feel that our model approximates the operation of a real battery.

Operation of the electrode at a constant overpotential, with other assumptions held the same, is described by the results presented by Gidaspow (15) for concentration. The dimensionless problem for a dimensionless overpotential Y is given by his Equations 20 to 23. As shown in his Figure 3, the current will decrease with time exponentially when pores close. We also suggest that kinetic data that are needed for further refinements of our model be obtained potentiostatically on real battery electrodes and analyzed as suggested by the models.

The Hydrogen Evolution Reaction on Ti-6Al-4V in Acidic Solutions of NaCl-HCl

Pedro J. Aragon

Facultad de Ciencias, Departamento de Quimica, Universidad de Los Andes, Merida, Venezuela

ABSTRACT

The HER on polycrystalline Ti-6Al-4V in acidic solutions of NaCl-HCl at constant concentration of $Cl^- = 0.5M$, and pH range from 0.65 to 2.5 was studied. Under the present experimental conditions, the reaction was shown to be first order with a Tafel slope of 0.153V. Exchange current densities were in the order of 10^{-8} A-cm^{-2}. An apparent energy of activation of $\Delta E = 45.3$ kcal-mol^{-1} was found. A sharp decrease in potential was observed after reaching about -1.220V (SCE). It is assumed that this effect is due to concentration polarization. Curves corresponding to cathodic polarizations showed a positive deviation from linearity for pH 0.65 and 1.22, presumably due to a second reduction process corresponding to the reduction of a surface oxide film.

The alloy Ti-6Al-4V was investigated because of its excellent corrosion and mechanical properties. Although considerable work has been done on titanium and some of its alloys, only a few papers report on the mechanism of the HER on pure Ti (1, 2) and none on Ti-6Al-4V.

Thomas and Nobe (1) investigated different concentrations of H_2SO_4 as the electrolyte solution. Hackerman and Hall (2), working in approximately neutral solutions of NaCl reported Tafel equations of $E = 1.93 + 0.154 \log i$, and $E' = 1.97 + 0.204 \log i$ for deaerated and aerated solutions.

In this paper the kinetics of the HER on Ti-6Al-4V at 25°C in NaCl-HCl solutions, at constant concentration of Cl^-, and in the pH range 0.65-2.5 is reported.

Key words: hydrogen evolution, kinetics, titanium alloys, corrosion.

Experimental

Several disks of Ti-6Al-4V[1] with an area of 0.363 cm^{-2} and their Teflon holders were polished with

[1] Provided by Titanium Corporation of America, U.S.A.

abrasive paper down to 600 grit. Samples were then polished with diamond powder of 6μ diameter to a mirror finish. Every sample was cleaned with acetone in a soxhlet extractor for at least 3 hr, washed generously in hot conductivity water, and stored in a vacuum desiccator. All solutions were prepared using analytical grade reagents and conductivity water. The pH of 0.5M NaCl solutions was adjusted with 0.5M HCl in order to keep constant concentration of Cl^-. The electrolyses were carried out galvanostatically at 25°C in an H-cell of 500-ml capacity.

Some runs were also made at 20°, 35°, and 40°C using 0.5M HCl. A few experiments using potentiostatic polarizations gave results in agreement with the galvanostatic results reported here. All solutions were deaerated for at least 24 hr before the start of any experiment with N_2 (ultra high purity grade) which was bubbled through a pyrogallol solution before entering the cell. Other details of the experimental procedure have been described previously (3).

Results

Cathodic polarization curves of Ti-6Al-4V in acidic solutions of NaCl are shown in Fig. 1. It can be observed that a positive deviation from linearity appears in the curves corresponding to pH 0.65 and 1.22. These deviations occur at about −1.100V (SCE), apparently due to a second reduction process (1). The results obtained using electrolytes of pH 1.65, 2.2, and 2.5 show a sharp drop in potential after reaching −1.220V. The curves then regain their orginal slope in the linear region B (see Fig. 1) before finally dropping off to a limiting current density. In this linear region (B) the curves regroup closely packed with the same slope as before, showing little or no dependence of the reaction rate on pH. The rest potentials (RP) varied with temperature and pH as shown in Table I.

In all cases a Tafel slope of 0.153V was obtained. The rate of the HER can be written as

$$i = Ka_{H^+}{}^{n}{}_{H^+} \exp\left(-\frac{\alpha F\psi}{RT}\right) \qquad [1]$$

where K = rate constant, a_{H^+} = activity of hydrogen ions, α = over-all transfer coefficient, n = electrochemical reaction order, and ψ = electrode potential.

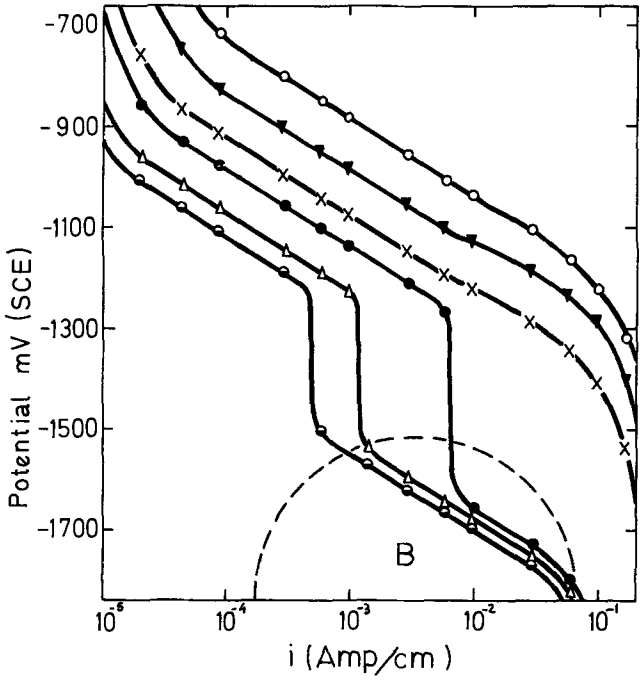

Fig. 1. Cathodic polarization curves of Ti-6Al-4V in NaCl-HCl solutions. For 35°C, ○ = pH 0.65. For 25°C, ▼ = pH 0.65; X = pH 1.22; ● = pH 1.65; △ = pH 2.20; ◒ = pH 2.50.

Table I. Electrochemical data for Ti-6Al-4V in acidic NaCl solutions

Temp, °C	pH	RP (SCE)	Tafel slope	Calculated exchange current (A-cm^{-2})
35	0.65	0.225	0.153	1.4×10^{-7}
25	0.65	−0.290	0.153	2.6×10^{-8}
	1.22	−0.272	0.153	1.1×10^{-8}
	1.65	−0.246	0.153	5.8×10^{-9}
	2.20	−0.194	0.153	2.8×10^{-9}
	2.50	−0.140	0.153	1.8×10^{-9}

According to Eq. [1]

$$\left(\frac{\partial \log i}{\partial pH}\right)_{\psi,T} = -n \text{ (electrochemical reaction order)} \qquad [2]$$

Figure 2 shows the variation of log i with pH, giving for [2]

$$n = 0.98 \cong 1 \qquad [3]$$

At the hydrogen equilibrium potential ψ_o, it follows from Eq. [1] that

$$i_o = K' a_{H^+}{}^{n} \exp\left(-\frac{\alpha F\psi_o}{RT}\right) \qquad [4]$$

Substituting the expression of ψ_o from the Nernst equation[2] into [4] and taking logarithms, yields

$$\log i_o = K''' - pH\,(n - \alpha) \qquad [5]$$

[2] $\psi_o = +\dfrac{2.303\,RT}{F} \log a_{H^+}$.

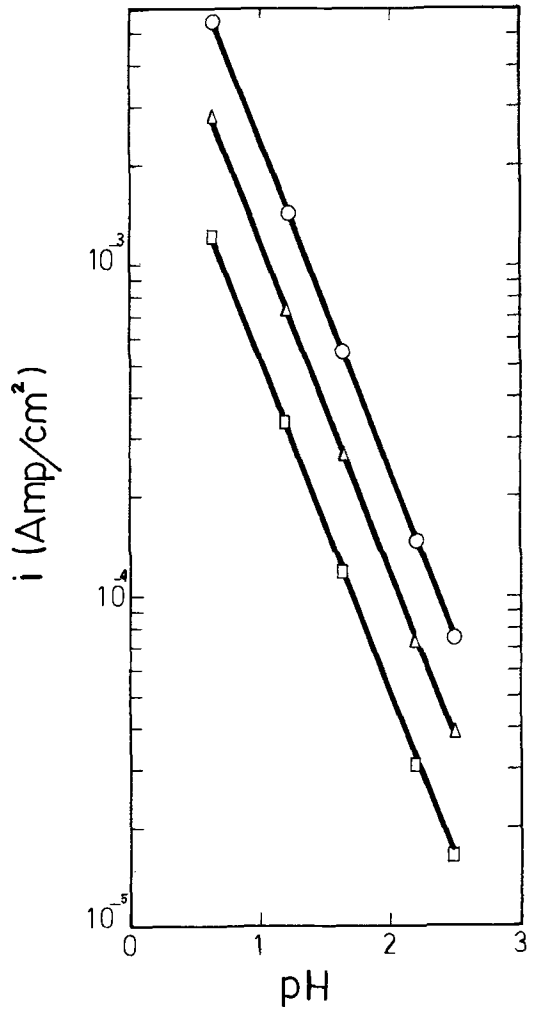

Fig 2. Dependence of the logarithm of i vs. pH in the first Tafel region: ○ 1.000V; △ 1.050V; □ 1.100V.

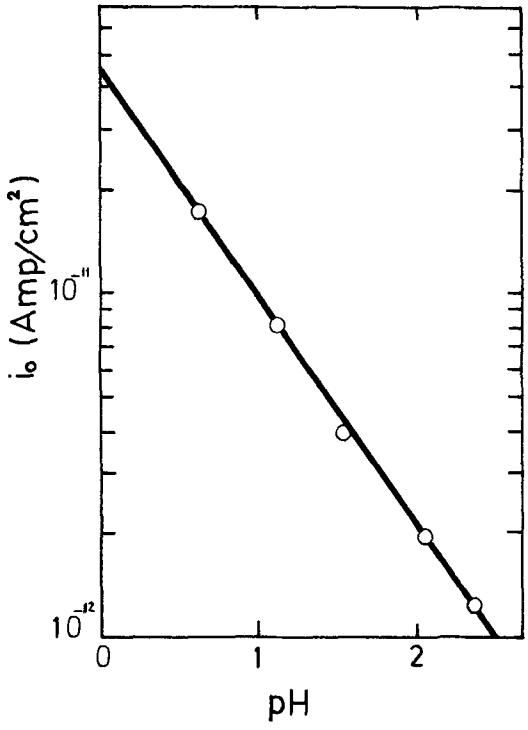

Fig. 3. Dependence of i_0 (exchange current density) on pH

Thus

$$\frac{\partial \log i_o}{\partial \mathrm{pH}} = -(n - \alpha) = -0.60 \qquad [6]$$

which agrees very well with the value obtained from Fig. 3, assuming for α a value of 0.4.

From [1] it can be shown that

$$\left(\frac{\partial \psi}{\partial \mathrm{pH}}\right)_i = -\frac{2.303\,RT}{\mathbf{F}}\frac{n}{\alpha} = -0.148 \qquad [7]$$

(assuming $\alpha = 0.4$ and $n = 1$) which agrees with the experimental values according to the plot in Fig. 4.

Figure 5 is a plot of log K (K = rate constant) as a function of $1/T$ for values of i taken at -1.000V (SCE) and pH 0.65. Since the electrode potential is being referred to a reversible reference electrode maintained outside the thermostatic system, an unknown electrolytic thermal junction potential will be included in the measured emf. Therefore, only an apparent heat of activation ΔE can be measured. The value for ΔE measured in this work was 45.3 kcal/mol.

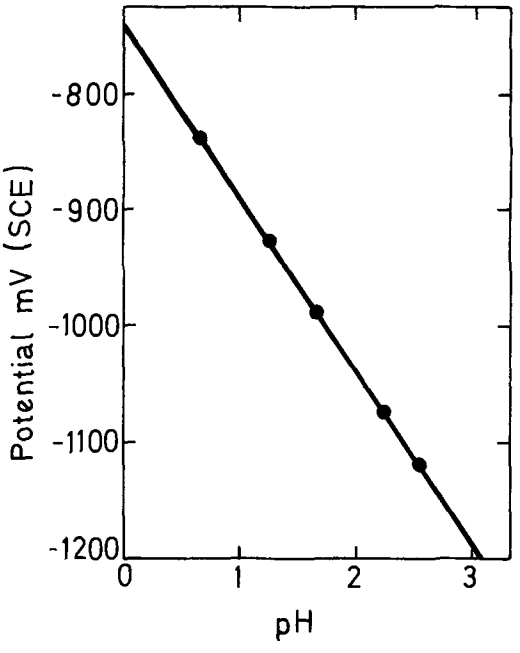

Fig. 4. Plot of potential vs. pH in the first Tafel region. Points correspond to $i = 10^{-4}$ A-cm^{-2}

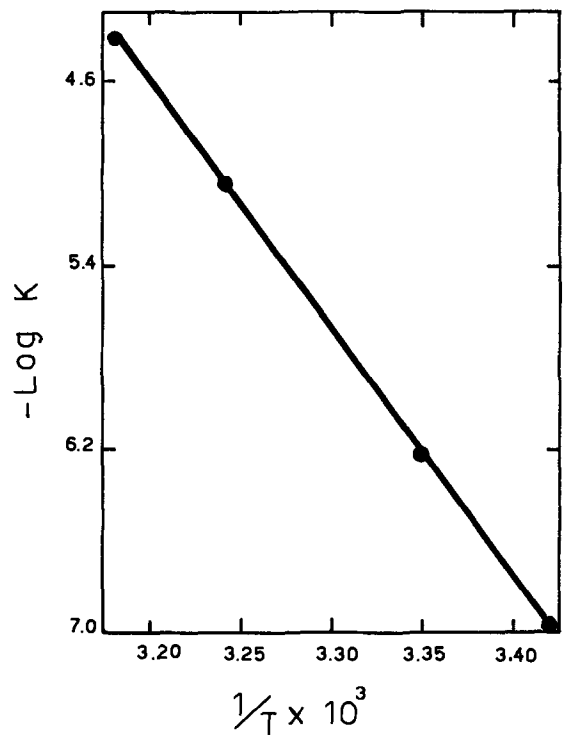

Fig. 5. Arrhenius plot of log K vs $1/T$

It is possible that a limiting current density could be observed at higher cathodic polarization for experiments corresponding to pH 0.65 and 1.22; but, because of equipment limitations it was not possible to increase polarizations beyond the points shown in Fig. 1.

Comparison of the experimental results with those obtained from theoretical derivations show excellent agreement and suggest that the HER on Ti-6Al-4V is a first-order reaction with an over-all transfer coefficient $\alpha = 0.4$.

Discussion

Hackerman and Hall (2) reported a rapid decrease in potential near 0.1 A-cm^{-2} for cathodic polarization of Ti in approximately neutral solutions of NaCl. They explained this behavior assuming the reduction of a small amount of O_2 dissolved in the solution. They interpret the sharp break in their curves as representing the limiting diffusion current density for the oxygen reduction reaction. However, the amount of dissolved oxygen under the present experimental conditions is very low and remains rather constant. Stern (4) found a similar effect for the HER on iron in acidic solutions of NaCl and assumed that the sharp decrease in potential was due to concentration polarization effects. Table II shows the values for i_L (limiting diffusion current) calculated from

Table II. Limiting diffusion current variation with pH

pH	i_L, calculated	i_L, experimental
0.65	3.2×10^{-2}	—
1.22	8.6×10^{-2}	—
1.65	3.2×10^{-3}	6.5×10^{-3}
2.20	9.0×10^{-4}	1.2×10^{-3}
2.50	8.1×10^{-4}	5.0×10^{-4}

$$i_L = \frac{nFD}{\delta} (10^{-3})\, a_{H+} \quad [8]$$

where n = number of electrons taking part in the reaction; F = Faraday constant; δ = thickness of the diffusion layer (= 0.05 cm); D = diffusion coefficient, for $H^+ = 7.39 \times 10^{-5}$ cm^2/sec; and a_{H+} = activity of hydrogen ions.

Except for the first two curves, the agreement between the experimental and calculated values is reasonably good, especially taking into account the uncertainty in the δ values.

The positive deviation from linearity of curves for pH 0.65 and 1.22 in Fig. 1 has been explained before (1) as due to a possible reduction of the thin film oxide attached to the surface of the electrode. For the linear portion of the polarization curves marked B in Fig. 1, it can be assumed that the HER is due to water discharge.

Finally, it is possible that the results published by Thomas and Nobe (1) do not show this type of effect because the electrode was rotated with a certain angular speed, thus, canceling out the diffusional effects.

Electrode Reaction Rates on Straining Aluminum-Magnesium Wires in Chloride and Sulfate Solutions

T. P. Hoar* and F. P. Ford

University of Cambridge, Department of Metallurgy and Materials Science, Cambridge, England

ABSTRACT

Electrode reaction rates on aluminum-7 weight per cent (w/o) magnesium wires exposed to chloride and sulfate solutions have been studied as a function of tensile strain rate, electrode potential, solution pH, degree of aeration, and anion concentration. An increase in rate of both anodic and cathodic reactions was observed on application of plastic strain; the increase depends on the strain rate, the anion concentration, and the degree of anodic or cathodic polarization in the chloride or sulfate solution. At electrode potentials remote from the chloride pitting potential, the difference in electrode-reaction rates in chloride or sulfate solutions is relatively minor; as the potential approaches the pitting potential, however, the anodic rate in chloride solution becomes significantly greater than that in sulfate solution. The anodic reaction is primarily dissolution and the cathodic is hydrogen-ion reduction.

There is a relationship between current density on the straining electrode and the rate of passivation found on cessation of plastic deformation. The shape of the current/time transients suggests that the change in reaction rate upon straining is controlled by the rate of oxide rupture (caused by slip-step emergence) and by the subsequent passivation rate of the new bared metal.

Stress-corrosion tests, conducted under potentiostatic control in sulfate and chloride solutions, indicate that the propagation rate of stress-corrosion cracks in isolated metal has the same dependence on pH, anion type and concentration, and degree of aeration, as does the anodic current density of a straining electrode. This suggests that the crack-penetration rate depends on the reaction rate at the crack advancing edge, which is controlled by the rate of oxide rupture and by the subsequent rate of passivation.

The aluminum-magnesium alloy system provides an important series of cold-worked and thermally stabilized commercial alloys that combine a relatively high strength-to-weight ratio with good general corrosion resistance. Unfortunately, there is an increasing susceptibility to intergranular stress-corrosion cracking as the magnesium content is increased, both in neutral and acid chloride solutions (1, 2). It is related (2, 3) to the presence of a discontinuous grain-boundary magnesium rich β-phase. Because of the high chemical activity of this phase in these solutions (4), an initiating notch may be formed, giving stress intensification dependent on the shape and size of the particle. A major problem in understanding the stress-corrosion behavior of these alloys is the mechanism by which a high aspect-ratio crack can propagate from these initiating notches.

Logan (5) suggested that cracks may propagate electrochemically by rupture of passivating oxide films at the crack advancing edge, which is yielding under the high stress there, followed by a high rate of anodic dissolution as compared with that of the crack sides. The high rate of dissolution of bared metal will be modified by passivation, the rate of which is also important.

The object of this paper is twofold: first, to determine the dependence of the anodic and cathodic reaction rates of an aluminum-7 w/o magnesium alloy on applied strain rate for various conditions of anion concentration, solution pH, and electrode potential, and to

* Electrochemical Society Active Member.

Key words: dissolution, passivation, straining, aluminum, alloy.

obtain data on the passivation rate observed when straining is stopped; second, by relating the plastic condition at the crack edge to the macroscopically applied strain rate, to predict the stress-corrosion behavior of the alloy in chloride and sulfate solutions.

Experimental Technique

The specimens used in the electrochemical studies were 0.040 in. diam wires fabricated from a high purity aluminum-7 w/o magnesium ingot.[1] The wet analysis was 7.15 w/o, magnesium, plus a total impurity content of 0.12 w/o, mainly silicon and copper. The wire specimens were transformed to a single-phase condition to simulate the structure at the phase margins, where stress-corrosion cracks propagate, after the final swaging and drawing operation, by annealing at 360°C for 4 hr and water quenching. (Strictly speaking, the composition at the advancing edge of a grain-boundary crack in the heterogeneous alloy is probably nearer 2 w/o, which is the equilibrium composition adjacent to the grain-boundary β-phase; however, preliminary work has indicated (7) that there is no significant difference in the chemical activity of an electrode of aluminum-2 w/o magnesium and aluminum-7 w/o magnesium).

The solutions used were unbuffered 1*N* NaCl and 1*N* Na_2SO_4 at *p*H values of 2.0 ± 0.2 and 5.5 ± 0.2 (adjusted with sulfuric acid); the *p*H values after the experiment remained within the quoted ranges. The solutions were deaerated by saturating with deoxygenated nitrogen (8) in order to confine the cathode reaction to that of hydrogen-ion reduction. However, since stress-corrosion tests are normally conducted in naturally aerated solutions, some straining experiments were made under such conditions in order to determine the effect, if any, of aeration on the anodic reaction rate.

Before each test, the specimens were mechanically polished to a 6 μm diamond finish, masked with Teflon tubing to expose a 1-in. gauge length, inserted into the test cell, Fig. 1, and immersed in deaerated solution for at least 16 hr to allow the surface to reach a pseudostable corrosion potential. Anodic or cathodic polarization to a constant potential was then applied by potentiostat, and the resultant current between specimen and platinum counterelectrode was recorded until a steady value was obtained. Thereupon a steady strain rate was applied by a motorized Hounsfield Tensometer for a time corresponding to 17.5% elongation. The current transient was recorded both during and after straining.

Results

Shape of current transient upon straining.—Figure 2 illustrates the nature of the current/time transient obtained on straining, at two extremes of anodic or cathodic polarization. As will be shown later the shape of the transient between these extremes varies with the anion concentration and *p*H of the solution. Two general observations may be made regarding the shape of these transients. First, there is an incubation period, corresponding to the time to reach the limit of proportionality on the stress/strain curve, before the mean current rapidly rises to a steady value, which will be shown to be dependent on the applied strain rate, electrode potential, solution *p*H, and anion concentration. Second, there is an oscillation superimposed on the current transient which has an amplitude and frequency that increase with applied strain rate. A detail of the net anodic current is shown inset in Fig. 2 for two extremes of strain rate; at the lower strain rate the oscillation can be resolved into a series of current surge and exponential decay events. In general, the oscillation of a net cathodic current is more damped, *i.e.*, the amplitude is lower than that of an anodic current obtained at the same strain rate. This oscillation, which is independent of the occurrence of the Portevin-Le Chatelier discontinuous yielding that occurs in these

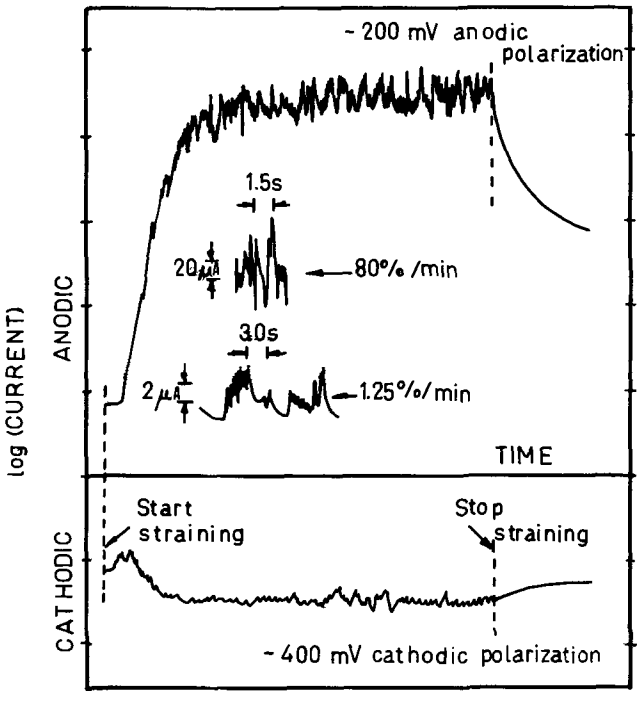

Fig. 2. Typical current/time transients obtained upon straining at extreme values of anodic or cathodic polarization with respect to open-circuit corrosion potential in deaerated solutions. Inset detail indicates nature of superimposed current oscillations at two values of applied strain rate.

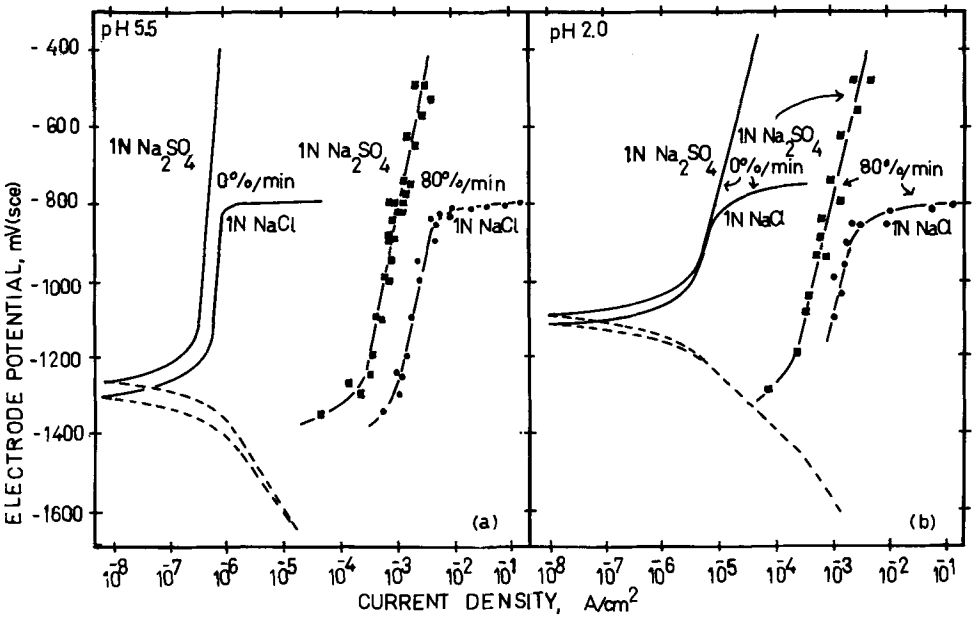

Fig. 3. Variation of steady-state anodic current density with potential in 1N NaCl and 1N Na_2SO_4 at (a) pH 5.5 and (b) pH 2.0. Values are quoted for strain rates of 0 and 80% per min.

alloys, is attributed to successive oxide-rupture and metal-passivation events; work by Grosskreutz (9) indicates that thin film rupture in aluminum alloys occurs at slip steps.

In interpreting the results in terms of current density at the bared metal surface, it might be assumed that the active surface area can be equated to the total slip-step surface area. This area may be calculated from the data of Thomas and Nutting (10), who investigated the slip-step geometries of various binary aluminum-magnesium alloys after different amounts of tensile elongation. The current density on the slip steps could be derived, therefore, from $I - I_o/A$, where I is the steady-state current during straining, I_o the steady-state current before straining, and A the slip-step area. The nonvalidity of this assumption, which is over-naive, is discussed in a later section.

Variation of steady-state anodic current density with electrode potential and strain rate.—The variation of the steady-state current density with electrode potential is illustrated in Fig. 3(a) and (b) for various combinations of anion concentration and pH; the strain rate applied to the specimen was 80% per min. For comparison purposes, the steady-state current density on the unstrained specimens is also shown in the same figures. The over-all mean anodic current density at a given potential increases by several orders of magnitude upon straining; results also indicate that, although the current density on the unstrained specimen at a given electrode potential decreases with increase in pH, the net anodic current density on the straining specimen is slightly lower at pH 2.0 than pH 5.5. At potentials more negative than −900 mV(SCE), the straining electrode current density is slightly higher in the chloride solutions compared to that in the sulfate solutions, but as the potential approaches −800 mV(SCE), this difference rapidly increases.

Figure 4 illustrates the relation between the steady-state anodic current density at −800 mV(SCE) with applied strain rate in acid chloride and sulfate solutions.

Variation of current density during and after straining.—The variation in current density during straining at 80% per min is illustrated in Fig. 5 for various combinations of anion concentration, solution pH, and electrode potential. For the sake of clarity, the superimposed oscillations mentioned previously are not shown. At potentials more positive than −1300 mV(SCE), the current density rises rapidly after an incubation period to a steady anodic value. At potentials more negative than −1300 mV(SCE), however, the current density initially changes in the anodic direction, to be followed by a slower return to cathodic values. In acid solutions the rate of this reaction is fast enough at −1400 mV(SCE) to attain a steady-state cathodic value by the end of the experiment; as might be expected, the reversion in neutral solutions is slower, and a steady-state cathodic value is not reached. At potentials more negative than −1500 mV(SCE), the initial change towards anodic values is suppressed and the current transient is entirely in the cathodic direction.

The current-density decay due to oxide formation that occurs when straining is stopped at 17.5% elongation is shown in Fig. 6 for the various anion-content-pH-electrode-potential combinations illustrated in Fig. 5. Initially the anodic current-density decay may be described by

$$j = j_0 \exp -\beta t^{1.0}$$

However, this simple law does not apply during the whole decay time because of complicating secondary reactions, two of which may be deduced from Fig. 6. The first is the initiation of pitting by straining in

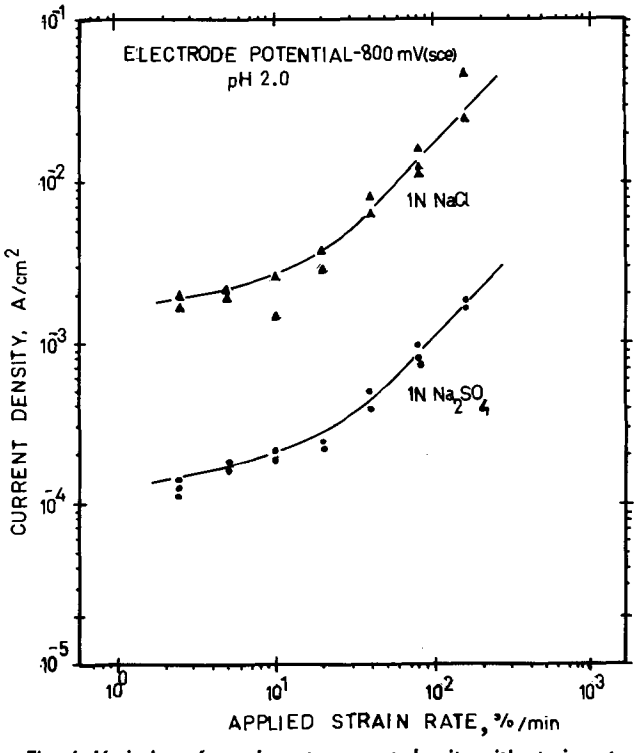

Fig. 4. Variation of steady-state current density with strain rate for 1N NaCl and 1N Na_2SO_4, pH 2.0, at −800 mV(SCE).

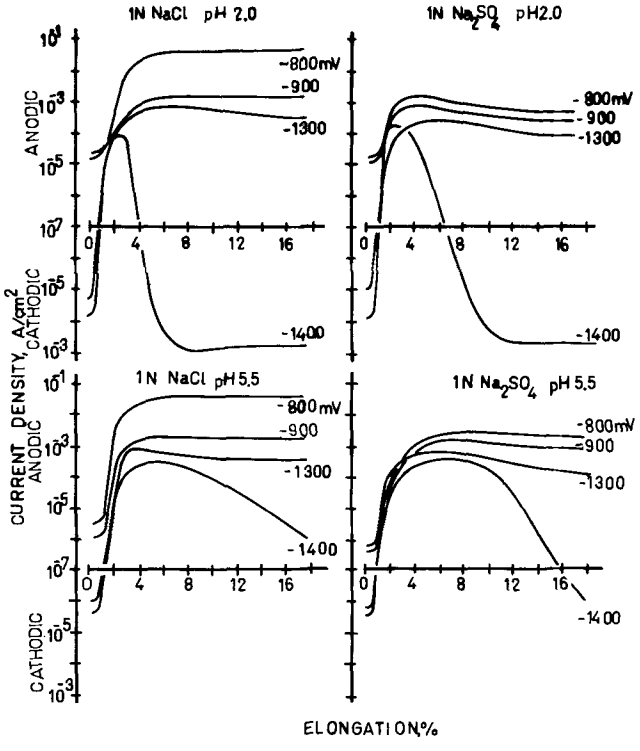

Fig. 5. Current-density/elongation transients obtained during straining at 80% per min. Values for various combinations of electrode potential, anion concentration, and pH.

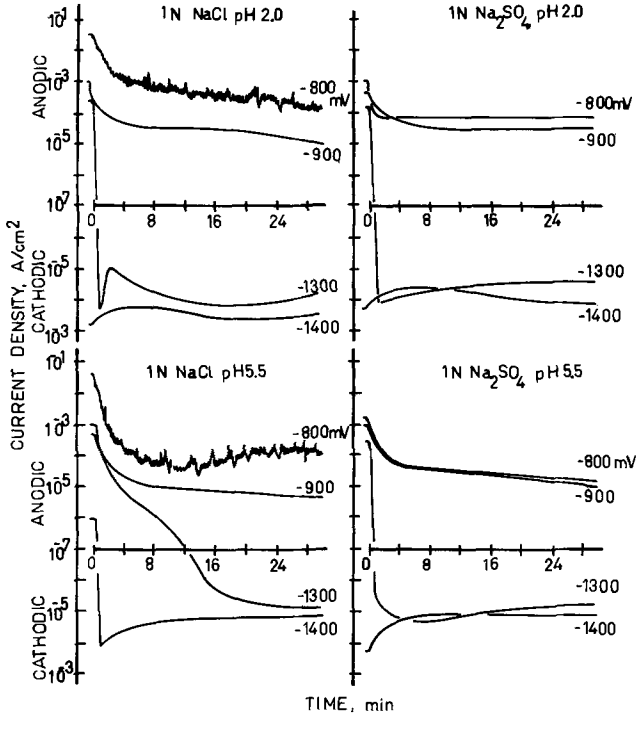

Fig. 6. Current-density-decay curves obtained when straining at 80% per min is stopped. Values for various combinations of electrode potential, anion concentration, and pH.

chloride solutions at potentials between −800 and −950 mV(SCE) as shown by anodic current oscillations and the rise in anodic current after the initial decay, and the second is the effect of the cathodic reaction on the passivating surface, which predominates at potentials more negative than −1300 mV(SCE). In an analogous argument to that suggested from Fig. 5, where it is seen that, upon straining in the potential range −1300 to −1400 mV(SCE), a rapid anodic reaction is followed by a slower cathodic reaction. The

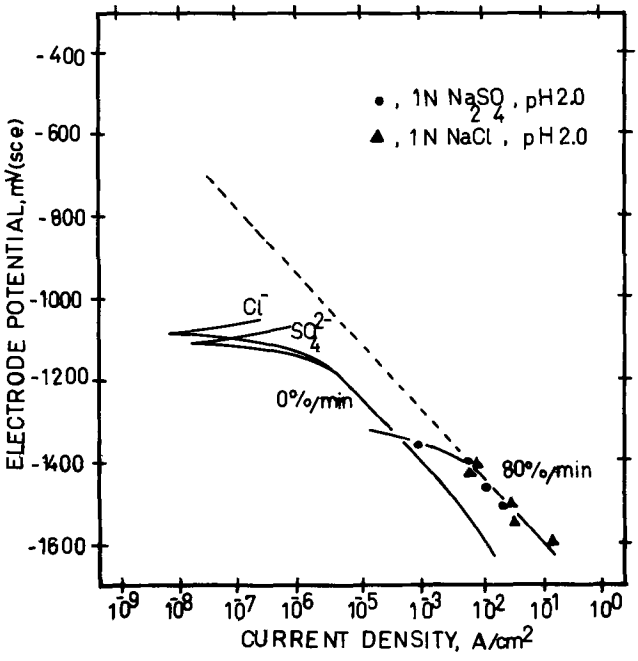

Fig. 7. Variation of steady-state cathodic current density with potential in 1N NaCl and 1N Na_2SO_4 at pH. 2.0. Values for strain rates of 0 and 80% per min.

subsequent decay behavior is dominated in this potential range by rapid anodic passivation followed by a slower cathodic reaction on the passivated surface.

Variation of steady-state cathodic current density with electrode potential.—The variation of the mean steady-state cathodic current density with electrode potential is illustrated in Fig. 7 for acid sulfate and chloride solutions. For comparison purposes, data for the unstrained specimen and a specimen strained at 80% per min are presented on the same graph. The rate of the cathodic reaction, which is observable hydrogen evolution, is increased by a factor of 5 to 6 by straining; this increase is the same in chloride as in sulfate solutions. In addition, there is no significant difference in the slopes of the cathodic polarization curves for strained and unstrained specimens in these acid solutions.

Discussion

Computation of active surface area.—Murata and Staehle (11) have suggested that the net current change observed upon straining a specimen in a film-forming solution can be analyzed in terms of the summation of a series of individual current surge and decay events associated with oxide rupture followed by passivation at emergent slip steps. The analysis predicts that the current will reach a steady-state value during straining through the introduction of new active slip steps and the complete passivation of earlier formed slip steps. The present work qualitatively supports this theory through the presence of an incubation elongation corresponding to oxide rupture at a sufficient number of slip steps to give an observable rapid current rise to an asymptotic value, and the superimposed oscillations suggest that the net effect is made up of a series of current surge and decay events.

The current densities were first calculated (see Results above) on the assumption that, during straining, the active surface area corresponds to the total area created at emergent slip steps. An estimate of this area may be made from the data of Thomas and Nutting (10), who showed that, in the aluminum-7 w/o magnesium alloy, slip steps emerge with a constant step height of 135 nm and with a step separation dependent on the tensile elongation. The assumption that this total slip-step area remains active throughout the time of straining is, however, far from valid, especially in a

system that exhibits fast passivation characteristics. Pagetti and co-workers (12) showed, by using a scratching technique to create a 'bare' surface on an aluminum-7 w/o magnesium alloy, that the anodic current density decay due to passivation at a scratch may fall by several decades within 100 msec in sulfate solutions. Since the experiments described in the present paper last for 20 sec or longer, the assumption that the active surface area on the straining wire corresponds to the total slip-step area grossly overestimates the active surface area in sulfate solution by a factor of around 10^2 for a strain rate of 80% per min, and by correspondingly greater factors at lower strain rates. (In chloride solutions at potentials near the pitting potential, this factor is smaller since the passivation rates are significantly lower than those in sulfate solutions.)

Electrode reactions occurring on the straining electrode.—The hypothesis outlined above concerning the origin of the current transient obtained during straining suggests that the resultant steady-state current density is an average slip-step current density encompassing all conditions from a bare surface to a surface that has just become completely passivated. This average current density should, therefore, be dependent on the passivation rate; as this rate decreases so the proportion of active sites with a higher current density at any given instant will increase. Such a relationship between the average slip-step current density and the passivation rate is noted experimentally and is illustrated in Fig. 8. In this figure the passivation rate is described in terms of the parameters β and n, which appear in the general decay equation $j_a = j_0 \exp -\beta t^n$ used to characterize the current decay when straining is stopped; the values of β and n taken 1 sec after straining is stopped, $\beta(1\text{ s})$ and $n(1\text{ s})$, are used, because the simple equation with β and n constant does not properly describe the j/t transient. The electrode potentials were in the range −1200 mV to −500 mV(SCE).

Figure 8 shows that the slip-step current density during straining has a unique relationship with the passivation parameters $\beta_{(1\text{ s})}$ and $n_{(1\text{ s})}$. This sug-

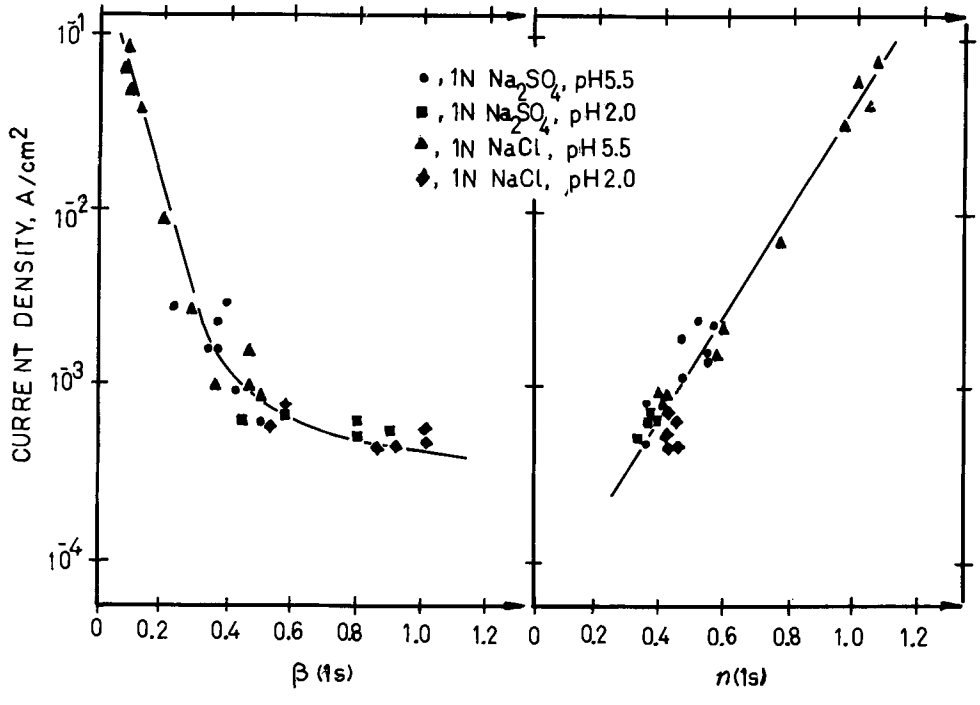

Fig. 8. Correlation between the steady-state anodic current density and the parameters β and n, in the decay equation $j = j_0 \exp -\beta t^n$. The decay characteristics were measured 1 s after straining at 80% per min was stopped.

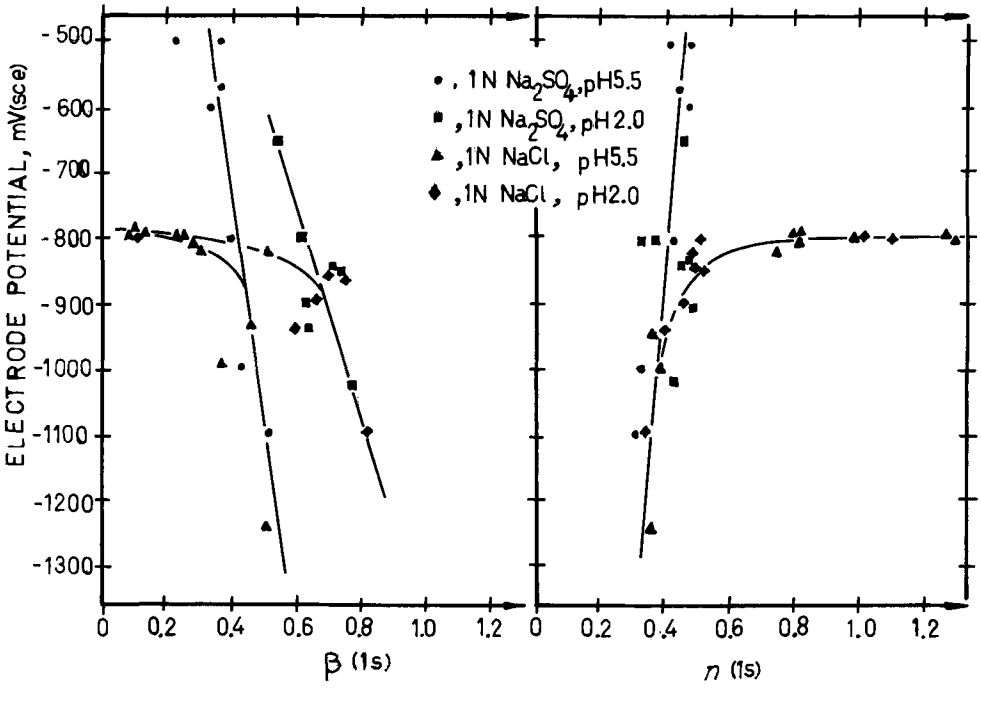

Fig. 9. Variation of the parameters β and n in the decay equation $j = j_0 \exp -\beta t^n$ with electrode potential, for various conditions of anion content and pH.

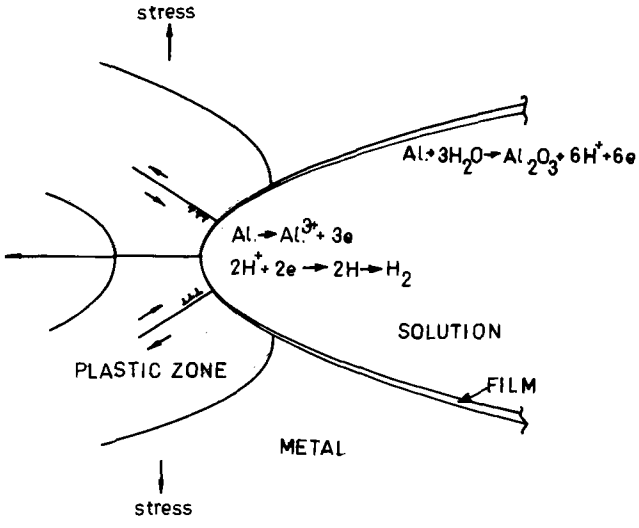

Fig. 10. Schematic representation of the electrode reactions occurring at a crack tip, in neutral and acid solutions.

gests that the dependence of this current density on potential, pH, and anion concentration illustrated in Fig. 3(a) and (b) is controlled primarily by the dependence of the passivation rate on these factors; this latter relationship is indicated in Fig. 9. Further, the fact that the slope of the anodic e/j curve at a strain rate of 80% per min is the same as that given by the unstrained surface in acid solutions confirms that the average is dominated by the current on a partially passivated surface rather than that on the bare slip steps.

From Fig. 7, the average cathodic reaction rate on a specimen being strained at 80% per min in deaerated acid solutions is, by the usual extrapolation, less than 10^{-7} A/cm^2 at potentials more positive than −900 mV(SCE). This is considerably smaller than the observed anodic current on the same specimen at these potentials; consequently, the observed current on the straining electrode is close to the true anodic current. This anodic reaction is presumed to be $Al \rightarrow Al_{aq}^{3+} + 3e$.

The cathodic reaction is evidently the observed hydrogen evolution, in deaerated solutions. Supplementary tests, conducted in aerated chloride solutions at pH 5.5 and −900 mV(SCE), indicated that above a strain rate of 10% per min there was no significant difference in the steady-state current densities obtained in deaerated solutions and those obtained in aerated solutions. Although the presence of oxygen affects the net current density on the unstrained surface, due to the additional oxygen-reduction reaction, the much greater observed current density on the straining surface is overwhelmingly anodic and is essentially the same as that obtained in a deaerated solution at the same potential.

Relationship between average slip-step current density and stress-corrosion cracking.—If the propagation of a stress-corrosion crack is controlled by the anodic dissolution at the crack advancing edge, where protective oxide is continuously undergoing a rupture and formation (passivation) process (see Fig. 10), then the observed propagation rate should have the same dependence on such parameters as pH, electrode potential, and anion concentration as does the steady-state current density observation on a plastically deforming electrode (Fig. 3(a) and (b) and 7).

Stress-corrosion experiments were conducted on specimens fabricated from the same ingot as that used in the straining electrode experiments. The metallurgical condition of the specimen wires was such as to yield a condition susceptible to stress-corrosion cracking in aerated chloride solutions at the corrosion potential: *viz.*, after solution heat-treatment at 360°C for 4 hr and water quenching, the rods were cold swaged a total of 86.5% reduction in area and given a final 110°C, 40 hr sensitization treatment. The specimens were prepared as described in the Results section above, mounted in the experimental cell (Fig. 1), and allowed to attain a pseudostable corrosion potential in the solution. Anodic or cathodic polarization was then applied and the resultant current recorded until a steady value was obtained; thereupon a strain rate of 0.127% per min was applied until failure occurred.

Longitudinal cross sections of the wire specimens were subsequently examined at a magnification of × 500 and the extent of the penetration of grain-boundary cracks was recorded; the average penetration rate was then calculated on the assumption that the longest cracks started propagating at the onset of straining.

The variation of the grain-boundary crack-penetration rate with electrode potential and various anion-concentration–pH combinations is shown in Fig. 11.

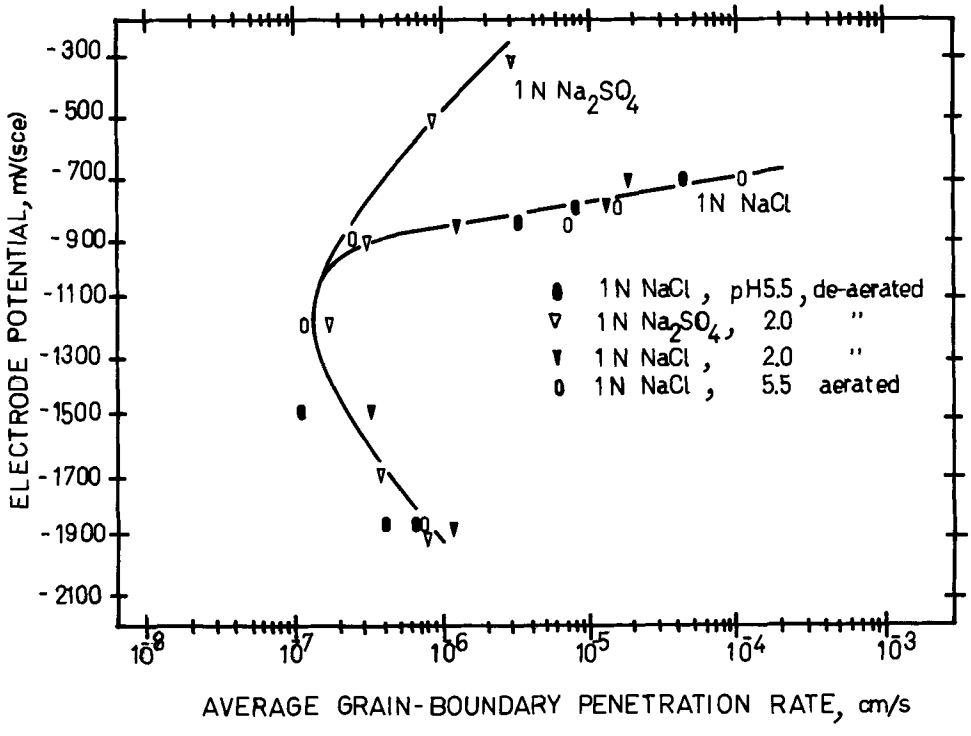

Fig. 11. Variation of the grain-boundary penetration rate in a cold-worked and sensitized aluminum-7 w/o magnesium alloy with electrode potential, for several combinations of anion content, pH, and degree of aeration. Applied strain rate ca. 0.127% per min.

The crack penetration rate is minimal at −1200 mV(SCE) and increases at potentials both more positive and more negative. This suggests that at potentials more positive than −1200 mV(SCE), the penetration rate is caused by an anodic process, presumably dissolution, whereas at more negative potentials, hydrogen-ion reduction controls the penetration by some unknown mechanism. The specificity of chloride anions on crack penetration has significant effect only at potentials more positive than −900 mV(SCE), *i.e.*, at potentials where pitting may be prematurely initiated by straining. This observation may be compared with the markedly greater increase in anodic current density on the straining electrode in chloride solutions as compared to sulfate solutions at these potentials. Changes in *p*H (and oxygen content) have no significant effect on the crack-penetration rate at potentials above −1200 mV(SCE), but there is some evidence in Fig. 11 that at potentials more negative than −1200 mV(SCE) an increase in *p*H may decrease the crack penetration rate.

Stress-corrosion cracking is normally encountered (1, 2) in this alloy when the cold-rolled and heat-treated material is exposed under freely corroding conditions to neutral or slightly acid aerated solutions. The open-circuit corrosion potential in chloride solutions under these condtioins is *ca.* −800 mV(SCE). The results illustrated in Fig. 11 show that the penetration rate may be decreased by the external application of a small amount of cathodic polarization (13) with respect to the open-circuit corrosion potential.

The present results suggest that the crack penetration rate in the aluminum-7 w/o magnesium alloy may be decreased at a given electrode potential by decreasing the over-all reaction rate at the crack edge. Apart from the mild degree of cathodic protection just mentioned, this may perhaps be achieved (6) by decreasing the oxide rupture rate and/or by increasing the passivation rate at the rupture region by attention to possible variations in alloy composition and deformation morphology at the crack edge.

In further experiments, to be reported shortly, we have found that the anodic current densities obtainable at the various potentials on bared, passivating aluminum-alloy surfaces are more than sufficient to account for the measured penetration rates shown in Fig. 11, if the cracks advance solely by electrochemical anodic dissolution.

Manuscript submitted Dec. 20, 1972, revised manuscript received Feb. 26, 1973. This was Paper No. 49 presented at the Miami Beach, Florida, Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Investigation of the Passivity of Iron by Nuclear Microanalysis Using Stable Oxygen Isotopes

B. Agius and J. Siejka*

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Tour 23; 11 Quai Saint-Bernard, Paris 5ème, France

ABSTRACT

A solution of 0.15*N* sodium borate and 0.15*N* boric acid in O^{18} enriched water was used to study the passivity of iron by means of nuclear microanalysis. It was established that the surface of the sample maintained under cathodic polarization is free of oxygen 18; while in open circuit, the presence of 5×10^{15} atoms/cm^2 of oxygen 18 was detected on the sample which was previously cathodically reduced. Moreover, in the passivity region, the quantity of oxygen 18 fixed on the metal surface varies from $\sim 5 \times 10^{15}$ to $\sim 20 \times 10^{15}$ atoms/cm^2 as a linear function of potential. The value of the apparent electric field of formation was calculated and compared with the literature data deduced from ellipsometric and coulometric measurements. The cathodic reduction of the films was studied by determining the O^{18} losses of the passive films as a function of the charge passed in the circuit and of the temperature. The mechanism of the cathodic reduction is discussed on the basis of the experimental data.

The passive film has been investigated in electrochemistry and metallurgy for many years (1, 2) and several models have been proposed (3-10), pointing out the important role played by oxygen in the mechanism of passive layer formation. Quantitative determination of oxygen contained in passivated films can be expected to provide a useful means for a better understanding of the phenomenon of passivity. Among the various methods, the method of nuclear microanalysis of the 16 and 18 isotopes of oxygen seems to be particularly well suited for this purpose (11, 12).

* Electrochemical Society Active Member.
Key words: iron passivity, nuclear microanalysis, O^{18} tracing, passive film thickness, cathodic reduction.

The present paper describes the use of this method to investigate the passivity of iron in a $pH = 8.4$ buffer solution of 0.15*N* sodium borate and 0.15*N* boric acid in deaerated water of either natural O^{18} isotopic concentration (0.204%) or enriched to 10% in O^{18}. The isotopic composition of hydrogen in the O^{18} enriched water[1] was normalized to natural abundance. By using the enriched solutions, one is able to distinguish the effects of oxygen coming from the solution from those due to atmospheric oxygen which may further oxidize the samples during their transfer from the electrolytic cell to the analytical set-up. Borate solutions were chosen as numerous works referring to such solutions have been published and this will facilitate comparisons. Moreover, borate anions are advantageous in that they isotopically exchange their oxygen with that of the water almost immediately (13), thereby leading to a uniform labeling of the solution. Nagayama and Cohen (5), in an investigation of iron passivity by coulometry and chemical analysis of iron dissolved in the solution, have shown that the thickness of the film varies from 8 to 30Å, depending on the potential of the layer formation. Foley *et al.* (14), by an electron diffraction investigation, have identified the structure of these films after obvious exposure to atmosphere as that of γ-Fe_2O_3. Recent ellipsometric investigations, which may be carried out *in situ*, have shed some new light on certain aspects of the nature of iron oxide films formed in neutral solutions. In particular, Sato and Kudo (15) have found that cathodically reduced iron oxide is characterized by the complex refractive index of the bare metal, and from this, they inferred the total absence of any oxide film. This observation and their measured value of the minimum thickness (9Å) required for passivation to occur led them to the conclusion that the mechanism of passive layer formation is similar to that for anodic films formed on valve metals; this mechanism has been proposed previously in Ref. (1) and (6). On the basis of coulometric measurements, it has been suggested by Frankenthal (9) that adsorption phenomena are responsible for passivation at low values of polarization. Recently, Bockris *et al.* (8) have shown by combining coulometric and ellipsometric methods that a ferrous hydroxide $Fe(OH)_2$ exists in the prepassive region and they assumed that it was transformed into ferric oxide Fe_2O_3 at the beginning of the passivity region and then grew linearly with potential up to 40Å

This short review of the literature shows that the problem of the proper choice of a mechanism of passive film formation still remains open. The purpose of the present work, which is an extension of previous investigations with similar methods on nickel (16, 17), is to obtain new information about the phenomenon of passivity by combining the methods of electrochemical measurements and nuclear microanalysis of the 16 and 18 isotopes of oxygen.

The main objects of the present experiments were to study: (*i*) the effects of polishing on the iron specimens and the definition of a test specimen which exhibits the thinnest surface oxide layer; (*ii*) the determination of the quantity of oxygen coming from the solution and fixed on the metal surface after cathodic reduction and under corrosion potential; (*iii*) the relationship between the potential and the quantity of oxygen fixed on the metal surface in the passivity region; and (*iv*) the measurements of oxygen loss due to the cathodic reduction of these layers. Some of these results have been presented (18).

Experimental Technique

Sample preparation.—The specimen (substrate) was a pure iron electrode (99.9% or 99.99% purity, see Table II) of 10 × 10 mm with an iron wire electrowelded to it to give the electric contact. Polishing of the specimen surface was carried out in a mixture of glacial acetic and perchloric acids (20:1) at a current density of 450 mA/cm², with intense mechanical stirring (19). All potentials are expressed on the standard hydrogen scale. Most of the experiments were carried out at 23° ± 1°C, while some of them were performed at −3° and 50°C.

After rinsing and drying, the specimens were stored in a vacuum of the order of 10^{-2} mm Hg. Immediately before the experiments, the samples were repolished for 1 min.

Experimental procedure.—First the samples were put in the solution and left unpolarized while their potential stabilized around a value of about −250 mV. They were then pretreated by cathodic reduction (10 μA/cm²) to remove any existing oxide from the surface (5). This brought a decrease in the potential to about −650 mV (ϕ_c). Polarization was then switched off. In 5 min, the potential rose to about −510 mV (ϕ_{s2}). After this pretreatment (summarized in Table I) samples were oxidized potentiostatically and analyzed following the proceedings and precautions described in Ref. (16, 17) where oxygen desorption was carefully studied. The possible losses were minimized here in the same way.

Nuclear microanalysis of O^{16} and O^{18}.—Nuclear microanalysis, by the observation of nuclear reactions, yields the number N_O16 (reaction $O^{16}(d,p)O^{17*}$) or N_O18 (reaction $O^{18}(p,\alpha)N^{15}$) of oxygen atoms per square centimeter fixed on the specimen surface (20, 21). The number of oxygen atoms coming from the solution, $\hat{N}_O18$, can be obtained by dividing N_O18 by the solution enrichment (ratio of O^{18} to the total oxygen in the solution), *i.e.*, by normalizing the results.

Results and Interpretation

Analysis of the state of the sample surface.—The quantity of oxygen present at the metal surface was determined before and after polishing for specimens of different purities supplied by different manufacturers.

Figures 1 and 2 show the spectra of the $O^{16}(d,p)O^{17*}$ reactions of oxygen obtained under identical experimental conditions for 99.9 and 99.99% iron before and after polishing. The spectrum for 99.9% purity iron (Fig. 1a) shows a tail on the lower energy side which tends to disappear after polishing (Fig. 2a), while the over-all oxygen quantity near the surface drops by a factor of 100. The depth scale of Fig. 1 is only illustrative; in fact, to deduce the concentration profile, $C(x)$, from the spectrum, one has to take into account the variation of cross section with depth (21). From this, it may be inferred that, in addition to the surface oxide layer, there exists some oxygen buried in the metal matrix which can be removed by polishing (12, 16, 21, 22). This component may be shown to extend to a depth of some microns. In the case of the 99.99% purity iron, practically no bulk oxygen was observed, even before polishing (Fig. 1b).

The results obtained from these spectra are shown in Table II, where the number of O^{16} atoms is given for various iron surfaces along with, for comparison, the

Table I. Successive steps of sample treatment

corresponding results for nickel (16). With reference to the data for unpolished specimens, Table II only indicates their order of magnitude, as the corrections for deep penetration were not taken into consideration, these results presenting a marked irreproducibility.

It is seen that the three iron specimens of different origin and purity are characterized by different amounts of surface oxygen, expressed as the number of oxygen atoms per square centimeter, after polishing.

Table II. Characteristic of the surface layers on iron and nickel

Metal	Surface preparation	$N_O^{16} \times 10^{15}$ atoms/cm²
Iron 99.99% (Johnson Matthey)	Unpolished	~80
	Polished*	23

* In a mixture of glacial acetic and perchloric acids (20:1) at a current density of 450 mA/cm², during 2 or 10 min for 99.99 or 99.9%, respectively.
** In 54.5% sulfuric acid at 400 mA/cm².

This could be explained by: (*i*) the roughness factor which would vary from one specimen to another; and (*ii*) the presence of oxygen atoms in the bulk which may be located within the first few thousand angstroms of the metal, in particular in grain boundaries. It should be noted that the finite depth resolution of our measurements [0.20 μm (21, 22)] does not allow one to distinguish between surface oxygen atoms and those situated in the volume up to 0.20 μm from the surface.

Of these two explanations, the second seems to us the most probable, as discussed below.

As the Materials Research Corporation (M.R.C.) 99.99% iron seems to have a lower surface oxygen level than that of Johnson and Matthey, the first named brand was used in all the following experiments on 99.99% purity iron.

Nature and equivalent thickness of the passive layer.—The quantity of oxygen fixed on the iron surface was studied as a function of the polarization potential V_{ox}. Following Ref. (16), it was thought necessary to stop the oxidation at a constant final current (5 μA/cm²) and to withdraw the specimens while maintaining their potential.

Oxygen content of films present in the prepassive and passive regions at 23°C.—First, we investigated the formation of the passive layer in a solution of natural isotopic O^{18} concentration, *i.e.*, practically only O^{16}. In the passive region, the function $N_O16 = f(V_{ox})$ is approximately a straight line, the slope of which is difficult to determine given the poor reproducibility of the measurements. In fact, the amount of oxygen fixed on the sample surface varies from about 12×10^{15} atoms/cm² at a potential $\phi_1 = -300$ mV, at the beginning of passivation, to about 25×10^{15} atoms/cm² at a potential $\phi_2 = +900$ mV, at the end of the passivation period. Furthermore, it should be noted that the quantity measured at potential ϕ_1 is of the same order as that determined after cathodic treatment of the specimen, about 12×10^{15} atoms/cm². This would imply that approximately 12×10^{15} atoms/cm² remain on the surface of specimens which have been cathodically polarized and exposed to air. Such a large quantity of oxygen, which is equivalent to an oxide layer 20Å thick if one assumes a γ-Fe_2O_3 structure with a roughness factor equal to unity, could be explained by two reasons: an oxidation due to atmospheric oxygen during transfer of the specimen from the electrochemical cell to the vacuum chamber of the accelerator, or an insufficient cathodic reduction in that it did not completely remove the surface film covering the polished specimen. However, this oxygen content seems to be essentially due to an oxidation in air during the transfer of samples from the electrochemical cell to the scattering chamber of the accelerator. This effect has been already observed in the case of nickel (17).

These results clearly show that the O^{18} tracing techniques are indispensable for obtaining further information; in particular, they should permit the effect of atmospheric oxygen to be distinguished from that of oxygen coming from the solution. All the oxygen 18 thus measured must come from the solution. Nevertheless, one cannot exclude the possibility of an exchange taking place by spontaneous oxidation when the sample is removed from the electrolytic cell. This would have the effect of decreasing the amount of O^{18} measured at the surface. In what follows this effect has been considered as negligible. This assumption has been confirmed by comparing our results with those obtained using other methods like ellipsometry and coulometry. Furthermore, nuclear microanaylsis measurements cannot be carried out *in situ*. After each oxidation, the specimens are withdrawn from the solution and immediately plunged into triple-distilled water of natural isotopic composition. Thus the nonpolarized specimen is in contact with a layer of enriched solution for the few seconds preceding immer-

sion in distilled water and is therefore under open-circuit potential of ~−60 mV (see Table I). Following literature data (7, 10), we may associate the quantity of oxygen fixed on the surface with the maximum value of the potential applied to the specimen. Thus it can be noticed that in the case of cathodically polarized specimens in an open circuit the potential increases, whereas it decreases when a potential greater than ~−60 mV is applied. In conclusion, this manipulation would not appear to affect the measurements except for cathodic polarization.

Cathodic pretreatment of the specimen before polarization was investigated in order to determine the state of the specimen at a potential $\phi_c = -650$ mV (Table I), *i.e.*, to determine whether oxygen from the solution fixes on the metal surface at the end of this period when it is still under cathodic potential. The following experiment was carried out: the specimen was cathodically polarized at 10 μA/cm^2 for 5 min and then, instead of withdrawing it from the solution [which, as we have described above, induces an oxidation by the layer of solution attached to the surface of the metal, about 3×10^{15} atoms/cm^2 of oxygen 18 (Fig. 3)], the 10 cm^3 of solution was diluted ten times with a deaerated solution having natural isotopic composition. Thus, the percentage of O^{18} enrichment was decreased by a factor of ten. During this dilution in a neutral atmosphere, the potential of the specimen was maintained at the previous level $\phi_c = -650$ mV. The specimen was then withdrawn from the cell and analyzed. No O^{18} was found fixed at the surface. This indicates that there is no oxygen from the solution at the surface of the specimen for $\phi_c = -650$ mV. However, from this experiment alone it cannot be determined whether the cathodic reduction completely removed the film at the surface of the polished specimen. Following literature data deduced from ellipsometric (8, 15, 23) and coulometric (5, 9) measurements, the specimen was assumed to be free of oxygen under these experimental conditions.

In a further experiment, before passivation of the specimen, the polarization was switched off for 5 min, causing an immediate increase of potential from $\phi_c = -650$ mV to a final value stabilizing at about −510 mV (ϕ_{s2}). This increase may be attributed to the process of oxidation at the surface and to the effect of hydrogen there. This intermediate stage before passivation was deliberately chosen to provide the experimental conditions under which the hypothesis recently proposed by Bockris *et al.* (8) could be studied. Bockris postulated the presence of an iron hydroxide $Fe(OH)_2$ in the prepassive region, which at the beginning of the passive region is transformed by the applied voltage into ferric oxide Fe_2O_3. The results obtained at this intermediate stage are discussed below.

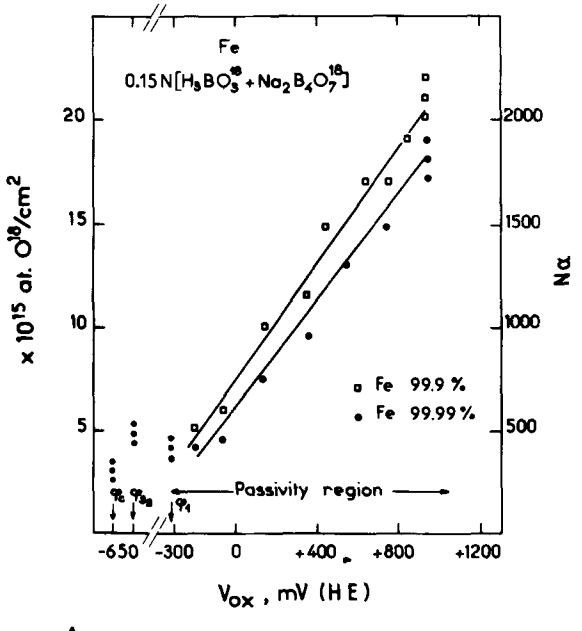

Fig. 3. $\hat{N}_{O18}$ as a function of applied potential V_{ox} for Fe 99.9% purity (□) and Fe 99.99% purity (●).

Then and only after this pretreatment, film formation was studied in the potential region, from −310 to +900 mV. Figure 3 shows the number of O^{18} atoms as a function of potential for 99.9% and 99.99% purity iron specimens. It should be noted that the error indicated between brackets is related to the irreproducibility of the formation of the passive films on several samples. It also should be remembered that the error of individual measurements only referring to the relative statistical precision of the counting rate is much lower than that previously mentioned. The results may then be summarized as follows:

1. The relationship between the number of oxygen atoms and the potential is approximately linear in the passive region.

2. For the iron of 99.9% purity, the slope of the line $\hat{N}_{O18} = f(V_{ox})$ is about 15% greater than that for 99.99% purity. This may be attributed to the different roughness factor of the 99.9% and 99.99% iron. One is now in a position to chose between the two hypothesis previously advanced to explain the presence of different quantities of oxygen at the surface of polished specimens of different origins (Table II). If this spread were due to varying roughness factors, then in the case of the polished 99.9% and 99.99% purity specimens this variation should be less than 15%, which is clearly not the case since this same variation calculated from the quantity of oxygen measured by the nuclear reaction is equal to 300% (see Table II). Consequently, it would seem reasonable to explain the above differences by the presence of traces of bulk oxygen, probably situated at the grain boundaries.

3. The maximum amount of oxygen coming from the solution and fixing on the surface does not exceed $(18 \pm 2) \times 10^{15}$ atoms/cm^2 for the 99.99% purity specimen. This corresponds to an oxide layer of about 35Å if one assumes a γ-Fe_2O_3 structure for the oxide, as suggested by Foley *et al.* (14) on the basis of electron diffraction experiments, and by Sato and Kudo (15) who reached the same conclusion using ellipsometric measurements.

4. The quantity of oxygen coming from the solution and fixing on the surface of iron speciments which have been subjected to cathodic reduction and have attained the corrosion potential ϕ_{s2}(−510 mV) is $(5 \pm 1) \times 10^{15}$ atoms/cm^2.

5. The quantity of oxygen present at the beginning of passive layer formation ($\phi_1 = -310$ mV) is $(5 \pm 1) \times 10^{15}$ atoms/cm^2. Thus, the difference in the quantity of oxygen (coming from the solution) at potentials ϕ_{s2} and ϕ_1 is statistically zero to within 2×10^{15} atoms/cm^2 (maximum value of error obtained by direct sum of errors). This is equivalent to about a monoatomic oxygen layer.

The above results referring to the passivity region agree satisfactorily with the corresponding data taken from the literature (7, 9) (Fig. 4), if one assumes a passive film with a γ-Fe_2O_3 structure and a roughness factor equal to unity. On the basis of this agreement, we shall deduce, in the following section, the apparent parameters of the passive film. However, at the corrosion potential $\phi_{s2} = -510$ mV, there is complete disagreement with regard to the presence [established in Ref. (8) and in this work] or the absence of oxygen [according to certain data in the literature (15)]. We have therefore taken great care to investigate the presence of oxygen at ϕ_{s2} and the following experiment was designed to exclude any oxidation effect caused by removal of the specimen from the electrolytic cell.

The iron specimen, subjected to the usual cathodic treatment, was stabilized for 5 min at the potential ϕ_{s2}. Instead of withdrawing the specimen from the O^{18} enriched solution, the 10 cm^3 of this solution were, as

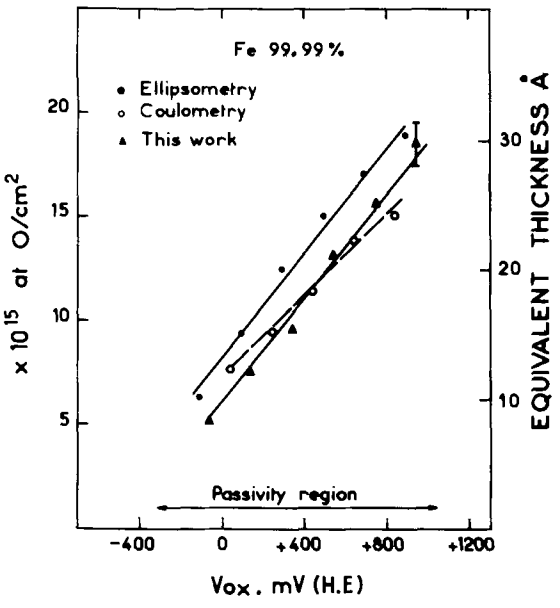

Fig. 4. Comparison between nuclear measurements and literature data for iron 99.99%. ● Foley *et al.* (14), ellipsometric measurements; ○ Frankenthal (9), coulometric measurements; ▲ This work.

previously, diluted with 100 cm³ of the same solution which was also deaerated but had a natural isotopic composition. During this transfer in a neutral atmosphere, the potential of the specimen was maintained at the previous level ϕ_{s2}. If the presence of oxygen at the spontaneous potential ϕ_{s2} were due to some oxidation caused by oxygen of the solution during removal of the specimen from the electrolyte cell, the quantity of oxygen 18 would be expected to be decreased by a factor of 10. However, this is not the case and thus the oxygen 18 adsorbed on the specimen surface originates from a real process of fixation of oxygen, between the moment when the specimen is no longer held at cathodic polarization and that when it reaches its spontaneous potential ϕ_{s2}. It should be noted that the corrosion potential ϕ_{s2} measured under the present experimental conditions, −510 mV, is closely consistent with the thermodynamic data for certain types of iron oxide or hydroxide (24). This constitutes further evidence, in agreement with Kruger and Calvert (7), for the presence of oxygen on the iron specimen at this potential. This question will be further developed in the section on Discussion.

Apparent electric field of formation.—Nuclear microanalysis allows one to determine the oxygen content of the passive layer as a function of the potential. Growth of passive layers at high potentials is generally accepted to be due to the transport of ions across a barrier layer as in the case of anodic oxides of valve metals. Thus, the growth laws established for anodic oxides like those of aluminum and tantalum (25) may also be valid for oxides forming a passive layer at high potentials; accordingly, we attempted to calculate some apparent parameters of these oxides and essentially the apparent electric field of formation.

The values of the field of formation E_{ox} were deduced from the slope of the curve $\hat{N}_{O}18 = f(V_{ox})$ for $J =$ const. Such a calculation, following (25), is possible provided this curve is linear, i.e., E_{ox} and the sum of the overpotentials $\Sigma\eta$ at the interfaces must be constant given the condition that the nature and structure of the oxide do not change. In fact, see Ref. (26), these physical parameters are connected through the following equation

$$V_{ox} - V_{eq} = E_{ox} \cdot l + \Sigma_{\eta} \qquad [1]$$

where l is the oxide thickness. If one assumes the stoichiometry, the density of the oxide, and the roughness factor to be constant, l is proportional to the oxygen content, $\hat{N}_{O}18$, of the compact passive film

$$l = a\,\hat{N}_{O}18 \qquad [2]$$

With reference to Eq. [1], if Σ_{η} is constant, as might be expected (25), is appears that V_{eq}, which corresponds to the thermodynamic potential V_{Th} of oxide formation, does not depend very much on the choice of one of the types of oxide or hydroxide which can be expected to occur (24).

The physical meaning of the calculation of the electric field E_{ox} depends on the condition that V_{eq}, Σ_{η}, and a be constant in the passivity region moreover, if V_{eq} and Σ_{η} vary only little for the different types of oxide, there must be a linear relationship between V_{ox} and $\hat{N}_{O}18$ under the condition that all the oxygen fixed on the specimen surface contributes to the formation of a barrier-type layer. This fact has indeed been observed in the present work (Fig. 3). The values of the fields E_{ox}, deduced from the slopes of the straight lines $\hat{N}_{O}18 = f(V_{ox})$ as obtained by nuclear microanalysis, have been calculated assuming, in agreement with the findings of other workers (5, 7, 8, 15), that the oxide has a structure of Fe_2O_3, a density ρ of 5, and a roughness factor equal to unity.

The values obtained for 99.99% purity Fe are $E_{ox} = 5.1 \times 10^6$ V/cm and 4.4×10^6 V/cm for 99.9% purity Fe. Values of E_{ox} calculated from various investigations are shown in Table III. These values refer to a potential region, ranging from + 100 to + 900 mV, in which there is a general agreement among all workers with regard to the structure of the thin oxide layers, *i.e.*, Fe_2O_3.

Our results obtained for $J = 5\ \mu A/cm^2$ are compared with those found in the literature for much smaller currents (Fig. 4). However, since for the system under investigation E_{ox} depends only slightly on the final current, our values recalculated with the densities indicated by the other authors are shown in brackets. Besides, the physical meaning of the quite small variation of E_{ox} with J has been analyzed by Kruger and Calvert (7).

Except for the large value of E_{ox} obtained by Nagayama and Cohen, it appears from the results obtained by the other workers that the slope of the $\hat{N}_{O}18 = f(V_{ox})$ curve depends apparently on the purity of the specimen. All we can say is that for a same degree of purity the results obtained by three different methods (coulometry, ellipsometry, and nuclear microanalysis) agree well.

Cathodic reduction.—Studies of oxygen loss during cathodic reduction were carried out at 23°C; for the iron specimen used, the rate of dissolution of the passive films was previously measured and found to be smaller than 7×10^{10} atoms/cm² sec (27). The passivation films formed at +940 mV in O^{18} solution were cathodically reduced in the same solution at a constant current density of 10 $\mu A/cm^2$. Figure 5 shows the variation of the number of oxygen 18 atoms fixed on the sample surface and the corresponding drop in potential during the cathodic reduction, as a function

(I_{final} = 5 μA/cm^2) at +940 mV. (a) n = 2/3e (theoretical value), (b) n = 2e (theoretical value), and (c) n = 1.38e (experimental value).

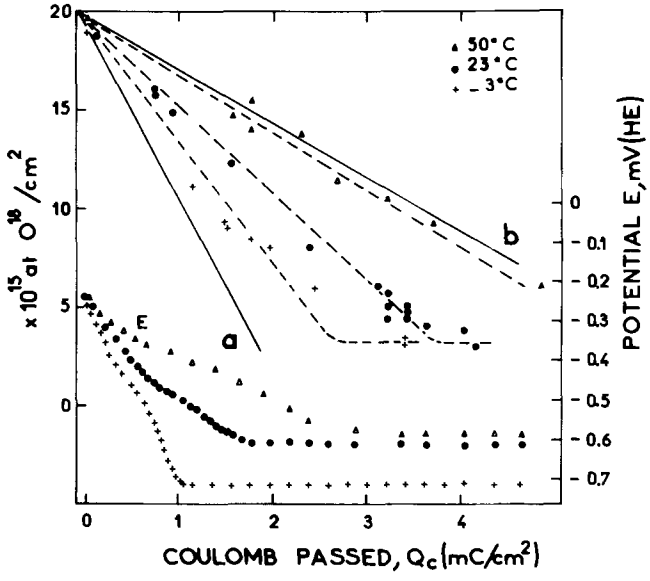

Fig. 6. Change in $\hat{N}_{O}18$ and in potential (*E*) of iron during the galvanostatic-cathodic reduction at 10 μA/cm^2 for the passive films formed in 3 min. (I_{final} = 5 μA/cm^2) at + 940 mV and at different temperatures.

of time, *i.e.*, as a function of the charge Q which has been passed. The slope of the curve $\hat{N}_{O}18 = f(Q_{mC/cm^2})$ gives the number n of electrons associated with an oxygen ion entering the solution. It should be mentioned that the nuclear microanalysis allows us to measure n directly, in contrast to other methods where n can only be deduced from changes of electrical or optical parameters of the film.

The problem of cathodic reduction has been studied for a long time (5, 10). Based on the mechanisms proposed in the literature, two slopes may be deduced theoretically relating $\Delta\hat{N}_{O}18$ to Q, (see Fig. 5). The first gives a value of 2/3e (electronic charge) associated with each oxygen ion passing into the solution. This is represented by curve a of Fig. 5 and was derived from the following mechanism

$$(a)\quad Fe_2O_3 + 6H^+ + 2e^- = 2Fe^{2+}{}_{(sol)} + 3H_2O$$

The second slope corresponding to curve b of Fig. 5 gives a value of 2e and corresponds to the mechanism

$$(b)\quad Fe_2O_3 + 6H^+ + 6e^- = 2Fe^\circ + 3H_2O$$

The experimental results gave us a value of 1.38 ± 0.07 electronic charge per oxygen ion passing into the solution. Our measurements were not precise enough to be able to distinguish between the first and second reduction stages; the existence of these two stages was deduced from ellipsometric measurements (6, 10).

To gain some insight into this problem, we have carried out the same cathodic reduction experiments at −3°C and +50°C. The passive films have been formed at this temperature, according to the process used at 23°C (see Table I) and we have shown that the rate of the oxygen losses, in open circuit, were negligible and smaller than 7 × 10^{10} atoms/cm^2 sec. Figure 6 shows the variation of the number of oxygen 18 fixed on the sample surface and the corresponding decrease in potential as a function of the charge passed. From Fig. 6, we deduce the value of n for two temperatures

$$n = 1.88 \pm 0.08e \text{ for } t = 50°C$$
$$n = 1.04 \pm 0.08e \text{ for } t = -3°C$$

This number n cannot be smaller than 2/3e [mechanism (a)]. Greater values of n could be obtained only with current efficiency smaller than 100% or if mechanism (b) also contributes to the cathodic reduction. In any case, it is not possible that the reaction takes place solely following mechanism (b). The value of the average charge cannot pass from 1.38 (at 23°C) to 2e since we have shown at the beginning of the paragraph that the chemical dissolution of the film is negligible. The ratio of the minimum theoretical slope to experimental slope is the minimum current efficiency for each temperature; it is equal to 66 and 35% at −3°C and +50°C, respectively.

Discussion

Presence of oxygen in the prepassive and post-passive regions.—The above results, *i.e.*, the presence of 5 × 10^{15} oxygen 18 atoms/cm^2 at the potential ϕ_1 and a maximum deviation of 2 × 10^{15} atoms/cm^2 between ϕ_1 and ϕ_{s2}, give rise to a question which may be stated as follows: does the passivation phenomenon result from oxygen fixed on the metal surface at a potential ϕ_{s1} or is it due to the oxygen corresponding to the difference between the two values at potentials ϕ_{s2} and ϕ_{s1}, *i.e.*, to the quantity of oxygen corresponding to the maximum deviation?

These two alternative interpretations may be formulated in the following manner: (*i*) passivation requires the presence of a monoatomic oxygen layer (~2 × 10^{15} atoms/cm^2); this would confirm the theory of adsorbed oxygen layers proposed by Uhlig (3) and Frankenthal (9); with increasing potentials in the passivity region, further formation of an oxide layer occurs on top of this monoatomic layer; and (*ii*) on the contrary, the onset of passive layer formation is associated with the presence of 5 × 10^{15} oxygen atoms/cm^2, as suggested by Sato and Bockris; this quantity of oxygen atoms would result from the transformation of the oxygen fixed at ϕ_{s2} into an oxide.

Presently, our results do not allow us to distinguish between these two mechanisms. However, we intend to obtain new information about this important problem by associating ellipsometric measurements to the results obtained from nuclear microanalysis with O^{18} tracing.

Cathodic reduction.—The results of nuclear microanalysis indicate, at 23°C, an electronic charge of 1.38e associated with each ion of oxygen passing into the solution. However, at the present moment, the precision of our experiments is insufficient due to the irreproducibility of the initial passive layers and thus cannot reveal the existence of two different slopes for

the rate of decrease of oxygen atoms as a function of the charge passed, as have been observed by Sato and Kudo (15).

If one takes for the current efficiency of the cathodic reduction a value of 50% at 23°C, then this value of $1.38e$ is reduced to nearly $2/3e$, which would imply that the cathodic reduction takes place essentially by mechanism (a). This value of 50% is the same as that proposed by Sato and Kudo (50%) for the over-all reduction process (two stages) but smaller than that proposed by Nagayama and Cohen (70%). One should notice that our experimental conditions were slightly different from those of the latter workers. The differences concerned are: (*i*) the conditions of preparation: 3 min in the present work instead of 1 hr anodic polarization; and (*ii*) the presence of dissolved iron in our solutions, since this is not changed after each cathodic reduction in O^{18} enriched solution; however, the quantity of dissolved iron is never greater than 10^{-5} mole/liter.

We are endeavoring to determine the influence of each one of these factors on the experimental slope of the curve $\hat{N}_O 18 = f(Q)$. The results should then enable us to decide whether or not the cathodic reduction takes place essentially according to mechanism (a). In the literature, Sato *et al.* (10) have suggested that reaction (b) takes place in two stages, the first one leading to the formation of an hydroxide $Fe(OH)_2$, while the subsequent step consists in the reduction of the hydroxide and the formation of the metal. The mechanism proposed by Nagayama and Cohen (5) is different (reduction of Fe_2O_3) but would also ensure a slope corresponding to an electronic charge of 2.

In the light of our results, it would appear that the temperature has a great influence on the cathodic reduction: at low temperatures, the curves $\hat{N}_O 18 = f(Q)$ imply that the cathodic reduction takes place in accordance with mechanism (a), while at higher temperatures mechanism (b), with two electrons associated with each oxygen atom, predominates. This, however, contradicts what one could reasonably deduce from the phenomenon of the decrease in potential, which is generally comprising two stages (5, 10). The first one would correspond to the reduction from Fe^{3+} to Fe^{2+}, while the second step indicates the formation of metallic iron from Fe^{2+}.

By determining the value of the current efficiency and by combining the results of ellipsometric measurements with those of nuclear microanalysis, carried out on the same samples, we are attempting to establish the detailed mechanism of the cathodic reduction.

Acknowledgments

The authors wish to thank Dr. G. Amsel for his numerous comments and suggestions during this work. The help of Mr. A. Laurent for his technical assistance was much appreciated. This work was supported by the Centre National de la Recherche Scientifique, (RCP No. 157), the DRME, and the DGRST.

Solution-Side Transport Processes in the Electropolishing of Copper in Phosphoric Acid

K. Kojima and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The unsteady-state anodic dissolution of copper in 5-10*M* phosphoric acid was carried out in the absence of convection, under galvanostatic and potentiostatic conditions. At a given bulk concentration of H_3PO_4, the product of current density, i, and the square root of the time (t_s) of onset of sharp potential rise (or abrupt decline of current) is nearly constant in the active dissolution range. $i\sqrt{t_s}$ decreases with increasing acid concentration. The transition times found are in substantial agreement with those reported by Elmore and Edwards. By using the most reliable diffusivity data available for phosphoric acid and for anodically formed copper phosphate, it is shown that the rate-limiting step in the active dissolution regime is the transport of copper phosphate from the electrode surface into the bulk solution. The potential jump in galvanostatic dissolution, or the peak current phenomena reported by numerous authors for steady-state potentiostatic dissolution can be best interpreted by assuming rapid increase of coverage of the anode surface with solid reaction product after the critical solubility limit of copper phosphate is reached at the surface. The concentration of phosphoric acid at the surface up to and including the peak current density where the critical solubility of copper phosphate is exceeded, remains finite. The magnitude of the peak current density can be predicted by considering the transport of copper phosphate away from the surface to be the limiting transport process.

Electropolishing of copper in concentrated phosphoric acid occurs under diffusion control (1, 2). Although the constancy of the product of current density and square root of transition time in galvanostatic unsteady-state dissolution has been confirmed (3-6), identification of the rate-determining species at the current plateau (2-4, 7, 8) has remained a controversial problem. Edwards (3) and Wagner (9) proposed that transport of one of the reactants from the bulk electrolyte to the anode surface is the rate-limiting process. The role of diffusion of water on the limiting current was discussed by Petit (8). On the other hand, Elmore (4, 10) claimed that without significant increase of applied cell voltage the current begins to decrease when the concentration of the dissolved copper species at the anode surface reaches the solubility limit. Hickling and Higgins (7) found that the limiting current decreases proportionally to the decrease of concentration difference of cupric ions between the anode surface and the bulk electrolyte. However, Hickling and Higgins' test was performed in dilute phosphoric acid (2*M*/1), where electropolishing is not possible.

In the decades that have passed since the two essentially opposite transport mechanisms have been proposed by Elmore and Edwards, a great deal of information has been developed on properties of the phosphoric acid-copper phosphate-water system. It appears therefore timely and worthwhile to undertake a reexamination of the question of the transport mechanism responsible for the smoothing and brightening action during electropolishing. Optical observations (11) of the copper surface undergoing dissolution, surface impedance measurements (12), ellipsometric studies (13), and wetting characteristics (mercury test) (1), all point to the fact that visible as well as invisible surface layers play an important role in the polishing process. In a qualitative study, preliminary to the present investigation, the present authors have found that in the unsteady-state active dissolution of copper in phosphoric acid the surface is free of solids. In steady-state electropolishing, however, solid material exists on and near the surface. These findings corroborate the observations reported earlier among others by Lorking (11) and Hoar *et al.* (1).

In the following, unsteady-state dissolution experiments are described, which were conducted deliberately under conditions similar to those used by Elmore and Edwards. Transition times in the active dissolution regime are interpreted using the best available transport property values.

The transport mechanism proposed on the basis of these unsteady-state experiments is then subjected to critical test using the peak current density data obtained by Hoar and Rockwell under steady-state potentiostatic conditions.

Dissolution of Copper under Galvanostatic Conditions

Experimental apparatus and procedure.—The experimental cell is shown schematically in Fig. 1. This simple cell was purposely designed to resemble the cell geometry employed by both Elmore (4, 10) and Edwards (3). The straight wall of the cylindrical anode compartment parallel to the direction of electric cur-

rent flow and the ratio of the height of the anode compartment to its diameter provide a geometry that gives a reasonably uniform current density distribution over the entire surface of the portion of the anode exposed to the electrolyte. The apparent area of the portion of the anode exposed to the electrolyte is 1.46 cm^2 and the inside area of the cylindrical cathode exposed to the electrolyte is 38 cm^2. During cell operation, the anode disk was in a horizontal position, facing upward. Since a more dense solution is forming upon anodic dissolution of copper, this configuration assures absence of convection during experimental runs. The laminar free convection occurring at the vertical cathode did not disturb the immobile solution in the anode compartment within the relatively short time spans (0.2-100 sec) involved in these experiments.

Analytical grade phosphoric acid (Baker, 85.9%) was diluted to desired concentrations (5 or 10*M*) for each experiment. The cathode was made from 99.9% polycrystalline copper; the anodes were prepared either from the same material, or cut from single crystals parallel to the (111) plane. Anode specimens were mechanically polished, washed with water and acetone, and subsequently anodically etched in concentrated H_3PO_4. In a few instances chemical polish was used in a HNO_3:H_3PO_4:HAc = 2:1:1 volume solution. Dissolution experiments were carried out at 22° ± 1°C.

After the current was cut off, anodes were immediately removed, washed with water and acetone, and dried at room temperature for weight loss measurements, or for microscopic observation of the surface. Anode surfaces were also observed *in situ* during dissolution under relatively low (10-45×) magnification. Constant current experiments were carried out by using external control of current (*a*) or, by potentiostatic control of the anode potential (*b*), involving approximately 2-7 ohm resistance between reference capillary tip, and anode surface.

(*a*). Constant current supply was provided by an Electronic Measurements Model C 621 power supply. The cell voltage was recorded by Sargent Model MR recorder. This technique was used for transition times of over 25 sec. This range allowed observation of the surface *in situ* under low level (10-45×) magnification.

(*b*). Anotrol Model 4100 potentiostat was employed to provide a constant potential between a reference electrode and the anode surface. In the active dissolution region the resistance between capillary tip and surface was sufficiently large compared to the impedance associated with the electrode reaction, so that potential control in this case corresponded to controlling current, at least up to the transition time. The current *vs.* time behavior was obtained by passing the cell current through a calibrated resistor and recording the resulting potential drop on a Tektronix Model 531 oscilloscope. Transition times in the range of 0.2-5 sec could be obtained with good reproducibility.

Visual observation of the anode surface during dissolution.—Typical cell voltage *vs.* time behavior in externally controlled constant current runs is illustrated in Fig. 2. After closing the circuit the cell voltage abruptly rises to a plateau and then increases only slightly (40-60 mV) to point A, at transition time t_s, after which the increase is quite sharp (the first voltage jump[1]). Visual observation under 10-45× magnification reveals, that at point A blue solid particles (probably copper phosphate) begin to form at the anode. As point E is reached (the second voltage jump) the number of particles becomes quite large; the blue color is spread over the entire surface. The onset of formation of small particles of blue color at point A becomes less distinct at higher applied current densities (above 0.05 A/cm^2). At the highest current density employed in these experiments, at i = 0.0676 A/cm^2, identification of two separate potential breaks was no longer possible.

[1] The first voltage jump is probably caused both by solid copper phosphate deposits and by the formation of copper oxides (18).

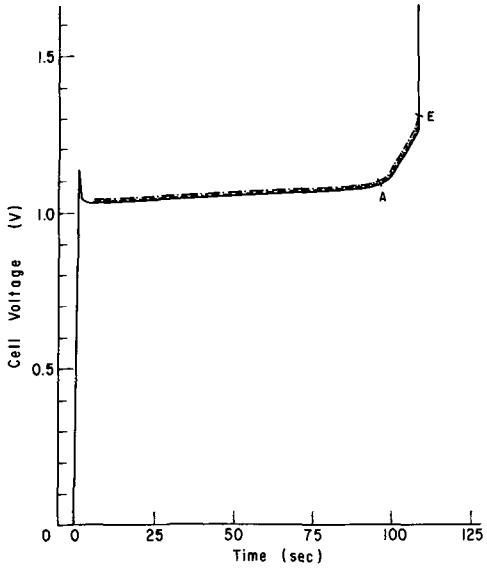

Fig. 2. Cell voltage change with time for polycrystalline copper in 10.0 M/liter H_3PO_4, i = 0.0362 A/cm^2 (six repeated runs are indicated by solid —, and dashed - - lines). The apparent valence is 2.0. Time elapsed to point A: transition time, t_s.

Valence of dissolution.—Weight loss measurements were carried out in runs extended up to the transition point A. The apparent valence of dissolution n' was obtained from

$$n' = \frac{M \cdot I \cdot t}{\mathbf{F} \cdot \Delta W}$$

where I is total current (A), t is time (sec), M is molecular weight of copper (g/g-mole), $\mathbf{F}$ is the Faraday, and ΔW is weight loss (g). From eight measurements, up to i = 0.038 A/cm^2, n' = 2.0 was obtained. In the following we shall assume that in the active dissolution regime, copper anodically dissolves in phosphoric acid with a valence of 2. Visual identification of the appearance of solid blue particles at the time when the voltage begins to rise rapidly in galvanostatic experiments suggests that the latter event is caused by the formation of solid copper phosphate at the anode surface. The change of concentration of reactants, or of reaction products at the anode surface is obtained by solving the diffusion equation with the appropriate initial and boundary conditions. Neglecting migration effects, we obtain (see Appendix B)

$$|C(t) - C(0)|_{x=0} = \frac{2i}{n\mathbf{F}} \left(\frac{t}{\pi D} \right)^{1/2} \qquad [1]$$

wheres $C(0)$ and $C(t)$ are the concentration of a reactant, or of a product at the surface, respectively, and n is the number of electrons transferred in the electrode process per g-mole (or g-ion) of the participating species considered. The concentration of a reactant or a reaction product at the anode surface at the transition time $t = t_s$ has some characteristic value, solely determined by the bulk composition, and temperature, independent of applied constant current density.

Figure 3 includes results from about 90 individual experiments obtained by current control (0.031-0.0676 A/cm^2) and potential control (0.16-0.6 A/cm^2) in 10.0*M* H_3PO_4. In this range of current densities, $i\sqrt{t_s}$ = 0.36 ± 0.015. Similar experiments conducted in 5*M* H_3PO_4 yielded $i\sqrt{t_s}$ = 0.73 ± 0.04, again indicating that the transition time t_s, as defined by the time of onset of the first voltage jump, is controlled by transport of one of the reactants or products.

Discussion

Comparison of present work with previous results.—Figure 3 shows that $i\sqrt{t_s}$ is nearly independent of cur-

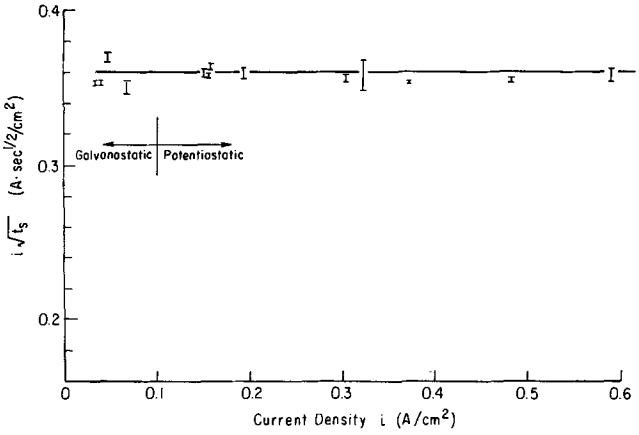

Fig. 3. Relation between $i\sqrt{t_s}$ and i in 10.0$_5$M H_3PO_4. (111) face of a single crystal (99.999%) was employed in runs at i = 0.308, 0.485, and 0.591 A/cm². All others involved were 99.9% polycrystalline copper. Number of experiments at a given current density: 3-10.

rent density in the range of 0.03-0.6 A/cm². This is in good agreement with the results obtained by Elmore (4), Edwards (3), Krichmar (5), and Vozdvishensky *et al.* (6). In 10M H_3PO_4 the values of $i\sqrt{t_s}$ obtained by interpolation from Elmore's and Edward's work are 0.36_8 (at 23.5°-24°C) and 0.37_4 (at 25°C), respectively, very close to the value of 0.36 obtained in this research.

The apparent valence of dissolved copper obtained in this work, 2.0 for the active dissolution of copper, is in good agreement with the value 2.00 reported by Petit and Schmitt (15).

Relation between $i\sqrt{t_s}$ and the concentration of phosphoric acid.—If the values of $i\sqrt{t_s}$ are characteristic of the properties of the electrolyte, it follows that they should be unique functions of the concentration of aqueous phosphoric acid at a given temperature. In Fig. 4, $i\sqrt{t_s}$ is plotted against the concentration of phosphoric acid. The values obtained by Elmore, Edwards, and by the present authors, are in good agreement with one another; $i\sqrt{t_s}$ decreases with increasing acid concentration. It is to be noted that the significance of this pattern of behavior was not recognized by the authors mentioned above.

Diffusion kinetics.—The reactants and reaction products in the active dissolution of copper move to or away from the anode by migration and diffusion. The diffusion layer is built up corresponding to the applied current density, time, diffusivity, and transference number of a species participating in the process.

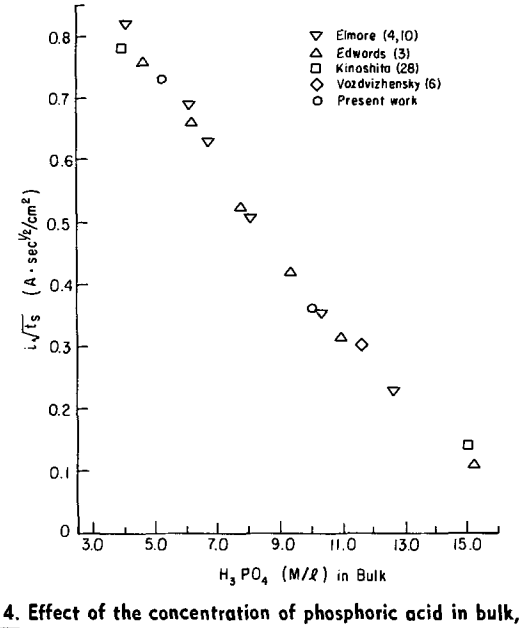

Fig. 4. Effect of the concentration of phosphoric acid in bulk, C_{rb}, on $i\sqrt{t_s}$

According to Laforgue-Kantzer (16), copper dissolves in concentrated phosphoric acid along the following over-all reaction scheme

$$Cu + H_3PO_4 + H_2O = (CuOH)^+(H_2PO_4)^- + 2H^+ + 2e^- \quad [I]$$

Krichmar and Galushko (17), on the other hand, claim that the copper dissolution reaction may be described by

$$Cu + 2H_3PO_4 = Cu^{++}(H_2PO_4)_2^- + 2H^+ + 2e^- \quad [II]$$

The first cell voltage jump may be expected to result (*a*) from the strong depletion of one of the reactants, that is, H_3PO_4 or H_2O in reaction [I] and H_3PO_4 in reaction [II], and (b) from the solubility limit of one of the reaction products (copper phosphate[2]) being exceeded and a high resistive film being formed on the anode.

In case (*a*), the concentration of a reactant C_r at the anode surface decreases with time and reaches $C_r \to 0$ at $t = t_s$, causing a sharp increase of the concentration overpotential. Here at $t = t_s$, the concentration of the reaction product is assumed to be below its solubility limit. In case (b), the concentration of the reactant at the anode surface does not reach $C_r \to 0$ at $t = t_s$.

Assuming that copper dissolution occurs with 100% current efficiency, the following relations [for derivation, see Appendix and also Ref. (18)] are applicable at the anode surface in reaction [I]

$$i = \frac{2F}{1 - t_{CuOH+}} D_p \left| \frac{\partial C_p}{\partial x} \right| \quad \text{for copper phosphate} \quad [3]$$

$$i = \frac{F}{t_{H+} - \frac{1 - t_{CuOH+}}{2}} D_r \left| \frac{\partial C_r}{\partial x} \right| \quad \text{for phosphoric acid} \quad [4]$$

In reaction [II]

$$i = \frac{2F}{1 + t_{Cu++}} D_p \left| \frac{\partial C_p}{\partial x} \right| \quad \text{for copper phosphate} \quad [5]$$

and

$$i = \frac{F}{t_{H+}} D_r \left| \frac{\partial C_r}{\partial x} \right| \quad \text{for phosphoric acid} \quad [6]$$

i, t_{Cu++}, t_{H+}, D_p, and D_r are applied current-density, transference number of Cu^{++}, that of H^+, diffusivity of copper phosphate, and that of phosphoric acid, respectively. Calculations of limiting current density in terms of water or H^+ concentration are not convenient because the necessary experimental data are not available. The diffusivity of phosphoric acid in the H_3PO_4-H_2O system has been measured at 25°C by Edwards and Huffman (19) and that of the anodic dissolution product of copper in phosphoric acid at 20°C by Krichmar *et al.* (20).

We now choose phosphoric acid as the reactant and copper phosphate as the reaction product in our diffusion calculations.

Case (*a*): If the first cell voltage jump is caused by the strong depletion of phosphoric acid at the anode surface, because of $C_r(t_s) = 0$ we get (see Appendix B)

$$i\left(\frac{t_s}{D_r}\right)^{1/2} = \frac{F}{2} \cdot \frac{\sqrt{\pi}}{t_{H+} - \frac{1 - t_{CuOH+}}{2}} \cdot C_{rb}$$

for reaction [I] [7]

and

[2] We use the terminology "copper phosphate" to denote the dissolution product of copper in phosphoric acid.

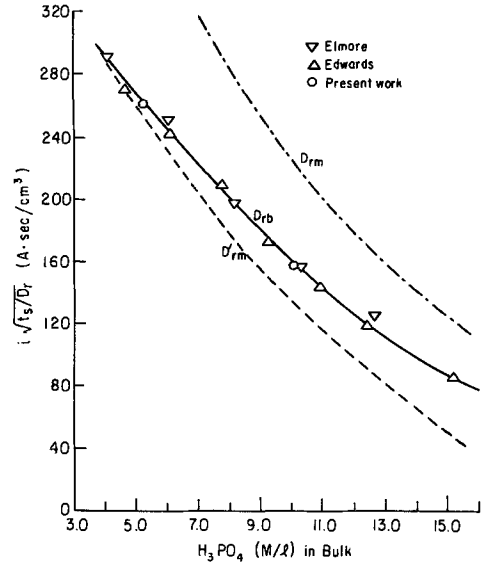

Fig. 5. Relation between $i\sqrt{t_s/D_r}$ and the concentration of phosphoric acid, C_{rb}. $i\sqrt{t_s/D_r}$ was obtained from Elmore, Edwards, and the present work. - - - curve indicates approximate pattern of experimental results of arithmetic mean diffusivity $D'_{rm} = \frac{1}{2}(D_{rb} + D_{ro})$. $D_{ro} \to D_r$ for $(H_3PO_4) \to 0$. —·—·— curve indicates qualitative behavior for $D_{rm} = \frac{1}{2}(D_{rb} + D_{rs})$, where D_{rs} denotes the value of D_r at the critical solubility of copper phosphate. Because copper phosphate increases considerably the viscosity of electrolyte $D_{rb} >> D_{rs}$ is assumed.

$$i\left(\frac{t_s}{D_r}\right)^{1/2} = \frac{\mathbf{F}}{2} \cdot \frac{\sqrt{\pi}}{t_{H+}} \cdot C_{rb} \text{ for reaction [II]} \quad [8]$$

Assuming that the transference number of H^+ or $CuOH^+$ is constant, the term $i\sqrt{t_s/D_r}$ should be proportional to C_{rb}, the concentration of phosphoric acid in the bulk of the electrolyte, the driving force for the diffusion of phosphoric acid. The relation between $i\sqrt{t_s/D_{rb}}$ and the concentration of phosphoric acid is shown by the solid curve in Fig. 5, where the values of $i\sqrt{t_s}$ measured by Elmore, Edwards, and the present authors are plotted. As shown, $i\sqrt{t_s/D_{rb}}$ decreases sharply as the bulk concentration of phosphoric acid increases. A sharper decline of $i\sqrt{t_s/D_r}$ with bulk H_3PO_4 concentration would be obtained, if we were to use some average value of diffusivity between bulk and interface (D'_{rm}). This would correct upward the effective diffusivities. The correction would be proportionally larger, the higher bulk concentration, because $D'_{rm} = (1/2)(D_{rb} + D_{ro})$ and the diffusivity of H_3PO_4 at the interface, D_{ro}, has the same (highest) value irrespective of C_{rb}.

Qualitatively the reverse situation arises if we take into consideration the effect of copper phosphate at the anode surface on the diffusivity of phosphoric acid (case of D_{rm}): because of the presence of copper phosphate the viscosity is higher at the interface than in the bulk. Consequently the relationship between $i\sqrt{t_s/D_{rm}}$ [3] and H_3PO_4 concentration would be described by a curve lying above the one obtained by assuming $D_r = D_{rb}$. As a further test of the hypothesis involving phosphoric acid as the limiting reactant, the ratio of calculated *vs.* experimentally obtained $i\sqrt{t_s}$ values are plotted in Fig. 6. For reaction [II] the calculated values were obtained by

$$i(t_s)^{1/2}_{calc} = \frac{\mathbf{F}}{2}(\pi D_r)^{1/2} C_{rb} \quad [9]$$

For diffusivities of phosphoric acid, the bulk values, D_{rb}, were employed, and the transference number of hydrogen ion, t_{H+}, was assumed to be unity. It should

[3] $D_{rm} = (\frac{1}{2})(D_{rb} + D_{rs})$.

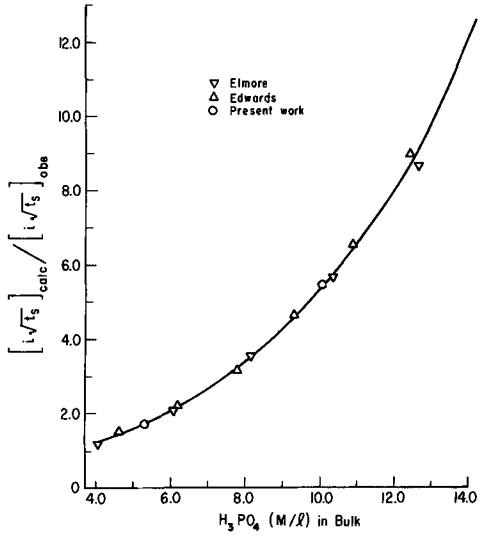

Fig. 6. Relation between $i\sqrt{t_s}_{calc}/i\sqrt{t_s}_{obs}$ and the concentration of H_3PO_4 for strong depletion of H_3PO_4 at the anode surface (reaction [II]). $i\sqrt{t_s}_{calc}$ was obtained by Eq. [9] with D_{rb}.

be noted that both the use of arithmetic mean values of diffusivities between bulk and surface, as well as the assumption of lower transference number for the hydrogen ion causes the ratios plotted in Fig. 6 to increase, *i.e.*, to depart further from correspondence of calculated *vs.* experimental values. Similarly, the discrepancy becomes larger, if we assume that the reaction stoichiometry is represented by reaction [I]. Lowering of t_{H+} at the anode surface due to large interfacial concentration of copper phosphate and low interfacial concentration of phosphoric acid could be expected when the bulk concentration of phosphoric acid is low. In reaction [II] the calculated value of $i\sqrt{t_s}$ increases inversely proportional to the value of t_{H+}. As shown in Fig. 6 the calculated $i\sqrt{t_s}$ obtained with $t_{H+} \approx 1$ in dilute phosphoric acid are, however, of the same order of magnitude as those of the measured $i\sqrt{t_s}$. [4] The analysis of transition time data presented above, indicates that available experimental evidence is incongruent with a model in which the transport limitation of phosphoric acid is responsible for reaching the limiting condition at the anode surface. If the transport of the reactant solute (*i.e.*, H_3PO_4) were to be limiting, $i\sqrt{t_s/D_r}$ should increase rather than strongly decline with bulk concentration.

We conclude therefore, that the transport of phosphoric acid is not directly responsible for the limiting phenomena in the anodic dissolution of copper.

Case (b): We will now proceed and assume that the interfacial concentration of H_3PO_4 is not approaching zero at the anode surface, rather it will have some finite value. The transference number of hydrogen ions, t_{H+}, then, will be close to unity,[5] and that of copper ions, t_{Cu++}, will approach zero. For $C_p(0) = 0$ and $C_p(t_s) = C_{ps}$ we get

$$i\left(\frac{t_s}{D_p}\right)^{1/2} = \frac{\mathbf{F}(\pi)^{1/2}}{1 - t_{CuOH+}} C_{ps} \quad \text{reaction [I]} \quad [10]$$

or

$$i\left(\frac{t_s}{D_p}\right)^{1/2} = \frac{\mathbf{F}(\pi)^{1/2}}{1 - t_{Cu++}} C_{ps} \quad \text{reaction [II]} \quad [11]$$

Assuming $t_{CuOH+} \to 0$ and $t_{Cu++} \to 0$, we obtain the

[4] When the bulk concentration of H_3PO_4 is high (6-15*M*), its interfacial concentration is also quite appreciable (approximately 4-10*M*), while that of copper phosphate is much lower (1-2*M*) (18). For this reason t_{H^+} should be not far from unity at the interface. However, even if we assumed $t_{H^+} = 0.5$, $i\sqrt{t_s/D_r}_{calc}/i\sqrt{t_s/D_r}_{obs}$ strongly increases with bulk acid concentration, rather than approaching unity.

[5] According to Kerker and Espenscheid (21) t_{H^+} in 4*M* H_3PO_4 is 0.89. In Chapman's critical review of transport properties (22) the range of $t_{H^+} = 0.93 \to 1.0$ is given for $4 \to 12M$ H_3PO_4.

simplified relation

$$i\left(\frac{t_s}{D_p}\right)^{1/2} = \mathbf{F}(\pi)^{1/2} C_{ps} \qquad [12]$$

for both reactions [I] and [II]. If the first cell voltage jump is caused by reaching the solubility limit of copper phosphate, followed by the formation of a resistive film, $i\sqrt{t_s/D_p}$ should be proportional to the solubility of copper phosphate, C_{ps}. For purposes of this calculation we employ Hickling and Higgins' experimental values (7) for the solubility of Cu^{++} in phosphoric acid at 20°C. Diffusivities of anodically formed copper phosphate were measured by Krichmar *et al.* (20). Because of the complex way in which the concentration dependent diffusivity influences t_s, values of $i\sqrt{t_s/D_p}$ in Fig. 7 have been evaluated using two different diffusivities: (*i*) D_{po}, the diffusivity of Cu^{++} at very low concentration (*i.e.*, corresponding to conditions in the bulk), and (*ii*) D'_{pm}, the arithmetic mean of D_{po} and D_{ps} (diffusivity at critical solubility). As shown in Fig. 7, in the range of phosphoric acid concentration (4-15*M*) the value of $i\sqrt{t_s/D_{po}}$ or $i\sqrt{t_s/D'_{pm}}$, in fact, increases approximately directly proportionally with the solubility of copper phosphate (1.3-2.4 *M*/l).

Another test can be made by examining the relation between $i\sqrt{t_s/D_p}$ and $(C_{ps} - C_{pb})$ for a fixed C_{ps} and a variable C_{pb}. Edwards (3) found that for a given phosphoric acid concentration the value of $i\sqrt{t_s}$ decreases with the increase of C_{pb}. However, because of lack of diffusivity data of copper phosphate the relation between $i\sqrt{t_s/D_p}$ and $(C_{ps} - C_{pb})$ was not investigated. This relation as evaluated by the present authors is shown in Fig. 8. $i\sqrt{t_s}$ and C_{pb} were obtained from Edwards (3). For the diffusivity of copper phosphate its

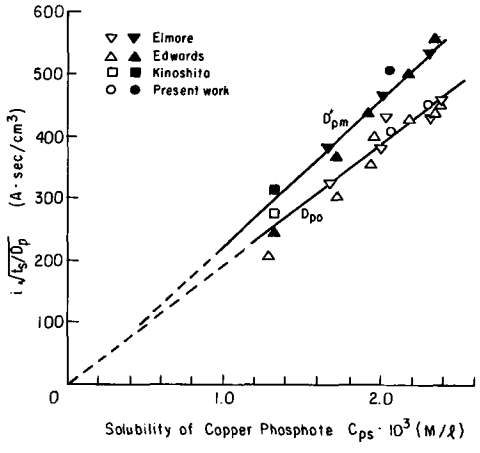

Fig. 7. Relation between $i\sqrt{t_s/D_p}$ and the critical solubility of copper phosphate. $D_{po} \rightarrow D_p$ at $C_p \rightarrow 0$, $D_{pm} = (1/2)(D_{po} + D_{ps})$.

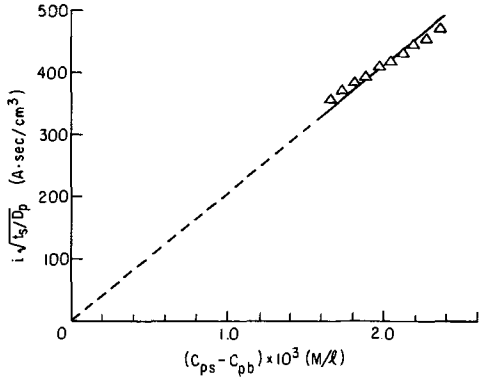

Fig. 8. Relation between $i\sqrt{t_s/D_p}$ and the concentration difference of copper phosphate between anode surface and bulk electrolyte. $i\sqrt{t_s}$ and C_{pb} data were taken from Edwards (3).

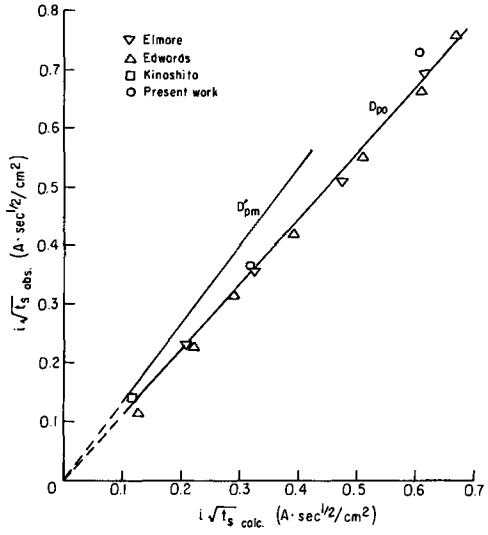

Fig. 9. Relation between $i\sqrt{t_s}$ calc and $i\sqrt{t_s}$ obs in the case of the reaction product control. $i\sqrt{t_s}$ calc was obtained by Eq. [12']. Ronge of bulk concentration of H_3PO_4: $4 < C_{rb} < 15M$. The slope of $i\sqrt{t_s}$ obs *vs.* $i\sqrt{t_s}$ calc line is about 1.1 for D_{po} and 1.3 D'_{pm}, respectively.

value in the bulk phosphoric acid (50%) is used. Direct proportionality of $i\sqrt{t_s/D_p}$ to $(C_{ps} - C_{pb})$ is again demonstrated. Thus, in contrast to the interpretation of Edwards, his data on the effect of presence of Cu^{++} in the bulk electrolyte indicate that the onset of voltage rise is caused not by the depletion of H_3PO_4, but rather by the accumulation of copper phosphate at the anode surface.

It remains to be tested whether the proportionality constant is in good agreement with the constant theoretically obtained. For the purpose of this test, the experimental values of $i\sqrt{t_s}$ are plotted against

$$i(t_s)^{1/2}{}_{calc} = \mathbf{F}(\pi D_p)^{1/2} C_{ps} \qquad [12']$$

Figure 9 shows that for D_{po} the calculated values are over a wide range in reasonable agreement with the measured values of $i(t_s)^{1/2}$. The ratios of calculated to measured values are about 1.1 for D_{po} and 1.3 for D'_{pm} respectively.[6] The above argument gives strong support to the view that the first cell voltage jump is caused by reaching the solubility limit of copper phosphate followed by the formation of a resistive film (18, 23). If the first cell voltage jump is really caused by the critical solubility of copper phosphate, the concentration of phosphoric acid at the anode surface at $t = t_s$, C_{rs}, is higher than zero. In Fig. 10, values of C_{rs}, calculated by using Eq. [7] or [8] are compared to those obtained by chemical analysis[7] (17, 24). The calculated C_{rs} values are in fairly good agreement with the measured concentrations of free phosphoric acid in the anolyte. The concentration of free phosphoric acid at the interface increases with the increase of the concentration of phosphoric acid in the bulk of the electrolyte.

When copper phosphate deposits on the anode surface the interfacial concentration of phosphoric acid, C_{rs}, is higher for reaction [I] and lower for reaction [II]. Simultaneous occurrence of both reactions would lead to intermediate values of C_{rs}.

The result obtained from the foregoing diffusion-kinetic study as well as the evidence for the formation of copper oxides at the current plateau (18) conclu-

[6] If we were to take into account the possible contribution of migration of Cu^{++} (or $CuOH^+$) to the mass flux, the agreement between experimental and calculated values would be further improved.

[7] The following assumptions are made:

total concentration of phosphoric acid $\cong$ free phosphoric acid concentration + concentration of phosphoric acid combined with Cu^{++}

and

$$\left[\text{total concentration of phosphoric acid}\right]_{x=0} \cong \left[\text{total concentration of phosphoric acid}\right]_{x=\infty}$$

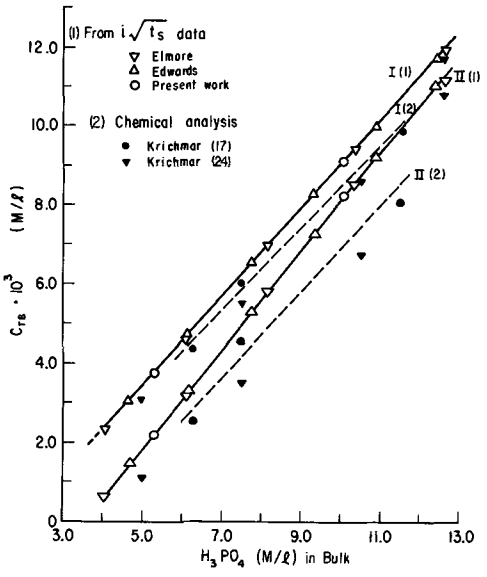

Fig. 10. Concentration of phosphoric acid at the anode surface, C_{rs}, as the function of bulk phosphoric acid concentration, C_{rb}. Lines I(1) and I(2) for reaction [I] and lines II(1) and II(2) for reaction [II] were obtained from measured values of $i\sqrt{t_s}$ and from chemical analysis.

sively support the view that the first cell voltage jump in galvanostatic experiments or the current decrease in potentiostatic experiments is caused by reaching the critical solubility of copper phosphate followed by the formation of a resistive film on the anode surface.

Peak Current Density

In the active dissolution of copper, the anodic current density increases with the increase of anode potential according to the Tafel relation (18). Under given hydrodynamic conditions, the concentration of copper phosphate increases with the increase of anode potential, and finally reaches the critical solubility. It is important to evaluate whether the onset of sharp potential rise in galvanostatic (unsteady-state diffusion) experiments (3, 4, 18) is caused by the same mass transport mechanism as the occurrence of the peak current density[8] phenomenon in steady-state anodic polarization runs obtained in forced convection (1).

In laminar forced convection, the correlation (26, 27)

$$\mathrm{Nu} = 1.85 \left(\mathrm{Re\ Sc} \frac{d}{L} \right)^{1/3} \qquad [13]$$

can be used as an accurate representation of mass transfer to an electrode in a flat duct, when the concentration of a reactant of a reaction product is kept constant over the whole surface of the electrode. Nu, Re, Sc, d, and L are Nusselt number, Reynolds number, Schmidt number, equivalent duct diameter, and electrode length, respectively.

For the particular electrode configuration in a horizontal rectangular channel such as the one used by Hoar and Rothwell,[9] the limiting current is difficult to estimate. However, the proportionality

$$\frac{i_{pk}}{F} \propto D^{2/3} V^{1/3} \Delta C \qquad [14]$$

is still expected to be valid (i_{pk} is the peak current density and V is the center line velocity of flow in the duct). For a given phosphoric acid concentration, we have $(i_{pk}/F) \propto V^{1/3}$. Examination of Hoar and Rothwell's data shows indeed proportionality of i_{pk} to $V^{1/3}$ for the entire range of H_3PO_4 concentration employed (6-10M). This suggests that the peak current densities are greatly affected by the hydrodynamic conditions near the anode surface.

If the peak current densities are caused by the strong depletion of phosphoric acid, the values of $i_{pk}/D_r^{2/3}V^{1/3}$ should be proportional to the concentration of phosphoric acid in the bulk electrolyte, the driving force for mass transfer.

The viscosity of the electrolyte saturated with copper phosphate at the anode surface is several times higher than that of the bulk electrolyte (18, 24). This should cause lowering of the diffusivity of phosphoric acid in the diffusion layer. Since there is no information available on the effect of Cu^{++} concentration on the diffusivity of phosphoric acid, two cases are considered: (a) the effective diffusivity of phosphoric acid in the diffusion layer is assumed to be equal to the diffusivity of phosphoric acid in the bulk electrolyte, D_{rb}, and (b) the effective diffusivity is same as the one corresponding to the concentration at the surface. Using either of these diffusivity estimates, the ratio $i_{pk}/D_r^{2/3}V^{1/3}$ decreases with increasing bulk concentration of H_3PO_4. This result indicates that the peak current cannot be explained by the limiting transport of phosphoric acid.

If on the other hand the peak current phenomenon is caused by the attainment of the critical solubility of copper phosphate followed by the coverage of the surface by solid deposits we should expect that

$$\frac{i_{pk}}{V^{1/3}} \propto D_{pm}^{2/3} (C_{ps} - C_{pb})\ ^{10} \qquad [15]$$

A reasonable confirmation of this proportionality is demonstrated in Fig. 11, in which the experimental peak current densities are those by Hoar and Rothwell (1). Again, as in the analysis of data obtained under galvanostatic conditions in pure diffusion, we conclude that the controlling step in the active dissolution range and up to the peak current is the transport of copper phosphate from the surface to the bulk electrolyte. For purposes of comparison, values of $i/V^{1/3}$ calculated with the current density at the polishing plateau, i_{pol}, as obtained by Hoar and Rothwell, are also shown in Fig. 11. The behavior demonstrated by i_{pol} is also consistent with the controlling role of the transport of copper phosphate from the surface into the bulk electrolyte.

Concluding Remarks

In the foregoing we have compared new results of unsteady-state experiments on the anodic dissolution of

[10] Because of a narrow range of the critical solubility of copper phosphate in the concentration range of 6M H_3PO_4 to 10M H_3PO_4, proportionality of $i_{pk}/V^{1/3}$ to $D_{pm}^{2/3}$ $(C_{ps} - C_{pb})$ is tested. $D_{pm} = (1/2)(D_{ps} + D_{pb})$.

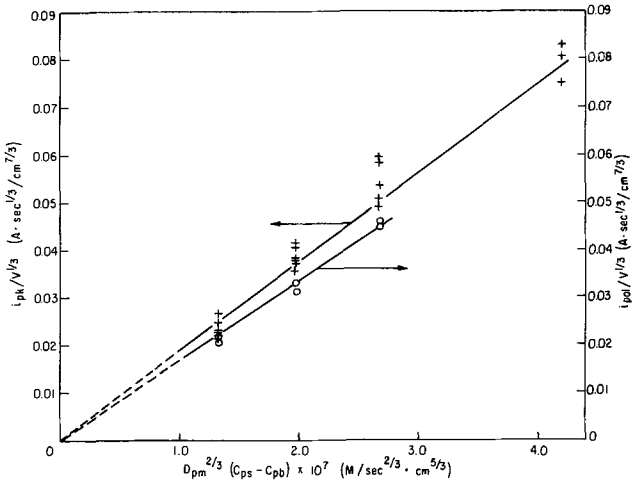

Fig. 11. Relation between $i_{pk}/V^{1/3}$ or $i_{pol}/V^{1/3}$ and $D_{pm}^{2/3}$ $(C_{ps} - C_{pb})$. Data from Hoar and Rothwell (1). $D_{pm} = (1/2)(D_{pb} + D_{ps})$.

[8] Using the analysis developed by Selman (25), we find that the potential scan velocities employed by Hoar and Rothwell indeed allow reaching the steady state.

[9] The velocity boundary layer in this cell is not fully developed at the leading edge of the electrode. Further, because of the circular geometry of the anode, the mass transfer boundary layer thickness varies across the anode, not only in the direction of flow, but also in a direction normal (90°) to it.

copper in phosphoric acid in the active dissolution regime with those obtained earlier by Elmore and Edwards. Transition times in 5 and 10*M* H_3PO_4 agree very well with those reported by the above authors. Analysis of transition times by using the best available diffusion coefficient and solubility data leads to the conclusion that in the limiting current phenomenon characteristic of the electropolishing of copper, transport of phosphoric acid is not the limiting process. The solubility limit if copper phosphate is exceeded while the concentration of phosphoric acid is still quite appreciable at the anode surface. This interpretation is congruent with the peak current density values reported by Hoar and Rothwell for electropolishing of copper in steady-state laminar flow. A more precise and definitive description of the controlling transport mechanism will only be possible when more extensive information becomes available on the properties of the ternary system Cu^{++}-H_3PO_4-H_2O.

APPENDIX

A. Derivation of Eq. [3]-[6]

Reaction I.—

$$Cu + H_3PO_4 + H_2O = [CuOH]^+[H_2PO_4]^- + 2H^+ + 2e^- \text{ (over-all)}$$

$$H_3PO_4 \rightleftarrows H^+ + H_2PO_4^-$$

$$Cu + H^+OH^- = CuOH^+ + H^+ + 2e^-$$

$$(t_{H+}) + (t_{H_2PO_4-}) + (t_{CuOH+}) = 1 \qquad [A\text{-}1]$$

in which $t_{HPO_4=}$, $t_{PO_4\equiv}$, t_{Cu++}, and t_{OH-} are neglected. The increase[11] of $[CuOH]^+[H_2PO_4]^-$ and decrease of H_3PO_4 per unit time at the anode surface may be calculated as follows

$$CuOH^+: \quad \frac{i}{2F}(1 - t_{CuOH+})$$

$$H_2PO_4^-: \quad \frac{i}{F}t_{H_2PO_4-}$$

$$\frac{i}{F}t_{H_2PO_4-} = \frac{i}{2F}(1 - t_{CuOH+}) - \frac{i}{F}t_{H+} + \frac{i}{2F}(1 - t_{CuOH+}) \qquad [A\text{-}2]$$

$$H^+: \quad -\left(\frac{i}{F}t_{H+} - \frac{i(1 - t_{CuOH+})}{2F}\right)$$

The first term on the right-hand side of Eq. [A-2] expresses the increase of $[CuOH]^+[H_2PO_4]^-$ and the second and third terms express the decrease of $[H_3PO_4]$. From this the rate of increase of $[CuOH]^+[H_2PO_4]^-$ by electrochemical reaction minus its decrease by migration away from the anode is

$$\frac{i}{2F}(1 - t_{CuOH+})$$

and the rate of decrease of $[H_3PO_4]$ is

$$\frac{i}{F}t_{H+} - \frac{i}{2F}(1 - t_{CuOH+})$$

Assuming that the increase in $[CuOH]^+[H_2PO_4]^-$ and the decrease in $[H_3PO_4]$ is a result of diffusion away from the anode surface or to it from the bulk of the electrolyte, we obtain the relations

$$\left.\begin{aligned} &\frac{i}{2F}(1 - t_{CuOH+}) = -D_p\frac{\partial C_p}{\partial x} \\ &\text{or} \\ &i = \frac{2F}{1 - t_{CuOH+}}D_p\left|\frac{\partial C_p}{\partial x}\right| \end{aligned}\right\} \text{ for } [CuOH]^+[H_2PO_4]^- \qquad [A\text{-}3]$$

and

$$\left.\begin{aligned} &\frac{i}{F}t_{H+} - \frac{i}{2F}(1 - t_{CuOH+}) = D_r\frac{\partial C_r}{\partial x} \\ &i = \frac{F}{t_{H+} - \frac{1 - t_{CuOH+}}{2}}D_r\left|\frac{\partial C_r}{\partial x}\right| \end{aligned}\right\} \text{ for } H_3PO_4 \qquad [A\text{-}4]$$

Reaction [II].—

$$Cu + 2H_3PO_4 = Cu(H_2PO_4)_2 + 2H^+ + 2e^- \text{ (over-all)}$$

$$H_3PO_4 \rightleftarrows H^+ + H_2PO_4^-$$

$$Cu = Cu^{++} + 2e^-$$

$$(t_{H+}) + (t_{H_2PO_4-}) + (t_{Cu++}) = 1 \qquad [A\text{-}5]$$

The increase of $[Cu(H_2PO_4)_2]$ and decrease of $[H_3PO_4]$ per unit time at the anode surface may be calculated in the same way as for reaction [I]

$$Cu^{++}: \quad \frac{i}{2F}(1 - t_{Cu++})$$

$$H_2PO_4-: \quad \frac{i}{F}t_{H_2PO_4-} = \frac{i}{F}(1 - t_{Cu++}) - \frac{i}{F}t_{H+} \qquad [A\text{-}6]$$

$$H^+: \quad -\frac{i}{F}t_{H+}$$

The first term on the right-hand side of Eq. [A-6] describes the increase of $[Cu(H_2PO_4)_2]$ and the second term the decrease of $[H_3PO_4]$. The net rate of increase of $[Cu(H_2PO_4)_2]$ is

$$\frac{i}{2F}(1 - t_{Cu++})$$

and the decrease of H_3PO_4

$$\frac{i}{F}t_{H+}$$

In the same manner, we obtain the relations

$$i = \frac{2F}{1 - t_{Cu++}}D_p\left|\frac{\partial C_p}{\partial x}\right| \quad \text{for } Cu(H_2PO_4)_2 \qquad [A\text{-}7]$$

and

$$i = \frac{F}{t_{H+}}D_r\left|\frac{\partial C_r}{\partial x}\right| \quad \text{for } H_3PO_4 \qquad [A\text{-}8]$$

B. Derivation of Eq. [7]-[12]

Solution of the diffusion equation in one dimension

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad [A\text{-}9]$$

with initial and boundary conditions

Initial condition: $C = C(0)$ at $t = 0$

Boundary condition 1: $i = -\frac{nFD}{k}\left(\frac{\partial C}{\partial x}\right)_{x=0}$ at $x = 0$

Boundary condition 2: $C = C(0)$ at $x = \infty$

and assuming that D, n, and k are constants, yields (14)

$$C(t) - C(0) = 2k\frac{i}{nF}\left(\frac{t}{D\pi}\right)^{1/2}\exp\left(\frac{-x^2}{4Dt}\right) - k\frac{ix}{nFD}\operatorname{erfc}\left(\frac{x}{2(Dt)^{1/2}}\right) \qquad [A\text{-}10]$$

At the anode surface

$$[C(t) - C(0)]_{x=0} = 2k\frac{i}{F}\left(\frac{t}{D\pi}\right)^{1/2} \qquad [A\text{-}11]$$

For phosphoric acid transport controlling [case (*a*)], $C_r(t_s) = 0$ at $x = 0$, $C_r(0) = C_{rb}$, $n = 1$; $k = t_{H+} - (1/2)(1 - t_{CuOH+})$ for reaction [I], and $k = t_{H+}$ for reaction [II].[12]

[11] Increase is shown by positive sign.

[12] For a rigorous treatment of migration effects in Nernst boundary layers see Ref. (28).

At $t = t_s$ we obtain for reaction [I]

$$i\left(\frac{t_s}{D_r}\right)^{1/2} = \frac{\mathbf{F}}{2} \cdot \frac{\sqrt{\pi}}{t_{H+} - \frac{1 - t_{CuOH+}}{2}} \cdot C_{rb} \quad [A\text{-}12]$$

and for reaction [II]

$$i\left(\frac{t_s}{D_r}\right)^{1/2} = \frac{\mathbf{F}}{2} \cdot \frac{\sqrt{\pi}}{t_{H+}} \cdot C_{rb} \quad [A\text{-}13]$$

For copper phosphate controlling [case (b)], $C_p(t_s) = C_{ps}$ at $x = 0$, $C_p(0) = 0$, $n = 2$; $k = 1 - t_{CuOH+}$ for reaction [I], and $k = 1 - t_{Cu++}$ for reaction [II].

At $t = t_s$

$$i\left(\frac{t_s}{D_p}\right)^{1/2} = \frac{\mathbf{F}(\pi)^{1/2}}{1 - t_{CuOH+}} C_{ps} \text{ for reaction [I]} \quad [A\text{-}14]$$

and

$$i\left(\frac{t_s}{D_p}\right)^{1/2} = \frac{\mathbf{F}(\pi)^{1/2}}{1 - t_{Cu++}} C_{ps} \text{ for reaction [II]} \quad [A\text{-}15]$$

Change in *pH* near the Cathode During the Electrodeposition of a Bivalent Metal. Analysis

Lee B. Harris*

Xerox Corporation, Rochester Research Center, Webster, New York 14580

ABSTRACT

An important factor in the cathodic electrodeposition of a base metal (M) is the increase in pH ("alkalization") of the electrolyte near the cathode.

Chemical equilibria and transport processes in the cathodic diffusion layer are analyzed by numerical integration of the transport equations. The analysis shows that alkalization is caused by the production of OH^- at the cathode and is prevented when the hydroxyl ions so produced react to form a soluble species (*e.g.*, MOH^+ or H_2O).

When complex ions are not formed, alkalization occurs if $i_W\delta > \mathbf{F}D_{H^+}[H^+]_o$, where i_W is the hydrogen reduction current, δ is the thickness of the diffusion layer, $[H^+]_o$ is the bulk hydrogen ion concentration, and D_{H^+} is the ionic diffusion coefficient for hydrogen. Formation of metal-hydroxy or metal-anion complexes can prevent alkalization even when this limit is exceeded. This is illustrated by specific numerical examples.

It has been well established by numerous experimental studies (1-5) that during the electrolytic deposition of nickel, the layer of electrolyte immediately adjacent to the cathode ("diffusion layer") is more alkaline than the bulk of the electrolyte. The degree of "alkalization" is strongly dependent on temperature and stirring as well as bulk pH and current density. Under some conditions precipitation of basic nickel salts may occur near the cathode (6-9), sometimes to such an extent as to be visible to the naked eye (9). It is likely that alkalization and precipitation are significant factors in determining the appearance, structure, and properties of electrodeposited nickel (10).

Although this problem has been discussed many times in the electrochemical literature, much of the discussion is qualitative and some is misleading. For example, scattered through the literature are statements that seem to imply alkalization is caused by the dissociation of water in the liquid phase near the cathode (in response to depletion of the hydrogen ion population by reduction of H^+ at the cathode). The present analysis indicates that this is not the case. To understand the mechanism of alkalization, and to determine the conditions under which precipitation is to be expected, it is necessary to analyze in some detail the transport and chemical equilibria of the various species present in the electrolyte near the cathode, including soluble complexes and complex ions. The analysis reported here shows that alkalization has its origin in the production of OH^- at the cathode, and can be moderated or prevented when the hydroxyl ions so produced can react to form a soluble species (*e.g.*, MOH^+). The formation of a soluble complex between the metal and its counterion can also play a significant (though less direct) role.

Method

Let us consider the very simplest model having the most essential features of the actual physical system: an aqueous solution of a bivalent metal ion M^{+2} that can form a hydroxy complex MOH^+ and/or a soluble one-to-one complex $MA^{+(2-Z)}$ with its counterion A^{-Z} ($Z = 1$ or 2).

The relative concentrations of these four species (and the concentrations of hydrogen ions and hydroxyl ions) are assumed to be governed by the same equations that hold in thermodynamic equilibrium. In other words, the rates of formation and dissociation of the complex species are assumed to be fast enough to establish equilibrium in less time than it takes for any of the reacting species to travel through an appreciable fraction of the diffusion layer.

Convective-diffusion determines the degree to which bulk concentrations are maintained near the cathode (11, 12). To describe this facet of the problem accurately would require that the convective-velocity field be known (as for the rotating disk electrode) and that it be included in the transport equations (11-13), thus making them very difficult to integrate. To avoid this problem, the following analysis makes use of the customary Nernst approximation in which the diffusion layer near the electrode is assumed to be stagnant. The stagnant layer is assumed to be separated from the well-mixed bulk of the electrolyte by a well-defined boundary plane (the "Nernst boundary") at which all species are present at concentrations characteristic of the bulk. The transport equations are formulated for the stagnant region, and the bulk concentrations comprise a boundary condition. The effect of convection is then reduced to a single parameter, the thickness of the stagnant diffusion layer. Starting at the Nernst boundary, one may, for a specified set of conditions (*e.g.*, total current density, hydrogen evolution current density, bulk pH, temperature, etc.) integrate the transport equations to calculate the concentrations and flux densities[1] of the various species as functions of distance from the boundary.

To apply these results to a particular case, one may then imagine the electrode to be at a particular distance from the boundary; the chosen distance is equal to the specified thickness of the diffusion layer for the particular case under consideration. The calculated concentrations and flux densities at that distance from the Nernst boundary are those that must (under the assumptions of the calculation) prevail at the electrode surface when the thickness of the diffusion layer, the bulk concentrations, the current densities, etc., are equal to the values specified for the particular case.

Analysis

Figure 1 shows all the species considered and the reactions among them, including the dissociation of H_2O. The circled number next to any species will be used in the text as a subscript to identify any variable associated with that species. From Fig. 1 it follows that the rate of formation of M^{+2} must be equal to sum of the rates at which $MA^{+(2-Z)}$ and MOH^+ are disappearing, *i.e.*, equal to the negative of the sum of their

* Electrochemical Society Active Member.
Key words: catholyte, alkalization, electrodeposition.

[1] I use "flux density" to denote normalization to unit area, *i.e.*, flux density = flux per unit area (mole/cm² sec).

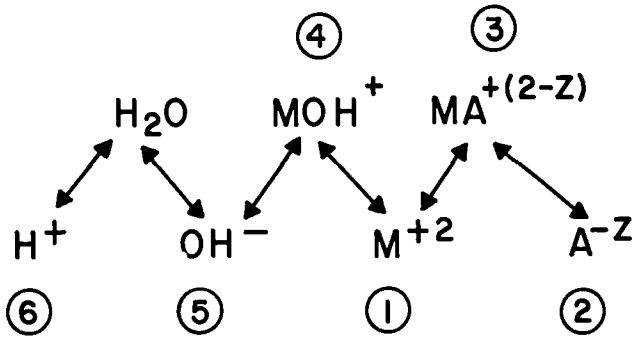

Fig. 1. Schematic diagram showing reactions among the various species. Circled numbers are used as subscripts in the text.

rates of production. In steady state[2] this condition yields the partial differential equation

$$\nabla \cdot j_1 + \nabla \cdot j_3 + \nabla \cdot j_4 = 0 \qquad [1]$$

where j_i is the flux density of the i^{th} species (mole/cm² sec). Similar considerations yield the equations

$$\nabla \cdot j_2 + \nabla \cdot j_3 = 0 \qquad [2]$$

$$\nabla \cdot j_4 + \nabla \cdot j_5 - \nabla \cdot j_6 = 0 \qquad [3]$$

In addition to Eq. [1-3] we have the three equilibrium conditions governing the concentrations C_i (mole/cm³); namely

$$C_3 = K_3 C_1 C_2 \qquad [4]$$

$$C_4 = K_4 C_1 C_5 \qquad [5]$$

$$C_5 C_6 = K_W \qquad [6]$$

and finally, there is the electroneutrality approximation[3]

$$\Sigma n_i C_i = 0 \qquad [7]$$

where n_i is the number of electronic charges (including sign) carried by the i^{th} species. The flux density of the i^{th} species is given by[4]

$$j_i = -\{D_i \text{ grad } C_i + \mu_i C_i \text{ grad } \Phi\} \qquad [8]$$

where μ is the electrical mobility (cm²/V sec), D the diffusion[5] coefficient (cm²/sec), and Φ the electrical potential (V). For this analysis we assume the Nernst-Einstein relationship between the electrical mobility and the diffusion coefficient; namely

$$\mu_i = n_i (\mathbf{F}/RT) D_i \qquad [9]$$

where $(\mathbf{F}/RT)$ is expressed in reciprocal volts. Substituting Eq. [8] and [9] into Eq. [1–3] and integrating once, we obtain the following three first-order differential equations

$$D_1C_1' + D_3C_3' + D_4C_4' + [2D_1C_1 + n_3D_3C_3 + D_4C_4]\phi' = -j_M \qquad [10]$$

$$D_2C_2' + D_3C_3' + [n_2D_2C_2 + n_3D_3C_3]\phi' = -J_A \qquad [11]$$

$$-D_4C_4' - D_5C_5' + D_6C_6' + [D_5C_5 - D_4C_4 + D_6C_6]\phi' = -j_W \qquad [12]$$

In these equations the divergence is replaced by simple differentiation (denoted by a prime) with respect to the position variable x; and ϕ is the dimensionless potential

$$\phi = (\mathbf{F}/RT)\,\Phi \qquad [13]$$

j_M is the total flux density (mole/cm² sec) of metal atoms in all forms, *i.e.*, as metal ions or contained in the anionic or the hydroxy complex. It is proportional to the electrodeposition current density i_M, *i.e.*

$$i_M = 2\mathbf{F}\, j_M \qquad [14]$$

Similarily, j_A is the total flux density of counterions A^{-Z} [as simple anions or associated into the complex $MA^{+(2-Z)}$]. In the present (cathodic) case it is assumed that the net combined flux of counterions in both these forms is zero. In other words, the flux of counterions moving toward the cathode in the form of $MA^{+(2-Z)}$ is balanced by an equal flux of A^{-Z} moving away from the cathode. This must be true if no reaction at the cathode either removes any counterions or adds to their total number. With this assumption, $j_A \equiv 0$.

j_W is proportional to the combined current density i_W carried by hydroxyl groups (either alone or contained in the hydroxyl complex) and hydrogen ions (i_W is the "hydrogen evolution" current), *i.e.*

$$i_W = \mathbf{F}\, j_W \qquad [15]$$

It is possible, by means of a change of independent variable in Eq. [10–12], to replace j_W and j_M by a single constant. For our present purpose it is convenient to use the dimensionless variable (see next section for physical significance)

$$y = x/L_H \qquad [16]$$

where

$$L_H = \mathbf{F} D_6 (C_6)_0 / |i_W| \qquad [17]$$

In terms of y, Eq. [10–12] are then changed slightly, by the substitutions

$$-j_W \rightarrow \pm D_6 (C_6)_0 \qquad [18]$$

and

$$-j_M \rightarrow \pm D_6 (C_6)_0 / 2(i_W/i_M) \qquad [19]$$

The positive x-direction is defined so that x increases with increasing distance from the electrode. With this convention j_W and j_M are negative and the upper signs in Eq. [18] and [19] are valid when the electrode is operating cathodically. The position origin ($x = 0$) is taken to be at the Nernst boundary; and the subscript zero refers to values at that boundary. (Within the diffusion layer, x is negative.)

To solve Eq. [10–12] (with the substitution of Eq. [18] and [19]) subject to the conditions of Eq. [4-7], the latter conditions were differentiated to yield four additional first-order linear differential equations. The whole set of seven equations was then integrated numerically by means of the Runge-Kutta method, using a double-precision Gaussian elimination to compute the derivatives from the values of the seven dependent variables and the specified value of (i_W/i_M).[6] The starting point for the integration is the Nernst boundary, at which the hydrogen ion concentration $(C_6)_0$ is chosen to correspond to a selected value of pH, and the other concentrations are adjusted to satisfy Eq. [4–7] and to fix the total amount of metal in solution at a specified value, namely, 10^{-3} mole/cm³ (*i.e.*, 1M) for all cases considered in this paper.

Results and Discussion

Figure 2a shows a plot of concentration profiles as a function of y for a particular case.[7] The curve labeled

[1] Steady state means that all concentrations are independent of time. Any gradual depletion or accumulation of constituents in the bulk is assumed to be insignificant. Initial transients in the diffusion layer itself are assumed to have died out.

[3] This approximation can be used whenever the actual space charge is so small it can be produced by concentrations that deviate insignificantly (by say less than 1%) from those calculated using the constraint of Eq. [7]. This is true for cases discussed in this paper.

[4] Whereas Eq. [1–3] hold everywhere in the electrolyte Eq. [8] applies only to the stagnant diffusion layer, since convective transport is not included in it.

[5] Diffusion coefficients are assumed to be constants in order to simplify the calculations. This assumption may not be too bad in view of Newman's finding (13a) that in solutions of moderate ionic strength (~0.01M) concentration dependence of the D's causes only very minor changes in the transport of H^+.

[6] The ratio i_W/i_N does not take on arbitrary values in real experiments. My approach is to calculate conditions in the diffusion layer when i_W/i_M has some reasonable value that corresponds roughly to an actual situation. The major advantage of this approach is that boundary conditions imposed by electrode kinetics need not be considered. The price we pay is that i_W/i_M must be measured in order to correlate theory with the experiment.

[7] The following values were used for all calculations. At 300°K, $D_1 = D_3 = D_4 = 1.0 \times 10^{-5}$; $D_2 = 2.0 \times 10^{-5}$; $D_5 = 6.0 \times 10^{-5}$; $D_6 = 1.0 \times 10^{-4}$ (cm²/sec) (14-15). At other temperatures, $D_i(T) = D_i(300°K)\ (T/300.)\ [\eta(300°)/\eta(T)]^{p_i}$ where η is the viscosity of water and $p_1 = p_2 = \ldots\ldots p_5 = 1$; $p_6 = 0.63$ (14). The dissociation constant for water was calculated from the formula given by Kortum (16), namely, $-\log K_W = 4471.99/T - 6.0846 + 0.017053T$.

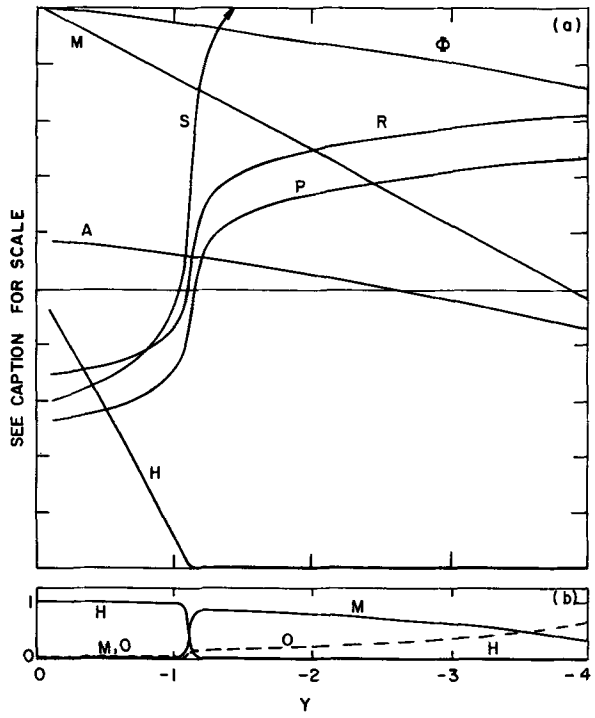

Fig. 2. (a) Curve *M*, total metal concentration normalized to bulk (scale: 0 to 1). curve *A*, fraction of metal complexed with counterion (scale: 0 to 1); curve *H*, hydrogen ion concentration normalized to bulk (scale: 0 to 2); curve *P*, ratio of hydroxyl ion concentration to hydrogen ion concentration (log scale: −10 to +10); curve *R*, ratio of metal-hydroxy complex to hydrogen ion concentration (log scale: −10 to +10); curve *S*, product corresponding to solubility product of $M(OH)_2$ (log scale: −30 to −20); Φ, electrical potential (scale: −200 mV to 0V). (b) *H*, fraction of hydrogen evolution current carried by hydrogen ions; *O*, fraction of hydrogen evolution current carried by hydroxyl ions; *M*, fraction of hydrogen evolution current carried by metal-hydroxy complex. Conditions: $Z = 1$, $T = 340°K$, pH = 4.0, $i_W/i_M = 10^{-3}$, $K_3 = 10^3$, $K_4 = 10^5$ (cm^3/mole).

M is the total concentration of metal (in all three forms) plotted on a scale from zero to one as a fraction of the bulk value (*i.e.*, 10^{-3} mole/cm^3 at the Nernst boundary). The curve labeled *H* is the hydrogen ion concentration, also normalized to the bulk value but with the scale compressed by a factor of two. *S* is the product $C_1(C_6)^2$ (*i.e.*, $[M^{+2}]\,[OH^-]^2$) plotted on a log scale running from −30 to −20 ($mole^3/cm^9$). *A* is the fraction of the total metal concentration that is tied up in the complex $MA^{+(2-Z)}$ (scale from zero to one). *R* is the ratio C_4/C_6 (*i.e.*, $[MOH^+]/[H^+]$) plotted on a log scale running from −10 to +10; and *P* is the ratio C_5/C_6 (*i.e.*, $[OH^-]/[H^+]$) on the same log scale. If we take the solubility constant for $M(OH)_2$ to be 10^{-25} ($mole^3/cm^9$) then the critical value y_c of the dimensionless position variable at the point where curve *S* crosses the horizontal midline $[C_1(C_6)^2 = 10^{-25}]$ corresponds to the thickness δ_c of the thickest diffusion layer for which no precipitation will occur under the other specified conditions. From the definition of y (Eq. [16] and [17] it follows that[8]

$$\delta_c = |y_c|\mathbf{F}D_6(C_6)_0/|i_W| \qquad [20]$$

or

$$|i_W\delta|_c = |y_c|\mathbf{F}D_6(C_6)_0 \qquad [21]$$

If the magnitude of the product of i_W and δ exceeds this critical product then precipitation of metal hydroxide is predicted. Of course, if that should be the case, the transport equations would be greatly modified by the formation, migration, and subsequent reactions of the precipitate. In this paper, we restrict ourselves to determining the margin of conditions that just avoids this possibility.

The form of curve *H* conforms almost exactly to Nernst's simplified description of transport in the diffusion layer. Near the Nernst boundary both the hydroxyl ion and the hydroxy complex are present only in small concentrations relative to the hydrogen ion, and do not contribute appreciably to i_W. Since the flux of hydrogen ions is almost constant in this region (there is no appreciable net recombination or dissociation), and since transport is primarily due to diffusion, the concentration gradient is nearly constant and is almost just sufficient to carry the current, *i.e.*

$$|i_W| \simeq \overline{|\text{grad } C_6|}\mathbf{F}D_6 \qquad [22]$$

(*cf.* Eq. [8] and [15]) where $\overline{\text{grad } C_6}$ is the average concentration gradient in this region. The distance required for the concentration to drop to nearly zero is

$$L = (C_6)_0/\overline{|\text{grad } C_6|} \qquad [23]$$

When the diffusion layer is this thick (*i.e.*, $\delta = L$) Eq. [22] and [23] yield the familiar Nernst relationship between the "limiting current" and the thickness of the diffusion layer, namely

$$\delta = \mathbf{F}D_6(C_6)_0/|i_W| \qquad [24]$$

Comparing Eq. [24], [17], and [16] it is clear that the dimensionless variable y gives the distance from the Nernst boundary in multiples of that critical diffusion layer thickness that would just support a diffusion-limited hydrogen ion current equal to i_W. If the diffusion layer is thicker than that, then in the region in which the hydrogen ion concentration is essentially zero (*i.e.*, $|y| \gtrsim 1$ in Fig. 2a) the current i_W must be carried by hydroxyl groups moving away from the cathode. Beyond $|y| \simeq 1$ the solution becomes more alkaline (see curve *P* in the figure) and precipitation will occur for thicker layers. The most important point here is that when alkalization occurs, the "hydrogen evolution" current exceeds the Nernst "limiting current" (*i.e.*, the maximum current that could be carried by hydrogen ions diffusing all the way across the stagnant layer). The two things are simply different manifestations of the same causative factor, namely, the production of OH^- at the cathode, either due to the decomposition of water according to one of the reactions[9]

$$e^- + H_2O \rightarrow OH^- + 1/2\,H_2 \qquad [25]$$

$$e^- + H_2O + M^{+2} \rightarrow MOH^+ + 1/2\,H_2 \qquad [26]$$

or due to the reduction of dissolved oxygen, *e.g.*, according to one of the reactions[10]

$$e^- + 1/4\,O_2 + 1/2\,H_2O \rightarrow OH^- \qquad [25a]$$

$$e^- + 1/4\,O_2 + 1/2\,H_2O + M^{+2} \rightarrow MOH^+ \qquad [26a]$$

Proof of this is shown in Fig. 2b, in which are plotted the relative fractions of j_W carried by H^+ (curve *H*), OH^- (curve *O*) and MOH^+ (curve *M*). In the vicinity of $|y| = 1$, the flux of hydrogen ions moving toward

[8] Because distance is measured positive away from the electrode and x is zero at the Nernst boundary, x and y are negative in the diffusion layer. And since positive current is equivalent to positive charge moving away from the electrode, cathodic current is negative. Hence, the absolute value signs used from here on.

[9] This and all other electrode reactions are written to show only what is felt by the transport system. Reaction [25] may actually occur as (*i*) $H^+ + e^- \rightarrow \frac{1}{2}H_2$, (*ii*) $H_2O \rightleftarrows H^+ + OH^-$; but when more H^+ is annihilated than can be supplied by diffusion the balance must be supplied by (*ii*) or else reaction [25] must occur directly. In any case the transport system sees only reaction [25], assuming electrode reactions occur within a few angstroms of the surface.

[10] If reaction [25a] or [26a] (or, say $e^- + \frac{1}{2}O_2 + H_2O \rightarrow \frac{1}{2}H_2O_2 + OH^-$) plays a significant role, then i_W cannot truly be called a hydrogen evolution current, since the net result of [25a] and [27] (or [26a] and [28]) is simply $e^- + H^+ + \frac{1}{4}O_2 \rightarrow \frac{1}{2}H_2O$.

Reactions such as [25a] or [26a] can, under ordinary ambient conditions, be the source of alkalization only for pH $\gtrsim$ 3.5. In more acid baths, because of the relatively low concentration of dissolved atmospheric oxygen ($< 2 \times 10^{-4}$M) and its relatively low diffusion coefficient $\sim 2 \times 10^{-5}$ cm^2/sec), the flux of molecular oxygen diffusing across the stagnant layer to the cathode cannot produce at the cathode a flux of hydroxyl ions greater than the flux of hydrogen ions that can diffuse from the bulk to the cathode across the stagnant layer.

the cathode (H) drops sharply with increasing $|y|$, and the flux of hydroxyl groups moving away from the cathode increases correspondingly. In the particular case shown in the figure, the total flux of hydroxyl groups is shared by the flux of hydroxyl ions (O) and the flux of hydroxyl complex (M). (The relative share is carried by each of these changes from point-to-point and is determined by their concentrations and concentration gradients as well as the electric field.) If we consider a region surrounding the transition zone in which the sharpest changes occur, it is apparent that the flux of H^+ entering the region on the left is much greater than that leaving on the right; whereas this picture is reversed for OH^- and MOH^+. Within the transition region the recombination reaction[11]

$$H^+ + OH^- \rightarrow H_2O \qquad [27]$$

$$H^+ + MOH^+ \rightarrow H_2O + M^{+2} \qquad [28]$$

remove equal quantities of hydrogen ions entering from the left and hydroxyl groups entering from the right. (The equality of production or removal of these two species is true for any region; that is the meaning of Eq. [3].) The important point is that to the right of the transition zone, most of the hydrogen evolution current is carried by hydroxyl groups, which must be produced at the cathode.

The particular case shown in Fig. 2 is of the simplest type, in which neither the hydroxy complex nor the complex $MA^{+(2-Z)}$ plays a dominant role. In that simple situation $|y_c| \simeq 1$ and Eq. [20] is essentially identical to the Nernst relationship, Eq. [24]. There is a very sharply defined critical diffusion layer thickness. For thinner layers i_W is carried almost entirely by hydrogen ions diffusing all the way across, but if this thickness is even slightly exceeded, alkalization must occur in order to produce the same value of i_W.

Figure 3 shows what happens when K_4 is increased by three orders of magnitude to 10^8 (cm^3/mole), a realistic value consistent with those listed for $NiOH^+$ in Bjerrum's compilation (17) of stability constants. The hydroxyl ion concentration (curve P) changes much more slowly than in Fig. 2 and is greatly exceeded (by five orders of magnitude) by the concentration of MOH^+ (curve R). The causative factor here is the greater tendency for metal ions to associate with OH^- thus removing the hydroxyl ions from the reaction scheme. The dynamics of the situation can be seen in Fig. 3b which shows that no significant part of the hydrogen evolution current is carried by OH^-.

This means that the production of OH^- at the cathode must take place according to the over-all reaction given in Eq. [26] or [26a]. The actual mechanism is not important for the present argument. The net result, however, must be that practically all of the hydroxyl groups generated at the cathode associate with cathode-bound metal ions within a very short distance of the cathode. The resulting high concentration of hydroxy complex produces a concentration gradient that actually causes (by diffusion) a net flux of this positively charged species away from the cathode against the electric field. Eventually these hydroxy ions recombine with hydrogen ions according to reaction [28]; however, since MOH^+ (as opposed to OH^-) can exist at relatively high concentrations even in somewhat acid solution, this recombination process occurs over a relatively wide transition zone in which the hydrogen evolution current is shared by H^+ and MOH^+ moving in opposite directions. As a result, $|y_c|$ is considerably greater than unity. (See Fig. 2a where curve S crosses the horizontal midline.) In other words, the diffusion layer thickness can be greater (as much as 70% greater) than that thickness which would allow i_W to be carried by the diffusion of H^+ to the cathode; and despite this thicker stagnant layer no precipitation of hydroxide will occur.

[11] Reaction [28] probably proceeds through the dissociation of MOH^+, but here again only the over-all reaction is shown.

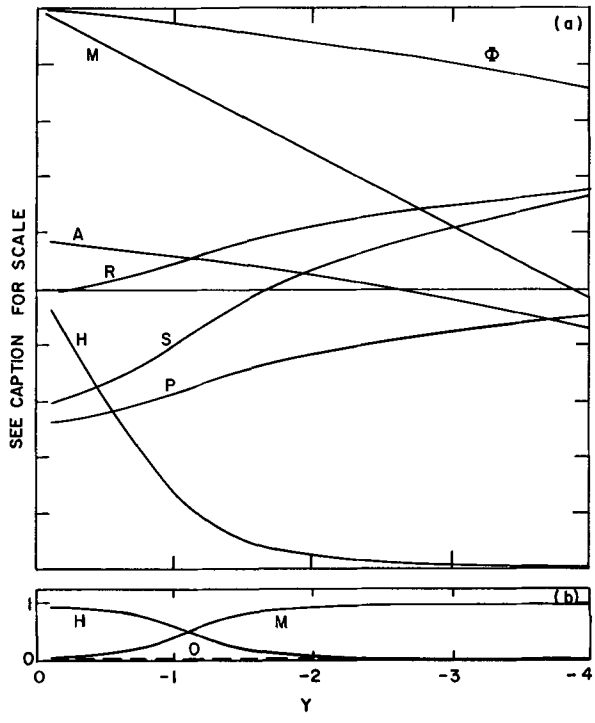

Fig. 3. (a) Curve M, total metal concentration normalized to bulk (scale: 0 to 1); curve A, fraction of metal complexed with counterion (scale: 0 to 1); curve H, hydrogen ion concentration normalized to bulk (scale: 0 to 2); curve P, ratio of hydroxyl ion concentration to hydrogen ion concentration (log scale: -10 to $+10$); curve R, ratio of metal-hydroxy complex to hydrogen ion concentration (log scale: -10 to $+10$); curve S, product corresponding to solubility product of $M(OH)_2$ (log scale: -30 to -20); Φ, electrical potential (scale: -200 mV to 0V). (b) H, fraction of hydrogen evolution current carried by hydrogen ions; O, fraction of hydrogen evolution current carried by hydroxyl ions; M, fraction of hydrogen evolution current carried by metal-hydroxy complex. Conditions: $Z = 1$, $T = 340°K$, $pH = 4.0$, $i_W/i_M = 10^{-3}$, $K^3 = 10^3$, $K_4 = 10^8$ (cm^3/mole).

An equally interesting but entirely different effect is shown in Fig. 4 and 5, which illustrate what may happen when the complex $MA^{(2-Z)}$ plays a significant role. The two cases differ in the value of K_3 (10^4 cm^3/mole in Fig. 4; 1.5×10^5 cm^3/mole in Fig. 5). The anion is divalent in both cases and all other conditions are equal.[12]

The electrical potential Φ is plotted on a scale running from -200 mV to 0V, and can be seen to drop much more sharply in Fig. 5 than in Fig. 4. The correspondingly higher electric field assists the movement of hydrogen ions, permitting them to penetrate the stagnant layer more deeply. The higher electric field is required to maintain i_M because of two closely related factors, both due to the higher value of K_3.[13] First of all, with 90% of the metal ions (and counterions) tied up in the neutral complex MA (see curve A) the conductivity is correspondingly lower; in fact, more than half the nickel ion flux is carried by diffusion of the neutral complex toward the cathode. This leads to the second related factor: the high flux of MA toward the cathode must be balanced by an equal, oppositely directed, flux of counterions away from the cathode, since $j_A \equiv 0$. The electric field must be sufficient to sustain this countercurrent against a concen-

[12] The reader may note that the slope of curve M is steeper in Fig. 4 and 5 than in Fig. 2 and 3. This is related to the fact that for Eq. [10] and [11] alone (no species present except M^{+2} and A^{-Z}) the concentrations of these two species drop linearly to zero over a characteristic distance

$$L_M = 2(2 + Z)\, FD_1(C_1)_0/Z|i_M|$$

This distance depends on Z in a manner quite independent of the other complications of the model. L_M corresponds to the maximum diffusion layer thickness for which i_M is not transport limited. For all cases considered in this paper, $L_H < \delta_c < L_M$.

[13] Note that this higher value is quite realistic. The values listed by Bjerrum (17) for $NiSO_4$ generally lie between 10^5 and 10^6.

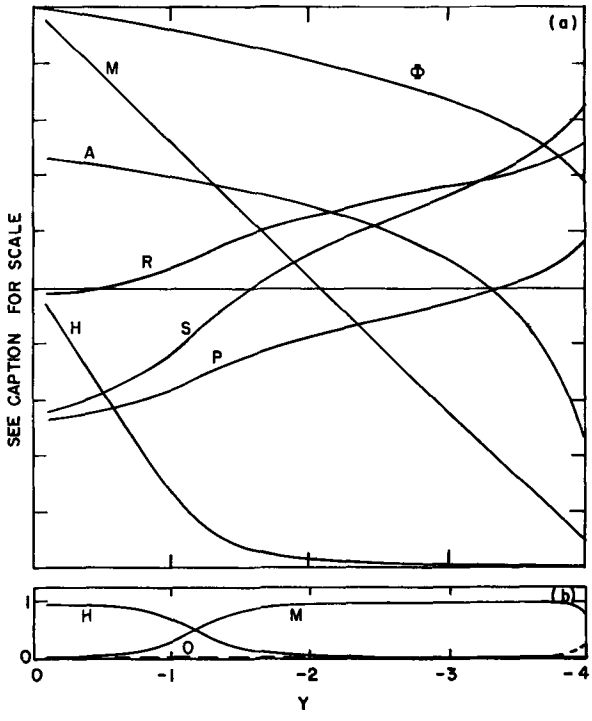

Fig. 4. Curve *M*, total metal concentration normalized to bulk (scale: 0 to 1); curve *A*, fraction of metal complexed with counterion (scale: 0 to 1); curve *H*, hydrogen ion concentration normalized to bulk (scale: 0 to 2); curve *P*, ratio of hydroxyl ion concentration to hydrogen ion concentration (log scale: −10 to +10); curve *R*, ratio of metal-hydroxy complex to hydrogen ion concentration (log scale: −10 to +10); curve *S*, product corresponding to solubility product of $M(OH)_2$ (log scale: −30 to −20); Φ, electrical potential (scale: −200 mV to 0V). (b) *H*, fraction of hydrogen evolution current carried by hydrogen ions; *O*, fraction of hydrogen evolution current carried by hydoxyl ions; *M*, fraction of hydrogen evolution current carried by metal-hydroxy complex. Conditions: $Z = 2$, $T = 340°K$, pH = 4.0, $i_W/i_M = 10^{-3}$, $K_3 = 10^4$, $K_4 = 10^8$ (cm^3/mole).

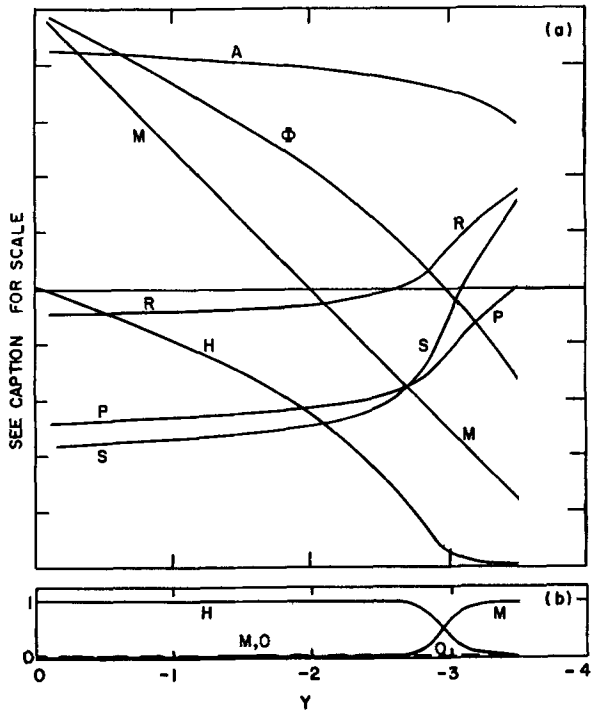

Fig. 5. (a) Curve *M*, total metal concentration normalized to bulk (scale: 0 to 1); curve *A*, fraction of metal complexed with counterion (scale: 0 to 1); curve *H*, hydrogen ion concentration normalized to bulk (scale: 0 to 2); curve *P*, ratio of hydroxyl ion concentration to hydrogen ion concentration (log scale: −10 to +10); curve *R*, ratio of metal-hydroxy complex to hydrogen ion concentration (log scale: −10 to +10); curve *S*, product corresponding to solubility product of $M(OH)_2$ (log scale: −30 to −20); Φ, electrical potential (scale: −200 mV to 0V). (b) *H*, fraction of hydrogen evolution current carried by hydrogen ions; *O*, fraction of hydrogen evolution current carried by hydroxyl ions; *M*, fraction of hydrogen evolution current carried by metal-hydroxy complex. Conditions: $Z = 2$, $T = 340°K$, pH = 4.0, $i_W/i_M = 10^{-3}$, $K_3 = 1.5 \times 10^5$, $K_4 = 10^8$ (cm^3/mole).

tration gradient and in spite of the relatively low concentration of counterions. Note that under these conditions more than half of the electrodeposition at the cathode is accounted for by the over-all reaction

$$2e^- + MA + A^{-2} \qquad [29]$$

the remainder being effected by the reaction[14]

$$2e^- + M^{+2} \rightarrow M \qquad [30]$$

Interestingly, the effect shown in Fig. 5 does not occur for a univalent counterion if only the one-to-one complex MA^+ is formed. Figure 6 illustrates this. The conditions are the same as in Fig. 3 except that K_3 is increased by three and one half orders of magnitude. Comparison of Fig. 2, 3, and 6 shows that this increase simply removes the effect of the hydroxy complex (*cf.* Fig. 2) by tying up almost all of the metal in the complex MA^+. Even though more than 99% of the metal is tied up this way, the electrical conductivity is not drastically affected since first of all, MA^+ is positively charged and secondly, more than half of the counterions are available to move in the other direction. It is likely that formation of the neutral complex MA_2 would have the same effect in the case of the univalent counterion as does the formation of the neutral complex MA in the case of the divalent counterion, but this still remains to be verified by calculation.

[14] Reaction [29] may actually occur at $MA \rightarrow M^{+2} + A^{-2}$ followed by reaction [30], but under the specified conditions the over-all result must be simply a weighted combination of Eq. [29] and [30], with weights proportional to the transport to the cathode of MA and M^{+2}, respectively.

Additional Comments

With the help of Eq. [24] a partial answer can be obtained as to whether alkalization and precipitation of hydroxide occur under ordinary plating conditions. For example, consider a nickel electroplating bath operating at pH = 4.0, plating current density ≃ 100 A/ft² ($i_M \simeq 10^{-1}$ A/cm²), $i_W/i_M = 10^{-2}$ (*i.e.*, current efficiency = 99% and $i_W = 10^{-3}$ A/cm²). Equation [24] yields $\delta = 10^{-3}$ cm. This is approximately the diffusion layer thickness that would be achieved by laminar flow at a rotating disk at 100 rps (11). Whether this degree of stirring is usually achieved is a moot point; if not, then i_W exceeds the Nernst limit. Since the assumed conditions are not unusual, it may be that precipitation of hydroxide usually occurs and plays an important role in the plating process as is often stated (18).

It has been reported that in concentrated chloride baths at temperatures above 80°C, hydrogen evolution is inhibited (19) and concurrently, macroscopic crystals of nickel are formed at the cathode (19, 20). At the other extreme, hydrogen evolution, alkalization, and precipitation may sometimes occur to such an extent as to interfere with the production of good nickel plate (9). Since neither of these extremes is a suitable situation for electroplating, it is necessary to maintain the proper balance, and it is not hard to imagine that this requirement plays a significant part in determining the carefully chosen combination of plating current, temperature, and pH that characterizes industrial nickel plating baths. The rate of electrolytic reduction of water (*i.e.*, i_W) is determined in part by the cathode potential required to achieve a specified plating current. This potential depends

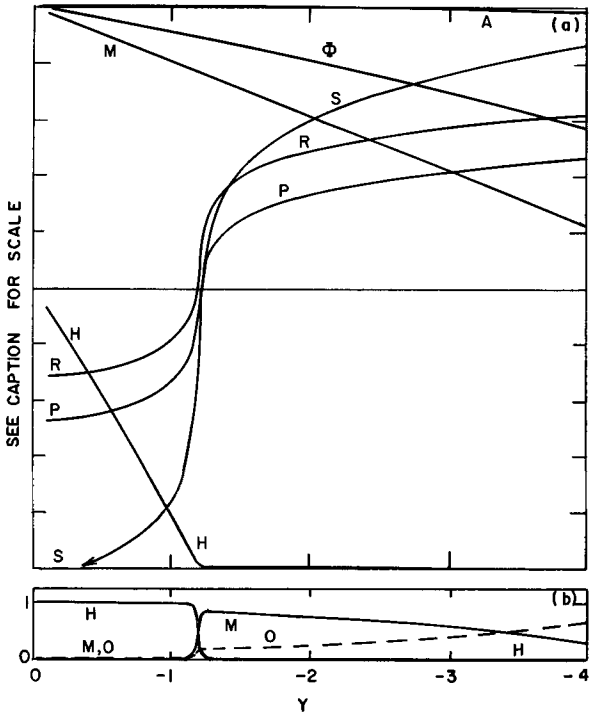

Fig. 6. (a) Curve *M*, total metal concentration normalized to bulk (scale: 0 to 1); curve *A*, fraction of metal complexed with counterion (scale: 0 to 1); curve *H*, hydrogen ion concentration normalized to bulk (scale: 0 to 2); curve *P*, ratio of hydroxyl ion concentration to hydrogen ion concentration (log scale: −10 to +10); curve *R*, ratio of metal-hydroxy complex to hydrogen ion concentration (log scale: −10 to +10); curve *S*, product corresponding to solubility product of $M(OH)_2$ (log scale: −30 to −20); Φ, electrical potential (scale: −200 mV to 0V). (b) *H*, Fraction of hydrogen evolution current carried by hydrogen ions; *O*, fraction of hydrogen evolution current carried by hydroxyl ions; *M*, fraction of hydrogen evolution current carried by metal-hydroxy complex. Conditions: $Z = 1$, $T = 340°K$, pH = 4.0, $i_W/i_M = 10^{-3}$, $K_3 = 3.0 \times 10^6$, $K_4 = 10^8$ (cm^3/mole).

strongly on temperature. Whether and to what extent precipitation occurs depends on the extent to which alkalization is moderated by the supply of hydrogen ions from the bulk (*i.e.*, pH) and by buffering reactions in the diffusion layer.

The role played by the hydroxy complex in preventing or moderating alkalization is important, not only *per se*, but also because of the hint it yields as to mechanisms by which other buffers may operate. In the region in which the hydroxy complex plays an important role, the fraction of metal ions tied up in this complex is very small (less than 1%). This means that an additive present in equally low concentration could still assist in preventing alkalization. For example, consider an additive species B^- that associates efficiently with M^{+2} to form a stable intermediate MB^+ which then reacts with OH^- to form a soluble complex. If the rate constant and equilibrium constant for this second reaction are high enough, (*i.e.*, $K \gtrsim 10^{10}$ cm^3/mole) then its effect may rival or exceed in efficiency the previously described process involving MOH^+. Reduced to simplest terms what is suggested here is a process in which B^- "hitchhikes" toward the cathode with M^{+2} (as MB^+) and then further combines with OH^- to form a soluble complex that can migrate back to a region of lower pH where it releases the OH^-. MB^+ then repeats the cycle.

With regard to the cause of alkalization, statements are frequently encountered in the literature implying it is caused by dissociation of water in a region near the cathode (in response to depletion of the hydrogen ion population by cathodic reduction). If this were true, the hydrogen ions produced by dissociation would add to the hydrogen ion flux, which would therefore become larger upon moving toward the cathode into the region of dissociation. Figures 2b-5b show that for all cases presented here this is not so. Nor is it so for any of the other cases studied in this investigation, covering a range of pH from 3 to 6 and with equilibrium constants ranging over many orders of magnitude. The presumption is therefore very strong that alkalization is not caused by dissociation of water in the liquid phase, but by production of OH^- at the cathode. This is not surprising if one considers that the electric field (the primary driving force in the liquid) is not likely to cause an increase in alkalinity toward the cathode since on the average it will tend to move OH^- away from the cathode.

Finally, I should again remind the reader that the detailed results of this analysis depend on the assumption of "fast" reactions. One referee pointed out that for nickel complexes this assumption may not hold. To explore in detail the implications of this possibility would be an interesting project, but probably is not justified until more experimental data is available to test the simpler model. However, a few comments and speculations may be *à propos*. Slow formation of MOH^+ would probably shift the transition zone (between the alkali and acid regions) toward the Nernst boundary and slow dissociation of MOH^+ would broaden this zone. However, the shift will not necessarily lower the threshold for precipitation if (as is likely) MOH^+ is usually an intermediate in the formation of the hydroxide. And broadening the zone will just cause some excess undissociated MOH^+ to be carried into the bulk where it will hardly be noticed as it dissociates while mixing. In connection with precipitation, I should also mention that supersaturation can be expected to delay the onset of precipitation unless the rise in alkalinity is quite abrupt (as in Fig. 2 and 6). If the reaction $M^{+2} + A^{-2} \rightarrow MA$ were slow, then (for example in the case of Fig. 5) there would be an excess concentration (*vis-à-vis* equilibrium) of free metal ions and counterions near the cathode. However, only a population excess that persists all the way across the diffusion layer can contribute to i_M. Slow dissociation of MA entering the diffusion layer would probably not appreciably affect the ion population near the Nernst boundary, in which case its effect would be mild.

Conclusions

1. "Alkalization" of the electrolyte near the cathode will occur only if OH^- is produced at the cathode (*e.g.*, due to the electrolytic decomposition of water). In the simplest case the criterion for precipitation is the same as the Nernst criterion for diffusion-limited hydrogen ion reduction; namely

$$i_W \delta > \mathbf{F} D_{H^+} [H^+]_o \qquad [31]$$

where i_W is the "hydrogen evolution" current density, δ the thickness of the diffusion layer, and $[H^+]_o$ the concentration of hydrogen ions in the bulk.

2. Precipitation is prevented when the hydroxyl ions produced at the cathode can immediately react to form some species (*e.g.*, MOH^+ or H_2O) other than an insoluble metal salt. In the absence of "buffers," precipitation is controlled by the ease of formation of the metal-hydroxy complex and by the depth of penetration of hydrogen ions into the diffusion layer. The latter can be significantly affected by the presence of a neutral metal-anion complex. If the equilibrium constant for the formation of the metal-hydroxy complex is greater than about 10^5 liter/mole (consistent with Bjerrum's list of values for say $NiOH^+$) then the limit on the right of Eq. [31] may be increased by a factor of two in some cases. If the equilibrium constant for the formation of the neutral complex MA (for a bivalent anion) is greater than about 10^5 liter/mole (consistent with Bjerrum's list of values for say $NiSO_4$) the limit may in some cases be increased severalfold (*vis à vis* Eq. [31]).

3. The results of this study indicate that to pin down the mechanism of alkalization experiments should be conducted in which the thickness of the diffusion layer is controlled, the "hydrogen evolution current" measured, and the onset of precipitation detected.

LIST OF SYMBOLS

A	Atomic species of counterion
C	Concentration, mole/cm^3
D	Diffusion coefficient, cm^2/sec
F	Faraday constant, coulomb/mole
i	Electrical current density, A/cm^2
j	Molecular flux density, mole/cm^2 sec
K	Equilibrium constant
L	Characteristic length, cm
M	Metal atom
n	Ionic charge number
R	Gas constant, joule/mole degree
T	Temperature, °K
x	Distance, cm
y	Dimensionless distance variable (see Eq. [16], [17])
δ	Thickness of diffusion layer, cm
μ	Electrical mobility, cm^2/V sec
Φ	Electrical potential, V
ϕ	Dimensionless potential (see Eq. [13])

Subscripts

A	Pertaining to the counterion
c	"Critical" in the sense that higher values may cause alkalization
i (or 1, 2, . . .)	Pertaining to the different species shown in Fig. 1
H	Pertaining to hydrogen ions
M	Pertaining to the metal
0	Pertaining to the Nernst boundary or the bulk electrolyte
W	Pertaining to water or its ionic substituents

Superscripts

+	Indicates a single positive electronic charge
−	Indicates a single negative electronic charge
± 2, 3, etc.	Indicates specific charge of ionic species

Potential Distribution in Axisymmetric Mercury-Pool Electrolysis Cells at the Limiting Current

ABSTRACT

An expression has been obtained and graphs are presented for the potential distribution at a disk working electrode located at the bottom of a cylindrical cell, with the counterelectrode separator taken to be a uniform-current disk placed concentrically at the solution level. The condition of maximum working electrode potential variations, *i.e.*, when the working electrode current density is uniform, is examined in detail. For cells of typical size, the most sensitive geometrical parameter in determining the potential distribution is the height of the counterelectrode separator above the pool. Recommendations on the placement of the reference electrode probe are given.

Uniformity of potential at the working electrode has become an important criterion in the design of cells for controlled-potential electrolysis and coulometry. Deviations of the actual electrode potential from the desired control potential may cause significant errors in coulometry (1-4) and unwanted product distributions in electro-organic syntheses (4-7).

Because deviations of the working electrode potential are minimized, the preferred configuration of a mercury-pool type cell is the axisymmetric arrangement in which the counterelectrode separator is placed concentrically above the pool. When the separator is parallel to the pool, and of nearly the same diameter, a virtually uniform potential distribution should be achieved, and this has been experimentally realized in several instances (1, 7-10). Use of a large-diameter separator, however, complicates the placement of the other cell components and renders the design of an efficient cell more difficult. For cells whose separators are significantly smaller in diameter than the working electrode, [see, for example, Ref. (6, 10-15)] a means for estimating the possible electrode potential deviations would be useful. Since the potential within the electrode material is uniform, attention is to be focused on the variation of potential within the adjacent solution.

Stouffer and Richardson (16) considered the boundary-value problem represented by this configuration and derived an equation [given in Ref. (2)] for the potential difference arising in the solution adjacent to the working electrode under worst case conditions, *i.e.*, when the cell is operating at the limiting current and a uniform current density prevails at the working electrode. However, none of the useful predictions afforded by the theory, *e.g.*, the relative influence of various geometrical parameters on the potential distribution, were explored by these authors in their brief treatment. This fact, the somewhat unwieldy form of the Stouffer-Richardson equation, and our recent need for a numerical evaluation of this potential distribution have prompted us to re-examine this problem. Graphical representations are presented that facilitate design calculations and provide insight to the properties of axisymmetric cells in general.

The basic problem is formulated for the geometry shown in Fig. 1, where the working electrode is assumed to be a uniform-current disk of radius r_w at the bottom of a cylindrical cell, and the counterelectrode separator is taken to be a uniform-current disk of radius r_c placed concentrically at the solution level, *i.e.*, in an insulating plane. This model does not take into account the typical experimental conditions of nonuniform mass transport at the working electrode, curvature of the mercury pool at its periphery, and deviations of the counterelectrode separator from the assumed uniform-current source, but these characteristics are expected to be of secondary influence on the potential distribution.

In cylindrical coordinates r and z, Laplace's equation for the potential Φ in the solution reads

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \Phi}{\partial r}\right)+\frac{\partial^2 \Phi}{\partial z^2}=0 \qquad [1]$$

and the boundary conditions stated above can be expressed explicitly as

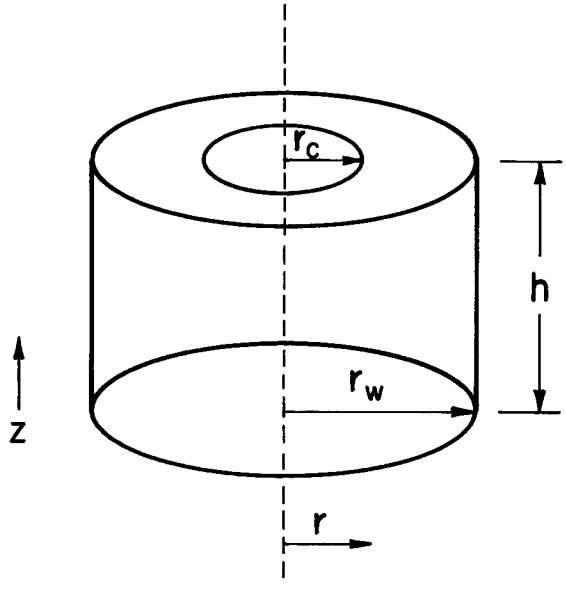

Fig. 1. Axisymmetric cylindrical cell. The working electrode (mercury pool) is at the bottom and the counterelectrode or counterelectrode separator is at the top. The term "very small counterelectrode" will refer to limiting expressions where r_c approaches zero.

* Electrochemical Society Active Member.

Key words: current distribution, electro-organic synthesis, controlled-potential electrolysis, controlled potential coulometry.

$$\frac{\partial \Phi}{\partial z} = \frac{i}{\kappa} \text{ at } z = 0 \text{ at the working electrode} \quad [2]$$

$$\frac{\partial \Phi}{\partial r} = 0 \text{ at } r = r_w, \text{ at the cell wall} \quad [3]$$

$$\frac{\partial \Phi}{\partial z} = \frac{i}{\kappa} \frac{r_w^2}{r_c^2} \text{ at } z = h,\ r \leq r_c \quad [4]$$

$$\frac{\partial \Phi}{\partial z} = 0 \text{ at } z = h,\ r > r_c \quad [5]$$

where i is the uniform current density at the working electrode and κ is the conductivity of the solution.

By the method of separation of variables (17), the appropriate solution of Laplace's equation is

$$\Phi = \frac{iz}{\kappa} + \frac{ir_w}{\kappa} \sum_{n=1}^{\infty} c_n \cosh\left(\lambda_n \frac{z}{r_w}\right) J_0\left(\lambda_n \frac{r}{r_w}\right) \quad [6]$$

where J_0 is the Bessel function of the first kind of order zero, and λ_n is one of a sequence of eigenvalues. The first term on the right represents a uniform current density i on the working electrode. Each of the terms in the sum is a solution of Laplace's equation having zero current density on the working electrode and also on the cylindrical wall of the cell. This latter condition is assured by choosing the eigenvalues λ_n so that the derivative of $J_0(x)$ is zero at $x = \lambda_n$. Since the derivative of $J_0(x)$ is $-J_1(x)$, the Bessel function of the first kind of order one, this means that the eigenvalues λ_n are the zeros of J_1. These are tabulated along with the values of $J_0(\lambda_n)$ in Ref. (18).

The coefficients c_n can then be chosen to yield the specified current-density distribution at the top of the cell: a uniform current density for $r < r_c$ and a zero current density elsewhere. Equation [6] is differentiated with respect to z, and then z is set equal to h, the height of the cell. Multiplication by $rJ_0(\lambda_m r/r_w)$ and integration from $r = 0$ to $r = r_w$ give for the coefficients

$$c_n = \frac{2\frac{r_w}{r_c} J_1\left(\lambda_n \frac{r_c}{r_w}\right)}{\lambda_n^2 [J_0(\lambda_n)]^2 \sinh(\lambda_n h/r_w)} \quad [7]$$

The expression for the potential distribution at the pool then is

$$\Phi_0 = \frac{2I}{\pi\kappa r_w} \sum_{n=1}^{\infty} \frac{\frac{r_w}{r_c} J_1\left(\lambda_n \frac{r_c}{r_w}\right) J_0\left(\lambda_n \frac{r}{r_w}\right)}{\lambda_n^2 [J_0(\lambda_n)]^2 \sinh(\lambda_n h/r_w)} \quad [8]$$

where I is the total cell current. Because the metal of the working electrode is of uniform potential, Φ_0 also defines the "electrode potential" gradient. Numerical evaluation of this equation for a range of typical cell parameters yields the curves shown in Fig. 2 and 3. The working electrode potential, relative to the adjacent solution, is most cathodic for a reduction process and most anodic for an oxidation process at the center of the cell.

Important in many design calculations would be the maximum potential difference, $\Delta\Phi_{max}$, between the center of the cell and its periphery. Figure 4 shows how this quantity varies with I, h/r_w, and r_c/r_w, as well as the over-all cell size as represented by r_w. Figure 5 emphasizes the effect of changing the size of the counterelectrode separator and provides a means for interpolating on Fig. 4. These figures demonstrate that one must increase the size of the counterelectrode separator considerably in order to obtain appreciable improvement over the potential distribution for $r_c = 0$. Changes in h affect the potential distribution more profoundly, and this design parameter can be adjusted

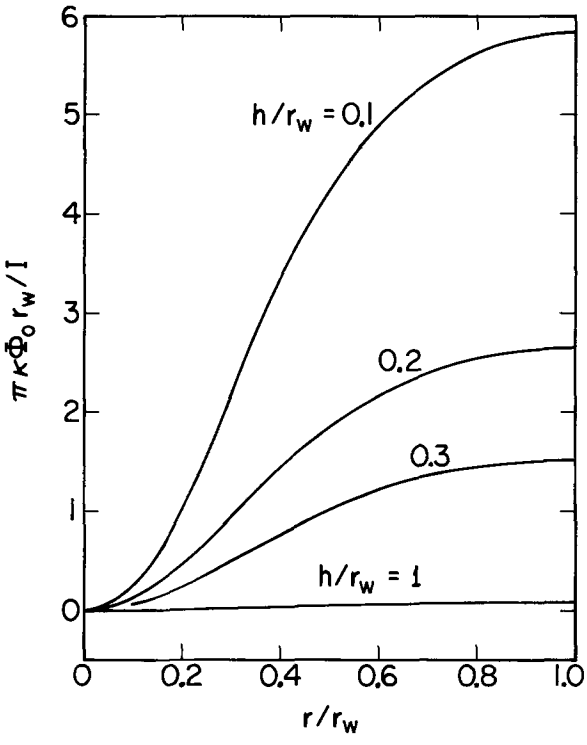

Fig. 2. Potential distribution in the solution at the pool for the limiting current, with $r_c/r_w = 0.3$. The lowest curve also appears on Fig. 3 with an expanded scale.

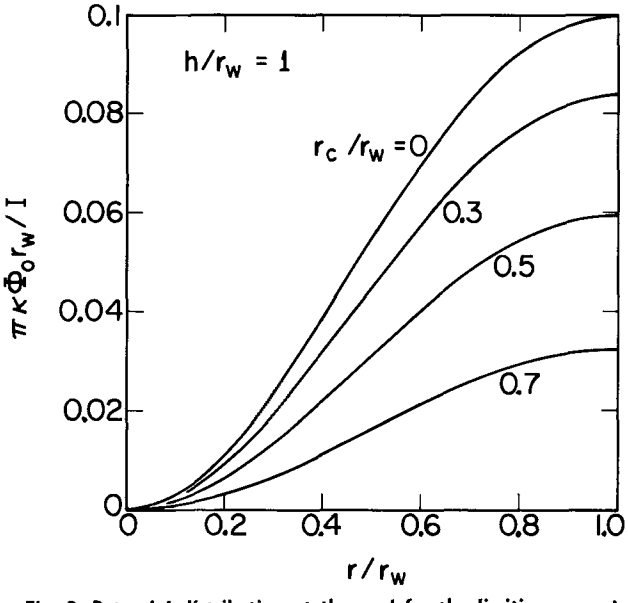

Fig. 3. Potential distribution at the pool for the limiting current, with $h = r_w$.

to render $\Delta\Phi_{max}$ negligible. However, increasing h for this geometry also would increase the volume of the solution and hence the time of the electrolysis, unless the rate of stirring were also increased.

The order of magnitude of expected electrode potential gradients is indicated by numerical evaluation of a typical case. For a cell in which $r_w = h = 3$ cm, $r_c = 1$ cm, and $I = 100$ mA, $\Delta\Phi_{max}$ would be 200 mV for a 0.1M solution of tetrabutylammonium perchlorate in DMF ($\kappa \approx 0.0045$ ohm^{-1} cm^{-1}) and 4 mV for 0.5M H_2SO_4 ($\kappa \approx 0.2$ ohm^{-1} cm^{-1}). The latter difference would be negligible in most work; note, however, that if h is decreased to 1 cm, $\Delta\Phi_{max}$ would then become 70 mV.

The dashed line on Fig. 4 indicates the potential variation for the two-dimensional rectangular geometry of Fig. 6, in which the counterelectrode separator is

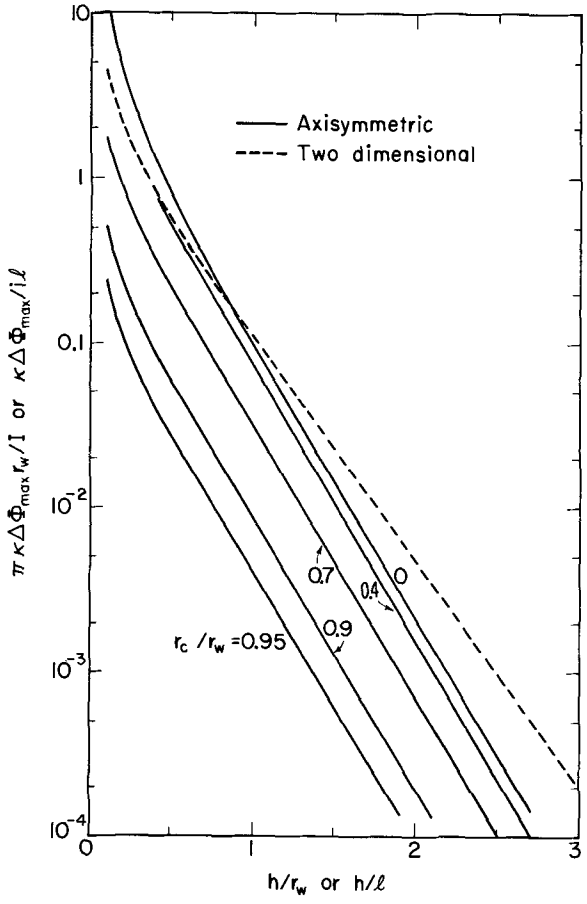

Fig. 4. Maximum potential difference in the solution adjacent to an electrode with a uniform current density.

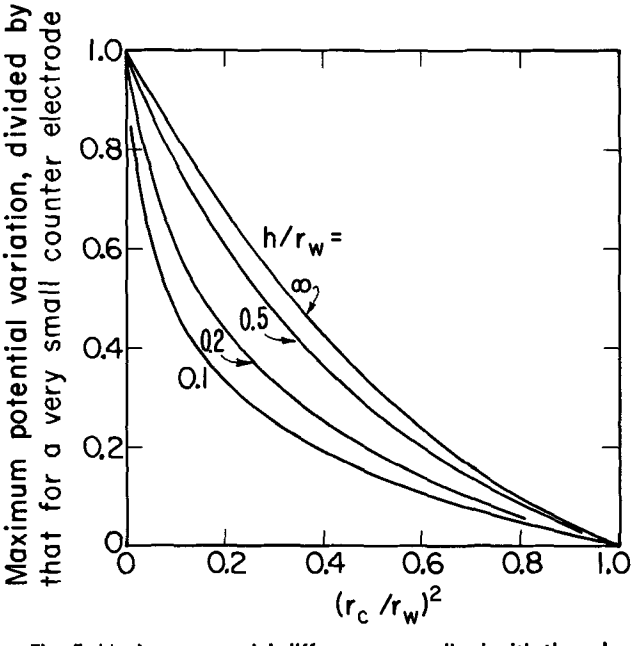

Fig. 5. Maximum potential difference, normalized with the value for a small counterelectrode ($r_c = 0$), showing the dependence on the size of the counterelectrode.

regarded as being a line at the upper edge of the cell. This configuration is thus a two-dimensional analogue of the axisymmetric geometry for $r_c = 0$.

Placement of the Reference Electrode

The position of the reference electrode probe within the controlled-potential electrolysis cell can be chosen on the basis of the known potential distribution at the working electrode and the specific purpose of the

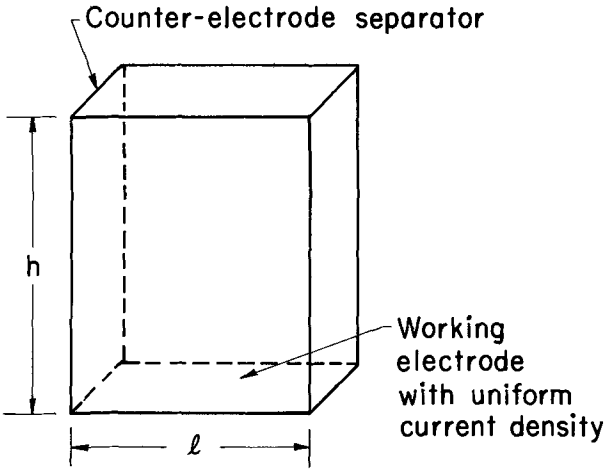

Fig. 6. Two-dimensional cell with counterelectrode separator reduced to a line at the upper edge of the cell.

electrolysis. In most analytical coulometry and separations, the optimum location for the probe is the center of the cell, because exceeding the desired control potential may cause the coelectrolysis of interferences or the supporting electrolyte (2). This configuration also ensures that the cell transfer function will have a minimum phase shift, which facilitates attaining good control system response (10). The probe should of course also be placed close to the working electrode to minimize the uncompensated resistance.

On the other hand, when controlled-potential electrolyses are utilized for the elucidation of electrode reaction pathways via coulometry and the analysis of current-time curves, or the technique is used as a tool for organic synthesis, it would usually be desirable to minimize the maximum difference between the actual electrode potential and the control potential. Such potential control in the axisymmetric cell could be established by positioning the reference electrode probe off center, at an appropriate location selected on the basis of the known potential gradient. The actual electrode potential would then deviate both above and below the nominal control potential. This configuration would result in increased phase shift in the cell transfer function, but in most cases this could be neutralized by adjustment of the phase compensation in the potentiostat.

Separation of Isotopes by Electromigration

Theory of Steady-State Enrichment at the Low Concentration Range

A. S. Roy*

Department of Chemical Engineering, University of the Negev, Beer-Sheva, Israel

ABSTRACT

The general differential equation for isotope separation by countercurrent electromigration is derived, normalized for the general case independent of properties of any particular liquid system, and solved for steady-state enrichment of an isotope of low abundance. Two primary process parameters are defined, the reduced reflux ratio, ρ, and reduced number of plates, ν, in terms of which the process is specified. The ranges within which the reflux ratio and number of plates may vary are determined. Minimum $\rho\nu$ is established as a criterion for preferred operation and a general solution is derived to comply with this criterion. The general solutions of the differential equations provide easy application of the results for any system of any particular properties.

Reviews of previous work on isotopic enrichment by electromigration in liquids have been published (1-3). Many of the investigations involve experimental derivation of the elementary process separation coefficient α (Eq. [14] below) and theories dealing with the functional relationships between α and the material properties, such as diffusivity, composition, and temperature. Given, however, the coefficient α and other properties of the system, the question may then arise as how to design an electromigration cell to obtain a selected isotope at a desired level of enrichment and a steady rate of production. A solution of such a problem has been given by Westhaver (4) with respect to a particular system. In the present work, a general solution to the problem in the low concentration range is obtained in a form which enables it to be easily applied to all systems and which facilitates interpretation of results.

The Countercurrent Velocity

Figure 1 illustrates a model cell for continuous isotope separation by electromigration, made of a U-tube containing two electrode compartments, cathodic and anodic, and two packed sections. The packing ("diaphragm") is a uniformly porous medium providing resistance towards pressure flow of liquid. This impedes turbulence and free convection in the liquid and also equalizes the velocity of the liquid at the full cross-sectional area of the tube. For simplicity, let the ionic liquid in the cell be a pure monovalent fused salt of the type MX in which M represents a metallic element consisting of two different isotopes, 1 and 2, while X is a halogen, such as chlorine.

By applying a voltage difference between the electrodes, the ionic liquid in the cell undergoes electrolysis. The prominent process responsible for isotope separation by electromigration is the specific (electro) migration velocity that each liquid constituent possesses in an electrostatic potential gradient. Within wide limits the migration velocity is proportional to the field strength and its magnitude in a unit field strength is known as the typical mobility of the particular constituent. The respective different migration velocities, w_1 and w_2 [cm/sec] of the two isotopes are shown in the packed section, directed towards the cathode. The migration velocity of the halogen, w_3, has an opposite direction (not shown). The main treatment here will deal with the transport in the cathodic packed section of the cell where velocities will have positive values for actual displacements towards the cathode, according to the positive z direction.

The other significant process that takes place in the cell is the faradaic electrodic reaction, which entails the reduction of neutral halogen at the cathode, as is formulated by the equation (from left to right)

$$1/2\ X_2 + e = X^- \qquad [1]$$

where e is an electron and X^- is a negatively charged halogen atom in the liquid, such as Cl^-. To provide for

* Electrochemical Society Active Member.

Key words: electromigration, isotope separation, ionic transport.

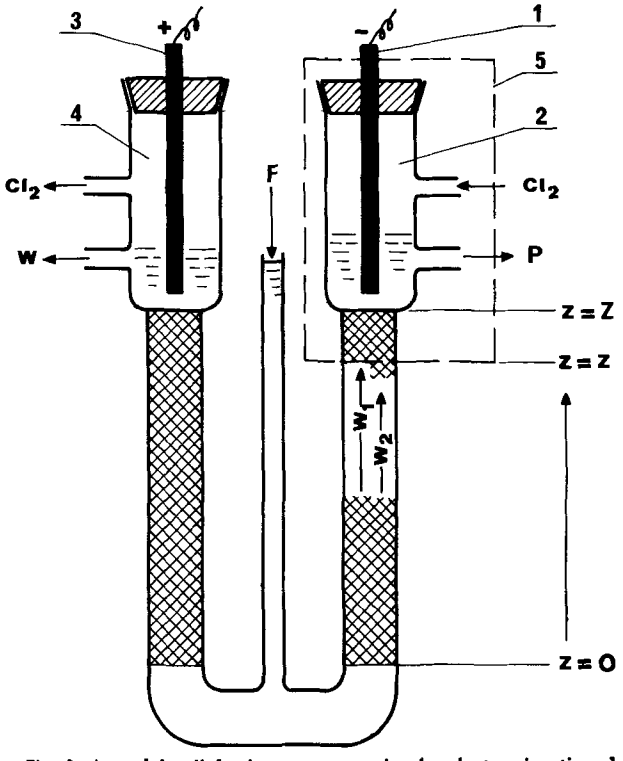

Fig. 1. A model cell for isotope separation by electromigration. 1, Cathode; 2, cathode compartment; 3, anode; 4, anode compartment; 5, material balance envelope around the catholyte.

this reaction, excess halogen gas is circulated at the cathode. At the anode, a reaction of an opposite direction of Eq. [1] takes place. In contradistinction to the halogen, the metallic isotopes M do not undergo any faradaic reaction and they permanently remain within the liquid phase-boundaries with no fluxes in or out of the (liquid) system.

The combination of the two distinct processes, the migration and the faradaic processes, results in a material flux into the catholyte (the liquid in the cathode compartment) as follows (streams F, P, W of Fig. 1 are considered zero now). By Faraday's law

$$\text{Flux of } X^- \text{ by cathodic formation} = i/\mathbf{F}[\text{mol/sec/cm}^2] \quad [2]$$

where $\mathbf{F}$ is the Faraday constant [96,500 coulombs/equiv.], and i is the current density (A/cm^2). The area to which fluxes and current density relate is the total cross-sectional area of the packed tube. For the current density we have

$$i = \mathbf{F}\,\Sigma_j z_j c_j w_j \quad [3]$$

where z_j is the valence (or charge number, *i.e.*, +1 for M and −1 for X), and c_j is the concentration of species j [mol/cm^3 (of packed volume)], and the summation is for all the constituents in the liquid. Substitution of Eq. [3] into Eq. [2] gives for our system

$$\text{Flux of } X^- \text{ by cathodic formation} = \Sigma z_j c_j w_j = c_1 w_1 + c_2 w_2 - c_3 w_3 \quad [4]$$

Drawing a material balance line around the catholyte (the dashed line, Fig. 1), the total flux of X^- into the catholyte is the addition of the separate fluxes originating from the two different mechanisms: one by migration, which is $c_3 w_3$, and the other by cathodic reduction, which is according to Eq. [4]. Summing these two fluxes results in

$$\text{Total flux of } X^- \text{ into catholyte} = c_1 w_1 + c_2 w_2 \quad [5]$$

Simultaneously, there are also fluxes of isotopes 1 and 2 into the catholyte. These, however, originate from migration alone and are given by

$$\text{Flux of } M^+ \text{ into catholyte} = c_1 w_1 + c_2 w_2 \quad [6]$$

Equations [5] and [6] state that the electrolysis (migration plus electrodic reaction) creates an equal molar flux into the catholyte of both M^+ and X^-, namely a flux of neutral salt MX (electroneutrality is preserved), and the magnitude of this flux is $c_1 w_1 + c_2 w_2$.

Concurrently, a flux of the same magnitude but of opposite sign goes into the anolyte. This brings the liquid-level higher at the cathode and lower at the anode (2), creating a hydrostatic pressure difference which causes a pressure flow of liquid of velocity v_h with an actual direction opposite to that of isotopes 1, 2; hence it is a "hydrodynamic back-flow" or "countercurrent flow." Because of this flow, the catholyte level will stop rising at some height which depends on the electric current density, liquid viscosity and the hydrodynamic permeability of the porous packing. For constant electric current and temperature and if the overall molar density of the catholyte is unchanged, then the liquid level, hence also the volume of the catholyte and the total number of moles it contains, will reach a steady state and stay constant. In order to have the catholyte at constant molar density, one of the following conditions has to hold: nonchanging concentration, equal molar volume of the isotopes, or a concentration profile (along the z-axis) that does not change in time (steady-state enrichment). If one of these is valid, then, because the molar content of the catholyte is unchanged, the total molar flux across level z into the catholyte should sum up to zero

$$c\,v_h + c_1 w_1 + c_2 w_2 = 0 \quad [7]$$

where $c = c_1 + c_2$, the total molar concentration of MX. In terms of mole fractions x_j of the isotopes, Eq. [7] gives

$$v_h = -x_1 w_1 - x_2 w_2 \quad [8]$$

The mole fractions fulfill

$$x_1 + x_2 = 1 \quad [9]$$

Consequently, the observed (over-all) velocity of isotope 1 (with respect to stationary axes), v_1, at any location z of the tube is, in fact, obtained by the superposition of the countercurrent velocity v_h on the migration velocity w_1 and (by using Eq. [8] and [9]) is equal to

$$v_1 = w_1 + v_h = w_1 - x_1 w_1 - x_2 w_2 = (w_1 - w_2) x_2 \quad [10a]$$

and similarly, for isotope 2,

$$v_2 = w_2 + v_h = w_2 - x_1 w_1 - x_2 w_2 = -(w_1 - w_2)\, x_1 \quad [10b]$$

For $w_1 > w_2$ these (over-all) velocities of the isotopes involve a net positive flux of isotope 1 towards the cathode, which will cause the enrichment of isotope 1 in a catholyte (and depletion of isotope 2) (2, 4, 5). The countervelocity v_h thus acts as the reflux in distillation for inducing separation, and the cathodic packed section, as a rectifying column.

All the above can be made true also for aqueous solutions and other ionic liquid mixtures, provided that a controlled countercurrent flow and material adjustments at the electrodes are accomplished to make Eq. [7] valid (4). In the case of the simple fused salt of the type MX, this countercurrent flow is formed automatically, thanks to the very interesting and fortunate combination of electrodic and migration fluxes, as shown above.

Now that isotopic enrichment can proceed, a continuous feed stream F (a pressure flow) can be added to the system from the outside in order to obtain a product stream P enriched with isotope 1, and a depleted stream, W, as shown in Fig. 1. However, for fixed migration velocities (namely, electric current density), length of column, and enrichment desired,

no more than a limited production rate can be obtained, otherwise the enrichment level will not hold. The solution of the problem lies in formulating and solving the appropriate differential equation in which the important process parameters will be interrelated.

The General Differential Equation

The total flux N_1 (mol/sec/cm^2) of isotope 1 in the enriching column is the sum of fluxes originating from the following origins: migration plus countercurrent flow (Eq. [10]), diffusion, and imposed production flow

$$N_1 = c\,x_1\,(w_1 - w_2)\,x_2 - D\frac{d}{dz}(cx_1) + c\,x_1\,v_p \qquad [11]$$

where D is the binary effective diffusion coefficient between isotopes 1 and 2 (cm^2/sec), "effective" meaning the over-all longitudinal coefficient of remixing by both pure diffusion, including the effect of the tortuous void passage in the porous medium (6) and also of some convective remixing (4). The velocity v_p (cm/sec) is an additional velocity component (by mechanism of pressure flow) resulting from stream F (Fig. 1).

As there is no generation of any isotope in the liquid phase, the material balance for a small volume element leads to the differential conservation law

$$\frac{\partial c_j}{\partial t} = -\nabla \cdot N_j \qquad [12]$$

where t is time (sec). For isotope 1 in our column of unidirectional and uniform velocity across the tube, the differential equation determining the distribution of concentrations is (by Eq. [11] and [12])

$$-\frac{\partial c_1}{\partial t} = \frac{\partial[c\,x_1\,x_2\,(w_1 - w_2)]}{\partial z} - \frac{\partial}{\partial z}\left(D\frac{\partial c x_1}{\partial z}\right) + \frac{\partial(c\,x_1\,v_p)}{\partial z} \qquad [13]$$

We limit our treatment to systems of constant c, v_p, D, and α, independent of isotopic concentration. The elementary process separation coefficient α is defined by

$$\alpha \equiv w_1/w_2 \qquad [14]$$

For low concentrations of isotope 1, the constancy of α implies also constancy of w_1 and w_2. Integrating Eq. [13] for steady state ($\partial c_1/\partial t = 0$) gives

$$(w_1 - w_2)\,x_1x_2 + v_p\,x_1 - D\frac{dx_1}{dz} = \text{constant} \qquad [15]$$

By comparison to Eq.[11], the constant is identified with N_1/c. At the steady state, N_1 is the constant net flux of isotope 1 which is independent of location z and therefore is equal also to the flux at $z = Z$ where x_1 is designated by x_p, the mole fraction of isotope 1 in the product stream P. Hence

$$\text{constant} = x_p\,v_p \qquad [16]$$

Defining the reflux ratio, R

$$R \equiv w_2/v_p \qquad [17]$$

and the height of an equivalent theoretical plate, h

$$h \equiv D/w_2 \qquad [18]$$

and replacing x_1 by x, Eq. [14-18] yield the equation (4)

$$-\frac{dx}{dz} + \frac{\alpha - 1}{h}x(1 - x) + \frac{1}{Rh}(x - x_p) = 0 \qquad [19]$$

or

$$\frac{dx}{d\xi} - (\alpha - 1)nx(1 - x) - \frac{n}{R}(x - x_p) = 0 \qquad [20]$$

where n is the number of plates

$$n \equiv Z/h \qquad [21]$$

and ξ, the reduced distance on the column

$$\xi \equiv z/Z \qquad [22]$$

Defining new parameters, ρ, the reduced reflux ratio

$$\rho \equiv R\,(\alpha - 1) \qquad [23]$$

and ν, the reduced number of plates

$$\nu \equiv n\,(\alpha - 1) \qquad [24]$$

Equation [20] takes the new form of

$$\frac{dx}{d\xi} - \nu\,x\,(1 - x) - \frac{\nu}{\rho}(x - x_p) = 0 \qquad [25a]$$

By using the reduced nondimensional parameters ρ and ν (rather than R and n), Eq. [25a] becomes the general differential equation for steady-state isotope separation by electromigration independent of any particular liquid system, and thus the solution of Eq. [25a] will be easily applicable for various ionic liquid systems. It is also worthy of notice that in order to determine the coefficients of Eq. [19], the values of four parameters, α, u, R, x_p, have to be given. However, by using ρ and ν (Eq. [23] and [24]) the three parameters ρ, ν, and x_p are sufficient to determine the coefficients of either Eq. [19] or [25a]. Needless to say, the number of parameters cannot be reduced to less than three.

The nondimensional parameters, the reduced reflux ratio, ρ, and the reduced number of plates, ν, are model parameters which express the effort necessary for separating the isotope. For instance, the case of $\nu = 1$ means that the number of plates in the column is (by Eq. [24]) $n = 1/(\alpha - 1)$. A larger ν or a smaller $\alpha - 1$ value involves a larger number of plates, *i.e.*, a longer column. Similarly, by Eq. [23], a larger ρ or a smaller $\alpha - 1$ value indicate a larger reflux ratio, namely, a smaller fraction of the migration velocity becomes useful for production. More specifically, by Eq. [14], [17], and [23]

$$v_p = (w_1 - w_2)/\rho \qquad [26]$$

Thus, a value of ρ equal to unity means that all the difference between the migration velocities of the two isotopes is utilized as the production velocity v_p. The larger the value of ρ, the less we utilize the migration difference for production. However, a larger ρ, as well as a larger ν, helps to produce a higher enrichment, as results from the solution of the differential equation [25a], as is shown below.

Solution for the Low Abundance Range

The problem of enriching isotopes available in nature at low abundance is of great interest. For this case $x << 1$, and the differential equation [25a] can be modified to

$$\frac{dx}{d\xi} - \nu\,x - \frac{\nu}{\rho}(x - x_p) = 0 \qquad [25b]$$

Let an "enrichment factor" E'_p be defined

$$E'_p = x_p/x_0 \qquad [27]$$

where x_0 is the mole fraction of the isotope at $\xi = 0$. For the low concentration range, this factor is an adequate approximation of the enrichment factor E_p of the column, generally defined as $[x_p/(1 - x_p)]$ $[x_0/(1 - x_0)]$. Solving the differential equation [25b] for the boundary conditions of $x(0) = x_0$ and $x(1) = x_p$, results in

$$E_p = \frac{1 + \rho}{1 + \rho\,e^{-\omega}} \qquad [28]$$

where the parameter ω is defined by

$$\omega \equiv \nu\frac{\rho + 1}{\rho} \qquad [29]$$

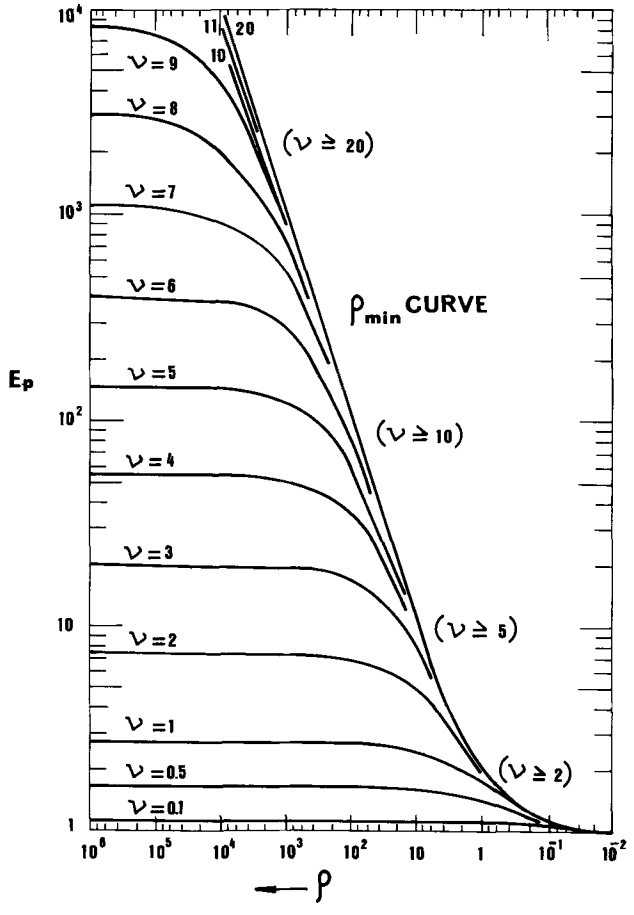

Fig. 2. E_p as a function of ρ and ν (Eq. [28])

Assigning numerical values to ρ and ν explicitly determine E_p. The same E_p, however, can be obtained from an unlimited number of different (ρ, ν) pairs, as can also be recognized from Fig. 2 which represents Eq. [28]. In Fig. 2, E_p is presented as a function of ρ on the abscissa (notice that ρ increases from right to left, $1/\rho$ from left to right), and ν is a parameter. The shape of the resulting curves resemble those given for the general case of isotope separation for square cascades (7).

The ranges in which ρ and ν may vary are limited. For obtaining a certain E_p, Eq. [28] indicates that ρ decreases as ν increases. For $\nu = \infty$, the smallest ρ value will be reached

$$\rho_{min} = E_p - 1 \qquad [30]$$

Namely, given E_p, then $E_p - 1$ is the minimum (reduced) reflux ratio. It requires however an infinitely long column. For a column of finite length

$$\rho > E_p - 1 \qquad [31]$$

The range of permissible ρ is, therefore

$$\infty > \rho > E_p - 1 \qquad [32]$$

The value of ρ_{min} for any E_p value can be ascertained graphically from Fig. 2 by drawing a horizontal line from the assigned E_p point on the ordinate until it intersects the steep line, the ρ_{min} curve, at the extreme right of the curve family, where the value of $E_p - 1$ is obtained for ρ, *e.g.*, for $E_p = 10$, $\rho_{min} = 9$. For $E_p = 2$, $\rho_{min} = 1$, etc. The ρ_{min} curve represents $\nu = \infty$. For the purpose of locating ρ_{min} the condition of $\nu = \infty$ is substantially realizable for quite finite ν-values, as is apparent from Fig. 2, *e.g.*, for $E_p \leq 2$, a $\nu \geq 2$ is practically infinity, for $E_p \leq 10$, $\nu \geq 5$, etc.

It is interesting to note in Fig. 2 the rise of E_p with the increase of ρ. There is a steep rise and then it levels to a plateau. For low ν values, the rise of E_p is slight. This represents short columns having a small number of plates. In this case, back-transport by diffusion controls the process and enrichment is very limited even at a high reflux. At large ν values, ionic transport overrides diffusion and a very high enrichment can be reached as ρ increases. However, with any ν value there is a limit to the enrichment (E_p) possible even for very high ρ-values, as is indicated by the plateaus. For $\rho = \infty$, *i.e.*, total reflux (no product withdrawal, $v_p = 0$), one obtains from Eq. [24], [28], and [29]

$$E_p = e^{\nu} = e^{n(\alpha-1)} \qquad [33]$$

As in general (except for H-D isotopes) $\alpha - 1 << 1$, hence $\alpha = e^{\alpha-1}$, and Eq. [33] takes the form of

$$E_p = \alpha^n \qquad [34]$$

This equation elucidates the concept of number plates, n, by identifying the height of a theoretical plate, h, (Eq. [21] and [18]) as the incremental length of the column over which the enrichment (concentration at low abundance) increases by a factor of α when the column is under total reflux. This also explains Eq. [18]: the higher the diffusivity D, the longer becomes such an incremental length of column.

By Eq. [28], in order to obtain a certain E_p, ν decreases as ρ increases, and for $\rho = \infty$, ν has a minimum value, which (by Eq. [33]) is

$$\nu_{min} = \ln E_p \qquad [35]$$

For any magnitude of E_p the corresponding ν_{min} value is identified in Fig. 2 as the parameter ν of the curve, the asymptotically horizontal part of which, intersects the ordinate at the prescribed E_p, *e.g.*, $\nu_{min} = 1$ for $E_p = 2.7$, $\nu_{imn} = 2$ for $E_p = 7.4$, etc. The ν_{min} is thus the lowest ν value for which an E_p (of value of e^{ν}) will be asymptotically reached as ρ increases infinitely. For low ν values the condition of infinite ρ is already realized at quite low ρ values (*e.g.*, 1 for $\nu = 0.1$ and 10 for $\nu = 0.5$, etc.)

In practice, for finite production rate, $\rho < \infty$, hence, in general

$$\nu > \ln E_p \qquad [36]$$

The range of permissible ν is, therefore

$$\infty > \nu > \ln E_p \qquad [37]$$

The permissible ranges for ν and ρ (Eq. [32] and [37]) still leave open the question of choice of a pair of ν and ρ out of their wide ranges in order to produce a liquid product of a certain enrichment factor E_p. Either infinite ν or ρ are impractical and the reasonable choice should be somewhere in between, governed by economic criteria.

The Preferred ρ and ν Values

As the cost of electrical energy is a major factor in the process of electromigration, it should be advantageous to search for a ρ and ν combination (as a function of E_p) that would minimize the electrical energy required for producing a unit quantity of enriched product. The energy per unit product is obtainable by dividing the electrical power $I^2 2Z/\kappa A$ (J/s) by the production rate $P = cv_p A$ (mol/sec), where I is the electric current (A), A the column cross section (cm^2), and κ the conductivity (mho/cm) of the column content (liquid plus packing). By Eq. [17], [21], [23], and [24] (and $i = I/A$), this ratio becomes

$$\frac{\text{joules}}{\text{mole}} = \frac{2\nu\rho i h}{c\, u_2 (\alpha - 1)^2} \qquad [38]$$

where u_2 is the mobility of isotope 2 (cm/sec per V/cm), or

$$u_2 = \frac{w_2}{i/k} \qquad [39]$$

It is interesting to note that the parameters appearing in the denominator of Eq. [38], c, u, and $\alpha - 1$, are all

properties of matter, whereas those in the numerator, ν, ρ, i, and h are operational. The parameter h is operational both because of w_2 (Eq. [18]), the magnitude of which is determined by the voltage we apply, and because D is not a pure property of the liquid as it includes also convective mixing effects. In fact, achieving a small h measures the degree of experimental accomplishment.

For a liquid of definite properties (c, u_2, $\alpha - 1$) and for operation at a selected current density (i) and a fixed height of a plate (h), the minimum energy consumption [joule/mol] will be achieved according to Eq. [38] when $\rho\nu$ is minimum. Minimization of $\rho\nu$ is required based on Eq. [28]. From Eq. [28] and [29] we obtain

$$\rho\nu = \frac{\rho^2}{\rho + 1} \ln \frac{\rho E_p}{\rho - (E_p - 1)} \qquad [40]$$

Differentiating $\rho\nu$ with respect to ρ and equating to zero yields the expression for minimum $\rho\nu$

$$\nu = \frac{\rho}{\rho + 2} \cdot \frac{E_p - 1}{\rho - (E_p - 1)} \qquad [41]$$

Values of ρ and ν complying with both Eq. [41] and Eq. [28] constitute the minimum $\rho\nu$ values for any chosen E_p. Direct solution of these two equations leads to a transcendental equation. Instead, ρ, E_p, and ν can all be expressed as functions of ω (Eq. [29]) consistent with both Eq. [41] and [28], to yield the E_p, ρ, and ν relationships for minimum $\rho\nu$. The expressions are

$$\rho = \frac{e^\omega - 1}{\omega} - 2 \qquad [42]$$

$$E_p = \left(\frac{e^\omega - 1}{\omega} - 1 \right) \Big/ \left[1 + \left(\frac{e^\omega - 1}{\omega} - 2 \right) e^{-\omega} \right] \qquad [43]$$

$$\nu = \omega \left(\frac{e^\omega - 1}{\omega} - 2 \right) \Big/ \left(\frac{e^\omega - 1}{\omega} - 1 \right) \qquad [44]$$

The results obtained from Eq. [42-44] are plotted in Fig. 3. The preferred ρ and ν for minimum $\rho\nu$ are shown *vs.* $E_p - 1$ in terms of $\rho/(E_p - 1)$ and $\nu/\ln E_p$. These ratios are in fact ρ/ρ_{min} and ν/ν_{min}, respectively, (by Eq. [30] and [35]). It is very interesting to note how little these preferred ratios vary even at an enormously wide $E_p - 1$ range. For extremely low enrichments, the two ratios start at values around 1.4 and 1.8, respectively, and change no more than to about 1.1 and 1.2 for extremely high enrichments.

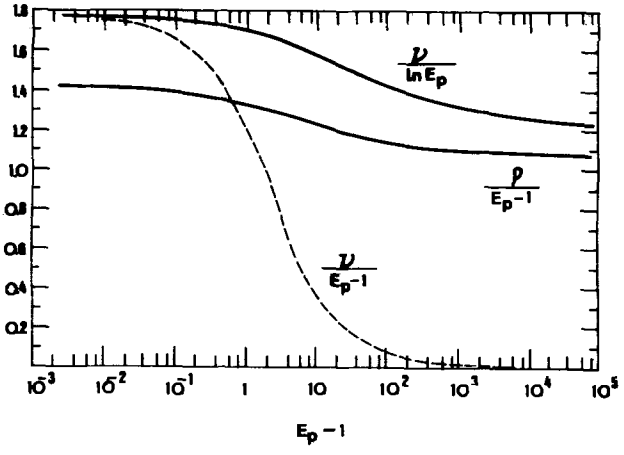

Fig. 3. Preferred ρ and ν for minimum $\rho\nu$ (Eq. [42-44])

It has been pointed out above (Eq. [26]) that ρ signifies the inverse "useful" fraction of $(w_1 - w_2)$ that is utilized as v_p for production. As, according to Fig. 3, $\rho/(E_p - 1)$ is nearly constant, this means that at the preferred conditions, this "useful" fraction is approximately inversely proportional to $E_p - 1$. For instance, the "useful" fraction is $\sim$ 10/1.4 for $E_p - 1 = 0.1$ (700% utilization of $w_1 - w_2$), going down to $\sim$1/1.4 for $E_p - 1 = 1$ (70% utilization), and to $\sim$0.1/1.4 for $E_p - 1 = 10$ (7%). For higher enrichments, the production velocity decreases further. This is very reasonable and is explainable even by the material balance alone, made around the whole enriching column (cathodic packing).

A different trend is shown by the curve of the reduced number of plates, ν. A constant $\nu/\ln E_p$ means, in fact, a very slow increase of ν with the increase of E_p (or $E_p - 1$). This is made more apparent by the curve $\nu/(E_p - 1)$ (dashed line) included in Fig. 3. The diminishing growth of ν with the increase of $E_p - 1$ (for $E_p > 1$) can be illustrated by the following figures

$E_p - 1$:	1.2	9.3	140	2,000	12,000	80,000
ν :	1.4	3.7	7	10	12	14

Figure 3 (Eq. [42-44]) gives the answer for the question of how to decide upon the basic parameters that define the electromigration column for steady-state isotope separation. The approximate constancy of $\rho/(E_p - 1)$ and of $\nu/\ln E_p$ constitute an interesting result.

The General Applicability of the Results

It has been shown how the enrichment is determined (Eq. [28], Fig. 2), based on the model parameters ρ (Eq. [23]) and ν (Eq. [24]). The ranges of these parameters have been derived (Eq. [32] and [37]). The minimum $\rho\nu$ relationship (Eq. [42-43], Fig. 3), has been established as a preference criterion.

Application of these results for any particular ionic liquid in the low abundance range is simple. For instance, given α and h of a particular system, the preferred ρ and ν are easily determined as a function of any enrichment E_p required, by use of Fig. 3. Non-preferred conditions can be obtained from Fig. 2. The length of column needed, Z, is easily obtainable from Eq. [24] and [21], and the reflux ratio R, from Eq. [23]. The relationship between v_p, w_2, i, and κ is given by Eq. [17] and [39].

Electrical Conductance of Molten Alkali Carbonate Binary Mixtures

P. L. Spedding

Department of Chemical and Materials Engineering, The University of Auckland, Auckland, New Zealand

ABSTRACT

The electrical conductances are reported for molten lithium, sodium, and potassium carbonate binary mixtures over the complete composition range. Molar concentration-equivalent conductance isotherms exhibit a negative deviation from ideal behavior. Attempts to handle the results by using conduction theories proved unsuccessful except in the case of the Markov equation. Calculations with the Markov equation gave values for the conduction of dissimilar interacting cations that indicated that the temperature dependence of the conduction is governed by the anion environment present, while the absolute value of conductance gives an indication of the ease of movement of the dissimilar interacting cations.

The alkali metal carbonates have been subjected to extensive study over recent years primarily because of their possible practical application in electrochemistry. This present study was undertaken as part of an integrated fuel cell research program aimed at obtaining a better understanding of the actual processes taking place in the molten carbonate-type cell.

Experimental

Methods which are used for measurement of electrical conduction of molten salts have been reviewed by a number of workers (1-5) who have concluded that the most accurate technique which is available for corrosive media is the capillary cell with the actual capillaries formed in noncorrosive insulating material (6-8). The technique therefore was used in this study. The actual apparatus employed is detailed in Fig. 1 and is similar to that of Janz and co-workers (9-10). Care was taken with the design and construction of the apparatus to ensure that the conduction path was entirely confined to the capillaries and the melt between their two immersed extremities. The capillaries were ultrasonically drilled in two single crystals of magnesium oxide. The salt bath was held in a Palau crucible (80% Au-20% Pd) in a controlled carbon dioxide atmosphere, in order to ensure the melt composition was unchanged during experimentation. The over-all details of the control and operation of the system have been presented elsewhere (11, 12). Temperature was better than ± 0.1° at 800°C.

The capillary cell was calibrated with aqueous KCl solution at 25°C using standard techniques (13). Coefficient of expansion data (14) then were applied to the particular cell geometry employed to give the operating cell constant. The calibration was checked against molten KCl data (15) at intervals during the entire work and was found to agree within ± 0.002%. The cell constants for the various cells used during the determination were approximately 370^{-1} cm in the operating temperature range used. Measurements were taken at approximately 20°C intervals at increasing and then at decreasing temperatures. During an actual measurement the furnace was switched off to avoid errors which arise because of interference from the furnace windings. The Jones bridge-oscillator-oscilloscope combination used to measure the conductance virtually eliminated any capacitance effects. Readings were taken over a frequency range of 2,000-40,000 Hz, so that the conductance value at infinite frequency could be determined thus eliminating any effect of polarization which may occur at the electrodes. One of the major sources of error with the capillary cell is caused by the presence of bubbles within the capillaries during a reading. Drying of the salt at 120°C and premelting under carbon dioxide eliminated the possibility of the formation of any water vapor bubbles on the internal surfaces of the capillaries. Raising and lowering the salt bath into the capillaries several times removed any possibility of mechanically formed bubbles adhering to the internal surface of the capillary cell.

Key words: conductance, molten alkali carbonates.

Results

The conduction data were presented as specific conductance, κ, expressed in the form

$$\kappa = A_\kappa \exp(-\Delta E_\kappa / RT) \quad [1]$$

The equivalent conductance, Λ was calculated from the specific conductance and melt density (12), via the equation

$$\Lambda = \kappa(\Sigma x_i E_i)/\rho \quad [2]$$

where x_i and E_i are the mole fraction and equivalent weight of the component, i, in the melt.

The equivalent conductance was expressed as the Arrhenius equation

$$\Lambda = A_\Lambda \exp(-\Delta E_\Lambda / RT) \quad [3]$$

The data exhibit a departure from the Arrhenius relation about the eutectic composition in the temperature range immediately above the melting point as shown by Fig. 2 and 3. This departure is in agreement with the findings of other workers (15). However, in each of these cases there is a region in a higher temperature range in which the Arrhenius relations of Eq. [1] and [3] satisfactorily fit the data. The constants of Tables I and II were calculated for this region alone using the method of least squares (16).

Discussion

Janz and co-workers (9, 10) determined the specific conductivities of the pure alkali metal carbonates and their eutectic mixtures and resolved most of the anomalies which existed in previous work (17-20). The present data show good agreement with that of Janz and co-workers except in the case of the $LiKCO_3$ eutectic where this work gave a smooth graduation in the magnitude of the conductance as the composition was varied, in contrast to Janz's data which showed correspondence with the K_2CO_3 values.

The effect of frequency, f, on the measured resistance, R, of the melt followed the relation (21)

$$R = R_\infty + a/\sqrt{f} \quad [4]$$

for each salt for the frequency range of 2,000-40,000 Hz. No satisfactory correlation with the value of the constant, a, and melt composition could be obtained.

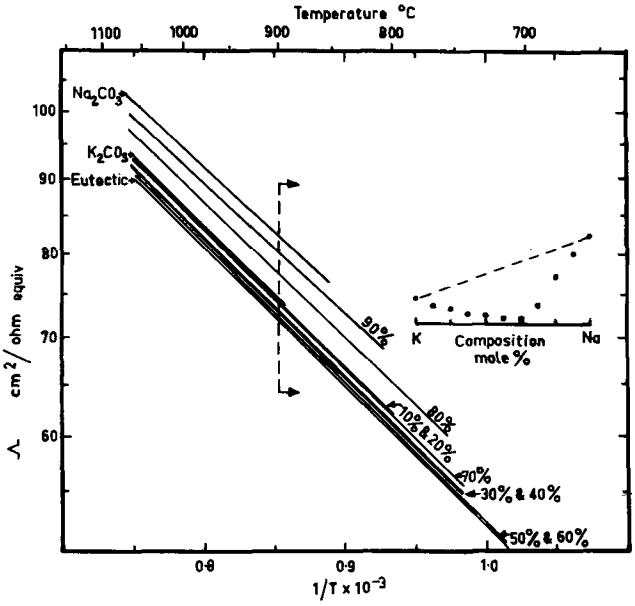

Fig. 4. Equivalent conductances of sodium carbonate-potassium carbonate binary mixtures.

There are a number of theories which have been advanced to explain conduction in melts. Most of these were inapplicable to the present discussion for one reason or another. Lack of data just above the melting point and in the high-temperature region precluded using the reduced volume concept developed by Angell (22) and the approach of Grantham (23), respectively. Furthermore, the frictional formalism has not yielded sufficient insight into the mechanisms of transport to warrant its inclusion in this discussion (24). Lack of necessary fundamental data for these salts did not allow the formal application to these data of the hole model as developed by Bockris *et al.* (25) or the free volume approach of Laidler *et al.* (26). However, estimates of the ionic radius (12), ion vibration (4), and jump distance for the pure alkali metal carbonates have allowed approximate calculations to be performed for the hole model, the results of which gave conductances of similar accuracy as those for univalent salts; that is the calculated Arrhenius coefficients were in reasonable agreement with experimental values but the absolute values were not. In the case of the binary mixtures the hole model predicted ideal behavior which is far from the actuality shown in Fig. 2-4. The possible reasons for these discrepancies between theory and experiment are enumerated by Brummer and Hills (27).

The equivalent conductance-molar composition isotherms exhibit the usual negative deviation from ideality even for Na_2CO_3-K_2CO_3 melts which possess ideal molar volume behavior (12). For ideal binary melt mixtures Markov (28) developed the equation

$$\Lambda_m = x_1^2 \Lambda_{11} + x_2^2 \Lambda_{22} + 2x_1x_2 \Lambda_{12} \qquad [5]$$

for the calculation of conductances and has discussed its importance as far as providing insight into the nature of the melt and its transport mechanisms. The equation has yielded predicted values of conductances for $PbCl_2$-$PbBr_2$ and KNO_3-$NaNO_3$ melts which are within ± 2% of experimental data (28). The Markov equation follows directly from a consideration of the probability of interaction between pure salts in the mixture and the electrical conductance of such an arrangement within the melt. Thus the probability of the interactions M_1X-M_1X, M_2X-M_2X, and M_1X-M_2X are, respectively, x_1^2, x_2^2, and $2x_1x_2$, where x is the mole fraction of the appropriate component. Strictly the Λ_{12} conductance in a mixture having only M_1X-M_2X type interactions, is a hypothetical concept. Markov avoided this issue and simplified the equation by replacing the conductance Λ_{12} by that of the pure salt with the larger Arrhenius coefficient. The reason for this procedure is obscure and calculations on the pure alkali metal carbonate eutectic melts (Table III) show the procedure to be unsatisfactory.

Actually the predictions of the Markov equations are improved considerably in this instance by taking the value of the Λ_{12} conductance as that component in the melt which possesses the smaller, more mobile ion. Accepting the M_1X-M_2X type interactions at face value, there is no good reason to suppose that the Λ_{12} conductance has not got a specific value which is completely dissimilar in magnitude from either of the pure components. Calculation back from experimental data using Eq. [5] confirms that the Λ_{12} conductances for each of the binary melts are different to those of pure melts

$$\Lambda Li,Na = 615 \exp(-4700/RT) \qquad [6]$$

$$\Lambda Na,K = 540 \exp(-4700/RT) \qquad [7]$$

$$\Lambda Li,K = 475 \exp(-4700/RT) \qquad [8]$$

The similarity of the Arrhenius coefficients for the Λ_{12} conductance for each binary melt suggests that the temperature dependence of conductance is influenced primarily by the anion environment which obviously is similar for each system. Rice (29) came to the same conclusion from theoretical considerations of melt transport. The pre-exponential term, on the other hand, exhibits a definite trend which may well reflect the ability of the interacting ion to move through the melt in a similar manner to that which has been suggested for other transport phenomena (30). Resubstitution of the Λ_{12} conductance values given by Eq. [6]-[8] back in the Markov equation leads to the predicted values given in the final column of Table III for the eutectic melts. The over-all error in these calculated values over the complete composition range is within ± 3.5%, ± 3.2%, and ± 14% for the Li_2CO_3-Na_2CO_3, Na_2CO_3-K_2CO_3, and Li_2CO_3-K_2CO_3 melts, respectively.

Closer examination of the data indicates that a significant difference between the calculated and experimentally determined values only occurs when the systems depart from ideal molar volume behavior (12). This is particularly noticeable with the Li_2CO_3-K_2CO_3 melt where satisfactory predictions (± 1.8%) are obtained in the ideal molar volume region up to 25% mole and beyond 67% mole lithium carbonate concentration. In the intervening region where nonideality is marked there is a significant difference between experimental and calculated conductances. Such behavior could be interpreted in terms of the formation of a complex in the region of the eutectic of the general type suggested by Bockris and Reddy (37). That is an entity is formed in which a certain num-

ber of ligand ions participate in the random walk of the ion for a period that is at least several orders of magnitude longer than the time required for a single vibration. These suggestions are at the best qualitative and it is not obvious how unequivocal conclusions about complex formation in the melts can be drawn from the data. Presumably Raman spectra studies are the only way to resolve the point unambiguously.

The Triangular Voltage Sweep Method for Determining Double-Layer Capacity of Porous Electrodes

II. Porous Silver in Potassium Hydroxide

E. G. Gagnon*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

One major problem in measuring the double-layer capacity of a porous electrode is the effect of distributed reactions. Ohmic resistance of the electrolyte makes it easier to charge or discharge the outer surface of the electrode, while the interior lags behind. Triangular voltage sweep results obtained with porous silver in 31 weight per cent KOH agreed well with predicted values obtained using a mathematical model which considers the physical properties of the electrode and electrolyte.

The surface area of a porous electrode may be determined by a number of techniques (*e.g.*, from weight/size distribution of particles, or BET measurements), but measurement of the double-layer capacity (DLC) of an electrode gives the best indication of internal area available for electrochemical reaction. One major problem in the measurement of the DLC of a porous electrode is the effect of distributed capacity. Ohmic resistance of the electrolyte within the pores of the electrode makes it easier to charge or discharge the outer surface of the electrode while the back of the electrode lags behind (1). This paper will compare experimental results with data obtained using a mathematical model proposed earlier (2, 3). The model considers the triangular voltage sweep technique and shows the effect of distributed capacity in the absence of faradaic current. The system investigated was porous silver in potassium hydroxide.

* Electrochemical Society Active Member.

Key words: double-layer capacity, porous electrode, silver electrode.

Theory

Assumptions and model.—The physical situation considered is illustrated in Fig. 1. The Luggin capillary of a reference electrode is positioned a distance, d, from the surface of the electrode having a thickness, L. One face of the electrode is exposed to the electrolyte and current collection takes place at the back of the electrode. It is assumed that (*a*) the porous system is so highly interlinked that the concentration of electrolyte in the pores of the electrode is constant over plane x in the electrode, (*b*) the electrode potential is constant over plane x, (*c*) transport gradients

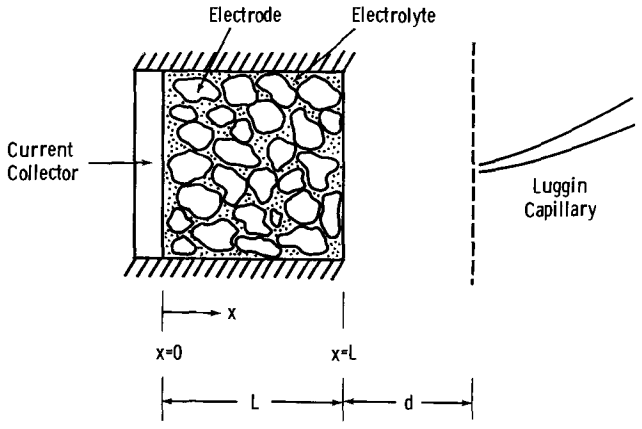

Fig. 1. Illustration of a Luggin capillary positioned a distance, *d*, from a porous electrode of thickness, *L*.

are one dimensional across x, (*d*) electronic conductivity of the electrode material is large compared to the ionic conductivity of the electrolyte within the pores, and (*e*) diffuse double-layer effects are negligible because the electrolyte used is concentrated.

Working equations.—The electrical double-layer between electrode and electrolyte has, in concentrated electrolytes, a thickness of only a few angstroms, and therefore follows the micro-contours of the surface. The DLC of an electrode is proportional to the electrode-electrolyte phase boundary and hence to the area available for electrochemical reaction. The DLC is defined by

$$i_c = C|dV/dt| \qquad [1]$$

where i_c is the capacitative current (A), C is the capacity (farads), V is the potential (V) between the electrode material and electrolyte near the phase boundary, and t is time (sec).

For the case where faradaic current effects are negligible, distributed capacity effects give rise to the behavior illustrated in Fig. 2 during a triangular voltage sweep (TVS) experiment (solid line); in the absence of distributed capacity effects, a square wave is seen (dashed line) which is what one would expect with a solid electrode. Elsewhere (2), it was shown that the current density at the face of a porous electrode (at $x = L$) may be predicted from

$$i(L) = \beta_1 kC' \qquad [2]$$

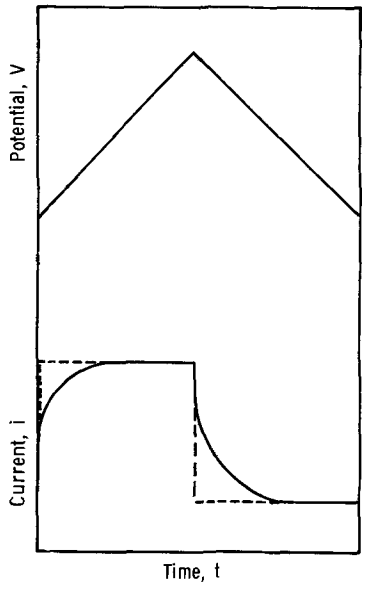

Fig. 2. Illustration of triangular voltage sweep results in the absence of faradaic currents: dashed line, negligible distributed capacity effects; solid line, significant distributed capacity effects.

where

$$\beta_1 = 1 - \sum_{n=1}^{\infty} \exp\left[-M_n^2 \frac{t}{\rho_e C' L}\right] \cdot \left[\frac{2\psi^2}{M_n^2(\psi^2 + M_n^2 + \psi)}\right] \qquad [2A]$$

$$\psi = \frac{L\lambda}{d} = \frac{\rho_e}{R_e A} = M_n \tan M_n \qquad [3]$$

$$\rho_e = \rho\lambda \qquad [4]$$

and k is sweep rate (mV/sec); C' is capacity (farads/cm^2) based on the geometric area, A (cm^2), of the electrode; L is electrode thickness (cm); t is time (sec); ρ is the specific resistance (ohm-cm) of the bulk electrolyte; ρ_e is the specific resistance (ohm-cm) of the electrolyte in the pores of the electrode; R_e is the resistance (ohms) of the bulk electrolyte; and λ is the labyrinth factor. For each value of ψ, values of M_n can be found from tables (4) listing the various roots of the transcendental equation $M_n \tan M_n = \psi$. Clearly, as time decreases, as the electrode thickness increases, or as the specific resistance of the electrolyte increases, distributed capacity effects become much more significant.

At the reversal point of the TVS, the current density at the face of the porous electrode was predicted (3) from

$$i(L) = \gamma kC' \qquad [5]$$

where

$$\gamma = \beta_1 - \beta_2$$

and

$$\beta_2 = \sum_{n=1}^{\infty} \exp\left[-M_n^2 \frac{t}{\rho_e C' L}\right] \cdot \left[\frac{2(\psi^2 + M_n^2)}{M_n^2(\psi^2 + M_n^2 + \psi)}\right] \sin^2 M_n \qquad [5A]$$

Experimental

Test cell.—The electrochemical cell used in this study was a 1000 ml beaker with a U-shaped side arm. A coil of platinum, which was used as the counterelectrode, was sealed into a ground glass joint and was placed in the side arm of the cell. A top made from acrylic sheet, with holes to admit the test and reference electrodes, was used to cover the main compartment of the cell. The electrolyte was 31 w/o (weight per cent) aqueous KOH, prepared from 45 w/o reagent grade KOH and distilled water.

The test electrodes were punched from a sheet of sintered, porous silver (99.8% purity). The electrodes were disk shaped, had a thickness of 0.127 cm, a diameter of 3.5 cm, a geometric area of 9.65 cm^2, a porosity of 62%, and a BET area of 0.18 m^2/g. They were inserted into an electrode holder similar to that used in a previous study (2). The test electrode was butted against a nickel current collector and current collection took place at the back of the electrode. The holder exposed one face of the electrode to the electrolyte.

All measurements were performed using a Hg/HgO (31 w/o KOH) reference electrode with a Luggin capillary. The tip of the Luggin was positioned close to the surface of the test electrode.

The cell was assembled in a constant temperature chamber which was used to control the temperature of the electrolyte (± 1°F).

Measurements.—Constant current measurements were made using a d-c power supply and a power resistance decade box. A Hg-wetted relay was used to switch on or interrupt the cell current. A storage oscilloscope with a dual trace amplifier and a time base was used to record potential-time traces. A high impedance vacuum tube voltmeter monitored the elec-

trode potential. Ohmic polarization, η_{ir}, was obtained using the vertical, blanked-out portion of the potential-time oscilloscope trace when current was switched on or off.

Triangular voltage sweep (TVS) measurements were performed using a potentiostat in conjunction with a signal generator. A dual trace recorder was used to record the potential (test *vs.* reference electrodes) and current (between test electrode and counterelectrode) as a function of time. From both traces, plots of current and/or capacity as a function of potential or time were obtained.

Results and Discussion

Figure 3 shows typical data obtained at room temperature when the potential of the test electrode *vs.* Hg/HgO was varied cathodically from 0 to −0.140V at a sweep rate of 56.5 mV/sec and then anodically back to 0V at the same rate. The curve shows the current flowing between the test electrode and counterelectrode as a function of time (top abscissa) and also potential (bottom abscissa). As the sweep begins, the cathodic current rises in region *ab* and reaches a plateau of short duration at c before passing through a peak at *d*. After the peak, the current starts to decrease again and at the reversal point of the sweep, the current becomes anodic. Some attempt will be made to explain the nature of the various regions in the cathodic portion of the curve.

Region abc.—To test whether the delay time observed in region *abc* is the result of a distributed capacity effect which can be predicted by Eq. [2], estimates of the parameters ψ, λ, d, and ρ_e were made to calculate β_1, since $\beta_1 = f(\psi, t/\rho_e C'L)$. The first parameter required was $\psi = L\lambda/d$.

The distance between the test electrode and tip of the Luggin capillary, d, was determined from η_{ir} measurements which were performed between 71° and −50°F. Figure 4 shows the variation of the effective resistance, R_e, as a function of temperature, for an undisturbed position of the Luggin capillary. Also shown is the specific resistance of the electrolyte, ρ (solid line). The results indicate that for the experimental set-up used, $R_e \simeq 1/10\rho$. Thus, the mean path length, d, can be calculated from $d = R_e A/\rho = (0.1\rho)(9.65/\rho = 0.965$ cm; A being the geometric area of the electrode.

An initial estimate of the labyrinth factor, λ, was made by curve fitting a set of experimental points found in region *abc* with calculated values using Eq. [2]. In this way, a value of $\lambda = 2$ was found. Since the porosity of the electrode, θ, was determined from porosimeter data to be 0.62, the tortuosity factor, q, was estimated (5) using $\lambda = q/\theta$, to be 1.24. This value

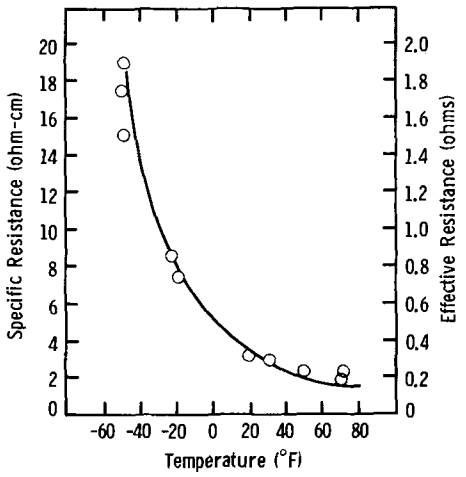

Fig. 4. Specific reistance of 31 w/o KOH (solid) and effective resistance (points) of electrolyte between the test electrode and tip of the Luggin capillary.

is in reasonable accord with values close to $\sqrt{2}$ found for electrodes in fuel cell and battery studies. It will be shown later that the determined value of λ holds quite well for other test conditions (*e.g.*, variations in sweep rate and temperature). De La Rue and Tobias (6), in their studies on the conductivity of dispersions, found that $\lambda = 1/\theta^n$, where $n = 1.5$. Using $\theta = 0.62$, a value of $\lambda = 2.05$ is obtained which is in good agreement with the value determined experimentally.

The value of ψ estimated using Eq. [3] has a value of 0.27. Taking $L = 0.13$ cm, $\lambda = 2$, $q = 1.24$, $d = 0.965$ cm, ρ_e (see Fig. 4) $= 1.9 \times 2 = 3.8$ ohm-cm, C (from the plateau region at c in Fig. 3) $= 0.45$ farads, values of $t/\rho_e C'L$ were calculated using the values corresponding to the experimental conditions. Thus, values of β as a function of ψ and $t/\rho_e C'L$ were obtained and the current, i, was predicted from $i = \beta_1 kC$. Figure 5A shows predicted *vs.* experimental results (region *abc*, Fig. 3) obtained using a sweep rate, k, of 56.5 mV/sec.

As a cross check on the capacity, C, used in the calculations, galvanostatic measurements performed from an open-circuit potential of −0.038V, using a current density of 31 mA/cm², gave an apparent capacity $C = 0.46$ farads, which is in good agreement with the 0.45 farads obtained using the TVS technique. The oscilloscopic potential-time trace was linear in the potential range of interest indicating that effects due to faradaic current in region *abc* were negligible.

Figures 5B, 5C, and 6 show similar results obtained using sweep rates of 27.1, 5.6, and 534 mV/sec, where the predicted values were based upon a C value of

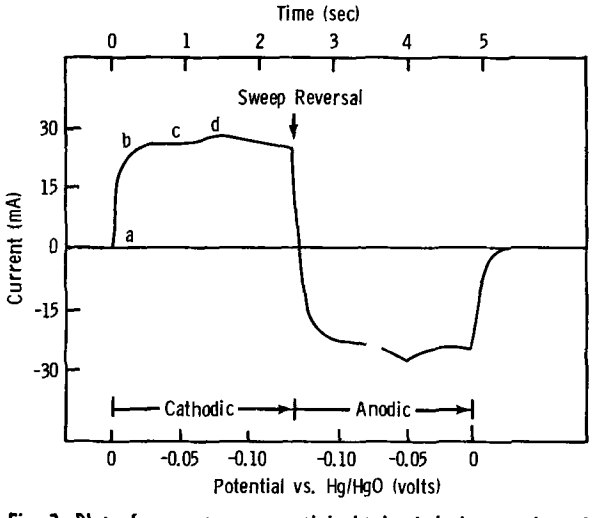

Fig. 3. Plot of current *vs.* potential obtained during a triangular voltage sweep at room temperature: $k = 56.5$ mV/sec.

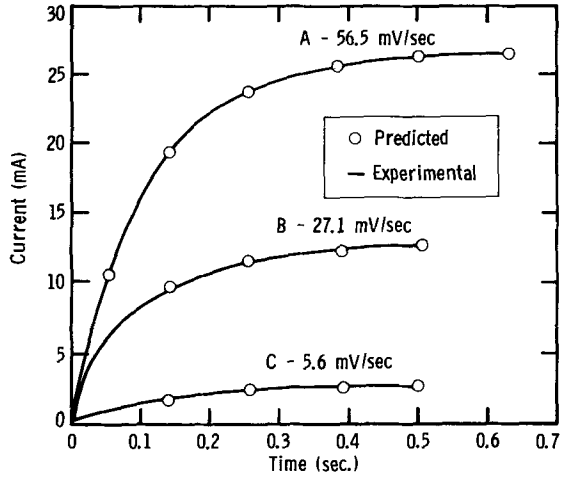

Fig. 5. Experimental *vs.* predicted results obtained in region *abc* at 71°F: A, 56.5 mV/sec; B, 27.1 mV/sec; C, 5.6 mV/sec.

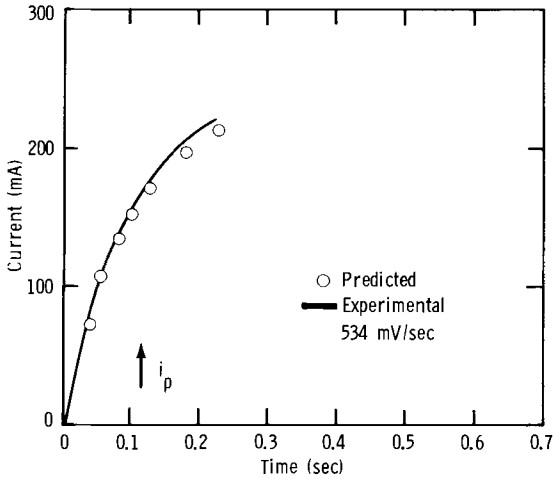

Fig. 6. Experimental *vs.* predicted results obtained using a sweep rate of 534 mV/sec at 71°F.

0.45 farads; in all the calculations, $\lambda = 2$ was used. For the two lower sweep rates, the agreement between the predicted and experimental results is good. For the results obtained using the fastest sweep rate, $k = 534$ mV/sec, the experimental results deviate from the predicted values at about 0.11 sec, which in this case corresponds to the appearance of i_p (region *d* in Fig. 3). For the lower sweep rates, the plateau region at c is reached well before i_p (region *d*) occurs.

Region d.—In this region a cathodic current peak, i_p, appears at about −0.070V *vs.* Hg/HgO. Plots of i_p *vs.* sweep rate at 71° and −19°F are shown in Fig. 7. The plots are linear and have the form

$$i_p = C^{\dagger}\,(dV/dt)$$

where $C^{\dagger}$ is a pseudocapacity which is potential and temperature dependent. Results obtained at higher sweep rates are not available because effects due to distributed reactions, as shown in Fig. 6, gave spurious results. The anodic peak was about 30 mV more positive than the cathodic peak indicating the possibility of a reversible process where the number of electrons transferred in the over-all process is equal to 2. McMullen (7) found that with Ag in 1*N* Na_2SO_4, a "hump" occurred in the same potential region reported here. Veselovsky (8) reported that for silver in 0.1*N* KNO_3, the point of zero charge occurs in the vicinity of these peaks. Bockris (9) has explained the "hump" generally in terms of a simple-lateral-repulsion model of contact adsorbing ions within the inner Helmholtz plane.

Figure 8 shows a composite of seven different cathodic sweeps where the start of each sweep was at a different potential, but each was run at the same sweep rate of 56.5 mV/sec. Included in Fig. 8 are apparent capacities, *C*, calculated using Eq. [1] and capacities, *C**, based on the BET area of the electrode. It appears that capacity decreases to a minimum value

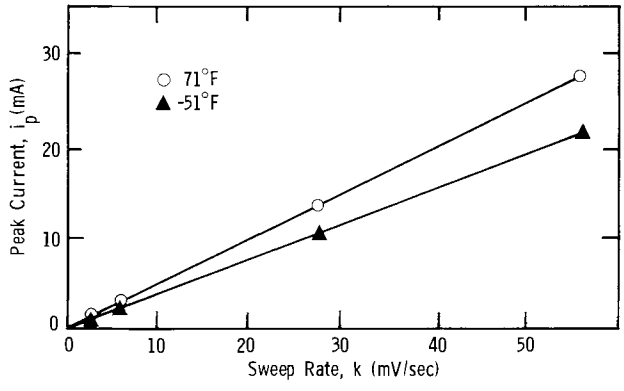

Fig. 7. Effect of sweep rate on peak current (region *d*)

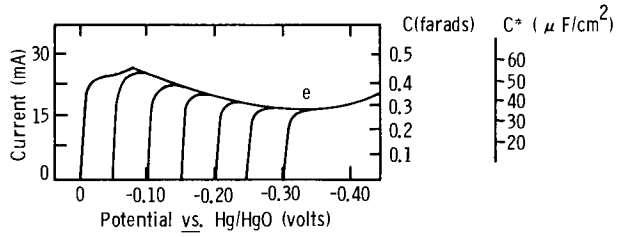

Fig. 8. Plot of capacity *vs.* potential for porous Ag in KOH at 71°F.

at *e*, before starting to increase again; the capacity based on a BET area varies from a peak value of 55 μF/cm² at −0.07V to a minimum value of 35 μF/cm² at about −0.33V. This is in reasonable agreement with results found in the literature for solid silver. It was found that capacities for solid Ag in 1*N* Na_2SO_4 ranged from 45 to 58 μF/cm² (7) and in 30 w/o KOH varied from 36 to 49 μF/cm² (10).

Low-temperature effects.—The theory predicts that, in the absence of faradaic current, distributed capacity effects will give rise to behavior illustrated in Fig. 2, where the upsweep and downsweep results are predicted using Eq. [2] and [5], respectively. The room temperature results in Fig. 5A, 5B, and 5C predicted the upsweep results quite well, but the downsweep results could not be easily checked because of interference by i_p in region *d*. To test the model, measurements were performed entirely in a region of minimum DLC (region *e*) by using a smaller potential excursion of 50 mV. Also, the test temperature was −51°F, where the specific resistance of the electrolyte was 19/1.9 = 10 times greater than that at room temperature, thus making the distributed capacity effects more severe.

Except for $k = 20$ mV/sec, $\rho = 19$ ohm-cm (see Fig. 4), and $C = 0.20$ farads (obtained experimentally), all of the parameters used in Eq. [2] and [5] were the same as before, including $\lambda = 2$. The predicted *vs.* experimental results are shown in Fig. 9. The agreement is seen to be good.

The results also indicate that the capacity of Ag decreases with temperature; in the region of minimum DLC, the capacity has a value of 0.20 farads or 21 μF/cm² (based on BET area) compared to a value of about 35 μF/cm² at room temperature.

Summary and Conclusions

With porous silver electrodes, distributed reactions in the absence of faradaic currents give rise to electrode behavior which is complex, but which can be quantitatively treated using a mathematical model previously developed (2, 3). Experimental results obtained with porous Ag in KOH agreed well with predicted values at temperatures between 71° and −51°F. The model considers the thickness, porosity, labyrinth, and tortuosity factors of the porous electrode, the distance be-

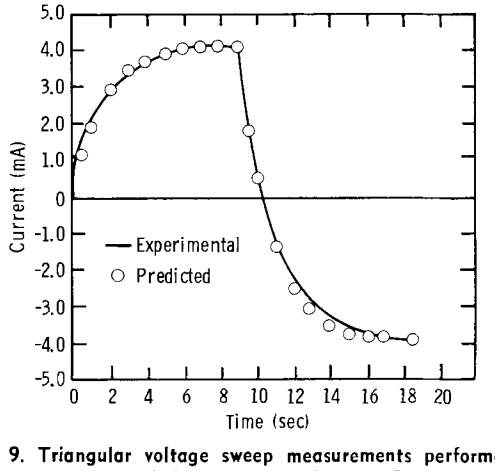

Fig. 9. Triangular voltage sweep measurements performed in a region of constant DLC (region e, Fig. 8) at −51°F.

tween the surface of the test electrode and the tip of the Luggin capillary, and the resistivity of the electrolyte in the pores of the porous electrode.

The capacity of porous Ag was potential dependent, and the values ranged from a peak value of 55 μF/cm^2 at -0.07V to a minimum value of 35 μF/cm^2 at about -0.33V. At -51°F, the capacity in the region of minimum DLC was found to be about 21 μF/cm^2.

The model enables one to select the proper experimental conditions to determine DLC free from distributed capacity effects.

Anodic Polarization Study of Mild Steel in NaCl Solution During Electrochemical Machining

Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A current interruption technique was used to study the anode potential of mild steel during electrochemical machining (ECM) in NaCl solution. The results show that in the turbulent region the iron dissolution process is not affected by flow rate, but is influenced by NaCl concentration. Anodic film effects were observed when the electrolyte flow is in the transition region.

Since 1959, when the first commercially available electrochemical machining (ECM) device was announced (1), considerable effort has been expended in studying this process. However, because of experimental difficulty, a meaningful anodic polarization study under actual ECM conditions is still lacking. Anode potentials of iron dissolution in NaCl at current densities less than 8 A/cm^2 have been determined by extrapolating the distance between the working and the reference electrode to zero (2). Landolt, Muller, and Tobias (3) used a galvanostatic-pulse method to study high-rate dissolution of copper. The results concerning active dissolution at current densities between 0.01 and 100 A/cm^2 were analyzed. Recently, Landolt (4) measured both anode and cathode potentials during ECM of nickel at current densities up to 15 A/cm^2 using a current interruption technique.

In this work, a current interruption technique was employed to study the anode potentials during ECM of mild steel in NaCl solutions at current densities from 5 to 100 A/cm^2.

Experimental

Flow cell apparatus.—The ECM experiments were carried out in an electrochemical cell operated at controlled fluid dynamic conditions. The flow cell apparatus is shown in Fig. 1. The electrolyte was continuously circulated by means of a stainless steel turbine pump. The pump was electrically insulated from the motor to avoid a complicated grounding system for the cell. The electrolyte flow rate was measured by a stainless steel rotameter. Stainless steel diaphragm pressure gauges were employed to measure the electrolyte pressures at various positions. All pipes, fittings, and valves were made of either stainless steel or PVC. The electrolyte reservoir had a capacity of 8 liters and was made of acrylic sheet.

The electrochemical cell consisted of a rectangular electrolyte flow channel 0.0508 cm deep (the distance between the two electrodes)[1] $\times$ 0.714 cm wide $\times$ 16.5 cm long formed between two acrylic plates. The cell was sealed by means of O-rings and toggle clamps. The rectangular mild steel[2] anode and the brass cathode 0.0635 cm (in the flow direction) $\times$ 0.254 cm, was cast into an epoxy cylinder 0.635 cm in diameter. The electrodes were located 14 cm, or 148 hydraulic diameters,[3] from the inlet of the cell to provide fully developed velocity profiles at the electrodes (5). Teflon fittings were used for the purpose of sealing and positioning the electrodes. The reference electrode compartments were connected to the cell through capillary holes (0.0254 cm diameter) which were positioned near and upstream from the electrodes. A calomel reference electrode saturated with NaCl was used to measure the anode potential. In the present work, the cathode potential was not measured.

The mild steel (or brass) electrode was degreased, washed, and dried before it was cast into the epoxy cylinder. The electrode was polished with a 600-grit wet grinding paper and, before a run, it was treated with 6*N* HCl for 30 sec followed by rinsing with distilled water. Reagent grade NaCl and distilled water were used to prepare the solutions. The electrolyte was frequently changed to avoid any accumulation of sludge. Experiments were conducted at 26° ± 2°C.

Polarization measurements.—A current interruption technique was used to measure the *IR*-free anodic potential. Figure 2 shows the electrical circuit for the measurements. A constant current was applied to the cell by a Sorensen DCR 150-5A constant voltage/constant current d-c power supply. Before the circuit was closed, the current passed through a variable resistor with a resistance comparable to that of the cell. A Weston milliammeter (Model 901) or ammeter (Model 931) was used to measure the current. A Clare HGS5018 mercury-wetted contact relay was employed to control the cell circuit. The changes of the anode potential and the cell current were observed on a Tektronix 555 dual-beam oscilloscope with

Type G preamplifiers and a time scale of 20 μsec/cm, and were recorded on photographic film. The current, measured by the voltage drop across a precision 1 ohm resistance, was interrupted after it had passed through the cell for 0.6-2.0 sec, depending upon the current density used.[4] The photographic picture was enlarged ten times to determine the initial slope (dV/dt) of the anodic decay curve after the current was interrupted. The IR potential drop between the anode and the reference electrode was determined by linear extrapolation of the decay curve to zero time ($t = 0$) since the drop is assumed to be instantaneous.

[4] By using a different trigger mode and slower oscilloscope time scale, it was found that, in the present system, a steady state was reached in less than 0.5 sec.

Results and Discussion

Figure 3 shows typical experimental results. Curve a represents the change of the anode potential due to the current interruption. The current transient is given by curve c. From curve c, it was noted that there was a slight decrease in the current before it was completely interrupted. This may result from a higher resistance of the relay due to the presence of a thin mercury filament. Various power supplies and relays have been tested for this work. So far, the

present combination provided the best results. In this report, the experimental data are analyzed using the steady-state currents and the small changes in current before interruption are neglected.

All data presented in this report represent average values of two or more runs. The maximum difference between the results of different runs is less than 10%.

Figure 4 shows the *IR* potential drops measured in the present cell in 4M NaCl at Re = 15,500[5] (flow velocity u = 2000 cm/sec) and in 2M NaCl at Re = 18,800 (u = 2000 cm/sec). The solid straight lines which pass through the zero point were determined by the method of least squares. Since the ratio of the two slopes (or apparent resistances), 0.0335/0.0241 = 1.39, is comparable to the ratio of the resistivities of the solutions, ρ (2M NaCl)/ρ(4M NaCl) = 6.69/4.37 = 1.53 (6), it is believed that the *IR* drop determinations made in this work are reasonably accurate. Similar results were obtained at different flow rates.

If one assumes that at the beginning of the open-circuit transient the electrode self-discharge process has the same rate as that corresponding to the steady-state current density (7, 8), then the double layer capacitance, C, can be determined by

$$C = -\frac{i}{(dV/dt)|_{t=0}} \qquad [1]$$

where i is the steady-state current density before the current interruption. Based on Eq. [1], it is observed that in the present system the capacitance does not vary with current density and average values are C = 73.4 ± 7.7 μF/cm² in 4M NaCl at Re = 15,500 and C = 49.4 ± 4.8 μF/cm² in 2M NaCl at Re = 18,800.

The *IR*-free anode potentials measured in 2 and 4M NaCl solutions at the flow rates mentioned above are shown in Fig. 5. Apparently, the anode potential is linearly related to the current density. The straight lines in Fig. 5 were drawn using the method of least squares. In 4M NaCl, the polarization data can be represented by two straight lines with slopes of 0.042 ohm-cm² from 5 to 22.5 A/cm², and 0.0665 ohm-cm², from 22.5 to 100 A/cm². In the case of 2M NaCl, a single straight line with slope of 0.0839 ohm-cm² is used to fit all the data. Experiments were also carried out in 2 and 4M NaCl solutions at Re = 4700 (u = 500 cm/sec for 2M NaCl and u = 600 cm/sec for 4M NaCl); the results are similar to those obtained at higher flow rates.

[5] Re represents the Reynolds number which is defined as the hydraulic diameter × flow velocity/kinematic viscosity.

Electrochemical machining of mild steel in NaCl solutions has been studied using a closed cell system (9). It was found that the anodic current is mainly consumed in iron dissolution ($Fe \rightarrow Fe^{++} + 2e$) although there is a slight decrease in current efficiency as the current density increases. Based on the results of this study, it is suggested that in the turbulent flow region (say Re > 4700), the ECM iron dissolution process in NaCl solutions is not affected by the electrolyte flow, but is influenced by NaCl concentration. It should be pointed out that the measured potentials shown in Fig. 5 bear no resemblance to common electrode potentials of a single interface. At the present time, there is no evidence which explains the linearity of the relationships between the *IR*-free anode potential and the current density under ECM conditions. However, it has been suggested (10) that during ECM the process of transfer of ions in the layer near the anode under the influence of a strong electric field is perhaps important; an activation control is not likely because of such high overpotentials. The dependence of potential on electrolyte concentration seems to reflect the change in conductivity of the solution.

In Fig. 5, the broken line shows the results obtained with 4M NaCl at Re = 3100 (u = 400 cm/sec). The anode potentials are apparently higher than those found at the higher flow rate, and a linear relationship between the *IR*-free potential and the current density is not observed. It was also noticed that at this low flow rate the data were less reproducible than at higher flow rates. This change in potential behavior may be caused by the presence of an anodic film resulting from the precipitation of the anode product (11) which, in turn, was caused by the reduction of the flow rate to a value in the turbulent/laminar transition region (12). By studying the surface finish, it was found that the surface obtained at R = 3100 (Fig. 6B) is brighter than that obtained at Re = 15,500 (Fig. 6A), both at 75 A/cm².

It is of interest to note that at this low flow rate (Re = 3100) the anodic potential always exhibited an arrest after the initial rapid decay (Fig. 7A). Such an arrest may be caused by the presence of an anodic film. Compared with the result at Re = 15,500 (Fig. 7B), the arrest potential at Re = 3100 is significantly higher. The difference between the two arrest potentials was found to be proportional to the difference between the two *IR*-free anode potentials which are shown in Fig. 5.

During ECM of steel in 4M NaCl at Re = 15,500, no arrest was observed at current densities lower than

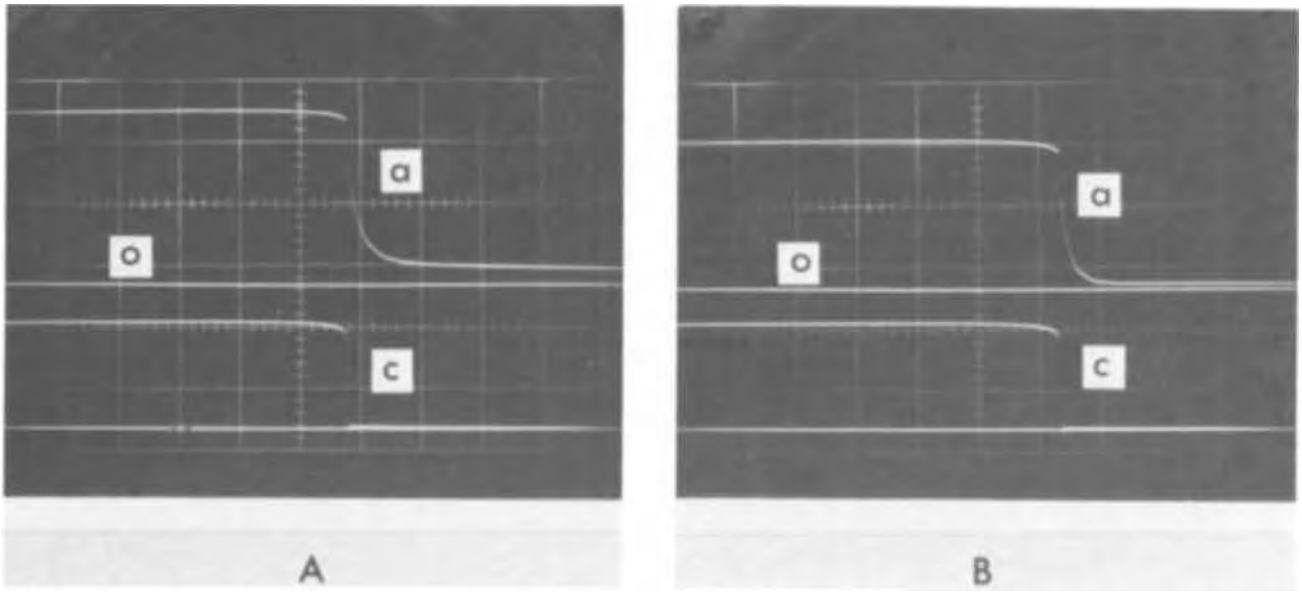

Fig. 7. Anodic potential decay in 4M NaCl at 50 A/cm². A, Re = 3100; B, Re = 15,500; time scale, 20 μsec/div; curve a, anodic potential transient, 2 V/div; curve o, open-circuit potential; curve c, current transient, 0.5 V/div.

25 A/cm², and the arrest potential becomes higher as the current density increases above 25 A/cm². This indicates that the change of the slope of the polarization curve shown in Fig. 5 may be caused by an anodic film. Figure 6C shows that the surface obtained at 10 A/cm² is sponge-like,[6] and is less smooth than that obtained at 75 A/cm² (Fig. 6A). The sponge-like surface is believed to be caused by a high rate of etching process. In the case of ECM in 2M NaCl at Re = 18,800, the arrest potential is significantly lower and, in most cases, is not observed. Hence, the anodic film effect is not significant, and the polarization curve can be represented by a straight line (Fig. 5). Figure 6D shows that the surface obtained in 2M NaCl at 75 A/cm² is still etched and is rougher than that obtained in 4M NaCl at the same current density (Fig. 6A).

From the above discussion it is apparent that during ECM of mild steel in NaCl solutions the presence of an anodic film, which can affect the surface finish, is influenced by the current density, the electrolyte flow rate, and the concentration. However, once in the turbulent region (Re > 4700) the flow rate has little effect on the anodic film. The *IR*-free anode potential is linearly related to the current density, and the iron dissolution process is mainly affected by NaCl concentration.

[6] By x-ray fluorescence analysis the white particles seen protruding from the surface in Fig. 6C and 6D were found to be rich in manganese.

Natural Convection Within Porous Electrodes During Electrolysis

Richard Alkire* and Roman Plichta**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Depletion of reactive solute species from interior regions of a porous electrode during electrolysis can result in a density difference between the electrolyte within the porous electrode and the bulk solution. The density difference which may thus arise can in some cases provide the driving force necessary for natural convection flow of electrolyte through the porous electrode. A one-dimensional steady-state theoretical model has been developed to investigate system conditions under which density-driven flows may be anticipated and to what extent these flows can enhance reaction rates. Calculations were conducted for three aqueous electrolyte systems: potassium hydroxide, sulfuric acid, and copper sulfate in excess sulfuric acid. The theoretical results predict conditions under which volumetric reaction rates may be increased significantly by the occurrence of natural convection. The results indicate that double-porosity high-rate porous electrodes may be designed within which electrochemical reaction would occur primarily in the fine, high surface area, pores while natural convection of electrolyte would take place in the larger pore structure.

The widespread usage of porous electrodes has come about in order to achieve large reaction rates per unit volume. Although the interfacial surface area of porous electrodes can be exceedingly large, a number of dilemmas arise in the design of these systems. For example, upper limitations on the effectiveness of the large reactive surface can be encountered, such as through ohmic resistance of the electrolyte in the pores, or through mass transfer limitations on the supply of reactants to the porous region. In the latter case of mass transport limitations, it seems clear that convection of reactants into the porous electrode is superior to diffusion as a mode of supply. Many practical systems, however, cannot afford the price or weight of a pumping system. The following investigation evaluates conditions under which mass-transport limitations may be substantially relieved by the occurrence of natural convection flow within porous electrodes during electrolysis.

The porous electrode structure consists of a connected matrix of electrically conductive solid material interspersed with connected pores totally filled with electrolyte. Electrode reactions take place within this porous matrix. Species may be removed or supplied to the porous region either by mass transport or by generation (or consumption) of species owing to reaction. When the availability of reactive species is hindered by slow transport in the electrolyte within the pore, concentration gradients arise during extended electrolysis. As a result of these concentration gradients, density gradients may occur within the electrode. Hydrodynamic instabilities may thus ensue so that electrolyte from the bulk would enter the pore, sweeping with it "fresh" reacting species. Natural convection would render the concentrations within the pore more uniform than would be observed under pure diffusion operation.

Key words: porous electrode, natural convection, mathematical model.

Natural convection owing to density differences has received widespread attention. Previous investigations indicate that the nature of the fluid motion depends strongly on the orientation of the reactive solid surface which bounds the fluid undergoing convection. Near vertical surfaces, the fluid motion takes on a boundary layer type of structure while near horizontal surfaces, the flow is usually cellular in nature and can exhibit multiple steady states (1-7). Multi-dimensional natural convection within an inert porous media has also received attention, both near vertical and horizontal solid reactive surfaces (8-10). The study presented below differs from previous studies in that the porous electrode, throughout which natural convection of electrolyte takes place, is reactive and thus contributes to the densification process. Moreover, the fluid passes through the electrode and returns to the upstream face through an external path.

The purpose of this work is to develop a theoretical basis for predicting the effect on electrode behavior of natural convection flow within the porous media, and to evaluate conditions under which operation of diffusion-limited porous electrodes may be enhanced by the occurrence of these flows.

Mathematical Development

A schematic diagram of the porous electrode system under consideration is shown in Fig. 1. The porous electrode is completely flooded with liquid electrolyte, and the reactive species diffuse into the porous region from both sides of the electrode. There is no mass transport resistance external to the porous electrode. Further, the porous electrode is positioned in a large well-stirred bath whose composition changes by negligible amounts during the period of electrolysis. Thus the solute concentration is the same on either side of the porous electrode and remains constant during the duration of electrolysis. Additional details of the cell geometry have not been included in the figure since they do not enter into this simple analysis of natural convection effects. The counterelectrode may be positioned either above or below the porous electrode; current does not flow around the sides of the porous electrode and enter from the rear. Figure 1 illustrates two possible situations for the case where the counterelectrode is above the porous electrode. If, owing to density changes during electrolysis, the fluid within the porous electrode becomes lighter than the bulk electrolyte, convective flow will tend to occur toward the counterelectrode as indicated in Fig. 1A. If, on the other hand, electrolyte within the porous electrode becomes heavier than the bulk solution, convection away from the counterelectrode will tend to occur as shown in Fig. 1B. Similar diagrams could be drawn for the situation where the counterelectrode is below the porous electrode.

Since rigorous calculations are not justifiable for a preliminary evaluation of natural convection effects, the following assumptions have been introduced:

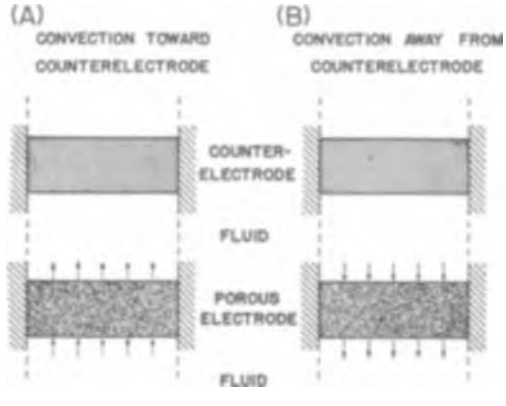

Fig. 1. Electrolysis cell configuration for natural convective flow in porous electrodes.

1. The pore structure is uniform and is sufficiently fine that the electrode behaves in a one-dimensional manner. The porous electrode is isopotential and isothermal; no appreciable structural changes of the solid phase occur during operation.
2. The electrolyte is sufficiently dilute that the transport parameters are constant, and activities can be replaced by concentrations. Diffusion resistances external to the porous electrode are negligible.
3. Density differences in the fluid are important only in the buoyancy effect which is the sole driving force for convection. Hydrodynamic motion occurs in plug flow and encounters resistance to flow only within the porous electrode.
4. A single electrochemical reaction occurs which obeys the Butler-Volmer rate equation.
5. Operation in the steady state prevails.

The preceding assumptions have been chosen in order to focus attention squarely on the influence of one type of natural convection on porous electrode behavior.

The region representing the porous electrode extends from $y = 0$, near the counterelectrode, to $y = L$, far from the counterelectrode. Within this region electrochemical reaction occurs with the stoichiometric form

$$\sum_i \nu_i M_i^{z_i} = ne^- \qquad [1]$$

The movement of solute species in the electrolyte occurs by diffusion, migration, and convection

$$N_i = -D_i \nabla c_i - z_i u_i c_i \mathbf{F} \nabla \phi + v c_i \qquad [2]$$

Under steady-state operation, a material balance for each solute species yields

$$\frac{dN_i}{dy} = -\frac{A\nu_i}{n\mathbf{F}} j \qquad [3]$$

where j is the local reaction rate for species i, given by the Butler-Volmer rate equation

$$j = i_o \left[\frac{c_a}{c_a^o} e^{-\frac{\alpha n\mathbf{F}(\phi - \phi_e)}{RT}} - \frac{c_c}{c_c^o} e^{\frac{(1-\alpha) n\mathbf{F}(\phi - \phi_e)}{RT}} \right] \qquad [4]$$

With use of the Nernst-Einstein equation

$$u_i = \frac{D_i}{RT} \qquad [5]$$

one may combine Eq. [2], [3], and [4] to find

$$D_i \frac{d^2 c_i}{dy^2} + \frac{z_i D_i \mathbf{F}}{RT} \frac{d}{dy}\left(c_i \frac{d\phi}{dy} \right) - v \frac{dc_i}{dy} = \frac{A\nu_i i_o}{n\mathbf{F}} \left[\frac{c_a}{c_a^o} e^{\frac{-\alpha n\mathbf{F}(\phi - \phi_e)}{RT}} - \frac{c_c}{c_c^o} e^{\frac{(1-\alpha) n\mathbf{F}(\phi - \phi_e)}{RT}} \right] \qquad [6]$$

Equation [6] states that solute species within the porous electrode move about owing to diffusion, migration, convection, and electrochemical reaction. The potential ϕ represents the potential in the solution phase under the prevailing (local) concentration, while ϕ_e represents the potential in the solution that would be observed under equilibrium conditions at bulk concentration. The potential ϕ therefore includes both concentration and activation overpotential.

The movement of charged solute species is restricted in accord with the requirement of electroneutrality

$$\sum_i z_i c_i = 0 \qquad [7]$$

The convective velocity within the porous electrode is based on an empirical balance between buoyancy

forces and viscous forces encountered during flow through packed beds (11), as derived in the Appendix

$$v = 0.24 \frac{g_c \epsilon r_H^2}{\mu} \Delta\rho \qquad [8]$$

The density driving force, $\Delta\rho$, is the difference between the density of the bulk electrolyte and the average density of the electrolyte within the porous region as determined from the solute concentration distributions (12).

Equations [6], [7], and [8] are sufficient in number for determining the velocity, potential, and solute concentrations throughout the electrode provided that sufficient boundary conditions are provided. At the external surface near the counterelectrode ($y = 0$) the potential and solute concentrations have known values

$$c_i = c_i^o$$
$$\phi = \phi_a \qquad [9]$$

At the rear surface ($y = L$) the concentrations have known values and the current density in the solution is zero

$$c_i = c_i^o$$
$$-F^2 \frac{d\phi}{dy} \sum_i z_i^2 u_i c_i - F \sum_i z_i D_i \frac{dc_i}{dy} = 0 \qquad [10]$$

Analysis of the foregoing set of equations is rendered more convenient if the variables are transformed to dimensionless quantities by defining

$$Y = \frac{y}{L}$$
$$C_i = \frac{c_i}{c_r}$$
$$\Phi = \frac{F}{RT}(\phi - \phi_e)$$
$$V = \frac{vL}{D_r}$$
$$J = \frac{jAL^2}{nFc_rD_r} \qquad [11]$$

Equations [6], [7], and [8], which serve to define the model, then take the forms

$$\pi_i \frac{d^2C_i}{dY^2} + z_i\pi_i \frac{d}{dY}\left(C_i \frac{d\Phi}{dY} \right) - V\frac{dC_i}{dY} = \nu_i\xi \left[\frac{C_a}{\gamma_a} e^{-\alpha n\Phi} - \frac{C_c}{\gamma_c} e^{(1-\alpha)n\Phi} \right] \qquad [12]$$

$$\sum_i z_i C_i = 0 \qquad [13]$$

$$V = 0.24\zeta \frac{\Delta\rho}{\rho} \qquad [14]$$

Upon transformation to dimensionless form, boundary conditions [9] and [10] become

at $Y = 0$: $C_i = \gamma_i$, $\Phi = \Phi_a$

at $Y = 1$: $C_i = \gamma_i$

$$\sum_i \left(z_i\pi_i C_i \frac{d\Phi}{dY} + z_i\pi_i \frac{dC_i}{dY} \right) = 0 \qquad [15]$$

The dimensionless parameters which appear in the foregoing model are

$$\xi = \frac{i_o AL^2}{nFc_rD_r}$$
$$\zeta = \frac{r_h^2 g_c \epsilon \rho L}{\mu D_r}$$
$$\gamma_i = \frac{c_i^o}{c_r}$$
$$\pi_i = \frac{D_i}{D_r} \qquad [16]$$

The two most important parameters which arise from the analysis are ξ and ζ. The quantity ξ denotes the ratio of diffusion resistance to charge-transfer resistance insofar as it contains the ratio i_o/D_r. The absolute value of the parameter ζ denotes the ease with which fluid can pass through a porous bed under a given hydrostatic head. The sign of ζ depends on both the cell geometry and the direction of flow as indicated in Table I. The role which these two parameters play in determining electrode behavior will be discussed carefully in the results which follow.

Once the potential and concentration distributions are determined, the local reaction rate may be calculated from the dimensionless form of Eq. [4]

$$\beta J = \xi \left(\frac{C_a}{\gamma_a} e^{-\alpha n\Phi} - \frac{C_c}{\gamma_c} e^{(1-\alpha)n\Phi} \right) \qquad [17]$$

where

$$\beta = \frac{i^* L}{nFc_rD_r}$$
$$J = \frac{ALj}{i^*}$$

Method of Solution

The central problem in the calculational procedure was that the convective velocity can be determined only if the concentration profiles are known, while the concentrations can be calculated only if the convective velocity is known. An iterative procedure was therefore utilized in order to converge on a solution. First, Eq. [12] and [13] were solved simultaneously with the convective velocity arbitrarily set equal to zero. Based on these results, the average density of the solution within the porous electrode was calculated (12) and a new estimate of the convective velocity was obtained by Eq. [14]. With use of the revised velocity, new calculations of concentrations and potential were obtained by solving Eq. [12] and [13]. Once again, the concentration distributions were used to generate a buoyancy force and thereby to obtain a new estimate of the velocity. The procedure was repeated until two successive calculations of convective velocity agreed within 0.001 dimensionless velocity units. The typical number of "outer loops" required for velocity convergence was seven.

At each stage in the iterative process, it was necessary to solve the nonlinear conservation equations along with the electroneutrality condition. These coupled equations were first linearized about an approximate solution and then put into finite difference form. The resulting set of tridiagonal matrices was inverted with the use of a computer-implemented numerical technique (13). The solution of the nonlinear problem was then obtained by iteration of the approximate solution. Convergence on the solution of the nonlinear problem was defined by the criterion that

Table I. Interpretation of the sign of ζ

two successive calculations of the potential in the solution with the convective velocity set equal to zero, agreed to within 0.01%. In typical cases, four iterations were usually sufficient. It was found that equally spaced mesh points of size $\Delta y = 0.01$ gave results which were essentially independent of mesh spacing. The calculations were conducted with an IBM 360 computer. A single calculation typically took 4000 centiseconds of processor time and cost $1.20 per run.

Results

Calculations have been conducted in order to illustrate conditions under which natural convection effects may be anticipated. Three types of electrochemical systems have been considered:

(a) Cathodic deposition of copper from an acidified sulfate electrolyte, a system for which the physical properties are known with accuracy, has the electrode reaction

$$Cu^{++} + 2e^- = Cu \qquad [18]$$

(b) Anodic operation of a secondary battery electrode with sulfuric acid electrolyte has the reaction

$$M + SO_4^= = MSO_4 + 2e^- \qquad [19]$$

(c) Anodic operation of a secondary battery electrode with potassium hydroxide electrolyte has the reaction

$$M + 2\,OH^- = M(OH)_2 + 2e^- \qquad [20]$$

The dimensionless parameters which have been used in describing these three systems, shown in Table II, should permit evaluation of a wide variety of actual systems.

Consider first the acidified copper sulfate system. In the complete absence of convection ($\zeta = 0$), the steady-state current distribution depends primarily on the parameter ξ as illustrated in Fig. 2. For electrode reactions having large exchange current densities (large ξ), reactant species are consumed primarily near the pore entrance so that the reaction rate distribution is highly nonuniform. Even though the counterelectrode is positioned on only one side of the porous electrode (toward the left of Fig. 2), the reaction distribution is nearly symmetric about $Y = 0.5$ since ohmic losses in the solution phase are small with respect to the concentration overpotentials which arise. For reactions having low exchange current densities (low ξ), current tends to be transferred more uniformly throughout the pore since diffusional limitations are less severe.

The results given in Fig. 2 will be altered when natural convection occurs. Of course, the convection effect will depend on the orientation of the system with respect to the gravitational field. For the cathodic copper reaction, flow of the copper-depleted solution occurs in the upward direction. In accord with Table I, positive values of ζ therefore imply that the counterelectrode is below the porous electrode so that flow is directed away from the counterelectrode. Conversely, negative values of ζ indicate that the counterelectrode is above the porous electrode and flow is toward the counterelectrode. Figure 3 illustrates the cupric ion distribution throughout the porous electrode for various values of ζ. For the value $\zeta = 0$, the concentration

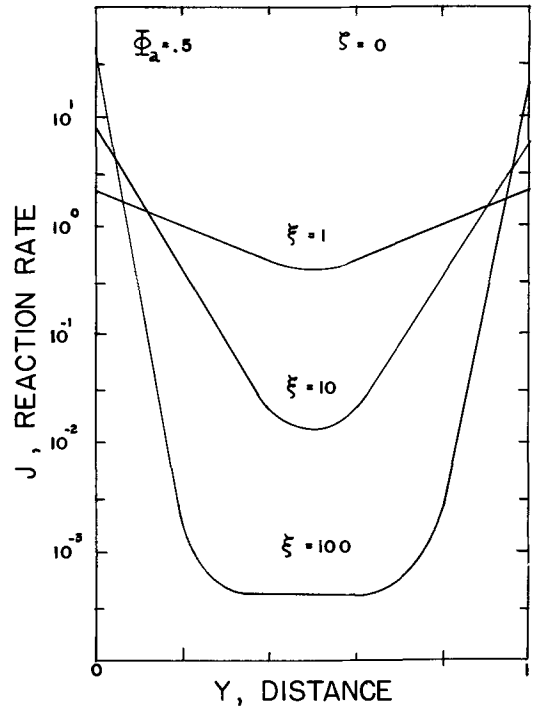

Fig. 2. Current density distributions for various values of ξ, acidified copper sulfate electrolyte.

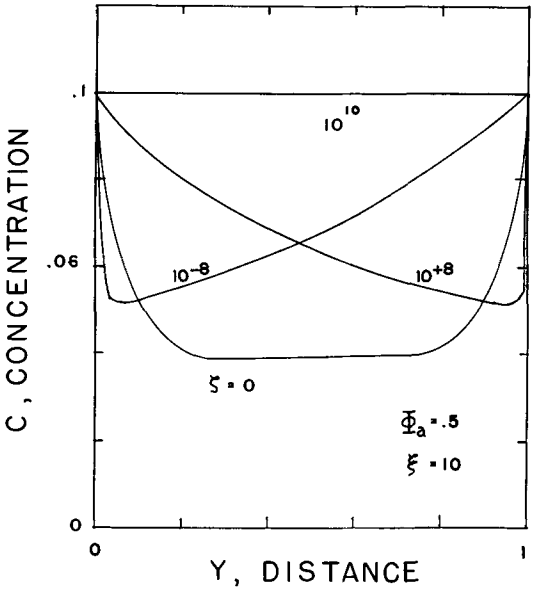

Fig. 3. Concentration distribution of cupric ions during natural convection with several values of ζ.

distribution corresponds to the results of Fig. 2. For positive values of ζ, the convective flow sweeps the cupric ions downstream, away from the counterelectrode, thereby shifting the minimum concentration toward the back of the electrode. "Fresh" electrolyte is swept in the upstream side, nearest the counterelectrode, and thereby increases the concentration of reactive species in that region. With sufficiently large values of ζ, the concentration distribution becomes nearly uniform; that is, only negligible concentration differences are sufficient to overcome viscous resistance and thus cause convective flow. For negative values of ζ, flow is directed toward the counterelectrode so that the minimum in the concentration distribution shifts toward $Y = 0$.

The effect of convection on the current distribution is illustrated in Fig. 4 for flow away from the counterelectrode. As ζ increases, the reaction rate distribution becomes more uniform since concentration overpoten-

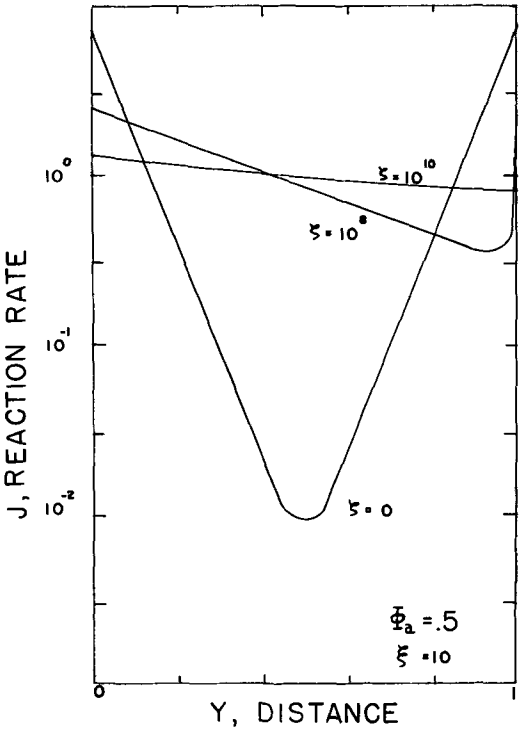

Fig. 4. Dependence of current density distribution on convective flow rate in acidified copper sulfate electrolyte.

tial restrictions are relieved. For extremely large values of ζ (negligible concentration overpotential), activation overpotential tends to force the current deeper into the electrode so that the reaction distribution is nearly uniform.

For the acid copper sulfate system, Fig. 5 gives two sets of current-potential curves which correspond to the complete absence of concentration gradients ($\zeta = \infty$), and to the complete absence of natural convection ($\zeta = 0$). These two sets of curves provide the boundaries within which natural convection can enhance current output. For example when $\Phi = 2.5$ and $\xi = 1$, the diffusion-restricted current (lower graph) has the value $\beta = -2$; it is seen from the upper graph that the value $\beta = -16$ could be obtained if concentration gradients would be relieved. For this example, natural convection could be expected to increase the diffusion-restricted current by a factor of $\Psi = -16/(-2) = 8$. For $\Phi_a = 2.5$ and $\xi = 100$, the convective effect could increase total current by a factor of $\Psi = -250/(-20) = 12.5$. The ratio Ψ is called the enhancement factor

$$\Psi = \frac{\beta_{\text{with convection}}}{\beta_{\text{diffusion restricted}}} \qquad [21]$$

The compilation of many calculations is provided in Fig. 6 for the acid copper sulfate system. The effect of Φ_a and ζ on the enhancement factor is shown for two values of ξ. It is seen that enhancement of performance is to be expected when Φ_a and ξ are large (large applied potentials, diffusion restricted operation) and when ζ is large (low resistance to flow). When Φ_a and ξ have small values, electrode operation is not diffusion controlled so that concentration gradients do not arise. When ζ has a small value, the viscous resistance to flow is so high that convection is impeded. It is also seen that the enhancement factor increases from unity to an upper value over a range of ζ which is about two orders of magnitude wide.

It was found that under identical conditions of operation, convection away from the counterelectrode resulted in a larger total current than convection toward the counterelectrode. With flow away from the counterelectrode, fresh reactants are swept into the highly reactive zone nearest the counterelectrode. When flow is in the opposite direction, on the other hand, reactants tend to be somewhat depleted by the time the solution reaches the (downstream) regions near the counterelectrode; that is, the electrode regions near the counterelectrode suffer concentration overpotential so that the total current is less. Under the conditions $\Phi_a = -5$, and $\xi = 100$, flow away from the counterelectrode yielded β values of 619, 715, and 791 for $\zeta = 10^3$, 10^4, and 10^5, respectively. Under the identical conditions but with flow toward the counterelectrode (negative ζ), β took on the values 571, 624,

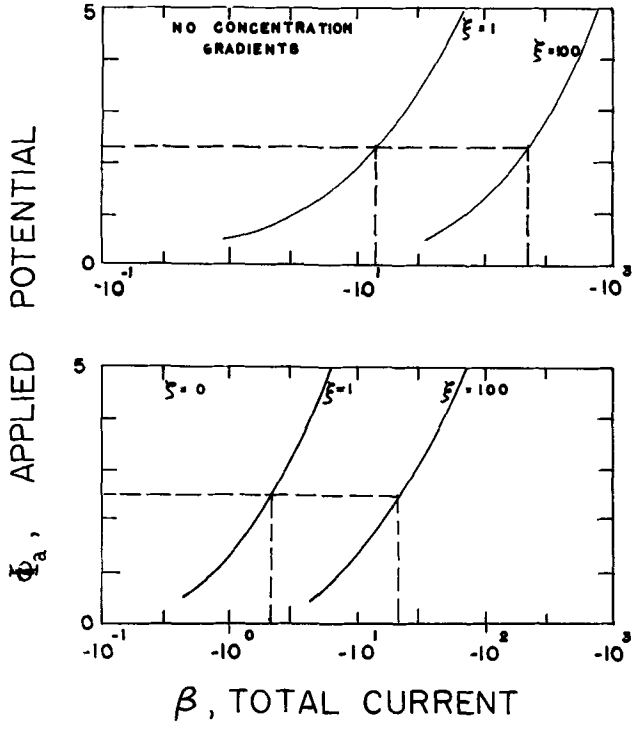

Fig. 5. Predicted current-potential behavior for the acidified copper sulfate system. Lower graph, diffusion-limited operation; upper graph, operation without diffusion restriction.

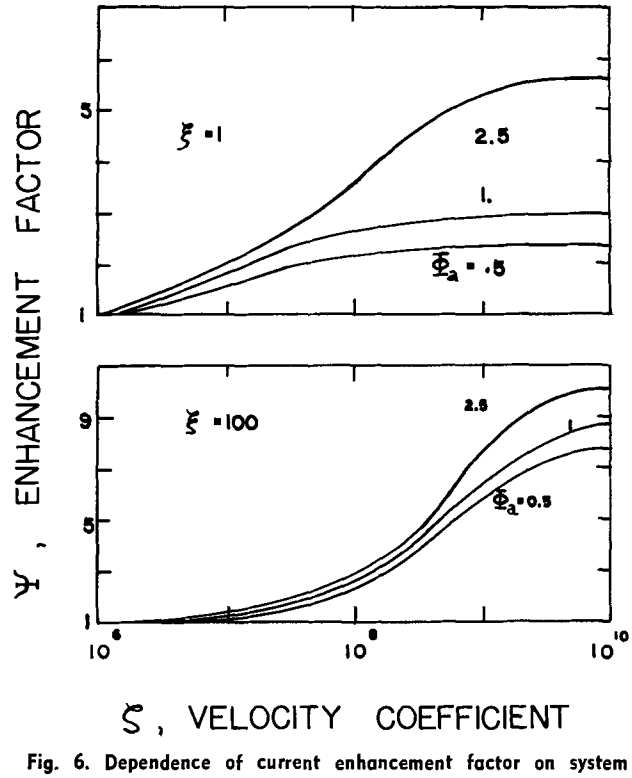

Fig. 6. Dependence of current enhancement factor on system parameters for acidified copper sulfate system.

and 757. That is, for flow toward the counterelectrode, the current was 92, 87, and 95% of the current for flow away from the counterelectrode with $\zeta = 10^3$, 10^4, and 10^5, respectively. For the range of parameters considered in this work it was found that the maximum effect of flow direction on total current was less than 5% for $\xi = 1$, and ranged between 10 and 30% for $\xi = 100$. All enhancement factor data reported in this study are for positive ζ and therefore represent the maximum enhancement with respect to flow direction. From these results it is recognized that direction of convective flow is inconsequential both for low values of ζ (no appreciable convection) and for high values of ζ (no appreciable concentration variation). However, for intermediate values of ζ, corresponding to the inflection points in Fig. 6, the direction of flow may influence electrode behavior significantly.

Let us apply the foregoing results to a copper sulfate system consisting of an electrode of thickness 5 mm and specific surface area of 775 cm^2/cm^3 void volume. Since $n = 2$ g-equiv./g-mole, $\mathbf{F} = 96{,}500$ coul/g-equiv., $D_r = 10^{-5}$ cm^2/sec, $c_r = 10^{-3}$ g-mole/cm^3, and $i_0 = 10^{-3}$ A/cm^2, one finds $\xi = 100$. Now proceed to calculate how large the pores would need to be in order that natural convection occur to an appreciable extent. Under an applied potential of 62.5 mV ($\Phi_a = 2.5$), Fig. 6 indicates that a three-fold enhancement of total current would be observed if the parameter ζ has the value 10^8. For an electrode of 35% porosity, $\mu = 1.3 \times 10^{-2}$ g/cm sec, $\rho = 1.1$ g/cm^3, one calculates that the hydraulic radius necessary to achieve the desired enhancement is $r_h = 0.0106$ cm. This value is similar to that found in industrial reactors containing, for example, graphitized pellets, but is orders of magnitude larger than the pore structure of present-day batteries.

Figure 7 shows how the current enhancement factor varies with several system parameters for reaction [19], anodic operation with sulfuric acid electrolyte. Although a severalfold enhancement may occur under proper conditions, the enhancement is not nearly so great as may occur for the acidified copper sulfate system. The transference number of the reacting ion is larger in reaction [19] than in reaction [18] with the result that concentration differences tend to be smaller in the binary system. If the transference number of the reacting ion were one, concentration differences would not arise at all. Even though natural convection may occur in the sulfuric acid system, the concentration overpotential tends to be a smaller portion of the total overpotential so that enhancement is limited. Figure 8 provides current enhancement data for reaction [20], anodic operation of a metal in potassium hydroxide. Enhancement of diffusion operation by only 40% may be expected owing primarily to the large transference number of the reacting ion.

Conclusions

The central emphasis in the foregoing development has been in demonstrating operating conditions under which natural convection may arise within porous electrode structures. The predictions of the model are naturally restricted by the suitability of the assumptions which were invoked. In order to deal with specific systems, however, several of the assumptions can be substantially modified without complicating the overall computational method. For example, alternative forms of the reaction rate equation could be employed with ease. Also, flux equations for concentrated electrolytic solutions could be used instead of the dilute solution equations. On the other hand, if the flow resistance of the electrolyte "return loop" is appreciable, more complex modes of natural convection may set in within, or near, the porous electrode which could not be accounted for by simple modification of the present model.

Similarily, different boundary conditions could be investigated. For example, the electrolyte at the downstream exterior face of the porous electrode may not be well-stirred with the result that the concentration there would be the same as that emanating from the porous electrode, but not the same as the bulk solution. Thus by ignoring back-diffusion at the downstream end of the electrode, one would have the condition

$$\frac{dc_1}{dy} = 0 \quad \text{at } y = L \qquad [22]$$

By neglecting diffusion at the downstream end, the use of Eq. [22] would result in greater concentration differences within the porous electrode, thus larger buoyancy forces, than with use of boundary conditions [9] and [10] used in this study. Therefore it may be recognized that the predictions made in this investigation represent conservative estimates of reactivity enhancement by natural convection. That is, mass transfer restrictions external to the porous electrode (not considered in the present model) will always act to increase the natural convection effect above that estimated here.

Enhancement of diffusion-restricted operation by natural convection was found to occur in each system studied. The extent of enhancement was highest for the acidified copper sulfate system and lowest for the potassium hydroxide system. In general, one may conclude that natural convection effects would tend to arise more easily in those systems in which the trans-

ference number of the reacting ion is low. Under identical conditions of operation, larger currents were predicted when the convective flow was directed away from the counterelectrode than toward the counterelectrode.

Although natural convection occurs most readily in electrodes of high permeability, there exists an upper permeability above which further enhancement will not be obtained. On the other hand, efforts directed toward increasing electrode permeability can be generally expected to result in a concomitant lowering of the specific surface area. As a consequence, diffusional restrictions would become reduced, so that the buoyancy driving force for natural convection would be suppressed. One may therefore anticipate the need for careful electrode design in order to achieve a desirable balance between high specific surface area and high permeability.

The foregoing results indicate that attention should be directed toward development of high-rate double porosity battery electrodes within which electrochemical reaction would take place primarily in the fine, high surface-area pores, while natural convection would occur in the larger pore structure. The present theoretical framework could be easily extended toward such double porosity systems.

APPENDIX

The friction factor for flow through a packed bed [Eq. 6.4-1 of Ref. (11)] is defined as

$$f = \frac{D_p (\mathcal{P}_o - \mathcal{P}_L)}{4L(1/2)\rho v_o^2} \qquad [A\text{-}1]$$

where D_p = bed particle diameter, $(\mathcal{P}_o - \mathcal{P}_L)$ = pressure drop across bed, and v_o = superficial velocity of fluid, external to the bed.

Experimental measurements indicate that over the range $(D_{p\rho}\, v_o/\mu)(1 - \epsilon)^{-1} < 10$, the friction factor is

$$f = \frac{(1-\epsilon)^2}{\epsilon^3} \frac{75}{D_{p\rho}\, v_o} \qquad [A\text{-}2]$$

where ϵ = volume of voids per volume of bed.

The pressure difference which leads to flow is due to the difference in density of the fluid within the pores and that outside the pores

$$(\mathcal{P}_o - \mathcal{P}_L) = g_c \epsilon L\, (\rho^{bulk} - \rho^{avg}) \qquad [A\text{-}3]$$

In addition, the particle diameter D_p is related to the hydraulic radius [Eq. 6.4-4, 5, and 6 of Ref. (11)] by

$$D_p = 6 r_h \frac{(1-\epsilon)}{\epsilon} \qquad [A\text{-}5]$$

By combining the four equations, one obtains for the superficial velocity

$$v_o = 0.24 \frac{g_c\, \epsilon^2\, r_h^2}{\mu} \Delta p \qquad [A\text{-}6]$$

The fluid velocity in the interstices is related to the superficial velocity by $v = v_o/\epsilon$.

Technical Notes

Surface Effects in the Measurement of Range Profiles by Oxide Dissolution

D. Phillips and J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

Range profiles in anodic tantalum oxide have recently been surveyed (1) by means of a sectioning technique (2). Originally, radioactive $^{198}Au^+$ was chosen as an example of a very heavy ion implant, but the results proved anomalous; the survey was therefore completed with $^{204}Tl^+$ and $^{222}Rn^+$. The anomaly with $^{198}Au^+$ was however investigated further, with the results described below.

Gold-198 was implanted at 40 keV by means of a mass separator, and the oxide sectioned by slow dissolution in concentrated HF almost saturated with NH_4F, according to the procedure described elsewhere (1, 2). Since the range profile for a species implanted in amorphous tantalum oxide depends only on its mass and energy, the range profile for 40 keV $^{198}Au^+$ was expected to be very similar to those for 40 keV $^{204}Tl^+$ and 40 keV $^{222}Rn^+$. The latter indicated that only about 10% of the initial $^{198}Au^+$ activity should remain after the removal of 200Å of oxide, yet the fraction observed experimentally was over 90%. Since thickness measurements and interference colors both indicated that the oxide was dissolving normally, the only possible conclusion was that the gold was not dissolving in the HF-NH_4F reagent. If it was not dissolving, it could only be present on the surface of the remaining oxide.

To prove this, the oxide was exposed for 30 sec to a reagent, aqua regia, known to dissolve gold, whereupon the activity fell to the expected 10%. (Fig. 1). This interpretation is only valid, however, if the oxide does not itself dissolve in the aqua regia, and this was established in separate experiments. No change (< 5Å) in oxide thickness was detected on prolonged contact, and when the surface layer was labeled with $^{24}Na^+$ implanted at the very low energy of 1 keV, no significant fraction of the activity was lost (1). Continued sectioning in HF-NH_4F, alternating with 30 sec treatments in aqua regia, gave the results shown in Fig. 1, from which it was obvious that the range profile had the expected form.

Integrated range profiles for implanted $^{198}Au^+$ were therefore obtained by means of this two-stage technique, and analyzed as error function complements using the least squares fitting procedure described in Ref. (1). The modal range at 40 keV was found to be 119.5 ± 2Å, and the standard deviation 66.5 ± 0.5Å; the errors quoted are standard errors of the fit, rounded to the nearest 0.5Å. For comparison, the modal range with 40 keV $^{204}Tl^+$ was 109.5 ± 2Å and the standard deviation 59.5 ± 1Å; the agreement is probably as good as can be expected (3). Two range measurements for 5 keV $^{198}Au^+$ gave 33 ± 2Å and 39.5 ± 1.5Å as the modal ranges, and 17 ± 1Å and 21.5 ± 0.5Å as the standard deviations, again in reasonable agreement with the 33 ± 2Å (mode) and 19 ± 1Å (standard deviation) observed with 5 keV $^{204}Tl^+$.

It is clear, therefore, that implanted ^{198}Au exposed by the dissolution of the oxide has a much greater affinity for the retreating oxide surface than for dissolution in the stripping agent. Unless this factor be taken into account, the measured ranges will be spuriously large. Phenomena of this kind have actually been observed with the rather similar sectioning technique for aluminum.

In this technique (4), a thin layer of the metal is converted to oxide via anodic oxidation, and the oxide is then dissolved in a mixture of chromic and phosphoric acids; the metal surface is thus re-exposed, and the process can be repeated. Extensive range profile measurements (5) and channeling studies (6) have been performed with this technique, using alkali metal or noble gas implants, and the results were in all cases excellent. Experience at this and other laboratories has shown, however, that the same is not always true for other implants. Thus the range of certain fission products, notably ^{111}Ag, appears to be anomalously large (7) when determined by this technique, and more detailed studies (8) have confirmed that this is because very little of the ^{111}Ag present in each aluminum layer is actually stripped from the specimen.

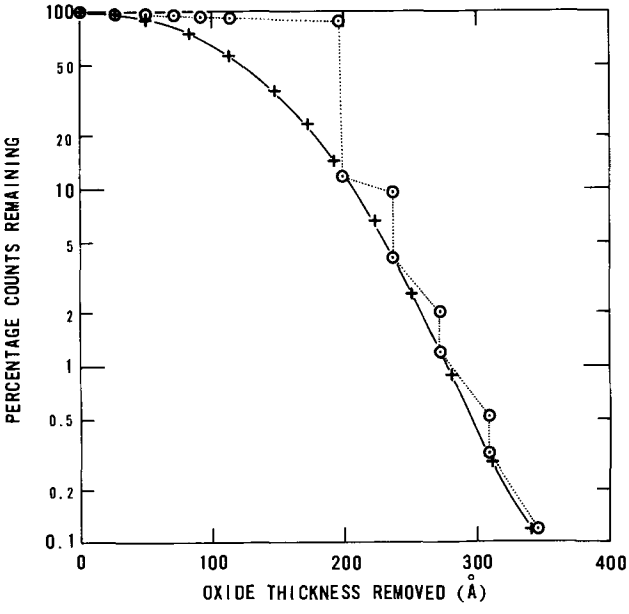

Fig. 1. Integrated range profiles for $^{198}Au^+$ implanted at 40 keV into anodic tantalum oxide. The dotted line connects points obtained with a specimen sectioned in the HF-NH_4F reagent until approximately 200Å of oxide had been removed; then alternately in aqua regia and HF-NH_4F. The crosses connected by the continuous line are experimental points for the specimen analyzed in the text; each point was obtained by treatment in HF-NH_4F, followed by 30 sec in aqua regia.

Key words: tantalum, anodic oxide, ion implantation, impurity dissolution.

In the case of an anodizing and stripping technique, two explanations are possible for the retention of a particular implant. The implant may fail to dissolve in the stripping agent, and hence remain on the specimen surface, as described here. Alternatively, it could fail to enter the oxide at all during the anodization process, and thus be segregated on the metal side of the metal/oxide interface. Rutherford scattering experiments by W. D. Mackintosh are currently underway in these laboratories to distinguish between these possibilities.

Very similar observations have been reported recently (9) in the silicon/silicon oxide system. Gold-198 dissolved in 10% HF was found to deposit on silicon surfaces; after subsequent thermal oxidation to 1100°C, part of the gold occurred at the oxide surface.

Porous Anodic Aluminum Oxide Membrane

Alan W. Smith

Boeing Aerospace Company, Seattle, Washington 98124

Anodization of aluminum in certain acids causes the formation of an oxide nearly penetrated by pores whose diameter (in angstroms) is about ten times the forming voltage (in volts) (1). Such porous oxides might be interesting membranes for ultrafiltration or reverse-osmosis applications. Burwell and May studied such membranes (2). However, they did not remove the thin barrier layer formed during anodization, and so their membranes had low permeabilities. In the work presented here, the barrier layer has been removed and interesting membranes produced.

The method used was to place an aluminum foil between two o-rings such that it formed a barrier between two chambers. Different solutions could be placed in either chamber for anodizing, etching, sealing, or measuring osmotic flow. For flow measurements a lid, containing conductivity electrodes to measure salt flow and capillaries to measure liquid flow, was placed over the chambers.

Foils of 0.0005 and 0.002 in. were used. Anodization was carried out from one side in various chromic and sulfuric acid solutions. The most uniform membranes were obtained in a 10% chromic acid-1% sulfuric acid solution. Voltages between 10 and 130V were used. Penetration of the foil by pits was apt to occur unless anodization was first carried out at a low voltage, 1V, until the as-received oxide was removed. Uniform membranes were rarely produced if the anodizing was allowed to proceed completely through the foil. The best membranes were produced by anodization part way through and then removing the unanodized aluminum by etching from the other side in a 50% HCl, 10^{-1}M $CuCl_2$ solution until the metal is just removed. Such membranes had low values of water and salt permeability.

To obtain high permeability membranes it was necessary to remove the barrier layer which is formed next to the metal interface during anodization. Since the thickness of the oxide between the pores is only about twice that of the barrier layer (1), it is not possible to etch away the barrier layer from the porous side without destroying the whole membrane. To remove the barrier layer, either an acid or basic solution was put into the chamber on the barrier layer side, while a buffered solution was placed on the porous side.

Figure 1 is a plot of the water flow to salt flow ratio *vs.* the water flow for a number of samples. These measurements were of the osmotic flow of water into a 1M NaCl solution and the counterflow of salt into the pure water. These samples were prepared in a variety of conditions in an attempt to obtain good salt rejection and high water flow. No correlations were found between parameters such as anodizing voltage. Only the kind of etching and sealing was significant. Samples were etched with acid solutions

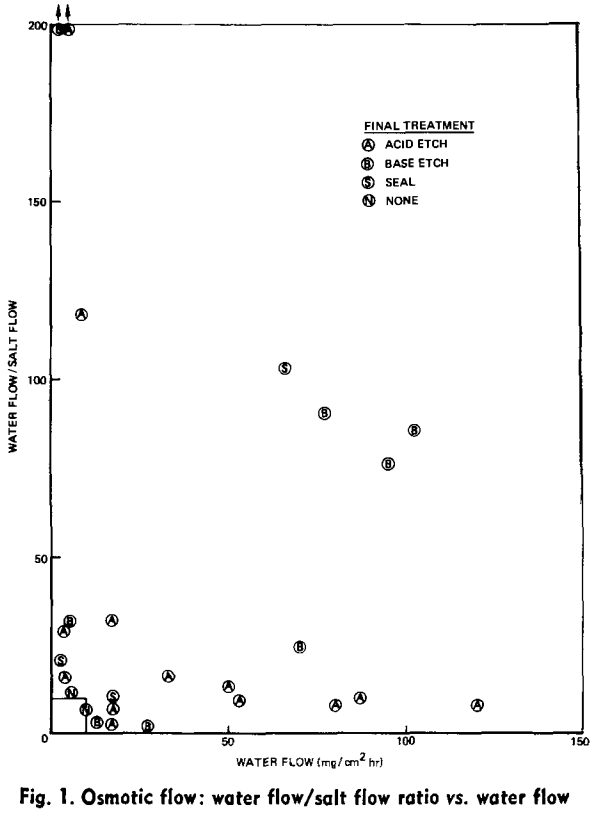

Fig. 1. Osmotic flow: water flow/salt flow ratio *vs.* water flow

Key words: membrane, anodic, aluminum, oxide, porous.

of various strengths and base solutions below 0.05M. In some cases the samples were partially sealed in 60°C water for 1 hr.

The thing to note about Fig. 1 is that the acid etch did not result in membranes with substantial water flows and good salt rejection (high values of water to salt flow). The good salt rejection in some cases of acid etch was for treatments not expected to remove the barrier layer completely.

Good salt rejection and substantial water flow were obtained when the samples were given an alkaline etch or when the samples were partially sealed after etching. Since the pores of the membrane are too large to reject salt it is not surprising that sealing which partially closes the pores increases the salt rejection. It is believed that the alkaline etch which dissolves the oxide rapidly and allows a hydrous oxide to reprecipitate also partially closes the pores. It seems likely that the membrane is similar to those formed by depositing hydrous oxides in porous solids (3).

It is believed that the upper limit of water flow in these measurements is due to concentration polarization so that the numbers given in Fig. 1 for the higher flow rates are presumably on the low side.

The acid etch should produce membranes useful for ultrafiltration. Pores of 100-1300Å in diameter should be formed under anodization conditions used here. For reverse osmosis desalination applications, an alkaline etch or partial seal is necessary.

Electrolytic Synthesis of Some Heavy Metal Tellurides

M. H. Miles*

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

and W. S. McEwan

Chemistry Division, Naval Weapons Center, China Lake, California 93555

The binary semiconductors $Pb_{1-x}Sn_xTe$ and $Hg_{1-x}Cd_xTe$ have special interest due to their composition-dependent energy gaps (1). Preparations of these alloy semiconductors often utilize the individual compounds of PbTe and SnTe or HgTe and CdTe (1-3). The use of these telluride compounds in the preparation of infrared detectors prompted further investigation into the electrolytic method of synthesis. Previous work has defined the conditions for the electrochemical preparation of small quantities of the compounds (4, 5). This work shows that specific problems become apparent when larger preparations are attempted. Methods for minimizing these problems are discussed.

Experimental

All preparations were performed in a controlled-atmosphere (N_2 + 3% H_2) glove box system to minimize unwanted reactions with oxygen (4, 5). Oxygen concentrations are claimed to be less than 1 ppm in this system. Electrical contact was made directly to both the tellurium cathode and the selected metal used as the anode. The geometrical electrode areas exposed to the solutions were usually between 5 and 15 cm^2. The two electrodes, along with a reference electrode (SCE), were positioned in a vessel containing the ammonium acetate-acetic acid *p*H 4.5 buffer solution. The anode and cathode were always placed as far apart as the vessel permitted; the usual separation being at least 10 cm. The passage of a constant current of 100 mA was used to generate the ions of the desired compound, which combine and precipitate from the solution. The rate of stirring was controlled magnetically.

[a] Data taken from Ref. (4).
[b] Average of data from Ref. (5).
[c] Reaction was observed when the dried sample was exposed to air. Apparently the Sn present was oxidized to SnO_2.
[d] Stirring was minimized to the slight agitation required to prevent the tellurium electrode from becoming heavily coated with precipitate.
All other solutions were vigorously stirred at nearly equal rates except for data taken from Ref. 4 where the rate of stirring was not mentioned.

scale preparations of PbTe and CdTe was found to be the ratio of the volume of the solution used to the surface area of the tellurium electrode exposed to the solution (V_{sol}/A_{Te}). For example, a preparation of PbTe where $V_{sol}/A_{Te} = 50$ showed less than 60% of the theoretical weight loss at the tellurium electrode. This experiment involved the passage of a constant current of 100 mA for 20,600 sec or 2060 coulombs. Upon increasing the V_{sol}/A_{Te} ratio to 250 by increasing the solution volume, the weight loss at the tellurium cathode increased to 98% of the theoretical. In this second experiment 5000 coulombs were used. In both experiments the weight loss at the lead anode was 101% of the theoretical weight. Analyses of the products by x-ray diffraction showed that free, crystalline lead was present in the first preparation, while the powder pattern for the second preparation, with $V_{sol}/A_{Te} = 250$, showed only the PbTe diffraction lines. Obviously, some of the Pb^{++} ions produced at the anode fail to find partners for precipitation as PbTe and, instead, become reduced to the free metal at the tellurium cathode. The extent of this contamination of the PbTe product by the free metal depends upon the V_{sol}/A_{Te} ratio and upon the total coulombs passed.

Results for the preparations of CdTe were similar to those found for PbTe. When a large V_{sol}/A_{Te} ratio is used, the x-ray powder pattern shows only the CdTe diffraction lines. However, the absence of foreign lines in such x-ray analyses indicates only that any contamination of the product by the free metal is small but not, necessarily, completely absent. It should be noted that the systematic error source found in this work was indicated by the statistical tests of preparations of small quantities of CdTe reported previously (6).

Mercury (II) telluride was conveniently prepared in large quantities by simply using a mercury pool, which is slowly stirred to expose fresh mercury, as the anode. Although Hg_2^{++} is produced initially, the reaction $Hg_2^{++} + Te^{--} \rightarrow Hg + HgTe$ produces the desired product (5). Most of the excess mercury was removed from the HgTe by centrifuging. The x-ray diffraction pattern corresponded to that of HgTe. Although the effect of the V_{sol}/A_{Te} ratio was not specifically investigated, using a ratio of about 250 gave a weight loss at the tellurium cathode which was 97% of the theoretical result for the 5700 coulombs used.

All attempts to prepare large quantities of SnTe resulted in a product highly contaminated with free tin. Even for V_{sol}/A_{Te} ratios as large as 500, low weight losses at the tellurium electrode and large amounts of free tin in the product were found. Using Te and Sn metals with purities exceeding 99.999% gave no significant improvement. Although a successful electrolytic preparation of SnTe in small quantities is reported by Panson (4), it is apparent that eventually the cathodic reaction becomes essentially the reduction of Sn^{++} ions to free tin.

Discussion

The probability of a metal ion, such as Pb^{++}, contacting the tellurium cathode and becoming reduced to the free metal is related to the V_{sol}/A_{Te} ratio. A larger ratio results in a smaller probability and allows a longer average time for the metal cation to find a Te^{--} partner. The Te^{--} ions, however, being a soft base, will tend to adsorb strongly to the tellurium metal surface (6, 7), thus relatively few Te^{--} ions reach the anode and become oxidized to free tellurium. Experimentally, most of the precipitation of the metal telluride is observed to occur near the cathode. Increasing the area of the tellurium electrode will increase the number of Te^{--} ions adsorbed, hence the probability of Pb^{++} ions coming close enough to the cathode for the charge-transfer reaction to occur will also increase.

The problems encountered in the attempt to prepare large quantities of SnTe could possibly result from the gradual formation of a tin plate or film on the tellurium electrode. Such a film would result in the cathodic reaction becoming essentially the reduction of Sn^{++} ions. Other metals such as Pb, Cd, and Hg are possibly less efficient in forming a film on the tellurium cathode. A possible solution to this problem would be to periodically reverse the current to oxidize the tin or other metals deposited on the tellurium electrode.

Another possibility is that a reaction such as

$$H^+ + SnTe + 2e^- \rightarrow Sn + HTe^- \quad [1]$$

may occur with the SnTe product. The calculated $E^\circ = -1.13$V (SHE) for this reaction suggests that such a reaction is thermodynamically possible for the experimental potentials of the cathode. However, the standard potential for the PbTe reduction reaction is only slightly more negative ($E^\circ = -1.18$V) while the standard potential for the HgTe reaction is less negative ($E^\circ = -1.03$V); yet both the PbTe and HgTe preparations, unlike the SnTe preparation, gave close to the theoretical weight loss for the tellurium cathode.

Some stirring of the solutions during the synthesis of the telluride compounds is desirable to remove the product which tends to form and collect at the tellurium cathode. Stirring also provides efficient use of the entire volume of the solution. However, rapid stirring will increase the motion of the metal cation and will, therefore, likely increase the probability of this ion contacting the cathode and becoming reduced to the free metal.

The free metal present in the telluride products could be removed by utilizing the differences in physical and chemical properties. For example x-ray diffraction studies showed that adding 1M HNO_3 to PbTe contaminated with free Pb dissolved the Pb and left the PbTe unchanged. Free mercury could likely be removed from HgTe by utilizing their different boiling points. Impurities other than the free metals will be controlled by the purity levels of the metals used as the electrodes and by purity levels in the ammonium acetate-acetic acid buffer solution used. Some electrolytic purification in this synthesis is possible. A highly pure, single crystalline telluride product could likely be produced from the electrolytic product by using liquid tellurium as the solvent for crystal growth (8).

Electrochemical Machining of High-Temperature Alloys in $NaClO_3$ Solutions

James P. Hoare,* Armand J. Chartrand, and Mitchell A. LaBoda*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

It has been shown in a series of recent reports (1-6) that an understanding of the electrochemistry of the processes occurring during the electrochemical machining (ECM) operation is desirable for obtaining a commercially finished product. Good control of dimensions and geometry, which is required for commercial exploitation, is obtained if a potential-dependent, protective, anodic film is formed on a given metal in a given electrolyte (1, 2, 6). For a given metal in a passivating electrolyte, the ECM process takes place in the transpassive region (1-3). If, in the transpassive region, the anodic film is reduced to a very thin, uniform, porous layer on the anode surface, an electropolishing or brightening of the surface will be realized (4-6). It was found (7) that $NaClO_3$ electrolytes gave superior results for the machining of steel by ECM, and that the behavior of the actual ECM of a metal on a laboratory ECM machine using $NaClO_3$ solutions correlated very well with the results of steady-state polarization curves obtained on soft iron (8), mild steel (2), and fully hardened steel (6) in terms of a potentially dependent, protective, anodic film.

Where ECM holds the greatest advantage is in the machining of high-strength, high-temperature alloys. Since these alloys contain large amounts of elements other than iron, it is important to determine how these elements influence the properties of the anodic film which, in turn, influence the quality of the finished product. It is the purpose of this report to describe the results of polarization studies made on seven high-temperature alloys and the machining behavior of these alloys in a $NaClO_3$ electrolyte.

Experimental

Small slugs or pegs were trepanned with the laboratory plunge-cut ECM machine shown in Fig. 1 from samples of the seven high-temperature alloys reported in Table I in which the composition of each alloy is listed. The composition of a mild (Type 1020) steel and of a fully hardened (Type 5160H) steel is also included. In all cases, the electrolyte (350g $NaClO_3$/liter) was pumped through the hollow, copper-tube cathode (0.25 in. or 0.64 cm, OD) at a rate of 0.5 gpm (0.031 liter/sec) and the cell voltage remained constant at 18.5V during the course of the plunge cut. The feed rate recorded was the highest value which could be obtained without tripping the cutoff switch.

After these slugs were degreased in trichlorethylene, washed in acetone, rinsed in distilled water, and dried, they were imbedded in polyethylene so that only the tip of the slug was exposed. The geometrical area of the exposed tip of the slug was determined from the dimensions obtained with a magnifier and calipers. For each run, three such electrodes as checks were mounted

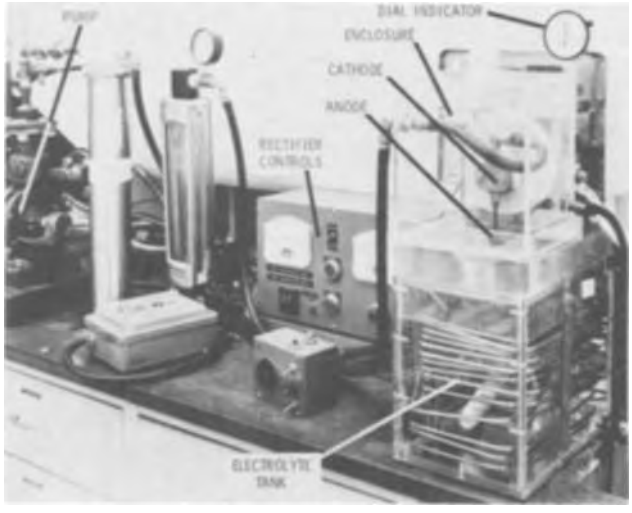

Fig. 1. Laboratory ECM plunge-cut machine

in one side of a two-compartmented Teflon cell (9). A saturated calomel reference electrode (SCE) was mounted in the other side which was separated by a fine glass frit from the first. After the cell was filled with the $NaClO_3$ solution (350 g/liter), the system was sealed with molten polyethylene.

Steady-state anodic polarization measurements were carried out on the slugs in O_2-stirred $NaClO_3$ electrolyte with a 61R Wenking potentiostat. Correction for the solution *IR*-drop was not made in the polarization data points because current interrupter measurements indicated that at current densities up to about 10 mA/in.^{2} (1.5 mA/cm^2) the *IR*-drop had values less than 1 mV. When the current output of the potentiostat became virtually steady, the potentiostat was disconnected mechanically from the circuit, and a constant-current stripping pulse was applied to the electrode by means of a mercury-wetted relay (10). The resulting transient was displayed on an oscilloscope and recorded photographically similarly to the methods used before (2). From the determination of the transition time of the arrests on the trace (11) and the knowledge of the value of the constant current, the amount of charge associated with the anodic film formed at the given potential could be calculated. In this way, the amount of film associated with the surface of the anode could be determined as a function of potential.

The plunge-cut samples were sawed in half to expose the sides of the plunged-cut hole so that an assessment of the quality of the machined surface could be made. The trace obtained from the stylus of the

Proficorder[1] shows not only the peak-to-valley roughness of the surface but also the profile of the cut. Scanning electron micrographs (SEM) of these machined surfaces were obtained at several magnifications.

All potentials are recorded with respect to the SCE, and the temperature at which the data were recorded was ambient.

Results

For each alloy, the experimental data are presented in a single figure with part (a) containing the steady-state polarization data averaged from three different runs on three different anode samples and part (b) showing a plot of the charge, Q, associated with the anodic film as a function of potential. Because of the difficulty of determining a true area due to the repeated formation and stripping of the anodic film during a given run, the polarization data are plotted as a function of the apparent current density, and a roughness factor of 10 was assumed in the calculation of values of Q. Included in each figure are SEM micrographs taken on the side of the plunge-cut hole at two or three magnifications depending on the complexity of the pattern. Finally, the Proficorder trace obtained along the side of the plunge-cut hole is reproduced at the top of each figure. The data for H13 tool steel are given in Fig. 2; for Inco 901 nickel-iron alloy in Fig. 3; for Inco 713C nickel-based alloy in Fig. 4; for GMR 235 nickel-based alloy in Fig. 5; for A286 nickel-chromium stainless steel in Fig. 6; for HS31 cobalt-based alloy in Fig. 7; and 410 stainless steel in Fig. 8. A plot of the cutting rate (feed rate), surface roughness, and weight per cents of Cr, Ni, and Fe for the seven alloys together with Type 1020 mild steel and 5160H fully hardened steel is presented in Fig. 9. From Fig. 9, it is seen that Fig. 2-8 are arranged in the order of alloys of increasing machining difficulty.

The rms roughness of the surface recorded in Fig. 9 was estimated from the Proficorder trace by calculating 1/3 of the peak-to-valley value. As noted in Fig. 2-8, the micropattern of peaks is superimposed on a macroundulation or long waviness reflecting the surface profile. The large amount of long waviness is caused by wobble in the cathode of the laboratory ECM machine and could be greatly reduced or eliminated in a more rugged machine.

Discussion

For an alloy which is low in Cr- but high in Fe-content, such as H13 tool steel (Fig. 2), the polarization curve is similar to that obtained on soft iron (7) or mild steel (2, 6). In such cases, the metal is active at low potentials but a protective film is formed on the anode surface at potentials of about 0.8V. This film begins to dissolve at the beginning of the transpassive region at about 1.5V. Such a metal can be machined by ECM at high-metal removal rates with good dimensional control and low surface roughness. For those

alloys rich in Ni but poor in Fe content, such as Inco 713C and GMR 235, the polarization curve is similar to that found (12) on Ni. Here, the metal is passive even at low potential values (Fig. 4 and 5), and the transpassive region begins at about 1.0V. The machining rate of these high Ni content alloys is low and the surface finish poor. With an alloy rich in both Fe and Ni, the experimental results lie between those for soft iron and for pure nickel. An example is A286 stainless steel (Fig. 6) which is passive at low potentials but the transpassive region begins at 1.5V. The machining rate is low but the surface finish is very good. Apparently, the electrochemical properties of the anode surface are a function of the electrochemical properties of the major metallic components of the anode material.

From the data in Fig. 9 it is seen that the machining rate falls, in general, as the Cr content of the alloy increases. The polarization curves for the high Cr content alloys do not have an active-passive transition but rather reach a sort of limiting current until the transpassive region sets in. This behavior can be interpreted in terms of an anodic film possessing good electronic conductivity since photomicrographs of the surface in this region show little or no attack of the metal surface and the solution was not colored.

As $CrO_4^=$ ion was added to a solution of KCl, Hoar and Evans (13) found that the passivating film on iron became thinner and more protective as the $CrO_4^=$ content of the electrolyte increased. From tracer studies, the composition of the protective film on iron in solutions containing $CrO_4^=$ ions may be as high as 25% Cr_2O_3 (14). It is possible that the anodic film on Cr containing alloy anodes becomes richer in Cr as the Cr content of the alloy increases thus imparting a higher degree of passivity to the protective film. Because of the high electronic conductivity of these films, the anodic current is consumed more in O_2 evolution and less in metal dissolution; and, consequently, the machining rate would diminish with the increased Cr content of the alloy.

In the presence of a high Cr content, the data of Fig. 9a indicate that the machining rate of the alloy in $NaClO_3$ is increased as the Ni content of the alloy is increased. Possibly, the presence of Ni in the anodic film lowers the electronic conductivity of the film. In such a case the current from O_2 evolution would be reduced and more metal would be dissolved for the passage of a given number of coulombs.

In the data shown in Fig. 9b, alloys with a high iron content are machined in $NaClO_3$ with very low values of surface roughness but those with a low iron content are machined with high values of surface roughness. It is possible that the high Fe content alloys (H13, 901, A286, 410) are more homogeneous in composition, and the surface grains or domains are more evenly dissolved across the surface as noted in Fig. 2c, 3c, 6c, and 8c where only a slight grain-boundary attack is evident.

In passing, the data of Fig. 6 and 8 are interesting because they point out the lack of correlation between reflectivity and surface roughness. The surface roughness of both A286 and 410 stainless steel is very low (between 2 and 5 μin. rms). However, the machined surface of A286 is mirror bright whereas that of 410 is dull. The SEM micrographs offer an explanation. On a microscopic scale (Fig. 8d), the machined surface of 410 has a sponge-type appearance and light becomes trapped in these cavities. Consequently, the surface appears dull to the unaided eye. On the other hand, the machined surface of A286 (Fig. 6d) suffers only from a mild grain-boundary attack which does not trap the light; and, as a result, the surface appears mirror bright.

For those alloys with low Fe content (713C, GMR235, HS31), the surface roughness is very high, and the SEM micrographs exhibit a high degree of heterogeneity in the metal removed from various parts of the surface. In the case of 713C [Fig. 4 (c-e)], there is evidence that one phase is dissolved more rapidly than another leaving a rock-pile appearance to the surface. The material at the grain boundaries is more resistant to attack than the material of the grains for GMR235 [Fig. 5 (c-e)] machined in $NaClO_3$. This situation results in a raised network of strands of material spread randomly over the metal surface. Preferential attack of one phase with respect to others is indicated in the micrographs (Fig. 7) of the machined surface of HS31 in $NaClO_3$, giving a cross-hatched appearance to the surface and a very high degree of surface roughness.

These data demonstrate that high-temperature alloys high in Fe content can be machined in $NaClO_3$ electrolytes with excellent surface finish but the machining rate may be low if the Cr content is high. The machining of low Fe content alloys in $NaClO_3$ yields high metal removal rates if the Ni content is high but the surface finish is poorer due to preferential phase attack. Consequently, no single universal electrolyte exists which will produce acceptable machining of all metals because the ECM properties depend on the properties of the anodic film formed in the given system. Since properties of the anodic film formed in a given electrolyte differ from metal to metal, one must choose or tailor the proper electrolyte for the given material which is to be electrochemically machined.

Partial Substitution of Oxygen in the Surface Layer of Vapor-Deposited Lead Monoxide Crystallites by Chemisorption of Hydrogen Chloride

A. H. Boonstra and R. M. A. Sidler

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

The reaction of HCl with the surface molecules of vapor-deposited PbO layers was investigated at different temperatures. Below about −150°C only a surface reaction was measured. This reaction causes a marked decrease of the surface area of such layers. Taking this decrease into account, the chemisorption of HCl results in a coverage of a monolayer, forming the surface compound Pb_2OCl_2. As a result of the chemisorption of H_2S at room temperature on such layers, two sulfur compounds with the formulas $Pb_8O_3S_3Cl_4$ and $Pb_4S_3Cl_2$ are formed having optical absorption edges of, respectively, 1.70 and 1.30 eV.

It has been shown previously (1) that the adsorption of H_2S on vapor-deposited PbO layers, at adsorption temperatures below −120°C, leads to the replacement in steps of the oxygen atoms by sulfur atoms. This results in a coverage of the PbO surface of about 0.25, 0.5, and 1 monolayer, forming surface compounds with bandgaps of, respectively, 1.45, 1.05, and 0.80 eV.

With chemisorption of HBr on vapor-deposited PbO layers at −160°C, it was found that half of the oxygen surface atoms were replaced by twice the number of bromine atoms, resulting in the formation of the surface compound Pb_2OBr_2 (2). The oxygen atoms in this compound could be replaced not only by other bromine atoms but also by sulfur atoms. In the latter case the surface compound $Pb_8O_3S_3Br_4$ was formed.

In this paper the results are given of investigations concerning the behavior of HCl on the surface of vapor-deposited PbO layers and of H_2S on layers previously treated with HCl.

Experimental Techniques

The adsorption of HCl at the surface of tetragonal lead monoxide was investigated on vapor-deposited PbO layers, prepared in the usual way (1, 3).

These layers consist of crystallites in the form of platelets and are oriented perpendicular to the substrate surface (4). The structure of tetragonal PbO can be described, according to Dickens (5), as a sandwich structure containing a plane of oxygen atoms flanked by two planes each containing half the number of Pb atoms. The lone pairs of electrons of the lead atoms hold the sandwiches together by van der Waal forces. Assuming that this also occurs in our vapor-deposited PbO layers, the surface density of lead and of oxygen atoms is $1.25 \cdot 10^{15}$ cm^{-2} (6, 7). On an adsorption apparatus the surface area of the PbO layers was determined at −195°C using krypton with the well-known BET method (8). These layers have a specific area of about 50 m^2 g^{-1} and a porosity of 50%. The mean space between the crystal plates is 5 nm. The dimensions of the platelets are approximately $2 \times 0.5 \times 3.5 \cdot 10^{-3}$ μm. These properties of the layer make it possible for the gas molecules to penetrate readily into the spaces throughout the entire thickness of the layer.

After the determination of the surface area, adsorption experiments were carried out at different temperatures. Some PbO layers were treated with HCl at room temperature, and the adsorption of HCl was found by measuring the change of the HCl pressure as a function of the adsorption time. The water liberated during this reaction was frozen out by cooling part of the system to −95°C with melting acetone.

During the adsorption of HCl at very low temperatures, as for example −160°C, there was a physical adsorption of HCl in addition to a fast chemisorption. The amount of physically adsorbed HCl could be readily desorbed by cooling another part of the system with liquid nitrogen. The change in surface area as a result of the HCl chemisorption and the reactivity of H_2S for these layers were also investigated.

For optical measurements on these layers, the windows with the PbO layers were separated from the tubes. The optical absorption spectra were determined with the aid of a Beckman Instruments, Incorporated DK 2 A spectrophotometer using a special integrating sphere accessory. The total (diffuse and specular) reflection spectra, R, and total transmission spectra, T, were measured, illuminating the layers with normal incident light.

After fracturing the PbO layers the depth of penetration of the HCl and the H_2S into the PbO layers was investigated under a microscope. This was possible because as a result of the H_2S adsorption the color of the PbO layer was changed.

Adsorption Results

The chemisorption of HCl on a PbO layer was measured as a function of the adsorption time at different

Key words: chemisorption, surface compound formation, photoconductivity, adsorption, phosphors, lead monoxide.

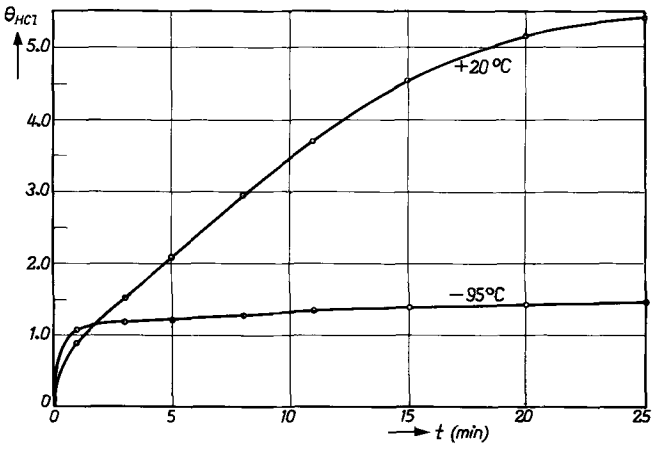

Fig. 1. Chemisorption of HCl on the surface of a PbO layer at +20°C and at −95°C, expressed in terms of monolayers (θ_{HCl}), as a function of the adsorption time.

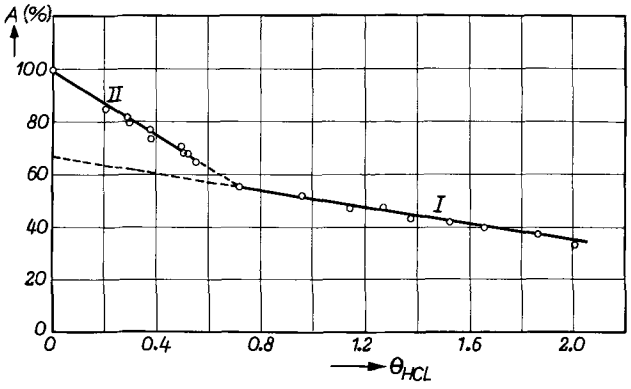

Fig. 3. Total surface area of PbO layers expressed in percentage of the total original surface area, plotted vs. the total amount of adsorbed HCl for: I, a PbO layer treated several times with HCl at −160°C and after each treatment warming up to room temperature, and II, PbO layers after one adsorption step of HCl and with a coverage less than 0.75.

temperatures. The results of these measurements are given in Fig. 1 for two temperatures. It is seen from this figure that, after an adsorption time of 25 min, an HCl adsorption at +20°C gives rise to a coverage of more than 5 monolayers, whereas at −95°C a coverage of only 1.5 monolayers is obtained in the same time. The initial rate of adsorption at 20°C is slower than at −95°C as a result of the desorption of water vapor at 20°C, through which the supply of HCl in the pores is hindered. Monolayer adsorption is understood as an adsorption of one gas molecule per PbO surface molecule. After the adsorption of about one monolayer the adsorption velocity strongly depends on the adsorption temperature. At room temperature the pressure of the HCl decreased from 1 Torr to about 10^{-1} Torr as a result of the adsorption.

At −160°C both a fast chemisorption and a physical adsorption were measured. The HCl pressure now decreased to less than 10^{-4} Torr. The amount of physically adsorbed HCl could be readily desorbed by cooling part of the system with liquid nitrogen. The chemisorption resulted in a coverage of about 0.75 of a monolayer, independent of the excess of HCl. This value of the coverage was also found with a chemisorption at −183°C.

It appeared that a PbO layer treated with HCl at −160°C to produce a coverage of 0.75 of a monolayer could adsorb a new quantity of HCl at −160°C, if the tube was first warmed up to room temperature and then cooled again to −160°C. This procedure could be repeated several times, as is represented in Fig. 2 in which the dots on the graph indicate the result of such a procedure. These coverages were calculated on the basis of the original surface area.

The results of these measurements suggest an interchange of chlorine ions from the surface layer with the oxygen of the underlying layers during the warming up of the tube to room temperature. At the next adsorption step at −160°C, the HCl can react again with the PbO surface molecules thus newly formed.

The surface area was also measured after each adsorption step. The results of these measurements are given in Fig. 3. In our opinion the small decrease of the surface area is caused by a recrystallization as a result of the diffusion process. Extrapolation of the straight line (I) in Fig. 3 to zero coverage suggests that at low degrees of coverage another recrystallization process occurs. Therefore the change of surface area was measured on a number of PbO layers treated at −160°C with less than 75% of a monolayer HCl. The results are also given in Fig. 3. With these coverages, we see a strong decrease of the surface area, which is linearly dependent on the coverage of the chemisorbed HCl. This decrease in surface area already occurs during chemisorption and not during the warming up of the tube to room temperature. This was determined by cooling some tubes to −195°C, directly after the chemisorption of HCl at −160°C, at which temperature the surface area was measured once again.

To find out if the HCl was built up homogeneously or inhomogeneously across the layer, the following experiments were made.

A number of PbO layers were treated at −160°C with different quantities of HCl. Then, H_2S was added to each of these layers at room temperature. After this the layers were broken and examined under a microscope. We see that as a result of the chemisorptions the first part of the layer was deep-red colored, followed by a black part, while the remaining part retained its original yellow-orange color. A photograph of such a layer is given in Fig. 4.

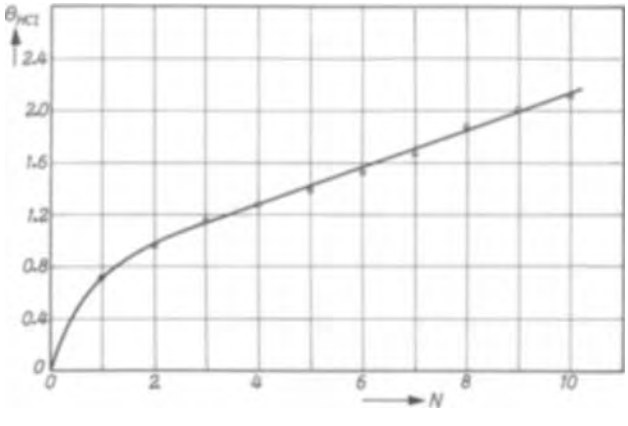

Fig. 2. Chemisorption of HCl on the surface of a PbO layer at −160°C vs. the number of processes (N). Each process consists of cooling to −160°C, adsorbing HCl, and warming up the layer to room temperature.

Fig. 4. Photograph of a PbO layer in which the large light-colored part is treated with HCl to a coverage of 0.60 and with H_2S to a coverage of 0.60, the dark part being treated with a monolayer of H_2S only, the small light part being the uncovered part of the layer.

It is known that a PbO layer treated with H_2S at room temperature becomes black colored (1). So we conclude that the red color is caused by the successive adsorption of HCl and H_2S, and that the HCl was built up inhomogeneously across the PbO layer.

To get an impression about the coverage of the HCl (θ_{HCl}) as a function of the depth of penetration into the PbO layer, and of the coverage of the H_2S on a thus treated layer ($\theta_{H_2S}^{HCl}$) a number of PbO layers were treated in the above described way. The amount of H_2S (Q_{H_2S}) was such each time that the depth of penetration of the H_2S into the PbO layer (D_{H_2S}) was greater than that of the HCl (D_{HCl}). During the H_2S adsorption water was liberated. No desorption of HCl or Cl_2 was measured in any of the H_2S processes.

The θ_{HCl} was calculated from these data as well as the known values of the adsorbed amounts of HCl.

From previous experiments (1) we know that the θ_{H_2S} of a PbO layer is about 0.90, therefore the coverage of H_2S on the part of the layer covered with HCl could also be calculated using the formula

$$Q_{H_2S} = Q_1 + Q_2 \qquad [1]$$

where Q_1 is the amount H_2S adsorbed on the part of the layer previously covered with HCl and Q_2 is the amount of H_2S used for the part covered with H_2 S only.

When Q is the amount of H_2S to cover the whole PbO layer with one monolayer then

$$\frac{Q_{H_2S}}{Q} = \theta_{H_2S}^{HCl}\frac{D_{HCl}}{D} + \theta_{H_2S}\frac{D_{H_2S} - D_{HCl}}{D} \qquad [2]$$

or

$$\theta_{H_2S}^{HCl} = \frac{D}{D_{HCl}}\frac{Q_{H_2S}}{Q} - \frac{D_{H_2S} - D_{HCl}}{D_{HCl}}\theta_{H_2S} \qquad [3]$$

where D is the total layer thickness.

The results are given in Table I. We see that the θ_{HCl} is independent of the depth of penetration and is about 0.60, and that the $\theta_{H_2S}^{HCl}$ is about 0.60. This θ_{HCl} is different from the coverage found by adding at −160°C an excess of HCl at which the coverage is about 0.75. This means that the chemisorption of HCl on PbO layers at −160°C takes place in two steps, the first resulting in a coverage of 0.60 and the second making the coverage up to 0.75.

The change in surface area of the part of the layer covered with HCl ($\theta_{HCl} = 0.60$) can be calculated, assuming that the uncovered part does not undergo a change in surface area.

We can now calculate also the coverage of HCl on the basis of the newly formed area. This calculation results in a θ_{HCl}' of about 1.0, assuming the same density of Pb atoms/cm². The results are given in Table II, in which A'/A (column 4 of Table II) is the ratio between the surface area of the covered part of the layer (A') and that of the same part of the layer before HCl had been adsorbed (A).

These results suggest that half of the amount of oxygen from the PbO surface molecules is replaced by chlorine, forming Pb_2OCl_2 according to the reaction equation

$$2PbO + 2HCl \rightarrow Pb_2OCl_2 + H_2O$$

To get a more accurate determination of the adsorption of H_2S as a function of the depth of penetration into a PbO layer covered with HCl, a number of PbO layers were treated with HCl to a coverage of 0.60 at −160°C. Different quantities of H_2S were then added to each of these layers at +20°C. The depth of penetration of H_2S into these layers was determined under a microscope after the layers had been fractured. This procedure of determining the depth of penetration is possible because of the sharp color boundary in the layer owing to the deep-red color of that part of the layer which is treated with HCl and H_2S while the rest of the layer, which is treated with HCl only is yellow colored. Figure 5 is a photograph of such a layer. The results of these measurements are given in Table III and Fig. 6. It is seen that the mean coverage of H_2S ($\bar{\theta}_{H_2S}^{HCl}$) of a PbO layer treated in this way is greater the deeper the depth of penetration.

From a determination of the surface area of layers treated in this way it was found that the further decrease of the surface area of the part that was treated with H_2S was about 10%.

Table I. Coverage of H_2S of part of PbO layer covered with HCl

Sample No.	Amount of HCl adsorbed at −160°C in % of a monolayer	Amount of H_2S adsorbed at +20°C in % of a monolayer	Depth of penetration HCl (%)	θ_{HCl}	Depth of penetration of H_2S (%)	$\theta_{H_2S}^{HCl}$

Optical Results

The results of the adsorption measurements suggest that, in the case of H_2S chemisorption at +20°C on a PbO layer covered with about 60% HCl at −160°C, more than one surface compound is formed. To obtain more information about this matter we carried out some optical measurements. Special care had to be taken to ensure that the depth of penetration of the H_2S was not larger than that of the HCl, for otherwise we would have measured the optical absorption spectra of a surface compound created by a reaction of PbO with H_2S only (1).

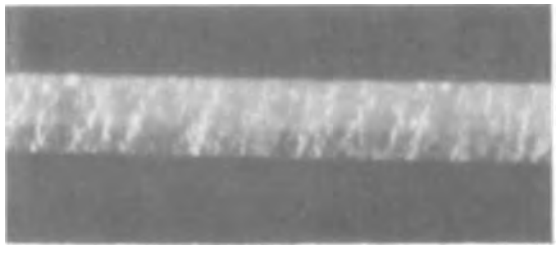

Fig. 5. Photograph of a PbO layer in which the dark part is treated with HCl to a coverage of 0.60 and with H_2S to a coverage of 0.50. The rest of the layer is only treated with HCl to a coverage of 0.60 of a monolayer.

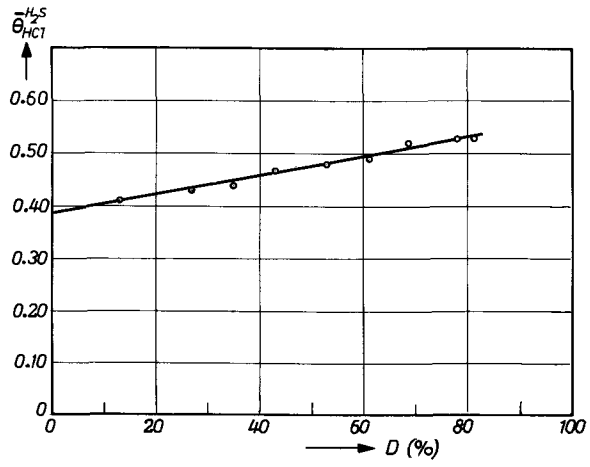

Fig. 6. Coverage of H_2S adsorbed at +20°C on a PbO layer previously treated with HCl at −160°C, *vs.* the depth of penetration (*D*) of H_2S into the PbO layer, expressed in percentages.

What interests us particularly is the wavelength at which the optical absorption of these layers becomes small and ultimately drops to zero.

In determining the absorption spectra one has to bear in mind that these vapor-deposited PbO layers scatter the incident light rather strongly. The form of the crystallites makes it impossible to handle the scattering rigorously. Therefore one has to fall back on the phenomenological reflection theory of Kubelka and Munk (9), on the basis of which Matzinger (10) shows that the optical absorption (A) in the bandgap region can be approximated by

$$1\text{-}R\text{-}T = A = \frac{\alpha D\left(1 + \frac{1}{2}\alpha D + \sigma D\right)}{1 + \left[\alpha + \sigma + \frac{1}{3}\alpha D(\alpha + 2\sigma)\right] D} \quad [4]$$

where R is the total reflection spectrum, T the total transmission spectrum, D the layer thickness, α the absorption coefficient, and σ the Kubelka-Munk scattering coefficient. Expression [2] is valid for $\alpha D(\alpha D + 2\sigma D)$ not exceeding one.

The product σD can be estimated from the reflection spectrum. For our layers it is generally somewhat smaller than one. Therefore, in the region of the bandgap ($\alpha D << 1$) the term $\alpha D(\alpha D + 2\sigma D)$ is also $<< 1$. Hence expression [2] reduces to simply

$$A = \alpha D \frac{1 + \sigma D}{1 + \sigma D} = \alpha D \quad [5]$$

The optical absorption as a function of the wavelength can be calculated from the total reflection and total transmission spectra. In Fig. 7 the total reflection and total transmission spectra are given for a PbO layer treated with HCl to a coverage of 0.55 at −160°C (curves 1), for a PbO layer treated with HCl to a coverage of 0.55 at −160°C and with H_2S to a coverage of 0.25 at +20°C (curves 2), and for a PbO layer treated with HCl to a coverage of about 0.60 at −160°C and with H_2S to about 0.10 at −125°C (curves 3).

The deviation of the reflection curve of 3 is caused by the difference in substrate temperature during the preparation of the layers. The dimensions of the crystallites of layer 3 are smaller than those of layers 1 and 2 because the specific area of this layer is 75 $m^2\ g^{-1}$. Figure 8 shows the superimposed spectra ($T + R$) of these layers, while Fig. 9 gives the square root of the absorption of these layers *vs.* $h\nu$. An $A^{1/2}$ which is linearly dependent on photon energy is characteristic of indirect energy gap media. For very small values of A deviations from the straight line show up. This absorption tail is always found in our vapor-deposited PbO layers and is probably caused by impurities. After subtraction of this tail from the absorption curve a square root dependence of the absorption on the photon energy is shown in Fig. 9b for samples 1 and 3. In the case of H_2S adsorption at room temperature on an HCl-covered PbO layer, the absorption spectrum consisted of two branches. After linear subtraction the square root of the values of the absorption was plotted against the photon energy, as is shown in Fig. 9b for sample 2.

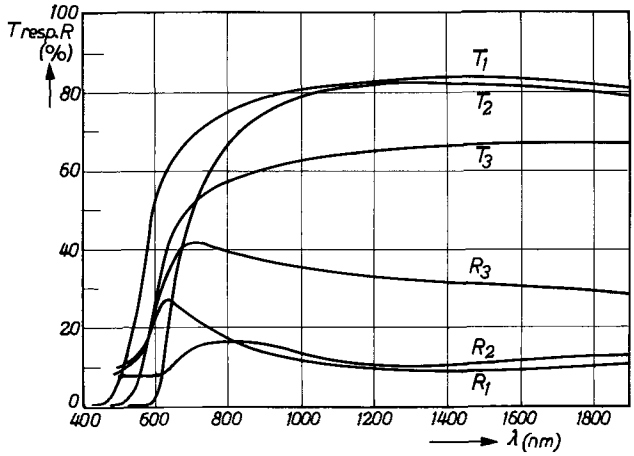

Fig. 7. Total reflection spectra (*R*) and total transmission spectra (*T*) as a function of the wavelength of the incident light, denoted by 1, for a PbO layer treated with HCl to a coverage of 0.55 (sample 1 of Table IV), by 2, for a PbO layer treated with HCl to a coverage of 0.55 and H_2S to a coverage of 0.25 (sample 6 of Table IV), and by 3, for a PbO layer treated with HCl to a coverage of 0.60 and H_2S to a coverage of 0.10 (−125°C), (sample 9 of Table IV).

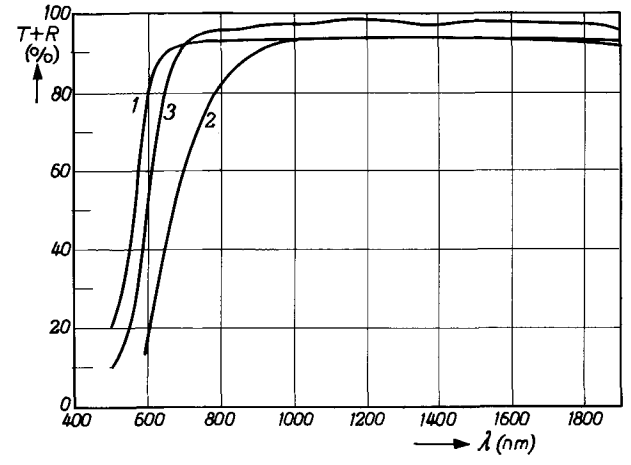

Fig. 8. Superposition of the total transmission and total reflection spectra ($T + R$) as a function of the wavelength of the incident light, 1 being used to denote sample 1, 2 to denote sample 6, and 3 to denote sample 9 given in Table IV.

Table IV gives the results for a number of layers treated in the normal way, and for the ones subjected to an H_2S treatment at low temperatures. All the layers treated with HCl and H_2S were found to have a bandgap of about 1.70 eV; besides this bandgap the layers treated in the normal way showed a bandgap of about 1.30 eV. The latter value was not found if the H_2S treatment took place at temperatures below −80°C. In the case of an HCl treatment only, an absorption edge of 1.91 eV was found. Compared with measurements on single crystals of tetragonal PbO, which gives an absorption edge of 1.94 eV (11), these results suggest that the value of 1.91 eV has to be ascribed to tetragonal PbO.

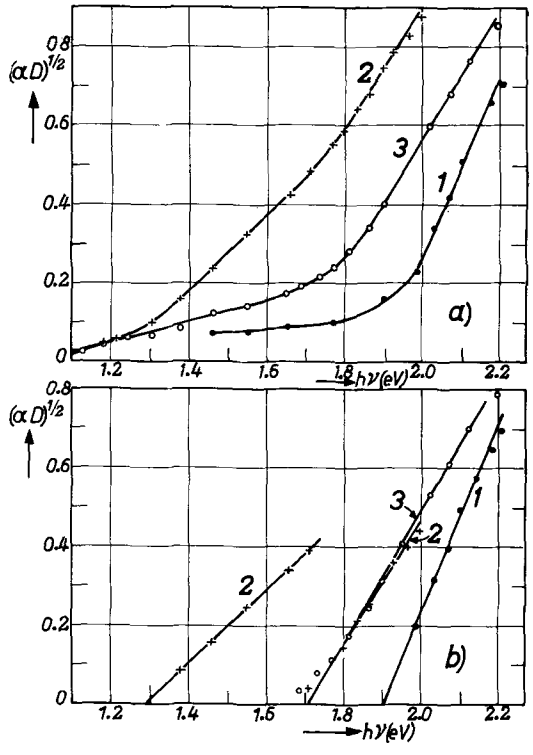

Fig. 9. a. The absorption spectra of sample 1 (curve 1) sample 6 (curve 2), and sample 9 (curve 3) of Table IV, vs. $h\nu$. b. The above absorption spectra after subtraction of an absorption tail always found in vapor-deposited PbO layers and probably caused by impurities.

Conclusions

From the adsorption measurements of HCl on a PbO layer at −160°C we found a θ_{HCl} of 0.75; the same value of the coverage was found at liquid oxygen temperature. At higher temperatures this value was not constant but depended on the HCl pressure during the reaction and on the adsorption time. We may conclude that at temperatures below −150°C there is only a surface reaction, whereas at higher temperatures there is in addition a reaction of the HCl with the underlying PbO layers. However, it was possible to chemisorb more HCl at −160°C by repeating this chemisorption process after warming up the sample to room temperature. So there must be an interchange of the chlorine of the first layer with the oxygen of the second layer. From surface area measurements we may conclude that this process is accompanied by surface recrystallization.

From the adsorption measurements of H_2S on PbO layers treated with different amounts of HCl at −160°C, we may conclude that $\theta_{HCl} = 0.60$, which is independent of the depth of penetration of HCl. If the whole layer is covered to a degree of 0.60, the chemisorption of HCl at −160°C increases to a coverage of 0.75. So chemisorption of HCl on PbO layers at −160°C takes place in two steps.

Table IV. Bandgap energy of PbO layer

Sample No.	Amount of HCl adsorbed at −160°C in % of a monolayer	Amount of adsorbed H_2S in % of a monolayer	Adsorption temperature of H_2S (°C)	E_{e_1} (eV)	E_{e_2} (eV)	E_{e_3} (eV)
1	55.0	—	—	1.91	—	—
2	29.6	10.3	+20	—	1.72	1.32
3	29.7	10.4	+20	—	1.70	1.25
4	50.1	19.0	+20	—	1.70	1.32
5	70.1	20.0	+20	—	1.68	1.32
6	55.1	25.2	+20	—	1.70	1.30
7	55.5	30.0	+20	—	1.69	1.30
8	61.3	20.6	−80	—	1.72	—
9	57.5	11.1	−125	—	1.72	—
10	53.6	7.7	−158	—	1.75	—

Surface area measurements on PbO layers treated at −160°C with HCl to a maximum of 0.60 of a monolayer showed a strong decrease of the surface area. Assuming that the surface area of the uncovered part of the layer had not changed, we see that the surface area of the part of the layer covered with a θ_{HCl} of 0.60 diminished to 60% of the original surface area. From surface area measurements before the sample was warmed up to room temperature we may conclude that the surface recrystallization was caused by the energy liberated during the chemisorption of HCl.

Assuming the same density of Pb atoms/cm², we see a θ_{HCl}' of 1.0 on the basis of the newly formed surface area. This means that half of the oxygen atoms of the surface molecules were replaced by chlorine atoms. In this process two chlorine atoms were necessary to replace one oxygen surface atom. This resulted in the formation of a new surface molecule with the formula Pb_2OCl_2.

The chemisorption of H_2S at +20°C on a layer treated with HCl resulted in a coverage of H_2S varying from 0.40 to 0.60, dependent on the depth of penetration. These values are based on the original surface area. Taking into account the decreases of the surface area caused by the chemisorption of HCl and that of H_2S of 40 and 10%, respectively, the values are 0.75 and 1.10. Our explanation is that a fast chemisorption to a θ_{H_2S}' of 0.75 was followed by a slower one which, in our conditions, reached a value of 1.10. This means that in the fast chemisorption process oxygen atoms amounting to 1.5 times the number of oxygen atoms present in the Pb_2OCl_2 surface layer were replaced by sulfur atoms. Thus, even during the fast chemisorption, part of the oxygen atoms of the second layer must also be replaced by sulfur atoms.

In our opinion the first and the second layer interact to form a new surface layer, consisting of a complex compound with the formula $Pb_8O_3S_3Cl_4$. As a result of the slower chemisorption process of H_2S the rest of the oxygen in this surface layer was also replaced by sulfur, forming a compound with the formula $Pb_4S_3Cl_2$. This hypothesis was confirmed by the optical results.

From the optical measurements on PbO layers treated with HCl to a coverage of 0.60 at −160°C and H_2S at +20°C we found two bandgaps, namely 1.70 and 1.30 eV. This second branch was not found if the H_2S adsorption took place at temperatures below about −80°C, where the slower chemisorption step is suppressed. So the bandgap of 1.70 eV belongs to the compound $Pb_8O_3S_3Cl_4$ and the value of 1.30 eV to the compound $Pb_4S_3Cl_2$.

The partial replacement of the oxygen atoms of the PbO surface molecules by atoms of another element, as described above, had already been found in the case of the elements sulfur (1), selenium (1), and bromine (2). It is known that the oxygen atoms in tetragonal PbO have an identical surrounding, so we may conclude that as a result of the replacement of a surface oxygen atom by that of another element the bond of the neighboring oxygen atoms with lead atoms becomes stronger.

At this stage of the investigations it is impossible to make more definite statements concerning the structure and types of bond of these surface compounds. In our opinion this must be possible by making selective use of the exising surface techniques and extending the investigations to other metal-oxygen compounds.

Piezoelectricity Induced by Charge Injection in Thin Polymer Films

G. Dreyfus and J. Lewiner

Laboratoire d'Electricité Générale, Ecole Supérieure de Physique et de Chimie, 75231 Paris Cedex 05, France

ABSTRACT

The vibrations produced in the electrodes surrounding a polypropylene foil in a three-layer capacitive microphone under an a-c field are analyzed. These vibrations can be due either to the electrostatic pressure acting on the electrodes (direct excitation) or to the vibrations of the central dielectric foil itself transmitted to the electrodes (transmitted excitation). Experimental evidence is given showing the separation between these two types of excitations. In the case of transmitted excitation, electrostriction of the central dielectric layer was to be ruled out as an explanation of the observed effects. They were interpreted in terms of piezoelectricity and were proved to be due, in this case, not to a high field effect, but to charge injection, even in the absence of macroscopic space charge.

Piezoelectricity has been reported to occur in various polymeric or biological substances, in either bending, elongational, or compressional conditions, leading to different and sometimes conflicting interpretations (1-3). Most of the experimental techniques use electrodes evaporated or deposited on the surface of the sample. In the case of elongational piezoelectricity, the samples are vibrated in a direction parallel to the plane of the electrodes, and the induced alternating voltage between the electrodes is studied (4-8). Experiments are also carried out on polymer films that have been "poled" by heating and subsequent cooling under high static electric field (9, 10) and piezoelectricity has been reported to exist in various conditions. To observe compressional piezoelectricity, an a-c field is applied and the vibration of the whole sample (polymer plus electrodes) is recorded (10). Inverse piezoelectricity has also been reported to be induced by a d-c field in untreated polyethylene (11).

The results of the above experiments have been interpreted in terms of the crystalline symmetry of the materials (1, 3, 5, 6, 8), in terms of surface charges appearing during the manufacturing process (12), or in terms of dipole orientation during heating or manufacturing (7, 11).

Generally speaking, one considers that piezoelectricity occurs when a linear dependence exists between the voltage or current induced in the electrodes and the stress or strain applied to the system, or reciprocally. However, two types of excitations, which are basically different in nature, may lead to a similar apparent effect. These two different situations are perfectly illustrated by two classical systems: (*i*) When an a-c voltage is applied across a piezoelectric transducer, the transducer itself vibrates and this vibration can be transmitted to the adjacent electrode, through a bonding agent, if the acoustic impedances are matched. (*ii*) When an a-c voltage is applied across an electrostatic transducer (for instance, a capacitive transducer), the electrodes are directly vibrated by the electric forces acting on them.

Key words: transducer, electrets, polypropylene, ultrasonics.

In the general case of transmitted excitation one still has to be careful before assuming piezoelectricity; the vibration of the material could also be due to electrostriction. In the present work we have used a capacitive ultrasonic transducer to investigate the mechanical vibrations produced in the electrodes surrounding a 10 μm thick polypropylene foil, in order to separate the above mentioned two types of excitations.

In the next section we shall describe the general principle of operation of our transducer. The section following will present the experimental setup and the analysis of the observed effects.

Principle of Operation of the Transducer

In order to analyze the vibrations produced by the polypropylene foils, we have used them as the central medium of an ultrasonic transducer.

Let us assume, for the time being, that the foil has no piezoelectric properties. Consider first that it is provided with two plane contacting electrodes, as shown in Fig. 1; the pressure exerted on each electrode is

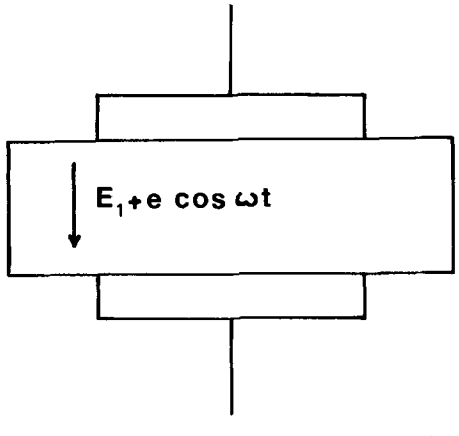

Fig. 1. Sample provided with two contacting electrodes. The field $E_1 + E \cos \omega t$ exerts an electrostatic pressure on the electrodes and vibrates them.

$p = \epsilon \frac{E^2}{2}$, where ϵ is the permittivity of the plate and E the field between the electrodes. Assuming that the field has a d-c component E_1 and an a-c component $E \cos \omega t$, the pressure is

$$p = \frac{\epsilon}{2}\left(E_1^2 + \frac{E^2}{2} + 2E_1 E \cos \omega t + \frac{E^2}{2}\cos 2\omega t\right) \quad [1]$$

If $E_1 >> E$, the component of p at frequency ω is much greater than that at 2ω; it is proportional to e, as would be the case if the dielectric plate were piezoelectric.

It must be pointed out that d-c field is the relevant parameter; it may be due either to an external voltage applied across the plate or to a distribution of charges within the dielectric or to both.

Let us now consider, as shown in Fig. 2, that the dielectric plate of permittivity ϵ and thickness d_2 is separated from two noncontacting electrodes of area S by layers 1 and 3, of permittivity ϵ_0 and thicknesses d_1 and d_3. If V is the voltage applied to the electrodes and if we assume that there exist, in the dielectric plate, surface charge densities σ_1 and σ_2 and a volume charge density $\rho(z)$, the field E_1 in layer 1 is given by

$$LE_1 = -V - \left(\frac{d_2 - \langle z\rangle}{\epsilon} + \frac{d_3}{\epsilon_0}\right)\frac{Q}{S} - \sigma_2 \frac{d_3}{\epsilon_0} - \sigma_1\left(\frac{d_2}{\epsilon} + \frac{d_3}{\epsilon_0}\right) \quad [2]$$

where $L = d_1 + \frac{\epsilon_0}{\epsilon} d_2 + d_3$. Q is the total volume charge in the dielectric plate, and $\langle z\rangle$ is the mean penetration depth of the charges, defined by

$$\langle z\rangle = \frac{\int_0^{d_2} z\rho(z)\,dz}{\int_0^{d_2} \rho(z)\,dz}$$

We have assumed z to be the only spatial variable. Relation [2] may be stated more briefly as

$$LE_1 = V_0 - V \quad [3]$$

In this expression V_0 is called the equivalent voltage of the electret. It only depends on the charge distribution and on the geometry of the system, assuming the charges to be independent of the applied voltage, which is the case if the electret is stable and if no discharge occurs through layers 1 and 3. If an a-c field is added, relation [1] still holds and the electrodes are vibrated. Conversely, if one of the electrodes is mechanically vibrated, an a-c current arises in the external circuit; it is proportional to E_1. It must be pointed out that the superiority of the assembly of Fig. 2 over that of Fig. 1 lies in the fact that the electric field E_1 can be canceled without canceling the field in the foil, by applying an external voltage equal to the equivalent voltage of the electret ($V = V_0$). If we assume now that the foil exhibits piezoelectric properties, the assembly of Fig. 1 is such that, with an a-c voltage applied, the electrodes will be vibrated, whatever the value of the applied voltage V. The assembly of Fig. 2 would exhibit a similar behavior provided that the medium filling layers 1 and 3 achieve proper acoustic impedance matching between the foil and the electrodes.

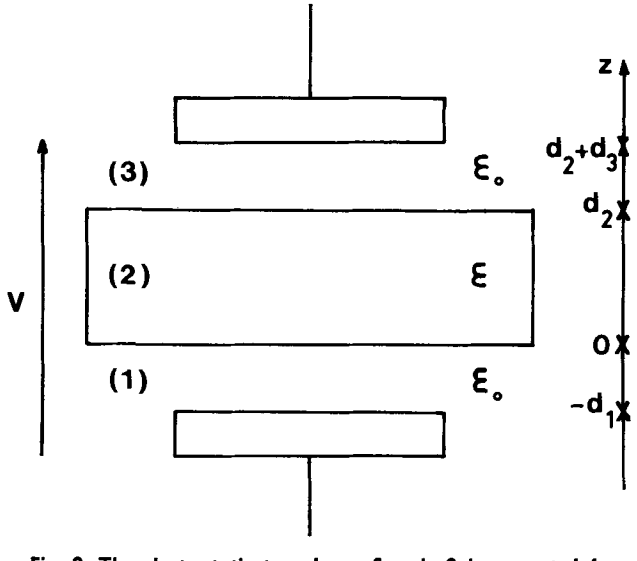

Fig. 2. The electrostatic transducer. Sample 2 is separated from the electrodes by gas layers 1 and 3.

Experimental Setup and Discussion of the Results

The dielectric under study was a 10 μm thick, highly isotactic, polypropylene foil, that had been corona-charged through gas layers 1 and 3. The maximum applied voltage was 4 kV; V_0 ranged from 0 to 2000V. A standard pulse echo ultrasonic technique was used combined with a high voltage supply for the electrostatic transducer (14). A block diagram of the system is shown in Fig. 3. The a-c voltage, at 10 mHz, was supplied by a pulsed oscillator; the lower, grounded electrode was an aluminum single crystal in which the ultrasonic pulses created by the transducer were propagated, and then received by an X-cut quartz crystal transducer at the other end of the crystal. The pulses were amplified, detected, and displayed on an oscilloscope. The detected pulses were also passed through a gated amplifier and integrated and the resulting d-c voltage was recorded on a strip-chart recorder. The voltage thus recorded was a function of the amplitude of the ultrasonic pulses, and, consequently, was directly related to the module of the electric field E_1. Assuming that the transducer operates as an electrostatic transducer, the dependence of the amplitude A of an ultrasonic echo as a function of applied voltage V is given by relation [2] and shown in Fig. 4a. In our experiments, no ultrasonic pulses could be observed under zero applied voltage before charging the foils. This shows that the foils which were used did not exhibit observable "natural" piezoelectricity. Figure 4b is the experimental dependence of A *vs.* V; the important feature is that, for most foils, A does not come exactly to 0 when $V = V_0$. This can be due either to some unexpected phenomenon related to the above process (since $E_1 = 0$ for $V = V_0$) or to the vibration of the polymer foil itself, transmitted to the aluminum crystal through layer 1. In the latter case, and for a given amplitude of vibration of the foil, the impedance mismatch between layers 1, 2, and the metal, would cause the transmitted vibrations to be so small that they would be seen only when the vibrations due to direct

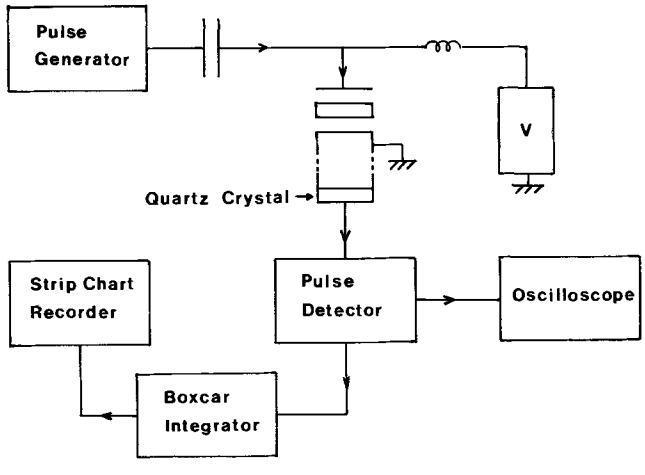

Fig. 3. Block diagram of the apparatus

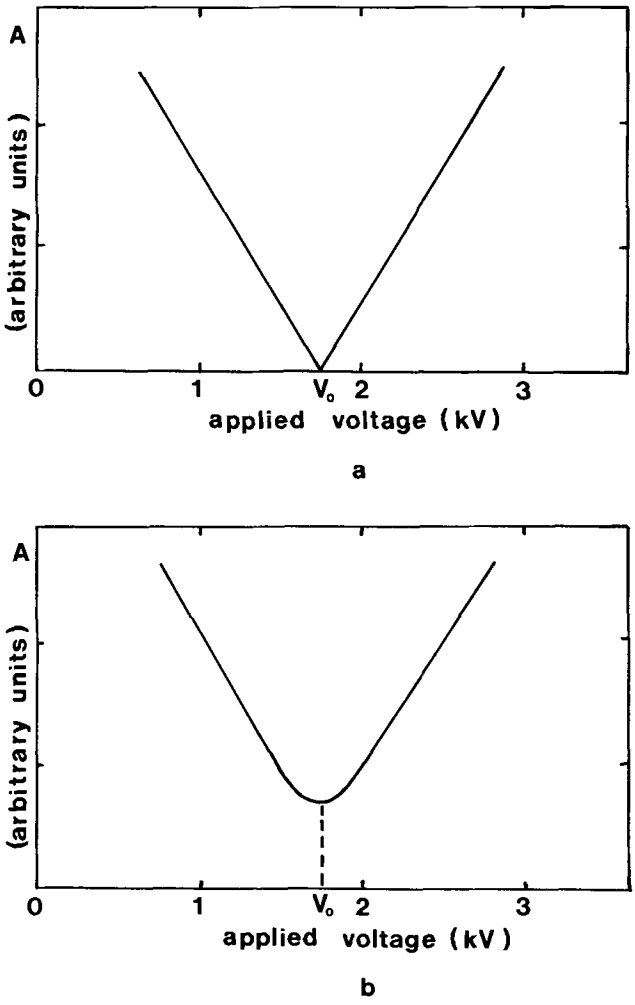

Fig. 4. a) Theoretical dependence of the amplitude of the ultrasonic pulses at frequency ω *vs.* applied voltage. Pulses cancel for $V = V_0$, as results from relations [1] and [3]. b) Experimental dependence of the amplitude of the ultrasonic pulses at frequency ω *vs.* applied voltage. Pulses do not cancel for $V = V_0$.

excitation of the metal are 0, *i.e.*, when $V \neq V_0$. If we assume this latter hypothesis, *i.e.*, that the foil itself vibrates, two synchronous vibrational waves should exist in the electrodes for V different from V_0. One of them is due to the direct excitation of the electrode and the other is due to the vibration transmitted from the foil to the electrode. Two experimental evidences support this hypothesis; first, we could measure a difference in the phases of the two types of waves; second, we were able to observe interferences between these 2 waves.

As to the first evidence, the shape of an echo was recorded on an XY recorder by sweeping linearly in time the position of the gate of the gated amplifier first for $V = V_0$, then for $V \neq V_0$. In order to scale the X axis the markers delivered by a quartz-crystal stabilized pulse generator were similarly recorded. It was observed that the echo produced at $V = V_0$ was delayed from that obtained at $V \neq V_0$ by 0.10 ± 0.03 μsec. Similar phase differences have been reported (15) to occur between directly excited waves and transmitted waves from conventional piezoelectric transducers.

As to the second evidence, the sample and sample holder were slowly cooled down to liquid nitrogen temperature. The mechanical properties of the assembly being a function of temperature, the phase of the pulses due to the polymer foil varied during cooling relative to that of the directly excited pulses, so that, when both systems of pulses were present (*i.e.*, $V \neq V_0$), the amplitude of the detected signal was modulated in time (and consequently in temperature) as shown in Fig. 5. This is due to the interference of the two systems; when the two waves are just in phase they add and the detected voltage is maximum; when they are out of phase the detected voltage is minimum. This oscillatory behavior of the detected signal as a function of temperature disappeared at $V = V_0$, *i.e.*, when only one type of wave was emitted.

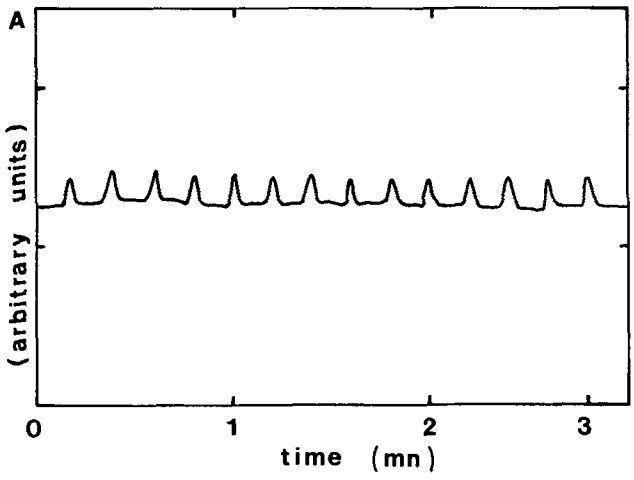

Fig. 5. Interferences between the wave emitted by direct excitation of the electrodes and that due to the vibration of the foil, transmitted to the electrodes.

The two experiments just described allow us to differentiate between the wave emitted by what we called the direct excitation and that produced by the vibration of the foil itself transmitted through layer 1.

Since the polymer foil itself vibrates, it seems desirable to know whether it is caused by electrostriction or piezoelectricity. The following experiments support the latter hypothesis. First, the electret was Corona-charged by applying a high positive voltage to the foil, so that it became negatively charged on the lower side, and positively charged on the upper side; a negative voltage was then applied, so that the inverse process took place: negative charges were injected on the upper side, positive ones on the lower side. The equivalent voltage was then measured, and, if it was still positive, more inverse charges were injected. This process was carried on until V_0 equaled zero. Considering relation [2], and taking into account the symmetry of the geometry and of the process, it can be seen that this implies that

$$\sigma_1 = \sigma_2 = \rho(z) = 0$$

The vibration of the foil due to an electrostrictive effect is described by a similar relation as relation [1], in which field E_1 is replaced by the field $E_2(z)$ within the dielectric foil. Since under the above assumptions on the symmetry of the process, we have $\rho(z) = 0$, then $E_2(z)$ is uniform. When no external voltage is applied, the field E_2 is 0 since $\sigma_1 = \sigma_2 = 0$. No signal at frequency ω should be observed if the relation between stress and electric field were quadratic. Such was not the case in our experiments, which proves that the relation between stress or strain and total electric field is linear. Finally the occurrence of piezoelectricity was proved by the following observation of the direct piezoelectric effect: ultrasonic pulses emitted by the quartz transducer were received by the upper transducer, in the same conditions as previously mentioned where fields E_1 and E_2 are canceled, leaving no other possibility for the conversion than piezoelectricity. Since the polymer foil did not exhibit any piezoelectricity prior to being corona-charged, we had to determine whether the origin of the observed piezoelectricity was related to the high field applied during the charging process (1 to 4 $\times$ 10^6 V/cm), or to the injection of the charges. To answer this question the foil was submitted to as strong an electric field as mentioned above, but without injecting charges. In order

to prevent electric discharges in layers 1 and 3, the sample was very slightly electrified by gentle rubbing; and thus adhered to the upper electrode, which was raised. The sample holder was placed in a vacuum chamber which was pumped until the pressure was about 10^{-5} Torr; the upper electrode was then lowered in vacuo and the electric field turned on. Fields as high as 2×10^6 V/cm were reached without charging the sample and without the foil becoming piezoelectric. The pressure was then raised, the voltage being kept constant, until the disruptive field was reached, according to Paschen's law. The foil was charged and became piezoelectric.

Conclusion

We have analyzed systematically the possible origin of an observed vibration of the electrodes surrounding a polypropylene foil, under an a-c excitation.

The deductive path that has been followed is summarized in Fig. 6. First we have separated the direct excitation from the transmitted excitations. In this latter case electrostriction of the central dielectric had to be ruled out to explain the observed effects. Finally the observed piezoelectricity was proved to be due, not to a high field effect, but to charge injection; this is in agreement with the fact that polypropylene is a nonpolar material. The foil becomes piezoelectric when equal quantities of positive and negative charges have been injected into it; since the penetration depth of such charges is generally small compared to the thickness of the sample (16, 17), we may assume that the piezoelectricity is due to two near-surface layers in which quantities of opposite charges are embedded. We know from Furukawa *et al.* (12) that the component in the direction α of the polarization created by a distribution of charges is

$$P_\alpha = \sum_\beta (u_{\alpha\beta})_0 \sum_i q_i x_{\beta i} + \sum_\beta \sum_\gamma \frac{\partial u_{\alpha\beta}}{\partial x_\gamma} \sum_i q_i x_{\beta i} x_{\gamma i}$$

α, β, γ stand for cartesian coordinates; $(u_{\alpha\beta})_0$ is the macroscopic strain under uniform conditions; q_i is the charge of the i^{th} electric charge; $x_{\beta i}$ is the coordinate of the i^{th} charge in direction β; and $\sum_i q_i x_{\beta i}$ is the dipole moment of the distribution. The second term is the quadrupole moment of the distribution. Since in our case the dipole moment is 0 ($V_0 = 0$), the observed effect is not first order piezoelectricity (*i.e.*, piezoelectricity due to uniform strain). We can infer that in polypropylene the location of traps for positive and negative charges is not completely random, and assume that charges are probably not trapped in the highly disordered surface region, but in the crystalline parts of the polymer foil (18). With this assumption the observation of piezoelectrity should be a powerful tool in order to get information on the symmetry of the crystallites, taking into account the symmetry required by piezoelectricity.

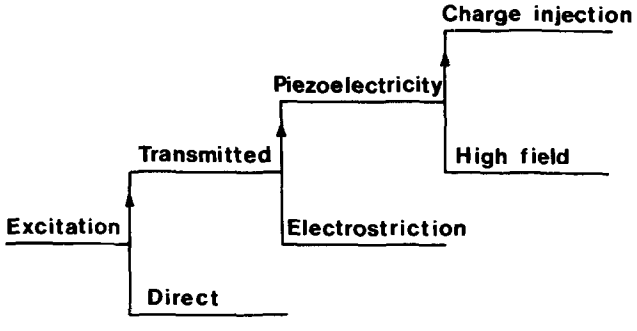

Fig. 6. Logical path followed in the analysis of the vibrations observed in the electrode.

Fabrication of GaAsP MIS Capacitors Using a Thermal-Oxidation Dielectric-Growth Process

D. H. Phillips, W. W. Grannemann, L. E. Coerver, and G. J. Kuhlmann

The University of New Mexico, Albuquerque, New Mexico 87106

ABSTRACT

Heterogeneous insulating films were grown on $GaAs_{1/2}P_{1/2}$ by thermal oxidation at atmospheric pressure. Good insulating and passivating properties of the films resulted from inert-atmosphere annealing. A processing temperature upper limit of 710°C on a minimum of 90 min annealing time are required. Evidence that the film is a mixture of β-Ga_2O_3 and $GaPO_4$ is presented.

Capacitance *vs.* voltage data for metal insulator semiconductor (MIS) capacitors are presented, and surface-state density instabilities are discussed. Use of thermal cycling and chromium doping to obtain stable MIS capacitors is described.

$GaPO_4$ is physically similar to SiO_2. Thermally grown SiO_2 on silicon is fundamental to the MIS integrated circuit technology. The results presented here suggest similar possibilities for GaAsP.

One of the important aspects of the technology of any new semiconductor material is the question of thermal oxidation of the semiconductor surface, both for surface passivation (1) and as the insulator for possible metal insulator semiconductor (MIS) structures. The thermal oxidation of GaAs and GaP have both been studied previously (2, 3). This paper reports the successful thermal oxidation of $GaAs_{1-x}P_x$ to create good, pinhole-free dielectric films suitable for use as insulators in MIS structures.

The goal of the research was to define an open-tube process for growing an insulating film suitable for use as the insulator in an MIS structure. It was evident that surface damage would be an important limitation on the process. Growth rate and dielectric constant of the grown film would also be important film properties to be determined.

Experimental

All experiments were performed on 100 × 100 mil chips using commercially available[1] (100) $GaAs_{1-x}P_x$ material with a phosphorus mole fraction of $x = 50 \pm 2\%$. The 4 mil thick GaAsP epitaxial layer was tellurium doped to a donor concentration of 2.0×10^{15} atoms/cm^3. This material represents the median between GaAs and GaP whose oxidation properties are better known. The epitaxial layer was grown on a 15 mil thick GaAs substrate. The tellurium-doped substrate had a resistivity of 0.003 ohm-cm.

There was a graded region (1-2 mil thick) between the epitaxial layer and the substrate in which the phosphorus mole fraction varied from 0% at the GaAs substrate to 50% at the epitaxial layer.

The growth of the insulating layer on this material was done by open-tube oxidation. Before introduction into the furnace, the chips were lapped and polished to a mirror surface. They were then degreased in trichloroethylene, cleaned in acetone, and chemically etched in a cold mixture of 5:1:1 H_2SO_4:H_2O_2:H_2O for several minutes. The total lapping, polishing, and chemical etch steps removed no more than 38μ of the $GaAs_{1/2}P_{1/2}$ material. The chemical etch was always performed immediately before introducing the chips into the furnace. The oxidation was accomplished by passing atmospheric pressure dry oxygen at a flow rate of from 0.2-1.0 liters/min over the GaAsP chips on a quartz boat in the center section of a Lindberg Diffusatron Mk II style M-50 furnace.

It was quickly discovered that an anneal step was necessary when measurements were made on MIS capacitors. Capacitors made on an unannealed insulator layer almost invariably showed metal semiconductor characteristics with the continuously decreasing capacitance *vs.* voltage (C-V) of a metal semiconductor junction. However, if the chips were put back in the furnace at a temperature no higher than 700°C in a 0.3-1.0-liter/min stream of argon or nitrogen for periods of greater than 1½ hr, most of the pinhole shorts disappeared, and MIS capacitors formed on the annealed insulator film showed capacitor characteristics rather than diode behavior. Consequently, the anneal in an inert atmosphere was always part of the film growth process.

MIS capacitors were formed on the chips by vacuum evaporation of either Al or Cr metal through a metal mask, leaving approximately 10 mil diameter capacitors. Metal contacts were applied immediately after removing the chips from the furnace after annealing. Aluminum was evaporated at pressures less than 2×10^{-5} Torr, and Cr at pressures less than 5×10^{-8} Torr.

After oxidation and annealing there was often some oxide on the GaAs substrate which had to be lapped off before making ohmic contacts on the substrate side.

Ohmic contacts were made on the GaAs by vacuum evaporation of elemental silver at a pressure of less than 2×10^{-6} Torr. This was followed by a microalloying step. The silver dots were alloyed at 650°C for 6 min in an argon flow of about 1 liter/min.

Results and Discussion

A large number of time and temperature experiments were run. An experiment consisted of growing and annealing a film, evaporating metal dots on the surface, and lapping off the oxidized surface of the GaAs substrate. The C-V curve of the device was examined. Experiments were evaluated on the basis of whether they showed MIS capacitor or metal semiconductor diode characteristics.

Figure 1 is a graphical presentation of the results of these experiments with dry oxygen. The dashed lines indicate general regions and are not intended to be exact demarcation lines.

Figure 2 shows four photomicrographs of the oxidized surfaces. Under no circumstances does the film grown look like a single crystal or a completely unstructured glass; it always shows a small crystallite structure. In Fig. 2a, which shows a film grown at 700°C in dry O_2 for 675 min, the film crystallites appear to be considerably less than 1μ in diameter. The background, as always, carries with it the character-

Key words: oxidation, semiconductor devices, dielectric films, $GaPO_4$, Ga_2O_3.

istic color of the film, which goes through the same color sequence as other insulator films on a reflecting semiconductor surface. In all four figures, there are many small white crystallites interspersed in the characteristic color matrix.

Crystallite size grows with increasing temperature, as can be seen by comparing Fig. 2b, c, and d with Fig. 2a.

The film grown at 875°C had varicolored patches on it; the photomicrograph (Fig. 2c) shows a boundary between two such patches. In order to show the structure, the microscope magnification had to be reduced for the 875° and 950°C films. At 950°C a pronounced growth of a white amorphous layer begins to cover considerable areas of the film. The increasing heterogeneity of the films with increasing temperature explains why the MIS structures grown at high temperatures show pinhole shorts and diode characteristics. For increasing temperatures, the crystallites are better defined and the grain boundaries show less tendency to be changed by annealing.

Figure 3, a and b, show the GaAsP surface after the insulating layer has been etched off. Figure 3a shows a chip on which a film had been grown in oxygen for 341 min at 660°C. Later the chip was photomasked and part of the film was etched off with NH_4F. The light part of Fig. 3a is the bare GaAsP surface after etching; the dark part is the unetched film. Small pits can be observed on the surface. Figure 3b shows a similar chip on which a film had been grown for 251 min at 740°C with a subsequent anneal. On this chip, the insulating layer was subsequently removed with NH_4F. It can be seen that there is much more surface

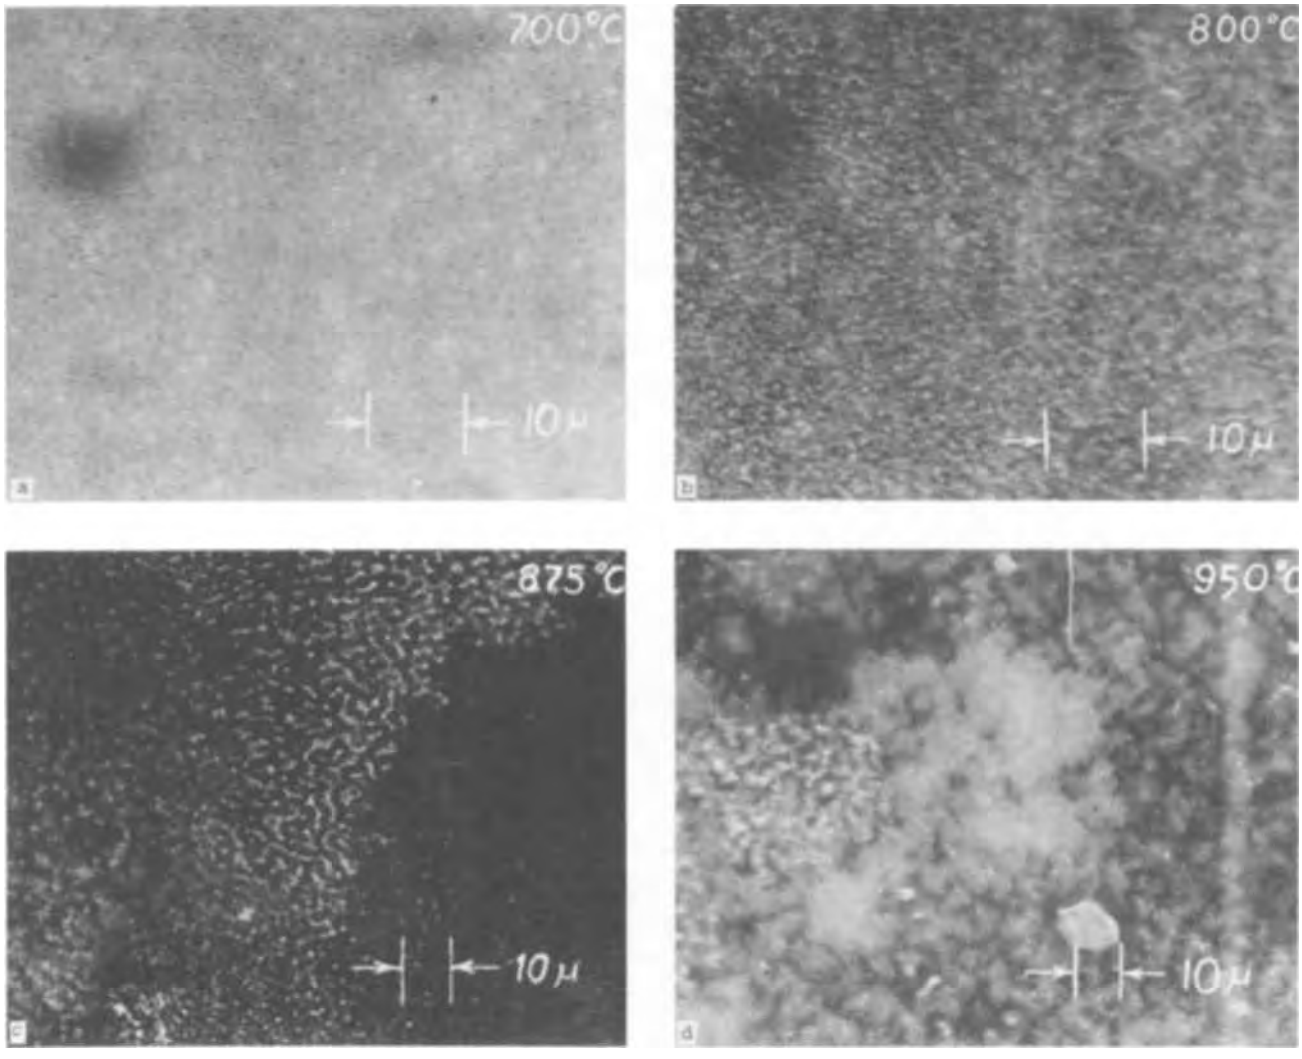

Fig. 2. Photomicrographs of insulating film grown on $GaAs_{1/2}P_{1/2}$ in dry oxygen for various temperatures. Note increasing grain size with temperature. a, 700°C for 675 min (X1000); b, 800°C for 630 min (X1000); c, 875°C for 630 min (X500); d, 950°C for 630 min (X500).

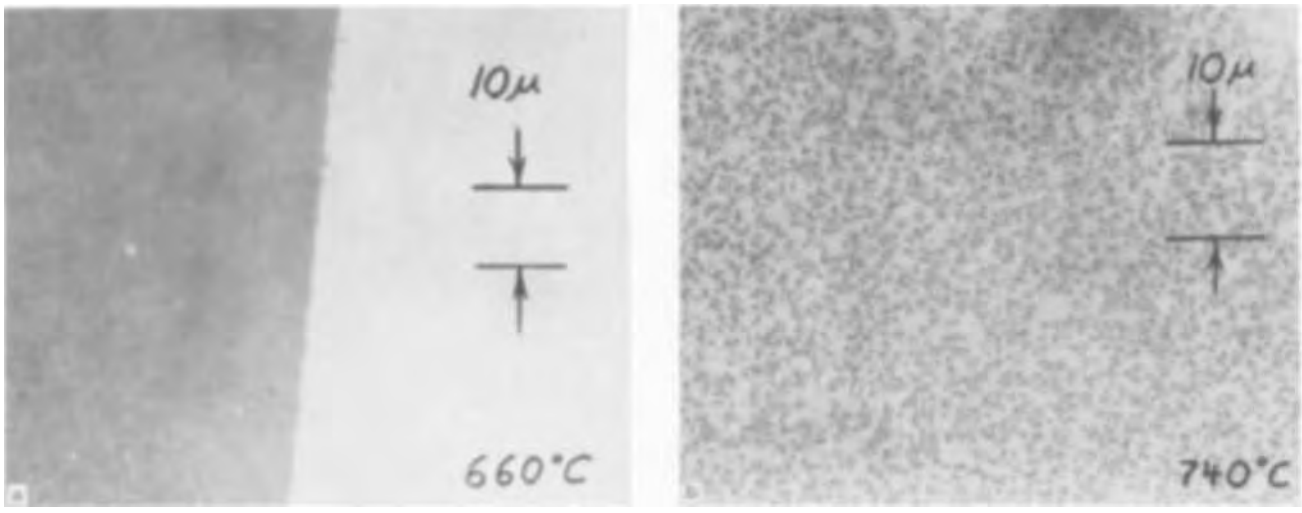

Fig. 3. Photomicrographs of surface of $GaAs_{1/2}P_{1/2}$ after thermal oxidation and etching off of film showing surface damage resulting from oxidation process. a, Partially etched (left-hand side is insulator) at 660°C for 341 min; b, completely etched surface at 740°C for 251 min. Note increase in pit size and density.

pitting and individul pits are larger. It is for this reason that film growth at temperatures higher than 700°C is not recommended.

Figure 3a also indicates the type of edge which can be obtained by photomasking. The edge definition is expected to be limited by the crystallite size, which is about ½μ or less. To check the effects of NH_4F on the surface, a freshly polished $GaAs_{1/2}P_{1/2}$ chip was placed in NH_4F for over 3 days and re-examined. Some slight etching at irregular points about 10μ apart could be seen, and these widely separated etch pits were all aligned along two directions at right angles to each other. The very slow etch rate and pronounced alignment of etch pits to crystallographic planes on a fresh surface indicate that the surface damage of Fig. 3 is due to the oxidation step.

Since the surface pitting dictated such a low oxidation temperature, the growth rate was measured. A number of chips oxidized for various times were selectively etched and the oxide thickness was measured by interferometry. In the process of etching the samples, many etches were tried: NaOH was very fast; NH_4OH very slow; buffered HF, hot HNO_3, and hot H_2SO_4 all etched the film with varying speeds. Hardened negative photoresist was successfully removed in J-100 at temperatures less than 65°C for up to 15 sec. Hot J-100 was also an etch if it was used at the recommended temperature of 80°C.

The most successful etch used was full strength NH_4F. It was slow enough for easy monitoring and did not undercut the photoresist as badly as HF did.

The growth rates for temperatures of 660° and 690°C are shown in Fig. 4. Although this seems slow, it is actually slightly faster than SiO_2 growth on Si at these temperatures. A color chart giving approximate thicknesses of the insulator, provided the order of the reflection is known, is also included in the figure.

There has been some work on the identification of the films but it is not conclusive. From the temperature at which growth must take place and the appearance of the film as a mass of submicron-sized crystallites, it appeared likely that the constituents are separate crystallites of different compounds. The most likely compounds are Ga_2O_3, $GaPO_4$, and $GaAsO_4$ with perhaps some As_2O_3 and/or P_2O_5 trapped in the interstices, although both of the latter are volatile at 700°C.

The very thin layers of insulator make ordinary x-ray crystallographic techniques difficult. One experiment has been performed using a low-energy electron beam to generate K-shell x-rays characteristic of Ga, As, and P. The beam was scanned over a region of the surface generating an x-ray count. The three counts give relative proportions of the three elements. The beam, although of low energy, still penetrated below the film, and the count was representative of the underlying substrate as well as of the film. After applying corrections for electron range, ionization cross section, and x-ray absorption, the results indicated that the arsenic count was much less than that of gallium or phosphorus. If the gallium and phosphorus are assumed to be present as $GaPO_4$ and Ga_2O_3, then the results indicated approximately 60% by volume of $GaPO_4$ and about 30% by volume of Ga_2O_3 with the remainder probably $GaAsO_4$ or As_2O_3. There must be some loss of phosphorus as well as most of the arsenic in order to account for these compounds simply.

If this result is legitimate, it is to be expected that the anneal step could be a process of removal of trapped volatile compounds from a substantial volume of grain boundary and the adjustment of grain boundaries between adjacent submicron crystallites.

If one compares the thickness between two adjacent orders of interference an index of refraction can be calculated. This is more accurate than calculating an index of refraction for a single color, since there are unknown phase shifts at the interfaces which will be subtracted out when a difference and the same color are used (4). Using the mean thickness of two blues and the wavelength of light for which this path length is an integer half-wavelength in Si_3N_4 and SiO_2, an index of refraction of about 1.6 is obtained. This compares with published indices of refraction for $GaPO_4$

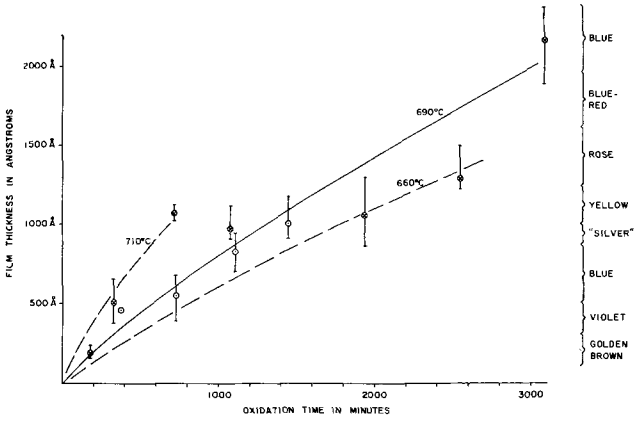

Fig. 4. Growth rate curves for $GaAs_{1/2}P_{1/2}$ oxidized in O_2 at 660°, 690°, and 710°C vs. oxidation time.

of 1.603 and 1.93 for Ga_2O_3 (5) and is taken as evidence that the crystallites carrying the film color are more likely $GaPO_4$ than Ga_2O_3.

Dielectric constant data were not conclusive. The dielectric constant was calculated from data obtained by incorporating thickness data, as described above, with accurate capacitance and area measurements. The MIS capacitors were formed as described above using chromium dots. Ohmic contacts were alloyed silver with a layer of indium soldered to the silver dots for more positive contact. Capacitance measurements were made on a Boonton Model 75C capacitance bridge at a frequency of 500 kHz. MIS capacitors were forward biased to minimize the effect of depletion in the semiconductor. No measurable parallel conductance like that seen with reverse-biased p-n junctions was seen during these measurements.

The thicker films (1500-2000Å thick) had dielectric constants as high as 2.9 with an average at 2.5. The thinner films (600-1200Å thick) had lower dielectric constants with the average at 1.8 and numbers between 1.4 and 2.0. This disparity could be due to a change in the proportions of the compounds in the film or a lower effective density of the film in the case of thinner growths compared with a more dense layer when the growth time was longer. Probably both effects are present.

The main evaluation of the films was the measurement of capacitance-voltage curves of MIS capacitors. The capacitance was measured with a Boonton Model 71A capacitance meter. Voltage was applied by means of an HP 202A low-frequency function generator operating in the triangular wave mode for a period of 50 sec. Provision for applying d-c offset voltage was also incorporated in the measurement system. Normally the offset voltage was set to provide a bias which was swept from +4 to −18V in 25 sec. C-V curves were plotted on a Houston Corporation X-Y plotter.

The original MIS structures used aluminum metalization. The C-V curves showed very bad instability. When the C-V curve was plotted on both the increasing and decreasing values of the triangular wave from the function generator, flatband voltage [see, for instance, Ref. (6), p. 279] shifted in an irregular manner indicating changes in the "fast" surface-state density as the bias was slowly varied from +8 to −10V.

Considerable improvement was obtained by thermal cycling of the MIS structure. A thermal cycle consisted of placing the chips on a quartz boat in the Lindberg furnace for 5 min and then withdrawing the boat to the furnace mouth for 5 min. This process comprised one thermal cycle. Ten such cycles gave adequate bias stability of the C-V curves except for the initial C-V trace. [This result was described in some detail by the authors in Ref. (1).]

Further improvement was obtained when chromium was used as the metal in the MIS structure in place of aluminum. The process was as described in the experimental procedure above except that the MIS structure was sintered, after chrome metalization, by heating the MIS capacitor at 600°C for 45 min or at 700°C for 5 min in an argon stream with a flow rate of about 0.5 liter/min. No bias stress shifts in the flatband voltage were observed.

The final shape of the C-V curves now being obtained is shown in Fig. 5. The insulator film was grown for about 10 hr at 700°C on n-type $GaAs_{1/2}P_{1/2}$ material with a tellurium doping of 5.36×10^{15} atoms/cm^3. An anneal of 285 min at 700°C in argon (0.3 liter/min) followed the oxidation. From the color, the thickness was determined to be approximately 1100Å. Evaporated 10 mil chromium dots formed the metal top of the structure. The capacitor area was 5.0×10^{-4} cm^2. Ohmic contact to the GaAs was made with a pattern of silver 10 mil dots which were pulse alloyed to break down residual metal semiconductor barriers.

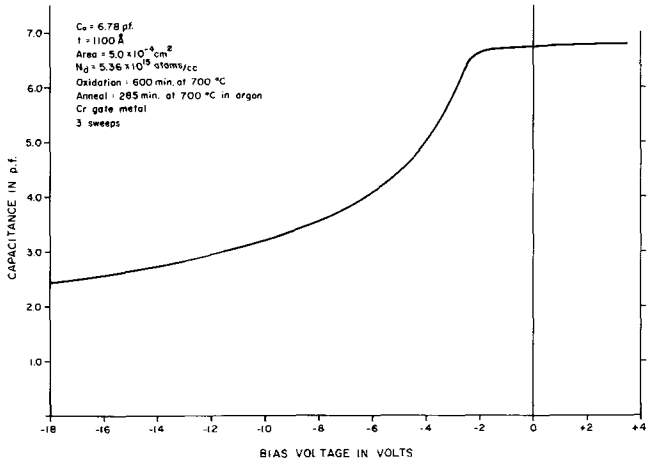

Fig. 5. Capacitance vs. voltage of typical MIS capacitor showing the continuous decrease in differential capacitance and the displacement of flatband voltage in the negative direction which is characteristic of positive surface charge density.

These MIS capacitors exhibit very good short and long-term bias stress stability. The flatband voltages of devices of this kind now exhibit the same positively charged surface-state densities which are common in silicon MIS capacitor structures.

The continuous depletion observed in the curves under steady-state (slow bias sweep) conditions is not fully explained. The effect is believed to be caused by the much lower generation rate in $GaAs_{1/2}P_{1/2}$, which has a 2.0 eV bandgap and intrinsic carrier concentration of about 10^3 carriers/cm^3. In silicon, with its 1.1 eV bandgap and intrinsic carrier concentration of 1.2×10^{10} carriers/cm^3, this effect does not occur under steady-state conditions.

In silicon, the inversion layer is formed by thermal generation of minority carriers in the depletion region. Under transient (nonequilibrium) conditions, such as when a rapid voltage pulse is applied, an inversion layer cannot build up rapidly enough at the surface to follow the voltage, and a continuously decreasing capacitance results (7, 8). This essentially means that the thermal generation rate is not high enough for minority carriers to respond to the applied bias voltage.

In $GaAs_{1/2}P_{1/2}$ the thermal generation of minority carriers in the semiconductor depletion region may not be sufficient to invert the semiconductor-insulator interface. This would result in a steady-state depleted region in $GaAs_{1/2}P_{1/2}$ similar to that observed under transient conditions in silicon. The depletion width will increase with increasing negative bias, and a depletion-type curve similar to that shown in Fig. 5 would result.

Conclusions

The work reported in this paper allows the following conclusions to be drawn.

Dry thermal oxidation of $GaAs_{1/2}P_{1/2}$ will result in a heterogeneous growth of an insulating layer of sufficient integrity to be used as the insulator for MIS structures provided the rigid temperature constraints are not violated and the film is annealed in an inert atmosphere.

MIS structures which have stable, reproducible electrical properties can be fabricated using sintered chromium as the gate metal, the mixture of compounds as the gate insulator, and the $GaAs_{1/2}P_{1/2}$ as the semiconductor.

Etch Rates of Doped Oxides in Solutions of Buffered HF

A. S. Tenney*,[1] and M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The dependence of the etch rates of vapor-deposited binary borosilicate, phosphosilicate, and arsenosilicate glasses on glass composition and per cent buffered HF (1 part 48% HF to 10 parts 40% NH_4F) in water are presented. The etch rates of these doped glasses generally increase with increasing dopant oxide concentration, the exception being those of borosilicate glasses in concentrated buffered HF which exhibit minima at about 18 mole per cent (m/o) B_2O_3. The use of these and similarly gathered results to infer new etchants is demonstrated.

The use of doped oxides as dielectric materials, passivation layers, diffusion masks, diffusion sources, etc. has become increasingly important to semiconductor device technology. The employment of these materials frequently demands a knowledge of their rate of dissolution in some convenient etching solution. Selective etchants—solutions which etch glasses at rates dependent upon the glass composition—have been employed extensively (2, 3, 5-7, 10, 14-16, 19, 25, 27). Particularly useful would be a general relation between etch rate and chemical composition in light of recent work allowing the nondestructive determination of borosilicate (18, 20, 21), phosphosilicate (12, 28), and arsenosilicate (22) glass compositions.

Usually, the composition of the doped glass, and thus its etch rate in a given solution, is dictated by the application planned for the glass. Frequently the resulting etch rate is either inconveniently slow or uncontrollably fast in familiar etchants. However, the isothermal etch rate of a glass may depend not only on the composition of the glass but also on that of the etchant. The effect of the systematic variation of etchant composition on the etch rate of SiO_2 has been studied (17). With the glass composition fixed, desirable etching characteristics may still be achieved by varying the etchant composition.

Thus the processing of these glasses can be facilitated with knowledge of the dependence of their etch rates not only on glass composition but also on etchant composition.

In the present work, the effect of dilution in water on the etch properties of buffered HF (10 parts 40% NH_4F solution to 1 part 48% HF solution by volume) is studied. Presented in this paper are the etch rates of borosilicate, phosphosilicate, and arsenosilicate glasses as functions of glass composition and dilution of buffered HF in water. Results for all these glasses after heat-treatment (simulating conditions often used to achieve dopant diffusion into silicon) and for phosphosilicate glasses as-deposited at 350°C are shown.

Experimental

The doped oxides were deposited on chemically polished 10 ohm-cm P-type silicon wafers 1 in. in diameter by the reaction of Ar-diluted mixtures of O_2, SiH_4, and B_2H_6, PH_3, or AsH_3 at 300°-500°C. The chemical vapor deposition system employed is identical to that described by Brown and Kennicott (16). The films were generally about 7000Å thick.

The glass compositions were calculated from their *IR* spectra, as obtained with a Perkin-Elmer double beam recording spectrophotometer, Model 457-A, employing calibration curves relating glass composition to the *IR* spectra of these glasses. Compositions were determined within an estimated ± 0.5 to 1% for borosilicate glasses (21), ±1.5% for phosphosilicate glasses (28), and ±1% for arsenosilicate glasses (22).

Heat-treatments were performed in an open tube furnace flushed with argon.

Etching solutions were prepared by adding distilled water in the desired proportion to buffered HF solution (10 parts 40% NH_4F: 1 part 48% HF by volume) prepared from Mallinckrodt Transist AR-grade chemicals. All etchings were performed at room temperature (26°±1°C).

The etch rate was defined as the decrease in film thickness per unit time in the etchant. Film thicknesses were determined from the interference colors observed perpendicularly to the film surface under a fluorescent "daylight" lamp employing the color chart of Pliskin

* Electrochemical Society Active Member.

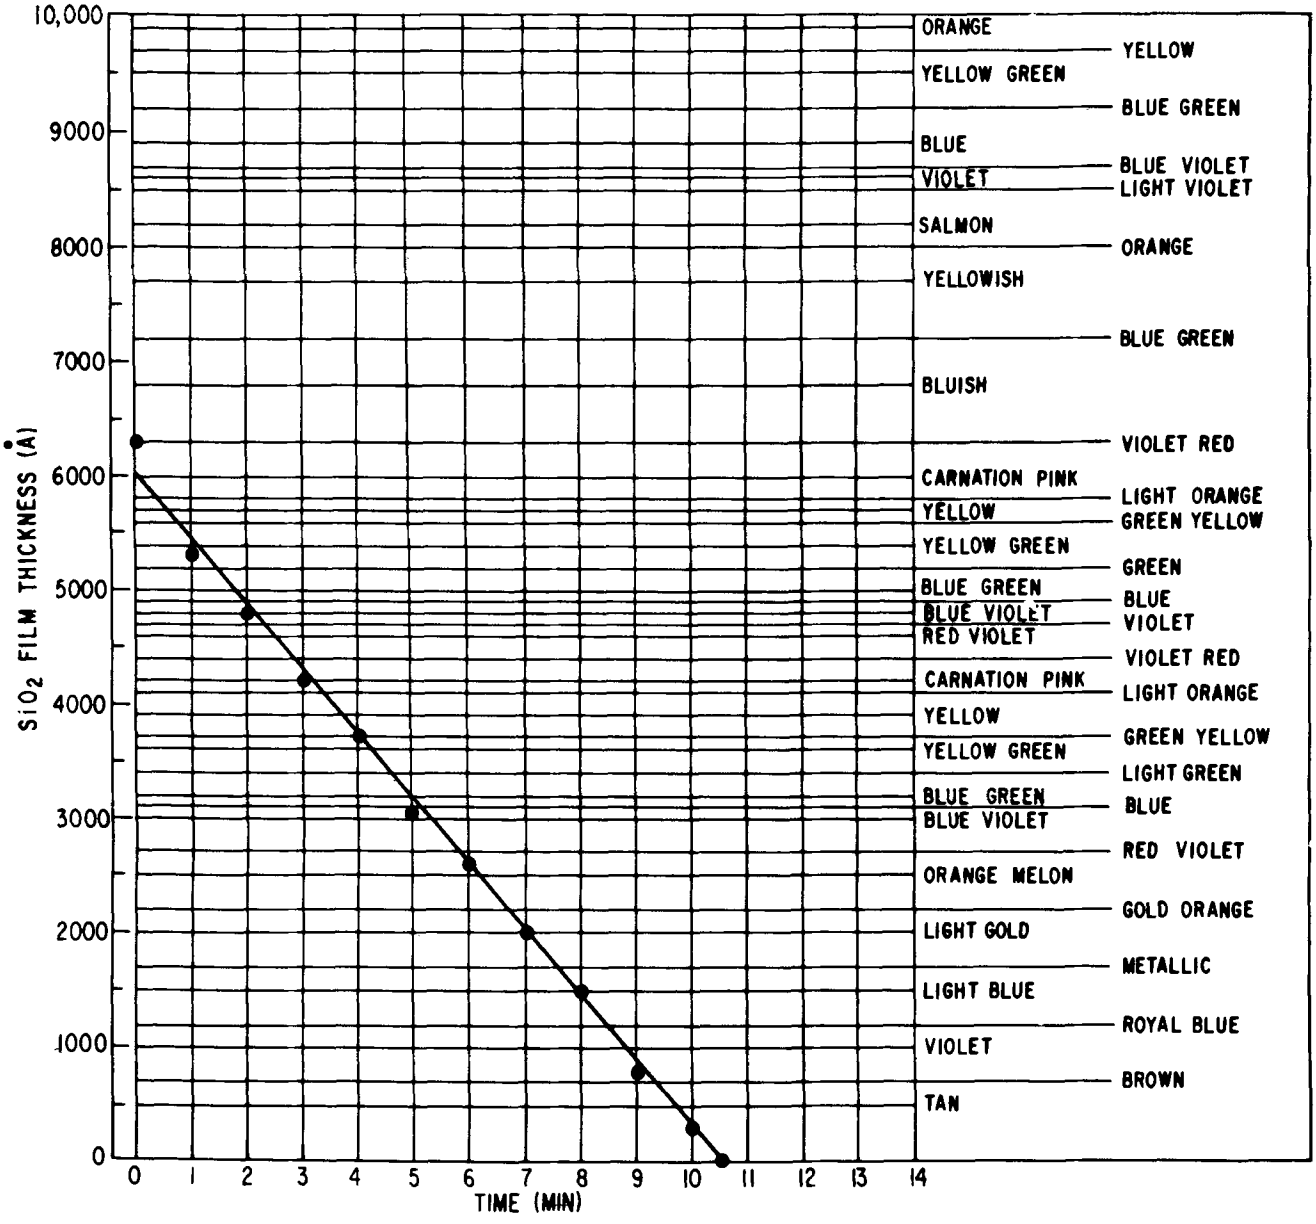

Fig. 1. Graphical representation of the interference color chart of Pliskin and Conrad (1). The data shown are for a heat-treated SiO_2 film etched in 50% BHF. The slope of the plot of residual thickness vs. etching time gives an etch rate of 570 Å/min.

and Conrad (1). It was determined ellipsometrically that the refractive indices of the doped oxides are close enough to that of pure SiO_2 to allow the use of this chart with the introduction of an uncertainty smaller than the experimental one. Figure 1 shows a graphical arrangement of this interference color chart which allows a direct plot of the residual film thickness *vs.* etching time. The slope of this plot is the etch rate.

Except for heat-treated borosilicate glasses [for which a hydrophilic, boron-rich phase may form at the silicon-glass interface (8, 9, 16, 29)], the complete removal of the oxide film is easily detected by observing a reversal of the meniscus formed by the etching solution with the partially immersed wafer held perpendicularly to the liquid surface (11). The oxide film is hydrophilic while the silicon surface is hydrophobic. The precise determination of this point is reflected in its agreement with the rest of the data plotted in Fig. 1.

Results

Borosilicate glass.—The etch rates of four glasses (0, 16.5, 23.5, and 30 mole per cent (m/o) B_2O_3] in four etchants buffered HF (BHF = 1 part 48% HF to 10 parts 40% NH_4F by volume), 50 volume per cent (v/o) BHF in H_2O, 10% BHF and 1% BHF) were determined. These glasses were heat-treated for 15 min at 1000°C.

In Fig. 2, the etch rates of these glasses in these four etchants are shown as functions of glass composition. Both 1% BHF and 10% BHF etch glasses of increasing B_2O_3 concentration at increasing rates while 50% BHF and BHF show minima in their etch rates at about 18 m/o B_2O_3. Brown and Kennicott (16) and Kern and Heim (15) have observed similar minima in the etch rate of borosilicate glasses in BHF.

The etch rates of these four glasses are plotted in Fig. 3 as functions of the concentration, in volume per cent, of BHF in water. As can be seen from either Fig. 2 or Fig. 3, the etch rate of SiO_2 decreases with decreasing BHF concentration, while borosilicate glasses with $16 < \text{m/o } B_2O_3 < 30$ exhibit etch rates which first increase then decrease with decreasing BHF concentration.

Phosphosilicate glass.—The etch rate of five glasses (0, 0.5, 3.0, 6.0, and 8.2 m/o P_2O_5) in six etchants (BHF, 50% BHF, 25% BHF, 10% BHF, 3% BHF, and 1% BHF) were determined. Both glasses as-deposited at 350°C and after heat-treatment for 2 hr at 1100°C were studied.

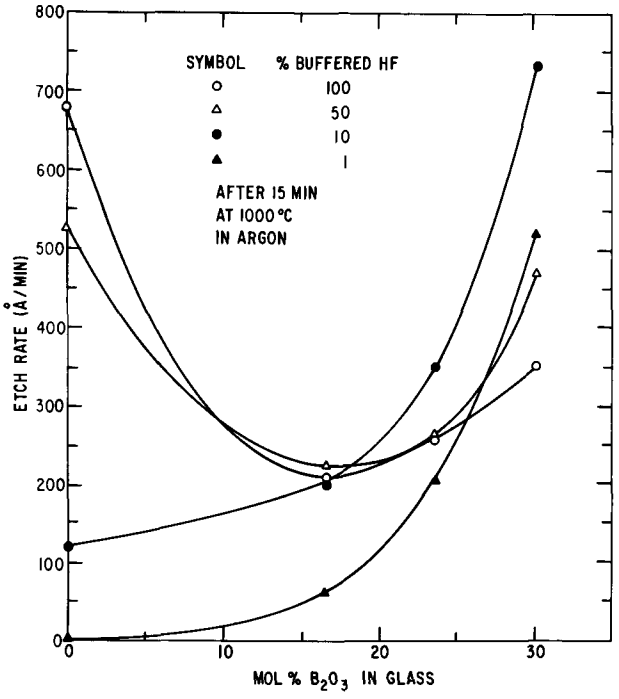

Fig. 2. Etch rates of heat-treated borosilicate glasses in buffered HF(BHF), 50% BHF, 10% BHF, and 1% BHF *vs.* mole per cent B_2O_3.

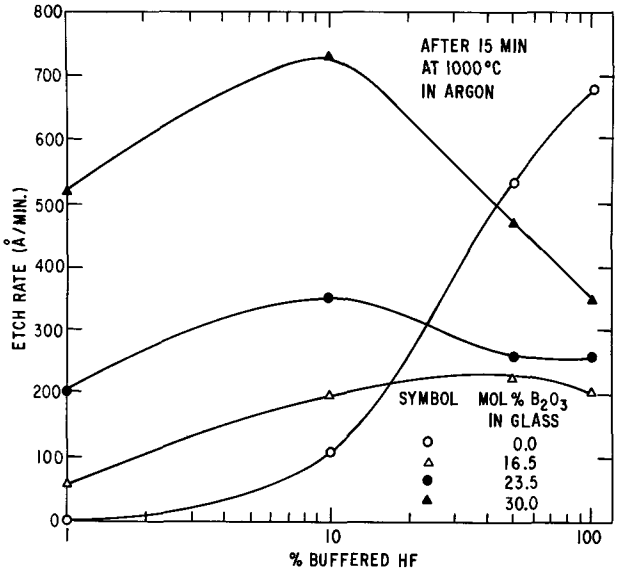

Fig. 3. Etch rates of heat-treated borosilicate glasses 0, 16.5, 23.5, and 30.0 m/o in B_2O_3 *vs.* per cent BHF.

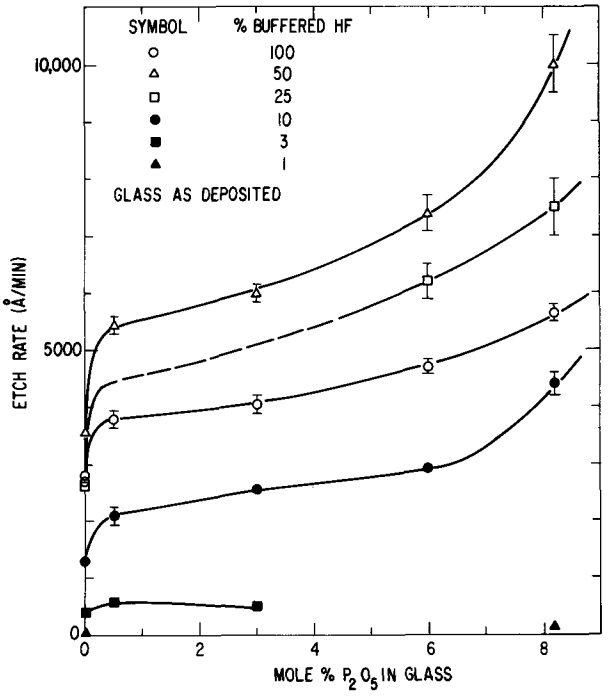

Fig. 4. Etch rates of as-deposited phosphosilicate glasses in BHF, 50% BHF, 25% BHF, 10% BHF, 3% BHF, and 1% BHF *vs.* mole per cent P_2O_5.

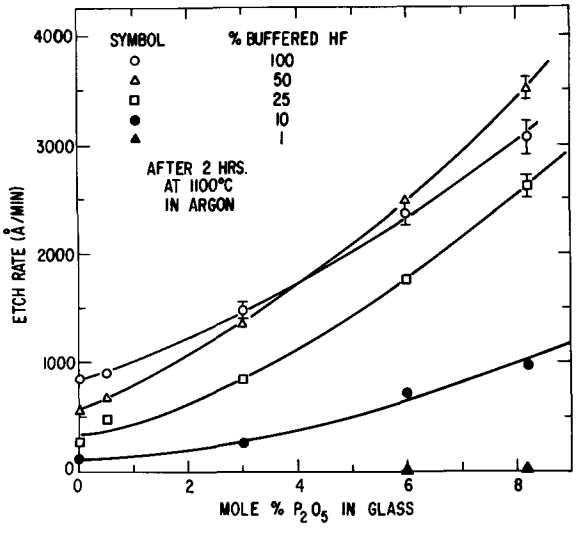

Fig. 5. Etch rates of heat-treated phosphosilicate glasses in BHF, 50% BHF, 25% BHF, 10% BHF, and 1% BHF *vs.* mole per cent P_2O_5.

The addition of an initial 1 m/o P_2O_5 to pure SiO_2 appears to cause a marked increase in the etch rate of as-deposited glasses (Fig. 4) which is not observed in that of heat-treated glasses (Fig. 5). The heat-treatment employed causes a decrease in the etch rates of the phosphosilicate glasses studied by a factor of three to five. Similar decreases in etch rates of borosilicate (15, 16), phosphosilicate (15), and arseno-silicate (25) glasses have been observed upon heat-treatment.

The etch rates of these glasses as-deposited and after heat-treatment, respectively, are shown in Fig. 6 and 7 as functions of per cent BHF. It is seen in Fig. 6 that the etch rates of all phosphosilicate glasses studied, and of pure SiO_2 as well, as-deposited exhibit maxima at about 50% BHF. After heat-treatment, however, only glasses greater than 6.0 m/o in P_2O_5 exhibit maxima in their etch rates while increasingly smaller shoulders are observed in the 50% BHF region for glasses of decreasing P_2O_5 content, as seen in Fig. 7.

Arsenosilicate glass.—The etch rates of four glasses (0, 0.5, 2.2, and 4.8 m/o As_2O_3) in four etchants (BHF, 50% BHF, 10% BHF, and 1% BHF) were determined after heat-treatment for 5 hr at 1100°C. These etch rates increase approximately linearly with increasing As_2O_3 concentration over the range $0 \leq$ m/o $As_2O_3 < 5$ as seen in Fig. 8. Although no maximum is observed in the dependence of etch rate on per cent BHF as seen in Fig. 9, the shoulder, increasingly prominent in this plot with increases in As_2O_3 concentration, suggests that glasses richer in As_2O_3 than those studied here may exhibit maxima. Such a determination was obviated by the fact that arsenosilicate glasses of more than about 7 m/o As_2O_3 are damaged on heat-treatment (27). The results for arsenosilicate glasses shown in Fig. 8 and 9 are remarkable only in their similarity, both in characteristics and in absolute values, to those for heat-treated phosphosilicate glasses, over the same concentration range, shown in Fig. 5 and 7.

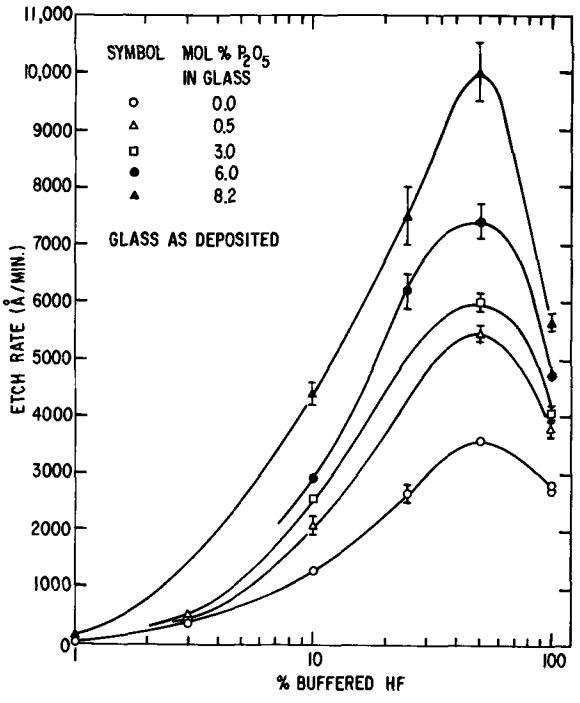

Fig. 6. Etch rates of as-deposited phosphosilicate glasses 0, 0.5, 3.0, 6.0, and 8.5 m/o in P_2O_5 vs. per cent BHF.

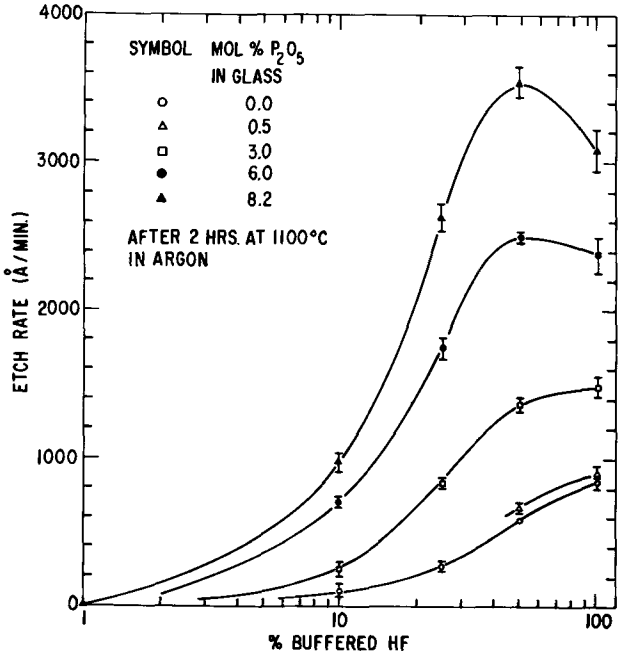

Fig. 7. Etch rates of heat-treated phosphosilicate glasses 0, 0.5, 3.0, 6.0, and 8.5 m/o in P_2O_5 vs. per cent BHF.

Discussion

Etch rate results such as those shown in Fig. 2-9 are helpful in semiconductor device processing. For instance, suppose that there were interest in etching a pattern in 30% B_2O_3 glass deposited over pure SiO_2. Forty-two per cent BHF will etch both glasses at about the same rate (as seen by the intersection of the 30% B_2O_3 and 0% B_2O_3 lines in Fig. 3) while 1% BHF will etch the 30% B_2O_3 glass at a reasonable rate (500 Å/min) leaving the SiO_2 beneath essentially unetched. Thus, either selective or nonselective etches may be inferred from these or similar results.

The monotonic increase in etch rate with increases in dopant concentration observed for borosilicate glasses in dilute BHF solutions and for phosphosilicate and arsenosilicate glasses in all concentrations of BHF

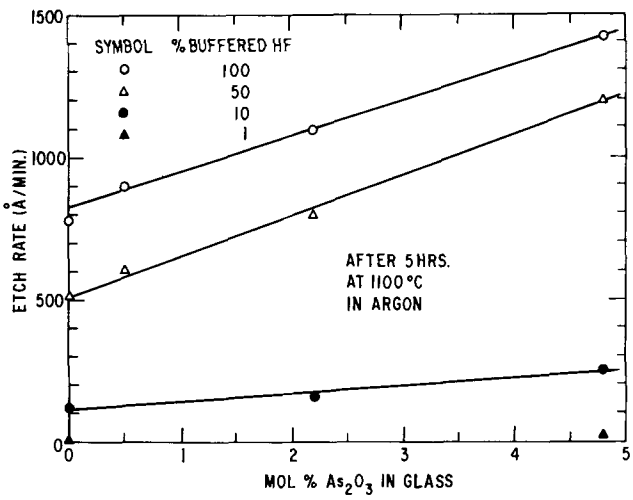

Fig. 8. Etch rates of heat-treated arsenosilicate glasses in BHF, 50% BHF, 10% BHF, and 1% BHF vs. mole per cent As_2O_3.

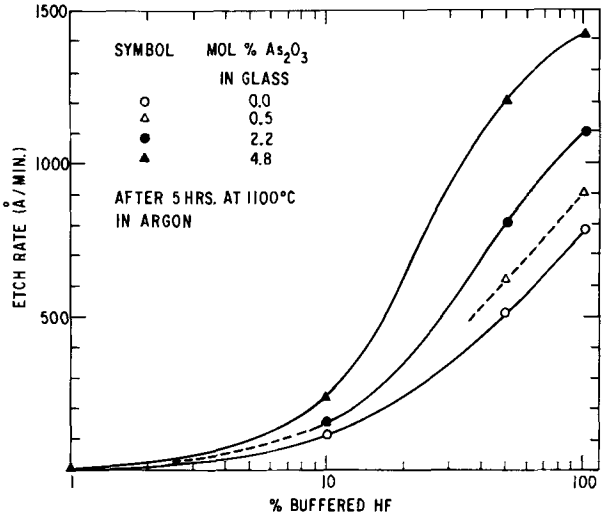

Fig. 9. Etch rates of heat-treated arsenosilicate glasses 0, 0.5, 2.2, and 4.8 m/o in As_2O_3 vs. per cent BHF.

suggests that these etch rates are controlled primarily by the dissolution of the SiO_2 in the glass. Adding dopant oxide essentially dilutes the SiO_2 facilitating its dissolution. Implicit in this description of the etching process is the assumption that the dopant tends to be removed from the glass more rapidly than SiO_2 does. Assuming further that the dopant is removed primarily by its dissolution in the water present in the etching solution is consistent with two observations: (*i*) there is an initial increase in the etch rates of heavily doped glasses with increasing water concentration and (*ii*) the etch rate maximum shifts to increasingly dilute solutions of BHF with increases in dopant concentration.

Thus the etching process may be seen most simply as a combination of the dissolution of the SiO_2 by BHF-originated species[2] and that of the dopant oxide by water.

Extension of this description to the etching of borosilicate glass in solutions concentrated in BHF requires the further assumption that the initial dopant species formed on addition of boron oxide to SiO_2 is not strongly soluble in water. This is not inconsistent with previous results for these glasses; for while B_2O_3 itself is soluble in water, it has been shown that the B—O—B bonds present in pure B_2O_3 are present only at very low concentrations in borosilicate glasses dilute in boron oxide (24).

The effect of boron oxide present at low concentrations in borosilicate glass appears to be to protect the

[2] J. S. Judge (17) has shown these to be HF_2^- and HF.

SiO_2 from the BHF, thus lowering the etch rate in concentrated solutions of BHF. As the B_2O_3 is increased in concentration, its solubility in water becomes a more important factor and the etch rate increases (see Fig. 2). The etching characteristics of borosilicate glass in BHF have been described similarly by Brown and Kennicott (16). As stated above, the etch rates of borosilicate glasses in dilute solutions of BHF appear to be limited for all B_2O_3 concentrations by the ability of this dilute BHF to dissolve the SiO_2.

The relative etching characteristics of borosilicate and phosphosilicate glasses appear to be related to the relative solubilities of B_2O_3 and P_2O_5, respectively, in water. This difference manifests itself in the fact that the etch rates of phosphosilicate glasses increase much more rapidly with increasing dopant concentration than do those of borosilicate glasses (compare Fig. 2 and 5). Also, phosphosilicate glasses exhibit maxima in their etch rates at BHF concentrations less than 100% for much lower dopant oxide concentrations than do borosilicate glasses (compare Fig. 3 and 7).

This relationship between etching characteristics and dopant oxide solubility does not extend to arsenosilicate glasses. These exhibit etching characteristics which are very similar to those of phosphosilicate glasses of similar dopant concentration in spite of the fact that the solubility of As_2O_3 is quite similar to that of B_2O_3—far less than that of P_2O_5. Such etching characteristics would be expected only if the dopant species in arsenosilicate glasses were As_2O_5, which has been shown not to be the case (22).

It should be pointed out that a direct comparison of the borosilicate phosphosilicate, and arsenosilicate glass etch rates is complicated by the fact that these glasses were subjected to different heat-treatments after deposition: 15 min at 1000°C for the borosilicate glasses, 2 hr at 1100°C for the phosphosilicate glasses, and 5 hr at 1100°C for the arsenosilicate glasses. It is clear that the thermal "history" of a glass can have a measurable effect on such properties as vibrational spectra (4, 7, 13, 15, 18, 20, 21, 24, 28, 30), strain density and damage (4, 7, 13, 22, 23, 26, 27), and, specifically, etch rates (4, 15, 16, 25).

Summary and Conclusion

The etch rates of vapor-deposited borosilicate, phosphosilicate, and arsenosilicate glasses have been determined as functions of glass and etchant compositions. Given is a qualitative explanation of these results based on the assumption that each oxide component of the binary mixture is preferentially etched by only one component of the etchant solution. Specifically, it is assumed that SiO_2 is dissolved by BHF and dopant oxide principally by water. A simple correlation between etching characteristics and dopant oxide aqueous solubility was not found in terms of this model.

The use of these results to infer the optimum BHF concentration for a specific processing situation has been demonstrated. Of more general interest, however, is the fact that the principle employed—the gathering of results for a few different substrate and etchant compositions followed by the interpolation of the results to new compositions—may be applied to the etching of any multicomponent system for which etchants which preferentially etch each component may be found (and mixed).

Finally, the graphical representation of Pliskin and Conrad's interference color chart (1) provides a convenient method for gathering etch-rate data and calculating the results.

Acknowledgment

The authors take the opportunity for thanking Dr. D. M. Brown for use of his chemical vapor deposition equipment and his continuing interest in this work.

The Use of Rutherford Backscattering to Study the Behavior of Ion-Implanted Atoms During Anodic Oxidation of Aluminum: Ar, Kr, Xe, K, Rb, Cs, Cl, Br, and I

F. Brown and W. D. Mackintosh

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

It is shown that from the energy spectra of He ions backscattered from aluminum, recorded before and after anodic oxidation, the thickness of the oxide films and the positions of ion-implanted foreign atoms within the films can be determined. Information on the composition and uniformity of the films is also obtained. The scope, limitations, and precision of the method are predictable and are discussed. As model experiments the behavior of ion-implanted noble gases was studied. The results agree with previous work and can be interpreted to show that, as expected, both aluminum and oxygen are mobile during the oxidation. The behavior of ion-implanted alkali metals and halogens was also studied. These species were found to be mobile during oxidation and behaved in a manner consistent with their expected ionic charges.

Background.—Radio-tracer techniques for studying the migration of metal and oxygen during anodic oxidation have been described in several publications (1-5). In these methods a very thin surface layer is tagged with radioactive marker atoms and after oxidation the position of the marker relative to the surface, *i.e.*, its depth, is determined. In one method (1-3) ^{125}Xe was used as the marker and its depth determined by β-ray spectrometry; the energy loss suffered by the low energy conversion electrons in traveling to the surface is a measure of the depth of the emitting marker atoms. In a second modification (4), ^{222}Rn was used as marker and its depth determined by measuring the energy loss of the emitted α-particles. In a third method (5), chemical sectioning combined with radio-assay was used to determine the positions of ^{222}Ra, ^{125}Xe, ^{85}Kr, and ^{41}Ar. All these experiments are interpreted by assuming that the noble gas markers are immobile during anodic oxidation, whereby transport numbers for metal and oxygen can be derived. Evidence for immobility of noble gas markers, in experiments on anodic oxidation of tantalum, has been discussed in detail by Pringle (5).

Direct observation of oxygen migration during anodic oxidation has been achieved by Amsel (6) and for thermal oxidation, by Ollerhead, Almqvist, and Kuehner (7) and by Cox and Roy (8). In these studies, isotopically enriched oxygen was located by means of nuclear reactions promoted by accelerated ions.

Whitton (9) has used radio-tracer and sectioning techniques to study the behavior of Rb, Kr, and Br during the anodic oxidation of zirconium and tantalum.

In this paper we describe a method for determining marker position using Rutherford scattering which requires neither radioactive tracers nor sectioning techniques. For the present we describe experiments to establish some of the advantages and disadvantages of the method, choosing systems that should serve as simple models. We have extended earlier work with noble gases in the anodic oxidation of aluminum, using a single technique to study the behavior of Ar, Kr, and Xe under identical oxidation conditions. In addition, since the argument for the immobility of noble gas markers is founded, in part, on the concept that they are uncharged, we have, following Whitton (9), studied the behavior of potentially charged species. The alkali metals and the halogens were used to find whether a consistent behavior could be observed.

Key words: anodic oxidation, Rutherford backscattering, aluminum, noble gases, alkali metals, halides.

In performing and interpreting the experiments we have attempted to cover the following points.

(*i*) The technique has been tested generally to confirm that practical results for sensitivity, resolution, and precision are in line with expectations and to indicate the types of systems that are amenable to practical investigation.

(*ii*) The behavior of a foreign atom during anodic oxidation might well be different according to whether it was initially in the metal or in a layer of oxide already formed. Experiments were therefore done with the markers both in the metal and in preformed anodic oxide of about 10 $\mu g/cm^2$ thickness.

(*iii*) Rutherford scattering requires more marker atoms than radio-tracer methods. It was therefore necessary to establish whether the amount of marker required for the analysis interferes with the anodizing process. To this end a series of specimens were used containing different amounts of marker.

(*iv*) Experiments were also carried out to establish whether or not markers were affected by an electric field under such conditions that the oxide was not growing.

(*v*) We have established that limited, but useful information can be obtained on the widths of marker distributions.

(*vi*) In addition to studying marker positions the technique gives useful information on the uniformity, thickness, and stoichiometry of the oxide films.

Principles of marker methods.—These principles, especially as applied to the use of noble gas markers, have been discussed in papers already cited. If the marker is regarded as immobile it forms a reference point from which the transport numbers of the metal and oxygen can be calculated. Given this reference point the movement of another species can, in principle, be established. In the case of a mobile species we have calculated a migration number, defined as the ratio of the distance moved (from the immobile reference point) to the thickness of oxide grown. This, of course, implies that the immobile reference point must be established or assumed for the particular system being studied.

Location of markers by Rutherford scattering.—The principles and analytical applications of Rutherford scattering have been reviewed by Mackintosh and

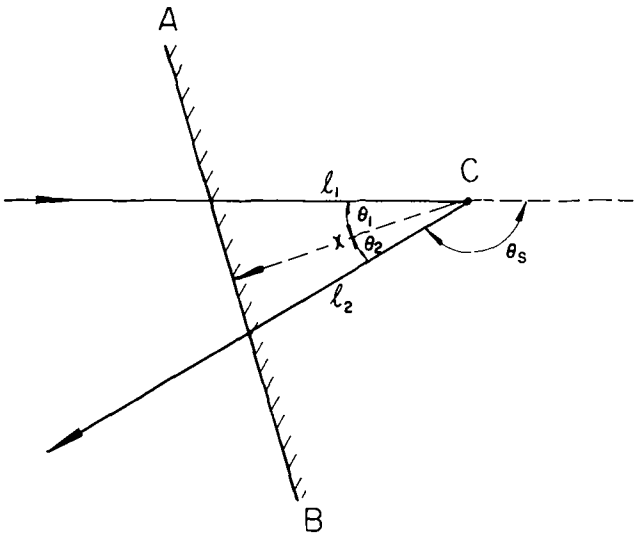

Fig. 1. Schematic diagram showing the geometric relationships of the angles involved in Eq. [1] and [2]. l_1 is the ingoing trajectory of the particles making an angle θ_1 to the normal to the surface AB. l_2 is the outgoing trajectory making an angle θ_2 to the normal. x is the depth of the target atom C below the surface. θ_S is the laboratory scattering angle.

Davies [(10) and references therein]. We reiterate here only those principles necessary for understanding marker location.

When a beam of monoenergetic ions strikes a surface some will be scattered from the surface atoms, losing energy in an amount dependent on the mass of the atom struck and the scattering angle. The energy of the reflected particle is given by

$$E_1 = k^2 E_0$$

where

$$k = \frac{M_1 \cos\theta_S}{M_1 + M_2} + \left[\frac{(M_1 \cos\theta_S)^2}{(M_1 + M_2)^2} + \frac{M_2 - M_1}{M_1 + M_2} \right]^{1/2} \quad [1]$$

M_1 is the mass of the incident ion, M_2 the mass of the struck atom, and θ_S is the laboratory scattering angle (Fig. 1). If the incident particle does not suffer scattering in the surface layer, it will lose energy as it penetrates to lower layers. Thus, just before being scattered, it will have an energy of E_0^1. The scattered particle will also be slowed down on its way back to the surface and will emerge with an energy E_1^1. If the rate of energy loss is given by the stopping power $S(E)$, then the energy of a particle emerging from a depth x below the surface is expressed by

$$E_1^1 = k^2 \left[E_0 - \int_0^{l_1 = x\sec\theta_1} S(E)\,dl \right] - \int_{l_2 = x\sec\theta_2}^{0} S(E)\,dl \quad [2]$$

The first and second integrals are, respectively, the energy losses along the ingoing and outgoing trajectories l_1 and l_2. The angles the trajectories make with the normal to the surface are θ_1 and θ_2; thus $l_1 = x\sec\theta_1$ and $l_2 = x\sec\theta_2$ (Fig. 1). $S(E)$, the stopping power, depends on the energy of the particle.

In the present work a beam of 2 MeV He^+ ions was used, with a solid-state detector and pulse height analyzer to record the energy spectra of backscattered ions. The spectra were then interpreted using Eq. [1] and [2] to obtain depth profiles.

Experimental

Preparation of samples.—The aluminum specimens were 0.9 cm diameter disks 0.5 mm thick. Surfaces were first prepared by mechanical and vibratory polishing (11). This was followed by four cycles in which the specimen was anodized and the oxide stripped with a solution of phosphoric and chromic acid at 95°C. Marker ions were implanted in the surface layers with an isotope separator (12) at energies of 20 keV and over an area of 0.7 cm diameter. The number of ions of each species implanted is given in Tables I and II.

Following implantation most specimens were anodized in a saturated solution (~5%) of ammonium pentaborate in water at a temperature of 23°C. The current was kept constant at 2 mA/cm² until the chosen voltages were reached. Supplementary anodizing and stripping experiments were carried out using much larger foils which could be weighed to obtain a linear calibration of voltage *vs.* oxide thickness. The ratio of weight gain to weight loss agreed with the value expected for the stoichiometry of Al_2O_3 within the experimental error (relative standard deviation 3.0%). The thickness values for the disk specimens shown under "calibration" in Tables I and II were obtained by reference to this calibration. In order to make direct comparison with earlier work (3) a few specimens were anodized in a solution of 50 g/liter of sodium tetraborate in 95% ethylene glycol, 5% water.

Backscattering experiments.—The specimens were bombarded with He ions at a nominal energy of 2 MeV, using a Van de Graaff accelerator. The actual energy in each run was obtained by calibration against

the 5.486 MeV α-particles from an ^{241}Am source. Target and counting arrangements are shown in Fig. 2. The aperture defined an area of 1 mm² on the target. The target holder could be moved both vertically and horizontally without breaking the vacuum so that various parts of one specimen could be examined and several targets could be examined. The surface barrier silicon detector had a resolution [full width at half maximum, (FWHM)] of 17 keV at 2 MeV. The target was connected to circuitry which stopped the pulse height analyzer at any preset integrated beam current, chosen to give the best statistics consistent with available time. The beam current was sufficiently low (20-30 nA) to prevent excessive dead-time losses in the counting system. The targets were tilted so their faces made an angle of 15° to the beam ($\theta_1 = \theta_2 = 15°$) and the detector was placed 30° ($\theta_s = 150°$) to the beam.

Interpretation of spectra.—A spectrum of backscattered He ions is shown in Fig. 3; the scattering material was Al with ^{134}Xe implanted at 20 keV. The depth of the implant is about 5 μg/cm² (~200Å) and the width of its distribution (FWHM) is about half its depth. The energy losses of the ions in traversing these distances is small (1 μg/cm ~2.0 keV). Thus scattering from the Xe produces the peak at the right-hand side of the figure, having an energy given by Eq. [1] less 2.0 keV for each μg/cm² of depth. The bombarding He ion energy in this case was 1.975 MeV; k^2 for Xe is 0.894, hence the peak occurs just below 1.766 MeV. The width of the peak is determined by the detector resolution (17 keV). The sharp step terminating the plateau at 1165 keV in Fig. 3 occurs at the energy given by Eq. [1] for He^+ scattering from surface atoms of Al. The counts recorded at lower energies are derived from ions scattered from progressively greater depths. As x increases the energy E_1^1 decreases according to Eq. [2].

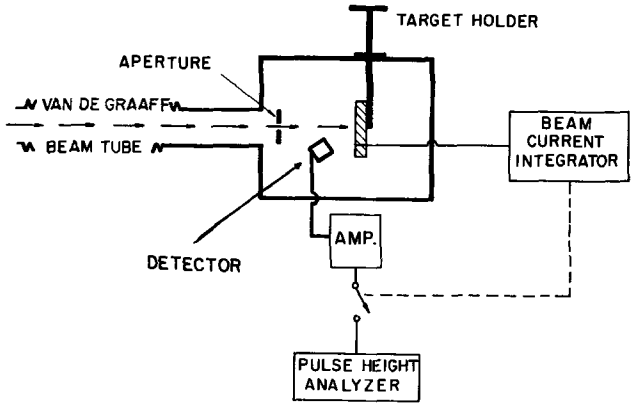

Fig. 2. Schematic diagram of the target chamber arrangements

Figure 4 is a spectrum obtained under the same conditions as Fig. 3 except that the Al specimen had been anodized after implantation and thus had ~100 μg/cm² of oxide on the surface and the thin layer of Xe was buried in the oxide. The Al edge occurs at the same energy as before. However, the continuum has a marked step. The height of the spectrum at any particular energy is proportional to the number of Al atoms contributing to the scattering at the depth corresponding to that energy. In the oxide layer this number is considerably less than that in the underlying metal, consequently, there is a reduced height until particles backscattered from the Al atoms in the metal are recorded in the spectra. This will occur at an energy E_1^1 given by Eq. [2] where the stopping power is that for Al_2O_3, k is that for Al, and x is the total thickness of the oxide (x_o). The width of the oxide step is thus a measure of the oxide thickness; its height reflects the stoichiometry. The Xe peak is displaced relative to its position in Fig. 3 because it is buried deeper beneath the surface. The energy of the peak is given by Eq. [2] where the stopping power is for Al_2O_3, k is for Xe, and x is now the depth of Xe below the oxide surface (x_m).

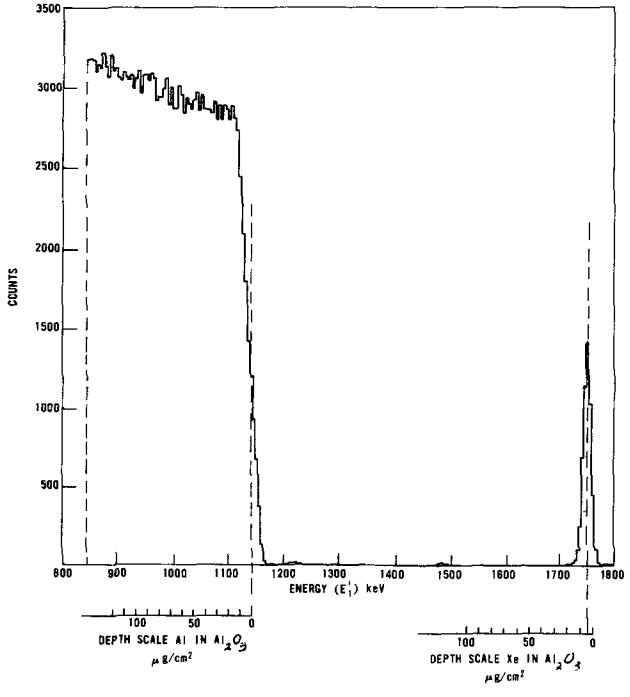

Fig. 3. Spectrum from 7×10^{15} Xe atoms implanted in Al. The incident energy of the He^+ was 1975 keV.

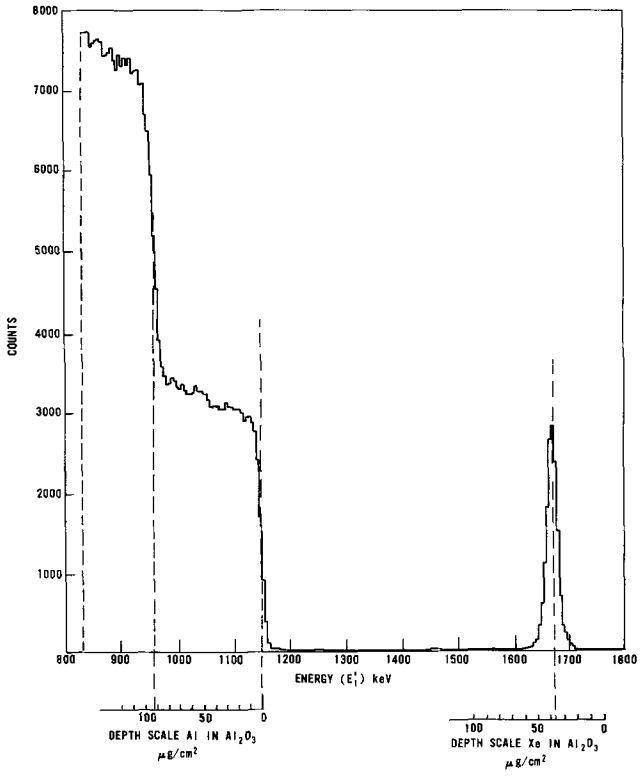

Fig. 4. Spectrum from 7 x 10^{15} Xe atoms buried in an oxide layer (95 μg/cm² thick) on the surface of Al. Incident energy of the He^+ was 1975 keV.

The transport number required from the experiments is the ratio of x_m to x_o. To obtain this ratio from the spectra two computer programmes were used. The first of these established a tabulation of the values of E_1^1 for small, successive x intervals (1 μg/cm²) using Eq. [2] when E_o, θ_1, θ_2, and k^2 were given appropriate values for the initial energy and geometric arrangements of the particular experiment. As the value of $S(E)$ is continually changing as E changes with depth, the programme included a tabulation of stopping power as a function of energy. This was obtained by the Bragg additivity rule using published data (13, 14) for oxygen and aluminum and assuming stoichiometric Al_2O_3. This input data is given in micrograms per square centimeter and since the unit of distance was also in the same terms it was not necessary to know the density of the oxide. The tabulations for the specific examples of Fig. 3 and 4 have been reproduced as scales on these figures. The scale for Xe differs from that for Al as a consequence of the difference in the value of k^2 for these two atoms. The scales are not linear since stopping power varies with energy.

The second computer programme produced values of E_1^1 for the Al(oxide) edge, the Al(metal) edge, and the implant from the raw data. These could then be read in terms of thicknesses and depths from the first tabulation. The programme smoothed the data by a least square fitting routine, then extracted the position of edges and implants, assuming that the peaks were Gaussian and that the edges were integrated Gaussians. Output was given directly in energy by inputing a calibration curve for the pulse height analyzer.

In these experiments with Al experimentally determined, values for the stopping power of Al and O_2 were available and as will be shown later the assumption of stoichiometric Al_2O_3 were justified. However the experimental technique can be extended to systems where good data are not available and the stoichiometry is unknown, with some loss in accuracy. The tabulations of depths of Xe and Al in Al_2O_3 differ from each other by less than 10% and differ from linearity by less than 5% over the range 0-100 μg/cm². As an approximation one could assume that the stopping power is independent of energy. In this case the ratio of x_m to x_o is simply the ratio of the energy shift of the marker to the energy width of the oxide step and can be obtained directly from the number of channels in the spectra. This approximation is good to about 10% under the conditions of the present experiment since the stopping power does not vary rapidly with energy.

In Rutherford scattering experiments it is possible, within limits, to determine the width of the marker distribution. Before anodizing (*e.g.*, Fig. 3), the width of the Xe peaks are determined, for all practical purposes, by the detector resolution (FWHM = 17 keV). After anodizing (*e.g.*, Fig. 4) the width of the Xe peaks (FWHM) are found to be typically 24 keV. The edges, or steps, in the spectra also have widths. The shape of these edges is, to a good approximation, an integrated Gaussian and hence these widths can also be expressed as a FWHM. In an anodized specimen (with approximately 100 μg/cm² of oxide) the width of the higher energy edge (outer surface) was typically 18 keV which is, as expected, identical for practical purposes with the detector resolution. The width of the lower energy edge (metal-oxide interface) was typically 23 keV. A brief discussion of widths and their significance is given in the discussion of results, below.

Since the areas of the peaks in the backscattering spectra are proportional to the number of marker atoms, the incident ion fluence and the scattering cross section, possible loss of marker atoms during anodizing could be detected. In comparing markers at the same depth it was merely necessary to normalize for the ion fluence. Another normalization was necessary if the markers were at different depths because the ion energies at the point of scattering would then differ, resulting in a difference of cross section proportional to $1/E^2$. Integration of the peak areas was included in the computer programme used to determine the energy.

One last piece of information can be gleaned from the spectra obtained in these experiments; it is possible to establish whether or not the anodic films are stoichiometric Al_2O_3. First, the ratio of the counts in any chosen channel of the Al(metal) step to a chosen channel of the oxide step that should be obtained for stoichiometric Al_2O_3 is calculated. The ratio of Al atoms/microgram of Al to Al atoms/microgram of Al_2O_3 is modified by (*i*) the ratio of the thickness represented by the energy interval of one channel in the Al to one channel in the oxide, and (*ii*) the inverse ratio of the squares of the energy of the He^+ particles at the instant they reach the depth represented by the chosen channels. For these purposes it is not only necessary to use the tabulations already described but to provide an additional one for Al in Al (as shown in Fig. 3) and one of E_o^1 *vs.* depth, where E_o^1 is the initial energy less losses in traversing depth x. These calculated ratio were then compared with the actual ratio in the spectra. The channels chosen were taken to be those indicated as the edges in the computer programme. The number of counts was extracted by a programme after smoothing the data and extrapolation of the plateau curves to the edge channels. Agreement of the calculated and experimental ratios indicates stoichiometric Al_2O_3. If there were disagreement the actual stoichiometry could be obtained by recording spectra which include the backscattered particles from O (they have been biased out in our spectra) and the Al:O ratio calculated in the manner described in Ref. (15, 16).

Results and Discussion

Table I lists results obtained from experiments with the inert gases implanted into preformed oxide films (30V = 11 μg/cm²) and Table II those obtained with the implants in metal beneath the natural airformed oxide (~0.7 μg/cm²). The tables indicate the implanted species and the number of atoms implanted.

Oxide thickness, stoichiometry, precision.—The thicknesses of the anodized oxide layers were determined

from the energies of the particles backscattered from the Al at the metal-oxide interface, *i.e.*, from the width of the oxide step (Fig. 4). These values are listed under "determined" in Tables I and II. Taking all of the results, Tables I and II, we find that a comparison of each individual thickness "determined" with its corresponding "calibration" value shows a relative standard deviation of 6.3%. The average of all determined thicknesses differs from the average of all calibration values by only +0.3%, suggesting that the absolute value used for the stopping power of Al_2O_3 is substantially correct. On comparing calculated values for the ratio of heights in chosen channels of the metal and oxide steps it was found that the average value obtained from 22 spectra differed from the value calculated for stoichiometric Al_2O_3 by 3.8%. The relative standard deviation for the 22 spectra was 2.0%. The difference of 3.8% cannot be considered significant in view of the limited accuracy of the stopping power data. More important is the fact that the relative standard deviation of 2.0% is entirely consistent with the statistical accuracy of the counting data, confirming that the techniques used can yield precise verification of film composition.

Sample 1 was measured four times to demonstrate the reproducibility of the thickness determination (relative standard deviation from the mean 3%) and the marker depth measurement (6%).

Noble gases.—In calculating the transport numbers for aluminum small corrections (3) have been made for (*i*) the finite initial depths of the marker in metal and in preformed oxide films, (*ii*) the fact that with implants in metal, oxidation of the metal lying above the implant will take place without either Al or O traversing the implant layer, and (*iii*) the small amount of Al that dissolves during anodizing. The amount dissolving is about 2% of the total Al converted to oxide (17).

The lower limit of dose is set by the practical limit of sensitivity of the technique, which for Xe is about 5×10^{13} atoms/cm^2. In the experiments with a dose of 1×10^{16} atoms/cm^2 more than half the Xe disappeared during anodizing, although the remainder behave normally, *i.e.*, as though the dose had been 5×10^{15} atoms/cm^2. It is suspected (but not established) that the heavy radiation damage results in some loosening of the oxide film which peels off at the start of anodizing. The somewhat higher transport number is consistent with this contention as the calculations would contain too great a correction for implant depth. Hence, in this case at least, there is an upper limit to the useful dose. In all the other experiments, with lower doses, no loss of marker was detectable.

There appears to be a tendency for the transport number to increase with dose. It is difficult to decide whether or not this is real. If it is, a possible explanation can be offered; the larger doses must have associated greater radiation damage to the outer layers which conceivably alters the anodization process. The implants in preformed oxides would be most affected; they do show the trend most clearly. Doses below 5×10^{14} do not show this tendency, consequently it is concluded that marker atoms do not significantly alter the results when the number implanted is no greater than 5×10^{14}.

All completely immobile markers should give the same value for transport numbers. Since the Rutherford scattering cross section varies as Z^2 the minimum useful dose for Ar was 2×10^{15} atoms/cm^2 and for Kr, 5×10^{14} atoms/cm^2. Bearing in mind the small dose effect already noted, the tables show that within experimental error Ar, Kr, and Xe do give the same value for the aluminum transport number. It should be noted however that Pringle (5), employing more sensitive techniques applicable to Ta_2O_5, has detected small differences for Ar, Kr, and Xe markers.

As far as the transport number is concerned there was no real difference between the behavior of implants made into metal and those made into preformed anodic oxide (30V $\approx$ 11 μg/cm^2), except for the slightly greater spread in results. As discussed in more detail later, the distribution of the implant atom tends to broaden in the "metal" case. This broadening is not reproducible from specimen to specimen and leads to more variation in the determination of the peak position.

The value for the cationic (aluminum) mobility obtained by taking a simple average of all the individual values listed in Table I is 0.39. The best value obtained by β-ray spectrometry (3) for anodic oxidation in tetraborate-glycol solutions at a current density of 1 mA/cm^2 was 0.6. The value obtained from the ^{222}Rn experiment (4) using aqueous ammonium citrate solution, was approximately 0.3. However, Table III shows that transport numbers depend on the electrolyte. Samples 1 and 2 (metal implants) were anodized in sodium tetraborate-ethylene glycol solution. These results agree quite well with those of Ref. (3) in which the specimens were similarly treated. The preformed oxide in samples 3 and 4 were formed in the aqueous electrolyte, the subsequent anodizing was in the glycol solution. The intermediate value of the transport numbers substantiates the conclusion that oxidation proceeds differently in the two electrolytes.

Halogens and alkali metals.—In the experiments with halogens and alkali metals it was immediately obvious that these species are mobile during anodizing. Hence, to formulate the results in Table IV we have calculated a migration number. To do this we calculated the position of an immobile reference point, using the transport number of Al. The transport number used was the average of all values given in Table I. Given this reference point we then calculated how far the marker had moved from this point. Finally, we took the ratio of this distance to the thickness of oxide grown. Corrections for the finite initial depth of the marker and for Al dissolution were made as before. Bearing in mind the limited number of experiments, the following comments can be made.

The direction of motion is consistent with the halogens and alkali metals moving as ions. Size appears to be one factor since we find the mobility of Cl > Br > I and of K > Rb > Cs. It is not the only factor, however, since all the alkali metal ions are smaller than the halogen ions but the alkali metals taken in a group, do not move faster than the halogens.

As far as the migration numbers are concerned there is no significant difference established between implants into metal and into preformed oxide. Nor is there any obvious dependence of the mobility on the thickness of oxide grown.

In two cases (I and Cs) the anodized specimen was returned to the electrolyte and a voltage equal to the original anodizing voltage was applied until the current had decayed to about 0.01 mA/cm^2 ($\approx$10 min). During this period a small additional amount of oxide

Table III. Data from experiments using ethylene glycol electrolyte (Xe implants)

Sample number	Implanted layer	Implant dose (ions/cm^2)	Oxide thickness determined (μg/cm^2)	Marker depth (μg/cm^2)	Aluminum transport number
1	Metal	2×10^{14}	40	25.5	0.68
2	Metal	2×10^{14}	35	21.5	0.66
3	Oxide	2×10^{14}	45	17	0.48
4	Oxide	2×10^{14}	39.5	14	0.46

Table IV. Data from experiments with halogens and alkali metals

Sample number	Implanted layer	Implanted species	Implanted dose (ions/cm²)	Oxide thickness from calibration (μg/cm²)	Oxide thickness determined (μg/cm²)	Marker movement (μg/cm²)	Migration number
14	Metal	Cl	2×10^{15}	35	40	32.5 (in)	0.35
15	Metal	Br	5×10^{14}	56	61	12.5 (in)	0.21
16	Metal	Br	5×10^{14}	112	116	20.9 (in)	0.18
17	Oxide	I	2×10^{14}	112	112	7.0 (in)	0.08
18	Oxide	I	2×10^{14}	112	121	12.7 (in)	0.11
19	Metal	I	2×10^{14}	112	101	14.3 (in)	0.14
20	Metal	I	2×10^{14}	112	104	11.1 (in)	0.11
			2×10^{14}			23.0 (out)	0.22
21	Oxide	Cs	2×10^{14}	112	112	18.6 (out)	0.18
22	Oxide	Cs	2×10^{14}	112	121	22.3 (out)	0.20
23	Metal	Rb	5×10^{14}	56	61	15.2 (out)	0.25
24	Metal	Rb	5×10^{14}	112	117	32.3 (out)	0.27
25	Metal	K	2×10^{15}	112	100	34.3 (out)	0.34
			Average:	96.3	97.2		

formed and allowing for this, the positions of the markers were unchanged. Similar specimens were returned to the electrolyte and held at a voltage slightly below the original voltage for 15 min, during which time the current was, as expected, essentially zero, no oxide formed and the markers did not move. Thus the markers have measurable mobility only when the oxide is growing.

For the implant doses used there was no detectable loss of implanted ions to the electrolyte nor any suggestion of the implant penetrating from the oxide into the metal. In fact, as seen in Table IV, the mobility of the implanted anions used in the present experiments was always less than that of oxygen and the mobility of the implanted cations always less than that of aluminum. This is not to be taken as a generalization applying to foreign atoms other than the ones mentioned in this paper.

Taking the results for the noble gases, the alkali metals and the halogens all together we can say that the picture is consistent with the assumption that the noble gases are immobile. It does not, of course, provide a complete proof of this assumption.

Peak widths.—The spectra for all specimens having approximately 100 μg/cm² of anodic oxide were analyzed to determine the widths of the upper energy edge (outer surface) and the lower energy edge (metal-oxide interface). For the outer surface the width (FWHM) was 18.3 keV with a standard deviation of 1.8 keV. For the metal-oxide interface the width was 22.8 keV with a standard deviation of 2.1 keV. The width from outer surface is composed of the detector resolution together with possible contributions from accelerator energy drifts and electronic gain changes. The observed width of 18 keV is clearly in agreement with the detector resolution of 17 keV. The width from the metal-oxide interface contains an added contribution from the energy straggling of the He ions in passing into and out of the oxide layer, together with possible contributions from nonuniformity of the oxide or diffusiveness at the interface. The straggling contribution is impossible to obtain exactly since there is no experimental data for the exact system in question. However, Hvelplund (17) has published data for 500 keV He ions in air and in Ne. An extrapolation of his data, admittedly very approximate, suggests that the whole of the difference between 23 and 18 keV can be accounted for by He ion energy straggling.

The spectra for the Xe implanted into preformed oxide and then anodized were analyzed to find the width (FWHM) of the Xe peaks. The average width was 24.0 keV with a standard deviation of 1.1 keV. Since the Xe is buried to the extent of about four-tenths of the oxide thickness its peak width contains, besides the detector resolution, a contribution from the He ion energy straggling. If allowance is made for these contributions the remainder is 12 keV, or 6 μg/cm²; however, in view of the corrections and errors this number has scarcely any significance. In the case of Ta_2O_5, Pringle (5), using a more sensitive technique, has detected small broadening of inert gas markers. If his results are applicable to Al_2O_3 they would suggest a broadening of about 2 μg/cm² in our experiments.

The number of experiments in preformed oxides using species other than Xe is limited. For the cases studied, Ar, Cs, and I, there is no evidence that the peak widths after anodizing are any different from those observed for Xe; see Table III.

The situation for implants made into metal, rather than preformed oxides, is quite different. The number of samples for each implant is not large; however, for all cases studied, Kr, Xe, K, Rb, Cs, Cl, Br, and I the peak width after anodizing was very obviously broadened. Widths (FWHM) ranged from 27.4 keV (potassium) to 39.2 keV (bromine) with no obvious correlation as to type of implant; see Table V. It appears therefore that the major factor contributing to broadening is the phase change in the region of the implant and not the behavior of the implant once it has become incorporated into the oxide.

Assessment of Method

An important advantage of the method is its generality, subject to the limitation that the foreign atoms be heavier than the matrix atoms. Clearly, of the noble gases, Xe is the most practical to use; the sensitivity is good (because of the Z^2 dependence of the scattering cross section) and it can be used in fairly heavy matrix. For example application of Eq. [1] and [2] shows that Xe atoms buried to a depth of 25 μg/cm² in ZrO_2 could just be resolved from the Zr continuum. In any particular case the behavior of the marker will also be important. In our experiments, potassium could be studied in films of 100 μg/cm² since it remains close to the outer surface. Chlorine, which moves inward, could be studied only in films that were <50 μg/cm² since it becomes deeply buried and the chlorine peak can be lost under the aluminum continuum.

Small quantities of foreign atoms, as listed in the tables, can be studied only if they lie in a depth distribution narrow enough to give a sharp peak in the spectrum. Obviously the ideal condition is when the width of the depth distribution is small compared to the detector resolution, *i.e.*, in the present case, small compared to 17 keV which corresponds to about 8 μg/

Table V. Widths (keV, FWHM) of edges and implant peak after anodizing to 300V

Average width from outer surface: 18.29 ± 1.82
Average width from metal-oxide interface: 22.84 ± 2.14

Peak widths for implants made into preformed oxide		Peak widths for implants made into metal	
Xe (8 expt.)	24.03 ± 1.13	Xe	33.11
Ar	22.64	Kr	35.15
Cs (2 expt.)	20.35 ± 0.58	K	27.40
I (2 expt.)	23.57 ± 0.39	Rb	29.09
		Cs	38.90
		Cl	~40
		Br	39.21
		I (2 expt.)	36.32 ± 3.88

cm^2. Ion implantation is especially useful since it produces a narrow distribution, gives the choice of incorporating the marker in metal or preformed oxide and offers an almost unlimited choice of marker species and matrix. However, the method could be applied to markers adsorbed on surfaces and with limitations, to species incorporated from solution or present as additives in the metal being oxidized.

At the other extreme, foreign atoms distributed uniformly through the matrix will produce a continuum and larger amounts of material will be required to maintain the statistical significance of the spectrum. Similar, but more extreme, considerations apply to studying atoms that are lighter than the matrix; the oxygen in Al_2O_3 film can easily be detected but oxygen as a minor constituent in aluminum would not be.

The quantity of marker required thus depends on several factors but in any case the sensitivity of the method is not as high as that obtainable with radiotracer methods and the quantity of marker is, by necessity, larger. This might be a serious disadvantage in some cases; we have noted that the amount of Xe implanted might have a small influence on the observed transport numbers. In these particular experiments the over-all behavior during anodizing was not affected, *i.e.*, the oxide had the expected thickness and was uniform and adherent. Similarly, the over-all behavior of specimens implanted with alkali metals or halogens, at the doses used, appeared normal. Nevertheless, there remains the obvious possibility that, in general, the presence of foreign atoms can influence the anodizing behavior and that the behavior of a mobile foreign atom will itself be influenced by its concentration.

A second major advantage of the method is that it measures the position of the marker and the thickness of the film simultaneously. Useful information can be obtained, if necessary, without any knowledge of the film composition, density, or stopping power. Indeed, spectra obtained in a suitable way can be used to measure the stoichiometry and to detect changes in stoichiometry with depths, *e.g.*, in duplex films (15, 16). The uniformity of the film throughout its thickness is automatically checked. These factors are of special advantage in studying more complex film forming processes, *e.g.*, anodic or thermal oxidation of compounds and alloys or the formation of intermetallic films, where information on the nature of the films is often minimal.

The presence of impurities, especially surface contaminants, will also be revealed under suitable conditions discussed above. For example, it is known (19) that aluminum that has been anodized and stripped in chromic-phosphoric acid retains a thin oxide containing Cr and P. All our specimens so treated give spectra that showed very clearly the presence of Cr at the surface; phosphorus was also detectable, although poorly resolved from the Al.

It is possible, by judicious selection, to use two or three markers in a single experiment, thus comparing their behavior under absolutely identical conditions. For example, in Table I, specimens 12 and 13 were implanted with both Ar and Xe. By the same methods it would be possible to check for the possible interference of one species with another.

The precision of the method, as found in practice, is consistent with expectations based on the detector resolution and counting statistics. The expected resolution (FWHM) corresponds to 8 $\mu g/cm^2$; in the four measurements made on sample No. 1, Table I, the standard deviation for oxide thickness was 2.0 $\mu g/cm^2$ and for the Xe depth 1.6 $\mu g/cm^2$. The stoichiometry of the oxide could be verified with a precision ($\pm 2\%$) consistent with the counting statistics.

ABSTRACT

The negative charge in Al-Al_2O_3-SiO_2-Si double layers was found to be located at the insulator-insulator interface. This charge is independent of the thickness of the Al_2O_3 and inversely dependent on the SiO_2 thickness. Evidence for a constant voltage drop across the SiO_2 during Al_2O_3 deposition was found for polycrystalline Al_2O_3, N_2-deposited and O_2-deposited amorphous Al_2O_3. It is suggested that the traps at the interface Al_2O_3-SiO_2 are due to oxygen vacancies.

Double layer insulators are becoming more and more common in semiconductor technology. One system of particular recent interest is the Al_2O_3-SiO_2 structure. Aluminum oxide films provide a barrier to sodium ions (1) and are also more radiation resistant than thermal oxide films (2). It is well known that thermal oxide on silicon tends to make the surface of silicon more n-type; Al_2O_3, on the contrary, makes the surface more p-type (3).

Aluminum oxide films have been deposited on silicon by various methods: by chemical vapor deposition from $AlCl_3$, CO_2, and H_2 at high temperature (1); from pyrolysis of alkoxydes of aluminum (3), by sputtering (4, 5), and by electron beam evaporation (6-8). The characteristics of the insulator charge and in particular the location of the resulting charges in metal-Al_2O_3-SiO_2-Si structures have been studied by several workers but there is still no complete agreement on this subject. Using polycrystalline Al_2O_3, Nigh (9) interprets his results for double layers Al_2O_3-SiO_2 on silicon to one or more of the following: a sheet of negative charge at the insulator-insulator interface, a positive contact potential of approximately +1.1V, and a change in the metal-insulator barrier energy when Al_2O_3 is substituted for SiO_2. Kalter *et al* (10), studying the same system, report a +1.5V potential step at the insulator-insulator interface but no interface charge. Nishimatsu *et al.* (11), using amorphous Al_2O_3, report the presence of a constant negative charge (3.5×10^{11} charges/cm^2) at the Al_2O_3-SiO_2 interface and a distributed negative charge in the Al_2O_3 but no contact potential. Gosney (8) finds a negative single layer of charge (7×10^{11} charges/cm^2), no contact potential and no bulk charge; he reports also that the effective charge is positive when Al_2O_3 is deposited directly on silicon. Salama (4) reports a single layer of positive charge at the interface and a contact potential of about +1V in his double layer structures; both positive and negative charge can be observed in the Al_2O_3-Si structure depending on the sputtering conditions and the annealing conditions (4, 5).

In this paper, the magnitude and location of the charge in Al-Al_2O_3-SiO_2-Si structures was studied for both amorphous and polycrystalline Al_2O_3.

Experimental

Aluminum oxide films, both amorphous and polycrystalline, were used in this study.

Amorphous Al_2O_3.—Low-temperature amorphous Al_2O_3 films were deposited from the pyrolysis of aluminum triisopropoxide at 425°C in either nitrogen or oxygen ambient. Details of the process have already been described (3). The deposition rate is 60 Å/min; the index of refraction is 1.6; and dielectric constant is 7.7.

Polycrystalline Al_2O_3.—High-temperature Al_2O_3 films were deposited by chemical vapor deposition from $AlBr_3$ + NO at 910°C in a resistance heated furnace in a forming-gas atmosphere. This process (12) is very similar to that developed by Rand (13) for depositing SiO_2 films from $SiBr_4$ + NO + H_2. Films were deposited at 70 Å/min; the index of refraction is 1.75; the etch rate, in hot phosphoric acid (150°C), is 150 Å/min, and the dielectric constant is 9.5.

Metal-insulator-semiconductor capacitor structures were used in the electrical evaluation. Capacitance-voltage (C-V) characteristics at 1 MHz were obtained to measure the charge stored in the double layers.

The metal-insulators-silicon structures were obtained as follows: Silicon wafers <100>, p-type 2 ohm-cm were thoroughly cleaned and oxidized in dry oxygen at 1050°C for various periods of time. Annealing at 1050°C was done in nitrogen for 30 min. The measured flat-band voltage for these oxides (300-1000Å thick) was (after evaporating aluminum electrodes and annealing again at 420°C in a forming-gas atmosphere for 30 min) −0.8 to −0.9V and the mobile charge (after biasing MOS dots for 30 min, at 200°C, at $\pm 2 \times 10^6$ V/cm) in the low 10^{10} charges/cm^2 range. Al_2O_3 films, approximately 3000Å thick, were subsequently deposited on the SiO_2 films. No annealing of the Al_2O_3 film was done immediately after deposition.

Depending on the Al_2O_3 film deposited, further processing was made as follows: *i*) For the amorphous Al_2O_3, steps of approximately 5 mm in width and approximately 500Å depth were made on the Al_2O_3 film. A first step was done by covering most of the wafer with tape and etching in buffered HF for a certain period of time. By decreasing successively the area of the wafer taped, several etching steps could be obtained. *ii*) For the polycrystalline Al_2O_3, a film of high-temperature SiO_2 was deposited on the Al_2O_3 film. A step was then etched in buffered HF as above for a certain period of time in hot phosphoric acid. Repeat of the same procedure several times resulted in a wafer with 5 or 6 steps, of about 5-6 mm width.

Finally 12 mil diam aluminum dots were evaporated on the structure and annealed at 420°C for 30 min in a forming-gas atmosphere. Aluminum was also evaporated on the bare backside of the silicon for contact. A cross section of the experimental structure is given in Fig. 1.

Results and Discussion

The flat band voltage of the metal-insulator structures is shown in Fig. 2 and 3 as a function of the Al_2O_3 thickness for various constant thickness SiO_2 films. The results for amorphous Al_2O_3 films are qualitatively

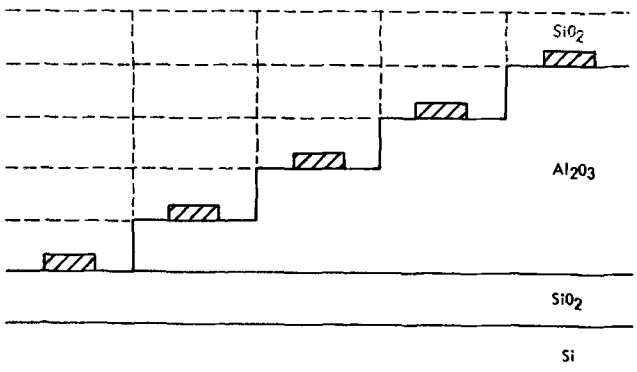

Fig. 1. Cross section of structures tested (see text for dimensions)

similar to those for polycrystalline Al_2O_3. The bars on the lines show that the spread in flatband voltage on each step is about ±0.1V (typically 5 devices measured). Thickness of the Al_2O_3 films were obtained by comparison of the color of the film with a predetermined color scale similar to that of Pliskin and Conrad (14). The error would probably be within 10% of the exact thickness.

The results obtained for N_2-deposited and O_2-deposited amorphous Al_2O_3 films on SiO_2-Si are compared in Fig. 4 for a constant SiO_2 thickness of 230Å.

In all cases, the flatband voltage of the Al_2O_3-SiO_2 structures increases fairly linearly with the increase of the Al_2O_3 film thickness for a constant SiO_2 thickness and reaches about −0.8V for zero Al_2O_3 thickness. The flatband voltage of the N_2-deposited Al_2O_3 structure is much more positive than that for the O_2-deposited one.

If we postulate sheet charges Q_{ox} and Q_{int} at the Si-SiO_2 and the SiO_2-Al_2O_3 interfaces, respectively, the flatband voltage will be given by

$$V_{FB} = -Q_{ox}\frac{t_o}{K_o} - (Q_{ox} + Q_{int})\frac{t_A}{K_A} + \phi_{ms} \quad [1]$$

where t_o and K_o are the thickness and dielectric constant of the SiO_2 film, t_A and K_A are the thickness and dielectric constant of the Al_2O_3 film, and ϕ_{ms} is the metal-to-silicon work-function difference. The fact that V_{FB} reaches the expected ϕ_{ms} value (−0.8V for aluminum and p-type silicon) for $t_A = 0$ indicates that Q_{ox} is essentially zero for our samples. This is not unreasonable for well-annealed oxides on <100> oriented silicon. Equation [1] then reduces to

$$V_{FB} = -Q_{int}\frac{t_A}{K_A} + \phi_{ms} \quad [2]$$

Table I. SiO_2-Al_2O_3 interface charge N_{int} (in units of 10^{11} charges/cm^2) for varied SiO_2 thickness and Al_2O_3 processes

SiO_2 thickness	Amorphous Al_2O_3 (O_2-deposited)	Amorphous Al_2O_3 (N_2-deposited)	Polycrystalline Al_2O_3
230Å	−2.1	−5.9	—
315Å	—	—	−5.3
425Å	—	—	−3.5
560Å	−1.1	−2.2	−3.0
1000Å	—	−1.4	−1.9

The data of Fig. 2-4 display the linear dependence of V_{FB} on t_A predicted by Eq. [2] and indicate in all cases a layer of negative charge at the SiO_2-Al_2O_3 interface. Values of $Q_{int}/q = N_{int}$ obtained from the slopes of the best straight-line fits to the V_{FB} *vs.* t_A data are shown in Table I. Note that the charge densities thus determined fall in the range 1-6 × 10^{11} electronic charges/cm^2, with an apparent inverse dependence of N_{int} on SiO_2 thickness for any particular type of Al_2O_3. This relationship becomes more obvious in Fig. 5, in which all the data of Table I is plotted as a function of SiO_2 thickness. It is seen that all the data can be well fit to parallel lines of −1 slope on the log-log plots, thus indicating that N_{int} is proportional to t_o^{-1}.

We subscribe to the mechanism proposed recently by Labuda *et al.* (15), which postulates that the Al_2O_3 is conductive enough during deposition to maintain internal fields within the Al_2O_3 at zero and, further, that the silicon and Al_2O_3 are in thermal equilibrium (equal Fermi levels). As shown in Fig. 6, a fixed voltage V_{ox} will then be dropped across the SiO_2 during deposition, which will be determined by the Fermi levels in the Si

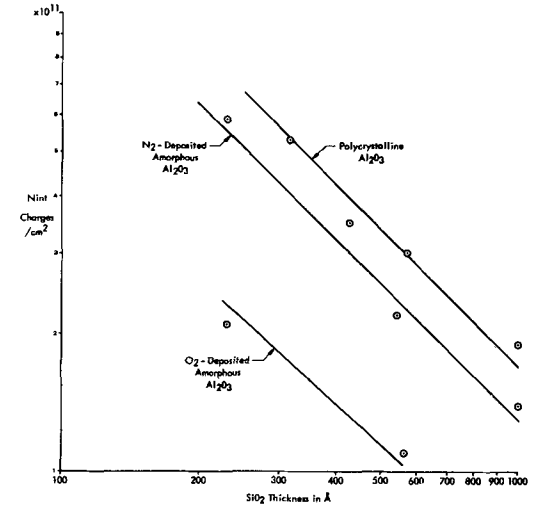

Fig. 5. Log-log plot of the interface charge vs. SiO_2 thickness for various polycrystalline and amorphous Al_2O_3 films.

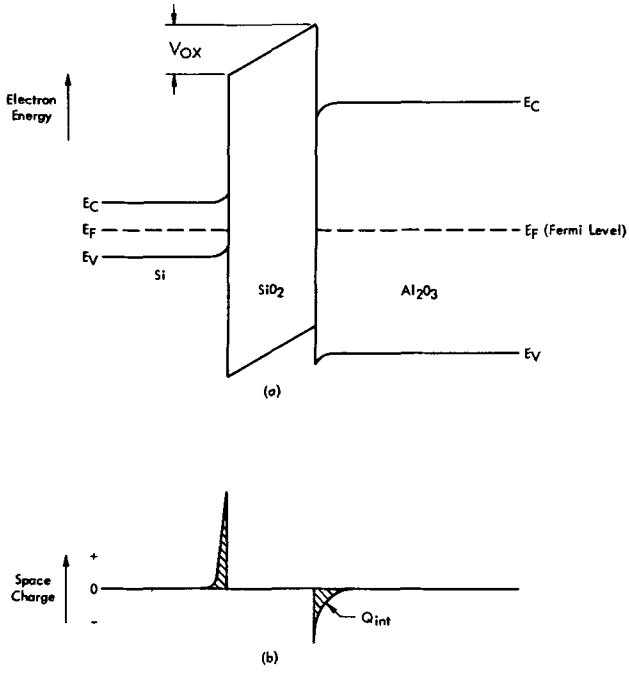

Fig. 6. Schematic picture of proposed energy-band diagram (a) and space-charge distribution (b) during Al_2O_3 deposition. Our measurements indicate V_{ox} values of 0.75V for polycrystalline Al_2O_3, 0.6V for N_2-deposited amorphous Al_2O_3, and 0.25V for O_2-deposited amorphous Al_2O_3.

and the Al_2O_3 and by the Si-SiO_2 and Al_2O_3-SiO_2 potential barriers, but should be independent of SiO_2 or Al_2O_3 thicknesses. An electronic charge K_oV_{ox}/t_o will be associated with V_{ox} and will reside in the Al_2O_3 close to the SiO_2-Al_2O_3 interface. This charge is assumed to remain in traps at this interface as the sample is cooled to room temperature to give Q_{int}. Calculating the voltage drop V_{ox} for the three types of Al_2O_3 gives values of 0.75V for the polycrystalline Al_2O_3, 0.6V for N_2-deposited amorphous Al_2O_3, and 0.25V for O_2-deposited amorphous Al_2O_3. Labuda *et al.* (15) used a 900°C $AlCl_3$ process for Al_2O_3 deposition and found a V_{ox} of 0.76V.

The Fermi level within the Al_2O_3, which in turn determines V_{ox}, will be sensitive to the density and energy distribution of traps within the Al_2O_3. The V_{ox} difference between N_2-deposited and O_2-deposited Al_2O_3 could be explained by a decrease in trap density when the Al_2O_3 is deposited in oxidizing conditions. This would suggest that the traps in the Al_2O_3 are oxygen vacancies and that an excess oxygen during deposition will reduce them. Balk (16) in his studies of metal-Al_2O_3-SiO_2-Si structures found that charge injection under negative bias is not observed in polycrystalline Al_2O_3, which was oxygen annealed at 900°C for 1 hr, and suggested that the trapping centers could be oxygen vacancies. From the electron microprobe analysis of N_2-deposited and O_2-deposited amorphous Al_2O_3 and polycrystalline Al_2O_3 (see Table II), it was not possible to differentiate the variation of the aluminum or oxygen content in the bulk of the film. An excess of aluminum is found in all deposited films in respect to single crystal sapphire. The data obtained for polycrystalline Al_2O_3 confirms the data reported earlier by Nigh (9).

Conclusions

It has been shown that negative charges are observed in double layers Al_2O_3-SiO_2 structures on silicon. The negative charge was found to be located at the interface Al_2O_3-SiO_2. This charge is independent of the thickness of the Al_2O_3 film and dependent on the

Table II. Electron microprobe analysis of aluminum oxide films

Monitoring Sodium Contamination in Silicon Devices and Processing Materials by Flame Emission Spectrometry

William R. Knolle and Theodore F. Retajczyk, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Sources of sodium contamination found in routine chemical treatment and handling of silicon slices have been identified and quantitatively measured using a flame photometric technique. Common processing chemicals generally contain less than 500 ppb of sodium. Ways to reduce the level of sodium contamination during silicon device processing have been determined. Sodium may generally be rinsed off silicon and silicon-dioxide-covered silicon slices with a dilute acid rinse followed by a deionized water rinse. Subsequent handling and contact with the slices should be done with freshly cleaned handling tools to prevent recontamination.

Sodium contamination of silicon devices and its adverse effect on the electrical properties of these devices is well known. In an effort to minimize sodium contamination of silicon slices, the sources and extent of sodium contamination found in routine silicon-slice processing were investigated. Because the level of sodium contamination is very small, *i.e.*, generally less than 0.1 ng (nanogram) of sodium on the surface of a clean silicon slice, sensitive methods of analysis are necessary. Emission flame photometry has been shown to be a sensitive and facile method for detecting sodium on silicon, silicon dioxide, and in processing chemicals (1, 2). Presented here is a discussion of the method used to detect trace amounts of sodium in the 100 part per trillion range, the sources and extent of sodium contamination found in routine processing, and ways to reduce this contamination.

Method of Analysis

An Instrumentation Laboratory Model 153 atomic absorption spectrometer was used in the flame emission mode with a Boling burner head. The rotary beam chopper was eliminated in order to increase signal intensity and an RCA 1P21 photomultiplier tube operated at 1200V was used for detection of the signal. A black anodized aluminum shield was placed around the top of the flame and the fume exhaust duct in order to minimize flame instability due to air currents.

The response of the instrument was calibrated with sodium standards prepared by dilution of an aqueous stock solution. The solutions were contained in polypropylene volumetric flasks that had been leached of sodium with frequent changes of a dilute solution of HF for several days prior to use. The flasks were then equilibrated for several weeks by frequent changes of the given standard. The deionized water used to prepare the solutions was first passed through a set of demineralizers and finally a 0.2 μm filter. The sodium content of this water was typically less than 2 ppb. Prior to an analysis, the instrument response was calibrated with several of these standards. The response was recorded on a Varian Model G-14A-2 strip chart recorder. Figure 1 is a typical curve.

Sodium analysis of water-soluble reagents was generally done on a sample diluted at least ten-fold with deionized water and stored in a polypropylene volu-

Key words: flame photometry, sodium analysis, silicon device processing.

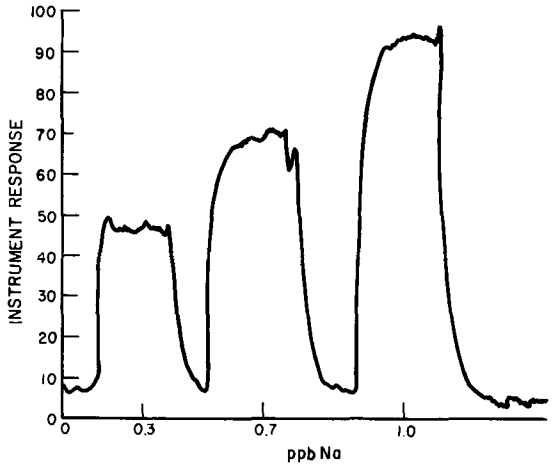

Fig. 1. Recorder tracing of sodium standards near maximum sensitivity.

metric flask for analysis on the same day. Analysis of sodium on silicon and silicon dioxide was done by placing a wafer in a preleached polyethylene sample vial and adding 2 ml of dilute HF dispensed from a preleached Nalgene automatic constant-volume pipette.

Rubber gloves freshly rinsed in deionized water were used to handle the samples during preparation and aspiration into the flame. All samples were prepared in a clean bench and capped until ready for analysis. Samples of deionized water that were carried uncapped through room ambient to the instrument had very large variations in the amounts of sodium measured.

Manipulation of the wafer with a pair of polyethylene tweezers in order to remove the wafer from the vial after etching proved to be another source of sodium contamination presumably arising from a mutual abrasion of the polyethylene surfaces which exposed fresh surfaces containing sodium. Substitution of a specially designed polyethylene holder in place of the tweezers so that the wafer might be readily transferred from vial to vial with a minimum amount of manipulation and contact with surfaces reduced the sodium level in the blank solutions. Figure 2 is a drawing of the wafer in this holder just prior to insertion into the vial containing the etching solution. Even with all of the above-mentioned precautions the chance of inadvertent sodium contamination during sample preparation and analysis was high and so generally several samples were analyzed and an average value of sodium on the wafer was reported.

A realizable working detection limit for sodium in solution when analyzed as above may be determined according to Gabriels (3). This detection limit for five, 2-ml samples of dilute HF was 0.10 ng of sodium. A detection limit of 0.10 ng of sodium in solution corresponds to 3.6×10^{11} atoms of sodium/cm^2 on the slice surface. The silicon slices used in this study were 10 ohm-cm, 2.16 cm in diameter, chemically etched on the back, and Syton-polished on the front side.

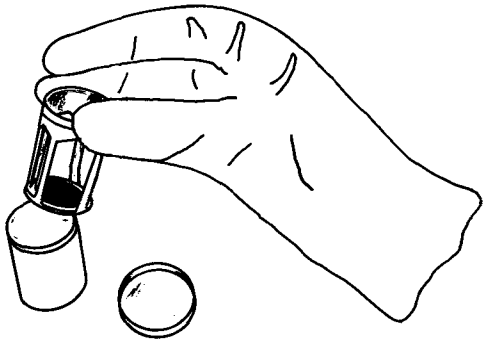

Fig. 2. Sample holder and etching receptacle

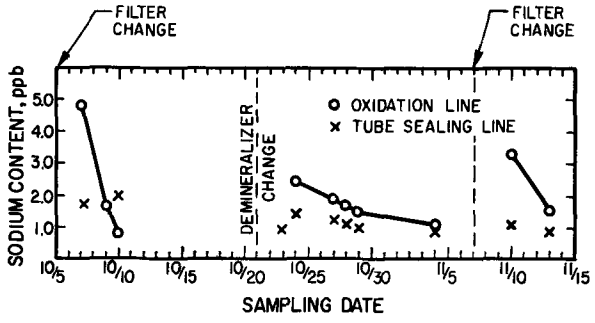

Fig. 3. Variation in sodium content of water from oxidation and tube sealing lines vs. time.

Sodium in Reagents

Deionized water.—Deionized water at two particular processing stations was monitored for sodium content over a period of 39 days. The data is presented in Fig. 3. The large values of sodium contamination in the oxidation line water were traced to filter changes and a demineralizer change in the water line prior to the sodium analyses. The manipulation required to make these changes plus any residual sodium on the new filters contributed to an initially high sodium content in the water that took several days to be reduced. No filter changes were made at the other processing line and the fluctuation of sodium content in the water was less.

Chemicals.—The typical sodium content of some common reagents used in silicon device processing are presented in Table I. Each value represents the average of measurements on four different samples. Some of these reagents are repackaged from bulk containers into polyethylene containers. The Triton X-100 surfactant solution and unstabilized 30% hydrogen peroxide solution are very high in sodium contamination. Most of the reagents contain less than 500 ppb of sodium.

Sodium Contamination of Reagents from Glassware

Pyrex glass contains about 4 w/o (weight per cent) Na_2O or 7×10^{20} atoms of sodium/g of Pyrex glass (4). Pyrex dishware is often used to contain hot or boiling reagents used to clean silicon wafers. To investigate the effect of dishware on reagents, the sodium content of reagents contained in Pyrex and quartz beakers was measured. Pyrex and quartz beakers were degreased with trichloroethylene followed by methanol and water rinses. The beakers were then cleaned with boiling aqua regia for 10 min and overflow-rinsed with deionized water for 10 min. Mere specification of time of rinse and not flow rate is meaningless since flow rates may vary from process to process. Throughout this work the flow rate was set to yield 40 volume changes in a 10-min rinse time. The acid treatment of the beakers removes any surface sodium that is not due to sodium in the glass. The deionized water rinse removes any sodium left on the beakers from the aqua regia. Fifty milliliters of deionized water was placed in each of the two Pyrex and two quartz beakers just cleaned. After standing covered for 1 hr, the sodium in the water

leached from the Pyrex was 2.7 and 7.1 $\times 10^{13}$ atoms/ml whereas the quartz beakers yielded 0.34 and 0.39 $\times 10^{13}$ atoms of sodium/ml.

The results of similar tests with various chemicals substituted for the water at room temperature are presented in Table II. Tabulated is the amount of sodium present in the reagents. Ten milliliters of the reagent were placed in the clean beaker and after 25 min were diluted to 100 ml and the solution analyzed. In all cases the sodium content of the reagents was much higher when contained in the Pyrex glass.

The effect of heating the reagents on the amount of sodium leached from the Pyrex was ascertained by heating 75 ml of water for 15 min in a Pyrex beaker. After cooling 15 min, the amount of sodium in the water had increased to 66 $\times 10^{13}$ atoms/ml. Water that was allowed to stand 14 days in a covered Pyrex dish at room temperature had an additional 50 $\times 10^{13}$ atoms of sodium/ml. From this it may be concluded that special low-sodium reagents should not be used with Pyrex containers for them.

Sodium Contamination of Glassware from Reagents

It is possible that glassware may become contaminated with sodium found in the reagents. To investigate this, Pyrex dishes were treated with boiling aqua regia or NH_4OH, H_2O_2, H_2O (1:1:4 by volume) for 10 min each, and overflow-rinsed for various times with deionized water. At the end of the rinse, the desorption of sodium from the glass into the still water within a 15-min interval was analyzed. The amount of sodium attributable to the Pyrex after 1 min of rinsing after treatment with the acidic solution was 8 $\times 10^{13}$ atoms/ml. See Fig. 4. After five more minutes of overflow rinsing, the sodium in the water attributable to the Pyrex had fallen to 1.35 $\times 10^{12}$ atoms/ml. For the dish treated with the basic solution, after a total of 16 min of rinsing 9 $\times 10^{12}$ atoms of sodium/ml was contributed by the container walls. Only after another treatment of the dish with aqua regia and a 5-min deionized water rinse did the sodium level in the water reach 1.35 $\times 10^{12}$ atoms/ml. Quartz beakers generally rinsed clean after treatment with both reagents without the lag that was observed for the basic peroxide solution in Pyrex.

These results indicate that a Pyrex dish, after a basic peroxide treatment and water rinse, will retain more sodium than after an acid treatment. Therefore silicon slices should not be allowed to sit very long in rinse water after a basic peroxide treatment. If slices must stand for any length of time in water, then quartz or polyethylene dishware is recommended unless subsequent treatments in the cleaning process are used to desorb the accumulated sodium.

Sodium Contamination of Silicon from Reagents

Silicon wafers that had been treated with hot dilute HCl, rinsed with overflowing deionized water, and finally pulled out of a dilute HF solution in a hydrophobic condition, were then analyzed for surface sodium. This treatment generally reduced sodium contamination of the silicon surface below the detection limit of 3.6 $\times 10^{11}$ atoms/cm^2. Slices cleaned in this manner were then placed in solutions of differing *p*H and known sodium concentration, added to the solutions in the form of NaCl. After 10 min in the solution, the slice was pulled out, blown dry with filtered dry nitrogen, and analyzed immediately for sodium content. The results are presented in Fig. 5. As expected, sodium adsorption onto silicon was found to be proportional to the sodium concentration in solution. Adsorption is greatest in the 0.1*N* NH_4OH and least in the acidic solutions. Adsorption of sodium from water is seen to be slightly greater than from acid solution. Adsorption from 0.1*N* HF is approximately the same as from 0.1*N* HCl, indicating that sodium adsorption on a bare silicon surface is about the same as on a silicon surface containing a native oxide, at least in acidic solution. Extrapolation of the data in Fig. 5 suggests that the sodium content of reagents should be well below 0.1 ppm in order to have sodium contamination levels on a slice below 10^{11} atoms/cm^2 if no subsequent desorption occurs later in the process.

The effect of *p*H on sodium adsorption onto silicon is more clearly shown in Fig. 6 where the sodium content of silicon slice surfaces is plotted *vs.* the *p*H of the adsorbing solution at a constant ionic strength of 0.1 and a constant sodium concentration of 10 ppm. Adsorption increased exponentially with *p*H. Although it was not practical to obtain data beyond the *p*H range indicated due to the difficulty of obtaining reagents with a low residual-sodium content, the curve suggests that sodium adsorption can become substantial at higher *p*H's.

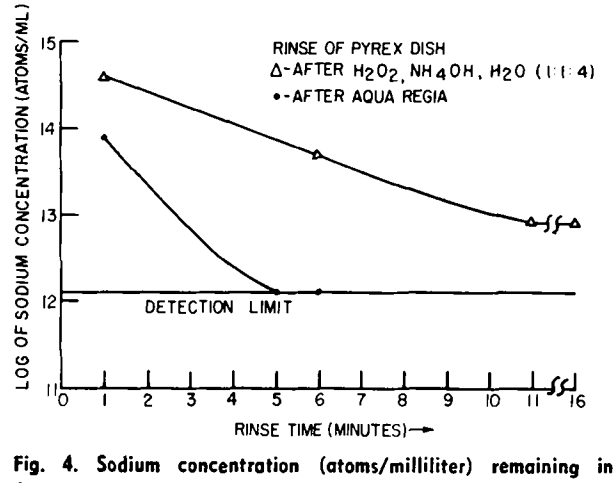

Fig. 4. Sodium concentration (atoms/milliliter) remaining in water.

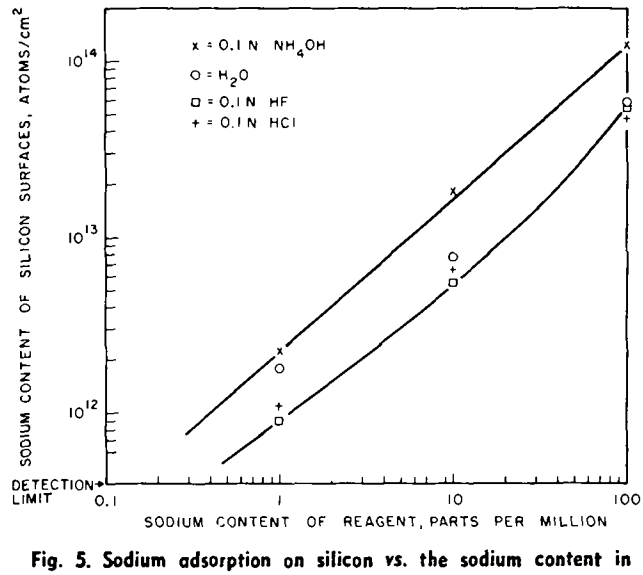

Fig. 5. Sodium adsorption on silicon *vs.* the sodium content in solution.

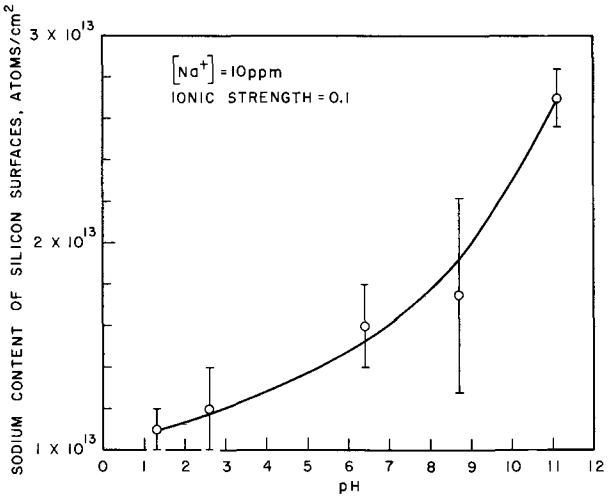

Fig. 6. Sodium adsorption on silicon vs. pH

Experiments were conducted to determine the efficiency of a deionized water rinse in removing sodium from slices. Slices were placed in a Fluoroware basket whose design allows for a laminar flow of water about the slice surface. For a surface sodium coverage of up to 3×10^{13} atoms of sodium/cm², the sodium on the slice surfaces was reduced to below the detection limit within 1 min of rinsing when the sodium was initially adsorbed onto the slice from neutral or acidic solutions. When sodium was adsorbed from a basic solution of 10% NH_4OH, the rate of removal was not so fast. It required several minutes rather than one minute to bring the sodium levels below the detection limit of 3.6×10^{11} atoms/cm². The rapid removal of sodium from slice surfaces suggests that most of the sodium is physically rather than chemically adsorbed. Increasing the *p*H increases the degree of dissociation of surface silanol groups ($\equiv Si-OH$) and thus the number of negatively charged $\equiv Si-O^-$ sites, thereby causing some sodium to become chemisorbed. This explains why it takes longer to remove sodium which was initially adsorbed from a more basic solution.

Sodium Contamination of Silicon-Dioxide-Covered Silicon Slices

Oxidized slices were checked to determine the influence of various chemicals on sodium contamination of their surfaces. A group of five slices was placed in a Fluoroware basket and rinsed for 5 min with overflowing deionized water. The slices were then treated with boiling aqua regia for 15 min and a slice immediately removed and placed in 2 ml of dilute HCl in a preleached polypropylene container and after 10 min the solution was analyzed for sodium. Then after 1.5, 3, 4.5, and 8 min of rinsing, slices were removed for analysis. See Fig. 7a. Initially 2.3×10^{13} atoms of sodium/cm² on the silicon dioxide were detected. After 8 min the sodium contamination was down to $4.7 \pm 3.3 \times 10^{11}$ atoms/cm². Slices treated with the acidic peroxide solution were rinsed of sodium in a similar manner. See Fig. 7b. Oxidized slices treated with the basic peroxide solution and checked for sodium as above did not reproducibly rinse free of acquired sodium on their surfaces. Plotted in Fig. 7c is the sodium content found on slices for two different trials. It appears that after a basic solution which has an initially high sodium content (probably greater than 480×10^{13} atoms of sodium/ml, the majority of which comes from the H_2O_2) a deionized water rinse is not sufficient to controllably remove the sodium from oxidized slices to as low a level as that observed after an acid treatment and water rinse.

A group of oxidized slices was treated with hot 0.01M NaOH (6×10^{18} atoms of sodium/ml) for 1 min, then treated with hot aqua regia for 10 min and finally overflow-rinsed with deionized water for 10

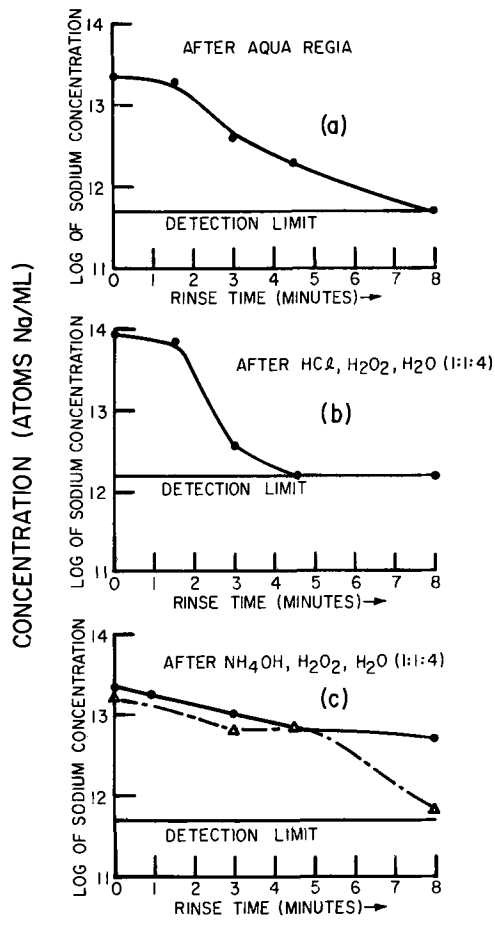

Fig. 7. Surface sodium concentration (atoms/milliliter) on oxidized silicon slices.

min. The sodium content of the first 400Å (taken to represent the surface) and the remaining bulk SiO_2 was not significantly different from the sodium content of the group of five slices not given the NaOH treatment (see Table III). It seems that an acid treatment is able to reduce sodium contamination of the surface from such a drastic treatment with NaOH. It is interesting to note that within experimental error the average bulk oxide sodium content was not affected.

Contamination of Silicon from Slice-Handling Tools

Since it was found that a high-purity water rinse is effective in removing adsorbed sodium, silicon cleaning processes that use this rinse as a final step should yield slices that are "sodium-free." That this is generally not the case is due to the fact that the slices must be handled after the water rinse.

Stainless steel vacuum chucks.—A group of four stainless steel vacuum chucks that were in routine use for handling of slices were checked for sodium contamination. See Table IV for the amount of sodium transferred from four different chucks into 15 ml samples of deionized water in 15 sec. This procedure is meant to simulate the actual practice of retrieving silicon slices from solution by submerging the chuck into the water in order to contact the slice. A simple deionized water rinse of the vacuum chuck for 30 sec prior to use reduced the amount of easily trans-

Chuck number	Atoms of Na $\times 10^{-14}$	% Increase of Na in water
1	0.44	13
2	3.22	91
3	16	460
4	20	570

ferrable sodium on its surface by a factor of 20. Touching the stainless steel vacuum chuck for 3 sec with three gloved fingers increased the sodium level by 310% while with ungloved fingers the increase was 4800%. Wiping dry a clean vacuum chuck with Twill-Jean cloth increased the sodium level by 300%. Similar results were obtained with stainless steel tweezers. If a dry vacuum chuck is necessary then a deionized water rinse and stream of dry filtered nitrogen gas just prior to use minimizes the amount of surface sodium ($<5 \times 10^{12}$ atoms of sodium transferred to 15 ml of water in 15 sec).

Spin dryer.—A standard procedure often found as a last step in slice cleaning just prior to loading oxidized silicon slices into a furnace is to spin dry them. To investigate the amount of sodium a slice might experience from the dryer, 2 ml of deionized water was placed on the anodized aluminum surface of a spinner that was in routine use and after 5 sec the water was removed with a polypropylene eyedropper. Appropriate controls of 2 ml of deionized water transferred with the eyedropper from one vial to another were run as a check of inadvertent sodium contamination. It was found that the sodium level was generally very high in the water (182 to 366 $\times 10^{13}$ atoms of sodium/ml for the two determinations). The amount of easily transferrable sodium on the anodized aluminum spinner was reduced after a dilute HCl and deionized water rinse to between 30 and 39 $\times 10^{13}$ atoms/ml. The HCl should not be spun off the surface of the spinner since it may damage the spinner mechanism of the dryer.

Five oxidized slices were treated with boiling HCl for 10 min and then given an overflow water rinse for 15 min (a treatment that reproducibly yields surface concentration of sodium near the detection limit of 3.6×10^{11} atoms/cm^2). The anodized aluminum spinner was wiped with a wet Twill-Jean cloth which raised the sodium concentration in the water on the spinner to 148×10^{13} atoms/ml. The five cleaned slices after spin drying had an average surface concentration of $38 \pm 30 \times 10^{11}$ atoms of sodium/cm^2. After a dilute HCl and water rinse the spinner surface yielded 6×10^{13} atoms of sodium/ml and five slices treated as before showed a surface concentration of $6.5 \pm 3.5 \times 10^{11}$ atoms of sodium/cm^2. Evidently a dirty spinner head can account for a large amount of surface contamination of the slices as well as a very large fluctuation in the amount of surface sodium from slice to slice.

Spinner heads that are ribbed so that the wet slice does not make full contact with the spinner surface and heads that are covered with an inert material such as Teflon would be an improvement over anodized aluminum. Such a spinner also in routine use had one-tenth as much sodium on its surface as did the aluminum head.

From this it can be concluded that metal spinner plates should be cleaned prior to use with dilute HCl and water to minimize sodium contamination of the slices. Spinner heads should be designed so that they are easily removed for cleaning prior to each use.

It should be made clear that the above cleaning procedures for slice-handling tools apply only for the removal of sodium. The stainless steel vacuum chucks and tweezers probably need a thorough degreasing to remove organic compounds that may be present on the surface. It should be recognized that other contaminants may be added to the silicon slice from the handling equipment, if they have not been previously removed.

Clean bench environment.—While most handling of silicon slices is done in vertical laminar flow hoods to minimize stray particle contamination, the possibility of sodium contamination of the slices during exposure to the filtered, partly recirculated air is possible. A 3.2-cm diameter polypropylene container with 20 ml of water was allowed to stand uncovered in such a hood for 5 min. Next to it a similar container of water stood covered. The sodium content of the uncovered water increased by $1.0 \pm 0.2 \times 10^{13}$ atoms/ml whereas no change was detected in the covered water. If a corresponding amount of sodium had adhered to the surface of a slice exposed to the ambient for 5 min, then $9.2 \pm 1.8 \times 10^{13}$ atoms of sodium/cm^2 would be measured as the average sodium concentration on the silicon surface. This indicates that slices even in a clean bench should be exposed to as little ambient as possible.

Rubber gloves.—A new pair of rubber gloves was put on with bare hands and rinsed in a stream of deionized water for 40 sec. The gloved index finger was dipped into 10 ml of water for 15 sec. The contamination attributable to the glove was 2×10^{13} atoms of sodium/ml. With three rinses of the glove in dilute HCl, a rinse in a stream of deionized water, and finally dry filtered N_2 gas to remove the water, the sodium contamination was down to 0.65×10^{13} atoms/ml or about one-third that of the uncleaned glove. All of these levels are high compared to the sodium levels attainable in properly treated dishes and on silicon slices. While rubber gloves are certainly better than bare hands, they should by no means be considered clean to the extent that they may contact chemical reagents, baskets, the working end of slice-handling equipment, or the interiors of containers used for critical sodium contamination reduction steps. Again, it should not be construed that rubber gloves need merely a dilute HCl rinse to be clean. The dilute HCl rinse removes easily transferrable sodium and not necessarily other contaminants.

Conclusions

Any handling or exposure to ambients increases the chance of sodium contamination of the silicon slice. Vacuum chucks used for handling slices should be rinsed at least with deionized water prior to use. Spin dryers of anodized aluminum have been shown to increase surface sodium content on silicon slices. Although a dilute HCl and water rinse will reduce sodium contamination, a better spinner head would be coated with an inert material such as Teflon and the head would be easily removable for cleaning with deionized water prior to each use.

Chemicals that come into contact with the silicon slice do not have to be especially low in sodium content. What is more important is that the high sodium content reagents be followed with an acidic solution for silicon-dioxide-covered slices. Then a water rinse is sufficient to reduce sodium contamination below 3.6×10^{11} atoms/cm^2. The solution of ammonium hydroxide, hydrogen peroxide, and water should not be used for sodium removal from oxidized silicon surfaces. It was not designed for sodium removal (5), and if sodium removal is desired, the basic peroxide solution should be followed by an acid treatment prior to final rinsing.

Either pulling a bare Si slice with an hydrophobic surface from dilute HF or spinning off water from an adequately rinsed (acidic solution plus overflow rinse) oxidized surface of silicon yields equally low levels of surface sodium contamination. This obtains provided the vacuum chuck and spinner head are clean, *i.e.*, rinsed free of easily transferrable sodium prior to use

and that recontamination is avoided by proper care in handling of them. Slices that must stand in water for any length of time prior to drying should not be contained in Pyrex dishes since sodium leaches out of the Pyrex. Quartz or Teflon dishes are viable alternatives. Low-sodium reagents should not be used with Pyrex and those reagents packaged in glass should either be used immediately or repackaged into clean polyethylene containers to minimize sodium pick-up from the glass.

ABSTRACT

Vacuum-deposited amorphous and crystallized silicon films were studied by sputter-ion source mass spectrometry. Crystallization was carried out in both argon and vacuum environments. Positive impurity ions and polyatomic ions (clusters) were examined. Impurities which arose from the crucible, residual atmosphere, substrate, and structural components in the system are described. Films crystallized in the vacuum generally contained more impurities than those crystallized in an inert atmosphere. Cluster distributions or relative amount of Si_n^+ (n = 1-6) *vs.* m/e for amorphous and crystallized samples are essentially the same. However higher order cluster peaks ($n \geq 6$) appear to be slightly lower in amorphous samples. The relation between cluster distribution and atomic nearest neighbor environment is discussed.

The study and application of vacuum-deposited amorphous and crystalline silicon films has been severely handicapped by the lack of information available on their impurity content and atomic structure. The grain size and total amount of material in the sample are usually too small for detailed spectrograph, chemical, or structural diffraction analysis. Electron microprobe x-ray fluorescence analysis has limited sensitivity (<100 ppm) and activation analysis is only suitable for specific impurities (1). The problem is further complicated by the fact that silicon films, as normally deposited, are amorphous and the characterization of their structure is somewhat speculative (2). Their structure furthermore depends on preparation conditions (3).

The sputter-ion source mass spectrometer (sometimes termed the ion microprobe mass spectrometer), which has recently become available, has the potential of providing much of the required analytical information on impurity content, and perhaps structure, in the films (4, 5). In this paper, an analysis of amorphous and crystalline silicon films using this mass spectrometer will be described. As far as known, this is the first study of this nature ever carried out.

The mass spectrometer records positive ion spectra of single atomic species (*e.g.*, Si^+), polyatomic species or clusters[1] (*e.g.*, Si_4^+) as well as complexes (*e.g.*, SiO^+). The impurity spectra and the cluster spectra will be dealt with separately. The two types of spectra are related, however, in that the cluster distribution is altered by the presence of impurities.

Impurities in both the amorphous phase and the crystalline phase, which is obtained by heating the amorphous phase, will be described. Every impurity will not be discussed in detail here, but a table of sample preparation conditions (Table I) and the resulting major impurities (Tables II-IV) will enable the reader to infer the origin of a particular impurity.

Mass clustering, which represents groups of atoms that leave the surface of the solid together, was first observed by Honig in the vapor of Group IV elements (6). Honig reported that the cluster distribution showed departures from a smooth curve. Using a spark-source mass spectrometer, Chupakhin *et al.* (7) reported differences in cluster spectra when silicon crystals were heavily doped. Chupakhin has suggested that this cluster distribution is related to the parent structure. Baun *et al.* (8) have similarly reported differences in the carbon cluster distribution from amorphous and crystalline carbon.

In view of the reported sensitivities of the cluster distribution to atomic structure, cluster spectra from silicon films were examined in an attempt to observe differences between the amorphous and crystalline phases. While it is well known from x-ray diffraction studies that both amorphous and crystalline silicon are four-fold coordinated and have similar first atomic nearest neighbor environments (9), their cluster dis-

Key words: silicon films, mass analysis, amorphous semiconductors, impurities, ion clusters.

[1] These clusters, found in the vapor phase, should not be confused with the clusters or aggregates sometimes used to describe amorphous structure in the solid phase (2).

tributions may be different, due to the presence of dangling bonds, voids, low density, and differences in second and third nearest neighbors in the amorphous phase (2, 3, 10).

During the course of this study, the silicon cluster spectra from amorphous SiO and SiO_2 were examined and will be reported here for the first time. A brief report of this study was presented at The International Conference on Thin Films, 1972 (11).

Silicon Sample Preparation

The deposition of silicon was carried out in a 12-in. diameter vacuum chamber using either a stainless steel or a Pyrex bell jar. The bell jar and feedthrough ring employed a Viton gasket; all other seals employed copper gaskets. Water-cooling coils were used to maintain low temperatures in the Viton gaskets. In the interest of cleanliness, only supports absolutely necessary were in the chamber. The pumping system consisted of a fast mechanical pump (130 cfm), an oil diffusion pump (2400 liters/sec) using DC 705 oil, and a titanium getter pump (550 liters/sec). A zeolite trap was located between the mechanical pump and the diffusion pump, and a liquid nitrogen trap was located directly above the diffusion pump. The titanium getter pump, located just below the chamber and baffled from it, employed a liquid-nitrogen-cooled surface. Titanium was not deposited during the deposition. The system contained a residual gas analyzer which was used extensively during the study. Predeposition pressures of less than 5×10^{-9} Torr were obtained. The substrates were outgassed at about 500°C by quartz, tungsten-filament, halogen-filled lamps.

Water-cooled crucibles, of various materials, about 1½-in. internal diameter, were used. As the study progressed, the cooling of the evaporation source crucible was improved. The source crucible used in series 42 through 82 and series 89 consisted of a heavy copper crucible cooled by ¼-in. diameter copper tubing which was brazed with Cu-Ag eutectic. In series 52, the entire assembly was silver plated. In series 86, a similar design was employed, but the crucible was molybdenum with stainless steel tubing. The design was changed in series 96 to a stainless steel, internally cooled, double-wall construction with a molybdenum liner. Zone-refined, 500 ohm-cm, silicon contained in these crucibles was melted by a focused electron beam with a power between 1 and 2 kW. Care was taken not to allow molten silicon to contact the walls of the crucible.

Silicon films, as normally deposited on substrates held at temperatures less than 300°C, are amorphous and must be heated to develop their crystalline structure. This crystallization process is a function of both time and temperature. A minimum temperature of 700°C for 30 min is required to crystallize the samples (12). Temperatures greater than 700°C were used in this study to insure good crystal growth and for future reference for processing at higher temperatures. The higher crystallization temperature also increased the introduction of impurities. Heating was performed either in the vacuum chamber or in tube furnaces flowing with high-purity argon gas. The conditions under which the samples were deposited are listed in Table I.

Sputter-Ion Source Mass Spectrometer

The sputter-ion source mass spectrometer (13) employed a 10 keV argon ion beam which was generated in a duoplasmatron. The ion beam ejected from the target atomic and polyatomic fragments of which a fraction was ionized. The beam could be focused for maximum resolution in performing trace analyses in bulk materials, but in this study the beam was defocused to provide the appropriate sputtering rate and, more importantly, uniform sputtering from surface to depth. The uniform sputtering rate eliminated the need for crater geometry corrections.

The sputtered positive ions were directed to a double focusing mass spectrometer and were detected by an ion multiplier. A compensation electron emitting filament was used to overcome charge-up in the samples on insulating substrates. The filament temperature was kept as low as possible to avoid heating the sample and introducing impurities. The instrument has an "energy window" feature which provides a means of selecting ions in a narrow energy range, enhancing either the polyatomic spectrum (zero energy window) or the atomic spectrum (100 eV window). Thus in the energy distribution curve of the sputtered species, the intensity of the polyatomic peaks falls off more rapidly at higher energies (100 eV) than the monoatomic peaks (5). The use of the 100 eV window thus reduced interference from the polyatomic ions. The spectra were recorded on an x-y chart recorder.

Polyatomic Ion Cluster Spectra

A typical mass spectrum using zero-energy window is shown in Fig. 1. The silicon positive ion intensities and their isotopes ($^{28}Si^+$, $^{29}Si^+$, $^{30}Si^+$) for Si_1^+, $Si_2^+ \ldots Si_6^+$ can clearly be observed. The ion intensities were normalized according to

$$Si_n^+ = \frac{I_{Si_n^+}}{\Sigma I_{Si_n^+}} \qquad n = 1\text{-}6$$

where $I_{Si_n^+}$ is the recorded silicon ion current for a cluster containing n atoms. Plots of the normalized intensities in per cent for each ion cluster *vs.* the number of atoms in each cluster (or the cluster mass) are shown in Fig. 2-4. The points to be observed in these figures are the fall off as the clusters become large and the structure in each individual plot.

Figure 2 shows typical distributions for amorphous and crystalline films. As can be seen, there are only

small differences between the amorphous sample, 77E, deposited at a substrate temperature of −50°C, and a crystalline sample deposited at a substrate temperature of 800°C. Both samples have essentially the same cluster distribution as the bulk single crystal. For clusters greater than Si_2^+, the relative number of clusters in the amorphous sample (77E) remains less than those in the crystalline samples. However it is difficult to determine, at present, whether this slight deviation is significant. A deviation at Si_6^+ will be

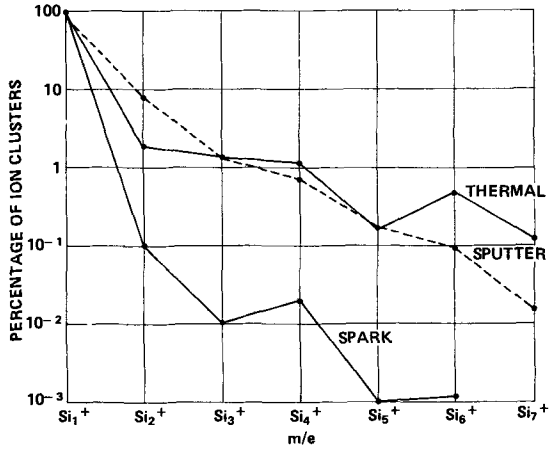

Fig. 3. Silicon ion cluster distribution from bulk samples. (a) Sputter-ion source, (b) thermal source [Honig (4)], and (c) vacuum spark source [Chupakhin (5)].

discussed in the next section. Differences in fall off and structure appear in samples 42 and 63F but this is believed due to the large amount of impurities present. Sample 42 contains 1.2% oxygen and 63F, 8.47% chromium. The impurity analyses of these samples are given in Table II.

The cluster distribution observed by Honig (6) for thermal sources and by Chupakhin (7) for vacuum spark sources, along with that obtained here, are shown in Fig. 3 for comparison. Note the characteristic Si_4^+ and Si_6^+ peaks in all these curves. The relative heights of the Si_4^+ and Si_6^+ peaks in the case of the sputter-ion source are lower than either the thermal or spark source. A change in bombarding ion mass could, however, change the sputter-ion source cluster distribution.

Cluster spectra from bulk fused SiO_2 (substrate), a deposited SiO film on fused silica, bulk crystalline SiC, and bulk crystalline Si for comparison, are shown in Fig. 4. Note the rapid fall off and lack of structure in SiO_2.

Discussion of Cluster Spectra

If one assumes that clusters represent groups of atoms ejected from the target in one piece, then their distribution should give an indication of the nearest neighbor environment in the material. This was pointed out in the beginning of the paper. In SiO_2, for example, there are ideally no Si-Si bonds and the clustering of Si atoms should be relatively small compared to pure silicon. This is observed in Fig. 4. There is no particular reason to expect a peak at Si_4^+ in SiO_2. The clusters that one observed in SiO_2 may be due to recombination on or near the surface or to a few Si-Si bonds that may exist. SiO, on the other hand, contains some fraction of Si-Si bonds and thus
