A detailed study of cumulative current efficiencies by Griffin (29) has shown that in a conventional plating bath at 45°C and at a C.D. of 200 mA/cm^2 the current efficiency distribution for the processes $2H^+ \rightarrow H_2$, $Cr^{6+} \rightarrow Cr^3$, and $Cr^{6+} \rightarrow Cr^0$ is about 60, 30, and 10%, respectively. In similar studies by Solov'eva and Petrova (28) at 40°C and at a nominal C.D. of 250 mA/cm^2 the current distribution for the above reactions was found 65, 15, and 20%, respectively. In the absence of $SO_4^=$, virtually all the current was consumed for the liberation of hydrogen at about 100% current efficiency. When $SO_4^=$ was added gradually up to the concentration level of the conventional plating bath, the reactions $Cr^{6+} \rightarrow Cr^{3+}$ and $Cr^{6+} \rightarrow Cr^0$ gradually increased in terms of the current consumption while $2H^+ \rightarrow H_2$ dropped steeply to the level quoted above.

It must be pointed out that in the above investigations large cathode areas were used for prolonged periods of electrolysis, thus providing average data.

Jones and Saiddington (30) have shown that practically all visible hydrogen evolution occurs at cracks which do not form continuously but in a periodic manner in a small restricted area of about 1 mm diameter. The crack formation is preceded by a period of quiescence. The period of quiescence, it is shown in the present work, precedes the formation of the first crack and begins at potentials associated with the end of the region I and with the beginning of the region II.

Photomicrograph (k) in Fig. 3B shows that the deposition of chromium is associated with the complete absence of gas evolution at the site under observation. The question arises, therefore, as to what processes are in progress when there is no visible gas evolution.

If we assume that hydrogen ion discharge and chromium deposition occur simultaneously at this site some of the reduced hydrogen will probably be incorporated

into the growing deposit, perhaps as hydride, thus, giving rise to high stresses which are eventually relieved by cracking. Some of it may be adsorbed in the deposit or in the cathode film, in the molecular form, until the formation of cracks begins when it is released as gas bubbles.

Alternatively one would have to assume that either no hydrogen ion discharge is taking place or that part or all of the discharged hydrogen is used up for the reduction of chromic acid to metal and to trivalent chromium. In the absence of more direct evidence all explanations on the cessation of gas evolution must necessarily remain speculative, although the first alternative is here considered more probable than the others.

The formation of a crack is a macro event that disrupts locally the progress of the electrochemical processes. The molecular hydrogen is released along the exposed ridges (see Fig. 3B), until the crack is bridged over (30). The evolution of hydrogen along the crack lines induces higher pH values and, hence, more favorable conditions for the precipitation of hydrated chromic oxide which is trapped inside the cracks as they are bridged over (31). The existence of the chromic oxide inside the cracks was demonstrated by Cohen (32) who stripped electrolytically the deposited chromium and analyzed the remaining network of isolated inclusions.

Higher current densities are expected to produce higher pH conditions at the cathode surface and, thus, a more favorable environment for the formation of the chromic oxide film. This contention has been borne out experimentally at a current density of 0.660 A/cm^2 as is evident from the photographic record in Fig. 4 that corresponds to curve 3, Fig. 1b. The individual photomicrographs in Fig. 4 show (a) the appearance of the surface immersed in the bath before electrolysis, (b) gassing in the 30th second at −0.61V, (c) hydrogen evolution in the 15th minute at −1.00V, (d) heavy gassing associated with the formation of a chromic oxide film at −1.01V, (e) the presence of a visible solid chromic oxide film at −1.035V, (f) transient gas-

sing after the break-up of the chromic oxide film during potential shift from −1.035 to −1.065V, (g) complete absence of surface gassing during chromium plating at −1.150V, and (h) formation of a first crack and the accompanying gas evolution.

Photomicrographs (b) to (d) show an increase of gassing with the increase of potential in region I. This gassing appears more intense than the one observed in Fig. 3A, a phenomenon not unexpected in view of the higher current density employed. The peak of gas evolution is seen in photomicrograph (d). From this level onward, the gassing continued to decline as the potential shifted to more negative values (region II). This decrease of gassing permitted one to observe quite clearly the presence of a solid chromic oxide film in (e). The chromic oxide film might have formed earlier but its presence cannot be detected in (d) because of the intense gas evolution. With the shift of the potential from −1.035 to −1.065V the chromic oxide film disintegrated rapidly and its absence is self-evident in (f). Residual gassing eventually ceased completely by the time chromium deposition potential of −1.15V was reached when photomicrograph (g) was taken. The first crack [Fig. 4 (h)] formed after about 1½ min of chromium plating at steady-state conditions.

The formation of a visible chromic oxide film was observed only at higher current densities. Hence the effect of higher pH and perhaps higher Cr^{3+} concentration in the diffusion layer on such a process is indicated. Susumu Igawa (33) who investigated the composition of such films with various techniques came to a conclusion that a general formula of the chromic oxide film is (CrO_3) $(Cr_2O_3) \cdot 10H_2O$ representing a hydrated chromic oxide with adsorbed chromic anhydride.

It should be noted that the formation of the chromic oxide film had no apparent effect on the progress of gassing decline during region II, on chromium deposition at steady-state conditions, and on the initiation of crack formation. This attests to the incidental nature of such a film and to its irrelevance in the transient processes that lead to the establishment of chromium plating processes.

The disintegration of the chromic oxide film occurred before commencement of chromium deposition as is evident in Fig. 4. The hypothesis of Okada and Yamamoto (5) about thickening of the film during transition in region II is thus contradicted.

The formation and break-up of the chromic oxide film was also observed visually at the highest current density examined (1.320 A/cm²). Turbulent conditions of electrolysis did not permit, however, successful photomicrography and detailed analysis of the visual observations could not be made.

Summary

The experimental results show that the transient processes in region I associated with the evolution of hydrogen prior to the deposition of chromium on platinum are extensively protracted in comparison with those on an Fe substrate. The observation can be explained plausibly by low overvoltage characteristics of Pt. The actual shift of potential with time during region I depends on the progress of processes that inhibit the evolution of hydrogen, which is the main current carrying reaction. These processes are affected by the conditions of the cathode surface and are accelerated at higher current densities.

The chromic oxide film that forms on Pt in region I disintegrates before the deposition of chromium begins just as it does on Fe. This evidence confirms the earlier findings made with Fe cathodes and contradicts the hypothesis of Okada and Yamamoto (5) about the increase of hydrogen overvoltage with the thickening of the chromic oxide film during potential shift in region II.

The transient processes associated with the shift of the potential in region II do not appear to be significantly affected by the conditions of the cathode surface nor by the overvoltage characteristics of the metal substrate.

The shift of potential in region II is unambiguously associated with a rapid decline of gas evolution prior to the commencement of chromium deposition. The decline of gas evolution and the simultaneous increase of the polarization are not affected by the prior formation of a solid chromic oxide film; they are assumed to be caused by some not yet determined transformations in the liquid layer adjoining the cathode surface that apparently involve the formation of a liquid cathode film.

Microscopic observations show that the initial deposition of chromium is accompanied by a complete cessation of the visible gas evolution in the area under examination. No conclusions can be made on the basis of this observation whether the discharge of the hydrogen ion ceases at this stage of electrolysis. Other evidence indicates that hydrogen enters the deposit and the substrate from which it can be expelled on heating (34). The current efficiency studies (28, 29) made with large cathodes during prolonged periods of electrolysis give average data that do not necessarily apply to the small areas examined in the present work. These average data show that up to 65% of the total current is consumed for hydrogen gas evolution. Such a high rate strongly suggests that the discharge of hydrogen ion is in progress throughout the electrolysis and that only the local gas evolution process is temporarily affected. Final conclusions cannot be reached, however, until detailed determinations of current efficiencies in the small surface areas affected are made.

A Study of Contamination on Electroplated Gold, Copper, Platinum, and Palladium

D. L. Malm and M. J. Vasile

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Electroplated gold, copper, palladium, and platinum have been examined for surface and bulk impurities using spark source mass spectrometry and ion scattering spectrometry. Electroplated metals were found to have more contamination on their surfaces than cast metals after the same cleaning procedures. Methods such as rinsing in distilled, deionized water or ultrasonic cleaning in trichloroethylene did little to remove surface impurities from electroplates. A mild etch followed by a distilled, deionized water rinse was found to be the most effective method for cleaning the surfaces, with the exception of the platinum electroplate. Bulk impurities indicative of plating bath contamination were found in many instances.

The use of electroplated metals as connector and contact surfaces within the electronics and communications industries is extensive. Little information is available concerning the nature or extent of the impurities on the surfaces of electroplates and the effectiveness of cleaning procedures used to remove them. A variety of techniques has been applied to the determination of the bulk impurities codeposited with hard gold electroplates (1-4) and their effects on vacuum arcs (5). During the course of the mass-spectrometric study on electroplated gold (5), it became apparent that electroplated surfaces were considerably more contaminated than other surfaces of corresponding cast specimens, even though in one case (soft electroplated gold) the bulk purity level was comparable to that of cast gold. This study was undertaken to extend the spark source mass spectrometric determinations to the detection of surface impurities on electroplated copper, platinum, and palladium. Each of these materials was also examined for bulk impurities.

The spark source mass spectrometer can be used to examine the surface impurities present on a given sample (6) with a high degree of sensitivity. However, its sampling depth resolution is only about 6000Å (5). To obtain a more detailed picture, ion scattering spectrometry (7) was also used in this study to investigate the changes in impurity concentrations with depth in some of the systems.

Experimental

A commercially available[1] RF spark source mass spectrometer with photoplate detection was used. The electroplates were deposited on 0.125 cm diameter OFHC copper rods. The rods were tapered with rounded ends to minimize shielding of the ions from the first accelerating plate of the mass spectrometer. The arc conditions were chosen such that each spectrum was obtained without over exposing any of the lines on the photoplate. Total ion exposure measured with the beam monitor was of the order of 10^{-11} coulombs.

The sampling procedure used for surface analysis was to record spectra from at least ten points on the electrodes. The electrodes were manipulated so that a fresh area on each of the members was subjected to the arc. Bulk analyses were performed by presparking a given area (5) and following this with five successive arcing events on the presparked region. The arithmetic means and standard deviations of the ion intensities were computed for all the ions recorded in the surface and bulk analyses. No corrections were applied for line width, ionization efficiency, or relative volatility of the ions observed; however, the response of the photoplate was corrected for the masses of the singly charged ions and the kinetic energies of the doubly charged ions. The results are expressed as ion per cent by first computing the total exposure for all ions and then taking the percentage of the total for each ionic species in the spectrum (5).

Ion scattering studies were performed on a commercially available ion scattering spectrometer.[2] Singly charged helium ions, accelerated to 1.5 kV were used as a primary beam. The ion beam profile was measured and found to be 0.7 mm, full width at half maximum intensity and 1.4 mm, full width at 10% maximum intensity. The corresponding current densities are 23 $\mu A/cm^2$ and 6.5 $\mu A/cm^2$, respectively. Ion scattering analyses were confined to gold- and platinum-plated specimens on planar substrates.

Electroplating of the substrate was done in a manner that maximized the plating efficiency of each of the systems. The electroplates were deposited to a thickness of approximately 0.0025 cm. A thin deposit of soft gold was plated on the copper rods prior to plating from acidic baths. Clean glass cells and platinum anodes were used in each plating operation. The plated samples were rinsed with distilled water after plating,

dried, and kept in glass containers prior to analysis. No special precautions were taken to purify or modify the plating baths, since one of the objects of this study was to determine the impurities that remain on the electroplated surfaces under normal circumstances. The compositions of the plating baths are given in Table I. (The exact compositions of some of these baths are proprietary to their manufacturers, so only information relevant to this study is given.)

To determine if cleaning methods have any effect on the type and amount of surface impurities, three different treatment were used: (*i*) ultrasonic cleaning in trichloroethylene, (*ii*) 10 min rinsing in deionized, distilled water, and (*iii*) etching in an appropriate acid for about 15 sec, followed by a rinse in distilled deionized water.

Etchants used for each system are given in Table I. The samples were dried by infrared heating in a laminar flow hood and mounted in the mass spectrometer ion source for analysis. High-purity control specimens of the same metal in cast form were treated and analyzed under identical conditions.

Results and Discussion

Surface analyses by spark source mass spectrometry sample only a small fraction of the total surface area. Surface contamination is frequently nonuniformly distributed; hence, a particular impurity may show a weak response at one location and a very much more intense response at another. As a consequence, the standard deviation of the ion percentage of a surface impurity is usually large. The ratio of the standard deviation to the ion percentage for many surface impurities ranges between about 0.75 and 1.5, while for bulk impurities, this ratio rarely exceeds 0.3. Bulk impurities usually exhibit no change in response between surface and bulk sampling.

Tables II through VI contain the results of the mass spectrometric analyses of electroplates and cast specimens. The water wash and bulk analyses for cast specimens are not listed, since the water-wash results do not differ significantly from those of solvent cleaning, and the bulk analyses showed no impurities.

The surface analyses of electroplated and cast (OFHC) copper are given in Table II. Cleaning the surface by water rinsing or ultrasonic solvent treatment had very little effect in removing surface impurities. Etching the surface removed all the surface impurities except carbon and oxygen, which result from adsorbed hydrocarbons and oxygen or water. It is of interest to note that the carbon concentration dropped by a factor of two with the etch treatment,

Table I. Electroplate bath descriptions and etchants for cleaning

Copper
Copper cyanide, potassium cyanide, potassium carbonate, potassium sodium tartrate.
pH 12.2-12.8.
Temperature 55°-66°C.
Dilute nitric acid, room temperature.

Palladium
Palladium diamino dinitrite, ammonium sulfate, ammonium hydroxide.
pH 7.5-8.5.
Temperature 27°-33°C.
Aqua regia, room temperature.

Platinum
Platinum ammonium chloride, hydrochloric acid.
pH 0.5-1.5.
Temperature 49°-60°C.
Aqua regia, room temperature.

Hard gold
Potassium gold cyanide, potassium citrate, cobalt citrate.
pH 3.3-3.9.
Temperature, ambient.
Aqua regia, room temperature.

Soft gold
Potassium gold cyanide, ammonium citrate.
pH 5.0-5.5.
Temperature 60°-65°C.
Aqua regia, room temperature.

while the oxygen concentration remained unchanged within the precision of the measurements. Some of the surface impurities such as Al, Mg, Cl, and S cannot be correlated with the nominal composition of the plating bath (see Table I). The distilled, deionized water treatment cannot be responsible for these impurities since it is also the last step in the etch treatment, and in that case they were absent. Plating bath contamination, airborne contamination, and sample handling are the most obvious sources of these contaminants. The bulk purity of copper electroplates was found to be quite high, with no measured impurity levels in the mass spectrum at as much as 0.1 ion per cent, which corresponds to an estimated purity of 1 part in 10^4 in the plate. The specimen of OFHC copper showed impurities due to adsorbed atmospheric gases and organics after solvent cleaning. Etching this sample reduced the concentrations of carbon and oxygen by an order of magnitude, and the surface analysis for the etched OFHC sample is probably indicative of the contamination level that can be expected from the adsorption of residual gases in the mass spectrometer.

Palladium electroplate (Table III) showed somewhat cleaner surfaces than copper, with only chlorine and copper as surface impurities which do not correlate with the bath composition. The water washing was somewhat more efficient at removing surface impurities from Pd than solvent cleaning. A mild etching of the surface removed all but atmospheric gases. The presence of nitrogen and oxygen in the bulk of the electroplate at effectively the same levels as the surface is a strong indication that some of the diamino dinitrite complex is being codeposited with palladium. If these were surface impurities, a considerable decrease in their intensity would be expected upon presparking. There was a small response for carbon in the bulk which is an order of magnitude less intense than on the surface. This could arise from the vaporization of surface adsorbed species at the periphery of the arc, but this effect would not account for the constant response for oxygen and nitrogen in surface and bulk sampling. The ratio of the standard deviations for the oxygen and nitrogen responses to the average responses for each of these elements was small (0.13-0.23), which is a further indication that they are bulk impurities. The analysis of cast palladium showed a considerably cleaner surface than its electroplated counterparts, with the most significant reduction occurring in the response for carbon.

Platinum electroplate (Table IV) exhibited a wide variety of surface impurities, none of which could be removed by the cleaning treatments used. The 15 sec etch did not yield any improvement over the solvent wash and only a small improvement over the water washing. Extending the duration of the etching to 30 and 60 sec again resulted in no significant improvement. Etching the specimen in aqua regia could have contaminated the surface with copper from the attack of the unplated end of the rod, and some chlorine might also well have remained on the surface.

At least four of the surface contaminants remaining after the etch treatments (viz., Fe, O, N, and C) persisted as bulk impurities in each of the tests. Sporadic low level responses were found for sulfur and aluminum in the bulk probing, and it is likely that the presence of the former is due to peripheral surface contributions. There are apparently two sources of contamination of the platinum electroplate: the plating bath and the etching procedure itself. The latter possibility produces a paradox, since the same procedure on a bulk platinum specimen yielded an extremely clean surface.

Table V contains the data obtained for surface analyses of cobalt-hardened gold, which is known to be heavily contaminated in the bulk with a polymeric material containing carbon, hydrogen, and nitrogen. This polymer is believed to be nonuniformly dispersed (8) below the surface of the electroplate, so etching or presparking should not reduce the response for carbon and nitrogen. Solvent cleaning produced the best results for the hard gold electroplates, but the contribution from bulk impurities is so extensive that comparisons of the cleaning procedures cannot be made.

Surface contamination of soft gold electroplates was also examined, since in this case it is known that the bulk impurity level is very low (3). Table VI shows that both solvent cleaned and etched soft gold surfaces are heavily contaminated with organic material and/or atmospheric gases. Comparison of the soft gold electroplate surface contamination with that of copper electroplates which has high bulk purity shows that the gold surface is more heavily contaminated. Similarly, the surface of the cast gold specimen was more contaminated than the surfaces of cast copper, platinum, or palladium. A high degree of very tenaciously held organic contamination on gold surfaces is in accord with the results of Schrader (9) and Bernett and Zisman (10). These authors found that a gold surface could be wet (zero contact angle) only if extreme precautions were taken to eliminate the possibility of organic contamination.

Ion scattering studies on hard gold electroplate indicated that the carbon-containing impurities are not uniformly dispersed either over the surface or in the bulk of the electroplate. The results of ^4He scattering from the surface of a cobalt-hardened gold are shown in Fig. 1. The diffuse scattering between relative energies of 0.3 and 0.5, which can be adequately explained by sequential double scattering from carbon and hydrogen atoms (11), dropped rapidly as about 20 monolayers were removed with a corresponding increase in the count rate for ions scattered from gold. The number of monolayers removed was computed using an average sputtering rate of 30 monolayers per hour (12) and is only an approximation. The results shown in Fig. 1 also indicate that in this particular instance, the organic surface impurity is not related to the codeposited bulk polymer, since it was removed rather easily by ion bombardment. In contrast to the removal of surface hydrocarbons, Fig. 2 shows that the ion scattering response for cobalt and potassium increased with depth of sampling. The mass spectrometric work also showed that potassium was a bulk impurity in most types of hard gold electroplates.

A sample of nickel-hardened gold electroplate gave opposite results, in that at one location the diffuse

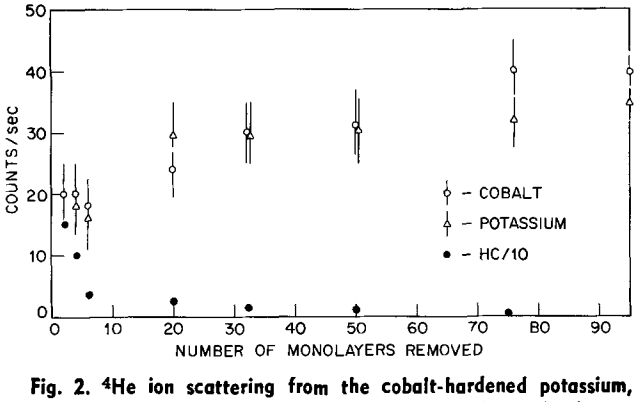

Fig. 2. ^4He ion scattering from the cobalt-hardened potassium, and surface hydrocarbons (cobalt-hardened gold electroplate).

scattering due to organic impurities intensified and then remained constant with sampling depth. At a different location on the same sample, no hydrocarbon response could be obtained after penetration to a depth of about 400 monolayers.

A sample of electroplated platinum was also examined by ion scattering, since the mass spectrometer consistently showed iron and the light elements carbon, nitrogen, and oxygen as bulk impurities. The presence of the light elements was confirmed to at least 120 monolayers, as can be seen in Fig. 3. The signal from ions scattered by platinum steadily decreased, while that due to scattering from oxygen increased. The diffuse scattering attributed to the carbon-containing species also increased with sampling depth. Iron in the bulk or on the surface of this sample could not be detected by ion scattering.

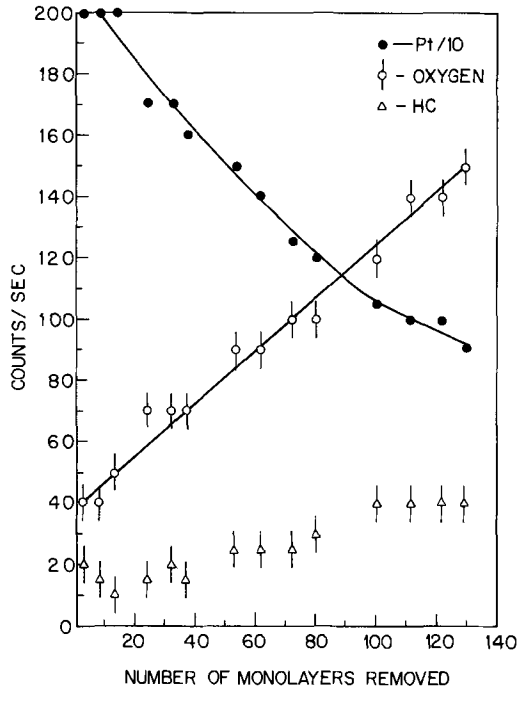

Fig. 3. ^4He ion scattering signals from platinum electroplate as a function of the number of monolayers removed.

The results presented in this study are indicative of the types of impurities that are present on the surface and in the bulk of electroplates. The plating was carried out under laboratory conditions, but the prior uses of the plating baths are not documented. One consistent result that appears in each of the systems studied is the higher level of surface contamination of electroplates relative to cast specimens. This may be due to a higher surface free energy of the electroplate coupled with an immediate supply of adsorbants. The incorporation of bulk impurities is also apparently not limited to hard gold plates.

It is unfortunate that quantitative data on surface coverage cannot be obtained from either of the techniques employed in his study without extensive calibration. It is appropriate to menion, however, that ions of elements with low ionization potentials will appear in the mass spectra at relative concentrations very much higher than their atomic ratios in the matrix would predict.

Acknowledgment

The authors would like to thank Mrs. I. D. Payne for reducing the mass spectrometric data and Mr. T. A. Palumbo for the electroplating of the specimens.

Anodic Current Efficiency and Dimensional Control in Electrochemical Machining

Der-Tau Chin* and Augustine J. Wallace, Jr.

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

An experimental study has been made to examine the relationship between dissolution current efficiency and dimensional control during the electrochemical machining (ECM) of steel in NaCl, $NaClO_3$, and $NaNO_3$ electrolytes. The current efficiency for iron dissolution was measured in a flow cell under controlled anodic current densities ranging from 1 to 100 A/cm^2. The laboratory results were then compared to those obtained under actual ECM conditions. It is shown that the current efficiency *vs.* current density curve is a useful tool to determine optimal ECM operating conditions for achieving the best possible combination of dimensional control and surface finish.

The high quality of electrochemical machining (ECM) dimensional control obtained with $NaClO_3$ and with $NaNO_3$ has generally been attributed to the ability of these electrolytes to form a passive film on the anode. According to a polarization hypothesis (1), metal is removed most heavily from the high current

* Electrochemical Society Active Member.
Key words: electrochemical machining, transpassive dissolution, throwing power.

density region of the anode where the distance to the cathode is small and where the dissolution takes place at a potential corresponding to the transpassive state on the anodic polarization curve. On more remote areas of the anode, away from the cutting area, the distance to the cathode is larger, and the anodic process takes place at a potential corresponding to the passive state on the polarization curve. Consequently, in the latter areas, there forms a passive film which prevents further passage of the current resulting in little or no metal removal at these places. This hypothesis appears to give a logical basis for the fact that ECM dimensional control can be more easily achieved in a passivating electrolyte than in a nonpassivating electrolyte.

Recently, Landolt (2) pointed out the importance of current efficiency in ECM dimensional control. His results indicate that good dimensional control can be achieved with an ECM electrolyte if the current efficiency for metal removal is an increasing function of anodic current density. This concept can be illustrated more clearly if we consider two points on the anode surface: one point is in the high current density (hcd) region, and the other point is away from the hcd region, *i.e.*, in the low current density (lcd) region. The current density on the anode is assumed to be the highest in the hcd region directly facing the cathode, and then to decrease asymptotically to zero with increasing distance from the hcd region. If we denote i_H and i_L as the hcd and lcd anodic current densities, respectively; d_H and d_L as the distances from the cathode; ϕ_H and ϕ_L as the sums of the anodic and the cathodic overpotentials; and η_H and η_L as the current efficiencies for metal removal at the hcd and the lcd points, then

$$\begin{pmatrix}\text{rate of metal removal}\\ \text{at the hcd point}\end{pmatrix} = \frac{i_H\,\eta_H}{n\mathbf{F}} = \frac{k\,(E-\phi_H)\,\eta_H}{n\mathbf{F}\,d_H} \quad [1]$$

$$\begin{pmatrix}\text{rate of metal removal}\\ \text{at the lcd point}\end{pmatrix} = \frac{i_L\,\eta_L}{n\mathbf{F}} = \frac{k\,(E-\phi_L)\,\eta_L}{n\mathbf{F}\,d_L} \quad [2]$$

Here E is the applied cell voltage; k, the conductivity of the electrolyte; $\mathbf{F}$, the Faraday constant; and n, the number of electrons transferred for the metal dissolution reaction. The metal removal ratio can be obtained by dividing Eq. [1] by Eq. [2]. It has been shown that during ECM, the cell voltage is much larger than the sum of the overpotentials on the electrodes (2, 3). Thus as a first approximation, we may assume $E - \phi_H \simeq E - \phi_L$. This leads to

$$\text{(metal removal ratio)} = \frac{\begin{bmatrix}\text{rate of metal removal}\\ \text{at the hcd point}\end{bmatrix}}{\begin{bmatrix}\text{rate of metal removal}\\ \text{at the lcd point}\end{bmatrix}} \simeq \frac{d_L\,\eta_H}{d_H\,\eta_L} \quad [3]$$

The higher the metal removal ratio, the better is the ECM dimensional control. Therefore, Eq. [3] implies that good dimensional control can be obtained by (*i*) operating at the smallest possible electrode gap, d_H, and (*ii*) choosing an electrolyte and a current density for the hcd region which give high current efficiency ratios (η_H/η_L) over the entire anode surface.

The fact that the smaller the electrode gap the better the ECM dimensional control has been known for some time (4). The purpose of the present study was to quantitatively verify Eq. [3] with regard to the current efficiency dependence on the metal removal ratio.

The current efficiencies of the dissolution of a mild steel in NaCl, $NaClO_3$, and $NaNO_3$ electrolytes were measured in a flow cell under controlled anodic current densities ranging from 1 to 100 A/cm^2. The results were then used to predict the ECM performance of the electrolytes, and the predictions were compared with results obtained in a practical ECM test apparatus. This paper summarizes the details of these studies.

Experimental

Current efficiency measurement.—The flow cell used for the current efficiency measurements is shown schematically in Fig. 1. It consisted of two acrylic semicylindrical cell blocks, each 5.25 cm in diameter and 13.34 cm long. The first block contained a replaceable anode and a reference capillary at its center; the second block contained a copper cathode and a shallow groove which was 0.635 cm wide by 5.7 cm long. During the run, the two cell blocks were held tightly together with two toggle clamps to form a rectangular channel for electrolyte flow whose depth could be varied by inserting stainless steel spacers of various thicknesses between the blocks. In this way, the anode and the cathode were facing each other across an electrolyte gap of controlled geometry. A 0.318 cm diameter mild steel rod[1] inserted through a hole of the same diameter in block 1 was used as the anode. The cylindrical surface of the rod was insulated by the block; only the rod end with a surface area of 0.0792 cm^2 was exposed to the electrolyte. The cathode was square in shape and had a larger surface area of 0.4 cm^2 exposed to the electrolyte. A 2-liter acrylic tank equipped with a cooling coil was used as a solution reservoir. The electrolyte was circulated between the reservoir and the flow cell with a variable speed micropump. A rotameter was used to measure the rate of electrolyte flow.

For each run, the end of the mild steel rod was polished with grinding paper, rinsed in water, and dried with hot air. The electrode was weighed and installed in the flow cell. A constant current supplied by a Magna 4700 potentiostat was then applied to the cell. An Eagle Signal Flexopulse was used to control the dissolution time which varied from 120 sec at low

[1] Composition of the mild steel rod: Fe, 98.5%; C, 0.08%; S, 0.26%; P, 0.021%; Mn, 1.06%; Si, 0.004%.

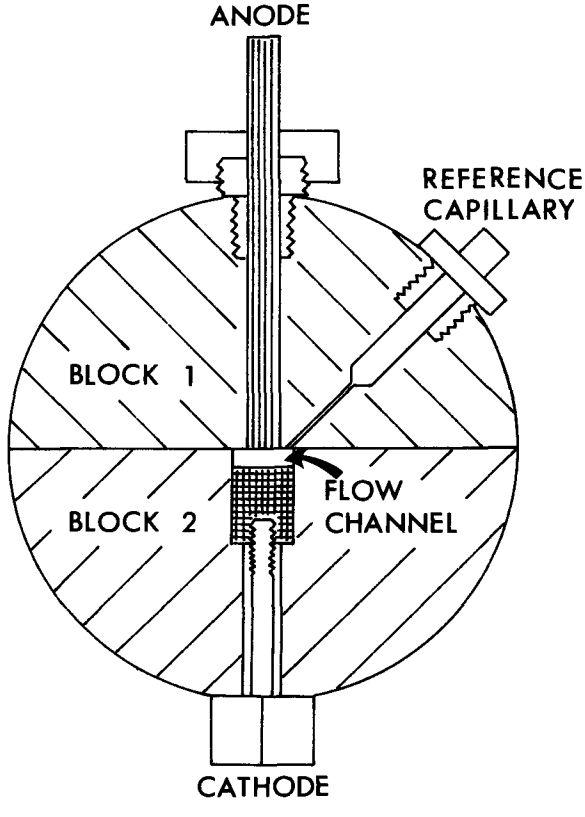

Fig. 1. Flow cell in which the direction of electrolyte flow is perpendicular to the plane of the figure.

current densities to 5 sec at 100 A/cm². After dissolution, the rod was rinsed, dried, and weighed again to determine the amount of metal removal. The current efficiency was then calculated on the basis of Fe going into the electrolyte as Fe^{++} ions. The electrolytes used were 4M NaCl, 4M $NaClO_3$, and 4M $NaNO_3$. An electrode spacing of 0.04-0.08 cm at the beginning of the run was used for the tests. The temperature of the electrolytes was maintained at 21° ± 1°C for all the runs.

ECM tests.—Two ECM tests were used to demonstrate the quality of dimensional control obtained with 4M solutions of NaCl, $NaClO_3$, and $NaNO_3$ at a temperature of 21°-25°C.

The first test was made in the same flow cell used for the current efficiency measurement with positions of the anode and the cathode reversed. The cathode was now a 0.159 cm diameter copper rod mounted in block 1, and the anode was a piece of mild steel having a much larger surface area mounted in block 2 (see Fig. 1). The ECM was carried out at a cathodic current density of 25 A/cm² with an initial electrode spacing of 0.02 cm. The rate of electrolyte flow was kept at a Reynolds number of 8000.

The second ECM test was made in an impinging jet-flow cell similar to that described in earlier studies (1, 5). The cathode was a circular copper tube, 0.440 cm ID and 0.627 cm OD with its outer cylindrical surface insulated by a vinyl coating. The anode was a flat 1008 steel panel, 7.5 cm wide × 2.5 cm long × 0.0625 cm thick, held horizontally above the tip of the cathode tube with an initial spacing of 0.05 cm. The electrolyte was introduced through the cathode tube to produce a vertical jet which impinged on the anode panel at a rate of 1.5 liter/min. In this way, the steel panel was electrochemically machined at current densities of 25 and 100 A/cm² based upon the annular cathode area. For each electrolyte, the running time was adjusted between 1 and 12 min in order to obtain 100 mg of metal removal. After ECM, the surface of the anode was examined with a topographic microscope (6) to determine the cutting profile.

Results and Discussion

Figure 2 gives the results of the current efficiency measurements in NaCl for two different electrolyte flow rates. The accompanying photomicrographs in the figure show the mild steel surface after dissolution at the various current densities. The indicated Reynolds numbers (Re) are calculated based on the equivalent diameter of the flow channel. Since the laminar flow region terminates at a Reynolds number of approximately 2000, these flow rates should both be turbulent. It is seen that the mild steel dissolves in NaCl with 100% current efficiency, independent of current density, until a critical current density is reached, whereupon the current efficiency decreases with increasing current density and then levels off at a constant value of 80%. The surface after dissolution is rough in the low current density region; however, some polishing seems to take place when the efficiency begins to drop to the lower level. Finally, at the lower constant efficiency of 80%, the surface appears to be highly polished. At this point, the surface is marked with flow streaks caused by recession of the tip of the mild steel rod into the channel wall during the dissolution process. These flow streaks imply a flow dependence for the surface finish obtained at high current densities. The effect of reducing the flow rate is to decrease the critical current density where the efficiency begins to drop, and thus to extend the current density region where polishing of the surface can be achieved.

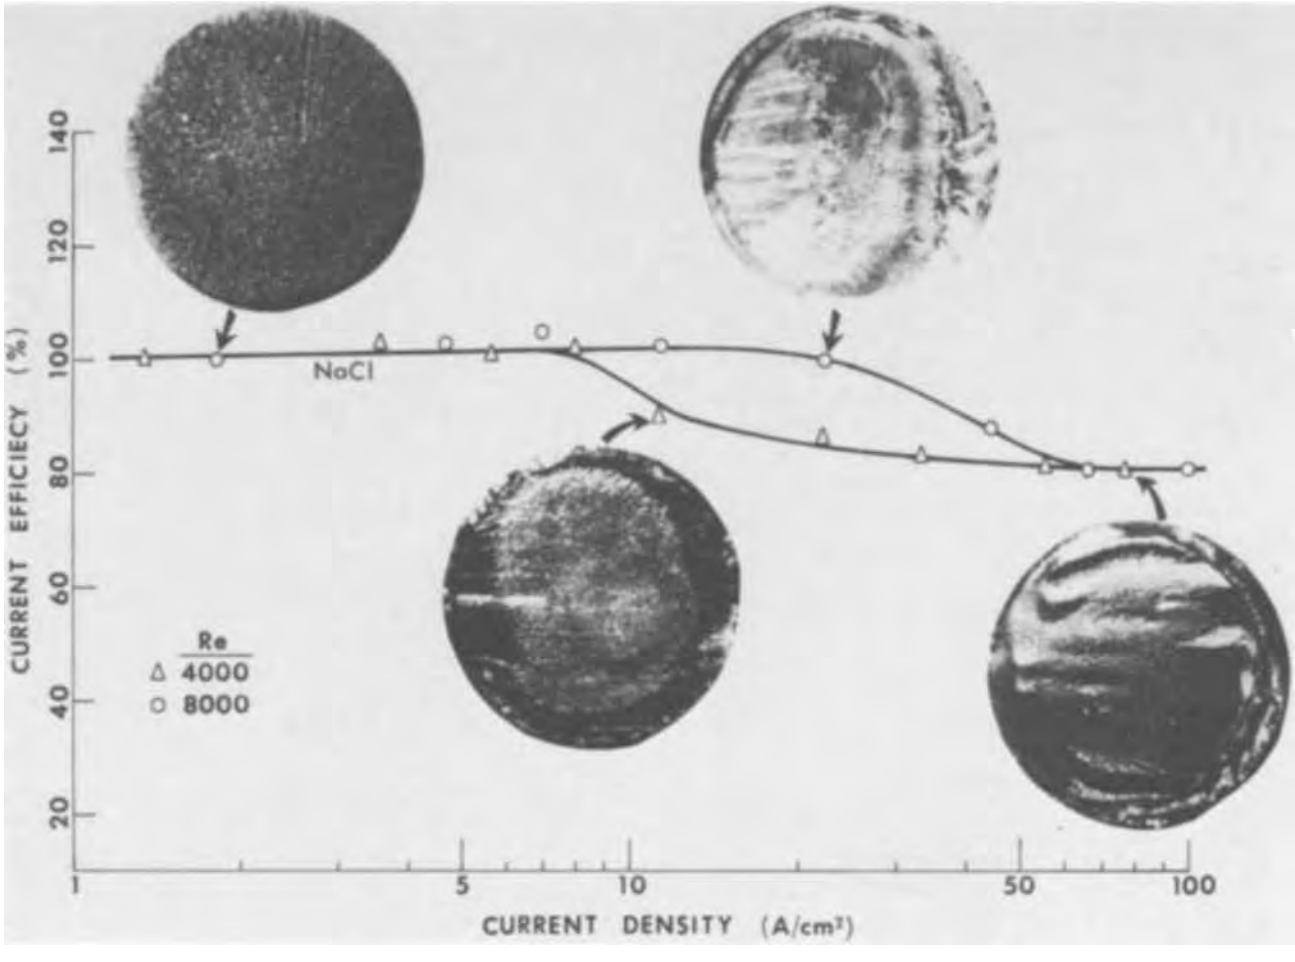

Fig. 2. Results of current efficiency measurements in NaCl electrolyte

The results of current efficiency measurements obtained in $NaClO_3$ and $NaNO_3$ electrolytes are given in Fig. 3 for two different flow rates. It is seen that both curves are an increasing function of anodic current density. In the low current density region (current densities less than 2 A/cm² for chlorate and less than 3 A/cm² for nitrate), the current efficiency is zero, and the current is presumably consumed in the generation of oxygen on the anode (7). Metal dissolution does not take place until the current density reaches a threshold value, whereupon the dissolution efficiency increases with increasing current density. The curve for $NaClO_3$ starts to level off at approximately 10 A/cm², beyond which the current efficiency becomes higher than 100%. The surface, after dissolution in $NaClO_3$, is rough for efficiencies less than 100% and polished for efficiencies of 100% or higher. Again, in the polished region, flow streaks are observed on the surface indicating the dependence of electropolishing on local flow rates over the anode. The curve for $NaNO_3$ starts to level off at a higher current density of 25 A/cm²; it never reaches 100% current efficiency within the current density region investigated. The surface obtained from $NaNO_3$ is rough throughout the entire range of 3-100 A/cm². Changes in the rate of electrolyte flow have apparently no effect on the current efficiency for current densities below the choking limit. Choking is causd by excessive gas evolution in the electrode gap resulting in the gap being filled with gas bubbles. At this point, the current efficiency drops sharply and finally, at a sufficiently high current density, electric sparking occurs across the gap resulting in excessive damage to both anode and cathode. The mechanism of choking and sparking has been studied elsewhere (8, 9) and will not be discussed further here.

The polishing phenomena observed in this study can be explained by Hoar's theory (10) that brightening of the surface is due to the presence of an ionically conductive film on the anode. The flow streaks on the polished surface suggest that, during the ECM of steel, this film is a salt layer resulting from the precipitation of anodic products on the anode surface (11). The salt layer formation requires supersaturation of the anodic products in the immediate neighborhood of the anode; it is obvious that the higher the electrolyte flow rate, the faster the products are flushed away and the lower is the possibility that the products will precipitate out on the anode surface. This notion agrees with the results shown in Fig. 2, namely, that the critical current density for electropolishing in NaCl increases with increasing flow rate. Since no oxygen was detected during the ECM of steel in NaCl (7), the drop in the current efficiency in the polishing region is probably caused by consumption of part of the current in the oxidation of a ferrous compound to a ferric compound at the metal/salt layer interface. Brightening of the mild steel surface in $NaClO_3$ can only be achieved in the current density region where the current efficiency is 100% or higher. The surface, after the dissolution, is always rough in the low current density region where there is oxygen evolution on the anode. The oxygen bubbles provide vigorous agitation in the immediate neighborhood of the anode; the anodic products, therefore, do not have a chance to form a salt layer on the anode surface. This explains why no polishing could be obtained in $NaNO_3$ electro-

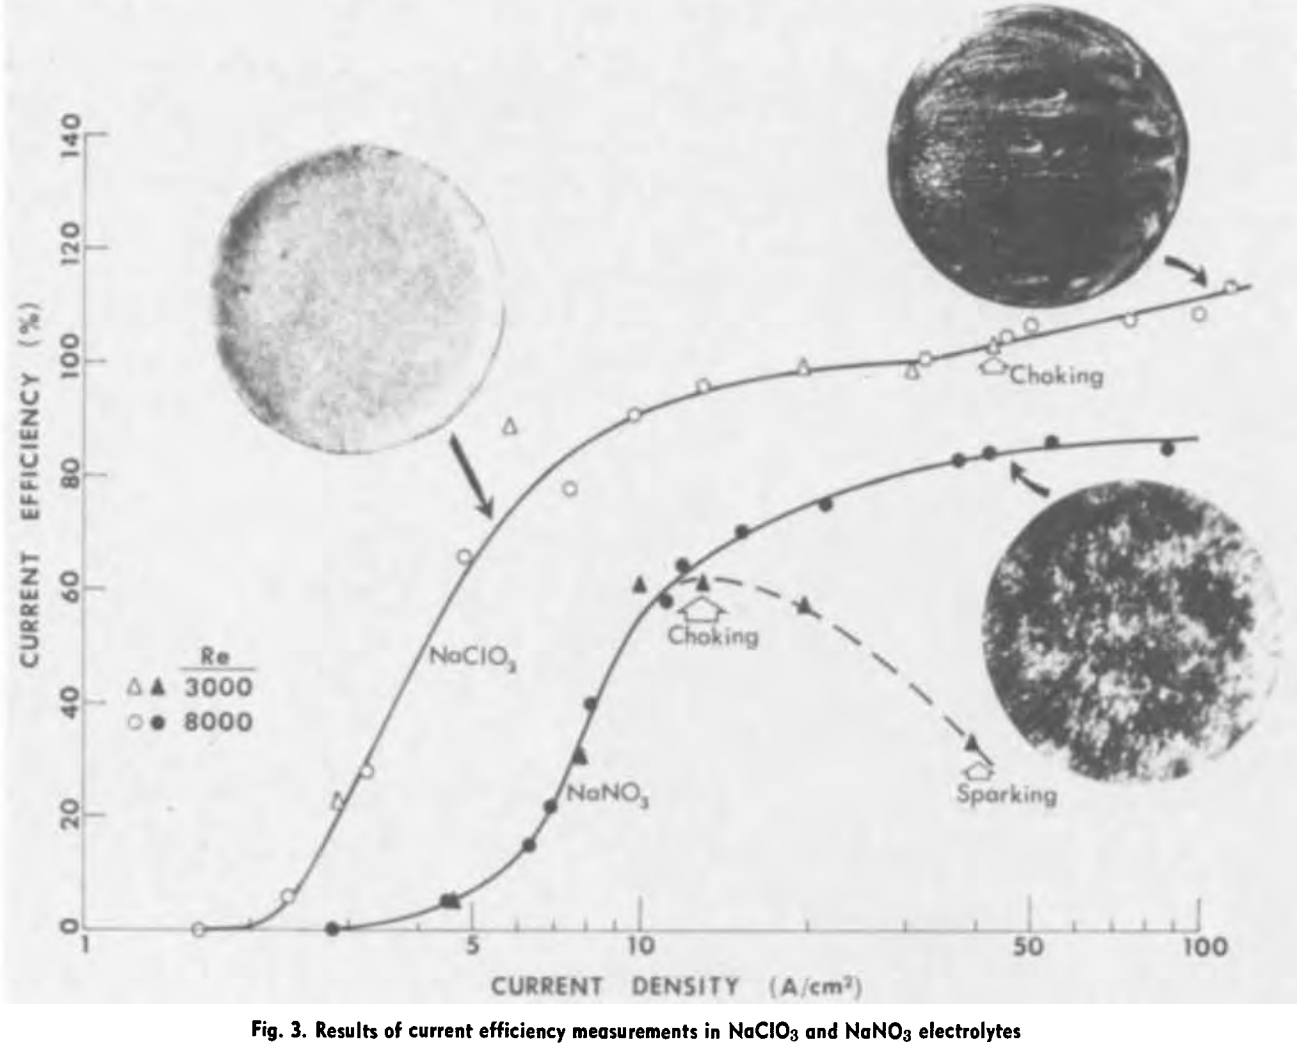

Fig. 3. Results of current efficiency measurements in $NaClO_3$ and $NaNO_3$ electrolytes

lyte, because oxygen was always generated on the anode within the current density range investigated. It is not known at the present time why the current efficiency in $NaClO_3$ continues to increase with current density after reaching the 100% level. Further study is necessary to resolve this particular issue.

Current efficiency and ECM dimensional control.— Since the current efficiency curve for NaCl is rather flat, it would be expected that the current efficiency ratio, η_L/η_H in Eq. [3] be approximately equal to unity at every point on the anode surface, and that the dimensional control be determined solely by the distance ratios, d_L/d_H. For $NaClO_3$ and $NaNO_3$, the S-shaped curves in Fig. 3 suggest that the current efficiency ratios are a dominant factor in obtaining successful dimensional control. They further suggest that an optimum current density can be chosen for the hcd region such that a high current efficiency ratio can be obtained throughout the lcd region on the anode surface. This optimum current density is about 10 A/cm² for $NaClO_3$ and 25 A/cm² for $NaNO_3$. If ECM is operated at current densities below the optimum value, the metal removal rate is too slow although the current efficiency ratio in Eq. [3] is large enough to provide good dimensional control. On the other hand, if ECM is operated above the optimum current density, then the leveling off of the current efficiency curve leads to a decrease in the efficiency ratio, and poor dimensional control is obtained. This suggests a two-stage operation for the average ECM process: the first stage is to cut the metal at the optimum current density in order to achieve the best possible dimensional control; and the second stage is to finish the surface at very high current densities with only a few seconds of running time.

In order to compare the qualities of dimensional control among the three electrolytes, we arbitrarily chose a current density of 25 A/cm² for the hcd region. Figure 4 shows the relationship between the ratio of the rate of the metal removal in the lcd region to that in the hcd region, $i_L\eta_L/i_H\eta_H$, and the current density ratio, i_L/i_H. These curves are calculated from the current efficiency curves (Re = 8000) given in Fig. 2 and 3, assuming i_H = 25 A/cm². Since the current density in the lcd region decreases with increasing surface distance from the hcd area, the ratio, i_L/i_H, should be equal to 1 at the edge of the hcd region, decreasing asymptotically to zero with increasing surface distance. The curve for NaCl is seen to fall on the diagonal line, indicating that metal removal is taking place even at locations remote from the hcd area. The curves for $NaClO_3$ and $NaNO_3$ are below the diagonal line, indicating that the actual metal removal rate in the lcd region is less than would be expected from the current density ratios. Since metal removal stops taking place at i_L/i_H = 0.2 for nitrate and at 0.1 for chlo-

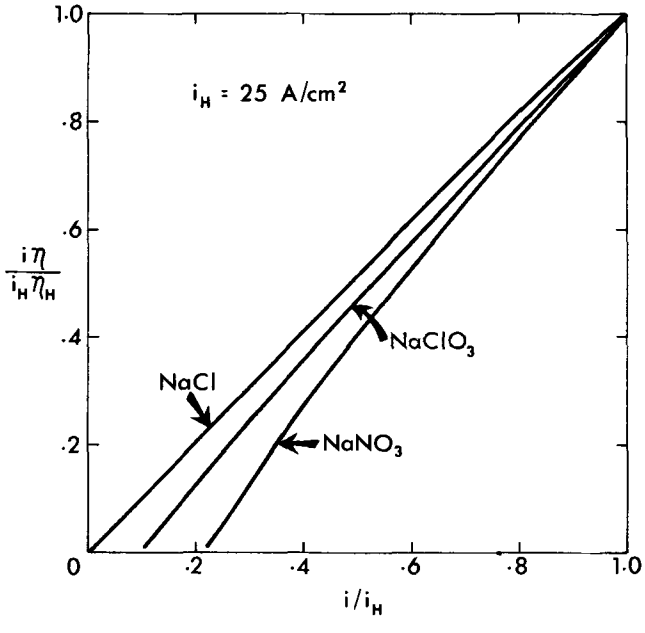

Fig. 4. Comparison of ECM dimensional control obtained at 25 A/cm² for NaCl, $NaClO_3$ and $NaNO_3$ electrolytes. The photomicrographs show the size of cutting areas after 4 mg metal removal in the first ECM test. The diameters of the cuts are: A, 0.236 cm; B, 0.223 cm; and C, 0.209 cm.

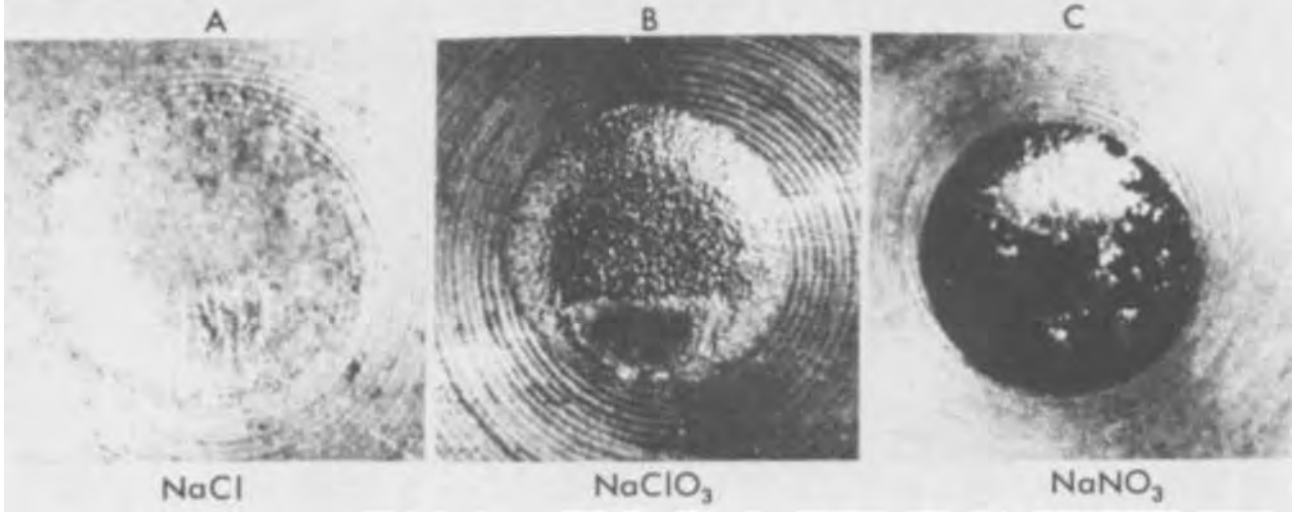

rate, it is expected that the quality of the dimensional control obtained from these electrolytes follows the order $NaNO_3 > NaClO_3 > NaCl$.

That this prediction agrees well with the ECM results is shown by the photomicrographs given in the same figure. These photomicrographs show the size of the cutting area after 4 mg of metal removal in each electrolyte at a cathodic current density of 25 A/cm², obtained in the first ECM test. The diameters of the cutting areas are 0.236 cm for NaCl, 0.223 cm for $NaClO_3$, and 0.209 cm for $NaNO_3$ as compared to the cathode diameter of 0.159 cm. Since the smaller the cutting hole, the better is the dimensional control, these results clearly verify the current efficiency dependence given in Eq. [3]. Also, the cutting edge for NaCl is not as sharp as the edges obtained with $NaClO_3$ and $NaNO_3$; this is in agreement with the measurement in NaCl metal removal of 100% efficiency even at very low current densities.

The results obtained from the second ECM test are given in Fig. 5 for two different cathodic current densities. The black horizontal line in each photomicrograph represents the surface profile after 100 mg metal removal. It is seen that at 100 A/cm², the best dimensional control is still achieved by $NaNO_3$ (Fig. 5D): the cutting edge is sharp with no metal removal in the area facing the center of the cathode tube (0.440 cm ID × 0.627 cm OD); the depth of penetration and the diameter of the cutting area are 0.042 and 0.787 cm, respectively, as compared to 0.036 and 0.863 cm for $NaClO_3$ (Fig. 5C). Again, the worst result is obtained with NaCl; Fig. 5A shows that not only is the edge

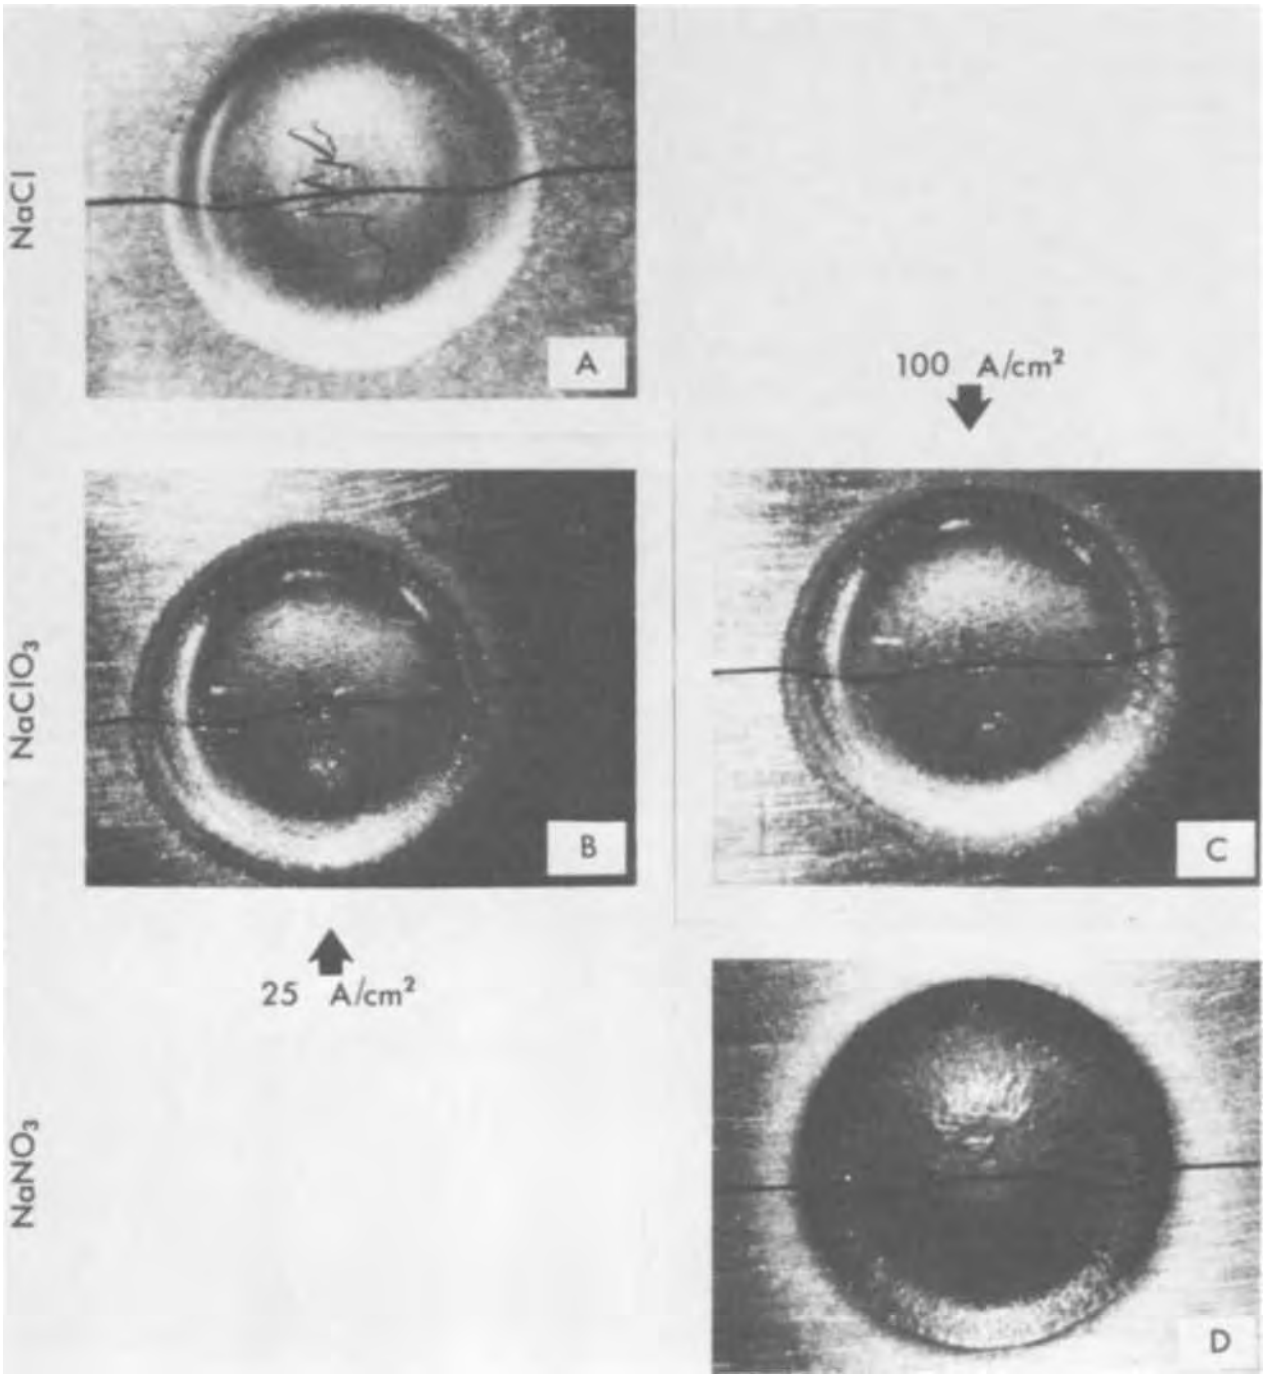

Fig. 5. Results of the second ECM test. The black horizontal line in each topographic photomicrograph illustrates the surface profile after 100 mg metal removal in each electrolyte. The numbers in the following parentheses denote diameter of the cutting area, depth of penetration in the area facing the tubular wall of the cathode, and depth of metal removal in the area facing the center of the cathode tube, respectively: A, (0.774, 0.037, and 0.019 cm); B, (0.762, 0.038, and 0.019 cm); C, (0.863, 0.036, and 0.018 cm); D, (0.787, 0.042, and 0 cm).

of the cutting area not sharp, but that there is metal removal taking place over the entire anode surface exposed to the electrolyte. At 25 A/cm^2, the depth and the diameter of the cut in NaCl are 0.037 and 0.774 cm, respectively, whereas the corresponding values in $NaClO_3$ (Fig. 5B) at the same current density are 0.038 and 0.762 cm. Figures 5B and 5C demonstrate that the quality of dimensional control in a passivating electrolyte becomes worse with increasing current density if the ECM is operated above the optimum current density (a cut 0.038 cm deep × 0.762 cm diameter in Fig. 5B as against a cut 0.036 cm deep × 0.863 cm diameter in Fig. 5C). Apparently this is due to the fact that, in the neighborhood of 100 A/cm^2, the current efficiency curve is flatter (Fig. 3), and the current efficiency ratio in the lcd region is correspondingly smaller than is the case at 25 A/cm^2.

Conclusions

The relation between the dissolution current efficiency and dimensional control has been demonstrated experimentally for the ECM of steel in NaCl, $NaClO_3$, and $NaNO_3$ electrolytes. The results indicate that the current efficiency measurement under controlled anodic current densities and electrolyte flow rates is a simple and useful method to determine the optimum operating conditions for achieving the best possible dimensional control and surface finish.

Electrosynthesis of Dialkyltin Derivatives

Harris E. Ulery

Organic Chemicals Department, E. I. Du Pont De Nemours and Company, Incorporated, Wilmington, Delaware 19899

ABSTRACT

Reduction of alkyl halides at a Sn cathode in TEAX/MeCN results in mixed degrees of alkylation of this metal. Primary products include RSn, R_2Sn, and/or reactive polytins containing these units. Final products depend on environment and tend to be complicated mixtures. A direct synthesis with good yields of dibutyltin oxide and dioctyltin oxide results from aerating the catholyte. A mixture of alkyltin halides is formed in an undivided cell by the interaction of anode and cathode products; other products include the tetraethylammonium alkylhalostannates. Factors governing the course of cathodic alkylation are discussed.

Previously (1) we reported that the reduction of organic bromides at a tin cathode results in an efficient alkylation of this metal. Typically, the degree of alkylation and the complexity of product mixtures vary with the nature of the alkyl source and the conditions of electrolysis. In $Et_4N^+Br^-$/MeCN, methyl bromide has been shown to give Me_4Sn and other organotins with essentially quantitative use of metal and with high electrical efficiency (1). Looking to cheaper alkyl sources we have found that alkyl chlorides are also readily reduced to mixtures of organotins.

Of particular interest would be a direct alkylation route to materials of commercial importance. Butyl derivatives of tin represent the largest group of industrially used organotins (2). They are employed chiefly as stabilizers for polyvinyl chloride, and the U.S. market for these materials is expected to exceed $15 million by 1975. Some dioctyltin derivatives have received official sanction in the U.S. and in Europe as stabilizers of PVC used for food packaging. In this report we disclose a promising electrosynthetic approach to this class of compounds.

Key words: electroreduction, sacrificial electrode, tin cathode, cathodic alkylation mechanism, dialkyltin, dialkyltin halides, dialkyltin oxides, dibutyltin, dibutyltin oxide, dioctyltin oxide, tetraethylammonium alkylhalostannates.

Experimental

Equipment.—The apparatus used in this work has been described previously (1). Modifications consisted of a settling tank in the catholyte circulation stream which was provided with an air inlet tube. To prevent loss of alkyl halide, the air stream was exhausted through a high efficiency condenser which was cooled with dry-ice acetone.

To allow reaction of anolyte and catholyte products, a mixing valve was employed between the independently circulated streams, or the separating membrane was removed.

Chemicals.—Reagents were Eastman White Label grade or the equivalent. The commercial grade acetonitrile contained *ca.* 0.5% water as determined spectroscopically. Tetraalkylammonium halides were used as received and are referred to by their acronyms (*e.g.*, TEAB, TEAC).

Tetraalkylammonium alkylhalostannates.—Frequently, insoluble by-product salts were formed which were identified as 2:1 complexes between TEAX and an alkyl tin halide. The preparation of many of these tetraalkylammonium alkylhalostannates has been reported by Seyferth (3). Elemental analyses for new

complexes prepared during these investigations are given in Table I. These were obtained by refluxing 2:1 molar mixtures of the tetraalkylammonium halide and the tin halide in MeCN. Since many of these salts do not have well-defined melting points, it was convenient to characterize them by differential thermal analysis (DTA) and gravimetric thermal analysis (GTA). The thermal characteristics of these complexes are given in Table II. In the second block of Table II, thermal data are given for the parent tetraalkylammonium salts.

Results

Electrolysis of n-BuCl (divided cell).—The reduction of n-BuCl in TEAC/MeCN approximates a 2**F** process. Under various conditions of temperature, catholyte composition, and current density, the average electrical requirement was 2.28 e^-/Sn atom consumed (Table III).

The catholyte becomes yellow to brown as electrolysis proceeds, and a solid product forms. The following observations indicate this is most probably a composition approaching that of polydibutyltin (5, 6a): (*i*) Initially formed, the composition is a filterable, flocculent, brown solid. (*ii*) When the solvent is removed from freshly isolated material, it undergoes a reaction in air, occasionally igniting the filter paper. (*iii*) Material collected under N_2 was analyzed and found to contain *ca.* 49% Sn *vs.* 51% expected for $(C_8H_{18}Sn)_x$. (*iv*) Fresh material suspended in MeCN and aerated was converted, apparently quantitatively, to dibutyltin oxide (6b). (*v*) The original wet solid darkens after several hours, forming a gum which reacts only slightly with air, but in the presence of chlorine dissolves to give a mixture of butyltin halides.

[a] Circulating catholyte with initial composition = 10% TEAC, 30% n-BuCl, 60% MeCN.
[b] Identified in catholyte by G.C.
[c] Constant current; voltage varied over 6-35V.
[d] Estimated from crude product.
[e] Catholyte contained only 15% n-BuCl.
[f] Catholyte not aerated.
[g] Catholyte aerated during electrolysis.
[h] Catholyte aerated after electrolysis.
[i] Catholyte purged with argon prior to electrolysis.

Below 0.1 A/cm² the formation of metal fines was negligible, the remaining cathode loss being represented by soluble Sn products. Material balances were not generally attempted due to the complicated nature of the product composition. Gas chromatography (G.C.) analyses invariably indicated major amounts of Bu_4Sn and lesser amounts of Bu_3SnCl. In some cases Bu_2SnCl_2 was detected. Product catholytes gradually produced Sn containing solids, which on the basis of their *IR* spectra were mixtures of the butyltin chloride/TEAC complexes. The amber tones of the catholytes are indicative of mixtures of soluble branched chain polytins (6a).

If oxygen is not carefully excluded, Bu_2SnO is invariably observed as a side product. When air is bubbled into the circulating catholyte, the brown $(Bu_2Sn)_x$ is converted to the solid oxide (white). The oxidation proceeds via a rapidly formed yellow intermediate, possibly a peroxide; this in turn is more slowly converted to Bu_2SnO. The oxygen does not appreciably lower the electrical efficiency. In semicontinuous operation the oxide tended to clog the cell. The oxidation rate was somewhat slower than the rate at which solids had to be removed. Alternatively, the heavy flocculent mass of $(Bu_2Sn)_x$ was readily removed from the circulating stream by bleeding the bottom of the catholyte reservoir. The concentrate could be aerated *ad libitum*, and the solution quantities to be filtered were much reduced.

Higher alkyl chlorides also enter into a sacrificial reaction with Sn. In one example, a 30/10/60 weight per cent (w/o) solution of n-octyl chloride/TEAC/MeCN was reduced at 0.025 A/cm². Postaeration gave

28% of the consumed Sn (10.7g) as dioctyltin oxide, which was identified by comparison of its *IR* spectrum with that of a known standard. The electrical requirement was 2.42 e^-/Sn.

Using a 10/10/20/60 w/o solution of n-octadecyl chloride/TEAC/PhCN[1]/MeCN, a similar run at 0.028 A/cm² resulted in a Sn loss of 15.6g. The sacrificial reaction required only 1.76 e^-/Sn. The dark alkyl polytin semisolid could not be isolated during the run. Attempts to aerate it subsequently showed it to be far less reactive than $(Bu_2Sn)_x$ or $(Oc_2Sn)_x$. The aeration product was inhomogeneous and was not identified.

Electrolysis of n-BuCl (undivided cell).—Using a range of electrolyte compositions, the electrolysis of n-BuCl was conducted at 0.1 A/cm², but without a separator. The electrical consumption varied over 2.0–3.4 e^-/Sn (Table IV). Only a small amount of dark polymeric material somewhat resembling $(Bu_2Sn)_x$ was formed during a run. It contained *ca.* 45% Sn and some chlorine. Most of the tin loss appeared as a complex mixture of the butyltin chlorides and their complexes with TEAC. The final electrolyte contained excess chlorine.

Aeration of the electrolyte during a run prevented the formation of the dark polymer. The white solids produced were a mixture of Bu_2SnO (less than 10% of Sn loss) and $(Et_4N)_2SnCl_6$ (up to 20%) which was identified by comparison with material prepared independently. Lesser amounts of the butyltin chloride/TEAC complexes formed more slowly. Bu_3SnCl was the major volatile tin produce identified by G.C. Aeration also reduced the average electrical consumption to less than 2 e^-/Sn (Table IV).

Similar results were obtained in a divided cell when anolyte was bled into the catholyte. On the basis of two runs at 0.025 A/cm², up to 68% of the tin converted appeared as Bu_3SnCl (48%) and $(Et_4N)_2SnCl_6$ + Bu_2SnO (9-19%).

[1] Benzonitrile was necessary to solubilize the alkyl chloride.

Table IV. Electroreduction of n-BuCl (undivided cell)

10	15	Yes	0.1	38	20.0	1.66
10	20	Yes	0.1	38	17.6	1.75
10	25	Yes	0.1	36	22.4	1.49

[a] Electrolyte also contained 1% MeOH.
[b] Average values.
[c] 60-90% of the tin loss appeared as butyltin chlorides and complexes with TEAC.
[d] Less than 10% Bu_2SnO was formed.

Electrolysis of EtCl (undivided cell).—A 30/1/69 w/o mixture of EtCl/TEAC/MeCN electrolyzed at 0.1 A/cm² yielded a dark, pyrophoric precipitate containing 15% Cl and 60% Sn [$(Et_2Sn)_x$ requires 67% Sn]. The electrical consumption was 2.37 e^-/Sn.

Electrolysis of MeBr (undivided cell).—In the absence of a separator, MeBr/TEAB/MeCN electrolytes rapidly developed a bright orange color indicative of polybromide. Eventually a yellow solid begins to precipitate. This was identified as tetraethylammonium dimethyltetrabromostannate, a 2:1 complex between TEAB and Me_2SnBr_2, by comparison with independently prepared material (Tables I and II). Of the consumed Sn, 10-40% appeared in this form. The principal volatile product was Me_3SnBr with lesser amounts of Me_4Sn and Me_2SnBr_2, all of which were identified by G.C. The product electrolytes were quite unstable at room temperature and continued to produce additional solid complexes on standing.

The observed electrical requirements for this system are summarized in Table V. These are inflated by a gas forming reaction due to hydroxylic inhibitor.

Discussion of Results

Divided cell.—For a variety of alkyl sources, the cathodic alkylation of Sn conforms to the general equation

$$n\,RX + M_x + ne^- \rightarrow R_nM_x + nX^- \qquad [1]$$

With n-BuCl, the observed dialkylation products and electrical efficiencies (Table III) indicate a major reaction which requires that $n = 2x$; the value of x depends on whether dibutyltin leaves the electrode as a monomeric species ($x = 1$) on a higher consolidated form ($x > 1$) retaining some Sn-Sn bonds. Results with other alkyl chlorides indicate that dialkylation is generally favored.

Other degrees of alkylation are also indicated. Nearly all alkyl halides studies (1, 12) have yielded products with significant amounts of R_4Sn. The alkyl chlorides typically required more than $2e^-$/Sn but less than $4e^-$/Sn. Since known (1) nonsacrificial reactions (R-X dimerization and reduction of H^+ and Et_4N^+) were unimportant below 0.05 A/cm², electrical requirements exceeding $2e^-$/Sn may be attributed to higher alkylation processes ($n > 2x$) or side reactions involving earlier formed reducibles (*e.g.*, R_3SnCl). The possibility of monoalkylation is indicated when the electrical consumption falls below $2e^-$/Sn. This was observed for both butyl (Table III) and octadecyl chloride.

Low current densities correlate with a higher degree of alkylation. This is seen in Table III as a decrease in the dialkylation product and an increase in the electrical requirement for Sn consumption. Our failure to obtain a higher degree of alkylation with certain alkyl bromides (1) may be due to the relatively high C.D. employed (0.1 A/cm²).

The primary source of Bu_3SnCl is probably the following known (8) reaction

Table V. Electrolysis of MeBr (undivided cell)

[b] Average values.
[c] Assuming 4 e^-/Sn.

$$[Bu_2Sn] + BuCl \rightarrow Bu_3SnCl \quad [2]$$

Our polymeric form of dibutyltin reacts only slowly and incompletely with BuCl (8). At the same time, reaction [2] may contribute to the dramatic decrease in dialkyltin products with decreasing C.D. Low electrolysis rates imply higher concentrations of reactant and lower concentration of primary products at the electrode surface. If the primary product is monomeric Bu_2Sn, its polymerization will be disfavored relative to reaction [2]. Similarly, aeration during electrolysis would scavenge Bu_2Sn, thereby minimizing reaction [2].

Undivided cell. Eliminating the cell divider allows the anodically produced halogen to react with both the cathode and the cathode products. The electrical consumption during the electrolysis of n-BuCl is no greater in the undivided cell than found in the divided cell. This indicates cathodic reduction of the polychloride is minimal. Some reduction may occur since polychloride effectively inhibits the formation of metal fines at 0.1 A/cm^2. Sloughing of the cathode is a consequence of the reduction of Et_4N^+ (1). In the presence of the polyhalide, the potential of this cation would never be reached. Had this been recognized earlier, the inhibitors used with MeBr (Table V) could have been omitted.

In all cases, the polyhalide was not consumed as fast as it was produced. This attests to the more selective behavior of polyhalide oxidizing agents (7) and may be a result of steric hinderance in the polytins.

With both EtCl and n-BuCl the formation of solid alkyltin polymers was not completely suppressed by the presence of polychloride. By contrast, no solid polymer was ever observed during reduction of MeBr. If polymer is formed by a subsequent reaction of a primary species (*e.g.*, R_2Sn), then polymerization is competitive with scavenging by polyhalide (*e.g.*, Eq. [3])

$$R_2Sn + X_3^- \rightarrow R_2SnX_2 + X^- \quad [3]$$

The failure to observe a polymer with MeBr may simply reflect a high rate of Sn-Sn cleavage by polyhalide when the alkyl group is quite small. While Me_2SnBr_2 (as its complex with TEAB) is the major product in an undivided cell, the high electrical consumptions (Table V) leave it unclear whether this results from Eq. [3] or halogenolysis of higher degree alkylation products.

Alternatively some alkyl polytin may form as a primary cathode product (Eq. [1], $x > 1$). This possibility is consistent with the range of electrical efficiencies based on Sn loss.

In combination but not separately, chlorine and oxygen appear to have changed the half-cell chemistry of the cathode. As a consequence of aeration, the current requirement for the electrolysis of n-BuCl at 0.1 A/cm^2 was reduced to average less than $2e^-$/Sn. Either chemical dissolution of tin occurs or there is competition from a 1**F** process. The appearance of $(Et_4N)_2SnCl_6$ in this case may be evidence that a viable monoalkylation species, [BuSn] (5) was formed (Eq. [4]-[7])

$$[BuSn] + 3/2\ Cl_3^- \rightarrow BuSnCl_3 + 3/2\ Cl^- \quad [4]$$

$$2BuSnCl_3 \rightleftarrows Bu_2SnCl_2 + SnCl_4 \quad [5]$$

$$BuSnCl_3 + Bu_2SnCl_2 \rightleftarrows Bu_3SnCl + SnCl_4 \quad [6]$$

$$2Et_4NCl + SnCl_4 \rightarrow (Et_4N)_2\,SnCl_6\downarrow \quad [7]$$

Removal of the hexachlorostannate operates to increase the degree of alkylation of tin remaining in solution. The build-up of tributyltin chloride in solution is dictated by this as well as the fact that alkyltin halides become progressively slower in their reactions with TEAC as the degree of alkylation increases.

A chemical source of free radicals might also increase the Sn loss/**F** (9). Bromination of R_4Sn has been described by an ionic mechanism (10). Under the influence of light, however, a radical chain process is established (10b), in which R· is an intermediate. Perhaps oxygen and chlorine interact to generate radicals independent of electron transfer at the cathode.[2]

Mechanistic considerations.—While we tend to refer to Eq. [1] as an "n-electron" reaction, the reduction undoubtedly involves a succession of one-electron transfers which result in the stepwise alkylation of the metal. We envision the alkylation as proceeding with metal-carbon bond formation being essentially synchronous with carbon-halogen bond rupture (4). Since the environment differs for each succeeding step, the rate of transfer and mechanistic details will vary in some discrete way.

Electronic considerations anticipate a discontinuity in the alkylation sequence after the second group is attached. At each step intermetallic bonding is necessarily reduced. Pauling (11) estimates the metallic valence of tin to be 2.64. A similar calculation gives a corresponding value of 2.76 for lead. In each case the introduction of two alkyl groups would reduce the valence to less than unity. Consequently, no further alkylation should be possible without freeing orbitals used for metallic bonding. Electron pairing order may also be a factor since the valence shells of tin and lead contain two *s* and two *p* electrons.

Variation in geometric details may not be critical during the first two alkylation steps. Photomicrographs (1) of tin cathodes sacrificed to MeBr give strong evidence that metal removal in this case is an orderly progression along lattice planes. Initiation of alkylation at an edge position is favored by the higher potential which develops here (15). Also, an edge provides greater exposure of the metal atom for a second alkylation step. From this point on, however, steric factors should be relatively more important in determining product distributions.

With modest thermal activation a weakly attached di- or trialkyl metal moiety may be free to diffuse[3] over the crystalline surface. Depending on the location of the metal atom, this mobility may be necessary to reduce steric interference to further alkylation. This situation is depicted schematically in Fig. 1.

If alkylation is fast compared to surface diffusion (*e.g.*, at high C.D.) reaction would shift to adjacent metal atoms. The larger this organometal aggregate, the larger will be its thermal energy compared to the residual metallic bonding; hence, the more likely its dissociation from the surface. Adjacent metal atoms become the most likely centers for further reaction: their free valence number has increased as a consequence of the reduced metallic bonding to an alkylated neighbor. With tin, this is consonant with the formation of stable polytin products.

Several factors could facilitate surface mobility and thereby promote the sacrificial reaction:

1. Weak intermetallic bonding. The lower melting point of tin (232°C) compared to lead (327°C) reflects less internal bonding in this metal. We expect greater mobility with tin. Conversely, metals with strong internal bonding would be expected to passivate after further alkylation becomes sterically impossible. Some confirmation of this derives from the observation that it is the "soft" or relatively low melting metals which are most receptive to cathodic alkylation (12) and alkyl radical scavenging (9).

2. Small alkyl group size. Diffusion rates decrease with increasing size of the diffusing group. Electron micrographs of tin (1) and lead cathodes used with MeBr are unique in that they reveal an exceptionally clean removal of metal along latttice planes. This suggests that metal removal was sufficiently rapid to maintain a fresh edge with a selectively higher potential. With higher alkyls, the reaction locus appears to "wander" so that lattice planes are no longer pre-

[2] Several chlorine oxides capable of radical dissociation are known (16), which are potential anode products.
[3] Via desorption-resorption equilibria.

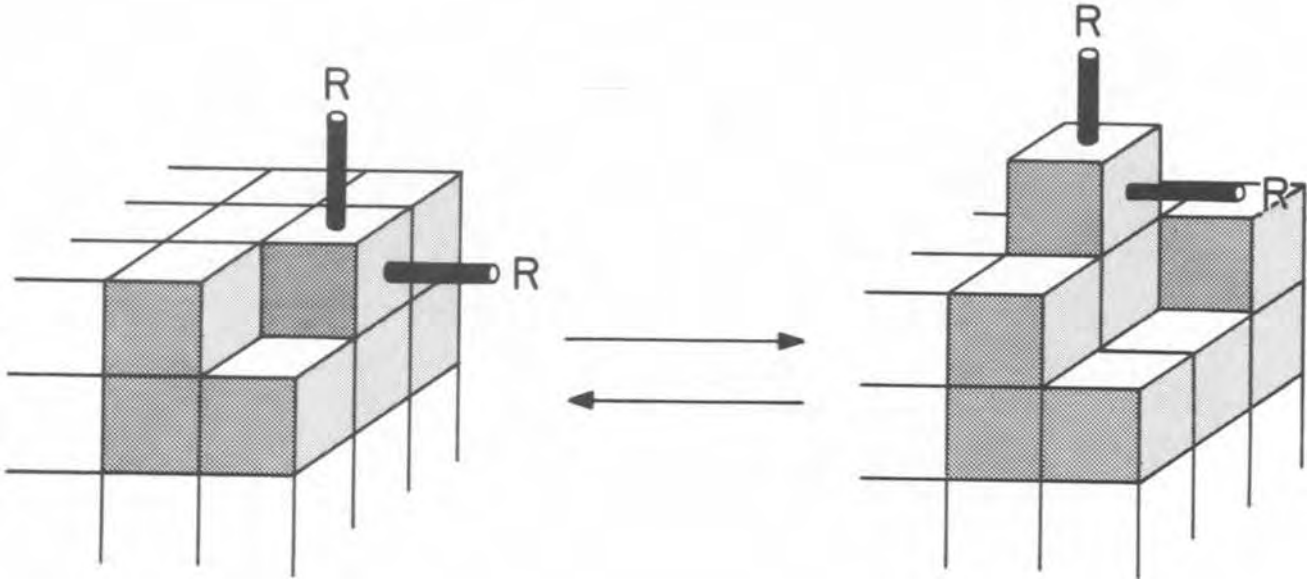

Figure 1

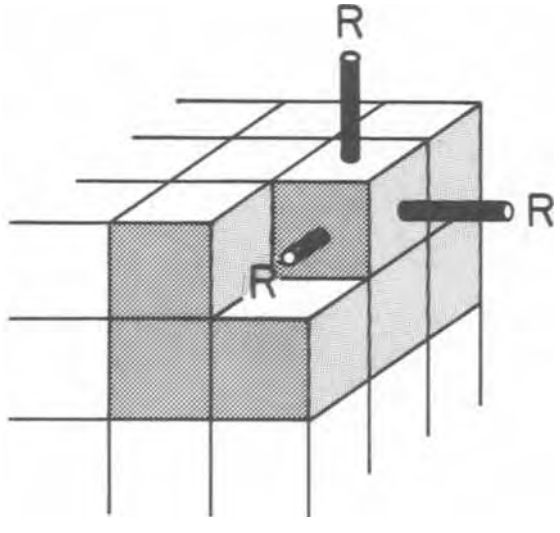

Figure 2

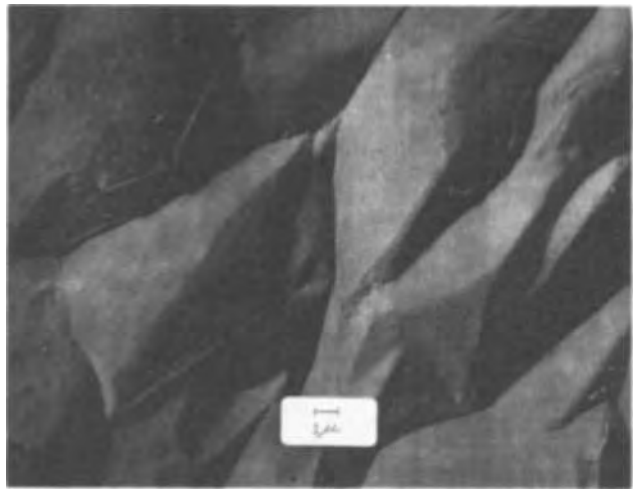

Fig. 3. Surface detail of tin cathode after electrolysis of n-BuCl. The cathode was: 30% n-BuCl, 10% TEAC, 60% MeCN (no aeration).

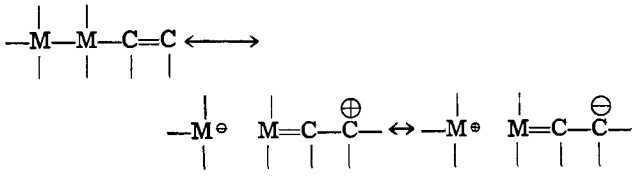
served (Fig. 3). This would be expected if alkylation centers on an edge remain in place long enough to force alkylation to move to nonedge positions. The methyl group is probably small enough to allow the rapid formation of three carbon-metal bonds before reorganization of the surface is required for further alkylation (Fig. 2).

With minimal bonding to other metal atoms as a restraint, the R_3M-group might reorient rapidly, permitting tetraalkylation at a higher C.D. Alternatively, facile trialkylation would enhance termination of polytin chains formed on the surface, thus favoring lower MW products. Alkyl group size may be particularly important for Pb in view of its higher metallic bonding: MeBr (1,4) can be quantitatively reduced at Pb according to Eq. [1] ($n = 4, x = 1$). While tetraethylation of Pb is also observed, a triethylation process (Eq. [1]; $n = 6, x = 2$) has been identified (13) as a principal side reaction. Dialkylation ($n = 2x$) may occur during the reductions of i-PrBr and PhBr (4), but the relatively unstable dialkyl lead was not isolated.

3. Strong C-M bonds. Enhanced bonding of the metal to the organic group as for example through a π-bond, would weaken intermetallic bonds, *i.e.*



The efficient formation of tetraallyltin, tetraallyllead and tetraphenyltin (1) in spite of the size of the organic group may be evidence of the influence of carbon-metal bond strength in favoring surface diffusion.

4. Low current densities. Surface diffusion can be important only at current densities low enough to result in partial alkylation of the electrode surface. Higher current densities eliminate the surface concentration gradient essential for diffusion and imply that nonpassivating products are formed.

5. Low electrolyte adsorption. Cation adsorption leads to high effective current densities, and hence, high alkylation rates by decreasing the active area of the electrode (14). Higher yields of Me_4Sn and Me_4Pb were obtained with TEAB than with TBAB. While several factors may be involved, adsorption of the latter electrolyte appears to be the greater. This would favor a lower degree of alkylation.

Conclusions.—There now appears to be a significant difference in the sacrificial behavior of Sn and Pb cathodes toward alkyl halides in TEAX/MeCN media. The reluctance of Pb to react with higher alkyl halides is pronounced. Reaction with alkyl chlorides in particular is generally disfavored by the high reduction potentials of the C-Cl bond on Pb. In contrast, the scope of the cathodic sacrifice of Sn encompasses not only the alkyl chlorides, but is far less restricted by alkyl group size. It is suggested that this contrasting behavior results largely from differences in the chemical stabilities of partially alkylated metal atoms at the cathode surface. This in turn may be related to the concatenation behavior of the metal.

While the Sn cathode is more readily sacrificed, the reduction is immensely complicated by the variety of stable lower alkylation products. Nonetheless, as illustrated by the formation of R_2SnO, useful products in good yields are possible by a suitable choice of conditions.

Acknowledgments

I am indebted to T. Tessmer for his considerable contribution as my laboratory assistant. Electronmicrographs were obtained by W. Kay. In particular I would mention J. D. Sterling, his critical comments and enduring encouragement are the backbone of this report.

This is contribution No. 471, Jackson Laboratory, Organic Chemicals Department, E. I. Du Pont De Nemours & Co., Inc., Wilmington, Delaware 19899.

Manuscript submitted Feb. 22, 1973; revised manuscript received April 9, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

ABSTRACT

The tetrasulfurtetranitride anion radical has been produced by constant potential electrolytic reduction and its ESR spectrum conclusively identified. The decay of the anion radical was followed by ESR and electrochemical methods and found to obey a first-order rate law. It is suggested that the anion radical decays by intramolecular bond rupture.

Tetrasulfurtetranitride (S_4N_4) is a molecule about which there has been discussion concerning its structure (1-3) and bonding (4, 5). In order to answer some of the questions raised in the above studies, several attempts have been made to generate the anion radical of S_4N_4 ($S_4N_4^-$) and to interpret its electron spin resonance (ESR) spectrum.

Chapman and Massey (6) reacted S_4N_4 with potassium in dimethoxyethane at room temperature. They first observed a claret-red solution which appeared to be diamagnetic. Later, the solution turned green and yielded a spectrum consisting of nine narrow lines with $a_N = 3.22G$. The spectrum is characteristic of a radical with four equivalent nitrogen atoms, suggesting delocalization of the unpaired electron. Further reaction with potassium caused an increase in the intensity, followed by a decrease almost to zero, followed by a second increase in intensity. The second strong spectrum was said to be identical to the first. The authors suggested that these observations might be explained by the formation of $S_4N_4^{-2}$, $S_4N_4^{-3}$, etc., some of which would be diamagnetic.

Meinzer, Pratt, and Myers (7) obtained a spectrum consisting of nine relatively broad lines with $a_N = 1.185G$ by the constant current electrolytic reduction of S_4N_4 in tetrahydrofuran (THF) at −25°C. They observed that this radical decomposed rapidly at higher temperatures and was difficult to detect above

Key words: tetrasulfurtetranitride, anion radical, ESR, cyclic voltammetry.

0°C. They also observed the same radical from the reduction of S_4N_4 with potassium at about −25°C. Further reduction with potassium yielded other spectra. They argued, based on a consideration of the g-value for the radical, the hyperfine splitting, and the line broadening effect produced by neutral S_4N_4, that the nine line spectrum which they had obtained at low temperature was the spectrum of $S_4N_4^-$, and that $S_4N_4^-$ had a structure similar to that of S_4N_4. However, no detailed electrochemical studies were carried out to confirm that the observed radical was produced by one electron reduction of S_4N_4.

In this paper we present the results of ESR and electrochemical studies of the kinetics of the disappearance of $S_4N_4^-$ and a confirmation of the assignment by Meinzer, Pratt, and Myers of the low temperature spectrum to $S_4N_4^-$.

Experimental

The S_4N_4 was prepared by the method of Jolly (8). All experiments were carried out in acetonitrile (MeCN) which had been slurried over CaH_2, triply distilled from P_4O_{10}, and bubbled with dry nitrogen. The supporting electrolyte was tetraethylammonium perchlorate (TEAP). A Wenking 66TS 10 potentiostat and a Hewlett Packard 7004 A X-Y recorder were used in all experiments.

The cyclic voltammetry study utilized a Beckman platinum button working electrode and a Ag/0.01*M* Ag^+ reference half cell. The low temperature cyclic voltammetry was carried out in a methanol constant temperature bath which was cooled with cold dry nitrogen passing through immersed copper coils. This cooling was bucked by a heating element in the methanol which was feedback controlled using a thermistor as a detector. The bath was continuously stirred and was found to hold the temperature constant to ±0.3°C. Temperatures were measured with a copper-constantan thermocouple and a Keithley Model 160 Digital Multimeter.

The *in situ* constant potential electrolytic reduction of S_4N_4 for the ESR studies was carried out in a 3 mm soft glass tube with a platinum wire sealed in the bottom. This wire was run up the outside of the tube and served either as the working electrode or as a contact for a mercury pool working electrode. The auxiliary electrode was a platinum coil at the top of the tube about 10 cm from the working electrode and well out of the ESR cavity. The reference electrode was a silver wire placed between the working and auxiliary electrodes.

The ESR measurements were made on a Varian V-4500-10 spectrometer employing a V-3900 12 in. magnet and 100 kHz field modulation. Temperature was controlled by means of a Varian V-4557 variable temperature controller. Measurements of the relative radical concentration as a function of time were made in the following manner. First, the magnetic field was set at that point at which the maximum in the first derivative of the center line occurred. Second, the electrolysis was terminated by disconnecting the working electrode and the decay of the ESR signal was measured as a function of time. Because of the broad lines (about 0.6G), small drifts in the magnetic field introduced a negligible error. In the work reported here, no change in the first derivative line width or line shape was noted with radical concentration; thus, the radical concentration can be considered to be proportional to the intensity of the ESR signal.

Results and Discussion

Cyclic voltammograms of S_4N_4 at room temperature and at −25°C are shown in Fig. 1. At −25°C, the peak currents and peak separation are consistent with a one-electron reduction as found coulometrically by Brown (9), although some charge transfer irreversibility is indicated. An additional reduction process is

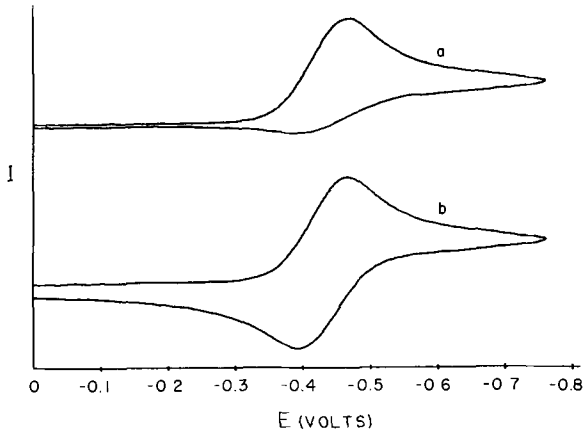

Fig. 1. Cyclic voltammograms of 1 mM S_4N_4 in acetonitrile/0.1M TEAP at a scan rate of 11.4 V/min. Potentials are vs. Ag/0.01M Ag^+. a, 25°C; b, −25°C.

observed at more negative potentials in the form of an ill-defined and totally irreversible wave. This process may be the production of the S_4N_4 dianion which Gleiter (4) has predicted to have a structure different from that of S_4N_4. At room temperature, the radical anion is quite unstable and gives rise to several products which are oxidizable at more positive potentials. There was no indication of any decomposition product being reducible at potentials more positive than the S_4N_4 reduction process.

In situ constant potential electrolytic reduction of S_4N_4 at the peak potential for the one-electron process gave rise to a strong nine-line ESR spectrum at −25°C as shown in Fig. 2. Computer simulation of this spectrum using nine overlapping Lorentzian lines of equal width yields a best fit for $a_N = 1.17 \pm 0.2$G. This value agrees, within experimental error, with the value of 1.185G reported by Meinzer, Pratt, and Myers (7) for the low temperature radical in THF. [The greater precision of the measurement in THF (7) results from their use of a digital technique in recording and analyzing the spectrum.]

The decay of this radical was followed as described above. The decay curves, such as the one shown in Fig. 3, were found to obey a first-order rate law over the temperature range −25° to +3°C and over the concentration range of S_4N_4 from 3 to 5 mM. Similar results were obtained from saturated solutions which were about 7 m*M*. The ESR signals obtained from 1m*M* solutions were too weak for kinetic measurements. The rate constants obtained by this method are presented in Fig. 4 in the form of an Arrhenius activation energy plot. This treatment yields a value of 11.2 ± 0.9 kcal/mole for the activation energy of the first-order decay reaction of the radical.

While the fact that this radical was detected after the constant potential electrolytic reduction of S_4N_4 at

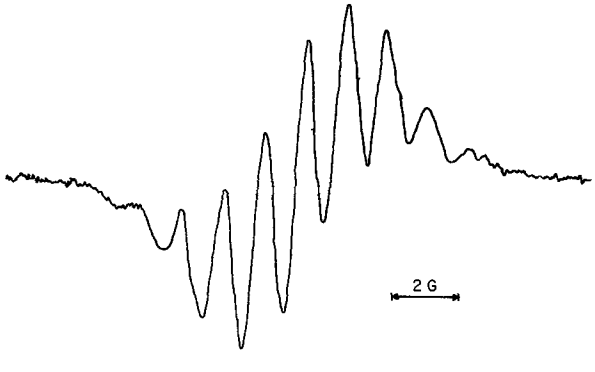

Fig. 2. ESR spectrum of $S_4N_4^-$ generated by *in situ* constant potential reduction of S_4N_4 in MeCN at −20°C.

the peak potential for the one-electron process would strongly suggest that this radical is $S_4N_4^{-}$, it is not impossible that the nine-line spectrum could be due to some decomposition product of $S_4N_4^{-}$. To eliminate this possibility, the kinetics of the disappearance of $S_4N_4^{-}$ (that is, the product of the one-electron reduction of S_4N_4), were measured electrochemically by monitoring the ratio of the anodic to cathodic peak currents obtained from cyclic voltammetry as a function of voltage scan rate and utilizing the first-order EC working curve of Nicholson and Shain (10). The results of such a study on 0.99 × $10^{-3}M$ S_4N_4 solutions are shown in Fig. 5. It is clear that the measured rate constants are functions of scan rate at a given temperature. It is felt that this scan rate dependence is due largely to charge transfer irreversibility. Thus, the measured rate constants were extrapolated linearly to zero scan rate. The extrapolated rate constants are presented in Fig. 4. The value of the activation energy obtained from the extrapolated electrochemical data is 11.1 ± 0.5 kcal/mole.

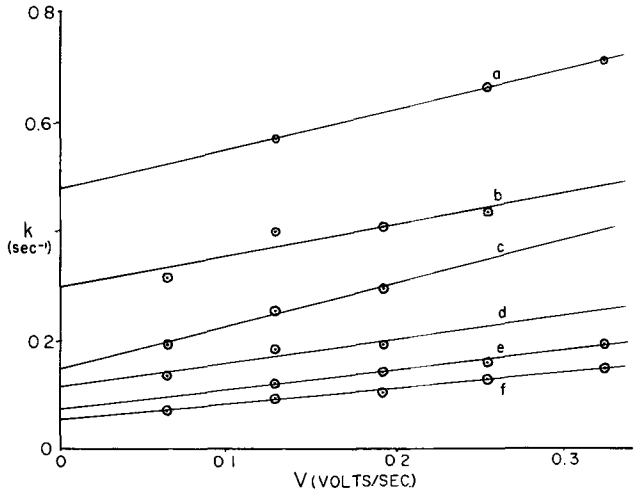

Fig. 5. Electrochemical first-order rate constants plotted vs. voltage scan rate. a, 15°C; b, 10°C; c, 5°C; d, 0°C; e, −5°C; f, −10°C.

The activation energy for the decay of the radical with the nine-line spectrum as measured by ESR and the activation energy for the decay of $S_4N_4^{-}$ as measured electrochemically are identical within experimental error. The values of the rate constants obtained in the two experiments are not identical, however, within the apparent experimental error of each set of results. It is seen that the rate constants obtained from the ESR experiment are larger and more scattered than those obtained from the electrochemical experiment. One could use this discrepancy to argue that the two decaying species were not the same. However, the agreement of the activation energies and all the other circumstantial evidence suggests that the radical with the nine-line spectrum is $S_4N_4^{-}$ and that some other explanation for the discrepancy in the rate constants must be sought.

Two possible sources of this disagreement have been considered. It is possible that the linear extrapolation of the electrochemical data to zero scan rate in order to eliminate the effects of charge transfer irreversibility yielded erroneous values for the rate constants. Admittedly, the choice of a linear extrapolation of the data was arbitrary; but assuming no anomalous behavior between 3.8 V/min and zero, any other type of regression would have yielded similar results. As soon as our rotating ring-disk electrode (RRDE) apparatus is modified to permit work at low temperatures, a RRDE study of S_4N_4 will be undertaken. Charge transfer irreversibility will not be a factor in this study.

The second source of error results from the fact that, since the ESR experiment was carried out in a tube of small cross-sectional area, in a fairly high resistance medium and with the auxiliary electrode some 10 cm from the working electrode, significant Joule heating of the solution in the cavity is probable. To test this hypothesis, a thermocouple was taped to the outside of the tube and the tube was then insulated. An electrolysis under conditions similar to those of the ESR experiment was then carried out. After about 2 min of electrolysis, a temperature rise of approximately 0.5°C was detected on the outside of the glass tube. Considering the poor thermal conductivity of glass, it seems reasonable to suppose that the temperature of the solution within the tube may have risen by as much as 3°-4°C. Such a temperature difference would be sufficient to cause the deviations which were observed. Joule heating would also explain the scatter in the ESR data as the electrolysis time before the kinetic measurement was made varied.

It is felt by the authors that, in view of the above arguments, one can safely conclude that the nine-line spectrum presented here as well as that presented by

Meinzer, Pratt, and Myers (7) is the ESR spectrum of $S_4N_4^{-\cdot}$. We can now consider some of the properties of $S_4N_4^{-\cdot}$ as indicated by this study.

It has previously been shown that orbitally degenerate hydrocarbon-free radicals exhibit anomalously broad ESR lines (11-14). For example, the benzene anion radical, which has a degenerate ground state, exhibits a line width of about 0.3G (12), while the nondegenerate anthracene anion radical exhibits a line width of 0.025G (15). Studies of bonding in S_4N_4 show that an added electron would be placed in a degenerate orbital (4, 5). Meinzer, Pratt, and Myers report the line width of $S_4N_4^{-\cdot}$ to be 0.461G in THF (7) while a value of 0.6G was observed in MeCN in this study. These line width values suggest that $S_4N_4^{-\cdot}$ should be regarded as an orbitally degenerate anion radical.

An analysis of the line widths in MeCN showed little temperature and no field dependence. Similar observations were made in THF (7). In addition, the spectra obtained from MeCN solutions showed no evidence of a statistical variation in line widths like that observed in situations where electron transfer and/or Heisenberg spin exchange are significant (16). The above indicates that exchange reactions and/or slow rotation (17) contribute only slightly if at all to the over-all line width, and that the difference in line widths for $S_4N_4^{-\cdot}$ in THF and in MeCN represents the effect of solvent on the relaxation times for this orbitally degenerate radical. Clearly, detailed studies of T_1 and T_2 for the $S_4N_4^{-\cdot}$ system would provide interesting information which could be compared with that previously obtained for hydrocarbon radicals (11-14).

The facts that $S_4N_4^{-\cdot}$ disappears by a process which is first order in $S_4N_4^{-\cdot}$ and zero order in S_4N_4 and that the activation energy for this process is on the order of a vibrational transition suggest that $S_4N_4^{-\cdot}$ decays by an intramolecular bond rupture. This further suggests that S_4N_4 fragments such as S_2N_2 and others which are known are likely products of the decay of $S_4N_4^{-\cdot}$. These possibilities will be considered in the RRDE study.

Finally, many colors have been observed in reduced solutions of S_4N_4. In none of our experiments in scrupulously dry and deoxygenated solutions could we detect a change in the already yellow solution upon production of $S_4N_4^{-\cdot}$. We conclude, therefore, that $S_4N_4^{-\cdot}$ is probably also yellow. In our early experiments, in which oxygen was not completely removed from the solutions, a fairly intense red color was observed upon reduction. This red substance was later found to result from a reaction between hydroxide ion, produced from the reduction of oxygen, and neutral S_4N_4. Identical uv-VIS spectra were obtained when the red substance was produced electrolytically and by direct reaction between S_4N_4 and NaOH in MeCN. Attempts to isolate the red substance failed. The final product which was isolated from either experiment was found to contain Na_2SO_4. Similar results have been obtained for the reaction between S_4N_4 and hydroxide in aqueous media (18).

Summary

The assignment by Meinzer, Pratt, and Myers of the low-temperature, nine-line ESR spectrum to $S_4N_4^{-\cdot}$ has been substantiated by the determination of the rate of decay of the ESR spectrum and by the electrochemical measurement of the rate of decay of $S_4N_4^{-\cdot}$. The anion radical was found to decay by a first-order process suggesting an intramolecular bond rupture.

Polarography of Some 1,1-Dithiolates and Their Mercury Complexes in Acetone

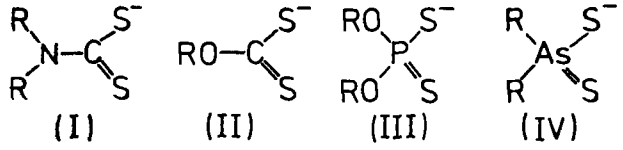
A. M. Bond,* A. T. Casey, and J. R. Thackeray

Inorganic Chemistry Department, Melbourne University, Parkville, Victoria 3052, Australia

ABSTRACT

Dialkyldithiophosphate and dimethyldithioarsinate anions (L^-) have been found to interact with the DME in acetone via the processes $6L^- + 2Hg^\circ \rightleftharpoons 2Hg^{II}(L)_3^- + 4e$ and $2Hg^{II}(L)_3^- + Hg^\circ \rightleftharpoons 3Hg^{II}(L)_2 + 2e$. The mercury complexes resulting from these steps have also been investigated polarographically, although many could not be isolated, and the over-all mechanism has been compared to those exhibited by other 1,1-dithiolate anions. No reduction steps were observed for any of the dithiolates studied.

Recent electrochemical studies on 1,1-dithiolate anions in nonaqueous solvents have shown that they can oxidize mercury at a DME to yield mercury dithiochelate complexes (1, 2). Interestingly, the closely related dialkyldithiocarbamates, (I), and O-alkylxanthates, (II), were found to react via completely different intermediates, although at sufficiently positive potentials both produced mercury(II) complexes of the formulation $Hg^{II}L_2$ (where L = dialkyldithiocarbamate or alkylxanthate).



(I) (II) (III) (IV)

(R represents an alkyl group)

In view of the considerably different polarographic behavior caused by simply changing an $-NR_2$ group (attached to $-CS_2^-$) for an $-OR$ group, it was thought that comparative studies on the distinctly different O,O'-dialkyldithiophosphate, (III), and dimethyldithioarsinate, (IV), anions would be of interest. Moreover, if these potential ligands do interact with the DME, then identification of the resulting products should provide an insight into the chemistry of their mercury complexes.

Apart from interaction with the mercury electrode, a number of alternative electrochemical oxidation and reduction processes can be envisaged for all of these entities. They could undergo a two-electron oxidation to yield the corresponding disulfides (*e.g.*, thiuram disulfides from dithiocarbamates and dixanthogens from xanthates), and in fact the formation of dixanthogens has been extensively studied at a number of electrodes because of their application to flotation technology (3-5). Isolated thionyl groups can also be reduced, and in this regard comparative studies have been made between thiones and ketones (6). Possible reduction pathways are therefore also of interest.

The behavior of uncoordinated 1,1-dithiolate anions also has direct application to the electrochemistry of transition metal complexes incorporating these ligands. Indeed, knowledge of the ligand behavior has already facilitated the interpretation of complicated electrode processes undergone by some vanadium(IV) dithiochelates at the DME (1,7). Thus the electrochemistry of 1,1-dithiolates is of interest to a number of fields, and it is envisaged that the work presented here will prove of value to other electrochemical investigations involving transition metal dithiochelates.

Key words: polarography, dialkyldithiophosphate, dimethyldithioarsinate, mercury complexes.

Abbreviations

The following abbreviations have been used in the text: dadtp, O,O'-dialkyldithiophosphate; dpdtp, O,O'-diisopropyldithiophosphate; dtcac, dimethyldithioarsinate (or dithiocacodylate); Et, ethyl; dedtp, O,O'-diethyldithiophosphate.

Experimental

Preparations.—Ammonium O,O'-dialkyldithiophosphates.—The stoichiometric amount of P_4S_{10} was added to the appropriate alcohol in benzene to produce a solution of the corresponding dialkyldithiophosphoric acid. Ammonia was then bubbled through the solution until the ammonium dialkyldithiophosphate precipitated.

Bis(dialkyldithiophosphato)mercury(II) complexes.—The stoichiometric amount of the required ammonium dialkyldithiophosphate was mixed with $Hg(NO_3)_2$ in water. The resulting white solid was well washed with water and finally recrystallized from ethanol. This compound has been reported previously (8).

Sodium dimethyldithioarsinate.—This compound was prepared by the method of Casey *et al.* (9)

Attempts to prepare bis(dimethyldithioarsinato)mercury(II).—When the stoichiometric amount of sodium dimethyldithioarsinate was mixed with $Hg(NO_3)_2$, a yellow solid deposited. This product immediately turned brown in the atmosphere and further attempts to isolate a pure sample under argon failed.

Materials.—Sodium dialkyldithiophosphates were used as received from Cyanamid, Wayne, New Jersey. Their solubility in acetone was not as great as the ammonium salts and so they were only used for specific experiments as indicated in the text. "Pronalys" acetone was employed for all polarographic measurements and was used as received from May and Baker.

Instrumentation.—Conventional d-c polarograms were recorded in acetone with a Metrohm Polarecord (E261) using 0.1M tetraethylammonium perchlorate as supporting electrolyte. A three-electrode, *iR* compensated system using a Metrohm *iR* compensator (E446) was employed for all conventional d-c measurements. The reference electrode was a Metrohm Ag/AgCl EA425 electrode (0.1*M* LiCl, acetone). The auxiliary (or third) electrode was either a tungsten or platinum wire electrode, or a Ag/AgCl electrode identical to the reference. Controlled drop-time and current sampled polarograms were recorded with a Princeton Applied Research Corporation (PAR) Electrochemical System, Model 170. A Metrohm Polarographie Stand (E354) was utilized to obtain short, controlled drop times between 0.16 and 0.32 sec. The PAR Model 172 Drop Timer was used with a drop time close to 2 sec to record current sampled polarograms

Table I. Dependence of half-wave potentials ($E_{1/2}$) and wave heights (i_d) on concentration for ammonium O,O'-diethyldithiophosphate

Concentration, M	$E_{1/2}$ (wave 2) (V vs. Ag/AgCl)	$(E_{1/4} - E_{3/4})$ (V)	i_d (μA)	$E_{1/2}$ (wave 1) (V vs. Ag/AgCl)	$(E_{1/4} - E_{3/4})$ (V)	i_d (μA)	$E_{1/2}$ (wave 4) (V)	i_L (μA)
10^{-2}	+0.185	0.076	13.6	−0.164	0.072	33.0	−0.380	1.8
5×10^{-3}	+0.171	0.072	6.8	−0.153	0.062	17.3	−0.368	0.8
10^{-3}	+0.140	0.072	1.34	−0.142	0.056	3.35	−0.335	0.2
5×10^{-4}	+0.135	0.069	0.62	−0.121	0.056	1.74	−0.335	0.08

The Metrohm Polarecord (E261) was used in conjunction with the Metrohm AC Modulator (E393) and the Metrohm *iR* Compensator (E446) to provide a three-electrode a-c polarograph as described elsewhere (10). With this instrumentation, the total alternating current was recorded using an applied alternating potential of 10 mV rms at a frequency of 50 Hz. Cyclic and linear sweep voltammetry were achieved with the PAR Electrochemical System using a J-tube mercury electrode as the working electrode.

All test solutions were thoroughly degassed with acetone-saturated argon and a continuous stream of argon was passed over solutions while measurements were being taken. Solutions were thermostated to 20.0° ± 0.1°C in a water-jacketed cell.

Results and Discussion

Polarographic behavior of ammonium O,O'-dialkyldithiophosphates.—O,O'-dialkyldithiophosphate anions show three characteristic oxidation waves (see Fig. 1). No reduction waves other than those attributable to the sodium or ammonium cations were observed up to the solvent limit of −2.2V *vs.* Ag/AgCl. Oxidation waves 1 and 2 were investigated over the concentration range 5×10^{-4} to 10^{-2}M; however, wave 3 occurred close to the positive potential limit (~ + 0.8V *vs.* Ag/AgCl) and therefore was not characterized. Typical results of studies at different concentrations are given in Table I.

The heights of waves 1 and 2 were both linearly proportional to $\sqrt{h}$ (where h is the height of the mercury column head) and to concentration over the range 5×10^{-4} to 10^{-2}M. With increasing concentration the half-wave potential of wave 1 became more negative and that of wave 2 more positive. A-C polarograms of waves 1 and 2 showed that they were asymmetric (see Fig. 2), but the current per unit concentration was large in both cases and characteristic of fast electrode processes. Cyclic voltammetry at a J-tube mercury electrode also confirmed the presence of two rapid and separate charge transfer steps.

In addition to the two main waves, a small wave was found at slightly more negative potentials than wave 1 (see Fig. 1 and 2). This wave (wave 4) was particularly evident in a-c polarograms and may arise from an adsorption/desorption process, since it occurs close to the electrocapillary maximum (see Fig. 3). The marked decrease in drop time of the DME in the potential range of waves 1 and 2 indicates that the compound(s) and/or product(s) of the anodic reaction is strongly adsorbed. Thus although both waves 1 and 2 arise from rapid charge transfer processes, their behavior is likely to be complicated by adsorption phenomena.

The ratio of the limiting current of wave 1 to that of wave 2 was approximately 1:2.2 ± 0.1 as measured

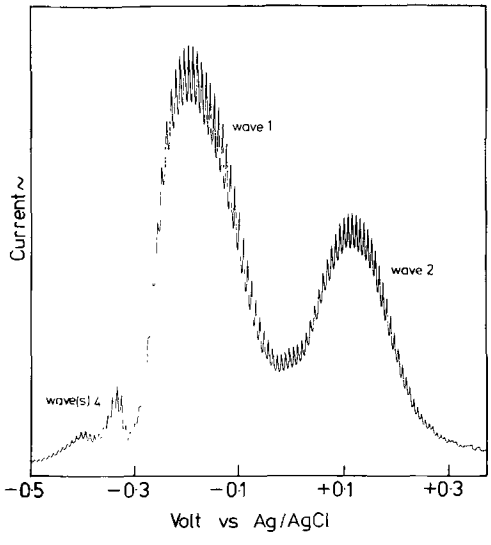

Fig. 2. The a-c polarogram of 10^{-2}M ammonium diethyldithiophosphate.

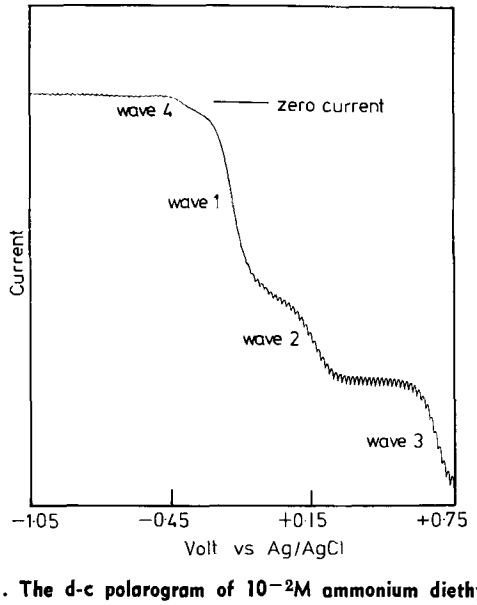

Fig. 1. The d-c polarogram of 10^{-2}M ammonium diethyldithiophosphate.

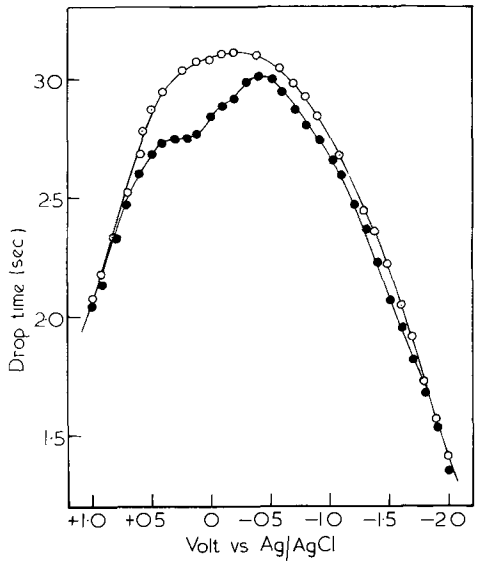

Fig. 3. The electrocapillary curves (DME at h = 74 cm) of (a) 0.1M Et_4NClO_4 (⊙), and (b) solution (a) plus 10^{-3}M ammonium diethyldithiophosphate (●).

from controlled drop-time polarograms, and the total height of waves 1 plus 2 was close to the height of the wave from the one-electron reduction of the sodium ion (from controlled, drop-time polarograms of sodium dialkyldithiophosphates).

Similar polarographic behavior was obtained from potassium O-alkylxanthates in acetone (2). For these ligands the following processes were found consistent with the observed polarographic behavior at the DME

$$2Hg^{\circ} + 6ROCS_2^- \rightleftharpoons 2Hg^{II}(ROCS_2)_3^- + 4e \quad [1]$$

$$2Hg^{II}(ROCS_2)_3^- + Hg^{\circ} \rightleftharpoons 3Hg^{II}(ROCS_2)_2 + 2e \quad [2]$$

where process [1] gave rise to wave 1 and process [2] to wave 2. Since the total height of waves 1 and 2 for dithiophosphates is close to that from the corresponding xanthate waves, it is likely that both ligand systems initiate the same processes at the DME. If the dithiophosphates undergo the above mechanism, and both electrode processes are reversible, then the potential at the DME for wave 1 ($E^{(1)}$) should be given by

$$E^{(1)} = C_1 + \frac{RT}{2F} \ln \left[\frac{[Hg(dadtp)_3^-]_0}{[dadtp^-]_0^3} \right] \quad [3]$$

and for wave 2 by

$$E^{(2)} = C_2 + \frac{RT}{2F} \ln \left[\frac{[Hg(dadtp)_2]_0^3}{[Hg(dadtp)_3^-]_0^2} \right] \quad [4]$$

where C_1 and C_2 are constants, and the subscript zero denotes concentrations at the surface of the DME. The equations for the two waves may be written

$$E^{(1)} = C_1' + \frac{RT}{2F} \ln \left[\frac{i}{(i_d - i)^3} \right] \quad [5]$$

$$E^{(2)} = C_2' + \frac{RT}{2F} \ln \left[\frac{i^3}{(i_d - i)^2} \right] \quad [6]$$

and the half-wave potentials of these waves should change with i_d (or concentration of $dadtp^-$) according to

$$E^{(1)}{}_{1/2} = C_1'' - \frac{RT}{F} \ln [dadtp^-] \quad [7]$$

$$E^{(2)}{}_{1/2} = C_2'' + \frac{RT}{2F} \ln [dadtp^-] \quad [8]$$

A plot of potential *vs.* $\log \left[\frac{i}{(i_d - i)^3} \right]$ for wave 1 from a 10^{-2}M solution of NH_4dedtp is shown in Fig. 4. The relationship was linear except for the negative potential extreme of the wave and the slope was 33 mV (cf. thoretically predicted value of 29 mV). These slight deviations from theory probably result from adsorption phenomena or incomplete reversibility. Figure 5 shows plots of potential against $\log \left[\frac{i^3}{(i_d - i)^2} \right]$ for wave 2. Slopes were again slightly higher than predicted and deviations from linearity were obtained from the negative potential side of the wave. The slope and deviation from linearity increased with increasing concentration, indicating that adsorption is the most likely explanation for these departures from theory.

The $(E_{1/4} - E_{3/4})$ values given in Table I may also be used as criteria for the proposed mechanism. From Eq. [5] and [6] it follows that $(E_{1/4} - E_{3/4})$ should be 56 mV for wave 1 and 69 mV for wave 2. The values agree with those theoretically predicted at low concentrations, but as the concentration is increased they become progressively higher.

The half-wave potentials of the waves vary with concentration in the directions predicted by Eq. [7] and [8]; however the magnitudes of the changes are not exactly those expected from theory. The ratio of the two wave heights is in close agreement with the 1:2 value required by the reaction mechanism.

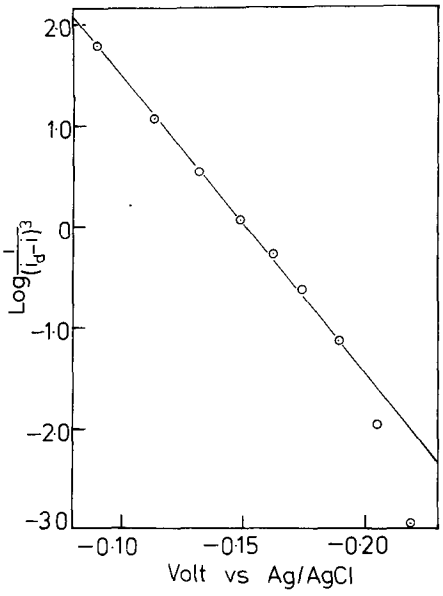

Fig. 4. A plot of potential *vs.* $\log \left[\frac{i}{(i_d-i)^3} \right]$ for wave 1, (from a 10^{-2}M solution of ammonium diethyldithiophosphate).

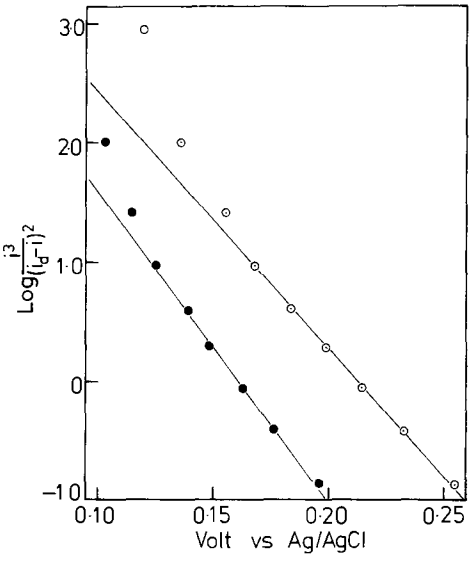

Fig. 5. A plot of potential *vs.* $\log \left[\frac{i^3}{(i_d-i)^2} \right]$ for wave 2, [from a 10^{-2}M solution of ammonium diethyldithiophosphate (⊙) and a 10^{-3}M solution (●)].

In summary, the proposed mechanism provides at least an adequate qualitative description of the system and departures from theoretically predicted behavior are most likely associated with adsorption phenomena. To test the validity of the mechanism further, studies were undertaken on mercury(II) dialkyldithiophosphates.

Polarographic behavior of mercury(II) dialkyldithiophosphates.—The polarogram of bis(dipropyldithiophosphato)mercury(II) was similar to that of the free ligand except that waves 1 and 2 were now cathodic, as expected from the proposed mechanism (see Fig. 6A). However, it was noted that wave 2 from the mercury compounds was somewhat more drawn out than the corresponding oxidation wave from the ligand anions, and the two cathodic waves were not as well separated as the anodic waves from the ammonium salt. Figure 6B illustrates the complexity of wave 2 further, since it is even more drawn out when both

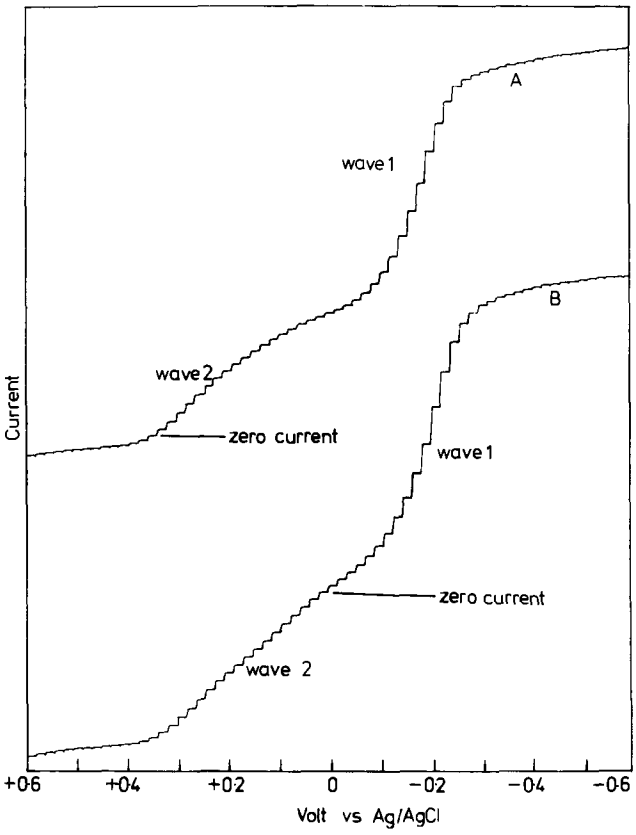

Fig. 6. (A) A current-sampled d-c polarogram of $Hg^{II}(dpdtp)_2$ ($\sim 10^{-3}$M). (B) A current-sampled polarogram of $Hg^{II}(dpdtp)_2$ plus one mole equivalent of dpdtp anions.

$Hg(dpdtp)_2$ and $dpdtp^-$ are present in solution. This indicates partial irreversibility, greater adsorption of mercury species, or that other additional complexities are associated with the $2Hg(dadtp)_3^- + Hg^\circ \rightleftharpoons 3Hg(dadtp)_2 + 2e$ process. Dakternieks and Graddon (8) have shown that $Hg(dadtp)_2$ complexes associate slightly to dimers in solution and it may be this phenomenon that causes the slight difference in behavior. The mechanism also requires the existence of $Hg(dadtp)_3^-$ species. Unfortunately attempts to isolate such entities as tetraethylammonium salts resulted in failure. Similar results to that illustrated in Fig. 6 were obtained by adding two and three mole equivalents of $dpdtp^-$ anions to a $Hg(NO_3)_2$ solution. Interestingly, the current height after adding one mole equivalent of $dpdtp^-$ anions was close to that after the addition of equimolar amounts. Furthermore, no cathodic current due to the reduction of solvated Hg^{2+} ions was seen. This suggests that $Hg(dadtp)^+$ species are viable entities in addition to $Hg(dadtp)_2$ and $Hg(dadtp)_3^-$. Prior to this work only the $Hg(dadtp)_2$ species has been reported (8).

Polarographic behavior of sodium dimethyldithioarsinate.—Polarograms from this ligand were qualitatively similar to those of the dithiophosphates except that oxidation waves 1 and 2 were much closer, making individual characterization of the waves difficult (see Fig. 7). Again no ligand reduction waves were found. At 10^{-3}M wave 1 had a half-wave potential of −0.378V, and wave 2 occurred at $E_{1/2} = -0.208$V. The limiting current of wave 1 was estimated as 34 μA and wave 2 as 17 μA. At higher concentrations wave 2 exhibited a severe maximum. The waves were too close to assess the individual dependencies of their limiting currents on the mercury column height; however the total limiting current of both waves was proportional to $\sqrt{h}$ and to concentration. The total limiting current was also close to that obtained from the one-electron reduction of the sodium ion introduced into solution as the counterion for the ligand.

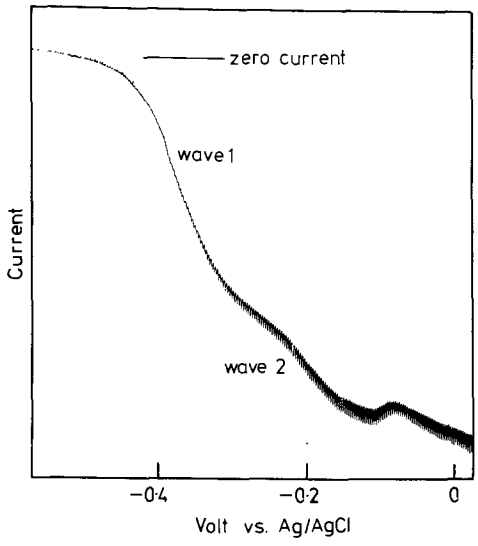

Fig. 7. The d-c polarogram of 10^{-3}M sodium dimethyldithioarsinate.

Polarographic behavior of mercury(II) dimethyldithioarsinate species.—Attempts to isolate a pure sample of bis(dimethyldithioarsinato)mercury(II) resulted in failure (see Experimental section); however the polarographic behavior of mercury(II) complexes with this ligand was investigated by preparing the complexes in the polarographic cell under argon, using stoichiometric amounts of mercuric nitrate and the ligand anion. Although polarograms were not as definitive as those of the mercury(II) dithiophosphate species (because of the close proximity of the two waves and the nature of the experiment), they strongly suggest that the dimethyldithioarsinate ligand interacts with the DME in a similar manner to the dithiophosphate ligands. Both waves 1 and 2 were cathodic after the addition of two mole equivalents of free ligand, and wave 2 became anodic after three mole equivalents had been added. A cloudy solution was observed when one mole equivalent of ligand had been added, probably due to the low solubility of ionic $[Hg(C_2H_6AsS_2)]^\oplus(ClO_4^-)$ in acetone. The solution cleared when a further mole equivalent of ligand was present owing to the greater solubility of the neutral bis complex; no precipitation of $[Et_4N]^\oplus[Hg(C_2H_6AsS_2)_3]^-$ occurred. As for the corresponding dithiophosphato complexes, the $Hg(dtcac)^+$, $Hg(dtcac)_2$, and $Hg(dtcac)_3^-$ species all appear to be viable entities and very strong evidence for the existence of hitherto unreported mercury(II) complexes of this ligand has therefore been obtained.

Discussion

Whereas alkylxanthate, dialkyldithiophosphate, and dimethyldithioarsinate anions interact with the DME via the processes outlined in Eq. [1] and [2], the behavior of dialkyldithiocarbamate anions (1) is fundamentally different and may be described by Eq. [9] and [10]

$$2Hg^\circ + 2R_2NCS_2^- \rightleftharpoons 2Hg^I(S_2CNR_2) + 2e \quad [9]$$

$$2Hg^I(S_2CNR_2) \overset{\text{rapid}}{\rightleftharpoons} Hg^{II}(S_2CNR_2)_2 + Hg^\circ \quad [10]$$

This difference in mechanism must be related to the stability of the various tris(1,1-dithio)mercury(II) complex anions, and possibly also to that of the mercury(I) species. Kemula *et al.* (11) have determined the following stability constants for diethyldithiocarbamatomercury(II) complexes from potentiometric studies in water

$$Hg^{2+} + {}^-S_2CNEt_2 \rightleftharpoons Hg(S_2CNEt_2)^+ \qquad K_1 = 2.1 \times 10^{22}$$

$$Hg(S_2CNEt_2)^+ + {}^-S_2CNEt_2 \rightleftharpoons Hg(S_2CNEt_2)_2$$

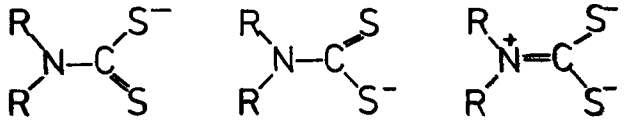
$$K_2 = 5.7 \times 10^{15}$$

$$Hg(S_2CNEt_2)_2 + {}^-S_2CNEt_2 \rightleftharpoons Hg(S_2CNEt_2)_3^-$$

$$K_3 = 1.7 \times 10^1$$

Thus the formation of the anionic tris dithiocarbamate complexes is strongly discriminated against in favor of the bis and $Hg(S_2CNEt_2)^+$ species (even with a large excess of ligand). The same conclusion was reached from polarographic studies in acetone (1).

The above observations are consistent with studies on transition metal complexes with these ligands. For example, NiL_2 complexes readily form base adducts when L is an alkylxanthate (12) or dialkyldithiophosphate (13, 14), but not when L is a dialkyldithiocarbamate (12).



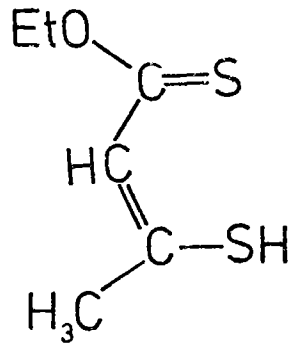
(a) (b) (c)

It is believed that canonical form (c) contributes greatly to the structure of dialkyldithiocarbamate complexes, whereas the corresponding form for the other ligands is of much less significance. Since form (c) results in a larger charge transfer from ligand to metal, the capacity for further coordination to the metal is lowered.

The greater ligand to metal charge donation for dithiocarbamates is also reflected by the relative $E_{1/2}$ values from the HgL_2 reduction waves. For diethyldithiocarbamate the reduction (see Eq. [9] and [10]) occurred at -0.505V (10^{-3}M). Comparable half-wave potentials for the mercury complexes with the other ligands may be calculated from the $E_{1/2}$ values of waves 1 and 2, since the processes given in Eq. [1] and [2] are over-all thermodynamically equivalent to the process $HgL_2 + 2e \rightleftharpoons Hg + 2L^-$. Half-wave potentials calculated for this reaction at concentrations of 10^{-3}M were -0.212V (L = ethylxanthate), -0.048V (L = diethyldithiophosphate), and -0.274V (L = dimethyldithioarsinate). The stability of the mercury(II) complexes is obviously greatest for the dithiocarbamate complex. The actual determination of stability constants was prohibited by the extremely complex nonreversible nature of the mercury(II) nitrate reduction and no data is available on the $E°$ value for the $Hg^{2+}|Hg(o)$ couple in acetone.

The polarographic behavior of 1,1 dithio acids is markedly different to that of the free 1,1 dithio ligands and obviously involves the hydrogen ion. Experiments on xanthate anions showed that the height of wave 1 diminished upon the addition of hydrogen ions whereas that of wave 2 increased. The equilibrium $L^- + H^+ \rightleftharpoons LH$ apparently must be considered in the presence of protons. Presumably the formation of tris species is inhibited for the dithio acids and the height of wave 1 probably reflects the equilibrium concentration of free ligand anions. The half-wave potential of wave 2 became more positive as the hydrogen ion concentration was increased, indicating a change in the electrode process and the need to incorporate terms involving protons in any description of the mechanism. Joris *et al.* (15) observed a similar shift toward more positive potentials with increasing hydrogen ion concentration for the oxidation wave from dithiocarbamate anions. They showed that the behavior was consistent with that predicted from the equilibrium existing between protonated and unprotonated forms of the dithiolate.

It is interesting to note that Bond *et al.* (16) observed an oxidation wave at $E_{1/2} = +0.226$V for O-ethylthioacetothioacetate, (V)



(V)

and a reduction wave at $E_{1/2} = -0.41$V for the bis-(O-ethylthioacetothioacetato)mercury(II) complex. In light of our observations it is likely that the behavior of the mercury(II) complex reflects the behavior of the free ligand anion, the sodium salt of which has not been isolated in a pure state. The difference in the electrode processes undergone by the mercury complex and the protonated ligand may be attributed in part to the presence of the hydrogen atom.

The lack of any reduction waves up to the solvent limit of -2.2V *vs.* Ag/AgCl is surprising considering the possible pathways mentioned at the beginning of this paper. This observation is of considerable significance in studies on transition metal dithiochelates since there is often difficulty in deciding upon the nature of any reduction waves obtained. The results of this work indicate that any reduction waves seen in metal complexes incorporating ligands (I)-(V) cannot be attributed to dissociated ligand. Furthermore, reduction pathways of the type observed for thioketones (6) must occur at extremely negative potentials, be markedly inhibited in aprotic solvents such as acetone, or be inapplicable to 1,1 dithiolates.

The Current Distribution Within Tubular Electrodes under Laminar Flow

Richard Alkire* and Ali Asghar Mirarefi**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A computational method has been developed for calculating the current density distribution within tubular electrodes under laminar flow. Calculations have been carried out for operating conditions which are intermediate between the secondary current distribution and the limiting current distribution. The potential distribution within the tube was determined from Laplace's equation while the reactant concentration along the electrode surface was found from the convective diffusion equation. The two equations were strongly coupled so that they needed to be solved simultaneously. Although central emphasis has been placed on details of the computational method, several salient features of behavior are discussed. The results illustrate how the current distribution within tubular electrodes depends on counterelectrode placement as well as the geometric, charge transfer, mass transfer, and ohmic parameters of the system.

Determining the current and potential distributions within electrolysis cells is important both for the analysis of experimental data obtained at individual electrodes, and for the design and scale-up of useful overall cell configurations. Accordingly, a variety of calculational methods have been developed. The purpose of these calculations has been to elucidate how the current and potential distributions depend on the characteristic nature of a cell including, for instance, its electrolyte conductivity, cell and electrode geometry, charge transfer characteristics, fluid flow patterns, solution concentrations, and electrode resistances. Owing to the large number of variables, the nature of the problem is very complex indeed. However, several situations of limited validity can be analyzed with comparative ease. For example, when the electrode reaction proceeds at low rates, the potential distribution may be determined on the basis of the Laplace equation. When the potential distribution depends solely on the cell geometry, the distributions are referred to as "primary" current and potential distributions. If the electrode reaction is sluggish, the potential distribution depends not only on cell geometry, but also on the solution conductivity and the electrode reaction overpotential; such results are called "secondary" distributions. On the other hand, at very high reaction rates, the rate of mass transfer to the electrode surface becomes the central phenomenon of interest. In the limiting situation where only mass transfer restrictions are important (*i.e.*, at the limiting current) then the current distribution along an individual electrode may be obtained from the laws of convective diffusion.

Electrochemical cells, however, are often operated under conditions which do not conform to either of the limiting situations described above. In order to gain an understanding of behavior in these more complex situations, it is necessary to take account simultaneously of the several phenomena which influence the current distribution (1). Owing to the complexity of the problem, only a few examples are available. These include treatments of natural convection in a cell with vertical electrodes (2), laminar forced convection in a two-dimensional slot (3, 4), and rotating disk electrodes (5). In the investigation reported below, an analysis has been conducted on a class of tubular electrodes operated under laminar flow.

Key words: current distribution, tubular electrode, mathematical model.

Theoretical Formulation

The system under investigation is shown in Fig. 1. The tubular electrode of length l is positioned between two long pipe sections made of insulator material. Electrolytic solution flows through the assembly in fully developed laminar flow and thereby supplies reactive solute species to the electrode surface where electrochemical reaction occurs. As indicated in Fig. 1, two coordinate systems find use: one is based on the pipe axis (x,r) and the other is based along the electrode surface, beginning at the upstream edge (z,y). The counterelectrode may take one of two positions with respect to the tubular electrode: upstream ($x = 0$) as in Fig 1B, or downstream ($x = l_1 + l + l_2$) as in Fig. 1A. Other than its position far upstream or far downstream, the detailed nature of the counterelectrode is not of interest in the present study.

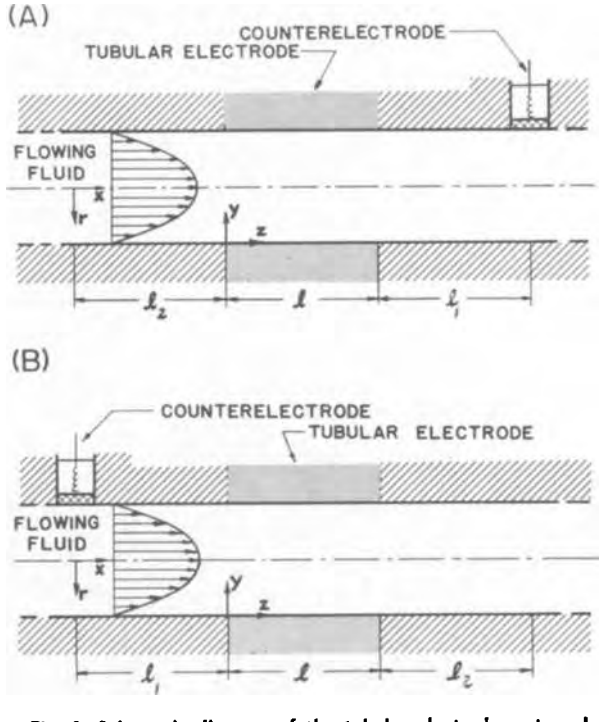

Fig. 1. Schematic diagram of the tubular electrode system. Laminar flow is from left to right. (A) The counterelectrode is on the right; (B) the counterelectrode is on the left.

The electrochemical phenomena which occur in the model tubular electrode system can be complex. Several simple aspects have been selected for study in accord with the following assumptions: (*i*) Electrolysis proceeds under steady-state conditions with fully developed laminar flow in the tubular electrode. (*ii*) The reactive solution species are present in dilute concentrations; owing to the presence of supporting electrolyte, the reactive species do not migrate in the electric field. (*iii*) Concentration differences in the electrolyte, caused by reaction, are confined to a thin shell near the tube periphery; the dimensionless Péclet number, $2R_o<v_z>/D_i$ is large.

Because concentration differences are confined near the electrode surface, two distinct regions may be identified within the electrolyte flowing through the electrode: (*a*) the diffusion layer region, near the electrode surface, within which the concentration of reactive solute varies, and (b) the bulk region, which fills the remainder of the volume within the tubular electrode. Separate equations will be developed for the two regions which share a common boundary at the outer edge of the diffusion layer.

Dimensional equations.—The potential applied between the tubular electrode and the nonpolarized counterelectrode, ϕ_A, is consumed by various irreversible phenomena occurring within the cell. These include ohmic losses in the electrolytic phase, surface overpotential owing to charge-transfer, and concentration overpotential within the thin mass transfer region

$$\phi_A = \phi^o + \eta_s + \eta_c \qquad [1]$$

The concentration overpotential, η_c, depends on the solute concentration at the electrode surface and thus varies with axial position along the electrode

$$\eta_c = \frac{R_gT}{n\mathbf{F}} \ln \frac{c_s}{c_\infty} \qquad [2]$$

Likewise, the surface overpotential depends on position since it is influenced both by the local solute concentration and by the local reaction rate. The rate expression chosen for study is

$$j = i_o \left(\frac{c_s}{c_\infty}\right)^\gamma \left[e^{\frac{\alpha n\mathbf{F}}{R_gT}\eta_s} - e^{-\frac{\beta n\mathbf{F}}{R_gT}\eta_s} \right] \qquad [3]$$

Additional equations are needed in order to determine the concentration distribution within the diffusion layer and the potential distribution in the bulk region. As mentioned previously, these two regions share a common boundary along the outer edge of the thin diffusion layer. It is convenient to denote the potential along this boundary by ϕ_o

$$\phi_o = \phi_A - \phi^o = \eta_s + \eta_c \qquad [4]$$

Diffusion Layer Region

In accord with the assumption that the Péclet number is large, the steady-state equation of laminar convective diffusion in the tube is

$$v_x \frac{\partial c_i}{\partial x} = D_i \left[\frac{\partial^2 c_i}{\partial r^2} + \frac{1}{r}\frac{\partial c_i}{\partial r} \right] \qquad [5]$$

Since the diffusion layer is very thin, the velocity distribution is approximately linear with distance from the wall; in addition, the second term in the brackets of Eq. [5] becomes negligible with respect to the first term. By changing the coordinates of Eq. [5] to the (z,y) system, and by inserting the approximations stated above, one obtains

$$\left(\frac{2v_{max}}{R_o}\right) y \frac{\partial c_i}{\partial z} = D_i \frac{\partial^2 c_i}{\partial y^2} \qquad [6]$$

wherein the velocity distribution in the diffusion layer is approximated by the relation $v_z = (2v_{max}/R_o)y$. Equation [6] corresponds to the Lévêque solution which is a good approximation provided that $(zD_i/2<v_z>R_o^2) << 0.01$. At the limiting current condition, the boundary conditions on Eq. [6] would be

$$\begin{aligned} &c_i = 0 \quad \text{at} \quad y = 0, \quad z > 0 \\ &c_i = c_\infty \quad \text{at} \quad y = \infty, \quad z > 0 \\ &c_i = c_\infty \quad \text{at} \quad z \leq 0 \end{aligned} \qquad [7]$$

By using the combination of variables approach, the solution for this limiting case of behavior is (6)

$$\frac{c_i}{c_\infty} = \frac{1}{\Gamma(4/3)} \int_o^\eta e^{-\eta^3} d\eta \qquad [8]$$

where

$$\eta = \left(\frac{2v_{max}}{9R_oD_iz}\right)^{1/3} y \qquad [9]$$

The limiting current distribution is therefore found to be

$$j_{lim} = \frac{n\mathbf{F}D_i}{s_i}\frac{\partial c_i}{\partial y}\bigg|_{y=0} = \frac{n\mathbf{F}D_ic_\infty}{s_i\Gamma(4/3)}\left(\frac{2v_{max}}{9R_oD_iz}\right)^{1/3} \qquad [10]$$

For currents below the limiting current, the surface concentration of solute is not zero and the boundary conditions of Eq. [7] do not apply. However, one may nevertheless obtain a relation between the surface concentration distribution and the current distribution by applying Duhamel's theorem (7) to Eq. [10]

$$j = \frac{n\mathbf{F}D_i}{s_i\Gamma(4/3)}\left(\frac{2v_{max}}{9R_oD_i}\right)^{1/3} \int_o^z \frac{dc_s(z')}{dz'}\frac{dz'}{(z-z')^{1/3}} \qquad [11]$$

Equation [11] will be used in the subsequent analysis.

Bulk Region

The potential distribution in the bulk region may be taken into account in two ways, the second of which is approximate but nevertheless useful in initiating calculations. The general solution corresponds to the solution of the Laplace equation in circular cylindrical coordinates

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \phi}{\partial r}\right) + \frac{\partial^2 \phi}{\partial x^2} = 0 \qquad [12]$$

With reference to Fig. 1A, the boundary conditions are

$$\begin{aligned} &\frac{\partial \phi}{\partial x} = 0 && x = 0, \quad 0 \leq r \leq R_o \\ &\phi = \phi_A && x = l_1 + l + l_2, \quad 0 \leq r \leq R_o \\ &\frac{\partial \phi}{\partial r} = 0 && 0 \leq x < l_2, \quad r = R_o \\ &\frac{\partial \phi}{\partial r} = -\frac{j}{\kappa} && l_2 \leq x \leq l_2 + l, \quad r = R_o \\ &\frac{\partial \phi}{\partial r} = 0 && l_2 + l < x \leq l_2 + l + l_1, \quad r = R_o \end{aligned} \qquad [13]$$

These boundary conditions indicate that the current distribution along the electrode surface must be known before the potential distribution in the bulk region can be determined. In order to obtain a preliminary estimation of the current distribution, an approximate method is used as described in the next paragraph. The approximate method is accurate when the tubular electrode is very long in comparison with its diameter.

Outside the diffusion layer, the concentrations are uniform. Thus one may, by differentiating Ohm's law, obtain an equation for the conservation of charge

$$\nabla \cdot i = -\kappa \nabla^2 \phi \qquad [14]$$

For long thin tubes, the potential in the solution is nearly uniform across the cross section. An approximation to the potential field, commonly invoked in the analysis of porous electrodes (8), is that the potential is one-dimensional. The local reaction thus appears as a pseudohomogeneous source term in the charge balance equation

$$\frac{d^2\phi}{dx^2} = \frac{2}{R_o\kappa} j \qquad [15]$$

Since reaction proceeds only on the electrode surface, one has

$$j = 0 \qquad 0 \leq x < l_2$$
$$j = 0 \qquad l_2 + l < x \leq l_2 + l + l_1 \qquad [16]$$

By combining Eq. [3] and [15] one obtains

$$\frac{d^2\phi}{dx^2} = \frac{2i_o}{R_o\kappa}\left(\frac{c_s}{c_\infty}\right)^\gamma \left[e^{\frac{\alpha n\mathbf{F}}{R_gT}\eta_s} - e^{-\frac{\beta n\mathbf{F}}{R_gT}\eta_s} \right] \qquad [17]$$

with the boundary conditions

$$\phi = \phi_A, \qquad x = l_2 + l + l_1$$
$$\frac{d\phi}{dx} = 0, \qquad x = l_2 \qquad [18]$$

Equation [17], with its boundary conditions, can be used as an approximation to Eq. [12]. In some situations, the approximation is a very good one; in other situations, it is merely necessary in order to proceed with an iterative solution of the more generally valid Eq. [12].

The equations listed above are sufficient in number to determine the behavior of tubular electrodes over a wide range of applied potentials. Before conducting the calculations, it is convenient to transform the equations into dimensionless form and thereby reduce the number of independent parameters.

Dimensionless model equations.—The following dimensionless ratios will find use

$$X = \frac{x}{l}, \qquad Z = \frac{z}{l}, \qquad \rho = \frac{r}{R_o},$$
$$\gamma_o = \frac{R_o}{l}, \qquad \gamma_1 = \frac{l_1}{l}, \qquad \gamma_2 = \frac{l_2}{l},$$
$$\Phi^* = \frac{n\mathbf{F}}{R_gT}\phi, \qquad \Phi_A{}^* = \frac{n\mathbf{F}}{R_gT}\phi_A,$$
$$\Phi_o{}^* = \frac{n\mathbf{F}}{R_gT}\phi_o, \qquad j^* = \frac{2n\mathbf{F}l^2}{R_gTR_o\kappa} j$$
$$\eta_s{}^* = \frac{n\mathbf{F}}{R_gT}\eta_s, \qquad \eta_c{}^* = \frac{n\mathbf{F}}{R_gT}\eta_c, \qquad C = \frac{c_s}{c_\infty}$$

The equations which define the model are therefore

$$\Phi_o{}^* = \eta_s{}^* + \eta_c{}^* \qquad [19]$$
$$\eta_c{}^* = \ln C \qquad [20]$$
$$j^* = \xi C^\gamma [e^{\alpha\eta_s{}^*} - e^{-\beta\eta_s{}^*}] \qquad [21]$$
$$j^* = \frac{2}{3} N \int_o^Z \frac{dC(Z')}{dZ'} \frac{dZ'}{(Z - Z')^{1/3}} \qquad [22]$$

and

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial\Phi^*}{\partial\rho}\right) + \gamma_o{}^2\frac{\partial^2\Phi^*}{\partial X^2} = 0 \qquad [23]$$

with boundary conditions

$$\frac{\partial\Phi^*}{\partial X} = 0 \qquad X = 0, \quad 0 \leq \rho \leq 1$$
$$\Phi^* = \Phi_A \qquad X = \gamma_2 + 1 + \gamma_1, \quad 0 \leq \rho \leq 1$$
$$\frac{\partial\Phi^*}{\partial\rho} = 0 \qquad 0 \leq X < \gamma_2, \quad \rho = 1$$
$$\frac{\partial\Phi^*}{\partial\rho} = -\frac{\gamma_o{}^2}{2} j^* \qquad \gamma_2 \leq X \leq \gamma_2 + 1, \quad \rho = 1$$
$$\frac{\partial\Phi^*}{\partial\rho} = 0 \qquad \gamma_2 + 1 < X \leq \gamma_2 + 1 + \gamma_1, \quad \rho = 1 \qquad [24]$$

An approximate potential distribution can be found from

$$\frac{d^2\Phi^*}{dX^2} = \xi\sigma[C^{\gamma-\alpha}e^{\alpha\Phi^*} - C^{\gamma+\beta}e^{-\beta\Phi^*}] \qquad [25]$$

with

$$\Phi^* = \Phi_A{}^* \quad \text{at } X = \gamma_2 + 1 + \gamma_1$$
$$\frac{d\Phi^*}{dX} = 0 \quad \text{at } X = \gamma_2$$
$$\sigma = \begin{cases} 0 & \text{for } 0 \leq X < \gamma_2 \text{ and } \gamma_2 + 1 < X \leq \gamma_2 + 1 + \gamma_1 \\ 1 & \text{for } \gamma_2 \leq X \leq \gamma_2 + 1 \end{cases} \qquad [26]$$

Two important dimensionless parameters appear in the foregoing equations of the model

$$N = \frac{3n^2\mathbf{F}^2l^2D_ic_\infty}{s_iR_gTR_o\kappa\Gamma(4/3)}\left(\frac{2v_{max}}{9D_iR_ol}\right)^{1/3} \qquad [27]$$

$$\xi = \frac{2n\mathbf{F}l^2}{R_gTR_o\kappa} i_o \qquad [28]$$

It seems worthwhile to comment briefly on how these important parameters are qualitatively related to the relative importance of ϕ^o, η_s, and η_c, which sum to the applied potential in accord with Eq. [1]. The parameter N contains the ratio D_ic_∞/κ and can thereby be thought of as the ratio of the importance of concentration overpotential to ohmic (IR) potential losses in the electrolyte phase. N may also be considered to be a dimensionless limiting current density averaged over the electrode surface since it contains j_{lim} as given by Eq. [10]. A large value of N therefore implies that the mass transfer process proceeds with relative ease in comparison with passage of current through the electrolytic solution. Consequently, large values of N may be expected to cause the concentration overpotential to be small with respect to the applied potential. For small values of N, the mass transfer process tends to be rate limiting so that one approaches the limiting current behavior. That is, with small values of N, the quantity η_c tends to be the dominant term on the right side of Eq. [1]. The parameter ξ contains the ratio i_o/κ and thereby indicates approximately the ratio of ohmic (IR) potential losses to charge-transfer overpotential by surface reaction. A large value of ξ corresponds to a situation where the current distribution tends to be highly nonuniform owing to the low solution conductivity and "reversible" electrode reaction. On the other hand, a small value of ξ suggests that the current distribution will tend to be uniform. The applied potential will then tend to be consumed more by the surface overpotential than by the (geometry-dependent) ohmic resistance.

Two additional quantities find use

$$\beta_a = \int_{\gamma_2}^{\gamma_2+1} j^* dX = \int_o^1 j^* dZ \qquad [29]$$

$$J = \frac{j^*}{\beta_a} \qquad [30]$$

The quantity β_a is the dimensionless average current density flowing to the tubular electrode and is obtained by integrating the current distribution over the entire electrode. The quantity J is the dimensionless current

distribution which has been normalized by the total current density. That is,

$$\int_{\gamma_2}^{\gamma_2+1} J dX = 1 \qquad [31]$$

Method of Solution

The equations which describe the theoretical model consist of three algebraic relations (Eq. [19]-[21]), one integral equation [22], and a differential equation (either Eq. [23] or [25]). The five equations must be solved simultaneously in order to determine the five unknown quantities: concentration overpotential, surface overpotential, current distribution, surface concentration distribution, and potential distribution. The procedure for solving the equations is complex because the equations are strongly coupled. An iterative procedure was developed whereby two groups of equations were solved alternately, with successive correction, until convergence was achieved. The calculations, outlined below, were carried out on an IBM 360 digital computer.

In the bulk region of electrolyte, the solution of Eq. [23] provides the potential distribution along the tube wall. The solution of Eq. [23] was obtained with use of Green's function (9, 10)

$$\Phi_o^* = \Phi_A^* + \sum_{n=1}^{\infty} \cos(\lambda_n X) \left[\frac{-\gamma_o I_o(\gamma_o \lambda_n) \int_{\gamma_2}^{\gamma_2+1} j^* \cos(\lambda_n X) dX}{(2n-1)\frac{\pi}{2} I_1(\gamma_o \lambda_n)} \right] \qquad [32]$$

The Appendix contains details of this step. From Eq. [32] it may be recognized that the potential distribution along the surface, Φ_o^*, may be calculated provided that the current distribution along the surface, $j^*(X)$, is known.

Within the mass transfer layer, the remaining equations [19]-[22] are solved simultaneously in order to obtain the reaction rate and the surface concentration distributions. The integral in Eq. [22] is evaluated by the method of Acrivos and Chambré (11). In order to obtain the solution, the potential distribution along the electrode surface must be known. However, in the preceding paragraph it was already mentioned that the potential distribution could be determined only if the current distribution was known.

During the iterative procedure outlined below, the first trial distribution was found to be crucial in determining the number of iterations and, in many cases, in determining the successful convergence of subsequent trials. In order to obtain reasonable initial trial values, the one-dimensional model for the potential field in the tube was employed. The solution of this approximate situation has been reported in other studies on porous and resistive electrodes (12, 13). The following iterative procedure has been found successful:

1. Obtain a trial potential distribution (one-dimensional) with uniform solute concentration ($C = 1.0$) by solving Eq. [25] with its boundary conditions.
2. With the trial potential distribution in hand, proceed to solve Eq. [19] through [22] simultaneously to obtain a trial distribution of current and surface concentration.
3. Integrate the trial current distribution twice, in accord with Eq. [15], to provide a new guess for the potential distribution along the electrode surface.
4. Repeat steps 2 and 3 above until two successive distributions agree within a specified convergence criterion. A trial solution is now available which obeys the one-dimensional potential distribution approximation.
5. Substitute the current distribution obtained from step 4 into Eq. [32] and obtain a trial distribution of the potential along the tube wall.
6. Proceed to solve Eq. [19] through [22] simultaneously to obtain a trial distribution of current and concentration.
7. With the trial current distribution in hand, employ Eq. [32] to generate a new trial potential distribution.
8. Repeat steps 6 and 7 above until convergence is achieved. The solution so obtained obeys the two-dimensional potential equation.

In most cases it was found necessary to average new and previous distributions in order to achieve convergence.

The over-all procedure outlined above involves a number of detailed calculations which deserve further comment. Step 1 was carried out by linearizing the nonlinear terms about a trial solution and then placing them in finite difference form. The resulting tridiagonal matrix was inverted easily, and the procedure repeated until convergence upon the nonlinear equation was achieved. Steps 2 and 6, which involve the simultaneous solution of Eq. [19] through [22], were accomplished by first substituting Eq. [19] and [20] into [21] with the result

$$j^* = \xi[C^{\gamma-\alpha} e^{\alpha\Phi_o^*} - C^{\gamma+\beta} e^{-\beta\Phi_o^*}] \qquad [33]$$

Now subtract Eq. [22] from [33] to eliminate j^*, and denote the difference by the function $f(C)$. With a trial potential distribution in hand, it is recognized that the simultaneous solution of [22] and [33] is now equivalent to finding the concentration distribution such that $f(C) = 0$ at every point along the electrode surface. In order to find the solution, one begins at the upstream edge where $C = 1$. The surface concentration at the first incremental step downstream is then found by trial and error following Newton's method of convergence

$$C_{i+1} = C_i + \frac{f(C_i)}{\frac{df}{dC}} \qquad [34]$$

where C_i represents a guess of the correct surface concentration and C_{i+1} represents an improved guess. The derivative df/dC is evaluated analytically, that is, by differentiating the function $f(C)$ and determining the value of the derivative. The integral expression which Eq. [22] contributes to the function $f(C)$ is evaluated by a numerical method (11). By this procedure, one proceeds downstream step by step, taking the first guess of C_i to be that of the preceding interval, and then solving [22] and [33] at each incremental step. The potential and concentration distributions obtained in this manner are then substituted into Eq. [33] in order to compute the trial current distribution. One may then continue with either step 3 or 7 in the over-all iteration sequence outlined previously.

Results and Discussion

Calculations based on the preceding theoretical model have been conducted in order to test the calculational method and to illuminate several characteristic features of tubular electrode behavior. All calculations have been conducted for cathodic deposition with use of a symmetric transfer coefficient ($\alpha = \beta = 0.5$). The dimensionless parameters employed in the following analysis should permit application of the results to a wide variety of actual systems.

First consider behavior when the reaction rate is sufficiently low that mass transfer limitations are absent. It may be realized that the current distribution depends on both γ_o (radius/length ratio) and ξ (ohmic/charge-transfer overpotential ratio). The most reactive portion of the tubular electrode will tend to be that

portion most accessible to the counterelectrode. Figure 2 illustrates the current distribution in a long tube of twenty-five radii in length ($\gamma_o = 0.04$). The counterelectrode is positioned on the right side of the cell. From Fig. 2 the current distribution is seen to depend on the parameter ξ which denotes the ratio of potential loss in the electrolyte to surface overpotential. For very small values of ξ, the current distribution is very uniform since the cell potential is consumed by surface overpotential which does not depend on distance from the counterelectrode. For large values of ξ, the resistance of the electrolytic solution is important so that the electrode regions nearest the counterelectrode are highly reactive. When the tubular electrode is very long with respect to its diameter, as in Fig. 2, the potential distribution in the solution tends to be one dimensional so that results are similar to those available in the literature on porous electrodes (14).

Continuing discussion in the complete absence of mass transfer, Fig. 3 shows how the tubular electrode radius/length ratio influences the current distribution for one particular value of ξ. For very long narrow tubes (small γ_o) the reaction rate is highest near the counterelectrode; the current does not penetrate into the tube owing to the high solution resistance. As the radius of the tube is increased relative to its length, however, the portion of the tube furthest from the counterelectrode becomes increasingly reactive. Regions in the middle of the tube become the least reactive. For large values of γ_o, the current distribution would become symmetric about the middle of the tube, in which case the counterelectrode position is immaterial. From these considerations it is recognized that the parameter γ_o determines to what extent the tube restricts current from flowing to the edge far from the counterelectrode, while the parameter ξ influences the uniformity of the reaction distribution. Results for $\xi = \infty$ would correspond to the "primary" current distribution in which case the current density at each edge of the electrode would tend toward infinity. The foregoing results have been obtained in the complete absence of mass transfer limitations and are thereby independent of the direction or nature of electrolyte flow in the tube.

In contrast to the previous paragraph, consider now the behavior encountered at the limiting current.

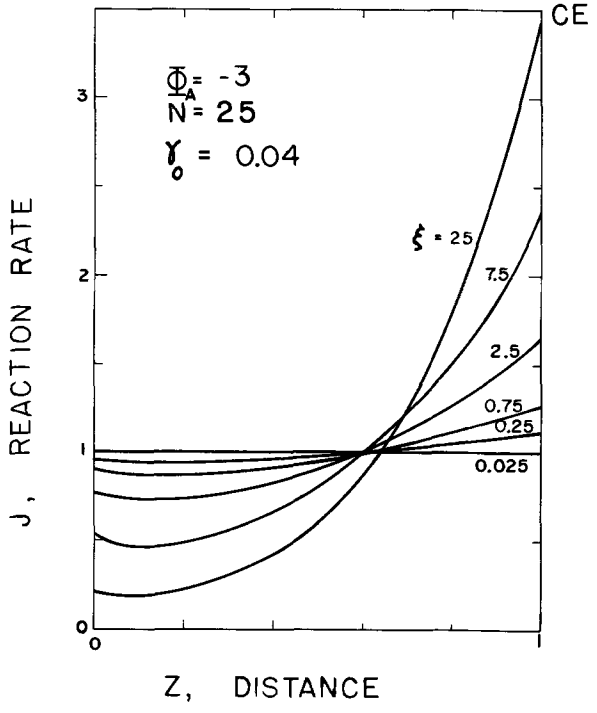

Fig. 2. Dependence of the secondary current distribution on the parameter ξ. The counterelectrode is on the right.

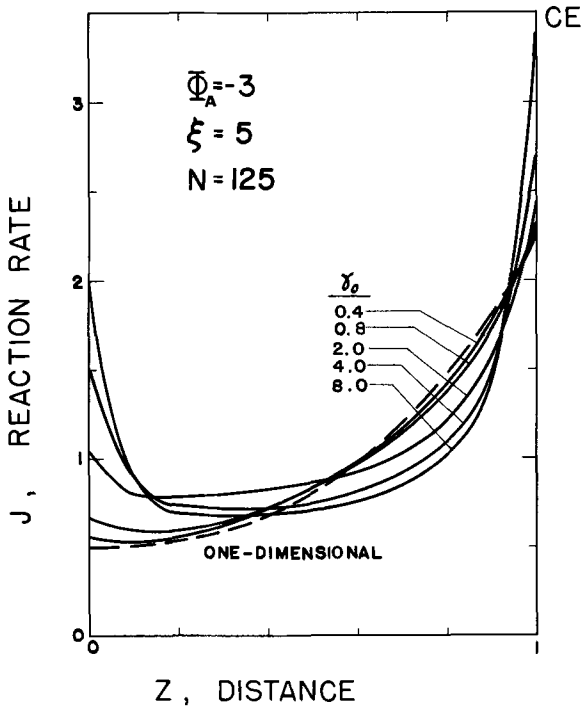

Fig. 3. Dependence of the secondary current distribution on the parameter γ_o. The counterelectrode is on the right.

As indicated in both parts of Fig. 1, electrolyte flows through the cell from left to right. Therefore the limiting current distribution, shown in Fig. 4, is highest at the left-hand (upstream) edge of the electrode and decreases with distance downstream owing to depletion of reactive species near the electrode surface. The limiting current distribution is given by Eq. [10] which in dimensionless notation is

$$j^*_{\lim} = \frac{2}{3} N \left(\frac{1}{Z}\right)^{1/3} \qquad [35]$$

Equation [35] indicates that the limiting current is infinitely large at the upstream edge of the electrode ($Z = 0$) since the mass transfer diffusion layer is of zero thickness. The limiting current distribution is independent of the parameters γ_o and ξ and, in addition, is independent of whether the counterelectrode is

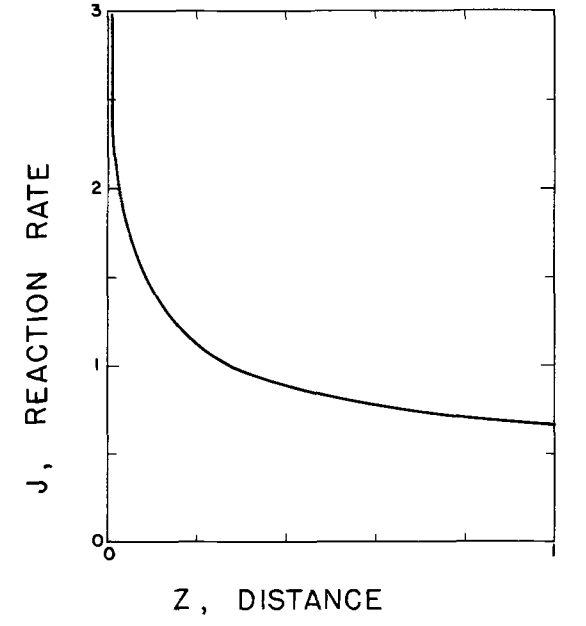

Fig. 4. The limiting current distribution. Electrolyte flow is from left to right.

placed upstream or downstream from the tubular electrode. Comparison of Fig. 4 with either of Fig. 2 and 3 indicates clearly that the limiting current distribution can be exceedingly different from the secondary current distribution, especially when the counterelectrode is placed downstream. By integrating Eq. [35] in accord with the definition of β_a, Eq. [29], one finds at the limiting current

$$\beta_{alim} = N \qquad [36]$$

Now let us turn to several examples of more complex behavior at intermediate currents. In view of the large number of system parameters, it would be cumbersome to report detailed parameter studies for every possible case. Only a few features, which seem to be of special interest, have been chosen for discussion at this time.

Consider first the behavior of long tubes where the counterelectrode is downstream with respect to the fluid flow, as in Fig. 1A. For one set of conditions ($\Phi_A^* = -3$, $\gamma_0 = 0.04$), Fig. 5 shows how the parameter N influences the current distribution. When the average limiting current density is very high (large N), mass transfer processes are inconsequential; the reaction rate along the tube is therefore highest near the counterelectrode (downstream region) owing to the high solution resistance and small tube radius. When the average limiting current density is very low (small N), then mass transfer processes predominate and the upstream region of the electrode is most reactive. At intermediate current levels, both ends of the electrode are more reactive than the center: the upstream region because it is accessible to reactive species, and the downstream region because it is accessible to the counterelectrode.

The concentration of reactive species adjacent to the electrode surface varies with distance along the electrode. Figure 6 illustrates how N influences the surface concentration distribution in a long tube ($\gamma_0 = 0.04$) with a reversible reaction ($\xi = 25$). The counterelectrode is downstream. When N has large values, concentration overpotential effects are relatively minor; depletion occurs primarily in downstream regions where the electrode is most reactive. As the average limiting current density (N) is decreased, lower surface concentrations are encountered. The surface concentration decreases more rapidly in upstream regions, where the diffusion layer is thin. At the limiting current, the concentration is uniform along the entire

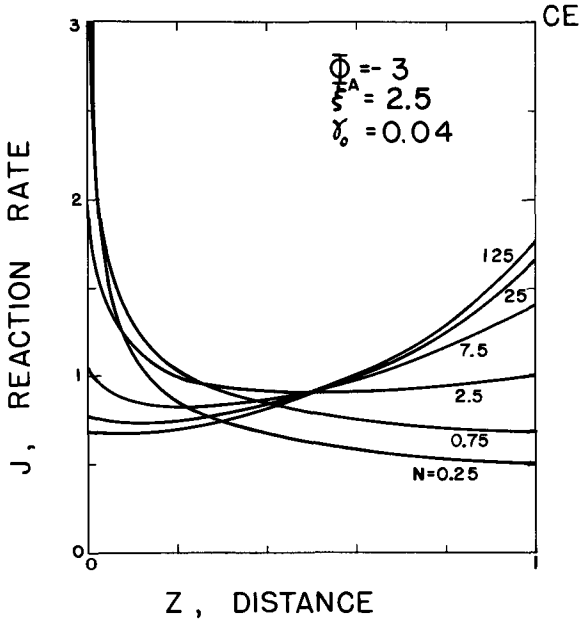

Fig. 5. Dependence of the current distribution on parameter N. Flow is from left to right; the counterelectrode is on the right.

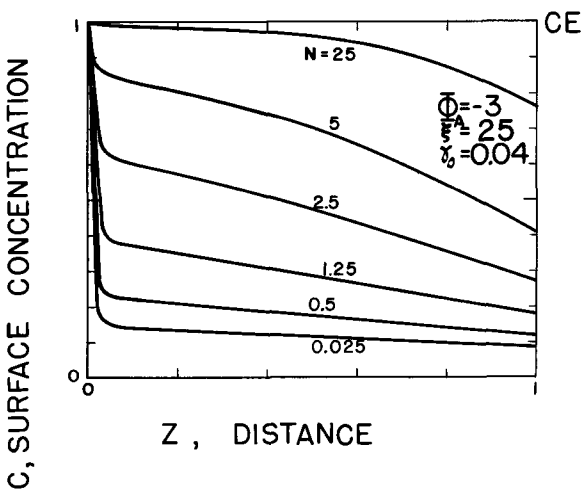

Fig. 6. Concentration distribution along electrode surface near the limiting current condition. Flow is from left to right; counterelectrode is on the right.

electrode surface and, in accord with Eq. [20], has the value

$$C = e^{\Phi_A^*} \qquad [37]$$

The concentration distribution along the electrode surface also depends upon ξ. For long tubes ($\gamma_0 = 0.04$) near the limiting current ($N = 0.5$), the results of Fig. 7 are typical. Flow of electrolyte is from left to right, and the counterelectrode is downstream on the right. For low values of ξ, the charge-transfer resistance predominates behavior so that the reaction distribution is uniform and the extent of concentration depletion is minor since the product (ξN) is small. As ξ is increased, charge-transfer becomes subordinate to mass transfer resistances; the surface concentration then decreases strongly over upstream portions of the electrode where reactivity is highest. For still larger values of ξ, the ohmic resistance of the electrolyte begins to influence behavior by rendering the upstream regions (far from the counterelectrode) less reactive owing to the resistance of electrolyte within the tube; therefore the concentration overpotential decreases.

In the concluding example, consider the behavior of a long tube where the counterelectrode is placed upstream with respect to the fluid flow, as indicated in Fig. 1B. The dependence of the current distribution on the level of the current is provided in Fig. 8. As in the discussion of Fig. 4, the limiting current distribution is encountered when N is small, and the secondary distribution is encountered when N is large. Based on the preceding discussion, it is recognized that the

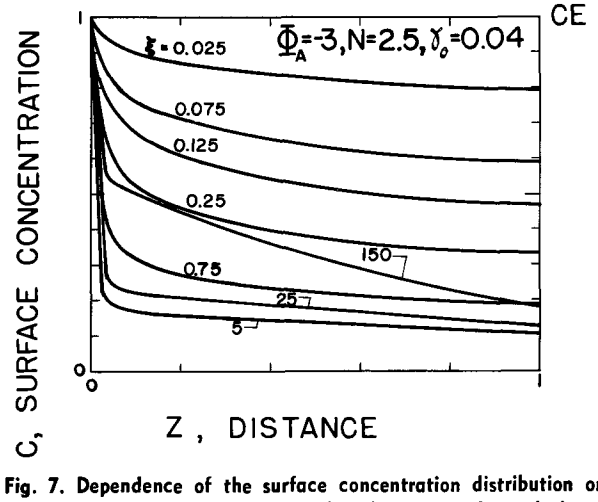

Fig. 7. Dependence of the surface concentration distribution on parameter ξ. Flow is from left to right; the counterelectrode is on the right.

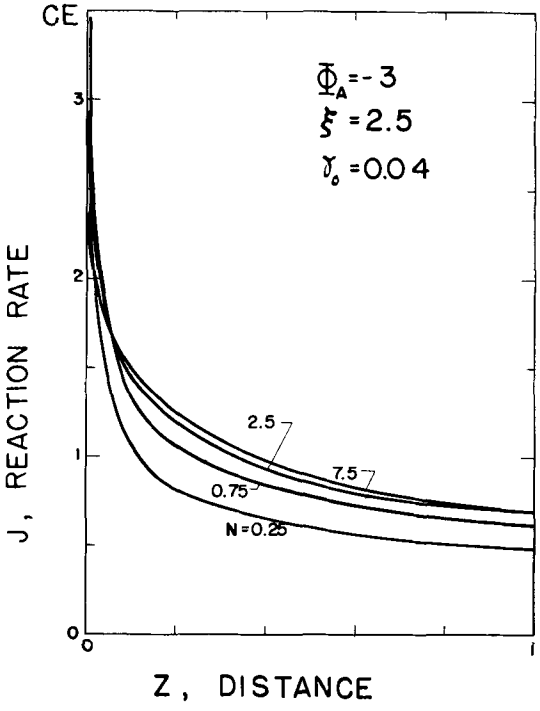

Fig. 8. Dependence of the current distribution on parameter N. Flow is from left to right; the counterelectrode is on the left.

secondary current distribution will be uniform to an extent which depends on the parameter ξ. For a situation somewhat near the limiting current, Fig. 9 illustrates how the reactant concentration varies with distance along the electrode surface for various values of ξ. For small values of ξ, the charge-transfer overpotential is of major importance and the concentration depletion is of minor extent. At intermediate values of ξ, concentration overpotential becomes predominant and the surface concentration takes on very low values. At still higher values of ξ, the ohmic resistance of the electrolyte renders downstream portions essentially inert with the consequence that the diffusion layer becomes replenished with reactant species which diffuse in from the bulk region. A minimum in the surface concentration distribution is thereby observed.

Conclusions

The computational method developed in this study provides a nonintuitive method for predicting electrochemical behavior over a wide range of current densities. The calculations provide a unified treatment of the dependence of two-dimensional tubular electrode behavior on charge-transfer, mass transport, ohmic and geometric parameters of the system as well as counterelectrode positions. The method of calculation is general in nature and may be applied to other geometries and other convective flow situations. The Green's function and the Lighthill transformation methods provide powerful routes for solving the potential distribution and the laminar convective transport aspects of the problem. The crucial assumptions are that the fluid moves in steady laminar flow (Re $<$ 2100), the reacting species do not migrate (small transference number), and the diffusion layer is thin with respect to the tube radius ($zD_i/2<v_z>R^2_o < 0.01$). The Lévêque approximation, invoked in this study to gain Eq. [6], could be improved upon by including higher order terms (15). Other assumptions are also made along the route, but these may be easily modified to suit special circumstances, for example, the choice of reaction rate expression. In order to extend the method to account for turbulent convection or the homogeneous chemical reactions which accompany electrochemical reaction, the Lighthill transformation method would have to be discarded in favor of an alternative method.

The treatment given above has emphasized details of the computational method and has discussed a few general features of the results; additional calculations would be profitable. For example the behavior of flow-through porous electrodes, although exceedingly complex from a physical point of view, has been mathematically modeled by one-dimensional equations of charge- and species-transport. The present study provides a method for assessing conditions under which these crucial assumptions are valid.

In a series of publications Blaedel *et al.* (16), investigated the utility of flow-through tubular platinum electrodes for use in electroanalytical studies. The principal advantages of the method were that it permitted steady-state measurements and thereby avoided fast-response electronic circuitry, and that it enjoyed a high sensitivity owing to the high rate of mass transfer. However the highly nonuniform potential field within the tubular electrode was found to cause deviations from behavior predicted for the limiting current condition. Attempts to modify the measurement circuit to account for the uncompensated resistance were unsuccessful. As a result it had been concluded that the method was restricted to low current densities for which ohmic resistance effects were negligible. The present theoretical formulation provides a sound basis for taking into account the uncompensated resistance phenomena which limited the analysis of Blaedel's experimental data at high current densities.

Acknowledgments

Portions of this study constituted partial fulfillment of requirements for a Master of Science degree in the Department of Chemical Engineering, University of Illinois, Urbana-Champaign. The authors acknowledge with appreciation the receipt of a DuPont Grant-in-Aid during the conduct of this investigation. The computer costs associated with the study were funded by the University of Illinois Research Board. Professor Robert L. Sani generously assisted by suggesting the Green's function method for solving the potential distribution problem.

Manuscript submitted March 16, 1973; revised manuscript received June 11, 1973. This was Paper 235 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

APPENDIX

It is convenient to change the variable in Eq. [23] and the boundary conditions [24] by introducing

$$\Psi = \Phi^* - \Phi_A^* \qquad [A\text{-}1]$$

Thus one obtains the equation

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial\Psi}{\partial\rho}\right) + \gamma_o^2\frac{\partial^2\Psi}{\partial X^2} = 0 \qquad [A\text{-}2]$$

with the boundary conditions

$$\frac{\partial\Psi}{\partial X} = 0 \qquad X = 0, \qquad 0 \leq \rho \leq 1$$

$$\Psi = 0 \qquad X = \gamma_2 + 1 + \gamma_1, \qquad 0 \leq \rho \leq 1$$

$$n \cdot \nabla\Psi = 0 \qquad 0 \leq X < \gamma_2, \qquad \rho = 1$$

$$n \cdot \nabla\Psi = -\frac{1}{2}\gamma_o^2 j^* \qquad \gamma_2 \leq X \leq \gamma_2 + 1, \qquad \rho = 1$$

$$n \cdot \nabla\Psi = 0 \qquad \gamma_2 + 1 < X \leq \gamma_2 + 1 + \gamma_1, \qquad \rho = 1 \qquad [A\text{-}3]$$

Equation [A-2] will now be integrated with use of the Green function, $G(\eta,\zeta;\rho,X)$ which is to be found such that it satisfies the relation

$$\frac{1}{\eta}\frac{\partial}{\partial\eta}\left(\eta\frac{\partial G}{\partial\eta}\right) + \gamma_o^2\frac{\partial^2 G}{\partial\zeta^2} = \frac{1}{2\pi\eta}\delta(\eta-\rho)\delta(\zeta - X) \qquad [A\text{-}4]$$

with the side conditions

$$\frac{\partial G}{\partial\zeta}(\eta,0;\rho,X) = 0$$

$$G(\eta,\gamma_2 + 1 + \gamma_1;\rho,X) = 0$$

$$n \cdot \nabla G(1,\zeta;\rho,X) = 0 \qquad [A\text{-}5]$$

Consider first the homogeneous portion of Eq. [A-4]

$$\frac{1}{\eta}\frac{\partial}{\partial\eta}\left(\eta\frac{\partial G}{\partial\eta}\right) + \gamma_o^2\frac{\partial^2 G}{\partial\zeta^2} = 0 \qquad [A\text{-}6]$$

One may postulate a solution of the homogeneous equation by separation of variables

$$G = x(\zeta)R(\eta) \qquad [A\text{-}7]$$

Substituting Eq. [A-7] into Eq. [A-6] generates an ordinary differential equation for determining the eigenfunctions

$$x_n(\zeta) = \sqrt{2}\cos(\lambda_n\zeta) \qquad [A\text{-}8]$$

where

$$\lambda_n = \frac{(2n-1)\pi}{2(1+\gamma_2+\gamma_1)}, \quad n = 1, 2, 3, \ldots$$

The quantity $\delta(\zeta - X)$ may now be expanded in terms of the eigenfunctions x_n. With use of the orthogonality property of the eigenfunctions, one thereby gains

$$\delta(\zeta - X) = \sum_{n=1}^{\infty}\frac{x_n(X)}{1+\gamma_2+\gamma_1}x_n(\zeta) \qquad [A\text{-}9]$$

Now we are prepared to postulate a solution of the inhomogeneous equation having the form

$$G(\eta,\zeta;\rho,X) = \sum_{n=1}^{\infty} x_n(\zeta)R_n(\eta) \qquad [A\text{-}10]$$

from which one obtains

$$R_n(\eta) = \begin{cases} \dfrac{-x_n(X)\left[I_o(\gamma_o\lambda_n\rho)K_1(\gamma_o\lambda_n) + I_1(\gamma_o\lambda_n)K_o(\gamma_o\lambda_n\rho)\right]}{2\pi K(\rho)I_1(\gamma_o\lambda_n)} & I_o(\gamma_o\lambda_n\eta), \quad \eta < \rho \\ \dfrac{-x_n(X)\left[I_o(\gamma_o\lambda_n\eta)K_1(\gamma_o\lambda_n) + I_1(\gamma_o\lambda_n)K_o(\gamma_o\lambda_n\eta)\right]}{2\pi K(\rho)I_1(\gamma_o\lambda_n)} & I_o(\gamma_o\lambda_n\rho), \quad \eta > \rho \end{cases} \qquad [A\text{-}11]$$

wherein

$$K(\rho) = \gamma_o\lambda_n\rho(1+\gamma_1+\gamma_2)\left[K_1(\gamma_o\lambda_n\rho)I_o(\gamma_o\lambda_n\rho) + K_o(\gamma_o\lambda_n\rho)I_1(\gamma_o\lambda_n\rho)\right] \qquad [A\text{-}12]$$

and I_o, K_o, I_1, and K_1 are modified Bessel functions. We are now ready to invoke Green's theorem

$$\int_v (G\nabla^2\Psi - \Psi\nabla^2 G)\,dV = \int_s (Gn\cdot\nabla\Psi - \Psi n\cdot\nabla G)\,dS \qquad [A\text{-}13]$$

in order to gain the preliminary result

$$\Psi(\rho,X) = \sum_{n=1}^{\infty}\frac{2\cos(\lambda_n X)I_o(\gamma_o\lambda_n\rho)\left[I_o(\gamma_o\lambda_n)K_1(\gamma_o\lambda_n) + I_1(\gamma_o\lambda_n)K_o(\gamma_o\lambda_n)\right]}{K(\rho)I_1(\gamma_o\lambda_n)}\int_{\gamma_2}^{\gamma_2+1}\left(-\frac{\gamma_o^2}{2}\right)\cos(\lambda_n\zeta)j^*\,d\zeta \qquad [A\text{-}14]$$

In accord with Eq. [A-1], the potential in the electrolyte just outside the diffusion layer is

$$\Phi_o^* = \Phi^*(1,X) = \Phi_A^* + \Psi(1,X) \qquad [A\text{-}15]$$

or

$$\Phi_o^* = \Phi_A^* + \sum_{n=1}^{\infty}\cos(\lambda_n X)\left[\frac{-\gamma_o I_o(\gamma_o\lambda_n)\int_{\gamma_2}^{\gamma_2+1} j^*\cos(\lambda_n X)\,dX}{(2n-1)\frac{\pi}{2}I_1(\gamma_o\lambda_n)}\right] \qquad [A\text{-}16]$$

SYMBOLS

C	c_s/c_∞, surface concentration, dimensionless
c_i	concentration of species i, g-mole/cm^3
c_s	reactant concentration at electrode surface, g-mole/cm^3
c_∞	reactant concentration in bulk region, g-mole/cm^3
D_i	diffusion coefficient of species i, cm^2/sec
$\mathbf{F}$	Faraday's constant, 96,500 coulombs/g-equivalent
i_o	exchange current density of electrode reaction, A/cm^2
j	local reaction rate, A/cm^2
j^*	$2n\mathbf{F}l^2j/R_gTR_o\kappa$, local reaction rate, dimensionless
J	j^*/β_a, normalized local reaction rate, dimensionless
l	length of tubular electrode, cm
l_1	distance from counterelectrode to edge of tubular electrode, cm
l_2	distance from rear edge of tubular electrode to rear plane of equipotential, cm
n	number of electrons taking part in electrode reaction
N	$\dfrac{3n^2\mathbf{F}^2l^2D_iC_\infty}{s_iR_gTR_o\kappa\Gamma(4/3)}\left(\dfrac{2v_{max}}{9D_iR_ol}\right)^{1/3}$, average limiting current density, dimensionless
r	spatial variable in radial direction, cm
R_o	radius of tubular electrode, cm
R_g	gas constant, 8.31 joules/g-mole deg
s_i	stoichiometric coefficient of the reacting species
v_{max}	fluid velocity along tube axis, cm/sec
$\langle v_x\rangle$	mass average fluid velocity, cm/sec
x	spatial variable in axial direction, cm
X	x/l, spatial variable in axial direction, dimensionless
y	spatial variable normal to electrode surface, cm
z	spatial variable along electrode surface parallel to direction of fluid flow, cm

Z	z/l, spatial variable along electrode surface, dimensionless
α	parameter in reaction rate expression
β	parameter in reaction rate expression
β_a	average current density, Eq. [29], dimensionless
γ	parameter in reaction rate expression
γ_0	R_0/l, geometric aspect ratio, dimensionless
γ_1	l_1/l, geometric ratio, dimensionless
γ_2	l_2/l, geometric ratio, dimensionless
$\Gamma(4/3)$	gamma function
η_c	concentration overpotential, V
η_c^*	$(nF/R_gT)\eta_c$, concentration overpotential, dimensionless
η_s	charge-transfer overpotential, V
η_s^*	$(nF/R_gT)\eta_s$, charge-transfer overpotential, dimensionless
κ	electrolyte conductivity, (ohm-cm)$^{-1}$
λ_n	eigenvalues of the Green function solution, Eq. [32]
ξ	$\frac{2nFl^2}{R_gTR_0\kappa} i_0$, reaction velocity parameter, dimensionless
ϕ	potential in electrolyte phase, V
Φ^*	$(nF/R_gT)\phi$, potential in electrolyte phase, dimensionless
ϕ_A	potential applied across cell, V
Φ_A^*	$(nF/R_gT)\phi_A$, applied potential, dimensionless
ϕ^o	ohmic potential loss in electrolyte, V
ϕ_0	potential at outer edge of diffusion layer, V
Φ_0^*	$(nF/R_gT)\phi_0$, potential at outer edge of diffusion layer, dimensionless

Technical Notes

The Hydrogen-Loss Concept of Battery Failure: The PbO_2 Electrode

S. M. Caulder,* J. S. Murday, and A. C. Simon*

Naval Research Laboratory, Washington, D.C. 20375

A problem common to all secondary batteries is the gradual loss of capacity during cycling. The cause of this degradation in performance has been attributed to loss of active material (PbO_2), rearrangement of the microstructure of the active material into a less porous configuration, loss of contact between individual particles of the active material, or of the contact between active material and the current-conducting grid. Recent preliminary pulsed nuclear magnetic resonance (NMR) investigations revealed a new factor, the presence of a hydrogen species in the electrochemically prepared PbO_2 structure, which appears to be related to the loss of capacity of the lead-acid batteries, and may be present in other battery systems as well (1).

Several observations made recently at this laboratory on lead dioxide electrodes are as follows. (*i*) X-ray analyses have shown the loss in capacity with charge-discharge cycling was not accompanied by a corresponding increase in lead sulfate on the charged positive plate, as would be the case if active particles were becoming insulated from the matrix. (*ii*) A difference in chemical and thermal reactivity was observed between chemically prepared lead dioxide samples and those prepared by electrochemical means. (*iii*) Differential thermal analysis (DTA) showed distinct differences in the thermal degradation mechanisms (2) of these two materials, although x-ray analysis failed to show any structural differences. DTA also indicated that, after long periods of cycling, the lead dioxide in the cycled plates gave a thermal decomposition path resembling that of the chemically prepared PbO_2, rather than that of the electrochemical form. (*iv*) Differential scanning calorimetry, established that the electrochemically prepared form of lead dioxide gave an exothermic peak at 180°C. (*v*) High temperature mass spectroscopy at 10^{-6} mm showed this peak to be associated with water evolution. No exothermic peak or water evolution was observed at 180°C with chemically prepared PbO_2. However, mass spectroscopy did show some adsorbed water to be evolved from both the chemical and electrochemical lead dioxide when the samples were subjected to a 10^{-6} mm vacuum and heated to 100°C. Previous investigations (3, 4) have also shown that upon heating PbO_2 gives off water of an undetermined origin.

* Electrochemical Society Active Member.

Key words: lead dioxide, lead dioxide electrode, pulsed nuclear magnetic resonance, hydrogen species, capacity loss.

These investigations did not show, however, whether the H_2O was present as a water molecule, as OH^- and H^+ ions, or as oxygen and hydrogen constituents in some unknown structure. To further illuminate this point, a pulsed NMR (5, 6) study of the hydrogen nuclear relaxation times was made of the two compounds. It is evident from the relative magnitudes of the hydrogen signals (Fig. 1) that the electrochemical form has more hydrogen. The nonexponential character of its relaxation time indicates that the electrochemically prepared samples of lead dioxide has hydrogen present in at least two different configurations. The chemically prepared samples showed uniform hydrogen behavior as evidenced by a single exponential relaxation time.

If one decomposes the relaxation data for the electrochemical PbO_2 into an exponential (long-time behavior) and a gaussian (short-time behavior) the long-time behavior (upper solid line in Fig. 1) is similar to that found in the chemical sample. The chemical nature of the slow relaxing hydrogen is not yet clear. The relaxation time of the fast component does not change appreciably with temperature in the range $3.0 < 10^3/T\ °K < 10$; this behavior coupled with the gaussian decay implies that hydrogen nuclei motion is so slow ($\gamma_j < 5 \times 10^4$ jumps/sec) that no motional narrowing of the NMR line occurs in this temperature range (the rigid lattice condition of NMR). From the magnitude of the relaxation time one can calculate a hydrogen-hydrogen separation of slightly greater than 2Å. This means the hydrogen species corresponding to the fast relaxation component are not present in the form of water molecules which have a separation of 1.6Å. Thus, it has now been established that another species other than water is associated with the electrochemically prepared PbO_2.

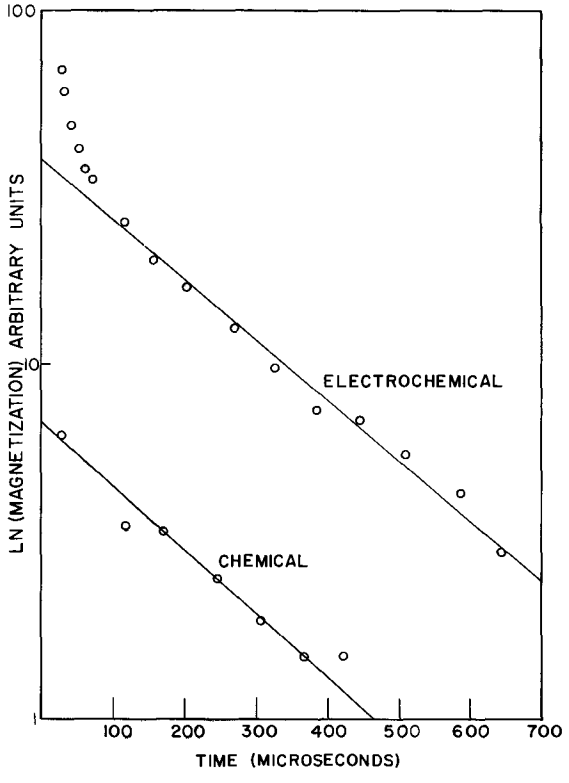

Fig. 1. Typical hydrogen signal of chemical and electrochemical PbO_2. Solid lines indicate slow relaxation component of the hydrogen signal. The fast relaxation component of the electrochemical PbO_2 is shown by the nonconnected circles.

The other interesting part of this investigation is that as the number of charge-discharge cycles increases the concentration of fast relaxing hydrogen species decreases. This observation seems to indicate that the reactive electrochemical form of lead dioxide changes upon extended cycling, perhaps reverting to the relatively inert chemical form.

The results of the NMR investigation suggest that the loss of hydrogen from the lead dioxide structure is connected with loss of reactivity and, consequently, capacity. The mechanism involved is not yet clear. It seems that the lead dioxide in its less reactive (chemically prepared) form cannot be reduced to lead sulfate. This suggests that the hydrogen species present in the electrochemical form are in some manner necessary for this reduction. It is possible that these hydrogen species may either catalyze the reduction or form a necessary chemical step in the reduction of lead dioxide. These and other possibilities will be investigated.

Nondestructive Monitoring by Mössbauer Spectroscopy of the Rate of Corrosion of Coated Metal at the Metal-Polymer Interface

Henry Leidheiser, Jr.,* G. W. Simmons, and Elsie Kellerman

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

Food containers, metals exposed to the atmosphere, and structural metals exposed to corrosive environments are often protected by polymeric coatings, simple or complex in formulation. The rate of corrosion at the metal-polymer interface in the earliest stages is difficult to determine, particularly when the coating

* Electrochemical Society Active Member.
Key words: Mössbauer spectroscopy, corrosion, cobalt, coatings, polybutadiene.

is opaque. The purpose of this communication is to describe, by means of an example, a method based on Mössbauer spectroscopy whereby the extent of corrosion in such systems can be followed. The example method is directly applicable to cobalt substrates and depends for its operation on having Co-57 at the interface, measuring the resonance absorption of the 14.4 keV gamma ray produced in one stage of the transition of Co-57 to the ground state of Fe-57, and determining from the resulting spectra the extent of conversion of elemental metal to a metal compound. Extension of the method to substrates containing tin and antimony is readily accomplished. It remains to be shown that the method can characterize the quality of protection offered by coatings to steel substrates.

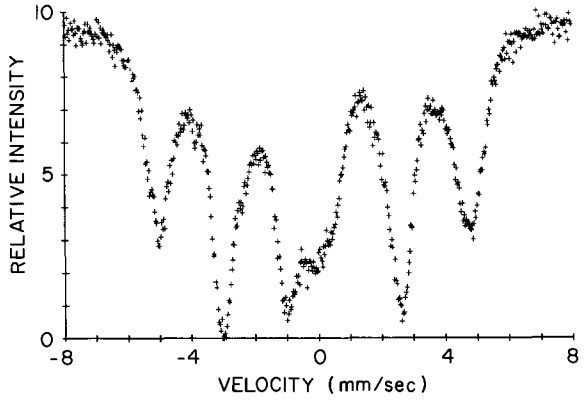

Fig. 1. Mössbauer spectrum obtained from a 50Å thick electrodeposit of cobalt containing Co-57.

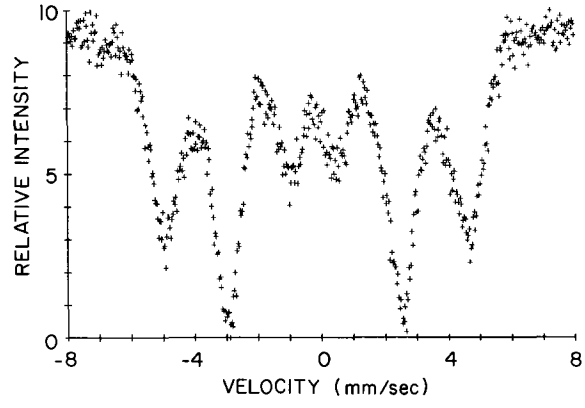

Fig. 2. Mössbauer spectrum of the Co-57 electrodeposit subjected to cathodic treatment in sodium hydroxide. Spectrum was taken *in situ* during cathodic treatment.

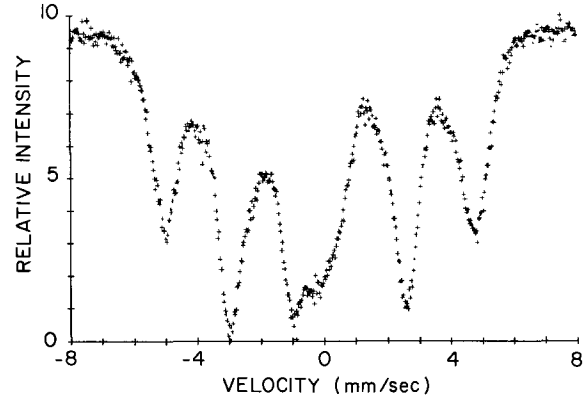

Fig. 3. Mössbauer spectrum after coating sample with polybutadiene to a thickness of 0.001 cm and curing in air at 200°C for 30 min. Ionic cobalt at the metal-polymer interface has increased in amount over that for uncoated sample.

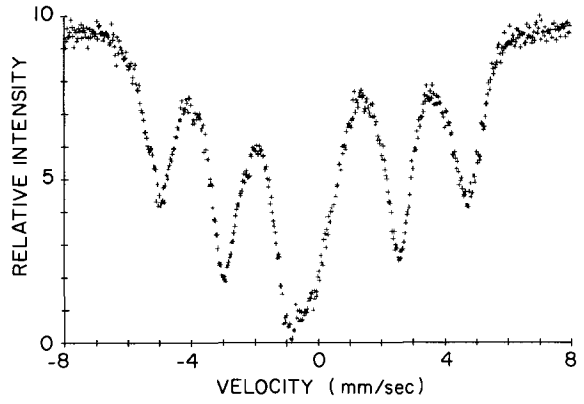

Fig. 4. Mössbauer spectrum of coated sample after exposure to 3% NaCl solution for 84 hr. Note that center peaks characteristic of cobalt oxide have increased in intensity relative to those in Fig. 3.

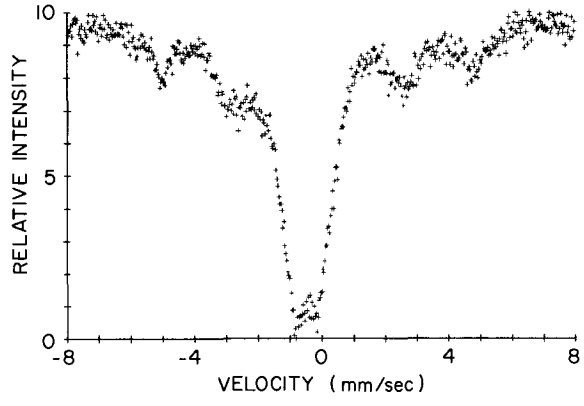

Fig. 5. Mössbauer spectrum of an uncoated sample exposed to 3% NaCl for 1 hr. Spectrum before exposure to NaCl was similar to that shown in Fig. 1.

Cobalt doped with Co-57 was electrodeposited on cobalt from a saturated ammonium oxalate solution. The mass deposited was equivalent to a uniform coating 50Å in thickness. The Mössbauer emission spectrum of such a sample using an enriched stainless-steel absorber is given in Fig. 1. The six-line spectrum (clearly shown in Fig. 2) is characteristic of elemental metal while the central peak (clearly shown in Fig. 5) is characteristic of ionic cobalt. Computer analysis of the spectrum of Fig. 1 leads to the result that 61% of the electrodeposit consists of elemental cobalt and 39% of the deposit consists of cobalt oxide. The oxide presumably forms after removal from the plating bath since *in situ* determination of the Mössbauer spectrum during cathodic treatment yields the six-line spectrum

Table I*

Sample description	Composition of 50Å thick cobalt at the interface: Per cent elemental cobalt	Per cent ionic cobalt
Starting sample with 50Å thick electrodeposit	61	39
Sample coated with polybutadiene to a thickness of 0.001 cm	61	39
Sample cured at 200°C for 30 min	52	48
Coated sample exposed to 3% NaCl for 84 hr	43	57
Uncoated reference sample exposed to 3% NaCl for 60 min	26	63 + 11 lost to solution

* The numbers in the table are computer determinations of the relative areas of the spectrum due to elemental metal and of the spectrum due to the compound. To a first approximation the numbers represent the relative amounts of the two species since it is reasonable to expect that the recoil-free fraction in both the metal and the compound will be approximately the same.

shown in Fig. 2 characteristic of elemental metal. It is estimated that the air-formed oxide is approximately 20Å thick.

The sample was coated to a thickness of 0.001 cm with a proprietary polybutadiene. The emission spectrum did not differ significantly from that of the uncoated sample. The coating was cured at 200°C in air for 30 min and the spectrum shown in Fig. 3 was obtained. The coated sample was then exposed to air-saturated, 3% sodium chloride for 48 and 84 hr. The spectrum of the sample exposed for 84 hr is given in Fig. 4 where it will be noted that the center peak characteristic of cobalt oxide has increased in relative intensity.

A companion uncoated sample, yielding an initial spectrum similar to that of Fig. 1, was exposed to the sodium chloride solution for 60 min. Approximately 26% of the electrodeposit remained as elemental cobalt after this time, as determined from the spectrum in Fig. 5 and the gain in radioactivity of the solution.

In the coated sample there was no loss of cobalt to the solution as indicated by the negligible radioactivity of the solution and the absence of any measurable change in the radioactivity of the solid. The uncoated sample lost approximately 11% in activity during the 60 min exposure to NaCl. A summary of the data obtained in this demonstration experiment is given in Table I.

Etching of High Alumina Ceramics to Promote Copper Adhesion

J. G. Ameen, D. G. McBride, and G. C. Phillips

IBM Corporation, System Products Division, Endicott, New York 13760

The electronic packaging industry is constantly trying to miniaturize all levels of circuit packaging to improve performance and to reduce the size of their machines. The first level of packaging, beneath the chip, is the module. For the size of this level of packaging to be decreased, circuit density must be increased so that more chips can be placed on the module. Increased circuit density requires reduced circuit-line widths.

For various reasons, such as dimensional stability, rigidity, and heat transfer, ceramic is used as a module material. Because thick film screening is limited to 0.005 in. wide lines, it is desirable to use copper metalization, photolithographic, and etching techniques to achieve the required fine-line circuitry. However, the adhesion of copper to ceramic is inherently low and becomes worse with thermal cycling (the result of mismatched coefficients of thermal expansion).

Elmore and Hershberger (1) have reported that fused[1] NaOH etches ceramic with resultant improved adhesion of copper to ceramic.

This pretreatment study was initiated to investigate other methods (2) of ceramic etching to increase surface roughness. The assumption was that of the two possible bonding mechanisms (chemical and mechanical), mechanical keying played the predominant role. Therefore, the hypothesis was that increased surface roughness would yield improved adhesion of copper to ceramic.

Experimental

Analytical Techniques

The analytical techniques (3) used for evaluation of the selected pretreatments were as follows.

Metallography.—The metallograph was used to observe opaque cross sections for internal structure analysis, depth of attack of the various pretreatments, and the nature of the copper/ceramic interface. The edge retention of cross-section samples was maintained by using a hard nickel plate over an electroless copper plate, and polishing was done in a unidirectional motion. The surface profile was highlighted by using oblique and polarized lighting techniques. The degree of polishing has an effect on the observable microstructure. Relatively coarse polishing reveals the alumina grain, whereas fine polishing eliminates the appearance of the alumina grain boundaries and exposes the glass and porosity phases.

SEM (scanning electron microscope).—For the ceramic surface morphology to be observed after pretreatments, it was necessary to vapor deposit between 200 and 350Å of gold on the surface for electrical continuity. Investigation of the range of magnification revealed that 2400× magnification was best for comparisons.

Surface finish by Proficorder.—Samples of all substrates characterized were submitted for surface-finish measurements by the Proficorder. Measurements included a plot of the peaks and valleys in addition to a cumulative plot of center-line averages (CLA) in microinches.

Surface area.—Surface area determinations were made by an outside vendor using the BET method, a krypton-gas absorption technique. The amount of absorption is proportional to surface area.

Flexural strength.—Because there was some concern that the pretreatments used to prepare the ceramic surfaces would be detrimental to the flexural strength (5) of the substrates, a three-point load flexural strength test was performed on selected pretreated samples.

Dot-bend test.—This adhesion test involves soldering a 185 mil diameter brass stud over a 150 mil etched Cu dot on the ceramic substrate. Care is taken to center the stud over the dot, forming a cantilever beam. The brass stud is then pulled at a 90° angle to the stud.

All of the preceding measurements are reproducible within experimental limits. See the text for specific details.

Pretreatments

The following is a summary of the various pretreatments considered; commercially available ceramic substrates (96% alumina) were placed into the solutions at various conditions of concentration, time, and temperature:

Key words: Cu plating, ceramic, adhesion, characterization, etching.

[1] There is an arbitrary distinction between the terms "fused NaOH" and "molten NaOH." The fused process refers to the technique of soaking a piece of ceramic in aqueous NaOH solution to coat it with a layer of NaOH, followed by a subsequent high-temperature bake. The molten NaOH process refers to treating ceramic substrates in hot (400°-500°C) liquid (nonaqueous) NaOH.

Treatment	Concentration	Temperature	Time (min)
HNO_3	70.6%	Boiling	30
HF	48%	120°F	30
H_2SO_4	95.7%	550°F	30
H_3PO_4	86%	Boiling	30
NaOH (aqueous)	25M	375°F	30
$HF:HNO_3$	2:1	Room temp.	30
NaOH	Molten	425°C	15
HBF_4	48-50%	Room temp.	30
HF (ultrasonic)	48%	120°F	15
TaF_5	100%	100°C	15
Vapor blast	—	—	5
$NH_4F \cdot HF$	(30% NH_5F_2, 50% H_2SO_4, 20% H_2O) by weight	120°F	10
No pretreatment	—	—	—

Metalization

Following pretreatment, the ceramic substrates were sensitized and activated using standard $SnCl_2$ and $PdCl_2$, respectively. The $SnCl_2$ and $PdCl_2$ concentrations and the length of time of soak in these were held constant to hold sensitizer and activator effects constant (6). The ceramic was then plated in a proprietary IBM electroless Cu plating bath and subsequently in a standard electrolytic pyrophosphate Cu bath. After the ceramic underwent standard photolithographic techniques, the desired patterns were etched.

Results and Discussion

Of the surface treatments investigated, many had no observable effect on dot-bend values; these were dropped from further study. The ones showing some effect were submitted for further testing.

Figure 1 shows a cross section of a substrate with no pretreatment. Fluoride type etchants (2HF : HNO_3, HBF_4, and HF with ultrasonic vibration) revealed a significant depth of attack but to various degrees. Figure 2 shows the results of the ultrasonic HF treatment which had the greatest depth of attack. The gray area (below the top) represents the depth of attack. With this treatment, the glassy phases between the grains were removed; the alumina grains pulled away from the surface during polishing. On the other hand, the NaOH (molten) vigorously attacked the surface of the ceramic (Fig. 3), but no depth of attack was observed. The etching appears to be a surface effect only. Figures 4 and 5 show substrates etched with HF (concentrated) and NaOH (molten), respectively, after copper plating. It is significant to note that although there is a greater depth with the HF treatment the Cu plating did not penetrate to that depth. In fact, in both cases, the copper is plated only onto the surface. None of the other pretreatments showed any observable effect.

Fig. 1. Cross section of substrate with no pretreatment (48X)

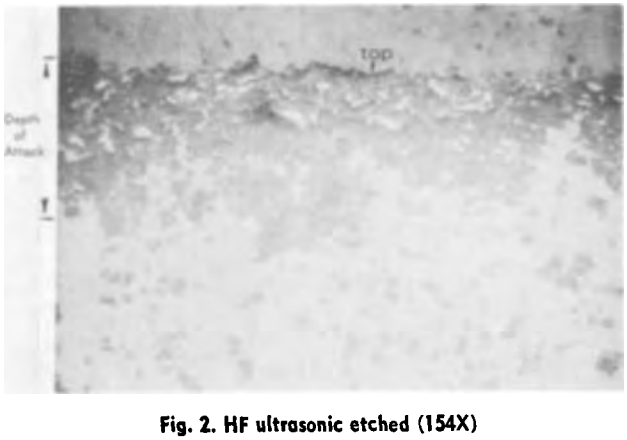

Fig. 2. HF ultrasonic etched (154X)

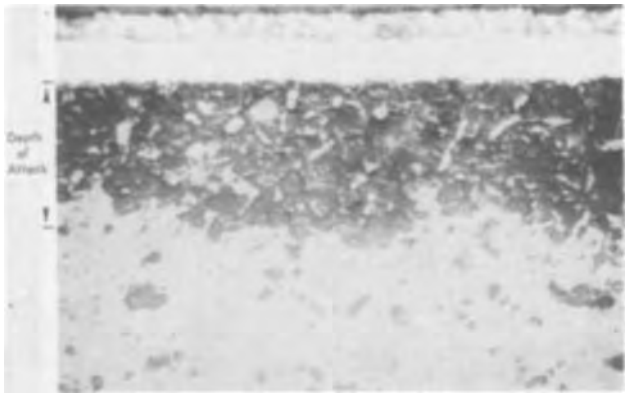

Fig. 4. HF etched, Cu plated (154X)

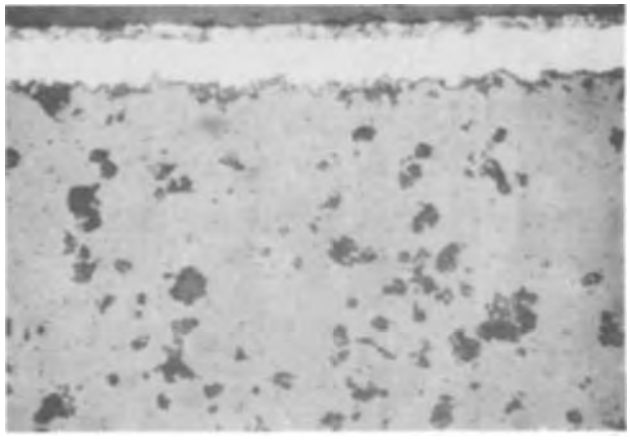

Fig. 5. NaOH (molten) etched, Cu plated (168X)

(SEM) Scanning Electron Microscope

Scanning electron microphotographs of the treated surfaces revealed definite differences between the pretreatments that were found to attack the ceramic.

Figure 6 is an SEM of a substrate with no pretreatment. After etching with HF (Fig. 7) (or any of the other fluoride systems), the alumina grains are more distinct because of the removal of the glassy phase. Figure 8 shows the effects of the NaOH (aqueous) pretreatment. The glassy phases were etched away first, followed by the preferential etch of the alumina grains along crystallographic directions producing a

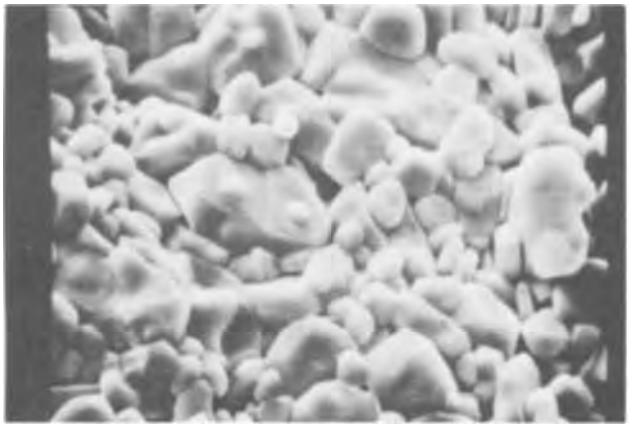

Fig. 6. SEM of substrate with no pretreatment (1152X)

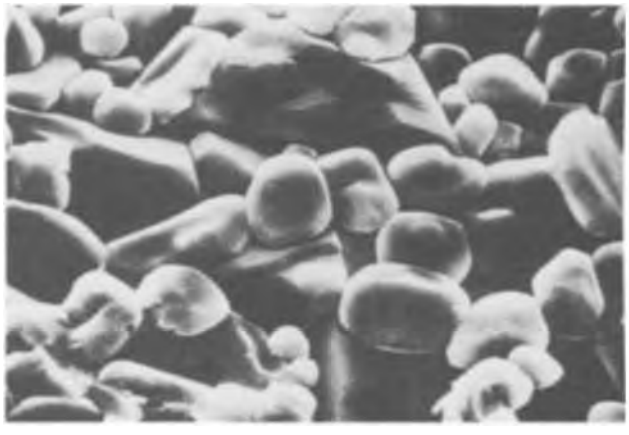

Fig. 7. SEM HF ultrasonic, etched (1152X)

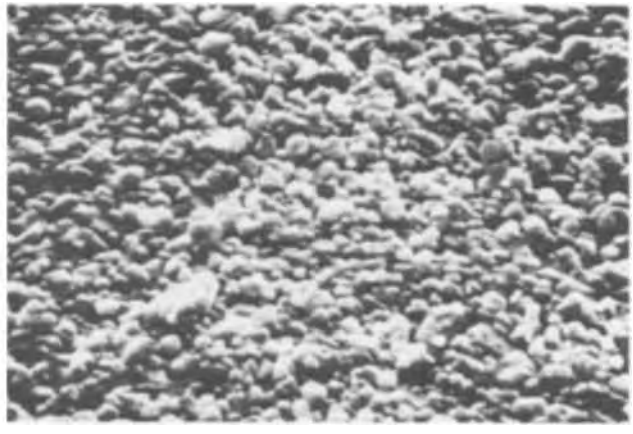

Fig. 10. SEM, activated alumina, with no pretreatment (1152X)

Fig. 8. SEM NaOH (aqueous), etched (1152X)

Fig. 11. SEM, activated alumina, NaOH (molten), etched (1152X)

well-defined grain structure. NaOH (molten) had the most aggressive attack (Fig. 9). The glassy phases are etched rapidly first and then the individual grains are etched at a constant rate.

Commercially available activated alumina (fine grain) was similarly etched in NaOH (molten). Since all the magnifications are the same, the smaller particle size for these substrates as compared to all previous substrates investigated are obvious. Figures 10 and 11 show the ceramic with no pretreatment and after etching in NaOH (molten), respectively. This surface also demonstrated the considerable microroughness characteristic of this process. The remaining treatments showed no difference in their SEM's from the as-received surface.

Dot-Bend Surface Finish

The proof of the hypothesis that mechanical interlocking played the key role in the adhesion promotion mechanism and that increased surface roughness would yield increased copper-to-ceramic adhesion was substantiated with the dot-bend and degree-of-roughness data. Figure 12 shows the plot of surface roughness (CLA) *vs.* dot-bend values. Substrates with no pretreatment yielded a dot bend $\bar{x}$ of 3.2 lb ($\sigma = 0.29$ lb) and a roughness of approximately 21 μin. (CLA). Substrates treated in boiling HNO_3 had a dot bend $\bar{x}$ of 2.6 lb ($\sigma = 0.23$ lb) with a surface roughness of approximately 16 μin. (CLA). The nitric acid slightly smoothed the surface, reducing adhesion. HF (ultra-

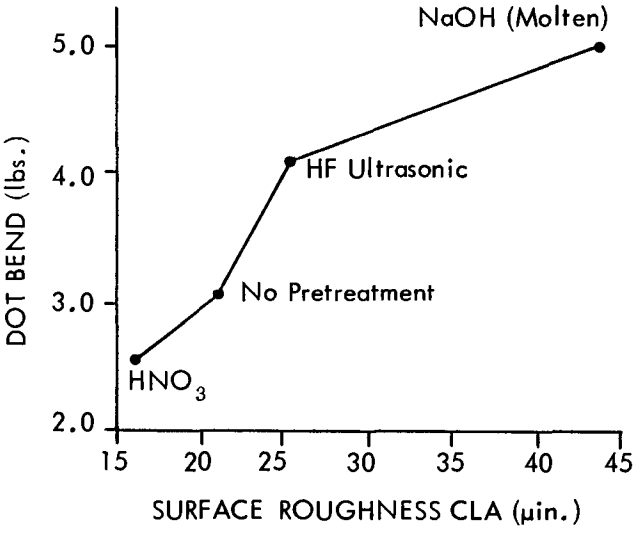

Fig. 12. Dot bend vs. surface roughness

sonic) etching resulted in a dot bend $\bar{x}$ = 4.2 lb (σ = 0.54 lb) with a surface roughness of 25 μin. (CLA). NaOH (molten) etching promoted the greatest copper-to-ceramic adhesion with a dot bend $\bar{x}$ = 5.0 lb (σ = 0.45 lb) and a surface roughness of approximately 44 μin. (CLA). The $\bar{x}$'s are at a 95% confidence level.

The other treatments gave dot bends and CLA's comparable to the no-pretreatment substrates and will not be mentioned further. The other fluoride treatments behaved similarly to HF (ultrasonic) but the effects were not quite as pronounced.

Surface Area

With the BET method of krypton absorption, surface area determinations were performed by Micromeritics Instrument Corporation, Norcross, Georgia, on substrates treated with the various etchants found to attack ceramic (Table I). Substrates having no pretreatment yielded a small surface area. A mild $NH_4F \cdot HF$ pretreatment approximately tripled the surface area; concentrated HF further increased the surface area to approximately 30 times; and HF (ultrasonic) drastically increased the surface area by two orders of magnitude. NaOH (molten) increased the surface area to three times that of the no-pretreatment case, but was many times less than that obtained wih HF. This information confirmed the depth of attacks observed by the metallograph. The HF etch produced a large depth of attack, producing a large surface area, while the NaOH (molten) roughened up the surface but with no appreciable depth of attack.

Flexural Strength

Flexural strength measurements (4) were made on substrates treated with the etchants found to attack ceramic (Table I). The NaOH (molten) process does not decrease flexural strength although there is a reduction in those substrates etched in $NH_4F \cdot HF$. This reduction is probably a result of the increased depth of attack characteristic of fluoride ceramic etchants.

Adhesion Optimization

Because the best copper-to-ceramic adhesion was obtained with NaOH (molten), experiments were run to optimize the adhesion, as measured by dot bend, with respect to time and temperature in the molten NaOH. Figure 13 demonstrates the characteristic effect on adhesion as a function of time of soak at a specific temperature. (The dot-bend values are statistical averages with a 10-15% variation.) Figure 14 displays the effect of the temperature of the molten NaOH on adhesion. These two studies show that the best adhesion was found to be at 420°C for 10 min of soak. The cyclic variance of the dot-bend values with time and temperature is believed to be due to the structure of the ceramic. In the first few seconds the glassy phases and surface debris are removed promoting adhesion; further etching attacks the alumina grains, resulting in a further increase in adhesion. Still further etching weakens the ceramic surface, resulting in the removal

Table I. Surface area and flexural strength vs. pretreatment

Pretreatment	$m^2/gm \times 10^{-4}$	Flexural strength (psi)
As-received	9.5	21,000
$NH_4F \cdot HF$	24.7	19,500
NaOH (fused)	34.9	21,000
NaOH (molten)	32.2	21,000
HF	341.4	—
HF (ultrasonic)	895.0	—

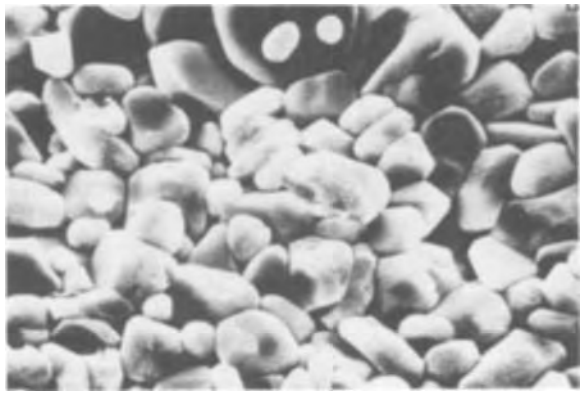

Fig. 15. SEM, 10 sec, NaOH (molten), etched (1152X)

of individual grains and, hence, a decrease in adhesion. Even further etching causes new grains to be exposed with a resultant improved adhesion. (See Fig. 15-18)

Summary

Twelve pretreatments on ceramic substrates were evaluated with a view toward increasing surface roughness and thereby increasing copper-to-ceramic adhesion.

NaOH (molten) yielded a microroughened surface with greatly improved copper-to-ceramic adhesion and no reduction in flexural strength.

Fig. 16. SEM, 30 sec, NaOH (molten), etched (1152X)

Fig. 17. SEM, 60 sec, NaOH (molten) etched (1152X)

Fig. 18. SEM, 3 min, NaOH (molten), etched (1152X)

NaOH (aqueous) slightly roughened the ceramic with only slightly improved adhesion over substrates with no pretreatment. Individual grains were preferentially etched along crystallographic directions.

HNO_3 smoothed the ceramic with a slight reduction in adhesion.

Various concentrations of HF roughened the ceramic surface. HF (concentrated) and HF (ultrasonic) roughened the surface moderately, but attacked to a considerable depth, thus reducing flexural strength with a moderate improvement in copper-to-ceramic adhesion.

Influence of Oxide Structure on the Oxidation Rate of Nickel Single Crystals

M. J. Graham, R. J. Hussey, and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada K1A OR9

ABSTRACT

The influence of metal orientation and the prior oxide film on the oxidation rate of nickel single crystals has been investigated at 600°C in 5×10^{-3} Torr oxygen using a manometric technique and the specimens examined before and after oxidation by electron diffraction, x-ray emission analysis, and electron microscopy. For nickel electropolished in sulfuric acid, the order of decreasing oxidation rate is found to be (100), (111), and (112). This anisotropy together with changes in oxidation rate with surface pretreatment can be explained by modification in the structure of the prior oxide; when a single orientation prior oxide persists the oxidation rate is low; when the oxide contains twin orientations or becomes polycrystalline, the oxidation rate is increased. The results may be interpreted in terms of a variation in the number of easy diffusion paths in the oxide; the higher the density of these paths the greater is the oxidation rate.

Recent investigations in this laboratory on the oxidation of polycrystalline nickel have emphasized the influence of surface preparation on the oxidation rate (1-4). Cold-worked nickel was considered to oxidize faster than annealed nickel because the oxide formed on cold-worked metal was finer grained and, therefore, contained more grain boundaries to act as easy paths for nickel diffusion (3, 4). Various pretreatments of annealed surfaces, e.g., electropolishing, etching, or hydrogen reduction also resulted in markedly different oxidation kinetics (2). The observed different rates of oxidation were explained in terms of a varying density of easy diffusion paths: hydrogen-reduced nickel oxidized most rapidly because the oxide produced contained the highest density of leakage paths, whereas electropolished or etched nickel oxidized more slowly because on some metal grains a single-crystal type of overgrowth, low in leakage paths, was produced. The role of leakage paths in governing oxidation anisotropy has been considered in the past by many groups, including Lawless and Gwathmey, Cathcart, Smeltzer and co-workers (5-12).

Preliminary experiments on a single-crystal spherical segment illustrated the variation of oxide thickness with nickel orientation; by visual observation the order of decreasing oxidation rate on electropolished nickel of the major crystallographic planes was determined as (100), (110), (111), and (112). This study deals with the chemical and structural analysis of the surface oxide before and after oxidation and examines the influence of the prior oxide film in determining subsequent oxidation behavior of these low index faces.

Experimental

Specimen preparation.—Nickel single-crystal disks (0.05-0.15 cm thick) with (100), (111), or (112) surfaces were spark machined from 1.2 cm diameter cylindrical rods supplied by Materials Research Corporation.[1] After an extensive chemical polish (1) to eliminate contamination and damage from cutting (~100 μm Ni removed), specimens were mechanically polished through 0.1 μm diamond, electropolished in a 4:3 (by volume) sulfuric acid solution and then annealed in vacuum at 700°C for 2½ hr. Prior to oxidation specimens were either electropolished in sulfuric acid or electropolished and then etched in 0.8*N* nitric acid for 30 sec. Electropolishing removed ~8 μm Ni and etching ~200Å Ni.

Procedure.—The prepared specimens were oxidized in a manometric apparatus (1). A "furnace-raised" starting procedure (2) was normally used in which the electropolished or etched disk was heated to the oxidation temperature of 600°C in 5×10^{-3} Torr oxygen. The specimen reached 600°C in about 3 min. Some runs were terminated once the specimen had reached 600°C, but most were continued for oxidation times up to 1 hr. In some experiments the oxide film remaining after a decarburizing anneal at 700°C (1) was reduced in hydrogen at 600°C, the specimen cooled, and oxygen admitted at room temperature. A furnace-raised oxidation at 600°C was then performed.

Surface and oxide examination.—Surfaces before and after oxidation were analyzed by an electron-excited x-ray emission technique (13) and were structurally characterized by reflection electron diffraction and electron microscopic examination of two-stage Formvar platinum-carbon replicas. Oxide films were stripped from the metal by immersing in 30% hydrochloric acid and examined by transmission electron microscopy.

Results

Oxidation curves.—Figure 1 illustrates the differing rates of oxidation of the (100), (111), and (112) electropolished surfaces at 600°C and 5×10^{-3} Torr oxy-

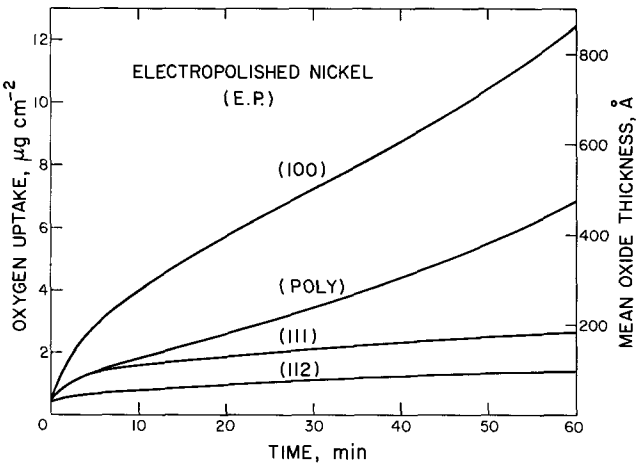

Fig. 1. Oxidation curves at 600°C in 5 × 10^{-3} Torr oxygen for nickel crystals electropolished in sulfuric acid.

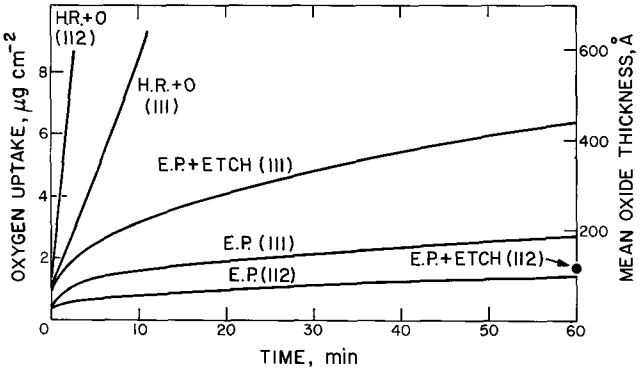

Fig. 2. Oxidation curves at 600°C in 5 × 10^{-3} Torr oxygen for (111) and (112) nickel after electropolishing in sulfuric acid (EP), after electropolishing and then etching in nitric acid (EP + etch), or after hydrogen reduction at 600° followed by oxygen exposure at room temperature (HR + O).

gen. Also included is the curve for polycrystalline nickel which oxidizes more slowly than (100) but more quickly than (111) and (112) surfaces. The oxidation curves for both polycrystalline and (100) nickel show an increase in rate after about 30 min of oxidation.

Figure 2 shows a comparison between the rates of oxidation of the (112) and (111) nickel disks at 600°C after different surface pretreatments. As was the case for electropolished specimens (EP), (112) nickel subsequently etched in nitric acid (EP + etch) oxidizes more slowly than etched (111) nickel. A much more rapid rate is found at 600°C if oxygen is first admitted at room temperature to a hydrogen-reduced surface (HR + O) and then the specimen heated to 600°C in 5 × 10^{-3} Torr oxygen. After this treatment the (112) surface oxidizes more rapidly than the corresponding (111) surface.

In calculating oxide thickness a surface roughness factor of unity has been assumed. This, together with a bulk density of nickel oxide of 6.75 leads to a calculated thickness of 69.2Å for an oxygen uptake of 1 μg cm^{-2}.

Surface analysis.—Table I shows the determination by x-ray emission of the C, O, and N content of prior oxide films on prepared nickel surfaces. The C content of the films after electropolishing or etching was relatively large (2-3 monolayers) and of the same order as oxygen. Nitrogen was found after the nitric acid etch; S was not detected following the sulfuric acid electropolish. Also included in the table are analyses of thin oxides formed during the heat-up period to 600°C of furnace-raised oxidations in 5 × 10^{-3} Torr oxygen: N and C are removed from the film during this period.

Structure.—Reflection electron diffraction patterns typical of nickel single-crystal surfaces before and after oxidation are presented in Fig. 3 and 4. Epitaxial relationships between the oxide and metal for both the prior oxides and those grown for different times at 600°C are given in Table II.

Figure 3a, c, and f show patterns from (112), (111), and (100) electropolished nickel. Strong elongated reflections from the nickel substrate and more diffuse streaks and spots from the oxide are observed. The pattern from the (112) surface is interpreted as (111) oxide growing on the (111) atomic steps which constitute the (112) macrosurface. The (111) oxide on (112) metal is oriented in a direction antiparallel with respect to the (111) steps. On (111) nickel the parallel orientation oxide was also sometimes observed. On (100) nickel the oxide formed from electropolishing has a preferred fiber axis, again with (111) oxide parallel.

After oxidation at 600°C, structural differences in the oxide are apparent. On (112) nickel a highly epitaxed mosaic oxide is produced (Fig. 3b). On (111) nickel a mosaic containing both parallel and antiparallel oriented oxide is formed (Fig. 3e). Two sets of these twin-related orientations are present on (100) nickel after 5 min oxidation (Fig. 3g); after 1 hr, the outer oxide is polycrystalline (Fig. 3h). (Twin-related oxide orientations will subsequently be referred to simply as twins or twinned oxide.)

The diffraction patterns from (112) and (111) surfaces after etching or hydrogen reduction both before and after oxidation at 600°C are given in Fig. 4. After etching, reflections from (111) nickel appear broader than from the (112) surface (Fig. 4a and c); the oxide reflections appear sharper and elongated for the (111) as compared to the (112) surface. In both cases only the antiparallel orientation of oxide is present. On heating the etched (111) surface to 600°C the nickel

spots sharpen (arrows indicate pertinent reflections in Fig. 4c and d), and the oxide spots broaden. After an hour of oxidation at 600°C a twinned oxide is formed both (112) and (111) surfaces (Fig. 4b and e) with the antiparallel twin predominant in the former case. In both instances a little polycrystalline oxide is present. A twinned oxide is produced at room temperature on (111) nickel previously subjected to a carbon burnout anneal (1) and hydrogen reduction at 600°C (Fig. 4i).[2] In contrast the oxide on the corresponding (112) surface (Fig. 4f) exists in the antiparallel orientation only. On heating to 600°C in oxygen two additional twins are observed, one parallel with respect to the substrate and the other parallel to the original antiparallel oxide (Fig. 4g). On oxidizing the (111) specimen an oxide comprising two sets of twins is observed (Fig. 4j). On further oxidation a polycrystalline oxide is formed on both (112) and (111) nickel (Fig. 4h and k).

Replicas of (111) and (112) nickel surfaces prior to oxidation are shown in Fig. 5a and b. Smooth featureless surfaces such as that shown in Fig. 5a for (111) nickel are observed after electropolishing. Some roughening is produced on etching (112) (Fig. 5b); etched (111) after heating in oxygen to 600°C is shown in Fig. 5c where large etch pits, some 200Å deep, are observed. A smoother surface is produced after the hydrogen reduction treatment; Fig. 5d shows a (111) surface subsequently exposed to oxygen at room temperature and then oxidized to 600°C.

[2] Twinned metal is sometimes observed. On annealing at 900°C after hydrogen reduction at 600°C the singly oriented (111) metal surface is restored; on exposure to oxygen at room temperature, a twinned oxide is still produced. Thus, twinned oxide results after HR + O treatment whether the metal is twinned or untwinned.

Surface replicas of oxides produced at 600°C are shown in Fig. 6. On slowly oxidizing (112) nickel, the ~100Å thick single-crystal oxide formed after 1 hr has maintained a fairly smooth surface (Fig. 6a). A rougher oxide is produced on etched (111) nickel (Fig. 6c). Thicker oxides on electropolished (100) and hydrogen-reduced (111) nickel (Fig. 6b and d, respectively) show a greater degree of roughening with increased oxide thickness.

Discussion

Although all the surface preparations produce initial oxide films on all nickel single crystals which are highly oriented, the subsequent oxidation behavior appears to depend on both minor differences in the initial oxide film and on the orientation of the underlying metal. With some orientations and pretreatments an initial single-crystal type of film is preserved for long periods of time, while with others the oxide becomes twinned or polycrystalline. The resulting oxidation rate is a function of the number and type of crystallite boundaries which act as easy diffusion paths in the oxidation process. As pointed out below, the oxide crystallite size and distribution appears to be independent of small differences in chemical composition of the initial oxide film.

Surface analysis.—X-ray emission analyses of the oxide films (Table I) showed that roughly equal quantities (2-3 monolayers) of oxygen and carbon are present in films on different single crystals after electropolishing or etching. The room temperature film on hydrogen-reduced nickel contains a similar amount of oxygen but much less C. The probable source of this

All ×30,000.

latter C is CO in the vacuum system which "cracks" on the nickel surface on cooling from 600°C to room temperature. The large C content after electropolishing or etching is more difficult to account for. The source could be residual impurity in the nickel which concentrates at the surface during polishing or, more likely, results from the absorption of atmospheric CO_2 or organic contaminants either during polishing or on subsequent air exposure. As seen in Table I, on heating to 600°C the oxide thickens and C and N are removed from the film. (Nitrogen is observed after a nitric acid etch.) Different single crystals with similar surface C levels are found to oxidize at quite different rates [cf. electropolished (100) and (112) in Fig. 1], and it is considered that the C content of the film is not a major factor in determining the observed oxidation anisotropy. Physical rather than chemical differences account for the variation in oxidation rate.

Oxidation rate anisotropy of electropolished nickel.— Electropolished (112) nickel oxidizes at the slowest rate (Fig. 1) because the single orientation prior oxide is maintained during oxidation at 600°C (Fig. 3a and b). We observed on oxidizing an electropolished spherical segment that orientations in the region of (112), *e.g.*, (113), (115), also oxidize at the low rate. Perhaps the growth stress in the oxide can be better accommodated when growing on such stepped surfaces and the original, unique epitaxy of oxide is retained.

As seen in Fig. 1, electropolished (111) nickel oxidizes faster than (112). While (111) oxide is formed on both (112) and (111) faces of nickel, in the latter case it is twinned. Two types of twin boundaries may be defined: a twin boundary that coincides with the (111) twinning plane is called a coherent twin boundary (14), whereas twin boundaries that do not coincide with the twinning plane are termed noncoherent twin boundaries (15). Coherent twin boundaries in the present case lie parallel to the film surface. Boundaries normal to the film surface would be noncoherent and as proposed by Cathcart *et al.* (8) could constitute paths of easy diffusion. The interfacial free energy of noncoherent twin boundaries approaches that of a high angle grain boundary (15) and so these boundaries have good potential as easy diffusion paths. The presence of these paths in the oxide on (111) nickel could account for the faster oxidation rate of this face compared with that of (112) nickel.

Electropolished (100) oxidizes much faster still. The prior oxide has a fiber texture (Fig. 3f), and on oxidation at 600°C the two sets of oxide twins (Fig. 3g) could provide a greater density of incoherent boundaries and hence more rapid nickel transport leading to a greater oxidation rate. The increase in oxidation rate after about 30 min for both (100) and polycrystalline nickel suggests recrystallization of the oxide, probably to relieve stress due to epitaxial strain, resulting in the production of mismatch boundaries which provide a greater outward nickel flux. The outer oxide as seen in Fig. 3g and h, eventually becomes polycrystalline. Polycrystalline oxide crystallites were observed in the early stages of oxidation of (100) nickel at 500°C in a recent study by Homma *et al.* (16).

Dark field electron microscopy gave some indication of oxide crystallite size. It showed the 104Å thick oxide growing on electropolished (112) nickel to have a large particle size, ~2000Å in diameter (Fig. 7). This large block mosaic shows angular misorientation with a maximum of about 5° as evidenced by the increase in half width of reflections with increasing order (Fig. 3b). Elongation of reflections toward the shadow edge is due to refraction by the flat surface facets of the mosaic blocks. Kikuchi lines were also observed from this oxide. The 179Å thick oxide on electropolished (111) is shown to contain triangular-shaped crystallites (bright field inset of Fig. 8). Between these grains, as revealed by dark field in Fig. 8, is a much finer grained mosaic; some crystallites are as small as 100Å in diameter. The line broadening in reflection diffraction (Fig. 3e) is due to this small mean particle size and small angular misorientation. As seen in Fig. 3e

Fig. 7. Dark field electron micrograph [from (200) reflection] of 104Å oxide formed at 600°C in 5×10^{-3} Torr oxygen on electropolished (112) nickel. ×16,000.

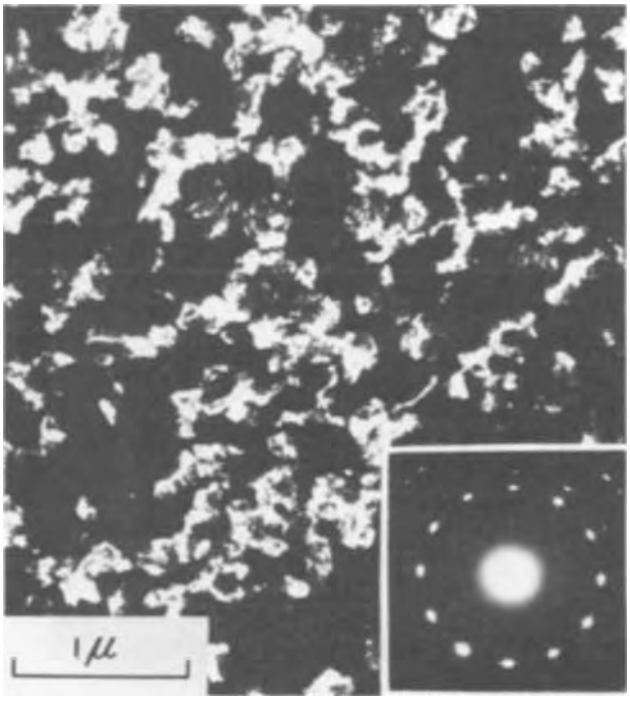

Fig. 8. Dark field micrograph [from (220) reflection] and selected area diffraction pattern from 179Å oxide formed at 600°C in 5×10^{-3} Torr oxygen on electropolished (111) nickel. Top inset: bright field micrograph showing triangular crystallites. ×30,000.

no significant increase in spot broadening is apparent with higher orders of reflection. The low angle boundaries between crystallites comprising the epitaxed mosaics are considered to be ineffective as easy diffusion paths and the oxide on the slower oxidizing (112) is growing at a rate essentially governed by diffusion of nickel through the oxide lattice (2).

Oxide grains, ~1000Å in diameter, are evident in dark field examination of the 212Å thick oxide stripped from (100) nickel (Fig. 9). The oxide grains are less well oriented and the oxide as seen by reflection diffraction shows some polycrystallinity (Fig. 3g). The high angle boundaries between crystallites of different orientations are considered to be very effective leakage paths for nickel transport. Hence, the oxidation rate of electropolished (100) is much faster than either (111) and (112).

Effect of oxide structure on the oxidation of (111) and (112) nickel.—Oxidation anisotropy of electropolished nickel arises from the effect of the underlying orientation on both the initial and final oxide structures. Differences in prior oxide structure and thus changes in oxidation rate of a given orientation were achieved by varying the surface preparation.

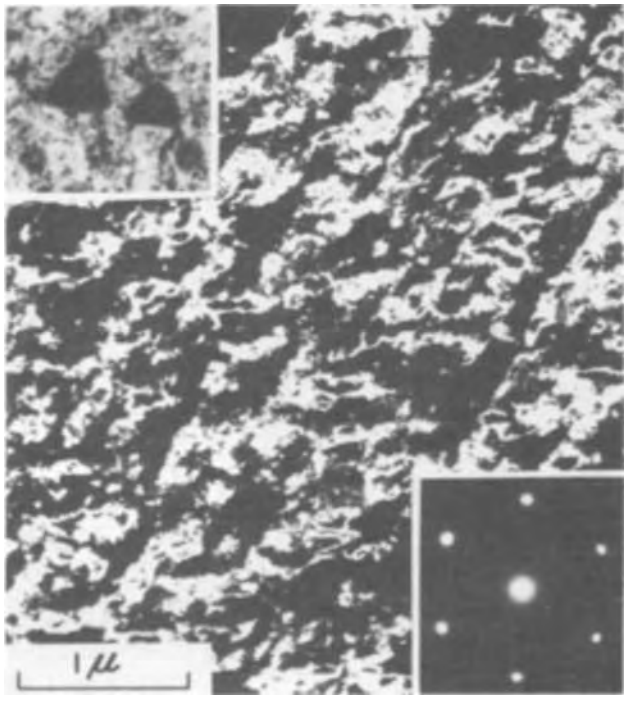

Fig. 9. Dark field micrograph [from (220) reflection] and selected area diffraction pattern from 212Å oxide formed at 600°C in 5×10^{-3} Torr oxygen on electropolished (100) nickel. ×30,000.

Previous work on nickel has shown that the particular order of oxidation of single-crystal faces depends very much on the surface treatment. Herchl *et al.* (12) found that vacuum-annealed (100) oxidized faster than (110) or (111). The hydrogen-annealed specimens of Cathcart *et al.* (8) oxidized at decreasing rates in the order (110), (100), (111) at 500° and 600°C; the oxide on the fastest oxidizing plane was found to be polycrystalline. In "hot-bare" oxidation (1) at 600°C of a hydrogen-reduced, single-crystal, spherical segment, (112) nickel oxidized at the fastest rate, quite the opposite of what is found after electropolishing. The change in oxidation rate occurs because the hot-bare procedure produces oxide with the highest density of easy diffusion paths (2), probably because the oxide is formed from an extremely large number of nuclei.

The increased oxidation rate of etched over electropolished (111) nickel (Fig. 2) is too large to be explained by a greater surface roughness. A twinned oxide is produced in both cases (Fig. 4e and 3e) but the ratio of each twin may be different. Cathcart *et al.* (8) have observed by an x-ray method different proportions of each oxide twin after different surface treatments, and find that the oxidation rate is greater the more equal is the amount of each twin. In the present case one twin orientation may be more predominant in oxides growing on electropolished (111) nickel giving the possibility of fewer incoherent twin boundary leakage paths than on etched (111) nickel where a more equal ratio could provide a larger number of incoherent boundaries and thus a greater oxidation rate. [A low density of leakage paths is also consistent with the observation that electropolished (111) nickel oxidizes only a little faster than the corresponding (112) surface (Fig. 1).] In support of this view, one oxide orientation did appear predominant in the 179Å thick oxide formed on electropolished nickel. Bright field electron microscopy revealed triangular-shaped crystallites [Fig. 8 (top insert)], most of which were oriented in the same direction. No evidence for twin-related orientations was apparent in micrographs of the oxide formed at 600°C on etched (111).

The antiparallel oxide twin predominates on the etched (112) sample after oxidation (Fig. 4b), and

the number of incoherent boundaries may be even less than those present in oxide on electropolished (111) (Fig. 3e). The small difference between the oxidation rates of etched and electropolished (112) (Fig. 2) suggests that the parallel oriented oxide together with the random oriented oxide observed in the etched case (Fig. 4b) are probably superficial and thus do not affect the rate-controlling process. The variation in rates could be within experimental reproducibility, or reflect the difference in initial surface roughness. [Cf. *e.g.*, Fig. 5a with Fig. 5b.]

In the present study, the fastest rates observed are on (112) and (111) nickel after an initial room temperature oxidation of a hydrogen-reduced surface (HR + O, Fig. 2). The room temperature oxide on (112) is of a single orientation while that on (111) is twinned (Fig. 4f and i). During oxidation at 600°C the oxide on (112) soon becomes twinned (Fig. 4g) and, as for the (111), becomes polycrystalline on further heating (Fig. 4h and k). Presumably, during oxide growth stress relief results in the production of arrays of leakage paths and a mismatched oxide after a short time (Fig. 4g and j). The number of crystallite boundaries in the polycrystalline oxide is high and so, consequently, is the oxidation rate. Hot-bare oxidation (1), *i.e.*, where oxygen is admitted at 600°C to an oxide-free surface, would be faster still since the propensity is for polycrystalline oxide to form at a very early stage (2). Thus, the density of high angle leakage path boundaries is very high initially and the oxidation rate would approach a maximum.

Summary

Consistent with the views of Cathcart and others, oxidation rate anisotropy may be explained by differences in population of leakage paths in the oxide. Structurally different prior oxides are produced by various surface pretreatments: where a single-orientation prior oxide is produced and maintained during growth, the oxidation rate is very low; if a singly oriented oxide becomes twinned, comprising one or two sets of twin-related orientations, the oxidation rate is increased; if, in the extreme case, the oxide becomes polycrystalline, then the oxidation rate is very high. Thus, correlation is observed between the density and type of easy diffusion path in the oxide and the oxidation rate.

The Anodization of Si in an RF Plasma

D. L. Pulfrey, F. G. M. Hathorn, and L. Young*

Electrical Engineering Department, University of British Columbia, Vancouver 8, British Columbia, Canada

ABSTRACT

The anodization of Si in a 1 MHz oxygen plasma is described. *In-situ* film thickness measurements were made using a single angle "s" light reflectance technique and this data, coupled with information on the variation of sample voltage with thickness, was used to determine the dependence of ionic current on oxide field strength. The data for a given oxide thickness could be described by an equation of the form given by the theory of ionic conduction by a thermally activated, field-assisted process. However, the ionic current and, in particular, the oxide field strength were dependent on oxide thickness. MOS C-V measurements on oxides of different thickness indicated a change in flatband voltage that could be attributed to a progressive build-up of positive charge within the oxide. This space charge could be reduced by a low temperature annealing treatment. The oxides were found to be slightly absorbing optically, to have a relative permittivity in the range 3.5-3.9, and to possess good insulation properties as long as the oxide thickness did not exceed about 2500Å.

The formation of a thin film of SiO_2 on Si is a key step in modern integrated circuit technology and, although the oxidation of Si by thermal means is well-established there would appear to be a need for a low temperature oxidation process that is compatible with other steps in the device-processing sequence. Plasma anodization would seem to satisfy these requirements and the technique applied to silicon has already re-

Key words: anodization, silicon, rf plasma.

ceived some attention (1-4). Several methods of producing the oxygen plasma have been tried: (*i*) A high frequency (2450 MHz) discharge (1, 2); this method with sample temperatures around 400°C, enabled reasonable quality oxide films to be grown at high rates (6000Å in 2 hr). (*ii*) A d-c arc hot-cathode plasma (4); high quality SiO_2 films have been produced by this method at fast rates (900Å in 10 min) using a sample temperature of 225°C. (*iii*) A d-c cold cathode discharge (3); in this case no data on oxide properties was given. The average oxide growth rate was very slow (1000Å in 4-5 hr) at the temperatures used (32°-55°C) and depended on the sample position in the discharge, with the positive column being the most productive region.

For the d-c cold cathode plasma (3) no detailed oxide growth mechanism was proposed although, following the work of O'Hanlon and Pennebaker (5), it was suggested that the growth process relied in some way on the presence of negative oxygen ions in the plasma. Recent work on this topic (6, 7) suggests that in d-c cold cathode discharges the plasma negative ions do not play an important part in film growth by plasma anodization. This conclusion is shared by Ligenza and Kuhn (4) in discussing the growth mechanism involved in film formation in a d-c arc hot cathode plasma. In this instance a low field diffusion process of negative ions, formed by electron attachment to positive or neutral oxygen mildly implanted in the oxide, is postulated. However, in the work using high frequency plasmas (1, 2) it has been suggested that the oxide growth mechanism involves a diffusion of negative oxygen ions which enter into the oxide from the plasma. The oxide growth rate dD/dt could be expressed as

$$dD/dt = K/D \qquad [1]$$

where K is a parabolic rate constant. This relationship differs from that presented in all other published work on plasma anodization in which a quantitative measure of growth rate dependence on oxide and plasma properties has been considered. These latter works (8-11) have all pertained to the anodization of Ta or Nb and have utilized rf (6.7 MHz) or cold cathode d-c plasmas. In both cases a thermally activated, high field-assisted, ionic conduction process, similar to that existing in the solution-anodization of many elements (12), has been suggested, *i.e.*

$$dD/dt = K_0 \exp \beta E/kT \qquad [2]$$

where K_0 is a temperature-dependent constant, β is a term relating to the charge on the mobile ion and the distance this ion moves between potential wells in the oxide, E is the field in the oxide, k is Boltzmann's constant, and T is the sample temperature.

Whether the difference in the growth mechanisms represented by Eq. [1] and [2] is due to the nature of the plasmas used, or to the differences in materials anodized, cannot be ascertained as no quantitative data on the growth mechanism for the anodization of Si in d-c or rf plasmas is available. It was the aim of this work to provide such information. The plasma source chosen was an externally coupled rf (1 MHz) voltage and this was preferred to a cold cathode discharge because an electrodeless system is desirable to minimize sample contamination and because oxide growth rates would appear to be higher in rf plasmas [*e.g.*, for Ta at 350°K, dD/dt is of the order of 3 Å/min in a d-c plasma (11), whereas a value of about 150 Å/min in a rf plasma (9) has been quoted].

Experimental Procedure

The discharge was maintained in a 5 cm diameter, 1m long quartz tube by a Philips (PH102-02-10-20 Model) 12 kW, 0.5-1.0 MHz generator. The rf power was coupled to the discharge by a two-turn coil and under normal operating conditions (oxygen pressure 30 mTorr) the generator output power was 3 kW. The discharge tube was supported by stainless steel end caps which were rigidly mounted to an optical bench. Seals were effected by Viton O rings. The system was sorption pumped through one end cap, to which a 1-cm diameter Al rod was attached to serve as the cathode for the anodization circuit. The other end cap allowed gas and sample holder entry. The sample holder was of fused quartz and is shown in Fig. 1. Gas (compressed air) or liquid (water) could be circulated through the sample holder and thermal contact between the sample and holder was achieved by the action of the tungsten wires, W, on the quartz sleeve, Q, which served to press the sample, S, onto the aluminum foil disks, A. The sample temperature could be estimated by the Chromel-Alumel thermocouple, T. A 6-mm diameter circular area on the face of the sample was defined by the mica washer, M. The mica mask was necessary to prevent film breakdown (13) which otherwise rapidly occurred at the edges of the film adjacent to the quartz shield, Q. The sample was situated about 30 cm away from the cathode. The exciting coil enclosed a region about 10 cm away from the sample and at the discharge pressure and power levels used the sample was just engulfed in the outer region of the visible plasma.

Typically oxygen pressure during anodization was 30 mTorr and this was maintained by manual adjustment of a leak valve in the gas supply line. The system was continuously pumped during anodization. Prior to anodization the system was evacuated to the limit of the sorption pump (about 4 mTorr) and then back filled to about 1 Torr with oxygen.

Silicon, p-type (10^{16} atoms/cm^3), of (111) orientation was used, and the substrates were about 1.5-mm thick and were cut into roughly circular pieces of about 1.5-cm diameter. The Si substrates were received with one face polished and the only further treatment given to the surface to be anodized was a 30-sec rinse in distilled water and 48% HF (ratio by volume 1:1), followed by drying in a stream of N_2 gas. Al was deposited by vacuum evaporation onto a circular (about 0.8-cm diameter) region on the back face of each substrate and alloyed in, at 580°C for 5 min in an atmosphere of H_2, to form an ohmic contact.

The optical properties of the thin anodic films were determined from *in-situ* measurements of the intensity of linearly polarized light after reflection by the sample (14). A schematic of the optical arrangement is shown in Fig. 2. The light source was a 0.5 mW He-Ne

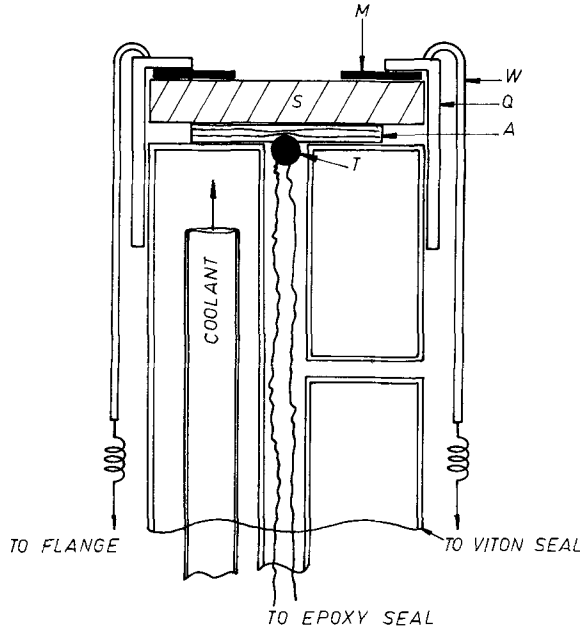

Fig. 1. Schematic cross-sectional view of the quartz sample holder. See text for description.

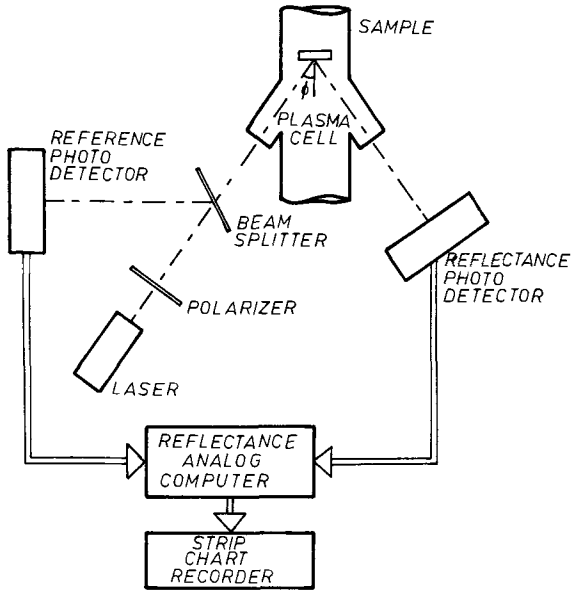

Fig. 2. Schematic of the optical system

(6328Å) laser and linearly polarized light (E vector perpendicular to the plane of incidence) was obtained by rotating the polarizer ("Polaroid" sheet) until a maximum output was obtained on the detectors. "S" light was employed in this investigation rather than "p"-light in order to obtain a larger sample reflectance at the angle of incidence (35°-37°) used. The angle of incidence was adjusted so that the laser beam entered and left the quartz windows of the cell at as close as possible to normal incidence. Bandpass filters (100Å) were placed in front of each detector to allow measurements to be made with the laboratory well-lighted and the sample immersed in the oxygen plasma. At the outset of the work RCA 7102 photomultipliers were used as detectors and a measure of the intensity of the reflected light as a fraction of the intensity of the reference beam was achieved by feeding the photomultiplier output signals through separate decade potential dividers and adjusting the values of the said dividers to obtain a null signal on an oscilloscope used with a differential input channel. At a later stage, the system was automated to provide a continuous record of the sample reflectance. Photodiode detectors were used in this case and the output signals were fed into a reflectance analog computer that has been described in detail elsewhere (15).

Electrical contact between the sample and the constant current source that was used as the anodizing power supply was provided via the thermocouple leads. Constant anodizing currents in the range 0.5-4.0 mA were used: the lower limit being set by the slow growth rate and the upper limit being determined by the onset of instabilities in the anodization circuit. Ionic current densities were obtained by taking the ionic current density producing a growth rate dD/dt for an oxide A_xO_y as given by

$$J_{ion} = \frac{\rho 2y\mathbf{F}}{M} \cdot \frac{dD}{dt}$$

where $\mathbf{F}$ is 9.65×10^4 coulombs, M the gram molecular weight, and ρ the density. For SiO_2, ρ was taken as 2.2 g/cm³ (16).

To obtain a measure of the oxide field strength, the sample voltages with respect to a fine Pt wire probe and also with respect to the cathode (grounded) were recorded on a strip chart recorder. The unshielded tip of the Pt probe was initially situated about 3 cm away from the sample surface, *i.e.*, directly under the exciting coil. Such a position of the probe seemed advantageous, as regards heating it to keep it clean during anodization (17), but ultimately the probe was withdrawn from the plasma because of system and sample contamination from vaporized or sputtered probe material. The voltage data reported here, therefore, all refer to potentials measured with respect to the cathode. To obtain reproducible data it was found necessary to clean the cathode after about 20 hr of exposure to the plasma. Calculations of both the integral field strength (V/D) and the differential field strength (dV/dD) in the oxide were made.

Table I. Comparison of oxide refractive index and thickness values as calculated by the reflectance technique and by ellipsometry

Sample No.	Oxide thickness, A: From reflectance	Oxide thickness, A: From ellipsometry	Refractive: From reflectance n_1	Refractive: From reflectance k_1	Refractive: From ellipsometry n_1	Refractive: From ellipsometry k_1

4	4000	4035	1.387	0.034	1.385	0.007

Results and Discussion

Refractive index of the oxide.—The refractive index ($N_1 = n_1 - ik_1$) of the oxide was calculated from a comparison of the observed and theoretical variations of sample reflectance with oxide thickness (14). The method is sensitive to the presence of optical absorption in the films and some absorption was detected in the plasma-anodized films of SiO_2. The values of n_1 for the various samples covered the range 1.35-1.42, while values of k_1 fell within the bounds of 0.014-0.034. Specific values for two samples are shown in Table I, along with results calculated from two-zone ellipsometer readings taken on the completed oxides. The refractive index was evaluated from the ellipsometer data by computing the value of N_1 that would give an oxide thickness close to that indicated from the reflectance data. The thickness agreement between the two methods, as shown in Table I, seems very reasonable in view of the fact that the ellipsometer laser beam was smaller (by an areal factor of 2) than the laser beam used in the reflectance measurements, and some nonuniformity in oxide thickness is to be expected on account of perturbation of the plasma by the sample holder. Because of this no attempt was made to obtain an exact match in oxide thickness, even though this may have resulted in better agreement between the values of k_1 as calculated by the two methods. In any event, the ellipsometer computations confirm that the oxides were somewhat absorbing and that the real part of the refractive index is similar to that previously reported (16) for the growth of thin film SiO_2 by various methods. No attempt was made to investigate the cause of the absorption in the films.

Oxide growth rate and current efficiency.—The current efficiency, η, of the oxide growth process was very low and for the range of anodizing currents and temperature used, see Fig. 3, never exceeded 0.5%. A low

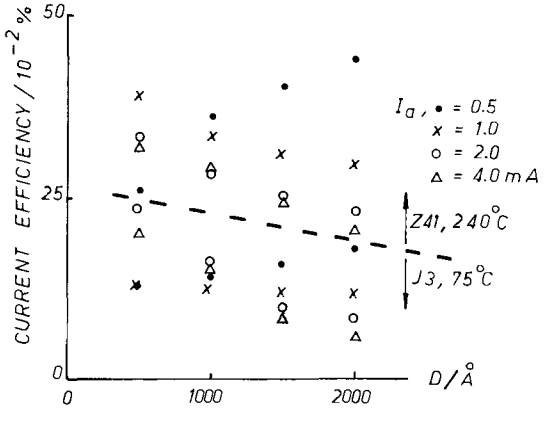

Fig. 3. Variation of current efficiency with oxide thickness

current efficiency seems to be a feature of plasma anodization (18) and presumably arises because of the availability of a copious supply of high energy electrons in the plasma which can readily enter the oxide. Thus even with materials such as Ta_2O_5 and Nb_2O_5, which can be grown anodically in aqueous solution at current efficiencies of 100%, current efficiencies of around 1% are realized in plasma anodization (11). The anodization of Si in solution (19, 20) however, proceeds at a current efficiency of about 1% and thus the low value reported here for plasma anodization is less unexpected. The behavior shown in Fig. 3 is typical of most samples anodized and the salient features are: (*i*) a decrease in η with film thickness, D, for anodizing currents of 2.0 and 4.0 mA, (*ii*) an independence (or sometimes an increase) of η with D for anodizing currents of 0.5 and 1.0 mA. The fall of η with D may indicate a deterioration in oxide insulating properties as growth proceeds. Alternatively, following Fritzsche's (20) idea of the growth mechanism being an impact ionization process in which Si ions are created at sites of collision between lattice atoms and high energy electrons, it would be expected that more ionizing collisions per electron would occur as D increases, *i.e.*, the electronic current would increase, and this would lead to a reduction in η if the oxide contained trapping sites for the Si ions (see section below on MOS measurements). Observation (*ii*) would then suggest a field dependence of the trapping mechanism.

Although current efficiencies were low, a value of 0.5% for $I_a = 4.0$ mA (sample area = 0.3 cm^2) corresponds to an oxide growth rate of 30 Å/min. Such growth rates are common in the thermal oxidation of Si in dry oxygen (16).

Oxide field strength (21).—The field, E, in the oxide was estimated in two ways, namely: the integral method in which E at a thickness D was taken as V_{ox}/D where V_{ox} represents the voltage drop across the film; and the differential method in which E at a thickness D was given by $\Delta V_{ox}/\Delta D$, where ΔV_{ox} is the change in voltage drop across the film in increasing the thickness by ΔD about the median value D. In the differential method, for a change in oxide thickness ΔD, the measured change in voltage (between sample and cathode) ΔV is likely to be a good approximation to ΔV_{ox}, providing the conditions in the plasma do not change during the time required to grow ΔD of oxide. The measured voltage (between sample and cathode) V will only approximate to V_{ox} if the voltage drop in the rest of the anodizing circuit is small and, furthermore, measurements of integral field, for a given anodizing current, taken at different oxide thicknesses will only be comparable if the plasma conditions do not change in the interim period. To get meaningful kinetics data (see below) this period will be much larger than that required to form ΔD as mentioned in the differential measurement. However in this investigation it was found that more reproducible data could be obtained using the integral method. Large errors in $\Delta V_{ox}/\Delta D$ are perhaps to be expected when both the voltage change and thickness change are small (ΔD was typically 100Å), and furthermore a measure of ΔV, (and ΔD) would seem to be relevant only when V (and D) was varying linearly with time. Whereas dD/dt was usually constant during a formation dV/dt was not. Even disregarding the voltage transient on switching anodizing currents the value of dV/dt invariably changed over any appreciable period of growth, *i.e.*, the field in the oxide was a function of D. Figure 4 compares integral and differential field measurements for a sample anodized at 240°C. In the integral field calculations, an attempt was made to allow for the voltage drop across the nonoxide components of the anodizing circuit by extrapolating the V *vs.* D curves to zero thickness and then taking E as given by $(V - V_0)/D$ where V_0 is the voltage intercept at the $D = 0$ axis, see Fig. 5. From Fig. 4 it can be seen that for low

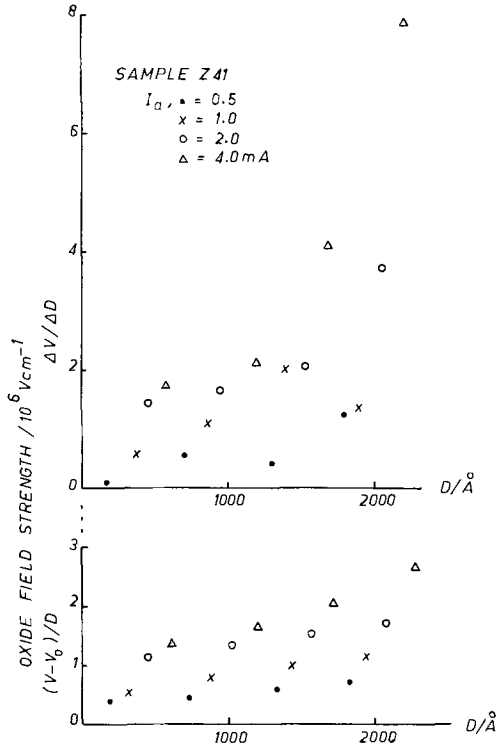

Fig. 4. Variation of oxide field strength with oxide thickness, using both "integral" and "differential" methods to estimate E.

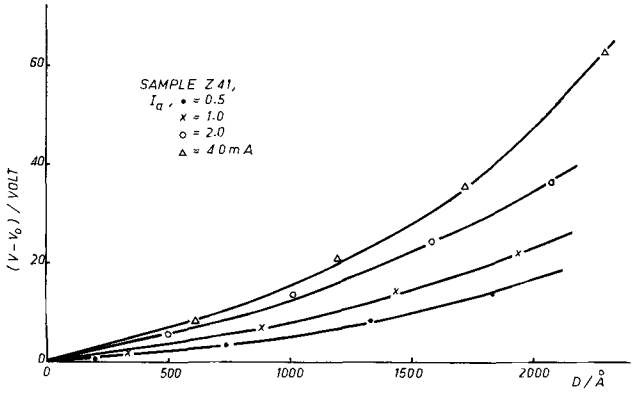

Fig. 5. Variation of estimated voltage drop across the oxide with oxide thickness.

(0.5, 1.0 mA) anodizing currents the integral field is slightly lower than the differential field; this is also the case for high (2.0, 4.0 mA) anodizing currents up to about $D = 1500$Å, after which the differential field values rapidly increase. This latter behavior can be anticipated from Fig. 5 and its explanation may be related to the field-enhanced trapping mechanism suggested earlier. Figure 4 indicates the reduced scatter in the integral field measurements and this was even more apparent at lower temperatures where the voltage transients on switching anodizing currents were longer, leading to large uncertainties in the $\Delta V/\Delta D$ calculations. For this reason the integral field method was used to estimate E.

Dependence of ionic current on oxide field strength.—Because of the thickness dependence of both E and J_{ion} the relationship between J_{ion} and E can be meaningfully derived only by using data at a particular value of thickness. Accordingly, for each anodization, plots of J_{ion} *vs.* D and E *vs.* D (see lower plot of Fig. 4) were made and, for each anodizing current, J_{ion} and E values were read off at thicknesses of 500, 1000, 1500, and 2000Å. The results are shown in Fig. 6, from which it appears that log J_{ion} is linearly related to E, with a

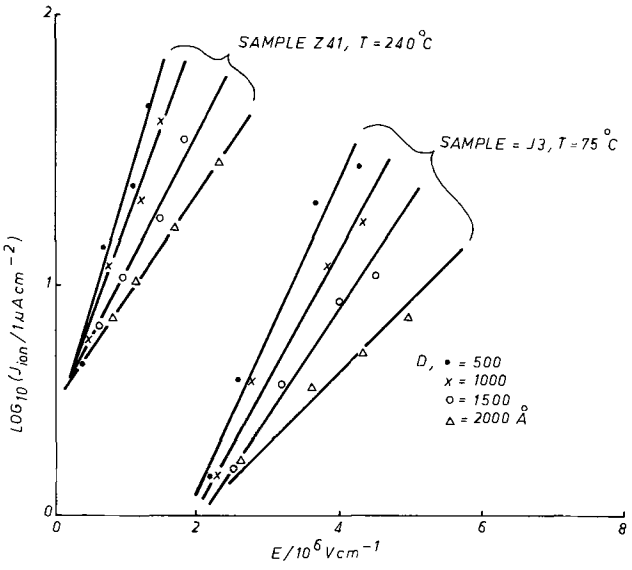

Fig. 6. Variation of ionic current density with oxide field strength

slope that is a function of film thickness. For a given thickness then, a field-assisted, thermally activated, high field ionic conduction mechanism, characterized by the following equation

$$J_{\text{ion}} = J_0 \exp \frac{(\beta E - W)}{kT} \qquad [3]$$

describes the data; J_0 and β are constants and W is the zero field activation energy. However, Eq. [3] would have to be modified by the inclusion of thickness dependent terms for J_{ion} and E, if the equation is to describe the oxide growth mechanism at all thicknesses. It is perhaps noteworthy that the "Tafel plots" of Fig. 6 can, for a given temperature, be made to coincide by plotting E *vs.* $(1 + D/D_0) \cdot \log J_{\text{ion}}$ where D_0 is a constant. The results of this operation performed on the two samples referred to in Fig. 6 are shown in Fig. 7, where D_0 has been taken as 2000Å for sample Z41 and 750Å for sample J3, thus suggesting that D_0 is temperature dependent. The implied equation for the ionic current relationship with field is thus

$$J_{\text{ion}} = J_0 \exp\left(-\frac{W}{kT}\right) \exp\left\{\left(\frac{D_0(T)}{D_0(T) + D}\right) \cdot \frac{\beta E}{kT}\right\} \qquad [4]$$

A particular growth process that can be described by Eq. [4] is not obviously apparent.

An alternative approach to explaining the variation of the log J_{ion} *vs.* E data with thickness would be to disregard the variation of J_{ion} with D and consider only the thickness dependence of E. This seems reasonable in view of the relative magnitudes of the two effects (see *e.g.* Fig. 3 and 4) and also because of the variation in the thickness dependence of J_{ion} from sample to sample. While in all samples anodized at 0.5, 1.0, 2.0, and 4.0 mA, J_{ion} at the two higher values of I_a decreased with D, a number of samples anodized solely at 2.0 mA showed a constant value of J_{ion}. Possibly the high current (4.0 mA) formations produced inferior oxide due to increased disturbances in the plasma. Thus, whereas the variation of J_{ion} with D may not be an intrinsic feature of the growth process, the variation of E with D would appear to be so as the samples anodized solely at 2.0 mA showed an increase of E with D similar to that recorded during anodizations using the four previously mentioned anodizing currents.

An increase in E with D could be caused by the progressive build up of positive space charge in the oxide such that the measured field in the oxide could be expressed as

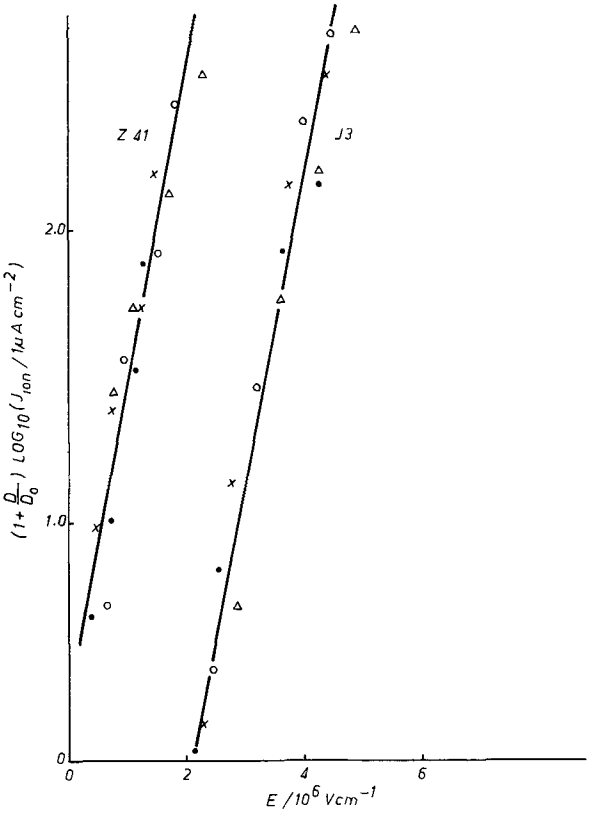

Fig. 7. Variation of $(1 + D/D_0)$ log J_{ion} with oxide field strength where D_0 = 2000Å for sample Z41 and 750Å for sample J3.

$$E = E_{J\text{ion}} + A(D) \qquad [5]$$

where $E_{J\text{ion}}$ is the field in the charge-free oxide required to drive an ionic current J_{ion} through the oxide and $A(D)$ is the component of field in the oxide due to the space charge. Using Eq. [5] in Eq. [3] it is possible to see in principle how the data of Fig. 6 could indeed be compatible with a high field ionic conduction mechanism. The simplest form of $A(D)$ would be that of a uniform distribution, ρ, of positive charge in which case

$$A(D) = \frac{\rho D}{2\,\epsilon_{\text{ox}}} \qquad [6]$$

where ϵ_{ox} is the permittivity of the oxide. However in practice, the distribution given by Eq. [6] would not allow the data of Fig. 6 to be completely described by a simple equation such as Eq. [3], as the slope of the log J_{ion} *vs.* E plots varies with thickness. Apparently the space charge term must also show a dependence on J_{ion} or I_a, say $B(D, I)$, with the effect being smaller at low total or ionic currents. A model involving the field-enhanced trapping of positive charge (holes or ions) could presumably produce the required general form of B. Evidence that the oxides did indeed contain a net positive charge density is furnished by the MOS C-V measurements described below.

MOS measurements.—MOS capacitors were fabricated from samples of various oxide thickness by evaporation of Al gate electrodes (diameter 76 × 10^{-3} cm) through a beryllium-copper mask. All the samples were anodized (separately) at I_a = 2.0 mA and T = 240°C. C-V measurements at 1 MHz were made using a Boonton capacitance meter; also C-V and G-V measurements were made at 500 kHz using a Boonton 75-C bridge.

An interesting point of the C-V measurements would seem to be the variation of flatband voltage V_{FB} with D; see Fig. 8. The increase in V_{FB} with D could be attributed to a progressive build up of positive charge within the oxide, and this apparently continues until

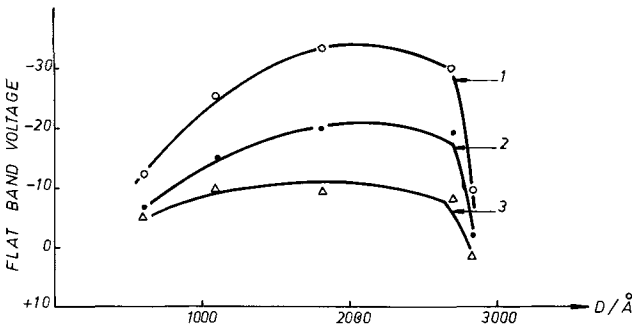

Fig. 8. Variation of flatband voltage with oxide thickness for Al/plasma-grown SiO_2 capacitors. ○ = unannealed samples; △ = samples annealed with Al gate electrode; ● = samples annealed without Al gate electrode.

around 2200Å whereafter V_{FB} falls, slowly at first to about 2700Å and then very rapidly. The decrease in V_{FB} presumably indicates a discharge or neutralization of the space charge. Supporting evidence for this suggestion may be inferred from the *G-V* relationships; namely, the sample of oxide thickness 2840Å (see Fig. 8) did not exhibit a peak in *G*, as shown by the samples of *D* equal to 1100, 1810, and 2695Å and consistent with the presence of surface states at the silicon/oxide interface, but rather displayed a conductance that increased rapidly with negative bias leading to oxide breakdown. The thinnest oxide tested, 590Å, also showed this behavior. Presumably in the case of these latter two samples the oxide conductivity is high and dominates the measured *G*. In the case of the thicker sample, where positive charge has been postulated to be present in the oxide, the increased conductivity of the oxide could be expected to result in neutralization of the trapped charge. Oxides thicker than about 2500Å exhibited small (3×10^{-5}m diameter) "blistered" regions and these are probably related to the suggested conductivity increase.

A positive space charge in the oxide can be thought of as either trapped holes or trapped Si ions. The distinction would appear to be that holes would be formed by ionizing radiation (or electrons) from the plasma, whereas the trapped Si ions could be a proportion of those released from the semiconductor in the normal course of supplying ions for the high field ionic conduction process. In either event, neutralization of this space charge would be expected on annealing the samples, *i.e.*, thermally injecting electrons into the oxide, and this is confirmed by the data shown in Fig. 8; curve 1 is the variation of V_{FB} with *D* for the unannealed samples and curves 2 and 3 show the effect of annealing for 1 hr in dry nitrogen at 350°C; curve 3 related to *C-V* measurements taken on capacitors where the Al gate electrode was evaporated prior to annealing, while curve 2 is for the case of post-anneal Al gate evaporation.

Fritzsche (20) has proposed that Si ions are involved in the anodic growth process and are created by ionizing collisions between lattice atoms and electrons accelerated to high velocities by the high field within the oxide. The oxide field strengths in the plasma anodization process reported here are an order of magnitude less than those recorded in solution anodization by Fritzsche (20), and Young and Zobel (19), so presumably ion formation would be much reduced in the plasma case. However, the fact that the current efficiencies for oxide growth appear to be similar for plasma and solution anodization suggests that growth-supporting Si ions are not produced in this manner. Furthermore, taking the ionization energy for SiO_2 to be 11 eV (20), at oxide field strengths of 2×10^6 V/cm an electron would need a mean free path of 550Å to gain sufficient energy to cause ionization. Such a path length seems improbable.

For the classical high field ionic conduction mechanism to be responsible for ion movement within the oxide the mobile Si ions, assuming these to be the sole ionic charge carriers during plasma anodization as is reputedly the case in solution anodization (22), would originate at the semiconductor/oxide interface. The region of densest trapped charge would thus perhaps be expected to be close to this interface, forming a charge region similar to that designated Q_{ss} in literature (23) on MOS structures with conventional, thermally grown, oxide. In this case, writing the oxide capacitance per unit area as C_{ox}, we have

$$V_{FB} = -\frac{Q_{ss}}{C_{ox}} = -\frac{Q_{ss}}{\epsilon_{ox}} D$$

and thus V_{FB} would be expected to increase with oxide thickness even if Q_{ss} was constant. By drawing a straight line through the data points up to $D = 2000$Å on curve 1 of Fig. 8, a value of Q_{ss}/ϵ_{ox} of 2×10^6 V/cm is obtained. The oxide permittivity can be estimated from measurements of the MOS capacitance in strong accumulation, see Fig. 9, and a value of $3.5\epsilon_0$ yields a Q_{ss} of 4×10^{12} charges/cm^2. Such a magnitude of charge is not unreasonable but, even though the space charge field is of the order of those measured during anodization, it is independent of oxide thickness and thus does not have the form required by Eq. [5]. A progressive build up of space charge throughout the oxide thus seems a more likely explanation of the flatband and oxide field dependencies on oxide thickness. The space charge could be due to trapped holes but if so these are not likely to be produced by Fritzsche's mechanism because the required mean free path of electrons in the oxide is comparable with the film thickness. Injection of holes from the substrate is also unlikely, Alternatively, positive space charge could be due to silicon (entering from the substrate) or to vacant oxygen sites. Whatever the mechanism it appears that trapping is field dependent and leads to a decrease in slope of the "Tafel plots" with increasing oxide thickness.

Acknowledgment

The authors would like to thank Mr. F. Scholz for experimental assistance during the early part of this work and Mr. J. J. H. Reche for many helpful discussions and for constructing the reflectance analog computer. Grateful acknowledgment for financial assist-

Physical Properties of Thick Sputter-Deposited Glass Films

D. M. Mattox and G. J. Kominiak

Sandia Laboratories, Division 5332, Albuquerque, New Mexico 87115

ABSTRACT

The coefficient of thermal expansion (CTE) of 5μ thick rf sputter-deposited Corning 1720 glass films was measured using a cantilever beam technique. The films were rf-bias sputtered in an argon (Ar films) and an argon-5% oxygen (Ar/O_2 films) gas mixture. The Ar films deposited with a low substrate bias (+30, 0, and −50V) exhibited an erratic CTE on initial heating but were well behaved after a 600°C air anneal. High bias (−100, −200V) Ar films and Ar/O_2 films showed no erratic behavior on initial heating. Chemical analysis indicated no significant change in the minor constituents of the sputtered glass, but neutron activation analysis showed a progressively greater oxygen depletion with increasing negative bias for both the Ar and Ar/O_2 films. Etch rates were shown to increase with increasing negative bias. It is suggested that the structural changes that occur in some glass films at temperatures far below the strain point of the bulk glass (670°C) are due to a combination of intrinsic stress and a high concentration of defects. Surface coverage by the sputter-deposited glass films is discussed.

The use of sputtered films of any type has several potential problem areas: (*i*) The films may contain high concentrations of defects and be highly stressed. This may be reflected in unusual physical behavior such as the room temperature structural changes noted in high-rate sputter-deposited copper (1). (*ii*) For complex materials such as glasses, alloys, and compounds, there may be compositional changes during deposition (2) which can affect the properties of the material. For SiO_2, oxygen depletion is a commonly observed compositional change (3). (*iii*) Sometimes there are unusual structural and crystalline modifications found in sputter-deposited films which may give properties differing from those of the bulk material (4). It is the exception rather than the rule when deposited films have bulk properties.

Generally, the physical properties of thin sputter-deposited glass films are not of great concern; however, as the film thickness increases, the properties may become important in specific applications. In this investigation, the coefficient of thermal expansion (CTE) of 5μ thick rf sputter-deposited glass films was investigated as a function of substrate bias during deposition and as a function of sputtering gas composition. It was found that after annealing, the sputter-deposited films had a CTE close to that of the bulk glass. Before annealing, films deposited under some conditions showed an erratic behavior of the CTE.

The ability of the deposited films to cover surface topography was also studied. Generally, it has been found that films deposited by some type of negative substrate bias deposition technique show a better ability to cover surface discontinuities than do films deposited with no bias (5).

Key words: sputtered glass films, bias, strain point, surface coverage, composition, coefficient of thermal expansion.

Experimental

An axially symmetric sputtering system with a planar diode design was used to rf sputter deposit the glass films (6). The substrates were clamped to an electrically isolated, water-cooled holder which was an integral part of the top plate of the vacuum system. This "sputter-up" design was used to minimize the problem of dust and debris falling on the substrate and causing pinholes. The 0.6 cm thick Corning 1720

glass (an alumino-silicate glass) plate used as a sputtering target was laid on a water-cooled copper block. A problem was encountered in nonuniform heating of the glass plate during sputtering, causing cracking. The edges of the cracks then showed increased sputtering rates. Copper was also found to migrate along nonseparated cracks, giving contamination in the deposited film. This problem was alleviated by the insertion of a 0.3 cm thick fused quartz plate between the 1720 glass sputtering target and the copper cooling block.

The rf sputtering supply was a commercial MRC Model 3007 unit capacitively coupled to the target and substrate holder by conventional "L" tuning networks. Power input and rf peak voltage were held constant during deposition and the reflected power was minimized. Substrate biases were obtained either by tuning the substrate with respect to ground (7) to obtain low positive (+30V), zero, and low negative (−50V) biases, or by utilizing the rf splitting network on the power supply to obtain higher negative biases (−100 and −200V).

A shutter which could be rotated in a plane parallel to the electrodes and moved vertically was used in the system. This shutter allowed sputter cleaning of the substrates and presputtering of the target without cross contamination. It also allowed slow target warm-up and a stable sputtering condition to be established before beginning sputter deposition on the substrates.

A target-substrate distance of 7 cm was used throughout the investigation. A 50 oersted axial magnetic field was used for all depositions except for the high negative bias conditions where the magnetic field prevented the establishing of a stable discharge.

Commercial pure argon (Ar) gas and an argon-5% oxygen (Ar/O_2) gas mixture was used for sputtering. Flow rates were controlled using a variable leak while the gas pressure was monitored using a Schultz-Phelps high pressure ionization gauge. Vacuum system throughput was controlled by throttling the gate valve. The gas inlet was in the top of the chamber, and gas was removed through the baseplate.

For measurement of physical properties, glass films deposited in pure argon (Ar films) were deposited on 1 × 7 cm tungsten beams 0.1 mm thick. When using Ar/O_2, plasma oxidation of the tungsten was excessive and the glass films (Ar/O_2 films) were deposited on 0.2 mm thick alumina beams. Films for chemical analysis were deposited on carbon, high resistivity low oxygen silicon slices, and low gas content platinum. The substrates were clamped to the water-cooled substrate block using no contacting material.

In order to cover steps and defects, film thicknesses of 5-10μ were desired. With the sputtering conditions used, the deposition rate was about 1 μ/hr (4 $\mu g/cm^2$/min). The sputtering rate in Ar varied from 5 $\mu g/cm^2$/min at 2 kV target potential and +30V bias to 3 $\mu g/cm^2$/min at −200V bias. Rates in Ar/O_2 showed the same variation with bias and about a 20% decrease in deposition rate at a given bias as compared to argon sputtering. This decrease of sputtering rate with the addition of oxygen is appreciably less than that reported in the literature for sputtering SiO_2 films (8).

The substrates were solvent cleaned before being mounted in the vacuum system. The vacuum system was pumped to 5×10^{-6} Torr, after which the gas inlet was opened and gas flow regulated to give 1μ indicated pressure in the chamber. The gate valve of the vacuum system was then throttled to give a final pressure of 10μ in the chamber. The pressure was monitored throughout the deposition.

The substrates were sputter cleaned at 1 kV rf for about 30 min with the shutter covering the sputtering target. The shutter was then moved to cover the substrates and the target was presputtered. The presputtering of the target was done by slowly increasing the input power so as to allow gradual heating of the target to prevent shattering from thermal shock. The target voltage was raised to 2 kV peak-to-peak rf which required a power level of about 1000W to the 15 cm diameter target.

After steady state was established, the shutter was opened and the deposition was made for a predetermined time to give the desired film thickness. After the deposition was complete, the system was allowed to cool under vacuum before the films were removed. In order to form pinhole-free films, it was found necessary to deposit the film using two to three depositions. Between depositions the substrates were removed and the surface rubbed with acetone on a lint-free cloth. This procedure apparently moved or removed particulate contamination to the extent necessary to prevent pinholes from propagating through the several glass layers. The layers were lightly sputter cleaned between depositions.

After deposition the coated beam was mounted in a muffle furnace having an optical window in such a way that the deflection on heating was perpendicular to the gravitational field to eliminate gravitational deflection. The cantilevered beam was then heated in 100°C increments and the deflection of the free end was measured using an optical cathetometer.

The radius of curvature ρ of the beam was then determined using the equation

$$\frac{1}{\rho} \approx \frac{2\delta}{L^2}$$

where δ = the deflection of the end of the beam and L = the beam length.

The coefficient of thermal expansion (CTE) was calculated using the equation (9, 10)

$$\frac{1}{\rho} = 6(\alpha_f - \alpha_s)\Delta T(1+m)^2/h \left\{ 3(1+m)^2 + (1+mn)\left(m^2 + \frac{1}{mn}\right) \right\}$$

where ρ = radius of curvature, α_f = expansion coefficient of film, α_s = expansion coefficient of substrate, ΔT = temperature increment, m = thickness of substrate/thickness of film, and h = total thickness. Bulk modulus values were used for the glass film.

Results

Figure 1 shows the normalized beam deflection of an Ar +30 film (argon gas, +30V bias) as a function of temperature. On initial heating, the deflection is seen to vary erratically and actually change sign. Other Ar low bias films showed the same behavior on initial heating, though not as radically as did the Ar +30 films. The Ar/O_2 films did not show this erratic behavior with the exception of the Ar/O_2 −50 films, in

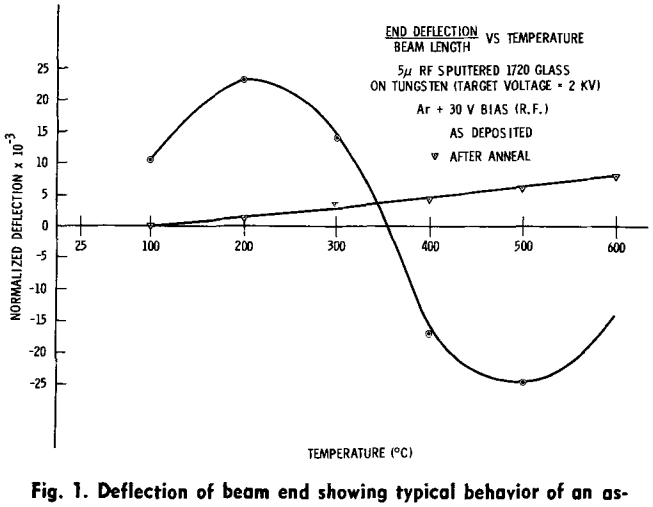

Fig. 1. Deflection of beam end showing typical behavior of an as-deposited film and an annealed film (extreme examples).

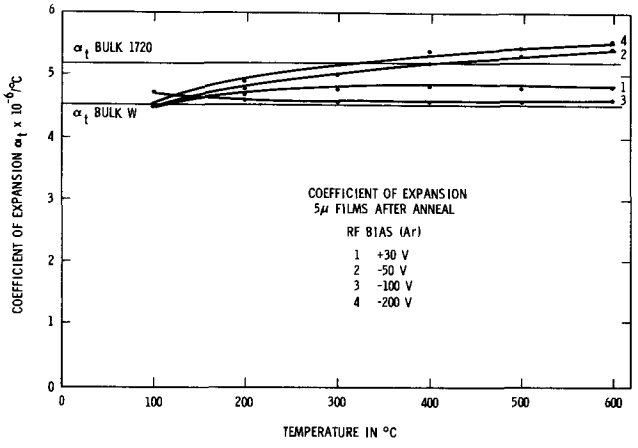

Fig. 2. Coefficient of thermal expansion of 5μ thick glass films after annealing as a function of rf bias on the substrate during deposition. Values accurate to ± 10%.

which it occurred to a slight extent. Initial deflection of the beam at room temperature showed that the Ar +30 as-deposited films had a high compressive stress.

After annealing to 600°C in air for less than 1 hr, all beams showed the type of deflection shown by the straight line in Fig. 1. Figure 2 shows the CTE of Ar films prepared with various biases after annealing compared with the literature values of bulk tungsten and bulk Corning 1720 glass in the 0°-600°C temperature range. The values compare very well. The CTE of the Ar/O_2 films was very close to that of the annealed Ar films. The initial erratic behavior of the Ar films was the source of some concern since stress during initial heating might cause failure in service.

The deposited glass films were analyzed by emission spectroscopy for the minor constituents which normally control the CTE. There was no appreciable change in the minor constituents of the sputter-deposited Ar glass films compared with those of the bulk glass. Neutron activation analysis of the silicon-oxygen ratio was made on the glass films using bulk 1720 glass as a standard. Table I shows that the oxygen depletion is greatest in the high negative bias Ar and Ar/O_2 films. Low bias Ar/O_2 films and the Ar +30 films show the least oxygen depletion. Some oxygen was recovered on annealing the high bias Ar films in air at 600°C, but little oxygen change was noted in the Ar/O_2 films on annealing. The oxygen depletion was also evident in the color; near stoichiometric films were clear and nearly colorless while the oxygen-deficient films had a brown coloration.

The *IR* transmission of thin films (5000Å) deposited on high purity, low oxygen silicon was studied. The +30V films show a broad absorption peak in the range 1100-900 cm^{-1}. The −200V films show a definite Si-O stretching band at about 1100 cm^{-1}. In the Ar +30V film a definite shift of 25 cm^{-1} toward shorter wavelengths was found on annealing, suggesting a bond length change due to stress relief (11, 12) or change in composition. The low bias Ar films also showed appreciable moisture pickup at room temperature, as evidenced by the absorption peak at 3333 cm^{-1} in the as-deposited films. The high bias Ar and Ar/O_2 films showed no such water pickup.

Table I. Oxygen content of glass films as a function of deposition conditions and subsequent anneal. Values obtained by neutron activation analysis using bulk glass as a standard

As deposited Gas	Bias	% (±5) depletion	After 600°C in air % (±5) depletion
Ar	+30	3	4
Ar	0	13	13
Ar	−50	17	15
Ar	−100	16	6
Ar	−200	20	8
Ar/O_2	+30	0	0
Ar/O_2	0	6	7
Ar/O_2	−50	13	12
Ar/O_2	−200	18	15

Thick films (~100μ) were deposited for etch rate studies. A region was masked using acid stopoff and the films were etched in "P-etch" (13)[1] for a period of time sufficient to give about a 25μ step in the glass. After etching, the acid stopoff was removed and the step height was measured using a Talysurf profilometer. Figure 3 shows the etch rates for Ar and Ar/O_2 as-deposited films. The etch rates increased with negative bias and even in the best films, exceed the rate of bulk 1720 by a factor of 2. The high bias films showed bubbling on etching while the low bias films showed no bubbling. After annealing to 600°C in air, the films became fragile, the etch rates approached that of the bulk, and no bubbling was observed on etching. Fusion analysis shows several weight per cent (w/o) argon in the −200V Ar and Ar/O_2 films before annealing and zero (0.01 w/o detection limit) to several tenths of a weight per cent in the zero bias films.

The ability of the sputter-deposited glass films to cover surface discontinuities was found to be very dependent on the type of discontinuity. As shown in Fig. 4, a 5μ glass film covered a 5μ step very well but did not bridge over a void in the surface. Very thick films can fill a void to some extent, as shown in Fig. 5, but the geometrical shadowing of void walls tend to leave a "pipe" of unfilled void. If the void geometry is such that the bottom and walls are out of the line of sight from the target, such as shown in Fig. 6, incomplete sealing of the void can result. This is also the case if the depth of the defect is large compared to the width.

It was found that a high negative rf bias on the substrates during deposition caused appreciable changes in the film morphology when the films were deposited on a surface having severe topological features. Figure 7 shows a fracture cross section of thick glass films deposited on a grainy carbon surface with a +30 and −200V bias. The low bias films show a columnar structure similar to that observed in thick metal films (4). The bias-deposited films show no such structure. The columnar structure is attributed to geometrical shadowing effects as the film is deposited over the rough surface. Ion bombardment of the bias-deposited film during deposition causes resputtering which tends to erode peaks and fill valleys, thus preventing the development of the columnar structure (4).

[1] P-etch = 15 parts hydrofluoric acid, 10 parts nitric acid, and 300 parts water.

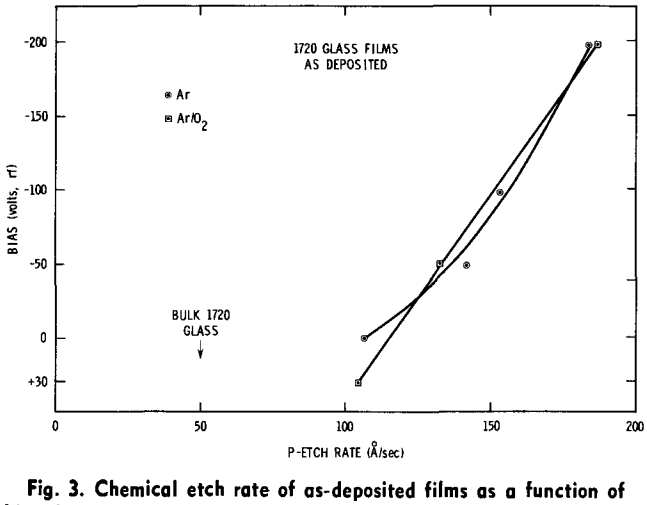

Fig. 3. Chemical etch rate of as-deposited films as a function of bias during deposition (P-etch is 15 parts HF, 10 parts HNO_3, and 300 parts H_2O).

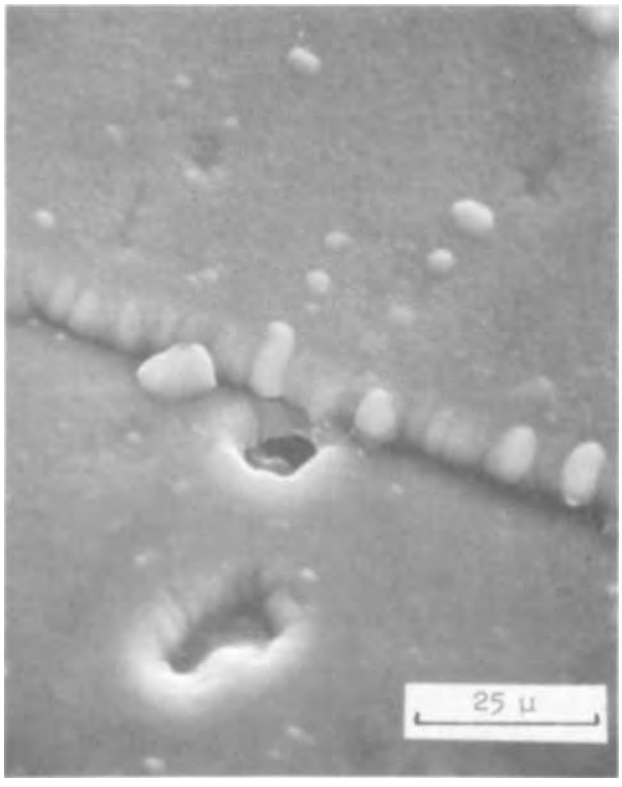

Fig. 4. A 5μ thick tungsten step on a porous surface coated with 5μ of glass. Note that the glass layers did not bridge over the pore in the substrate [scanning electron microscope (SEM)].

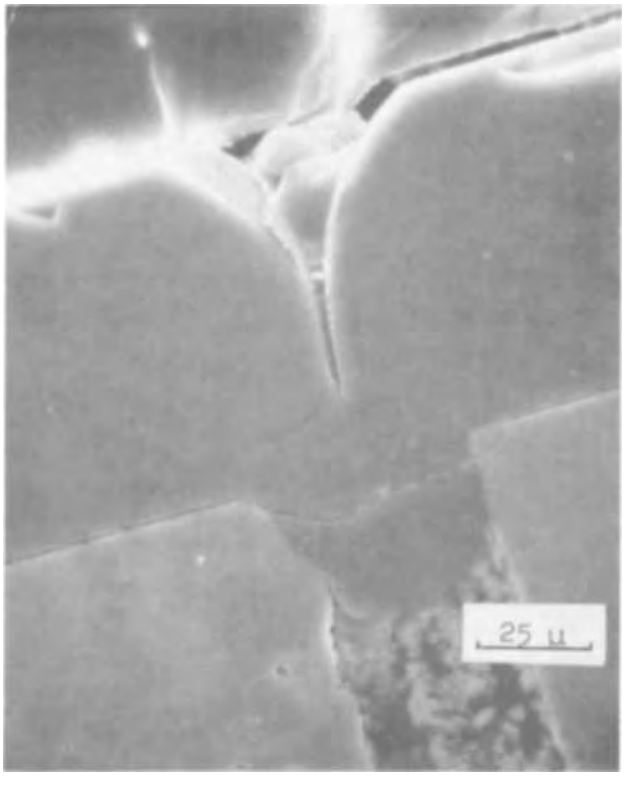

Fig. 5. Very thick glass film deposited over large defect between glass bonded plates. Note the "pipe" of unfilled void caused by geometrical shadowing (SEM fracture cross section).

Discussion and Conclusions

These data indicate that the sputter-deposited 1720 glass films may show structural changes, as evidenced by the CTE behavior, at temperatures as low as 300°C,

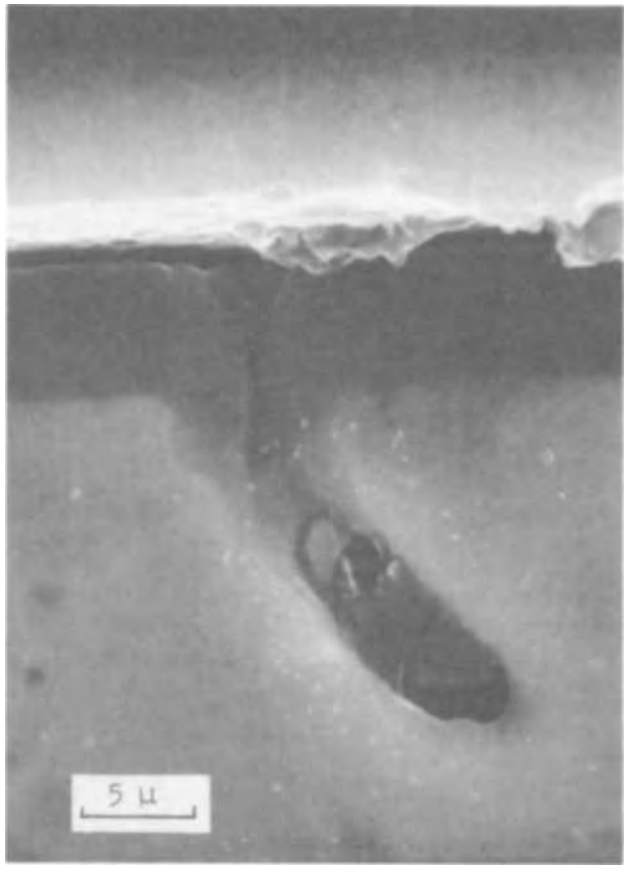

Fig. 6. Small pore in which the bottom is uncoated because of the inability of the depositing glass to reach the bottom either by migration or resputtering (—50V bias) (SEM fracture cross section).

which is far below the strain point of the bulk glass (670°C). The effect is particularly pronounced in films sputtered in pure argon with a low bias on the substrate during deposition. The effect is less pronounced with high substrate biases, probably due to heating during deposition. The effect is also less pronounced when the films are sputter deposited using an Ar-5% O_2 gas mixture for the sputtering gas. After annealing, all films showed a well-behaved CTE and have values close to that of the bulk glass.

All films deposited using pure argon as the sputtering gas showed oxygen depletion. The oxygen depletion increases with negative bias for both Ar and Ar/O_2 films. The oxygen depletion did not seem to drastically affect the CTE of annealed films.

Optical analysis data are not definitive because of the lack of sharply defined adsorption peaks. These data indicate some shift in the Si-O absorption peak in the low bias Ar films with annealing due either to stress relief or compositional change.

The etch rate data seem to be inconsistent with the other data if compared to similar data for SiO_2 films (13). In deposited SiO_2 films, oxygen depletion leads to decreased etch rate while stress and radiation damage give an increased etch rate. In this study the increased etch rate with the substrate bias may be due to appreciable argon incorporated in the deposited films at the high negative biases (14, 15) as well as the ion bombardment damage introduced during the deposition.

It seems that the most stable stoichiometric films are produced by sputtering in Ar/O_2 with a zero or slightly positive (+30V) bias. Films having stable CTE's can be deposited by applying a negative rf substrate bias during deposition, though this leads to an oxygen deficiency. The bombardment during deposition probably causes heating, which anneals the film. A similar effect could probably be obtained by

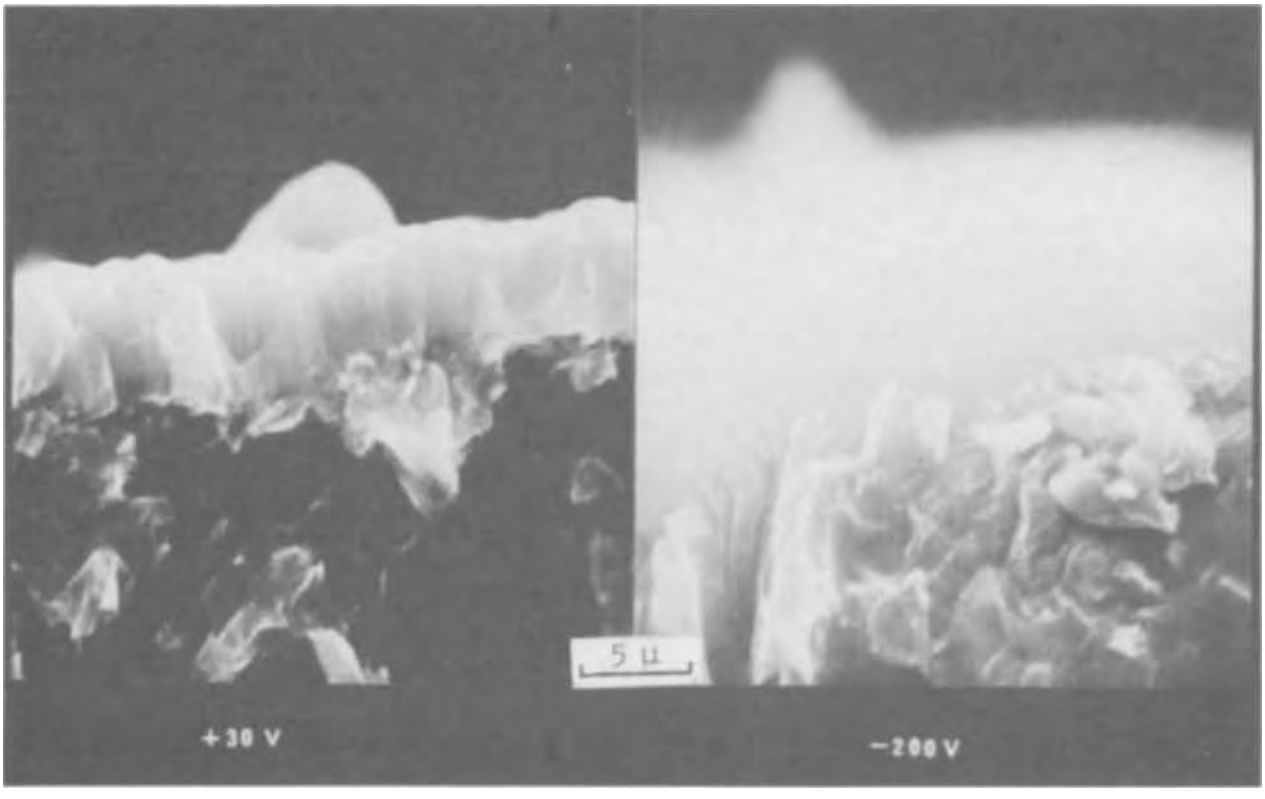

Fig. 7. Fracture cross section of glass films deposited on grainy carbon surfaces with and without a negative substrate bias during deposition. Note the isotropic morphology of the deposit made with a negative substrate bias (SEM).

heating the films to 300°-400°C during deposition. The ion bombardment during deposition could have the undesirable effect of incorporating appreciable amounts of inert gas into the film which could be released during subsequent heating.

The origin of the initial erratic CTE behavior of some films does not appear to be directly related to oxygen deficiency since the most erratic films (+30 Ar) show little oxygen deficiency. It is suggested that a combination of high intrinsic film stress and a high concentration of point defects is the origin of the initial behavior of the CTE. This is consistent with the findings for neutron and x-ray irradiated glasses where low temperature annealing of such defects is noted in their optical behavior (16).

Though the bias deposition of the glass films did significantly change the structure of the films and improve the defect-covering ability, it was still unable to cause complete coating of some defects.

Microstructural Analysis of Evaporated and Pyrolytic Silicon Thin Films

R. M. Anderson

IBM System Products Division, East Fishkill Development Center, Hopewell Junction, New York 12533

ABSTRACT

Transmission electron microscopy, scanning electron microscopy, and x-ray analysis are used to study the structure of evaporated and pyrolytic silicon films (less than 1μ thick) deposited at or heat-treated in the temperature range of 500°-1040°C. It is established that the thin silicon film subjects of this investigation can have three different morphologies: pseudoamorphous, equiaxed grains, or dendritic. These are attributed to be functions of deposition temperature for pyrolytic films and heat-treatment temperature for evaporated films. The nucleation phenomena of pyrolytic silicon thin films as a function of time spent in N_2 prior to silicon deposition is investigated. Also the analysis of possible silicon film impurities is performed.

The use of polycrystalline silicon thin films has lately become of interest in the fabrication of monolithic integrated circuits (1, 2). Several processes can be used to deposit silicon. These include sputtering, evaporation, and chemical vapor deposition. The microstructural analysis of the resulting silicon films has been limited to films deposited on Si_3N_4 or SiO_2 at temperatures over 800°C, and/or films from 10 to 50μ thick (3-5). DeLuca (6) examined pyrolytic thin silicon films deposited on fused silica with deposition temperatures in the range of 700°-1000°C. He employed x-ray diffraction techniques, reflection electron diffraction, and replication electron microscopy to determine the crystallinity, preferred orientations, and surface roughness of the films.

In this paper the internal structure of thin evaporated and pyrolytic polycrystalline silicon films, as revealed by transmission electron microscopy, is of prime interest. Specifically, knowledge of the internal structure of the polycrystalline silicon as a function of the heat-treatment for evaporated silicon films and the effect of deposition temperature for pyrolytic silicon films is studied. The effect of substrate and substrate cleanliness on the structure of pyrolytic silicon thin films, including the sensitivity of the silicon nucleation process as a function of time at temperature in the reactor, is also considered. Transmission electron microscopic results are correlated with scanning electron microscopy of the silicon film surfaces and x-ray analysis of the bulk. Structural data are correlated with sheet resistances of the films. The extension of the temperatures of interest down to 500°C is prompted for reasons of compatibility with the processing of shallow-junction semiconductor devices and the smooth polycrystalline silicon films we find produced at low temperatures.

Key words: semiconductor silicon, electron microscopy, FET (field effect transistor), thin films.

Experimental

Evaporated silicon film sample preparation.—The silicon film evaporations were performed in a Temescal CV-10 four-pocket 180° E-gun system at a pressure of 1×10^{-6} Torr. The rotary hearth substrate temperature was maintained at 300°C. The deposition source was 0.001 ohm-cm boron-doped silicon and the substrates consisted of 3700Å of steam grown SiO_2 on <100> p-type silicon wafers. The deposition rate was 3000 Å/min and the films thickness was 9000Å. The films were heat-treated in flowing nitrogen in an open tube furnace. Four-point probe sheet resistances were measured and are included in Table I.

Pyrolytic silicon film sample preparation.—An Applied Materials Nitrox system modified for high purity FET (field effect transistor) applications was used for all pyrolytic polycrystalline silicon depositions. The samples to be studied for effect-of-deposition temperature were deposited on Si_3N_4 (300Å) on a <100> 1 ohm-cm n-type silicon wafer. The carrier gas was N_2 at a flow rate of 72 liters/min and a SiH_4[1] flow of 55 cm^3/min. Samples were prepared at deposition temperature increments of 25°C from 500°-900°C. Deposition parameters and some relevant electrical measurements from selected samples are tabulated in Table II. To investigate the influence of the substrate on the growth of the films, samples were deposited at 725°C, an N_2 flow of 60 liters/min, and a SiH_4 flow of 30 cm^3/min. The substrates were: (*i*) thermal SiO_2 (500Å), (*ii*) pyrolytic Si_3N_4 (300Å) on pyrolytic SiO_2 (300Å), and (*iii*) pyrolytic Al_2O_3 (900Å) on pyrolytic SiO_2 (300Å). All wafers were <100> 1 ohm-cm n-type silicon. The wafers were fractured in half. Both halves were then chemically cleaned using standard procedures, and then one half was given an additional 160°C, 5-min H_2SO_4 cleaning step.

** V_{BD} for 900°C samples exhibited two gaussian peaks.

Nucleation experiments were made on samples deposited at 710°C, the N_2 flow was 60 liters/min and SiH_4 flow equaled 55 cm^3/min. The substrates were Si_3N_4 (300Å) on pyrolytic SiO_2 (300Å).

Specimen Preparation

The samples were first examined by x-ray diffractometry and low-angle Laue techniques and then fractured into small rectangular pieces to fit in the JEOLCO JEM-200 electron microscope specimen holder. The electron microscope specimens were inverted on a glass microscope slide and masked with wax, leaving the silicon exposed at the center of the back of the specimen. The silicon substrate was etched through the wax mask with a mixture of HF-HNO_3-CH_3COOH (1:2:3) down to the insulator film. All subsequent removal of insulator films and polycrystalline silicon thinning was performed in a Commonwealth ion milling machine. Final Si film thicknesses varied from 1000-7000Å.

Results

Evaporated polycrystalline silicon films.—The morphology of the as-deposited evaporated polycrystalline silicon is pseudoamorphous, *i.e.*, a very small nondiscernible microstructure with just enough order to produce broad diffuse rings centered on major reflections in the electron diffraction patterns. The polycrystalline silicon is unchanged after heat-treating at 450°C for 60 min in N_2.

After the 650°C, 60-min heat-treatment, silicon dendrite structures were observed, indicating that the nucleation of crystalline silicon occurs at a temperature $\leq$ 650°C. Several dendrites are seen in Fig. 1 nucleated in the pseudoamorphous silicon film. The dendrite at A in Fig. 1 is seen in the dark-field electron micrograph. Figure 2 was taken with the $(1\bar{1}1)$ spot as the operating reflection. The selected area electron diffraction pattern is shown as an insert in Fig. 2. Selected area electron diffraction patterns of the individual dendrites were all similar to the Fig. 2 insert which is indexed as the silicon [011] zone. When the directions in the selected area diffraction patterns are rotated to coincide with the directions in the corresponding micrographs, it is noted that the $[01\bar{1}]$ is parallel to long, central arms of the dendrites indicating that the growth direction of the dendrite is in the close-packed $[01\bar{1}]$ as expected. Further, the fine radial structures on the dendrite central arms are normal to the [111] directions in the micrographs. The angle that new dendritic arms make with the central arm is 107°, which is close to the angle (109.5°) that separates the traces of the $(\bar{1}11)$ and the (111) planes in a cubic [011] stereographic projection. The parallel lines and gray spots on the amorphous film are artifactual thickness variations produced during ion-milling of the specimen.

X-ray diffractometry of the 650°C heat-treated sample produced only a weak silicon (220) peak, after the silicon single-crystal substrate reflections were rotated off the Ewald sphere (7). This confirms the highly oriented early stages of the film's crystallization.

Fig. 1. Dendritic silicon nucleating in amorphous evaporated silicon film. Parallel lines and gray spots on amorphous film are ion-milling specimen preparation artifacts.

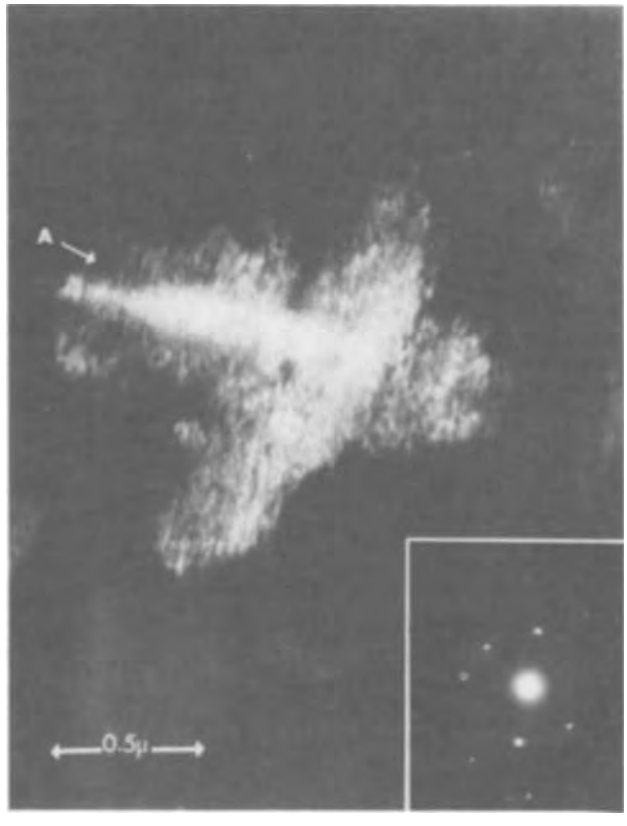

Fig. 2. Dark-field photograph of the dendrite at A in Fig. 1. Insert is selected area electron diffraction pattern from dendrite. The $(1\bar{1}1)$ reflection at 12 o'clock was the operating reflection for the dark-field photograph.

The microstructures of the films heat-treated at 850°C for 60 min indicated that these films went through a dendritic nucleation process as dendrite remnants are observed in the microstructure of the film. Figure 3 depicts several silicon dendrite remnants separated by equiaxed polycrystalline silicon grains. The density of dendrite remnants is lower than the density of dendrites observed in the 650°C film. The polycrystalline silicon grain structure is obscured by a combination of a thin amorphous film on the surface and by occasional crystalline inclusions within the film. The thin amorphous film can be successfully removed by ion-milling and reflections from the crystalline inclusions observed, as shown in the electron diffraction pattern insert in Fig. 3. There are too few unique reflections to make a positive identification of the crystalline inclusions; however, the indexed reflections we noted correspond to the strong reflections reported for Si_2ON, SiO_2 (tridymite), and/or the low temperature modification of Si_3N_4. The normal mean grain size of the equiaxed grains in the 850°C, 60-min film samples is 6400Å with a standard deviation of 1300Å. Now that the polycrystalline silicon film has fully crystallized we see a dramatic decrease in sheet resistance as tabulated in Table I.

After the 1040°C, 60-min heat-treatment the polycrystalline silicon film had a microstructure consisting solely of equiaxed silicon grains (Fig. 4). No dendrite remnants were observed. The film had a lower number of defects but grain boundaries were still unclear. The normal mean grain size for this film is 2050Å with a standard deviation of 230Å. Confirmation of the decreased grain size compared with the 850°C, 60-min sample is seen in the diffraction pattern inserts in Fig. 3 and 4, taken with the same selector aperture, where the polycrystalline silicon rings are observed to be more nearly continuous for the higher temperature. The same nonpolycrystalline silicon reflections mentioned above were occasionally observed in the diffraction pattern of this sample.

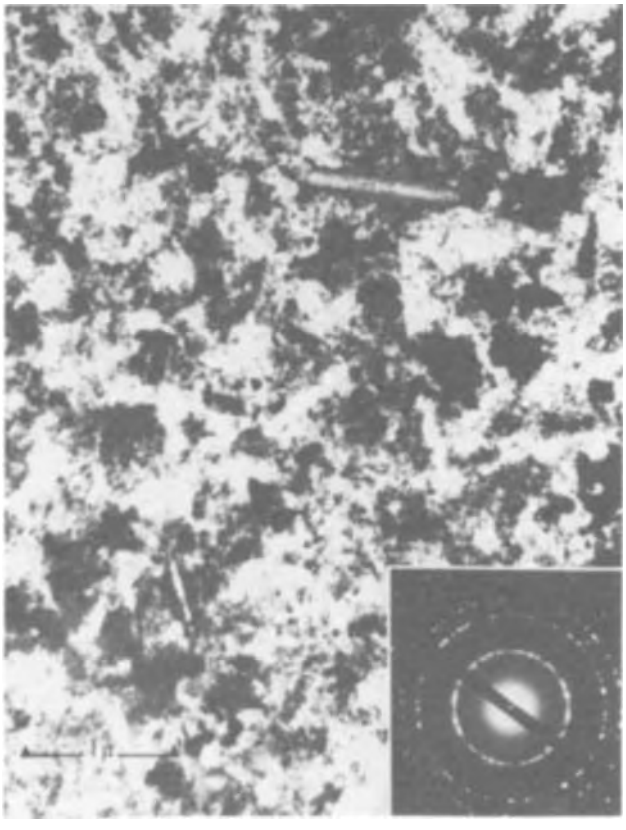

Fig. 3. Microstructure and diffraction pattern of evaporated film after 850°C heat-treatment; dendrite remnants are seen at D.

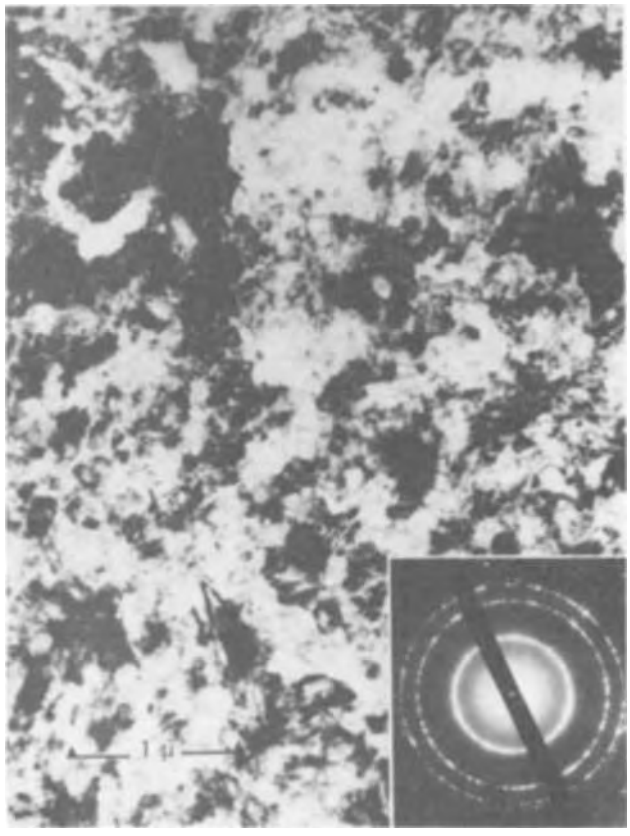

Fig. 4. Microstructure and diffraction pattern of evaporated film heat-treated at 1040°C.

X-ray diffractometry of the 850° and 1040°C heat-treated samples produced a sufficient number of diffraction peaks for a Nelson-Riley function plot, which in turn yielded stress data for the films (7). The higher order peaks in the back-reflection region were too weak, due to sample thinness, to yield a stacking fault calculation or two-exposure stress analysis. Table I shows that all films have a high faulting density, which is listed as twin probability. This probability decreases with increasing heat-treatment temperature which correlates with the lower number of defects observed in the 1040°C samples. Of significance is the observation from Table I that the stress determined from the Nelson-Riley function plots is reduced with increasing heat-treatment temperature, halving from 850° to 1040°C.

Pyrolytic polycrystalline silicon films.—Pyrolytic silicon films deposited at temperatures up to 650°C have pseudoamorphous structures. Typical diffraction patterns show broad diffuse rings. The first ring corresponds to the silicon (111) diffraction radius and the second ring spans the radii of the (220) and (311) silicon rings. SEM micrographs of the films show smooth featureless surfaces for deposition temperatures to 650°C.

The sample deposited at 675°C exhibited a small equiaxed polycrystalline-silicon grain structure, indicating that the transition between a pseudoamorphous silicon film and a crystalline silicon film occurs between the 650° and the 675°C deposition temperatures. This transition point is confirmed by x-ray, low-angle Laue photographs and the change in appearance of the surface as seen by the SEM. The samples retained an equiaxed grain structure from 675° through 875°C depositions, exhibiting only grain growth. All of the samples observed in this lot in the deposition temperature range from 675° to 875°C had a vertical duplex grain structure consisting of small discontinuous 200-300Å grains at the film-substrate interface, and con-

tinuous large grains[2] through the balance of the film's thickness. This morphology is seen in Fig. 5 taken through an entire 1μ thick film; the large grains (~1 cm in the photo) have small (~1 mm) grains superimposed on them. A sample was prepared by ion-milling the polycrystalline silicon from the surface side down to the substrate interface, as seen in Fig. 6. Some areas are etched completely through the large grains (at E) revealing the small slower etching grains at the interface clearly. Figure 7 is a montage of a diffraction pattern from the small silicon grains contrasted with a diffraction pattern from large silicon grains. As seen in Fig. 7, the small-grain silicon diffraction pattern contains extra silicon rings which arise from silicon reflections which are normally disallowed due to crystal structure factor reasons.

To gain a better understanding of the formation of the small grain silicon layer at the oxide interface, we prepared a set of samples with increasing thicknesses of polycrystalline silicon; 130, 270, 400, 800, and 1600Å thick films were examined. The 130Å thick film was discontinuous and the remainder of the films were continuous with the grain sizes reported in Table III. Interestingly, the small grain layer did not nucleate under the thin samples. Selected area diffraction patterns of the thinnest (130Å thick) sample exhibited the normal complement of silicon reflections, which eliminated one reason for the forbidden reflections as being due to the relaxation of the diamond cubic structure factor rules as a result of extreme sample thinness.

A TEM sample prepared using the center of the thick, polycrystalline silicon specimen instead of the interface (Fig. 8) shows a normal polycrystalline silicon microstructure consisting of uniform equiaxed grains which contain numerous twin lamella. The microstructure in Fig. 8 is also seen throughout the thickness of the thin nucleation layer specimens and

[2] Grain size data is tabulated in Table III.

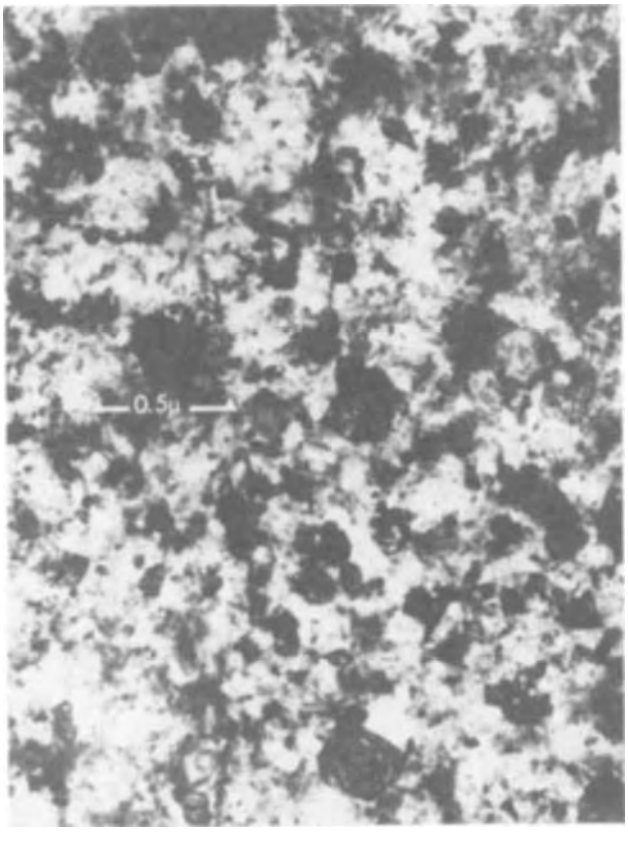

Fig. 5. Microstructure of pyrolytic silicon film deposited at 700°C. Superposition of large grains in bulk of film and small anomalous grains at the substrate interface.

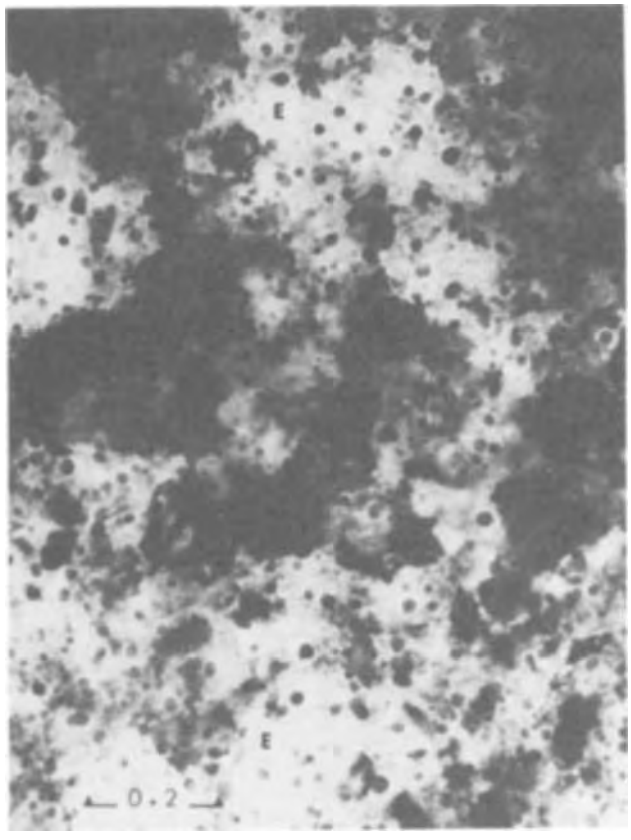

Fig. 6. Silicon film from Fig. 5 after ion-milling down to ~500Å from film substrate interface. Discontinuous anomalous silicon grains are clearly visible.

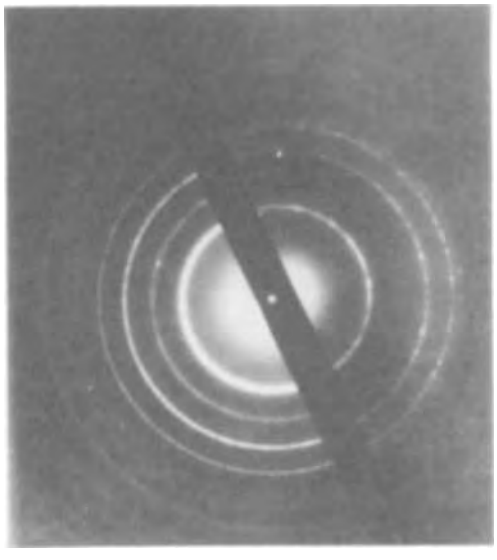

Fig. 7. A montage of selected area electron diffraction patterns from normal polycrystalline silicon grains, left, and anomalous grains, right.

is typical of virtually all of the polycrystalline evaporated and pyrolytic silicon samples observed in this study.

X-ray, low-angle Laue photographs of the 1μ thick 700° and 800°C deposited samples show a randomly oriented polycrystalline silicon film with a crystallite size in the 1500-8000Å x-ray insensitive region.

The 1μ thick films have a very low stress (3000 psi) and a moderately high lattice parameter shift due to solid solution effects.

SEM photos of the 700° and 800°C samples (Fig. 9) show a typical polycrystalline surface: the bumps are about 1000Å high.

Table III. Grain size data for pyrolytic silicon thin films

1. Effect of deposition temperature samples

Dep. temp, °C	Normal mean grain size, Å	Standard deviation, Å	Grain boundary area per unit volume,*** mm^2/mm^3
<675	—*	—*	*
700	1470	50	4.1×10^5
800	1870	90	3.3×10^5
900	—**	**	5.2×10^5

* Films are amorphous.
** Film has dendritic structure consisting of 1.5μ dendrites and ~500Å equiaxed grains.
*** Calculated using appropriate grain shape factors.

2. Effect of substrate and substrate cleanliness

Substrate,	Dep. temp, °C	H_2SO_4 step?	Normal mean grain size, Å	Standard deviation, Å
SiO_2	725	No	2419	100
Si_3N_4	725	No	2590	130
Al_2O_3	725	No	2680	100
SiO_2	725	Yes	2410	140
Si_3N_4	725	Yes	2340	120
Al_2O_3	725	Yes	2590	120

3. Thin nucleation layer experiment

Dep. temp, °C	Dep. time, sec	Film thickness, Å	Normal mean grain size, Å	Standard deviation, Å
715	10	130	210	10
715	20	270	290	10
715	30	400	380	20
715	60	800	560	40
715	120	1600	800	70

* Film not continuous.

Polycrystalline silicon samples deposited at and above 900°C exhibit a dendritic structure. A typical morphology is seen in Fig. 10. The dendrites "D" bear the same crystallographic relationships to the substrate and internally as the dendrites observed in evaporated films. The spaces between the dendrite arms are filled with small, equiaxed polycrystalline silicon grains approximately 500Å in size. X-ray diffractometry confirms the {110} sheet texture.

SEM photographs (Fig. 11) of the 900°C deposited sample show that dendrite arms stick up from the surface to heights of up to 2μ. We measured the density of dendrites taller than 1μ as one per $10\mu^2$ and the density of smaller sharp dendrites at about ten times the density of the larger ones. The sharpest point observed on a tall dendrite had a tip radius of 500Å; most of the tall dendrites have tip radii of 2000-3000Å. A subsequent oxidation and HF strip of the film removed the large dendritic spikes.

As seen in the grain size data in Table III, there is very little difference between the films deposited on SiO_2, Si_3N_4, and Al_2O_3. In all cases the films were morphologically similar and the thin layer of anomalous silicon grains was noted at the substrate interfaces. The films were also insensitive to the different cleaning procedures performed on the substrates prior to deposition.

Selected wafer samples from the effect-of-deposition temperature lot were divided in half: one half for microstructural analysis and the other half for a thermal SiO_2 deposition 1750Å thick. Breakdown voltage measurements were made of the SiO_2 and are tabulated in Table II. Breakdown voltage is seen to correlate with the surface morphology of the film; the double peak on the 900°C samples probably is due to random samples either containing or not containing dendritic spikes.

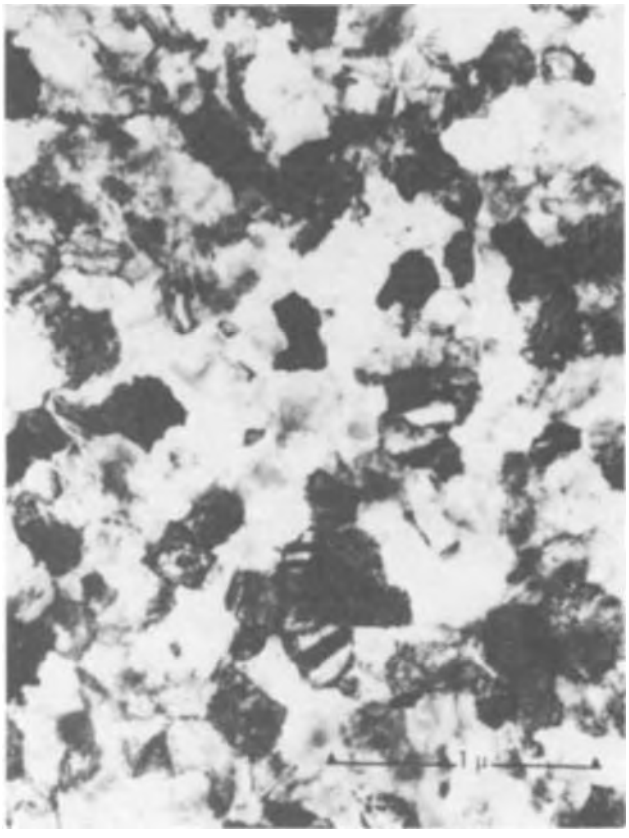

Fig. 8. Microstructure of normal polycrystalline pyrolytic silicon grains, 800°C sample.

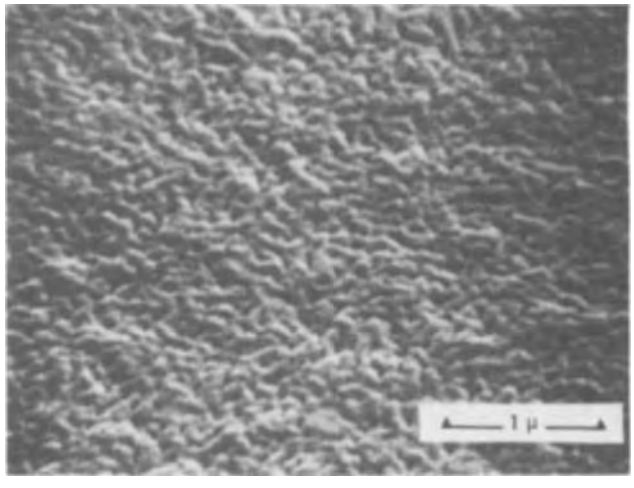

Fig. 9. Scanning electron micrograph of surface of 800°C polycrystalline silicon surface.

Analysis of silicon film impurities.—Reference has been made in the text to the observation of impurities, viz., amorphous surface films, crystalline inclusions in the films, defects within the silicon grains, and anomalous small silicon grains at the substrate interface of certain pyrolytic silicon films. The possibility exists that some of the results obtained may be due to impurities in the films. The silicon films that are the subject of this investigation were fabricated in carefully controlled laboratory apparatus used for FET applications, and only the highest quality materials obtainable were used. Electrical resistivity and Hall effect measurements could not detect any trace of impurities in the films. X-ray diffractometry and low-angle Laue analysis revealed no gross crystalline impurities.

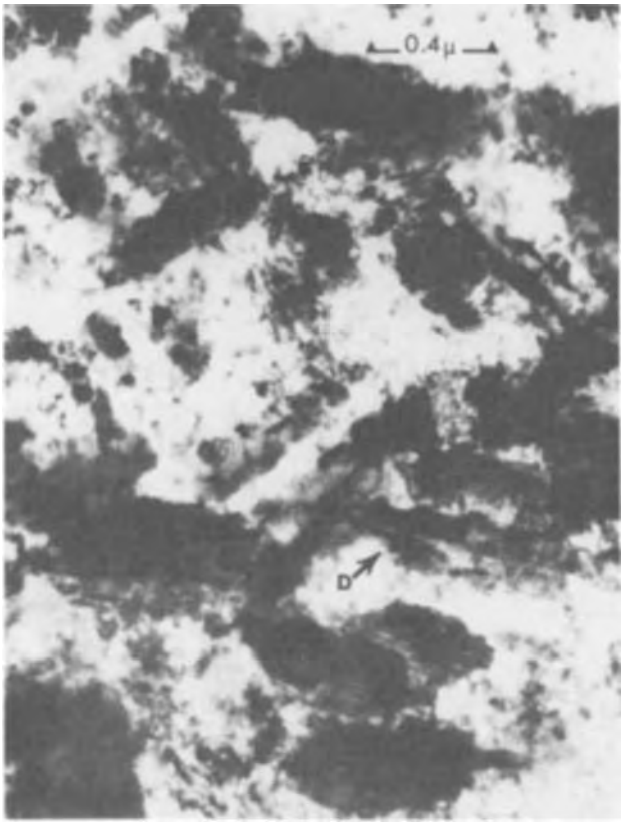

Fig. 10. Transmission electron micrograph of mixed silicon dendrites and equiaxed silicon grains between dendrites on 900°C pyrolytic sample.

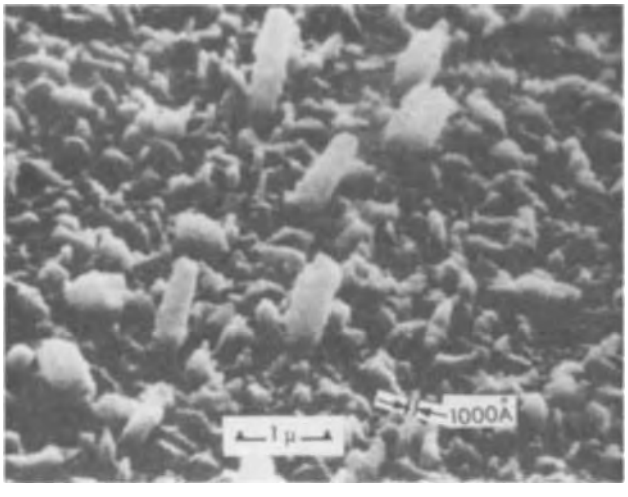

Fig. 11. Scanning electron micrograph of surface of dendritic 900°C sample.

Selected area electron diffraction techniques were able to obtain nonsilicon reflections from the occasional crystalline inclusions observed in the films and, as discussed above, tentatively identified the inclusions as silicon-oxy-nitride compounds. No silicon carbide reflections were observed.

X-ray microprobe analysis of the films was performed. Using the microprobe's energy dispersive analyzer (variable fraction-of-a-per cent sensitivity for elements with atomic numbers of eleven and above), no impurities were detected. Three specimens representing amorphous, polycrystalline, and dendritic morphologies, from both the evaporated and sputtered lots of specimens, were chosen on the basis of maximum TEM observable impurity content. The six specimens were examined by the microprobe's wavelength dispersive analyzer for carbon, oxygen, and nitrogen content with calibration against graphite, SiO_2, and BN standards. The microprobe's electron beam accelerating potential was varied to obtain a rough distribution of the above elements with depth. The microprobe's sensitivity for nitrogen may be as poor as 1% due to a high background signal arising from scattering from multiple orders of silicon. The microprobe detected a thin oxide film on the surface of all of the samples, but no nitrogen or carbon impurity was observed.

Next, the ESCA technique was used to examine the surfaces of virgin pieces of the samples examined by the x-ray microprobe wavelength dispersive analyzer. Essentially, the technique consists of bombarding the sample with monoenergetic x-rays and measuring the kinetic energy distribution of the ejected electrons. Since the ejected photoelectrons have kinetic energies of approximately 1 keV or less, the mean free paths of these electrons are short and the total sampling depth is within the first 100Å. Each element has a characteristic photoelectron spectrum which allows for the analysis of elements above helium in the periodic chart. A major feature of information provided by the ESCA technique is that a shift in kinetic energy of the photoelectron for an individual element is related to its chemical bonding in a molecule. The surface spectra from all of the samples were essentially identical. Silicon, oxygen, carbon, and SiO_2 were detected. Comparison of the peak height and area of the silicon and SiO_2 peaks, with appropriate standards, established that the surface SiO_2 films are 20-50Å thick. The significance of the observed carbon peak is questionable in that a small carbon peak is artifactually produced in the oil-diffusion pumped ESCA apparatus.

Another set of four virgin samples was examined in a Cameca secondary ion mass analyzer. The samples examined were the worst-case pyrolytic dendritic, polycrystalline, and amorphous samples and a polycrystalline evaporated sample. An ion spectra was obtained as the analyzer sputtered into the silicon film. The mass numbers detected corresponded to various orders of silicon, oxygen, silicon oxides, carbon, and argon. Ionized argon was used used as the primary ion species. The analyzer cannot detect nitrogen in the presence of doubly ionized ^{28}Si, due to interference from the silicon half mass. Otherwise the sensitivity of the ion analyzer is 1-10 ppm. Next, an analysis in depth for silicon, oxygen, and carbon was made. The argon ion beam of the analyzer is swept in a square raster on the sample eroding through the film and insulator and into the substrate. The mass spectrometer is set to detect a particular mass number, $^{30}Si^+$ for example, and the detector current is plotted *vs.* time as the argon beam moves into the sample. The substrate silicon and its oxygen and carbon content are assumed to be standards and the ratio of detector currents for silicon, oxygen, and carbon in the film is compared with the silicon, oxygen, and carbon in the substrate silicon. Table IV lists the ratios of detector currents for the species indicated. When the experimental error for this procedure is considered, ratios of

Table IV. Ion mass analyzer data

Sample	Spectrometer detector current ratio $I_{film}/I_{substrate}$		
Mass:	^{30}Si	^{16}O	^{12}C
Pyrolytic			
Amorphous	1.0	1.3	1.6
Polycrystalline	1.0	2.1	6.1
Dendritic	1.0	1.5	6.0 → 2.0*
Evaporated			
Polycrystalline	1.0	2.3 → 1.4*	1.7

* These current ratios started at the high value at the surface of the film and decayed exponentially to the lower value at the substrate interface.

two or less may be discounted for planar samples. Increasing surface topography induces surface effects which increases the yield of sample ions, decreasing the significance of higher detector current ratios. In addition, for the dendritic case, the angle of impingement of the primary beam is such that enhanced sputtering yield may be obtained. In the light of these arguments it is concluded that there is very little real difference in the carbon and oxygen contents of the films compared to their substrates, with the exception of the effects of the surface native oxide film.

Discussion

Evaporated polycrystalline silicon film.—When the silicon crystallite nucleates in the thin amorphous silicon film at 650°C, the associated volume contraction and orientation change sets up stresses in the amorphous silicon. This stress, when combined with the residual stress present in the amorphous film, apparently provides the driving force for dendritic growth.

At 850°C the nucleation is initiated as a dendritic process in competition with the nucleation of equiaxed grains resulting in a relatively low density of dendrites in a matrix of equiaxed polycrystalline silicon grains. At 1040°C the nucleation of low-mobility equiaxed polycrystalline silicon grains is dominant, and the large number of crystallites nucleated limits the initial grain size when the nuclei coalesce. Further, the silicon-oxy-nitride compounds may have a greater role in limiting the silicon grain size as they undergo nucleation and growth.

Pyrolytic polycrystalline silicon film.—The observation of the small-grained layer of polycrystalline silicon at the substrate interface of the initial effects-of-deposition temperature samples, with the attendant anomalous diffraction pattern and the absence of the small-grain layer in the nucleation study, may be explained as follows. The silicon wafers in the pyrolytic reactor are sitting at an elevated temperature in a nitrogen atmosphere prior to the silicon deposition, causing the surface monolayer to be composed almost entirely of adsorbed nitrogen atoms. The nucleation samples had their silicon depositions started immediately after they came to temperature; whereas the effect-of-temperature samples sat at temperature for roughly 20-40 min prior to silicon deposition. We, therefore, speculate that the initial small-grain silicon layer is nucleated on an altered surface, most likely a gaseous nitrogen saturated surface which produces anomalous small silicon grains. There will be large amounts of interstitial nitrogen in the lattice leading to distortion of the lattice. When the silicon film builds up to a thickness that reduces the effect of nitrogen at the interface, through long diffusion distances, then the silicon renucleates a normal silicon lattice with large grains. The presence of interstitial impurities distorting cubic lattices and giving forbidden reflections in electron diffraction patterns is well known (8). Additional evidence for this explanation of the small grain layer is the high, lattice-parameter shift due to solid solution effects, noted by x-ray diffractometry, and the absence of any differences in the grain size of thick films as functions of substrate cleanliness.

Impurity effects.—The role that impurities play in the nucleation of the three morphologies is limited. Without a doubt, the effect of prolonged heating in nitrogen prior to the deposition of polycrystalline pyrolytic silicon is important in that it induces the formation of a small-grain silicon layer at the interface. Having established the necessity of starting the silicon deposition immediately on reaching temperature in nitrogen, we have never again observed the small grain silicon layer on comparable subsequent samples. More significantly, no variation in the temperature of transformation from amorphous to polycrystalline silicon morphologies was detected in samples with or without the small grained layer of silicon.

The author feels that the 20-50Å thick SiO_2 layer on all samples is inescapable and is of no consequence to the nucleation of the three morphologies. Likewise, the unproven possibility of carbon contamination in pyrolytic samples deposited at temperatures in excess of 900°C would presumably come from the graphite susceptor under the specimens and is only seen after the dendrites are nucleated. This is evidenced by the decay of the questionable ion analyzer carbon ratio from high values at the surface to low values at the nucleation interface.

This leaves the occasional TEM observed silicon-oxy-nitride compounds. They are certainly real and except for their possible role of inhibiting grain growth they would appear to have no effect on the nucleation of the three morphologies. Support for this statement comes from subsequent work with silicon films wherein the transformation temperatures between morphologies was constant despite a near total absence of silicon-oxy-nitride compounds.

Conclusion

We have established that the thin polycrystalline silicon film subject of this investigation can have three different morphologies: pseudoamorphous, equiaxed grains, or dendritic, as functions of deposition temperature for pyrolytic films and heat-treatment temperature for evaporated films. We note that the pseudoamorphous films are smooth and uniform and should perform best in semiconductor applications. We further note that polycrystalline silicon has a slightly rougher surface and has a morphology which is apparently sensitive to the time spent at temperature in nitrogen prior to silicon deposition for pyrolytic silicon. The dendritic polycrystalline silicon has the least satisfactory surface morphology due to the presence of large dendritic spikes.

Acknowledgment

The author wishes to thank R. Gdula, J. Gardiner, and H. Demsky for preparing the silicon films, N. O'Neil for transmission electron microscopy specimen preparation, C. Goldsmith for x-ray analyses, F. Ordonez for performing scanning electron microscopy, S. Cvikevich for x-ray microprobe analysis, R. Flitsch for ESCA analysis, and P. Kuehner for ion analyzer work. The author is indebted to G. Das and G. Walker for helpful discussions. Constructive suggestions made by the Journal's reviewer are gratefully acknowledged.

Manuscript submitted March 5, 1973; revised manuscript received June 6, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

An Interstitial Model for the Dielectric Relaxation of ZnF_2 Doped with Lithium

Thomas A. Roth

Department of Industrial Engineering, Kansas State University, Manhattan, Kansas 66506

ABSTRACT

The thermally activated release of the dielectric polarization, obtained by the ionic thermoconductivity method, of ZnF_2 doped with lithium is examined in terms of an interstitial model. Single crystals of lithium-doped ZnF_2 are studied in the range of temperature from that of liquid nitrogen to 275°K. Crystals cleaved such that the electrostatic potential can be applied in the [001], [100], and [110] directions are used. Of the three crystallographic orientations studied, only when the polarizing electrostatic potential is applied in the [001] direction is a strong discharge current observed. Peaks, several orders of magnitude smaller than those found in [001] oriented crystals, are found when the potential is applied in the other two directions. The dipolar imperfections in ZnF_2 doped with lithium give a discharge current peak at $T_m = 236.5° \pm 5.0°K$ for all three crystal orientations following polarization at 285° ± 2.5°K for 3 min. The activation energy for the dipolar relaxation for the [001] orientation is 0.320 ± 0.002 eV and the observed relaxation times are given by

$$\tau(T) = 1.70 \times 10^{-13} \exp(0.32/kT)$$

The number of dipoles is found to be 1.40×10^{18} cm^{-3}. Agreement between the number of dipolar defects experimentally determined and the number calculated from doping level information is good. It is proposed that the dielectric relaxation of ZnF_2 doped with lithium is due to the $(Li_I^{\cdot} - Li_{Zn}')$ dipole and that rotation of the dipole is accomplished by interstitial lithium ion movements parallel to the c-axis of the crystal.

The dielectric relaxation of ZnF_2 doped with lithium was examined in a previous paper (1) in terms of possible vacancy movements. The presence of the relatively small and mobile lithium ion suggests re-examination of the relaxation process in terms of possible interstitial movements. It is the intent of this paper to propose an interstitial model for the relaxation process in order to provide the basis for comparison of the two mechanisms and to attempt to resolve which is responsible for the dielectric relaxation of ZnF_2:LiF.

Zinc fluoride has the tetragonal rutile, TiO_2, type crystal structure (2, 3). Each zinc ion is surrounded by six fluorine ions approximately at the corners of a regular octahedron, and each fluorine ion is surrounded by three zinc ions approximately at the corners of an equilateral triangle.

Electric dipoles may be formed in ZnF_2 when it is doped with lithium, as illustrated in Fig. 1. One monovalent lithium ion is proposed to replace the divalent zinc ion in the normal cation lattice position. To maintain charge neutrality in the crystal, for the case under consideration, a second monovalent lithium ion is considered to accompany the substitutional Li^+ and is expected to occupy an interstitial position between the fluorine ions in the immediate neighborhood of the substitutional Li^+. The interstitial Li^+ and the substitutional Li^+ can form a $(Li_I^{\cdot} - Li_{Zn}')$ dipole.[1] The substitutional Li^+ is expected to be relatively immobile and remain in the normal lattice position in the presence of an external field. Rotation of the dipole due to application of the external field is accomplished by movement of the relatively mobile interstitial Li^+ cation from one interstitial position to another. The most probable interstitial sites are taken to be the same as those reported for the rutile crystal (5).

Key words: dielectric relaxation, dielectric loss, zinc fluoride, crystal defects.

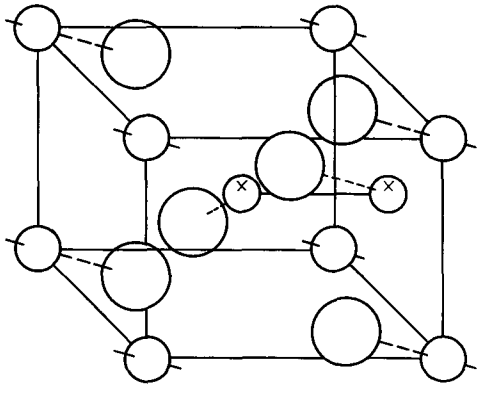

Fig. 1. Tetragonal crystal structure of ZnF_2 in which one Zn^{++} has been replaced by a substitutional Li^+ and an interstitial Li^+ resulting in a $(Li_I^{\cdot} - Li_{Zn}')$ dipole. The zinc ions are represented by the smaller circles; the fluorine ions, by the larger circles; and the lithium ions, by the circles marked with an x.

The orientation of the $(Li_I^{\cdot} - Li_{Zn}')$ dipoles is random and variable in the absence of fields since the interstitial cation can occupy a number of equivalent sites around the substitutional Li^+. Application of an electric field results in movement of the interstitial cations with dielectric relaxation occurring when the field is removed due to the redistribution of the interstitial cations among the possible lattice sites. The activation energy in the low temperature range is expected to be the motion energy for the interstitials.

The dielectric relaxation of ZnF_2 single crystals doped with lithium has been studied in the present work using the ionic thermoconductivity method of Bucci *et al.* (6-9). Since the dielectric relaxation of doped materials is expected to be dependent on movement of defects in the crystal, as proposed above, the occurrence of strong, thermally activated current discharges observed in the ionic thermoconductivity method are expected to be dependent on the crystallo-

[1] The dipoles described here are written in terms of Kröger's notation (4) in which the major symbol is the ion or vacancy in the lattice position normally occupied by the subscripted symbol. A subscripted I indicates that the ion is in an interstitial position. The superscripted symbol indicates the effective charge on the ion or vacancy with ·, x and, ' indicating positive, neutral, and negative, respectively.

graphic orientation of the single crystals. ZnF_2:LiF single crystals cleaved such that polarization and discharge may be studied in three different crystallographic orientations have been used in order to determine the orientation dependence of the discharge current.

As outlined by Bucci and Fieschi (6), the ionic thermoconductivity method for the study of dielectric relaxation consists of the following three basic steps: (*i*) The sample is polarized in a static field F_p, for a time t, at a temperature T_p. (*ii*) The sample is cooled to a temperature $T_o << T_p$, where any ionic motion is completely hindered, and the external field is taken off. (*iii*) The sample is subsequently warmed at a constant rate $b = dT/dt$, and the discharge current is registered as a function of temperature.

The dipoles, initially, are randomly oriented in the absence of an external electric field. The dipoles will be distributed in a random way among the possible orientations, so that the total polarization will be zero. The application of the field F_p causes the dipoles to become polarized, *i.e.*, assume a preferred orientation. The preferred orientation of the dipoles is preserved by reducing the temperature to a value low enough to hinder the relaxation, *i.e.*, rerandomization, of the dipoles. The lowering of the temperature insures a long relaxation time for the rerandomization process. When the sample is warmed at a constant rate b, the relaxation time is gradually shortened, the dipoles lose their preferred orientation and a depolarization, or discharge, current $i(T)$ is observed. The discharge current is characterized by an initial exponential rise as the temperature increases, peaking, and a falling off to zero.

When the discharge current is due to the relaxation of dipoles, the peak of the current corresponds to the particular type of dipolar imperfection in the sample and can be used to obtain information on the relaxation time and number of dipoles in the sample (6). If several types of dipolar imperfections are present in the sample, several peaks are to be expected, each peak corresponding to a particular type of dipolar imperfection in the sample.

When only one kind of dipolar defect is assumed to be present in the material, the following parameters can be obtained from the ionic thermoconductivity data (6-9):

(*i*) The activation energy for the dipole orientation, E, can be obtained from the initial slope (the low temperature side) of the curve obtained by plotting $\ln i(T)$ *vs.* $1/T$ and from the equation

$$\ln i(T) = -E/kT + \ln (P_o/\tau_o) \qquad [1]$$

where P_o is the induced polarization per unit volume and τ_o is the relaxation time at 0°K.

(*ii*) When E is known, τ can be obtained from

$$kT_m^2 = bE\tau(T_m) = bE\tau_o \exp(E/kT_m) \qquad [2]$$

where T_m is the temperature corresponding to the peak, $i(T_m)$, in the ionic thermoconductivity curve and b is the warming rate, dT/dt.

(*iii*) The number of dipolar defects, N_d, is obtained from

$$N_d = P_o kT_p/\alpha p^2 F_p A \qquad [3]$$

where T_p is the polarizing temperature, α is a geometrical factor depending on the possible dipolar orientation, p is the electrical moment of the dipole, F_p is the polarizing electrical field, and A is the sample area.

Experimental Procedure

Single crystals of ZnF_2 doped with lithium, in the amount of 2.9×10^{18} atoms of Li per cm^3, were grown in the crystal growth facilities of the Center for Materials Research at Stanford University. The concentration of the lithium was originally determined in the melt based on the assumption that the content of the solid would be the same. No evidence of segregation was apparent in the single-crystal boule. Inference of the lithium content from atomic absorption measurements on the lithium-doped ZnF_2 crystals indicated the assumption to be valid. The crystals were cleaved into right rectangular parallelepiped samples on the order of $4 \times 4 \times 1$ mm in size. The crystallographic orientation of the cleaved crystals was such that the electrostatic potential could be applied in the [001], [100], and [110] directions of the ZnF_2:LiF crystal. Conductive silver lacquer was used to provide electrical contacts on the crystals.

Polarization of the samples was done at 285.0° ± 2.5°K under vacuum followed by a liquid nitrogen quench. Heated high-purity nitrogen, at a flow rate of 3.5 liters/min, was used to warm the samples at a warming rate of approximately 0.1°K/sec. The temperature was measured by means of a copper-constantan thermocouple attached to the sample holder in contact with one of the electrodes. Current measurements were made using a Cary 401 vibrating-reed electrometer with a current sensitivity of 10^{-17} A. The current and temperature were recorded simultaneously on strip-chart recorders from liquid nitrogen temperature to approximately 275°K in most tests with an occasional sample being heated to about 300°K. Reproducibility of ionic thermoconductivity measurements made on different samples was on the order of magnitude of 7.5%. Measurements on the same sample gave a reproducibility on the order of 2.5%. These errors arose mainly from a translation of the scale of the current and therefore are not expected to affect the values of E and τ_o.

Prior to placement in the sample holder for the ionic thermoconductivity studies, the crystals were heated in a high-purity helium gas atmosphere at about 475°K for one-half hour and then quenched to room temperature with high-purity helium gas. The purpose of the heat-treatment was to dissolve clusters of dipoles thereby increasing the intensity of the dielectric relaxation (8). In samples that had not been given the above treatment prior to testing, only relatively weak discharge currents were observed.

Results and Discussion

Only when the polarizing electrostatic potential is applied in the [001] direction, of the three crystallographic orientations studied, is a strong discharge current observed. Figure 2 illustrates a typical ionic thermoconductivity discharge of the [001] direction oriented crystals during heating from liquid nitrogen temperature to near room temperature. Also shown in Fig. 2 are the weaker discharges observed for the [100] and [110] oriented crystals. The curves of the figure have been smoothed and do not exhibit the

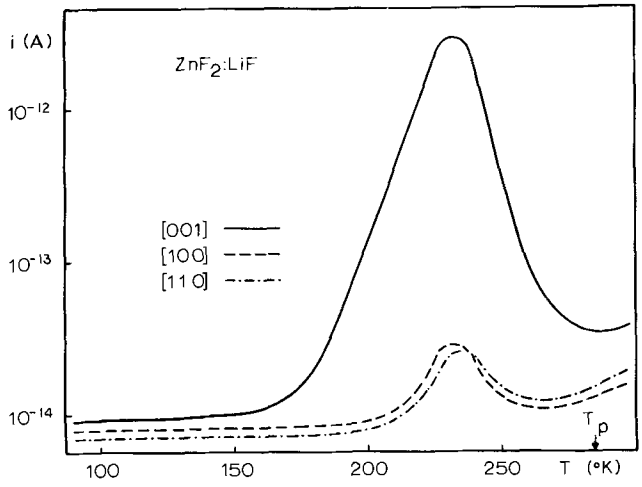

Fig. 2. Typical ionic thermoconductivity discharge currents in ZnF_2:LiF for the three crystallographic orientations of this work.

discontinuities resulting from the translation of the current range actually experienced in the tests. As seen in Fig. 2, peaks, several orders of magnitude smaller than those found in [001] oriented crystals, are found when the potential is applied in the [100] and [110] directions.

The dipolar imperfections in ZnF_2 give a discharge current, $i(T_m)$, at $T_m = 236.5° \pm 5.0°K$ for all three crystal orientations following polarization at $T_p = 285.0° \pm 2.5°K$ for 3.00 ± 0.25 min.[2] The activation energy for the dipolar relaxation obtained from the slope of the [001] orientation, as shown in Fig. 3, is $E = 0.320 \pm 0.002$ eV[3] and the observed relaxation times are given by

$$\tau(T) = 1.70 \times 10^{-13} \exp(0.32/kT) \quad [4]$$

By putting $p = 1.5 \times 10^{-17}$ esu, $\alpha = 2/3$, and $T_p = 285°K$, the number of dipoles is found to be 1.40×10^{18} cm^{-3} from Eq. [3].

As indicated above, the temperature T_m corresponding to the maximum current in all cases, regardless of crystal orientation, is similar, $236.5° \pm 5.0°K$. Since all samples were given the same treatment prior to and during the study, the apparent reason for the strong discharge current peaks only for [001] oriented crystals is that the rotation of the dipoles due to movement of the defects is easier in this orientation than in the other two directions.

In the previously proposed vacancy model for the dielectric relaxation of ZnF_2 doped with lithium (1), ($V_F{\cdot} - Li_{Zn}'$) dipoles were discussed. When only one monovalent lithium ion replaced the divalent zinc ion, an anion vacancy was proposed to maintain charge neutrality. Rotation of the dipole during relaxation was considered to be due to fluorine ions moving between adjacent lattice sites as made possible by the existence of the relatively mobile vacancies created by the addition of the relatively immobile lithium ions to the crystal. The vacancy has six possible equivalent positions around the lithium ion and the orientation of the dipole can change by an anion moving to the vacant site. Possible movements of the adjacent fluorine ions into the vacant site are given in Fig. 4. From Fig. 4, it is apparent that movement of the fluorine ions and vacancies, with the resulting rotation of the dipoles, should be as easily accomplished when polarization and relaxation are studied in the [100] direction as when studied in the [001] direction. Figure 4 and inspection of scale size solid models of the ($V_F{\cdot} - Li_{Zn}'$) dipole in ZnF_2 suggest that ion and vacancy movement, when polarization and depolarization are studied in the [110] direction, may be slightly more difficult due to the coordination of the fluorine ions in the crystal structure. Nowick and Heller (5), however, indicate that the relaxation behavior for the [100] and [110] directions should be similar.

Dielectric relaxation of ZnF_2 resulting from rotation of dipoles due to the presence of vacancies was observed in some early tests of the crystals. Prior to placement in the sample holder for the ionic thermoconductivity studies, the crystals were heated in a high-purity helium gas atmosphere at about 475°K for one-half hour, then quenched to room temperature with high-purity helium gas, as noted above. In the early stages of the investigation, the quench was attempted in air. The air-quench however resulted in oxidation of the crystals, as evidenced by discoloration of the originally colorless crystals. Crystals thus exposed to an air cooling gave discharge currents as shown in Fig. 5 for a [110] oriented crystal. Two discharge current peaks were observed for air-cooled ZnF_2:LiF crystals. The initial peak, T_{m1}, corresponds to the peak shown in Fig. 2 for the helium-cooled crystal. The peak at T_{m1} in Fig. 5 and the peak in Fig. 2 for the [110] orientation both are found at 236.5°K. The higher temperature peak, T_{m2}, of Fig. 5 was observed in both lithium-doped ZnF_2 and undoped ZnF_2 crystals which were heat-treated together and equally exposed to the atmosphere during the air-quench. The current peaked at 265°K in each case when the second discharge was observed. No second discharge was observed when the doped or undoped crystals were quenched in the high-purity helium gas. The second current discharge was therefore attributed to ($V_F{\cdot} - O_F'$) dipoles formed during the oxidation of the air-cooled crystals. The anion vacancy of the ($V_F{\cdot} - O_F'$) dipole would be expected to be more mobile than the substitutional oxygen with rotation of the dipole during relaxation occurring via a vacancy movement mechanism. The activation energy for dipole orientation for the second discharge was found to be 0.46

[2] For all numerical values reported in this paper in the form $A \pm B$, B is the standard deviation.

[3] The value of the activation energy previously published (1), 0.641 eV, was incorrectly reported and found to be in error by a factor of 2.

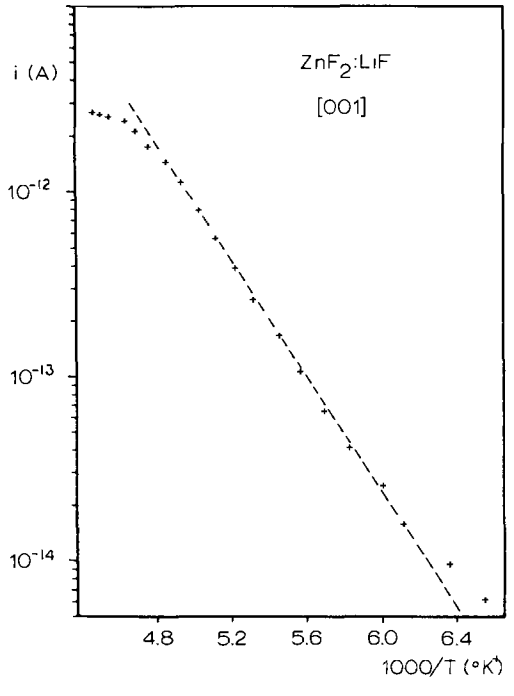

Fig. 3. The $\log_{10} i$ as a function of $1000/T$ for the low-temperature side of the current discharge for lithium-doped ZnF_2 in the [001] orientation. The activation energy is determined from this plot.

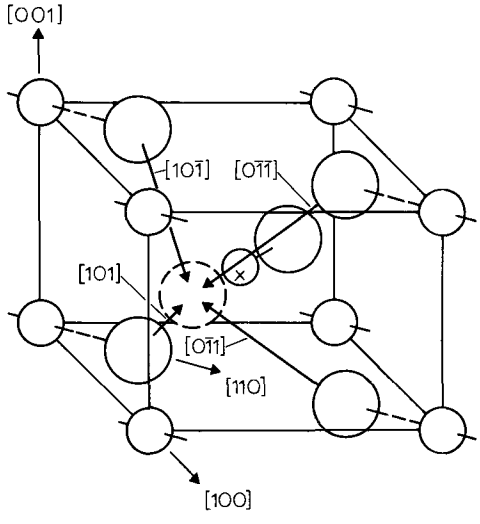

Fig. 4. Crystal structure of ZnF_2 in which one ZnF_2 has been replaced by one LiF resulting in a ($V_F{\cdot} - Li_{Zn}'$) dipole. The crystallographic directions possible for changes in the vacancy position, as represented by replacement of the vacant lattice site by a neighboring fluorine ion, are indicated.

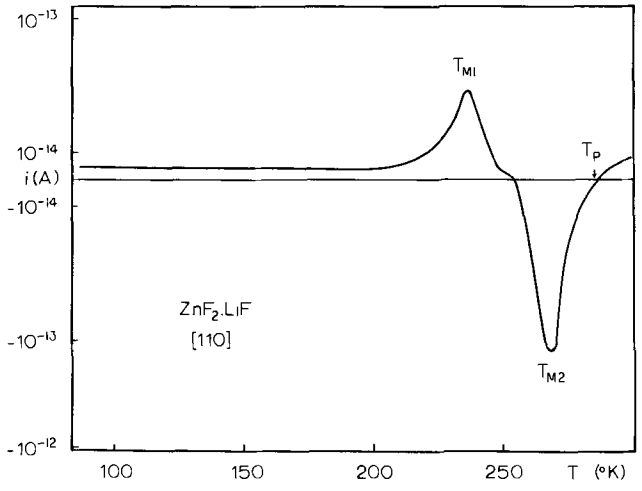

Fig. 5. Typical ionic thermoconductivity discharge current in lithium-doped ZnF_2 after air-cooling from the annealing temperature.

eV which is similar to the 0.42 eV value Rossing and Coble (10) found for the dipole in CaF_2. The crystal structure of lithium-doped ZnF_2 containing both ($Li_I^{\cdot}$ — Li_{Zn}') and ($V_F^{\cdot}$ — O_F') dipoles is illustrated in Fig. 6.

The magnitude of the second discharge peak was similar, *i.e.*, the same order of magnitude, for each of the three orientations studied implying that the movement of vacancies in each of the three directions occurred with equal ease. Referring back to the current discharge peaks observed at 236.5°K in Fig. 2 and 5, should this relaxation result from a vacancy movement mechanism involving the ($V_F^{\cdot}$ — Li_{Zn}') dipole, the magnitude of the current discharge peak for each of the three orientations should be similar.

The higher temperature discharge, T_{m2}, of Fig. 5 is noted to exhibit a change in the sign of the current discharge. The change in sign of the current was observed for all the oxidized ZnF_2 crystals, doped and undoped. A change in the sign of the current may be achieved by inverting the crystal with respect to the electrodes between the polarizing and depolarizing stages of the test. However, no such inversion was performed to obtain these results. Until further study of the occurrence of the change in the sign of the current discharge can be undertaken, the phenomenon remains unexplained.

The number of dipolar defects determined using Eq. [3] provides additional verification that an interstitial mechanism is responsible for the current discharge peak at 236.5°K. Bucci *et al*, (8), in testing samples with different concentrations of impurity atoms, found that as the concentration of impurity atoms in the melt increased, a relatively smaller fraction of them entered into the crystal. For the relatively low concentration of lithium added to the ZnF_2, the number of dipoles should be directly proportional, and quite similar, to the number of added impurity atoms should the ($V_F^{\cdot}$ — Li_{Zn}') dipole be responsible for the relaxation since one F^- vacancy is proposed to be created for every Li^+ substituted for a Zn^{++}. Formation of the ($Li_I^{\cdot}$ — Li_{Zn}') dipole requires two Li^+ ions for each Zn^{++} replaced. The experimentally determined number of dipolar defects for the interstitial model would thus be on the order of half the number of Li^+ ions originally added to the ZnF_2. The number of dipolar defects calculated using Eq. [3] is slightly less than one-half the number of lithium ions added in the doping process, thereby, supporting the interstitial model.

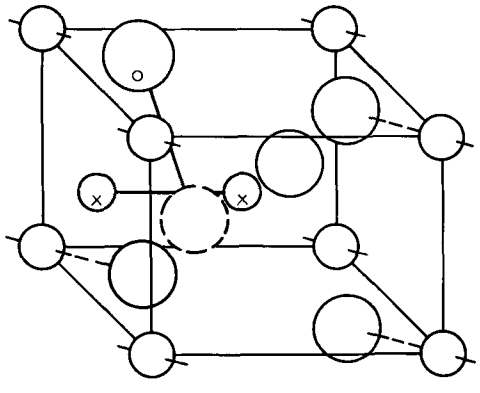

Fig. 6. Crystal structure of ZnF_2 containing both ($Li_I^{\cdot}$ — Li_{Zn}') and ($V_F^{\cdot}$ — O_F') dipoles. The larger circle, marked with an o, represents the oxygen.

In a study of the diffusion of lithium in rutile, Johnson has found the movement of the interstitial lithium ion to be extremely anisotropic (11). Diffusion was found to be several orders of magnitude faster parallel to the c-axis, *i.e.*, in the [001] direction, than diffusion perpendicular to the c-axis. Similar results would be expected for the movement of lithium in ZnF_2 with the same crystal structure and similarly sized interstices as TiO_2. Similar results were indeed found; the [001] direction in the ZnF_2 crystals was the only direction studied which gave appreciable dielectric relaxation currents, thus, strongly suggesting that the currents were the result of movement of the interstitial lithium ions.

Although the dielectric relaxation of ZnF_2:LiF as associated with interstitial ion movement has been compared to the diffusion of lithium in rutile, the comparison must be limited. The polarization of the dielectric and subsequent relaxation is due to the orientation of the dipoles uniformly distributed in the volume of the crystal. The components making up the dipole are assumed to be near neighbors and to remain associated during the polarization and relaxation processes, as indicated by the low activation energies observed for dielectric relaxation involving interstitial ions. The movement of defects considered here is limited to smaller distances than would be the case for dissociation of the dipoles and diffusion of the defects.

Surface Oxide on Etched Aluminum

Alan W. Smith

The Boeing Company, Seattle, Washington 98124

ABSTRACT

The formation and properties of the surface oxide formed on aluminum etched in a sulfuric acid-sodium dichromate solution have been investigated using electrical impedance, electron microscopy, and contact angle measurements. The frequency dependence of the impedance measurements is shown to follow the theory of Gevers and DuPré for amorphous dielectrics. By anodizing in neutral solutions, known oxide layers are added. From this and literature data, the dielectric constant at any frequency, the roughness factor, and the thickness of the oxide layer can be estimated. From the roughness factor, a porous cell structure is derived which is confirmed by electron micrographs. From the effects of drying the oxide, the presence of a hydrous layer which has a high dielectric loss and poor wettability is indicated. Upon heating to high temperatures, the loss decreases and the surface becomes more wettable. It is shown that this hydrous layer occurs, except when the surface is polarized anodically during eching. When the surface is polarized anodically, the anodic cell structure is prominent and little or no hydrous layer forms. The addition of copper ion to the etch causes a surface layer to form as under anodic polarization.

The surface of etched aluminum displays a variability with respect to adhesive bonding and a high sensitivity to slight changes in etching conditions. In order to help explain the causes of this sensitivity, the formation and properties of the surface oxide were examined. Electrical impedance measurements as a function of frequency give one of the few ways of characterizing such thin layers. This was the principal technique used, but electron microscopy was also used to confirm certain conclusions and contact angle measurements were used to amplify the characterization of the surface.

Experimental

Unless otherwise noted, the samples examined consisted of 99.99% aluminum etched in a 300 g/liter sulfuric acid, 30 g/liter sodium dichromate solution at 65°C.

The electrical impedance was measured with a Hewlett-Packard vector impedance meter, Model 2800A. High accuracy was obtained by monitoring the output with a recording potentiometer and calibrating the meter at each frequency with precision capacitors and resistors. The low applied voltage of this instrument, 3 mV for most measurements, helped avoid errors due to electrode reactions.

Three different electrolytic cells were used. The one with the best geometry consisted of two 0.32 cm diameter aluminum wires covered with varnish except at the ends. The wires were bent so that the two ends nearly touched forming a parallel plate cell. In another cell two flat aluminum samples were separated by an O-ring filed with solution. The area of each sample exposed to the solution was 0.40 cm^2 and the samples were 0.2 cm apart. In both cases, the impedance is twice that of a single oxide layer. A one aluminum plate cell used the same O-ring which was connected to a reservoir containing a large platinum electrode. This cell was used for anodization. Concentrated solutions of potassium sulfate and potassium dichromate (adjusted to $pH = 6$) were used with little difference in results.

The results for the three cells showed only minor differences. Corrections for series resistance of the solution were substantial for the two O-ring cells but negligible for the wire cell except at the highest frequencies. This correction was made by subtracting from the measured impedance the infinite frequency extrapolated equivalent series resistance. The impedance values in the platinum electrode cell increase for a time, amounting to a small anodization of the aluminum.

Key words: aluminum, impedance, etching, wettability, oxide.

Measurements of impedance were also made by evaporating a layer of aluminum on top of the oxide layer as previously discussed (1).

The topology of the surface was examined by use of replicas. The replicas were obtained by pressing an acetone-softened, acetate-based film on the surface and peeling it off when hardened. The replica was shadowed with germanium at 45°, covered with carbon and then the acetate film was dissolved away. The carbon-germanium films were then examined in a JEM-6A electron microscope.

To make comparative measurements of wettability, contact angles of liquid drops have been used. Because of the variability of results from sample to sample (or even across some samples), simple techniques were used. A Gaertner goniometer was used to measure the contact angles of water and of 1-Bromonapthalene. Liquid drops were touched to the surface and measured immediately. On mechanically polished surfaces the results found for 1-Bromonapthalene were similar to those reported in the literature (2).

Contamination is an important consideration. It has been stated that clean metal oxides should give a zero contact angle with water (2, 3). However, it was possible here to obtain high contact angles as well as low, depending only on the etching conditions, immediately after evaporation of the rinse water. These angles did not change after hours in a clean desiccator or oven at 60°C.

Results and Discussion

Frequency dependence of electrical impedance.—The inverse specific capacitance, A/C, is given by

$$\frac{A}{C} = \frac{4\pi}{\epsilon' r} d \qquad [1]$$

where A is the apparent surface area, C is the measured capacitance, ϵ' is the dielectric constant, r is the roughness factor (ratio of true to apparent surface area), and d is the thickness of the dielectric.

Although both ϵ' and r do vary, the term $4\pi/\epsilon'$ is of the order of one and, when r is not too different from one, A/C is thus of the order of the layer thickness.

For thin surface oxide layers on aluminum, the log of the inverse specific capacitance is linear in the log of the measuring frequency. This is shown in Fig. 1. The various treatments shown in Fig. 1 will not be

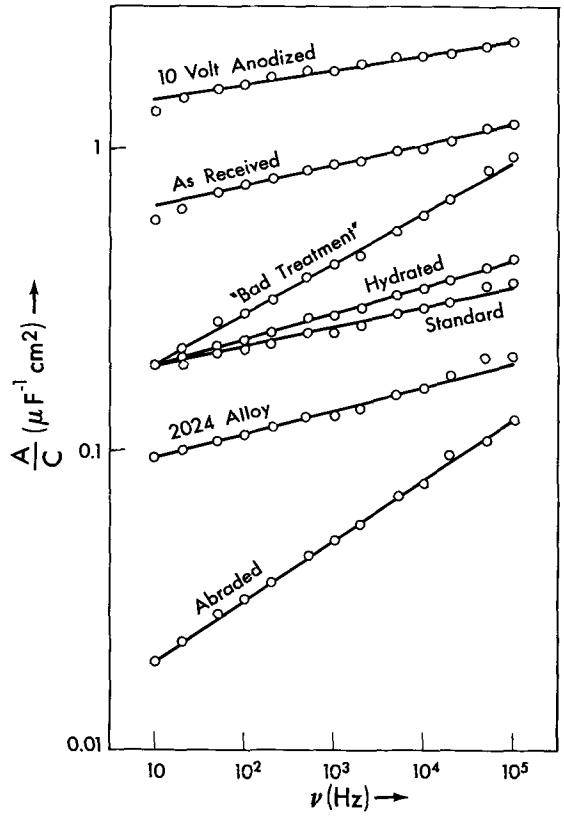

Fig. 1. Log inverse specific capacitance vs. log frequency. Two plate cell, "bad treatment" is contaminated standard etch. Hydrated is exposed to steam for 1 min.

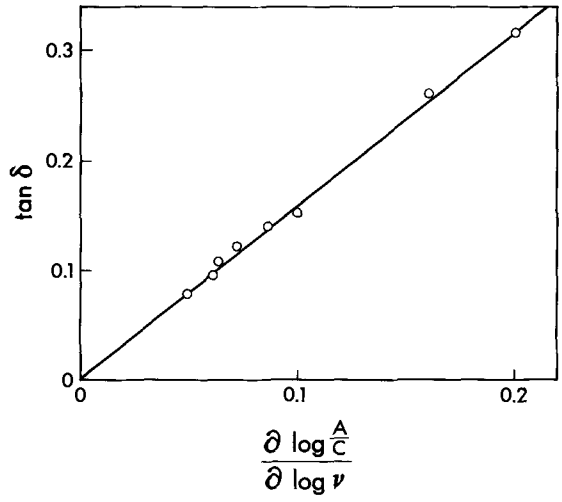

Fig. 2. Loss tangent vs. slopes of lines in Fig. 1

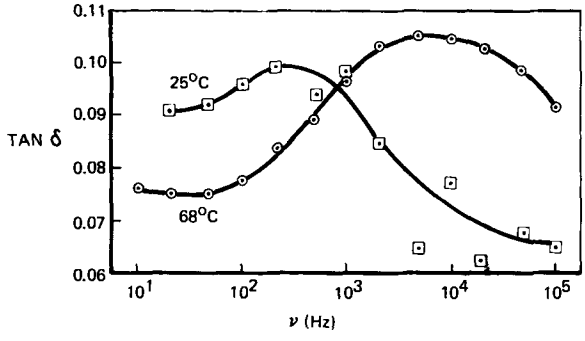

Fig. 3. Loss tangent vs. frequency, wire cell

pursued further. They are included here to show the generality of this linear relation.

The frequency dependence of the capacitance of thicker anodic films has been attributed either to a resistivity varying across the layer or to relaxation processes with a variable activation energy (4). The latter explanation is preferred here because of the good fit with a theory which is less arbitrary in nature.

Gevers and DuPré have developed expressions for the electrical impedance of amorphous dielectrics assuming relaxation processes with a broad distribution of activation energies (5). The oxide produced on aluminum at low temperatures has been held to be truly amorphous (6). Gevers and DuPré give the relationship between the dielectric constant, ϵ', and the angular frequency, ω, as

$$\frac{\partial \log \epsilon'}{\partial \log \omega} = -\frac{2}{\pi} \tan \delta \qquad [2]$$

where δ is the loss angle. In the treatment for thicker anodic layers, Eq. [2] was developed by setting ϵ'', the imaginary part of the dielectric constant, to be independent of frequency (4). The relationship shown in Fig. 1 is obtained by setting the loss tangent independent of frequency. Since the capacitance is proportional to the dielectric constant, Eq. [2] may be transformed to

$$\frac{\partial \log A/C}{\partial \log \nu} = \frac{2}{\pi} \tan \delta \qquad [3]$$

where ν is the frequency. This is precisely what is seen in Fig. 1. Figure 2 is a plot of the slopes from Fig. 1 *vs.* the loss tangent. The solid line is drawn from Eq. [3] and is a good fit to the data. The loss tangent is, in fact, fairly independent of frequency for our data whereas ϵ'' is not.

Figure 3 shows data taken with the two wire cell with care taken to get the highest accuracy. It seems that, although the loss tangent is fairly constant with frequency, there is a peak. The shift in peak with temperature is similar to previous observations on thicker layers, and is what would be expected from a relaxation process (1).

Figure 4 shows the inverse capacitance from the same set of measurements. The modest variation in loss tangent is hardly reflected in the inverse capacitance-frequency dependence. Gevers and DuPré obtained the relation

$$\frac{\partial \log \epsilon'}{\partial T} = a \tan \delta \qquad [4]$$

and also obtain a value of a from 0.04 to 0.06, nearly independent of the frequency and of the type of dielectric. The data shown in Fig. 4 gives $a = 0.05$.

It should be noted that the agreement of these results with the relations of Gevers and DuPré indicates that a variation in resistivity across the layer is not necessary. Such a variation is not precluded, however.

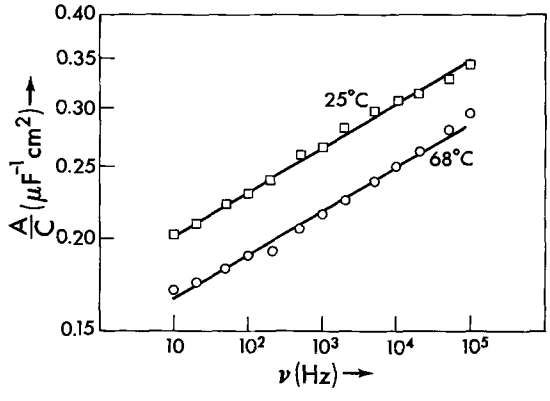

Fig. 4. Log inverse specific capacitance vs. log frequency, wire cell.

Effect of barrier layer addition.—From the large variation in dielectric constant with frequency noted above, it may be concluded that the thickness of the oxide layer cannot be learned from impedance measurements. However, more information may be obtained by adding further oxide thickness by anodization.

It has been shown that the oxide layer on the surface can be thickened to a limited amount by anodizing in nearly neutral solutions of sodium sulfate or sodium dichromate (7, 8). This thickening has been shown to be due to growth in barrier layer without the formation of porous layer seen in acidic solutions (7). If the increase in inverse capacitance with increase in voltage of anodization on a flat surface is known, then anodization on a rough surface can be used to obtain the roughness factor (9). Results in the literature on anodizing aluminum in near neutral electrolytes indicate that the oxide layer has a dielectric constant of about 9.0 and that the oxide layer thickness increases by about 12.7 Å/V of anodization potential (10-12).

For thick barrier layers the loss tangent is less than 0.01 (1, 4). It is interesting to observe the change in loss tangent as the thin etch-produced oxide is thickened. Figure 5 shows such results for two samples which differed in initial loss tangent. The inverse of the loss tangent is linear in anodization voltage and goes to zero in both cases at about −3V. The samples were anodized *vs.* a platinized platinum electrode which has been seen in some tests to approximate a hydrogen electrode when acting as a cathode. The above inverse relation has been seen in data on thicker anodic oxides (13).

If one assumes that centers of dielectric loss are formed during etching and that anodization causes little increase in their number, then the loss tangent which is averaged over the thickness will be inversely proportional to thickness. This implies that samples with zero applied voltage already have about 3V across the barrier layer. This agrees well with the work of Videm who found a value of −3.15V for the point of zero oxide thickness (14).

Since the loss tangent decreases steadily with anodization, we might expect the slope of log A/C *vs.* log ν to decrease steadily. In Fig. 6 we have divided A/C by $V + 3$ where V is the anodizing voltage. This normalizes the inverse capacitance with respect to thickness. Not only does the slope decrease with anodizing voltage but the lines converge at about 10^7 Hz. It can be assumed that the relaxation processes cease to be important at some high frequency. Here the inverse capacitance would become frequency independent. Not knowing the inverse capacitance curve at all frequencies until it becomes flat, one could not calculate the dielectric constant at lower frequencies. However,

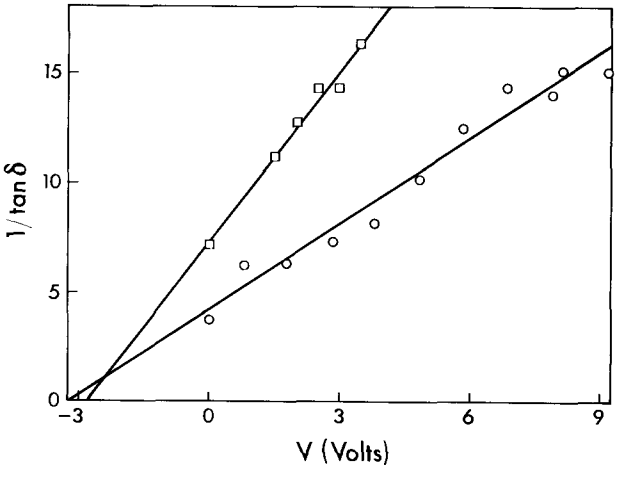

Fig. 5. Inverse loss tangent *vs.* anodizing voltage. ○, 10% $Na_2Cr_2O_7$ (*p*H-6); □, 5% K_2SO_4.

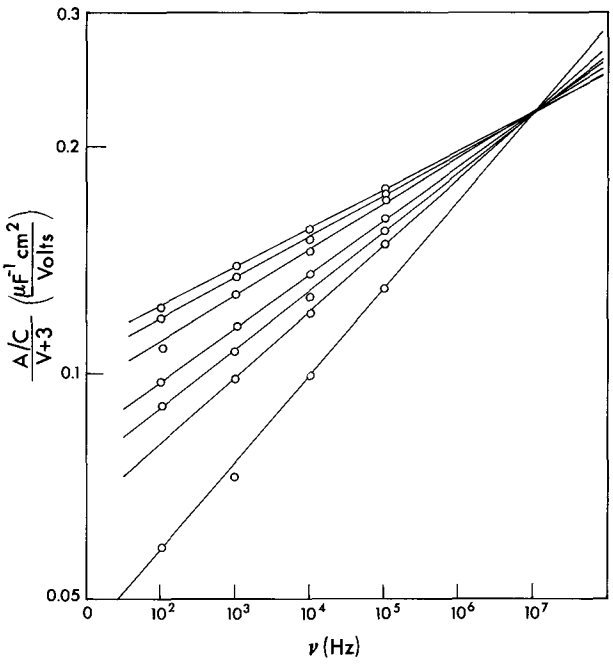

Fig. 6. Log inverse specific capacitance divided by anodizing voltage plus three volts *vs.* log frequency. The lines (going from bottom to top) refer to anodization voltages of: 0, 0.8, 1.8, 2.8, 4.8, 6.9, and 9.2V respectively.

if the shape of the curves of all samples is the same except for relative slope they must flatten out to reach a value equal to that given by the extrapolated line at 10^7 Hz. We may assume this value to be the value of 9 obtained for low loss anodic oxides. Equation [2] may be solved, for example at 1 kHz, to give

$$\log_{10}(\epsilon'_{1kHz}/9) = \frac{8}{\pi}\tan\delta \qquad [5]$$

Knowing the dielectric constant and using $\Delta d = 12.7$ Å/V one may obtain a roughness factor. This has been done for the data shown in Fig. 6 and a roughness factor of 0.74 obtained. Although these surfaces are rather flat, a roughness of less than one is impossible. However, the results are real, the low value of r coming from the fact that this etch produces a porous oxide like a porous anodic treatment would. Anodizing in a neutral electrolyte merely increases the thickness of the oxide at the base of the pores. If the oxide between the pores is considerably thicker, the area obtained from the anodization experiment will be simply that of the pores. When the oxide was removed by a one minute dip in cold 10% HNO_3 + 10% HF (by volume) only a thin barrier layer oxide remained. After anodizing this surface and making the same calculations, a roughness factor of 1.1 was obtained. Electron micrographs showing the presence of a porous cell structure will be given later.

The thickness that is obtained by impedance measurements can only refer to the thickness of the oxide at the pore bottoms. The fact that the samples with zero applied volage to a platinum electrode have about 3V across the oxide layer gives a thickness of about 38Å. Freshly etched samples have somewhat thinner layers.

Effect of drying.—The thickness of the oxide obtained by impedance measurements varied from sample to sample and more so if the samples were allowed to dry before impedance measurements. Figure 7 shows inverse capacitance of samples before and after drying. Not only is there an increase in inverse capacitance on drying but also an increase in loss tangent except at low frequencies. The curvature of the line for the undried sample at low frequencies indicates some leakage

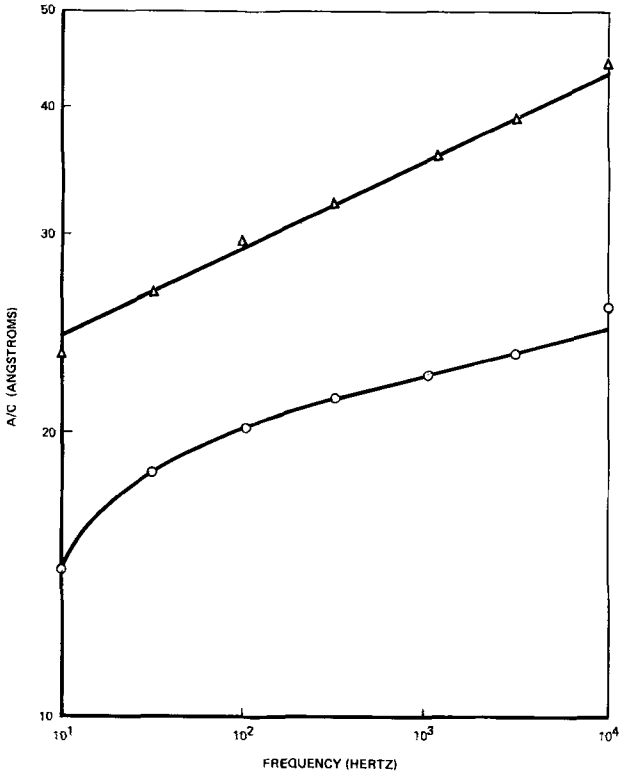

Fig. 7. Inverse specific capacitance vs. frequency. ○, sample not dried; △, sample dried overnight.

across the barrier layer. The imperfections causing this disappear after drying, giving the nearly straight line as is usually observed.

The increase in specific capacitance on drying is not held to be due to oxidation of the surface at this temperature. Rather it is held to be due to changes in an outer layer rendering it less permeable to the solution. A highly permeable oxide layer would not be noticed by impedance measurements.

A further means of probing the total thickness of the oxide is to evaporate aluminum on the surface and to measure the impedance of this capacitor. Initial attempts gave low resistive impedances. Concluding that aluminum was evaporating into pores or cracks, an evaporation angle of 45° was chosen. Low loss samples were obtained in most cases. Eight values of A/C scattered between 340 and 1300 Å were obtained.

Thus the total thickness of these oxides are more than an order of magnitude thicker than the barrier layer observed in electrolytic solutions and they are quite variable in thickness. This will be discussed more later.

When samples dried in air were heated, the loss tangent decreased. This is shown in Fig. 8. This decrease is believed to be due to the loss of moisture which is the source of much, if not all, the dielectric loss. Figure 9 shows how the inverse capacitance changes with drying at elevated temperatures. In concurrence with the results for anodic layers, there is a convergence at about 10^7 Hz for the lower temperatures. These results are interpreted to indicate that the oxide dried out but did not grow in thickness up to 262°C, but that a thickening did occur at 325°C.

Another measurement that was made during the drying studies was the contact angle of liquids on the surface. Figure 10 shows the effect of drying to higher temperatures. The same treatment which caused the loss tangent to decrease also causes the wettability to increase, giving lower contact angles for water. Great care was taken in these samples to avoid contamination.

Effect of potential during etch.—One of the most likely sources of variability in an etch is the potential

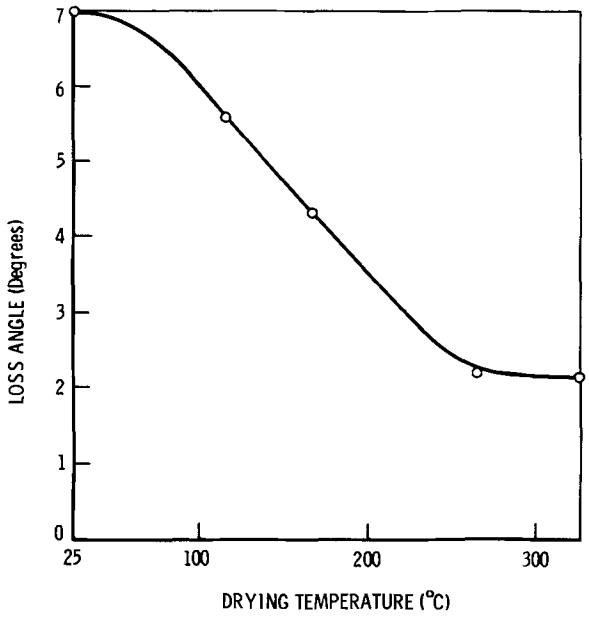

Fig. 8. Dielectric loss angle vs. drying temperature (22 hr at temperature).

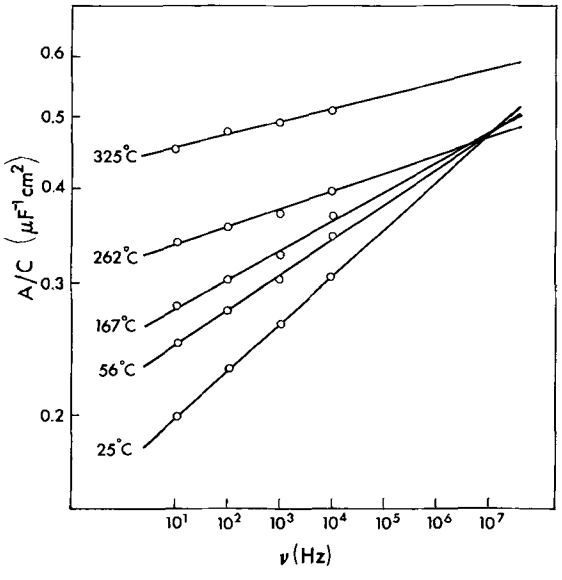

Fig. 9. Log inverse specific capacitance vs. frequency, samples heated one day to temperatures indicated.

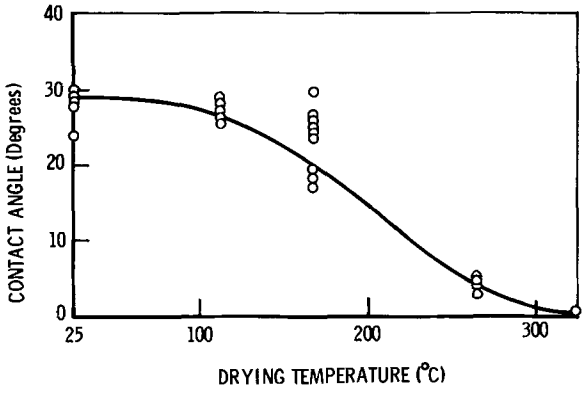

Fig. 10. Contact angles for water on samples etched in "used" solution vs. drying time (22 hr at temperature).

of the surface. When the potential is not controlled, the surface will reach a potential where the cathodic and anodic reactions have equal rates. On any specific

area, due to small chemical differences in the solution or in the metal, either the anodic or cathodic reactions may predominate. In an anodic area, the solution becomes more acidic and positive ions are drawn away from the surface. In a cathodic area, the opposite is true. For these reasons, it should be interesting to etch the surface under controlled potential.

Figure 11 shows the increase in inverse capacitance on drying as a function of the potential applied during etching. It seems clear that the layer noticeable after drying occurs when the surface becomes cathodic, rather than anodic. On a surface with more cathodic than anodic reaction, the aluminum ions formed tend to be held near the surface and because of the increased pH caused by the cathodic reaction, have more tendency to precipitate as a hydroxide or hydrous oxide. Note that this outer hydrous layer is still being formed when the net reaction is neither cathodic or anodic. The inverse capacitance of one anodic sample, measured using the evaporated electrode technique was 210Å, which was smaller than any nonanodic sample.

Contact angle measurements show the same trend. Figure 12 shows that the contact angle is low when the surface is anodic and high when it is cathodic. This was confirmed by a strong adhesion of electron microscope replica films to the anodic sample but not to the neutral or cathodic sample.

The above discussions can be clarified by actual examination of the surface by electron microscopy. Figures 13-15 show the appearance of the surface etched under different applied potentials. The porous

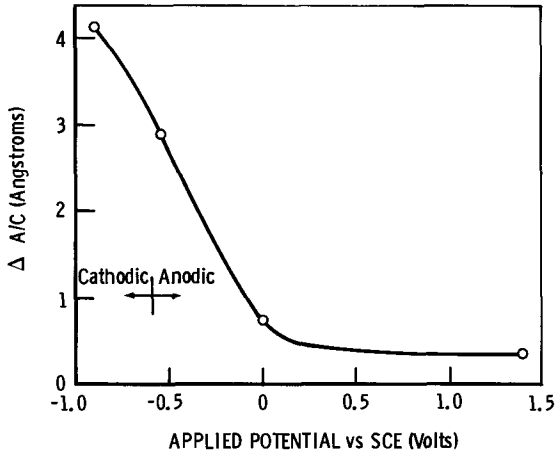

Fig. 11. Change in inverse specific capacitance (at 3.16 kHz) of samples dried in oven at 60° vs. potential applied to sample during etching.

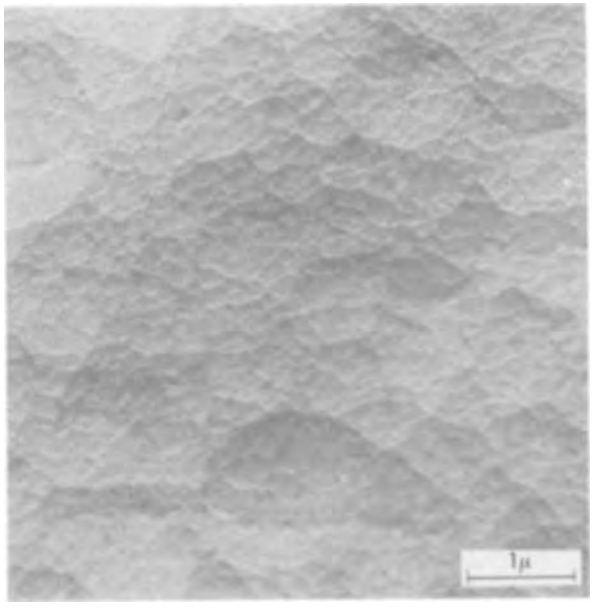

Fig. 13. Electron micrograph of surface etched with no applied potential.

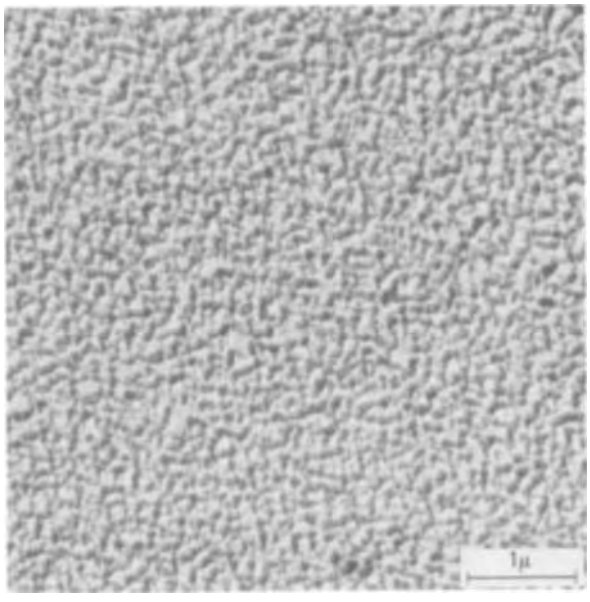

Fig. 14. Electron micrograph of surface etched with + 1.9V vs. SCE applied.

cell structure postulated in the first section of this paper is clearly evident with an anodic polarization during etching. When there is no applied potential, the cell structure is absent. It is presumed to be hidden by the hydrous layer. There is some structure present which appears similar to that characterized as a pseudo subgrain structure (15). This structure is absent in the anodic polarization which is actually a mild electropolish, the anodic surface being noticeably shinier than the others.

The cathodic surface shows some pores or pits which differ from the anodic cell structure. It is possible that these are due to the release of hydrogen from the surface. Although the normal cathodic reaction is the reduction of dichromate ion, hydrogen bubbling is seen on cathodic surfaces and when the oxide layer is thick.

Effect of copper.—An effect that has been shown earlier but not discussed, is the effect of impurity ions. It has long been known by practical etchers that a solution is apt to give unreliable surfaces until it has been used for a while. Copper ion was chosen for the

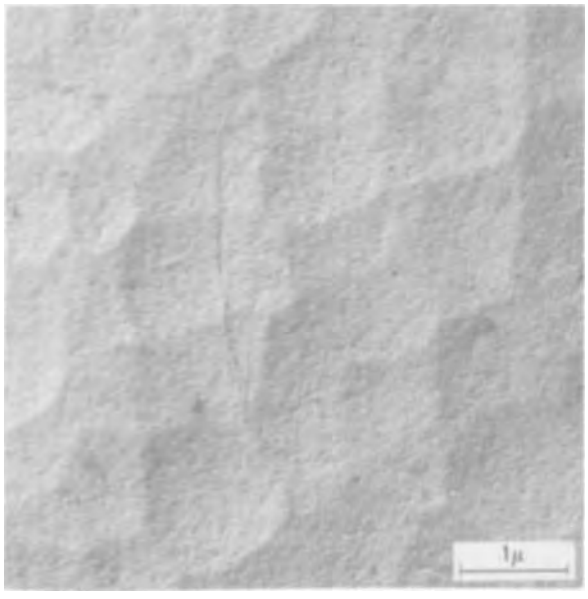

Fig. 15. Electron micrograph of surface etched with —1.0V vs. SCE applied.

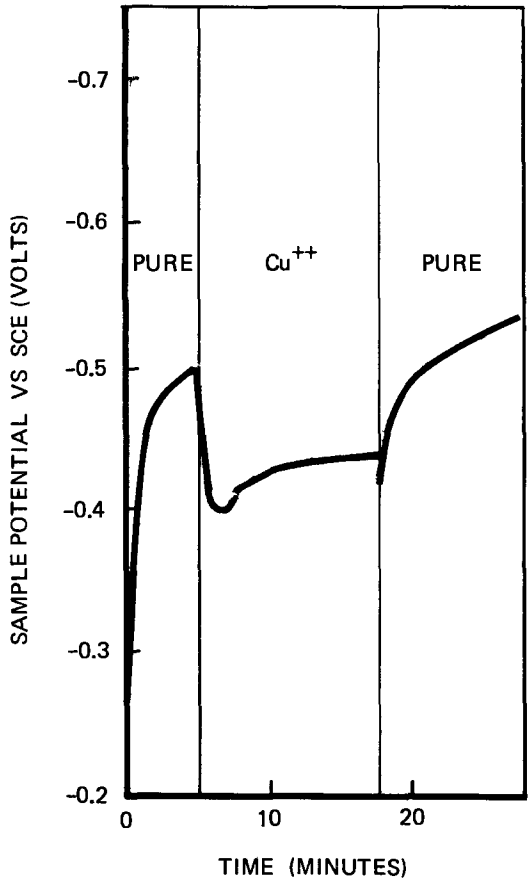

Fig 16. Sample potential vs. time in FPL etch with addition of 1.6×10^{-2}M cupric sulfate.

present study since it is an easily reducible ion which might be expected to catalyze the cathodic reaction. Copper ions increase the etch rate by a factor of 2 for 1.6×10^{-2}M copper sulfate. The anodic reaction, metal dissolution, is limited by the rate of the cathodic reaction. Figure 16 shows that the surface potential becomes more positive when copper is added to the solution.

Figure 17 shows how the inverse capacitance changes as a function of copper ion concentration. Both the

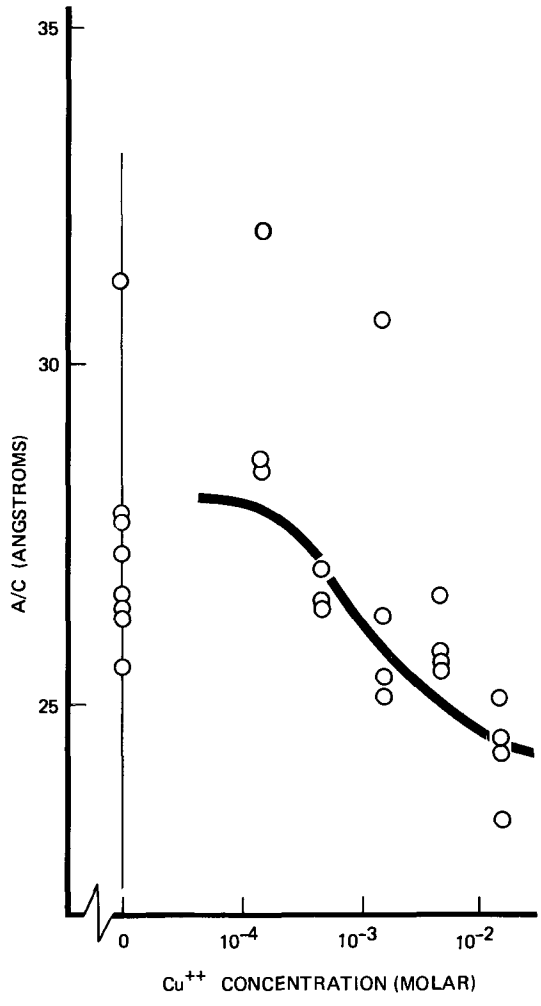

Fig. 17. Inverse specific capacitance (at 3.16 kHz) of samples dried in oven at 60°C vs. concentration of cupric ions in etchant.

average value of the inverse capacitance and the spread in the values decreases as the copper ion concentration is increased.

The increase in inverse capacitance shown by drying is more marked if the sample is heated in water vapor which tends to seal the oxide. Figure 18 shows the results of a study of rinse time using this sealing technique. There was no effect of rinsing within these limits. However, the high, variable values of the inverse capacitance obtained with a pure etchant are in sharp contrast to the low, nearly constant values obtained with a copper containing etchant.

In other regards, the addition of copper ions gives the same effects as anodic polarization. Figure 19 is an electron micrograph of a surface etched in a copper containing solution. The porous cell structure is quite obvious.

Figure 20 shows the effect of copper ion concentration on the contact angle. This is again similar to an anodic potential.

It is believed that copper ion actually deposits out on the surface providing local copper cathodes while the rest of the surface becomes anodic. At copper concentrations above that used here, a definite copper hue is given to parts of the surface by the etchant treatment. The surface examined in Fig. 19 looked uniform under the electron microscope but only a tiny fraction of the surface was examined. Alloys' surfaces have been examined which showed areas with and areas without the porous cell structure.

Manuscript submitted Dec. 11, 1972; revised manuscript received April 16, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Growth of GaP Layers from Thin Aliquot Melts: Liquid Phase Epitaxy as a Commercial Process

A. A. Bergh, R. H. Saul, and C. R. Paola

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The highest electroluminescent device performance in most III-V semiconductor materials was obtained on thin layers grown by liquid phase epitaxy (LPE). LPE has not been developed, however, as a commercial process. From a comparison of the factors affecting layer quality and process economy, it is concluded that a commercial LPE process favors the use of thin melts (possibly discarded after deposition), should provide substrate protection prior to deposition, and should be able to terminate LPE growth. A system has been designed in which a large volume of a saturated melt is sectioned into many small but equal thin melts (aliquot) for each substrate. The key to forming aliquots is wetting the substrate by the large volume of the melt in an apparatus constructed of nonwetted materials. The application of the above concepts to a multislice operation is described. Gallium phosphide LPE layers were grown in a single slice aliquot system from melts of 0.5-12 mm in thickness at cooling rates of 0.6°-6°C/min. Constitutional supercooling had no effect on the surface quality of the grown layers. The layers were degraded, however, if the substrates were thermally etched prior to deposition. High deposition efficiency and excellent thickness control were obtained for layers grown from thin melts. The deposition efficiency for layers grown from thick melts is limited by diffusion controlled mass transport in the melt. The diffusion coefficient of P in Ga has been evaluated at ~1000°C and no spontaneous nucleation was observed in melts supercooled by less than approximately 15°C.

The first commercial application of liquid phase epitaxy (LPE) in the semiconductor industry was the manufacture of germanium alloy junction transistors (1). Since this process required the LPE growth on each individual device, it could not compete economically with gas phase epitaxy or diffusion used in batch processing over the entire semiconductor wafer. The interest in LPE was revived with the successful utilization of this process for III-V semiconductors. Some high performance devices could be achieved only through the application of this method. Two outstanding examples are GaP LED's (2, 3) and heterostructure GaAs, GaAlAs lasers (4). Other device applications are discussed in a recent review article (5).

The quest for improved device performance, increased yield, and the requirements for batch processing have placed increased demands on the LPE technology. Higher quality material is demanded at lower cost. The purpose of this paper is to show, using GaP LED material as an example, that both requirements can be met simultaneously.

Requirements for GaP LED Material

To produce p-n junctions in GaP with high electroluminescent efficiency, two consecutive LPE layers must be grown, each approximately 25μ thick. Layer growth is accomplished by the depletion of a saturated Ga melt; the dopants are introduced into the melt prior to deposition.

High-quality devices impose the following material requirements: (*i*) uniform distribution of dopants in the plane of the junction with only a limited variation in the doping level perpendicular to the junction; (*ii*) precise thickness control and junction planarity over large-area substrates (usually over an inch in diameter); and (*iii*) smooth surface morphology to meet the requirements of subsequent device processing.

Economic considerations of a commercial LPE technology, on the other hand, ask for (*i*) small quantities of starting materials, (*ii*) short throughput time, *i.e.*, large production capacity, and (*iii*) reproducibility to achieve high production yields.

Key words: crystal growth, light emitting diodes, gallium phosphide.

Doping Uniformity

The uniform distribution of dopants in the plane of the junction requires that the dopants are evenly distributed in the melt. The distribution of dopants perpendicular to the junction plane is affected by the change in distribution coefficients with decreasing temperature during LPE growth (6), and by the loss of volatile dopants. The temperature dependence of the distribution coefficients of two commonly used dopants, Zn (p-type) (7) and Te (n-type) (8) have been determined. The solid solubility of Zn decreases, while that of Te increases as LPE growth proceeds. Combining this information with the Ga-GaP liquidus data (9), the variation of the net carrier concentration is obtained in the growth direction, as shown in Fig. 1. Following a relatively small change over the first two thirds of deposition, the Zn concentration drops sharply, while the concentration of Te rises abruptly at the end of deposition. This affects the concentration

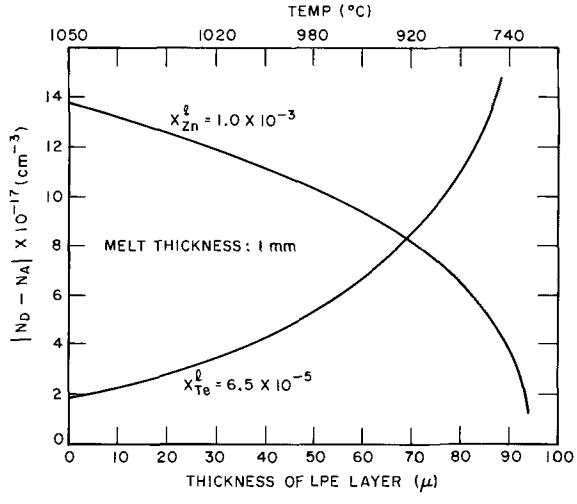

Fig. 1. Variation of the net carrier concentration perpendicular to the plane of the p-n junction in GaP layers grown from Zn- or Te-doped melts assuming 100% deposition efficiency.

of dopants at the p-n junction and/or at the surface where ohmic contacts are applied. Large changes in doping level can have a deleterious effect on both the efficiency of the junctions and on the properties of the ohmic contacts. This condition therefore must be avoided by terminating the LPE deposition after the depletion of approximately 50-75% of the melt or it must be corrected by removing part of the LPE layers after deposition. To avoid extra processing steps and the inherent risk of introducing damage and contamination during the material removal steps, it is desirable to design the LPE apparatus to terminate the growth.

Thickness Control and Planarity: Quality of LPE Layers

Although the Ga-GaP liquidus curve is well known, the fraction of the supersaturated GaP which deposits on the substrate during LPE is usually unpredictable. The uncertainty in the deposition efficiency, ζ, can be attributed to the slow transport of phosphorous atoms to the substrate and the loss of phosphorous atoms from the melt due to spontaneous nucleation and growth from the melt resulting from constitutional supercooling. (Deposition efficiency, ζ, is defined as the ratio of GaP deposited onto the substrate to the amount computed from the Ga-GaP liquidus curve.) To consider the transport of phosphorous atoms to the substrate, it is assumed that the cross-sectional area of the melt is equal to that of the area of the substrate exposed to the melt. It is also assumed that no convection occurs in the melt during LPE growth.

Two types of transport phenomena may in general be considered (10) for deposition: the transfer of heat away from the melt, and the diffusion of phosphorous atoms from the melt to the substrate. The relative transport rates can be assessed by comparing the values of thermal diffusivity of Ga ($\alpha \sim 10^{-1}$ cm^2/sec) and diffusion coefficient of P in Ga ($D \sim 10^{-5}$ cm^2/sec). The value of thermal diffusivity is higher by approximately four orders of magnitude, and hence mass transport and not heat flow limits the rate of LPE deposition under most LPE growth conditions. As a first approximation, we assume that the melt is isothermal and that the temperature is abruptly lowered from the initial to the final value. Rode has given an analytical treatment of the P concentration gradient for arbitrary cooling rates and a temperature-dependent P diffusion coefficient in the absence of convection (11). The concentration gradient in the melt for abrupt cooling can be described by the following equation (12)

$$\frac{C}{C_o} = \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{1}{(2n+1)} \exp\left[-D(2n+1)^2\pi^2 t/w^2\right] \sin\frac{(2n+1)\pi x}{w} \quad [1]$$

where C is the concentration of phosphorous atoms at distance x from the substrate toward the melt in excess of the equilibrium value. The initial concentration of excess phosphorus in the isothermal melt of thickness w is C_o, and the LPE deposition proceeds over time t. Some numerical values for this problem are given in Ref. (12) and are reproduced in Fig. 2. The substrate is at $x/w = 0$ and parallel to the ordinate. The numbers on the plotted curves are the values of Dt/w^2. Taking $D = 2.6 \times 10^{-5}$ cm^2 sec^{-1} for P in molten Ga, a value which fits best our experimental data (see section on Deposition Efficiency), the distribution of phosphorous atoms in the melt after 30 min of deposition is given by curves 1.5, 0.3, 0.1, and 0.03 for melt thicknesses of 1.8, 3.9, 6.8, and 12.5 mm, respectively. While over 90% of the 1.8-mm melt is depleted, only approximately 20% of the phosphorus is depleted from the 12.5-mm thick melt. Increasing the deposition time to 3 hr ($Dt/w^2 = 0.18$) still results only in approximately 50% deposition efficiency.

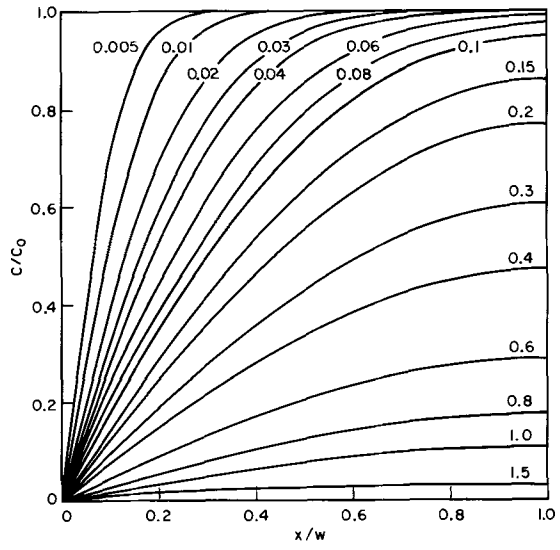

Fig. 2. Computed values of phosphorous concentration in the melt during LPE deposition assuming an instantaneous temperature drop in the near isothermal melt and the absence of spontaneous nucleation in the melt. The numbers on the curves are the values of Dt/w^2.

Although the above calculations give optimistic values for some practical LPE conditions (the available phosphorous atoms are reduced by spurious nucleation in the supersaturated melt and cooling is accomplished over a finite time, reducing the effective value of C_o in Eq. [1]), they clearly point out the importance of using thin melts to obtain high deposition efficiency.

Tiller and Kang (13) and later Minden (14) mathematically treated the effect of cooling rate and melt thickness on the minimum temperature gradient perpendicular to the substrate required to avoid constitutional supercooling. Table I shows the minimum temperature gradients calculated for typical GaP LPE conditions from Eq. [26c] of Minden's paper (14). It is assumed that a 20μ thick LPE layer is to be grown in 30 min. Cooling rates and temperature ranges for deposition (ΔT) are adjusted accordingly. In terms of the required temperature drop across the melt, the 0.5-mm melt is the most favorable. In fact, for layer thicknesses exceeding 4 mm, the required temperature drop across the melt is greater than the total cooling interval, indicating that supercooling cannot be avoided in LPE runs using thick melts and fast cooling. Since the degree of supercooling and hence the onset of spontaneous nucleation in the melt can be expected to change with the experimental conditions, a high degree of thickness control can be expected only for layers grown from thin melts if the melt is to be substantially depleted.

Economic Considerations

Economic considerations also favor thin melts. One of the major expenses in a conventional LPE process

Table I. Minimum temperature gradient (dT/dx) required across the melt of thickness w at the end of deposition to avoid constitutional supercooling. Computed from Eq. [26c], Ref. (10)

Total cooling time = 30 min
LPE layer thickness = 20μ
Initial temperature, T_i = 1040°C
Temperature range, $\Delta T = T - T_f$
(T_f = temperature of substrate at the end of deposition)

w, mm	ΔT, °C	Depletion of melt, %	Cooling rate, °C/min	dT/dx, °C/mm
0.5	108	67	3.6	6.0
1	40	33	1.3	4.5
2	18	17	0.6	4.1
4	8	8	0.3	2.9
12	3	3	0.1	1.1

is the large amount of starting materials. This expense can be recovered by the extensive reuse of the melt, placing stringent requirements, however, on the apparatus and ultraclean operating conditions. The reduction of the melt thickness, on the other hand, greatly reduces the cost of the starting material, and hence both layer quality and process economy favor the use of thin melts.

LPE Apparatus

The use of thin melts to grow III-V semiconductor layers has been suggested before. Donahue and Minden (15) proposed, for example, a limited volume boat, as shown in Fig. 3. Since the spacing between the substrate holder and the crucible wall was not wetted by Ga during the rotation of the boat, the minimum melt thickness obtainable was ~3 mm. We have achieved much smaller melt thicknesses by using surfaces wetted by Ga. Since the formation of very small volumes of melt is not practical, a large volume of saturated melt is divided into small but equal fractions (aliquot) using two sliders. The thin melt can be discarded after the LPE growth.

The parts of the apparatus are shown in Fig. 4. A melt reservoir is held in the frame with cover plates to seal the top of the frame. Two sliders are positioned into the frame, moving underneath the reservoir and cover plate from left to right. Slider 2 contains the substrate and the dump well used in the removal of the aliquot from the substrate when the growth is terminated. Slider 1 has an opening slightly larger than the substrate and is used to form the aliquot. Both sliders are aligned under the reservoir and simultaneously translated from left to right to form the aliquot.

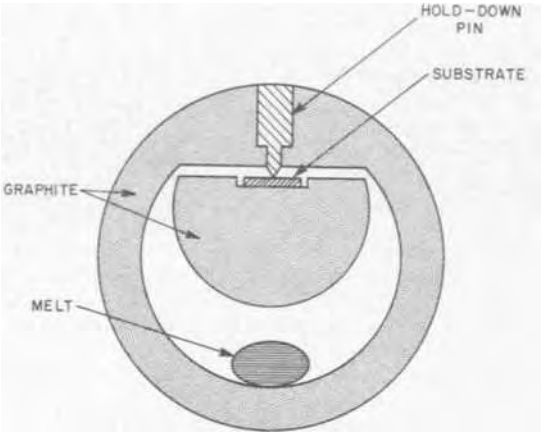

Fig. 3. Transverse cross section of a limited volume boat proposed by Donahue and Minden (15).

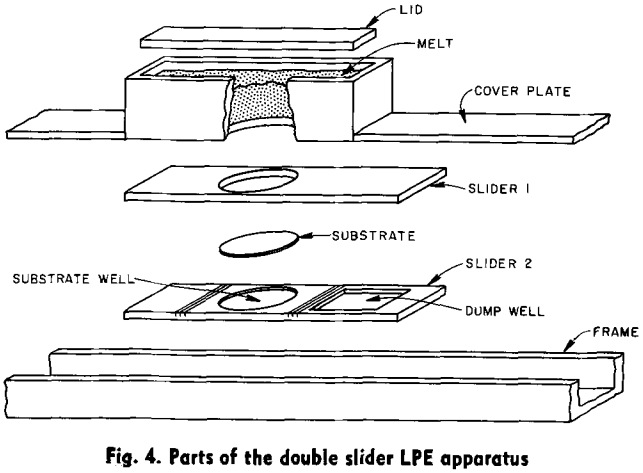

Fig. 4. Parts of the double slider LPE apparatus

Table II. Effect of the gaseous ambient on the contact angle (degrees) of gallium on various surfaces at two temperatures (750°/1000°C)

Surface	Ambient: Hydrogen	Ambient: Nitrogen (containing 5 ppm O_2)
GaP	110/60	100/60
Graphite	130/120	98/50
Quartz-smooth	125/100	90/90
Quartz-rough	110/100	98/60

Formation of Aliquot and Termination of LPE Growth

In order to form a thin aliquot, the liquid must be in contact with a surface which is wetted by the liquid. On the other hand, the removal of the melt must be accomplished with a surface which is not wetted, to avoid the formation of a film between two wetted surfaces. The wetting of GaP and various structural materials by molten gallium were determined from linear cross sections of Ga droplets (16). The contact angles are listed in Table II for two temperatures, 750° and 1000°C. The gaseous ambient in the furnace was changed from reducing (hydrogen) to slightly oxidizing (nitrogen + 5 ppm O_2). The GaP surfaces were wetted ($\theta < 90°$) at the higher temperatures in both ambients. None of the structural materials was wetted in the reducing ambient; however, the contact angles decreased in the oxidizing ambient, especially for graphite. This change in wetting is probably caused by the formation of Ga_2O_3 on the liquid which is then deposited over the adjacent surfaces. It can be expected, therefore, that a reducing ambient facilitates the termination of the deposition.

The essential features of aliquot formation are shown in Fig. 5. First the substrate is lined up with the saturated melt in the reservoir, (a). Note that the GaP is wetted by the liquid gallium, while the other parts of the apparatus are not.

The aliquot is formed by the simultaneous movement of the two sliders past the reservoir, (b). Since the liquid wets the entire GaP surface, melts of 0.5 mm can be formed reproducibly. After the deposition of the LPE layer, the growth is terminated by wiping the melt into the dump well, as shown in Fig. 5(c). Since the graphite is not wetted by the melt (in reducing ambients), complete wiping can be obtained with a clearance of less than 75μ between the grown LPE layer and the bottom of slider 1.

Multislice LPE Operation

The essential features of the system described so far are: (i) the formation of aliquots for each sub-

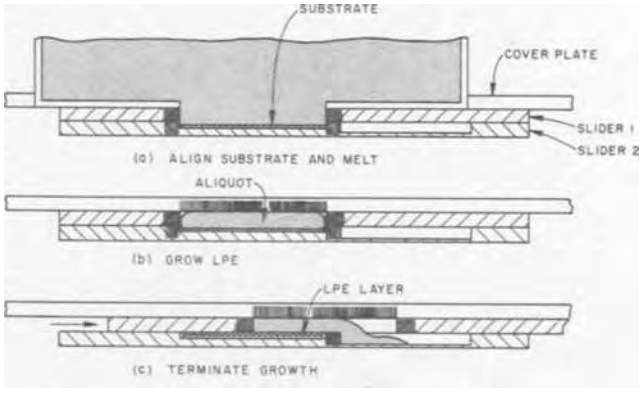

Fig. 5. The substrate is exposed to the saturated melt (a). A small but equal fraction (aliquot) is confined over the substrate during LPE growth (b). The melt is wiped off to terminate LPE growth by the relative movement of the sliders (c).

strate using the wetting of GaP by molten Ga, (*ii*) LPE deposition from thin, confined melts (aliquots), and (*iii*) the ability to terminate LPE growth. There are many ways to incorporate the above principles into a production system. Aliquots can be formed sequentially or simultaneously. LPE deposition can be carried out in a single temperature zone which is cycled or in a lower temperature zone of the same furnace in which the saturated melt is formed. In principle, a variety of forces (mechanical, gravitational, pneumatic, or centrifugal) can be applied to remove the aliquot melts upon the termination of growth.

Figure 6 demonstrates the operational steps for a multislice LPE deposition. Each slider pair contains one substrate and one dump well. After the saturated melt is formed (a), the slider pairs are moved along to sequentially form the desired number of aliquots (b) and (c). After LPE deposition is accomplished, the sliders on the top are moved to wipe off the aliquots, thereby terminating the growth (d). LPE deposition can be carried out simultaneously in a single zone furnace or sequentially in a multizone furnace.

The experiments described in the following sections were carried out with only one pair of sliders using quartz or graphite apparatus. A conventional diffusion furnace with a 24-in. flat zone was modified to provide constant cooling rates. This was accomplished by inserting a Eurotherm variable emf ramp generator in series with the primary thermocouple. Only one aliquot was formed from a saturated melt at 1030°C. In a typical run, the furnace temperature was lowered by 10°-100°C, the LPE growth was terminated, and the substrate was removed from the furnace. After inserting a new substrate, the furnace again was equilibrated at 1030°C and the growth sequence repeated. The layers were grown on the P{111}-face of chemically polished GaP substrates grown by the liquid encapsulation Czochralski method (17). The cross-sectional areas of the substrates and aliquot melts were approximately 6 cm^2.

Deposition Efficiency

The control of layer thickness requires tight control over the precipitation of GaP from the melt. Two factors will influence the effective deposition efficiency: (*i*) the degree of supersaturation in the melt, and (*ii*) precipitation at places other than the substrate. Under normal growth conditions, spontaneous nucleation is expected to reduce the concentration of phosphorous atoms in the melt, and hence the effect of cooling rate on layer thickness will be smaller than anticipated.

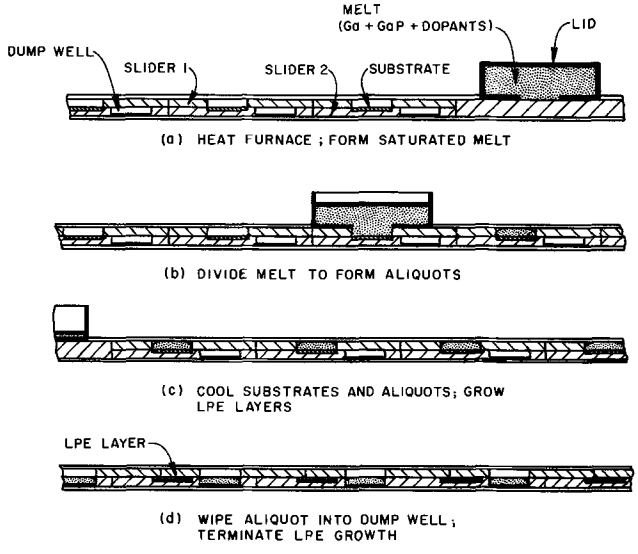

Fig. 6. Multislice LPE deposition in a double slider aliquot LPE apparatus. (a) A large volume of the saturated melt is prepared at the initial growth temperature. (b) Small fractions of the melt (aliquots) are formed over each substrate. (c) LPE layers are deposited by cooling to a lower temperature. (d) LPE growth is terminated by wiping off the aliquots.

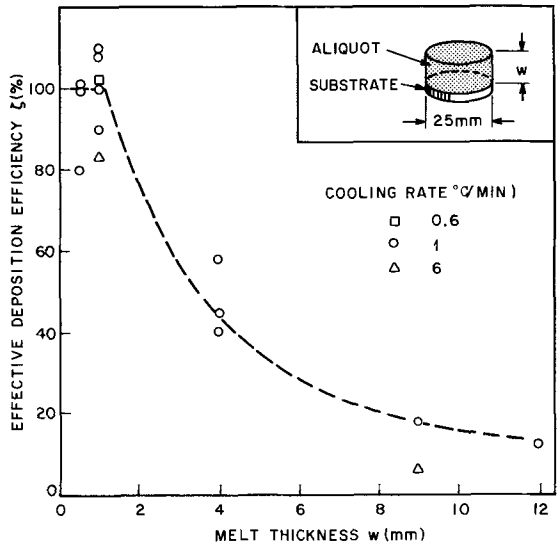

Fig. 7. The effective deposition efficiency as a function of melt thickness and cooling rate.

To evaluate the effect of melt thickness, w, on the effective deposition efficiency, ζ, a series of layers were grown, varying the thickness of slider 1 to obtain the desired values of w. Figure 7 schematically depicts the geometry of the melt and substrate used in the experiments as well as the determined values of ζ as a function of w. Each data point represents a separate run. The initial temperature was 1030°C and the temperature increments for growth were selected (see Table III) to produce layer thicknesses in the range compatible with effective wipeoff. The data in Fig. 7 show that close to 100% effective deposition efficiency is obtained for $w \leq 1$ mm. The efficiency falls off roughly as w^{-1} for increasing values of w. For a given temperature interval of growth, the thickness of the grown LPE layer is proportional to the melt thickness, w, for $w \leq 1$ mm. The decrease in efficiency with melt thickness for $w > 1$ mm results in the following paradox. Since ζ falls off as w^{-1} for thicker melts, the thickness of the grown layer is approximately independent of the melt thickness. As a consequence, the growth of thick LPE layers requires growth over wide temperature ranges or material transport from a source piece to the substrate in a thermal gradient. The values in Fig. 7 agree reasonably with the results of other LPE systems, such as tipping ($w \sim 5$ mm) (18) or dipping ($w \sim 15$ mm) (19).

Diffusion limited deposition efficiency for abruptly cooled melts can be expressed from Eq. [1] as follows

$$\zeta = 1 - \int_{x=0}^{w} \frac{C}{C_o}\, dx \qquad [2]$$

The variation of ζ as a function of the dimensionless parameter Dt/w^2 is given in Fig. 8. The experimental data in Fig. 7 are transposed into Fig. 8 by selecting a value of $D = 2.6 \times 10^{-5}$ cm^2 sec^{-1} and defining t as the cooling interval, ΔT, divided by the cooling rate. The value of D was selected to obtain best fit for the

Table III. Cooling increments used for LPE growth

Melt thickness, w (mm)	Cooling increment, ΔT (°C)
0.5	75
1.0	75
4	18
9	12
12	12

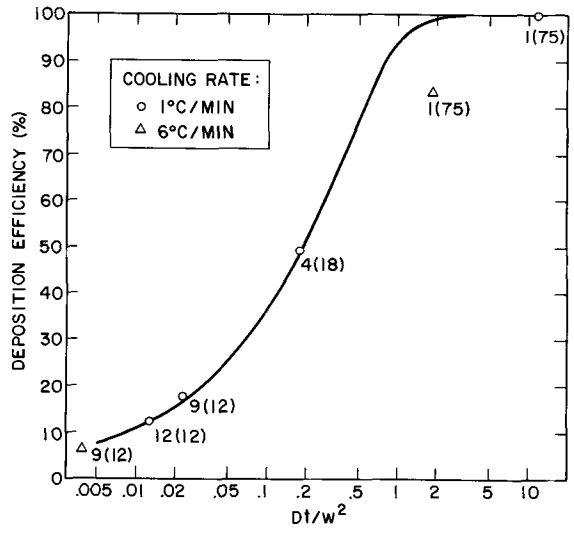

Fig. 8. Deposition efficiency as a function of the dimensionless parameter Dt/w^2. The solid curve is calculated from Eq. [2] assuming $D = 2.6 \times 10^{-5}$ cm^2 sec^{-1} and the data points are transferred from Fig. 7 as discussed in the text. The numbers adjacent to the data points denote the melt thickness in millimeters and the cooling increment in degrees centigrade, respectively.

calculated universal curve. Exact calculations of Ref. (11) for each data point indicate a time value of $D = 5.7 \times 10^{-5}$ cm^2 sec^{-1}. The numbers next to the data point indicate the respective melt thickness, w, and cooling increments, ΔT. For cooling intervals of $T \leq 12$°C, good agreement can be obtained between the experimental and calculated values by the proper selection of the diffusion constant, D, even for large values of w. The agreement is also quite good for large temperature increments ($\Delta T = 75$°C) and slow cooling. The deviation from the theoretical curve for the large ΔT and fast cooling is attributed to spontaneous nucleation in the melt. Supercooling in this experiment exceeds 15°C.

Quality and Surface Morphology of Grown Layers

Under our experimental conditions, melt thickness and cooling rate had little effect on the uniformity of the thickness of the grown layers. However, the largest taper and the only nonplanar junction was observed with the extreme conditions of thick melt ($w = 9$ mm) and high cooling rate (6°C/min). For all other cases, the variation in layer thickness was less than ±10%, reaching values as low as ±3% across the 2.5-cm substrate diameter. Constitutional supercooling, present in the thick melts, had been shown to have little effect on the surface morphology (20), contrary to previous observations (21). However, two factors were found to influence the surface quality of the grown layer: (*i*) the condition of the substrate surface prior to deposition, and (*ii*) formation of a second phase in heavily doped melts. Thermal decomposition of the substrate exposed to a large volume of the apparatus results in rough substrate surfaces (22). This leads to perturbed internal boundaries (junctions) and Ga occlusions, as shown in Fig. 9. Occlusions of this type point to the importance of the protection of the substrate prior to LPE growth, as provided by the cover plate in Fig. 4. Although rough surfaces can be substantially corrected by melting a part of the substrate in a slightly undersaturated melt, the over-all surface planarity cannot be fully restored. In fact, nonuniform meltback itself can lead to an irregular growth interface with subsequent Ga entrapment (23). It has been reported that the formation of a second phase leads to similar surface degradation in layers heavily doped by oxygen (24) or nitrogen (25). We have observed similar effects in tellurium-doped layers with net carrier concentrations in excess of 5×10^{18} cm^{-3}, presumably due to the formation of gallium telluride.

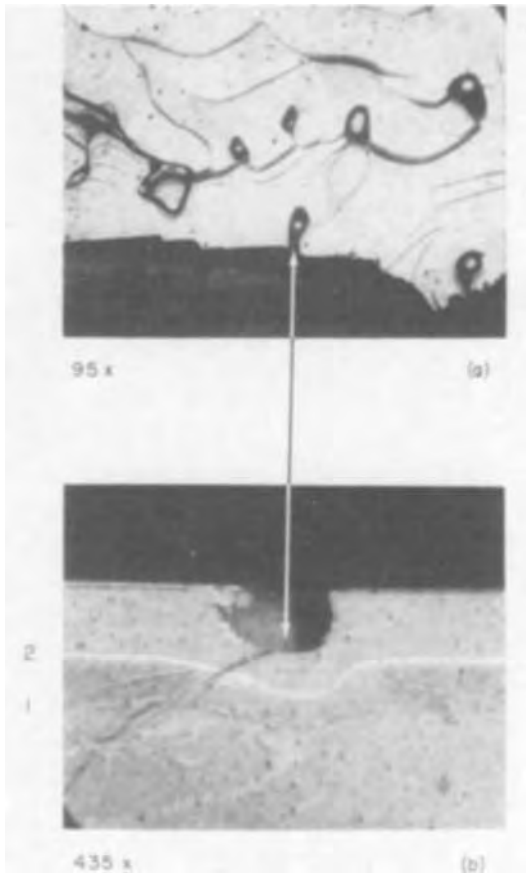

Fig. 9. Gallium occlusions in a 70μ thick LPE layer on a vapor etched substrate. Topview of a 70μ thick LPE grown on a vapor etched substrate showing gallium occlusions (a) and the cross-sectional view of an occlusion from which the gallium is removed (b). The depression at the substrate-LPE layer interface denoted 1 on (b) resulted from the vapor etching. The interface denoted 2 was introduced by an abrupt increase in the cooling rate and it amplifies the depression in the substrate leading to the gallium occlusion.

Summary

It is shown that a commercial LPE system for GaP LED material where the dopants are added to the melt can be optimized by using thin melts and by the termination of the LPE growth. An LPE system is proposed which forms thin melts by sectioning off small but equal parts of a saturated solution (aliquot) taking advantage of the fact that GaP is wetted by molten Ga. The performance of a prototype system has been evaluated, and conceptual modifications for mass production techniques are enumerated. Close to 100% deposition efficiency and hence excellent control over layer thickness and uniformity is obtained with aliquot melts of less than 1 mm. The deposition efficiencies obtained with larger melt thicknesses are in good agreement with calculated values assuming diffusion limited material transport and a low value of the diffusion constant, $D = 2.6 \times 10^{-5}$ cm^2 sec^{-1}. Exact calculations (11) yield $D = 5.7 \times 10^{-5}$ cm^2 sec^{-1} for P in Ga. The deviation from the calculated values for large temperature increment and high cooling rate is attributed to spontaneous nucleation in the melt when supercooling exceeds ~15°C. The thickness of the grown layer is roughly independent of the thickness of the melt for melt thicknesses in excess of 1 mm. The utility of the grown layer is affected by the quality of the substrate and the amount of dopants in the melt and not by the degree of constitutional supercooling.

Acknowledgment

The authors would like to acknowledge helpful discussions with D. L. Rode on mass transport during

LPE deposition and the exact value of the diffusion constant of P in Ga as well as access to his unpublished work. D. L. Rode has also provided the numerical solutions given in Table I. O. G. Lorimor assisted in the preparation of Fig. 1. D. D. Roccasecca assisted in the crystal growth and in the evaluation of LPE layers. We have also benefited from helpful discussions with F. A. Trumbore, L. R. Dawson, and O. G. Lorimor.

Manuscript submitted Feb. 12, 1973; revised manuscript received *ca.* June 1, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Thin Silicon Film on Insulating Substrate

Greg L. Kuhn and C. John Rhee

Motorola Incorporated, Semiconductor Research and Development Laboratories, Semiconductor Products Division, Phoenix, Arizona 85008

ABSTRACT

Experimental results on a new technique for making a thin silicon epitaxial layer on an insulating substrate are presented. The technique utilizes the anisotropy of the etch rate of silicon in the aqueous potassium hydroxide-isopropyl alcohol system. The silicon film can be either n- or p-type with a thickness in the low micron range (under 3 μm). The thickness variation can be controlled to ± 0.5 μm across a 2 in. diameter wafer.

The great interest in silicon-on-insulator can be readily understood if one considers its potential application in device technology, especially in JFET's, fast MOST logic/memory circuits, and in radiation resistant devices.

Work is being done in the field of silicon-on-insulator by utilizing silicon-on-sapphire (1), silicon-on-spinel (2), and silicon-on-polycrystalline silicon (3). Mechanical polishing and electrochemical and electrolytic thinning (4-6) are the most commonly used techniques in fabricating silicon-on-polycrystalline silicon.

This paper describes another possible technique for making a thin silicon epitaxial layer on an insulating material by utilizing a self-regulating silicon etching step to precisely control the layer thickness. This layer can be n- or p-type with a thickness in the low micron range (under 3 μm) and with uniformity of control of ± 0.5 μm across a 2 in. diameter wafer.

There is one basic chemical etching process, called the KOH etch stop, which makes this SOIS (silicon-on-insulating-substrate) technique fundamentally different from dielectric isolation techniques. The etch stop consists of a highly boron-doped silicon layer. Figure 1 shows the etch rate of <100> oriented silicon as a function of boron doping concentration. An etch rate differential of as high as 50:1 is observed.

Key words: silicon-on-insulated-substrate (SOIS), anisotropic etch, polycrystalline silicon, P+ etch stop.

Experimental

Steps 1 through 7 of Fig. 2 depict the basic processes of the SOIS technique. One begins with a planarized, polished N or P^- silicon substrate. Boron is diffused into the substrate to obtain the etch stop buffer layer (step 1). Depositing a boron doped epitaxial layer is

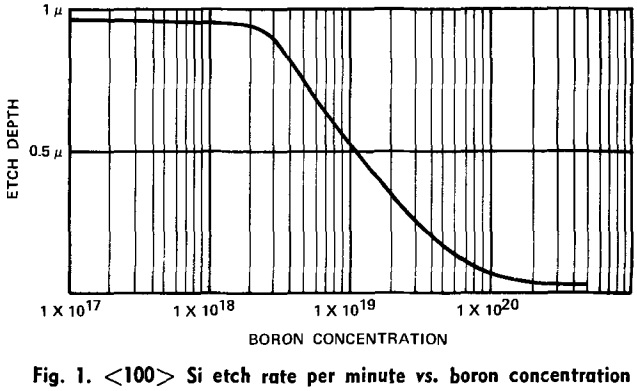

Fig. 1. <100> Si etch rate per minute vs. boron concentration in KOH-H_2O-isopropyl alcohol system at 80°C.

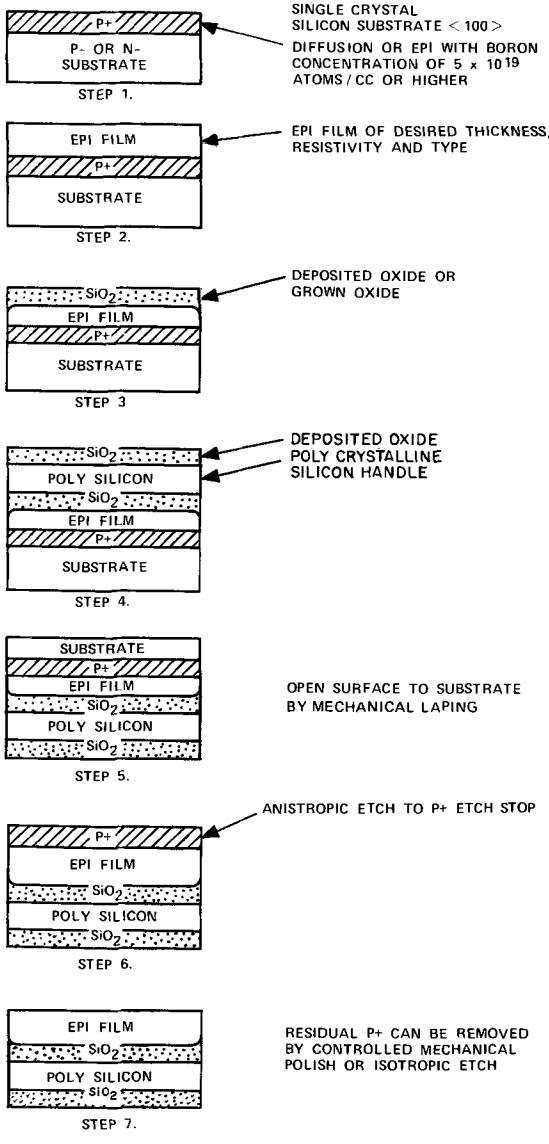

Fig. 2. Fabrication steps for thin single crystal silicon on SiO_2

an alternate method of obtaining this P^+ film. A thin single crystalline film of desired thickness and resistivity, in which the active devices will be fabricated, is epitaxially deposited on the P^+ layer (step 2). At the end of the epi cycle an insulator is deposited. The insulator can be SiO_2, Si_3N_4, or others, or any combination thereof (step 3). Polycrystalline silicon is then deposited directly on the insulator and is capped with another layer of insulator (step 4). The wafer is then mechanically backlapped to within 7.5×10^{-3} cm (3 mils) of the P^+ buffer layer. An additional 5×10^{-3} cm (2 mils) are removed by isotropic etching (step 5).

The remaining substrate is removed using the anisotropic KOH etch solution (step 6). The P^+ buffer layer acts as an etch stop when it is exposed to the solution. This allows one to remove the remaining portion of the substrate which may be left across the wafer due to any error introduced by the mechanical backlapping. The large etch rate differential allows one to obtain a uniform silicon layer at this point. The P^+ etch stop is now removed using an isotropic silicon etch and the SOIS material fabrication is complete (step 7).

Results and Discussion

In this section the material fabrication steps are discussed in detail and the experimental results are presented. The initial substrate in our experiment was a 2 in. diameter <100> silicon wafer that was 5-6 ohm-cm n-type. An n-type wafer was chosen to enable one to easily test when the P^+ etch stop was reached. The testing was done using a standard hot-point probe and visual inspection. During the boron diffusion into the starting substrate prior to epi deposition the highest possible P^+ concentration is needed to obtain the maximum etch rate differential. However, deposition of a high quality epi layer on the heavily doped substrate is a difficult task. Both epi deposition on a diffused P^+ layer and on a doped P^+ epi layer are under investigation. For our experiment the P^+ diffused layer had a surface concentration of 2.5×10^{20} atoms/cm^3 with a junction depth of 2 μm, and the initial n-type epi thickness was 5 μm. Then 1 μm of SiO_2 was deposited directly on the epi. The thickness and type of this insulator are dictated by the subsequent devices and circuits to be fabricated on the finished wafer.

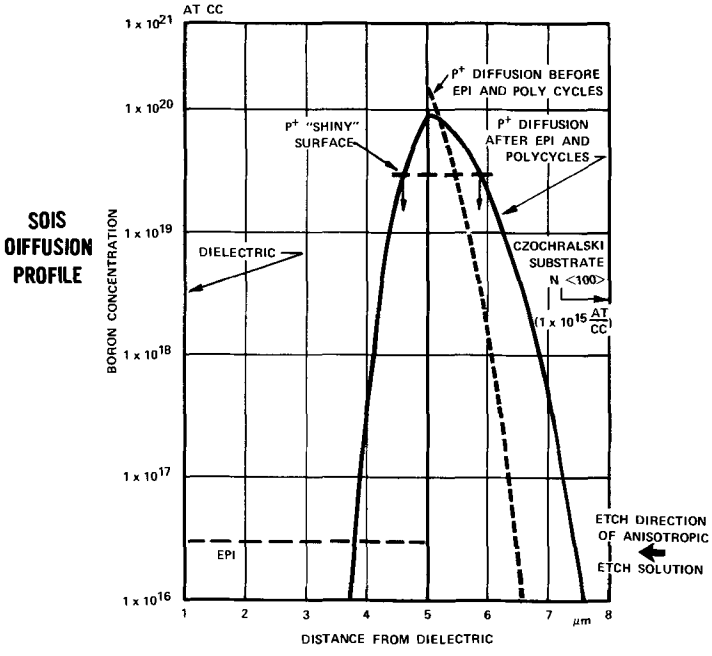
In order to minimize the boron out-diffusion into the epi and original n-type substrate during the polycrystalline silicon deposition cycle, the poly should be deposited at the lowest possible temperature with a maximum deposition rate. The buried layer diffusion profile for our work is shown in Fig. 3(a). The P^+ diffusion curve, before epi and polycrystalline cycles, was calculated as the complementary error function with boundary conditions of surface concentration and diffusion depth. The P^+ diffusion curve after epi and polycrystalline silicon cycles was calculated as a Gaussian redistribution also using surface concentration and diffusion depth as boundary conditions. The boron redistribution was predominantly a function of the polycrystalline silicon deposition cycle. For our experiment we deposited 3.5×10^{-2} cm (14 mils) of polycrystalline at 1000°C using a SiH_4 (silane) source. The calculated and experimental redistribution data match well as can be seen by comparing Fig. 3(a) and 3(b).

A wafer warpage problem was encountered for polycrystalline silicon deposition at temperatures $\leq$1000°C. This problem was somewhat alleviated by using a thicker starting substrate, which was 5×10^{-2} cm (20 mils) for our experiment. At present, several sources, deposition temperatures, and rates are being investigated to solve the problems of warpage and out-diffusion during the polycrystalline silicon deposition cycle.

After polycrystalline deposition, the original <100> substrate is removed to within 25 μm of the P^+ etch stop by standard backlapping and back etching. The remaining 25 μm of starting substrate are removed at the rate of 0.9 μm/min in the aqueous KOH-isopropyl alcohol anisotropic etch. The surface appearance becomes shiny as the P^+ layer becomes exposed because of the surface leveling with respect to the boron diffusion profile.

The control in thickness uniformity by the use of the etch stop can be illustrated by the use of an example. Assume that there is a 25 μm (1 mil) taper across a 2 in. diameter wafer. Further assume that the P^+ etch stop is just becoming exposed in certain portions while there are other areas that still have 25 μm substrate material remaining (see Fig. 4). By the time this 25 μm thick portion etches out (about 25 min) the portion where the P^+ etch stop was first exposed is only etched by 0.5 μm. Thus it can be seen that the 25 μm taper has been reduced to a 0.5 μm taper across a 2 in. diameter wafer. However, it should be mentioned that there is a change in etch-rate differential due to boron redistribution, and thus the uniformity control degrades accordingly. Figure 5 shows a typical wafer with P^+ etch stop exposed across an entire wafer.

The wafer now has a P^+ layer, epi and insulator on supporting polycrystalline silicon as shown in Fig. 6. What remains before achieving a finished substrate is the removal of the P^+ etch stop. This is accomplished using an isotropic silicon etch. Among several silicon etches that were investigated the HNO_3:CH_3COOH:HF silicon etch, as reported by Sumitomo (9), was found to be most reliable. He reported an etch rate



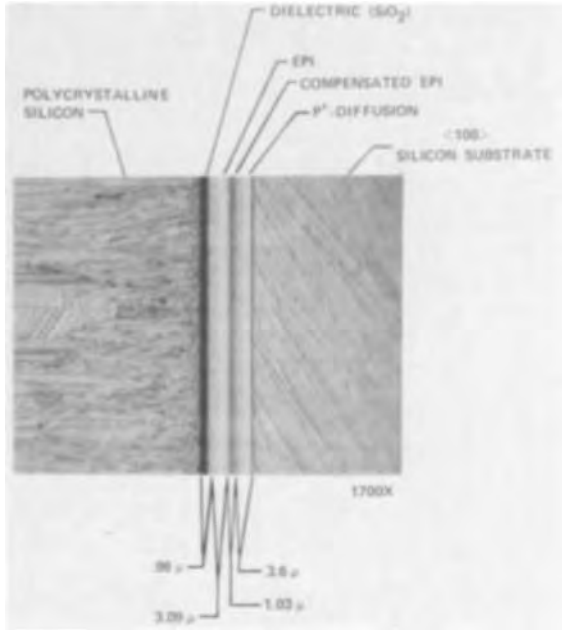


Fig. 3. P+ etch stop doping profile. (a) Theoretical, (b) experimental

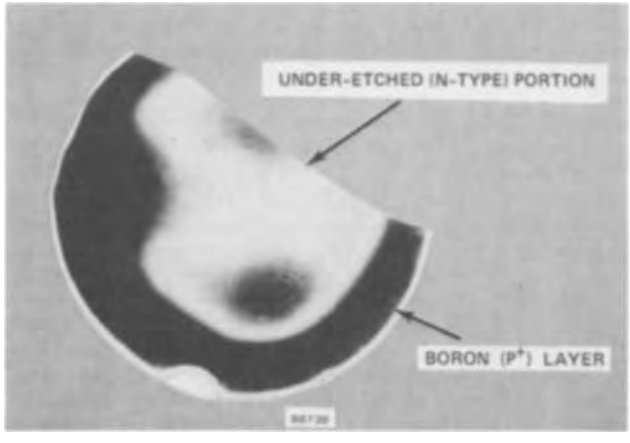

Fig. 4. A wafer with underetched portion (n-type)

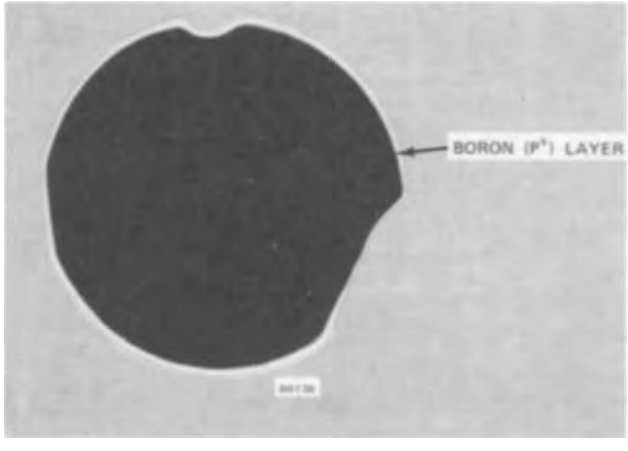

Fig. 5. A wafer with P+ etch stop exposed on entire surface

differential of approximately 70:1 between 5.8×10^{-3} and 3×10^{-1} ohm-cm p- or n-type material. This etch rate differential provides an adequate etch stop at the interface between the P+ buffer layer and n-type epi.

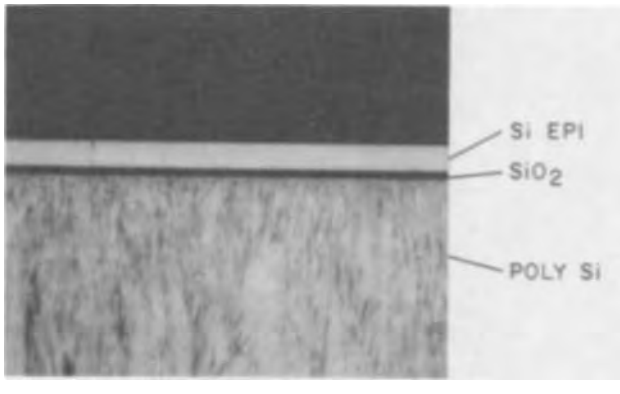

Fig. 7. Thin silicon film on SiO_2 with P+ etch stop removed

Figure 7 shows a cross-sectional view of a finished wafer.

Conclusion

In conclusion, it has been shown that a thin single crystal silicon film with an epi uniformity of ±0.5 μm across a 2 in. diameter wafer can be produced on an insulating substrate. This is attained by the use of two etch stops. The first etch stop is the P+ buffer layer and the second etch stop is the relatively high resistivity epi layer. Further refinement in the poly-

crystalline silicon deposition cycle, and limitation of the extent of boron out-diffusion, will determine the feasibility of this technology as applied to batch processing.

Etch Rate Characterization of Boron-Implanted Thermally Grown SiO_2

F. N. Schwettmann,* R. J. Dexter, and D. F. Cole*

Texas Instruments Inc., Dallas, Texas 75222

ABSTRACT

The effect of boron implantation on the etch rate of thermally grown SiO_2 has been studied for a wide range of energies, doses, and anneal conditions. For unannealed oxides, a significant increase in etch rate is observed with increasing dose. The depth of maximum damage as determined by the peak in the etch rate profile occurs at approximately 60% of the ion range as predicted by LSS theory. When annealing is carried out in nitrogen, high temperatures (~1200°C) are required to remove all measurable damage created by high dose implants. When an oxygen or steam ambient is used, considerably lower temperatures achieve the same result. Although the ion profile as determined from the etch rates can be approximated by LSS theory, skewing of the profile towards the surface indicates that higher moments are required in the distribution calculation.

In the fabrication of silicon semiconductor devices using ion implantation, thermally grown SiO_2 is frequently used as a mask to define the area which is to be implanted. The nature of the damage and the ion distribution in the oxide mask before and after annealing can affect both the subsequent processing steps and the final device characteristics. A recent study by Dalton and Pickar (1) provides a measure of the damage caused by the implantation process. They found a significant increase in the oxide etch rate when a boron dose of 1×10^{15} ions/cm^2 is implanted through a 2000Å thick layer at 150 keV. It was also indicated that anneal temperatures as high as 1050°C are required to remove any measurable damage. At the high energy used in their study, most of the energy dissipation of the implanted ions will be due to electronic interactions. This will result in considerably less damage than will occur in the case of a masking oxide where nuclear interactions become significant as the ions come to rest within the oxide.

At the present time there is little information concerning the ion distribution in the oxide. Volod'ko *et al.* (2) have reported that the range for boron implanted in thermally grown SiO_2 is in good agreement with LSS theory (3). On the other hand, they report a range straggling that is greater than theory predicts. Their experimental technique involved the measurement of the surface resistivity of the annealed underlying silicon after implanting through various thickness oxide films. This technique, as indicated by the authors, suffers from two deficiencies. One is the use of an average value of mobility, thereby neglecting its variation with concentration. Also, the SiO_2-Si interface is assumed to have no influence on the distribution of the impurity atoms in the oxide.

The purpose of this paper is to determine by an etch rate characterization study the following: (*i*) the damage distribution in the oxide caused by the implantation; (*ii*) the effect of anneal temperature, time, and ambient on this damage; and (*iii*) the ion distribution in the oxide so that the minimum oxide thickness for masking can be determined.

Experimental

Czochralski grown silicon slices of (111) orientation with a resistivity of 5-10 ohm-cm were oxidized at 1100°C in steam to an oxide thickness of about 1 μm. The implantation was carried out with B^{11} ions obtained from an rf source using BF_3 as the source gas. The ion beam was accelerated, focused, mass analyzed, and electrostatically scanned over the target surface. The dose was varied from 1×10^{12} to 1×10^{16} ions/cm^2 at energies of 30 to 150 keV. The dose rate was approximately 0.1 μA/cm^2. After implantation, the slices were cleaned in an rf glow discharge at room temperature with an oxygen ambient followed by a 20 min soak in a solution of 7 parts sulfuric acid and 3 parts hydrogen peroxide (30-35%) at 60°-80°C. The slices were then rinsed for 20 min in deionized water and spun dry.

Etch rate profiles were obtained on both annealed and unannealed slices. Annealing was carried out at 900°-1250°C in a fused quartz tube and unless otherwise indicated, in a nitrogen atmosphere. Other ambients considered were oxygen and steam. Two differ-

* Electrochemical Society Active Member.

Key words: ion implantation, silicon dioxide, boron, etch rates, annealing.

ent etch solutions were used in order to separate the damage and the boron profiles. It has been shown (4) that when P-etch[1] is used as etchant, the etch rate for boron doped SiO_2 is greater than for an undoped oxide. The opposite is true for a buffered HF solution, *i.e.*, the etch rate for boron-doped SiO_2 is slower than for the undoped oxide. For this study a buffered HF, referred to hereafter as C-etch, of the following composition was used: 40 parts HF (49%), 325 parts NH_4F (40%), and 10 parts H_2O. Etching was carried out at 25°C for 15-180 sec depending on the implanted dose and anneal conditions.

Two different techniques were used to determine the oxide thickness for the etch rate calculation. For well-annealed slices, ellipsometry was used. Since the refractive index of boron-doped oxides has been shown to be the same as for undoped thermal oxides (5), interpretation of the measurement is straightforward. For slices which were implanted at high doses and not annealed, an increase in the refractive index has been reported (6). For these samples a different technique was used to determine the oxide thickness. Prior to the implantation the slice was coated with photoresist and a pattern formed. The oxide defined by the photoresist was then implanted, the resist removed, and the slice cleaned as described earlier. The step difference between the implanted and unimplanted region formed during etching was measured by a Taylor-Hobson Talystep.[2]

Results and Discussion

Etch sensitivity.—The sensitivity of P-etch and C-etch to the boron concentration and extent of damage was determined by measuring the etch rates for a wide range of boron doses. A summary of these results for implants made at 82 keV is shown in Table I. Considering the P-etch data first, a relatively high dose of 1×10^{16} ions/cm^2 annealed at 1200°C for 30 min in N_2 gives, within experimental error, an etch rate comparable to unimplanted oxide. Since both the damage and boron should cause an increase in the etch rate, it is apparent that the etch is not sensitive enough to detect boron at this concentration level [theoretical peak value based on LSS theory (3) = 7×10^{20}/cm^3]. Therefore, any enhancement in the etch rate for lower doses and anneal conditions can be attributed to residual damage in the oxide. This result also shows that no residual damage can be detected using P-etch for a sample annealed at 1200°C.

The sensitivity of P-etch to damage is shown by the low dose results in Table I. For a dose of 1×10^{12} ions/cm^2, an unannealed oxide has an etch rate that is only slightly greater than that of unimplanted SiO_2. When the dose is increased to 1×10^{13} ions/cm^2, the damage becomes more apparent as the relative etch rate increases to 1.06. At a dose of 1×10^{14} ions/cm^2, this increases to 1.49 and at 1×10^{15} ions/cm^2 to 3.82. These results are the average values for the top 4000Å of oxide, hence larger values are to be expected at the peak damage depth. A similar result is also shown for C-etch at a dose of 1×10^{15} ions/cm^2. In this case, the relative etch rate is less, 1.89 compared to 3.82 for P-etch.

Table I. Sensitivity of etch rate to boron concentration and damage

Dose (ions/cm^2)	Anneal conditions: Temp. (°C)	Anneal conditions: Time (min)	Etch	Relative etch rate
1×10^{16}	1200	60	P	1.02
1×10^{13}	None		P	1.03
1×10^{13}	None		P	1.06
1×10^{14}	None		P	1.49
1×10^{15}	None		P	3.82
1×10^{15}	None		C	1.89
1×10^{13}	1200	30	C	0.99
1×10^{15}	1200	30	C	0.99
1×10^{16}	1200	30	C	0.79

The last three rows in Table I illustrate the effect of dose on the relative etch rate for well-annealed samples using C-etch. At low doses the etch rate is identical to unimplanted oxide, while at 1×10^{16} ions/cm^2 a reduced rate is observed. At this dose level, the boron concentration is sufficiently high that the expected decrease in etch rate is easily detected.

The calculated relative etch rates are based on comparison with an unimplanted sample etched at the same time. The average etch rate for unimplanted oxide is 2.4 Å/sec using P-etch and 16.8 Å/sec with C-etch. The observed maximum variation in the absolute etch rate was ± 10% while the variation in the relative etch rate was usually better than ± 2%.

Unannealed profiles.—Typical etch rate profiles obtained with P-etch for unannealed implants of 82 keV B^{11} at 1×10^{14} and 1×10^{15} ions/cm^2 are shown in Fig. 1. At the lower dose, the maximum etch rate is twice that of the unimplanted oxide, while at 1×10^{15} ions/cm^2 the peak rate is about 5.5 times greater. These peak values are observed at a depth of 1900 ± 100Å. A similar result was observed with C-etch, except that the peak value in the etch rate was lower. It should be noted that for the higher dose, the etch rate shows a higher value for the initial surface layer. This was found in almost all the high dose samples investigated. The depth of the peak value is approximately 60% of the ion range as predicted by LSS theory (3). This value is typical of the damage/ion depth ratios observed when various ions are implanted in silicon (8).

Effect of anneal variables.—The effect of anneal temperature on the average relative etch rate using P-etch is shown in Fig. 2. As expected, higher anneal temperatures are required to remove the damage formed by heavier doses. However, a significant fraction of the damage is annealed out at all of the temperatures indicated. For example, at 1×10^{15} ions/cm^2, the average relative etch rate of the unannealed oxide is 3.82. At 900°C after 60 min, the relative etch rate is down to 1.25. Increasing the anneal temperature to 1000°C results in a small decrease in the relative etch rate to 1.15. A similarly small decrease is observed at 1100°C.

If the curves shown in Fig. 2 are extrapolated to a relative etch rate of 1.0, the dose at which all the measurable damage is removed can be determined. A plot of this dose *vs.* anneal temperature is shown in Fig. 3. For a given dose and anneal temperature, this figure indicates whether residual damage will be present in

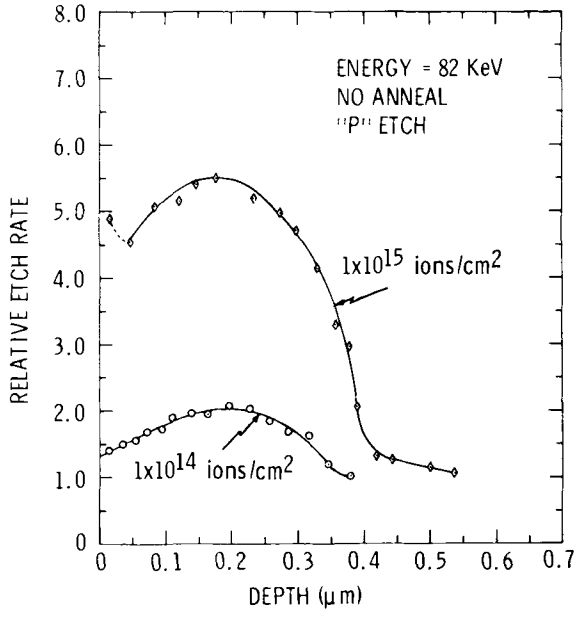

Fig. 1. Effect of dose on the etch rate profile for unannealed oxide.

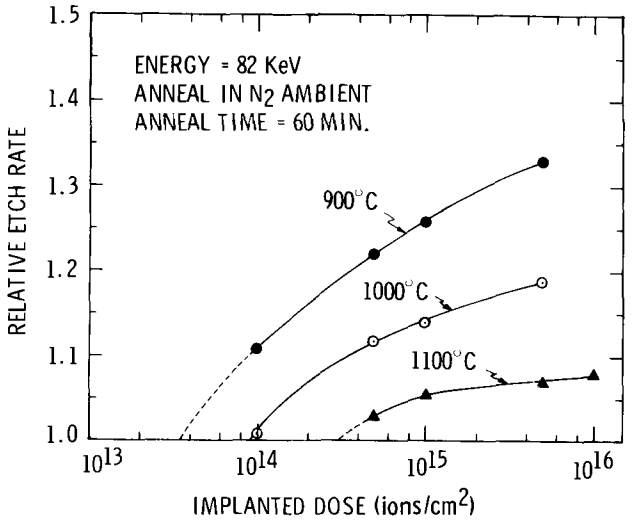

Fig. 2. Effect of dose and anneal temperature on the relative etch rate.

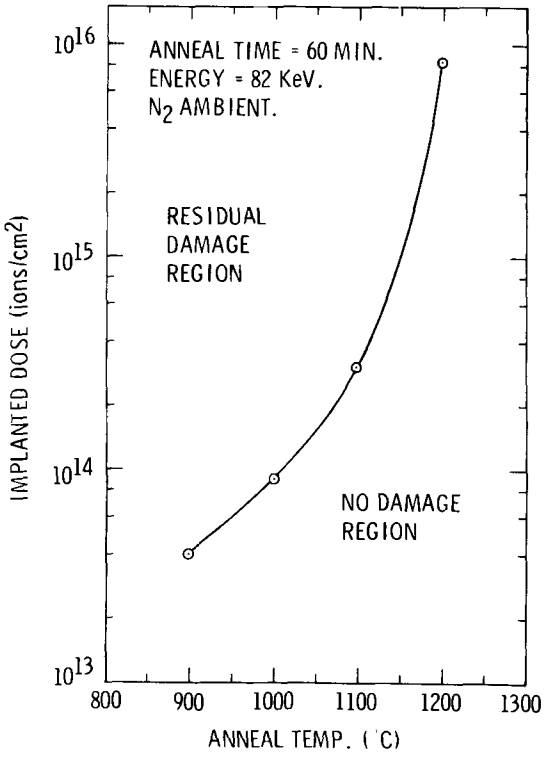

Fig. 3. Implanted dose-anneal temperature correlation defining regions of damage and no-damage.

the oxide. The area to the right of the curve is the "damage free" region while to the left residual damage will be observed.

The effect of anneal time and ambient are shown in Table II. At 1×10^{14} ions/cm², increasing the anneal time from 30 to 120 min at 900°C results in a small decrease in the relative etch rate, 1.12-1.06. Annealing in an oxygen ambient also results in a small decrease in the etch rate. The most dramatic change is observed for annealing in steam. As indicated in Table II, the damage resulting from a dose of 1×10^{16} ions/cm², can be completely removed by annealing at 900°C in steam. In a nitrogen ambient, a comparable result requires a temperature of 1200°C. This is not surprising since it has been shown (9) that steam is more effective than a dry atmosphere in densifying oxides deposited at low temperatures (300°-400°C).

The etch rate technique is a relative measure of a number of oxide properties such as density, stoichiometry, and bond strain. The initial rapid decrease in etch rate at all anneal temperatures and ambients is believed to be due to densification as vacancy clusters anneal out. In the second stage where the etch rate decreases slowly with time and temperature, recombination of oxygen with immoble silicon atoms having unsaturated bonds is suggested. The migrating oxygen can be either that present initially in the oxide and displaced during implantation or from trace quantities in the nitrogen ambient. Since oxygen diffuses slowly in the oxide (10), particularly at 900°C, the recombination process restoring the stoichiometry of the oxide will be slow as observed. In the case of steam, both the solubility and diffusivity are considerably larger (10), giving rise to the more rapid annealing.

Table II. Effect of anneal time and ambient on the relative etch rate using "C"-etch

Dose (ions/cm²)	Temp. (°C)	Time (min)	Ambient	Relative etch rate
1×10^{14}	900	30	N_2	1.12
1×10^{14}	900	60	N_2	1.10
1×10^{14}	900	120	N_2	1.06
5×10^{14}	1000	30	N_2	1.26
5×10^{14}	1000	30	O_2	1.15
5×10^{14}	900	60	N_2	1.22
5×10^{14}	900	60	Steam	0.98
1×10^{15}	900	60	N_2	1.26
1×10^{15}	900	60	Steam	1.02
1×10^{16}	900	60	N_2	1.35
1×10^{16}	900	30	Steam	1.03

Annealed profiles.—The variation of relative etch rate with depth for a dose of 1×10^{16} ions/cm² annealed at 1200°C is shown in Fig. 4. As expected from the results shown in Table I, the relative etch rate decreases with the increase in boron concentration. The two lower energy curves, 55 and 82 keV, are nearly symmetrical about the minimum, while at the higher energy the curve is skewed towards the surface. A plot of the minimum etch rate depth as a function of energy is shown in Fig. 5. The solid curve is the projected range values taken from Johnson and Gibbons (7) and corrected for the difference in density of quartz (2.66 g/cm³) used in their calculations and that of thermally grown SiO_2 (2.26 g/cm³) used here. This correction gives a projected range that is about 18% greater (2.66/2.26 = 1.18) than the tabulated values (7). The etch rate minimum is seen to be in good agreement

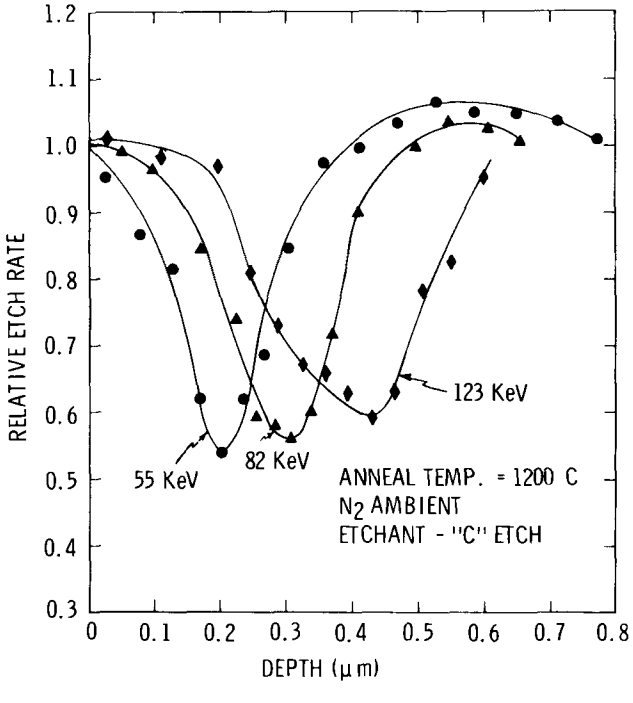

Fig. 4. Variation of the etch rate profile with implant energy

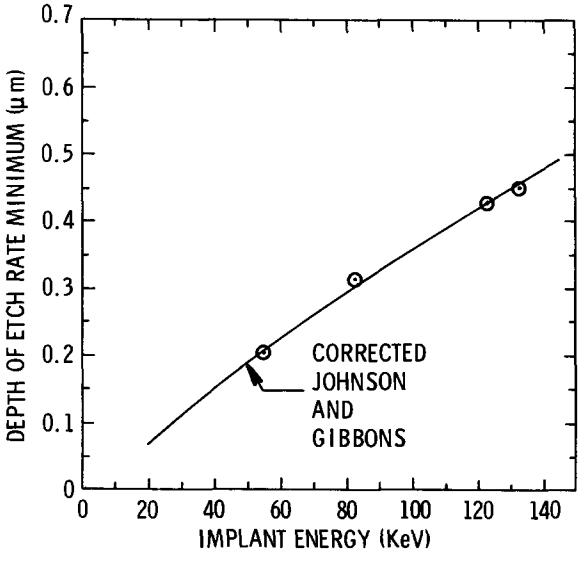

Fig. 5. Comparison of experimental and calculated projected range.

with the calculated projected range values. These values also agree well with the results of Volod'ko *et al.* (2).

A direct measure of the range straggling cannot be obtained from Fig. 4 since a relation between the etch rate and boron concentration is not available. In order to generate an approximate calibration curve, the etch rate profiles for a wide range of implant energies and doses was obtained. It was assumed that the minimum value in the profile corresponded to the peak boron concentration calculated using the range straggling values given by Johnson and Gibbons (7). The results are shown in Fig. 6. The minimum concentration which can be detected by the C-etch is approximately 10^{19}/cm^3. Using this data and the etch rate profiles in Fig. 4, the concentration profiles shown in Fig. 7 were generated. The solid curves shown were calculated using the experimental range value in Fig. 5 and the range straggling of Johnson and Gibbons (7). For the two lower energies, the experimental results agree quite well with the calculated values except at the low concentrations where the error in the calibration curve is greatest. In each case, agreement is better at depths beyond the peak concentrations. The region closer to the surface shows a greater departure from Gaussian, particularly at the higher energies. The range straggling agreement is in contrast to the results of Volod'ko *et al.* (2) who found that the range straggling was 2 to 3 times the LSS value.

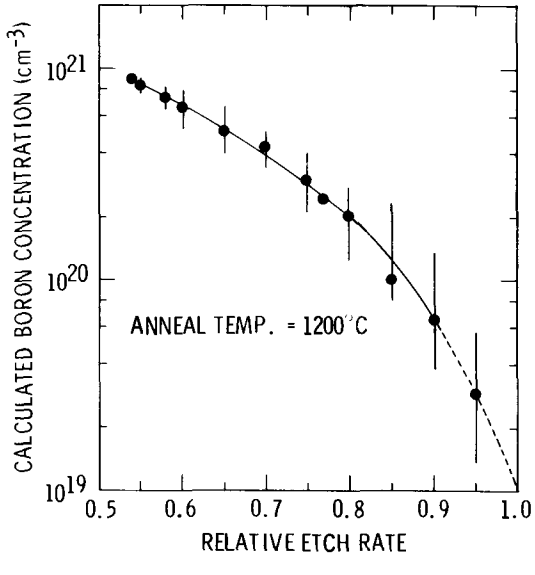

Fig. 6. Calibration curve relating the etch rate to the calculated boron concentration.

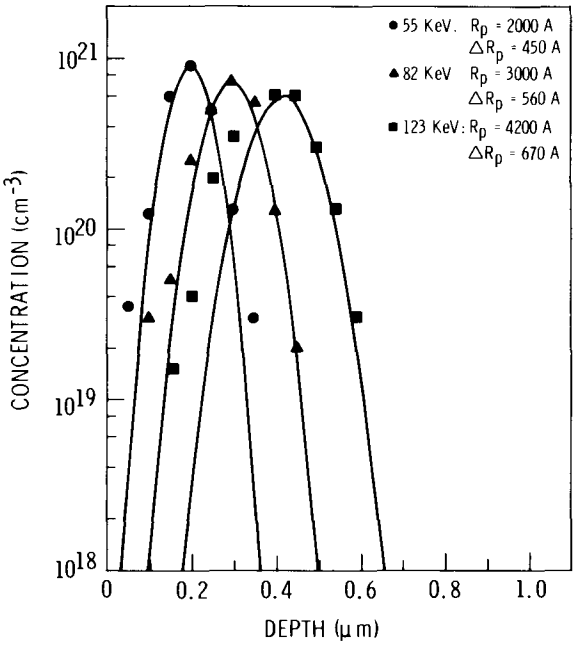

Fig. 7. Comparison of the calculated and experimentally derived boron concentration profiles. The curves were calculated using the indicated projected range and projected range straggling values.

In making a comparison between the experimental and theoretical predictions, several factors need to be kept in mind. First, since an assumption concerning the shape of the ion distribution was made in generating the calibration curve, some degree of circular reasoning is involved in generating the ion profiles. The final result then, is more of a check for consistency than an absolute determination. Second, the etch rate profiles were determined after the samples had been annealed at 1200°C. Possible broadening of the distribution could have occurred as a result of thermal diffusion. Preliminary measurements obtained by ion microanalysis (12), however, indicate that the 1200°C anneal for 30 min does not cause any measurable change in the boron profile. These data also show that the range straggling used in generating the calibration curve (Fig. 6) are reasonably close to the measured values on the deeper side of the distribution.

An important observation in the data of Fig. 7 and also in the initial ion microanalysis results is that the boron profiles are not symmetrical about the range value but are skewed towards the surface. If the amount of enhanced diffusion towards the more heavily damaged surface layer during implantation is assumed to be small, then higher moments need to be considered in calculating the ion distribution. Gibbons (13) has shown that for boron implanted in silicon, a profile that is skewed towards the surface is expected when higher order terms are included. At higher energies the effect should be even more pronounced. Similar results are expected for boron implanted in SiO_2 (13). The need for higher order moments makes comparison with tabulated values where only the first two moments are considered, invalid. However, for most practical applications, a reasonable approximation can be obtained by using the range values shown in Fig. 5 and the range straggling given by Johnson and Gibbons (13).

Minimum oxide thickness for masking.—The data shown in Fig. 7 were used to determine the minimum oxide thickness required to prevent boron from penetrating into the underlying silicon. The minimum thickness was chosen as the depth at which the concentration of boron was 10^{14}/cm^2. The results for the dose

range 1×10^{14} to 1×10^{16} ions/cm^2 are shown in Fig. 8.

In order to confirm that the boron did not penetrate through the oxide at the values given in Fig. 8, a number of samples were implanted with 1×10^{16} ions/cm^2 at the energy corresponding to the minimum thickness and standard MOS C-V measurements (14) made to determine the average surface concentration. Half of each slice was unimplanted as a standard for comparison. For the six energies investigated, the surface concentration on the implanted side was found to be identical within experimental error, to the unimplanted side.

Conclusions

Determination of the etch rates of boron-implanted SiO_2 using P-etch and a buffered HF solution provides a simple technique for evaluating both the damage and boron distributions. The maximum etch rate in the damage profile is located at a depth that is approximately 60% of the ion range as predicted by LSS theory (3). High anneal temperatures are required to remove all measurable damage when annealing is carried out in nitrogen. Considerably lower temperatures can be used when annealing in a steam ambient. While the boron distribution can be approximated by a Gaussian, the skewing of the measured profiles indicates that higher moments are required in the determination of the distribution.

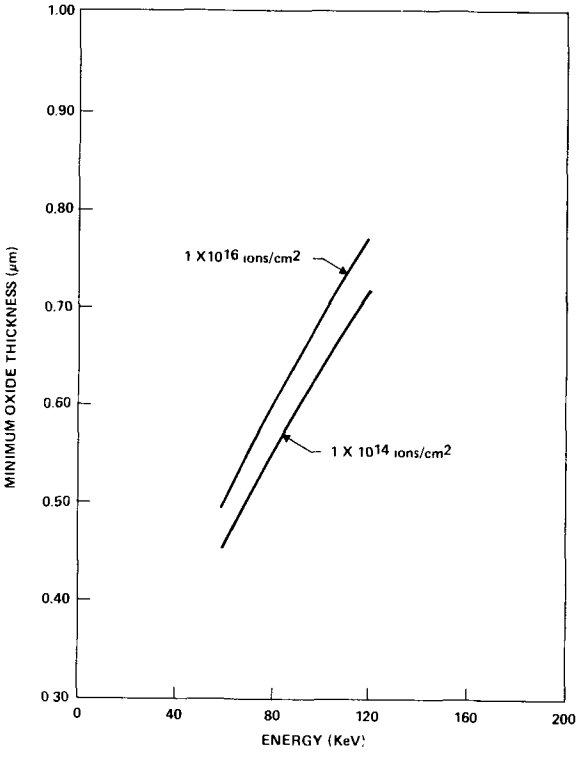

Fig. 8. Minimum oxide thickness required to mask a boron implant

Liquid-Phase Epitaxy Growth of Gallium Phosphide by a Centrifugal Tipping Technique

S. Y. Lien and J. L. Bestel

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

ABSTRACT

A new growth technique for GaP single crystal material based on the liquid-phase epitaxial growth method is presented. This technique relies on centrifugal force to bring the saturated growth solution in contact with the substrate. The apparatus, referred to as the "centrifugal tipper," is described and its principles of operation are explained. Epitaxial layers, both n- and p-type, up to 100 μm thick, have been grown over a temperature range of 950°-1050°C. These layers exhibit good surface quality and variations in thickness of less than ± 1 μm. A p-type material with photoluminescence efficiency of 1.5% was produced. This new technique has demonstrated multi-slice capability for the growth of GaP light-emitting diode material.

Liquid-phase epitaxial (LPE) growth has been, to the present time, the most successful method for producing high quality GaP light-emitting diode material (1). This report describes a growth technique based on LPE growth which produces luminescent epitaxial material with good surface and thickness uniformity. The apparatus used in this growth technique is referred to as the "centrifugal tipper" since it relies on centrifugal force to "tip" the growth solution over the substrate.

The centrifugal tipper and its fundamental principles are described, and the properties of the epitaxial layers grown by this method are presented.

Apparatus

Description of the apparatus.—For the purpose of discussion, the centrifugal tipper (Fig. 1) can be divided into three major subsystems: the crucible assembly, the drive assembly, and the heating unit.

The crucible assembly, which is made of ultrapure graphite is depicted in Fig. 2 and consists of four major parts: the outer crucible which contains the growth solution, the inner core which holds the substrate, the middle core which protects the substrate, and the nut which holds the inner and middle crucibles fastened together. The crucible used on the centrifugal tipper was designed to accommodate eight 25 mm diameter substrates.

The drive assembly consists of a motor-driven shaft which passes through the crucible and is guided above and below by two sets of bearings. Two sets of chevron seals are placed next to the bearings toward the crucible in order to seal the tipping chamber from the outside atmosphere. These seals also prevent the bearing lubricant from being pumped out during evacuation of the chamber. The drive shaft serves another very important function besides rotating the crucible assembly. It is used to remove the heat from the crucible during cooling by a flow of water in the shaft (this water cooling also protects the bearing and seals from overheating).

The heating unit consists of an rf generator and coil. The coil was designed in such a way that the spacing between its loops can be varied. The loops can thus be kept close together where more heat is needed and farther apart where less heat is needed.

Principles of operation of the centrifugal tipper.—The principle of operation of the centrifugal tipper is to spread the saturated GaP in Ga solution over the substrate by centrifugal force. When the crucible is spun the solution is forced outwards by the centrifugal force and flows through the canals which connect the solution cavity to the growth cells. When the cavity is filled with the solution, the temperature of the crucible is lowered thus promoting the growth of an epitaxial layer on the substrate. At the end of the growth process, the rotation of the crucible is stopped and the solution returns to the solution cavity via the connecting canals.

Effect of the centrifugal force on the liquid solution.—In choosing a suitable rotation rate to fill the growth cavity with the liquid solution, a cylindrical crucible without internal structural restrictions rotating on a vertical axis was assumed. The free surface of the liquid under the centrifugal force is then paraboloidal, and the relationship between the height of the paraboloid from the vertex (h), the radius of the cylinder (r), and the rotation rate (N) is given by

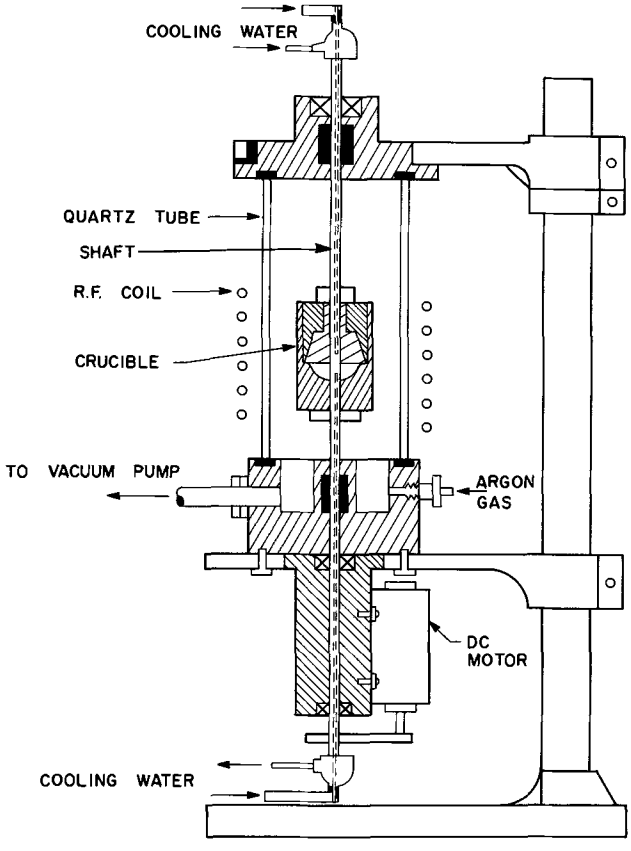

Fig. 1. Apparatus for centrifugal tipping. The cross-sectional view of the centrifugal tipper is shown.

Key words: crystal growth, liquid-phase epitaxy growth, gallium phosphide, centrifugal tipping.

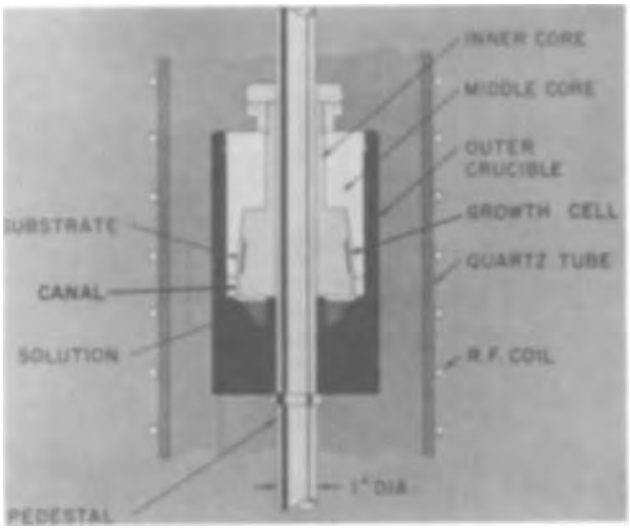

Fig. 2. Crucible assembly. The cross-sectional view of the crucible assembly is shown.

$$h = r^2\omega^2/2g$$

or

$$h = 2\pi^2N^2r^2/g \qquad [1]$$

where ω is the angular velocity and g is the gravitational constant. For a growth cavity situated 25 mm from the rotation axis and about 50 mm from the bottom of the crucible, a rotation rate of 500 rpm or more is needed to completely fill the cavity.

Effect of the buoyancy forces on the substrate.—There is a radial pressure gradient inside the growth cavity due to the centrifugal force field since the pressure is proportional to the square of the radius. When a substrate is immersed in the solution under a centrifugal force field, it experiences two buoyancy forces: the first one is in a vertical direction and is due to the earth's gravitational field; the second is in a radial direction and is due to the centrifugal field. At 500 rpm the magnitude of the centrifugal force ($\sim 10g$) is much larger than that of the gravitational force and the latter can be neglected. The force acting on the solid is therefore

$$f = \omega^2(r_2^2 - r_1^2)(d_s - d_l)A/2 \qquad [2]$$

Where r_1 is the radial distance from the axis of rotation to the inner surface of the solid, r_2 the radial distance from the same axis to the outer surface of the solid, d_s the density of the solid, d_l the density of the liquid, and A the cross-section area of the solid in a tangential plane. If the density of the liquid is greater than that of the solid, the latter will be pushed toward the axis of rotation and vice versa. In the case of a GaP substrate in a GaP-Ga solution, the density of the solid GaP is 4.13 g/cm^3 (2), and the density of the solution is about 5.91 g/cm^3 (since the concentration is so low that we are assuming its density to be equal to the density of pure Ga). As a consequence, the GaP substrate will be pushed toward the axis of rotation when the growth cavity is filled with the growth solution.

Effects of adverse temperature gradients in the liquid.—Bénard (3) experimentally demonstrated that a layer of liquid will display a cell pattern through thermal convections. Rayleigh (4) gave a theoretical interpretation of the Bénard cell formation. He showed that the formation of cells under a temperature gradient depends on the numerical value of a nondimensional parameter, R. This parameter is now referred to as the Rayleigh number and is given by

$$R = g\cdot\alpha\cdot\beta\cdot d^4/k\cdot\nu \qquad [3]$$

where g is the gravitational constant, d the thickness of the liquid layer, β the temperature gradient across the liquid layer, and α, k, and ν the coefficient of volume expansion, thermometric conductivity, and kinematic viscosity, respectively. Rayleigh showed that cell formation will occur when the parameter R exceeds a certain critical value R_c.

Chandrasekhar (5) has calculated R_c values for different boundary conditions. In the case of a layer of liquid lying between two rigid surfaces, $R_s = 1708$. The centrifugal tipping apparatus was therefore designed in such a way as to keep the Rayleigh number below 1708. If this precaution were not taken, Bénard cells would arise in the growth solution which would lead to uneven epitaxial surfaces.

Two types of temperature gradients can occur in the centrifugal tipper: those which lie in a direction parallel to the substrate, and those which lie in a direction perpendicular to the substrate. These two types of gradients will give rise to two types of Bénard cells. The first type of temperature gradient can and should be eliminated by proper spacing of the coils. The second type of gradient, however, is desirable to prevent constitutional supercooling. The growth cavity must therefore be designed around this temperature gradient. According to Eq. [3], R varies as d^4 and therefore R can be drastically reduced by decreasing the thickness of the solution layer (or growth cavity thickness).

From Eq. [3] the growth cavity thickness was estimated, again assuming the solution was pure Ga; the data for liquid Ga were taken from the "Liquid Metals Handbook."[1] For a temperature drop across the layer of 5°C and a centrifugal field of $10g$ (corresponding to about 500 rpm) it was found that the cavity thickness should be less than 3 mm.

Operation.—In the growth of an epitaxial layer, the first step is to place the Ga-GaP and dopants (25g Ga, 0.06 mole fraction of GaP, 0.0005 mole fraction of pure Zn, 0.0035 mole fraction of Ga_2O_3 for p-type, and a 0.00015 mole fraction of Te for n-type) in the outer crucible and the substrate with (111) orientation in the growth cell of the inner crucible. The middle crucible is then placed over the inner one, tightened in position with a nut, and placed inside the outer crucible. The crucible assembly is then placed on the shaft and enclosed in an argon atmosphere. The whole unit is heated with the rf generator to the growth temperature (about 1050°C) at the rate of 50°C/min. The temperature is monitored by a fixed thermocouple placed near the top of the crucible. When the growth temperature is reached, the crucible assembly is allowed to equilibrate and is then spun at a rate sufficiently high (500-1000 rpm) to force the solution into the growth cell. The temperature is then lowered at a 100°C/min cooling rate to 950°C by reducing the rf power until the end of the growth operation is reached at which point the rotation of the crucible assembly is stopped. The temperature at the end of the growth operation has been determined experimentally in such a way as to allow for the growth of an epitaxial layer of about 100 μm thickness. This thickness can be reduced by narrowing the temperature range over which epitaxial growth occurs. After cooling to room temperature, the crucible assembly is dismounted and the substrate removed.

Results

The object of these experiments was to demonstrate the growth of LPE layers of uniform thickness, high surface quality, and luminescence uniformity using the centrifugal tipper.

The surface roughness of the epitaxial layers was measured on a Taly-Surf machine and was found to be low. A typical value for the center line average is about 1 μm. The surface irregularities were found to consist of steps (Fig. 3a and b) which occurred only in one direction on a given substrate. This direction was found to be unrelated to the position of the sub-

[1] "Liquid Metals Handbook," second edition, published by Atomic Energy Commission, June 1952.

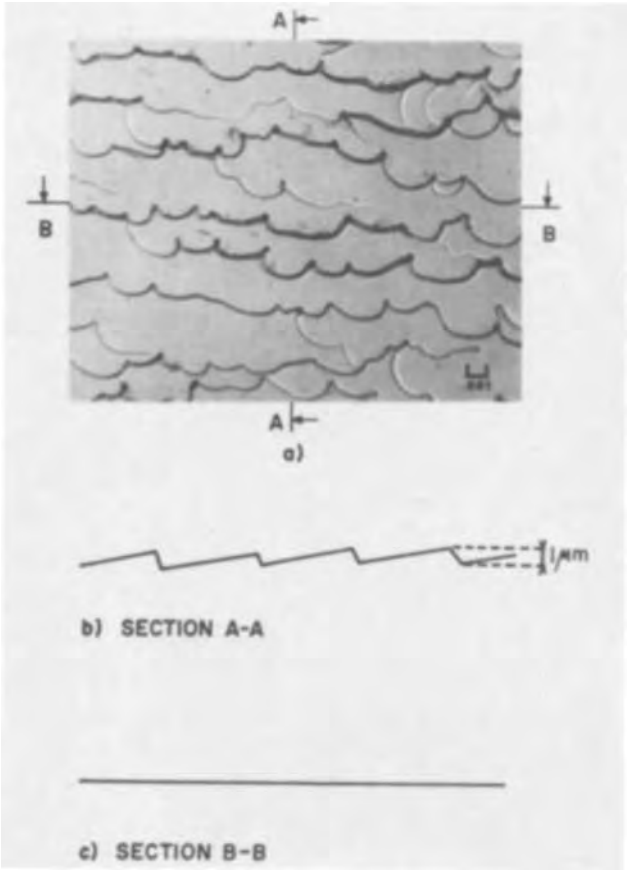

Fig. 3. Surface morphology of the grown p-layer. The surface of the grown p-layer has directional steps which are not related to the substrate position in the crucible, and is thought to be related to the crystal orientation.

strate in the crucible and therefore is thought to be related to the substrate orientation.

The centrifugal tipper has yielded epitaxial layers of extremely good thickness uniformity. No taper was apparent upon examination under the microscope (200X) of several 25 mm long cleaved layers.

Preliminary results indicate that material with a photoluminescence efficiency of about 1.5% can be grown. Photoluminescence scanning of the layers indicates that the efficiency is uniform across the samples (Fig. 4, the ripples in the photograph are due to interference effects inherent to the scanner). The carrier concentration for the n-type material was found to be around 10^{18} cm^{-3} near the outer surface of the layer and to decrease to 5×10^{17} cm^{-3} at a depth of 100 μm.

Conclusion

The centrifugal tipper technique described in this paper demonstrated its potential as a production method for the fabrication of GaP LED material. Its use could also be extended to the fabrication of other devices requiring the growth of epitaxial layers.

Growth and Characterization of InP-InGaAsP Lattice-Matched Heterojunctions

G. A. Antypas* and R. L. Moon*

Corporate Research Laboratories, Varian Associates, Palo Alto, California 94303

ABSTRACT

Liquid phase epitaxy has been employed for the growth of InP-InGaAsP lattice-matched heterojunctions. The epitaxial layers were grown at 650°-625°C on (100), (111)A, and (111)B oriented InP substrates from In-rich liquid solutions. The layers were characterized by x-ray diffraction, photoluminescence, and electron microprobe measurements for the determination of lattice constant, bandgap energy, and composition. Quaternary layers lattice matched to InP substrates were grown having bandgap energies between 1.12-1.41 eV. Mirror-smooth layers have been routinely grown over 100% of the substrate with absolutely no solution droplets remaining on the surface following growth. We experimentally determined a number of liquidus isotherms in the In-rich region of the quaternary system. In the concentration range and temperature investigated the distribution coefficient of G, $K_{Ga} = 25$ while that of As varies between 9.7 and 13.4 for X^s_{Ga} of 0.055 and 0, respectively.

Semiconductor heterojunctions are necessary for the efficient operation of a number of electronic devices, *i.e.*, heterojunction lasers, light emitting diodes, photoemitters, heterojunction transistors, etc. The solid solution properties of III-V ternary alloys injected new interest in the fabrication of these devices. With the exception of Ga-Al-V ternary alloys, however, all other III-V ternary systems are faced with severe lattice-mismatch problems which are detrimental to the growth as well as the electrical and optical properties of these alloys. The one-to-one dependence of bandgap on lattice constant can be relaxed by the addition of a fourth component to the solid, introducing an extra degree of freedom and permitting the independent variation of lattice constant and bandgap. The first system to demonstrate the lattice-matching properties of quaternary alloys was GaAlAsP-GaAsP (1) in which the substitution of Al for Ga results in a bandgap increase while the constant ratio of As/P across the heterojunction maintains lattice matching. This system was used for the fabrication of heterostructure lasers that were operated pulsed at room temperature. Lattice-matched heterojunctions operating at lower energies than GaAs can be fabricated using the lattice-matching properties of InP-InGaAsP which makes possible the growth of low defect density heterojunctions between 0.7 and 1.35 eV. The ease of fabrication of heterojunctions in this system exceeds that of the AlGaAs-GaAs for a number of reasons: (*i*) low growth temperatures (~650°C), (*ii*) heterostructure lasers operating in the infrared can be fabricated by the growth of only two layers, (*iii*) ease of electrical contact to InP compared to AlGaAs, and (*iv*) absence of the formation of tenacious oxides such as Al_2O_3 requiring special boat design. Figure 1 shows the variation of the bandgap as a function of lattice constant. The area bounded by the four ternaries represents the quaternary region with bandgap variations between 0.35 and 2.23 eV. In this system neither the substitution of Ga for In nor As for P, or vice versa, results in lattice matching, therefore, to obtain lattice matching, a simultaneous variation of Ga/In and As/P is necessary. In this system two readily available substrates can be used in obtaining lattice-matched heterojunctions. The GaAs-GaInAsP system can cover the energy range of 1.425-2.23 eV, while the InP-InGaAsP covers the range of 0.7-1.35 eV. The former will result in heterojunctions covering an almost identical range to that covered by the GaAs-GaAlAs heterojunctions; therefore its utility could be considered rather limited. The latter, however, is the only system for which lattice matching can be obtained for energies lower than 1.35 eV. Lattice-matched heterojunctions such as InGaAs-InGaP can, in principle, be fabricated in a manner similar to that used in the preparation of GaAs-InGaP (2,3). No information has been reported as yet on the preparation or properties of such heterojunctions.

Materials Growth and Characterization

The important property of III-V quaternary alloys is that lattice matching can be achieved over a wide energy range. Considering the large number of quaternaries, lattice-matched heterojunctions can be prepared (at least theoretically) over the energy range of 0.3-2.45 eV. In the absence of any available thermodynamic data on any quaternary system, our investigations consisted of trial-and-error procedures for determining the growth properties of such systems. Thus, we have investigated the InGaAsP (4), GaAlAsSb (4), and InGaAsSb (5) systems, along with the GaAlAsP sys-

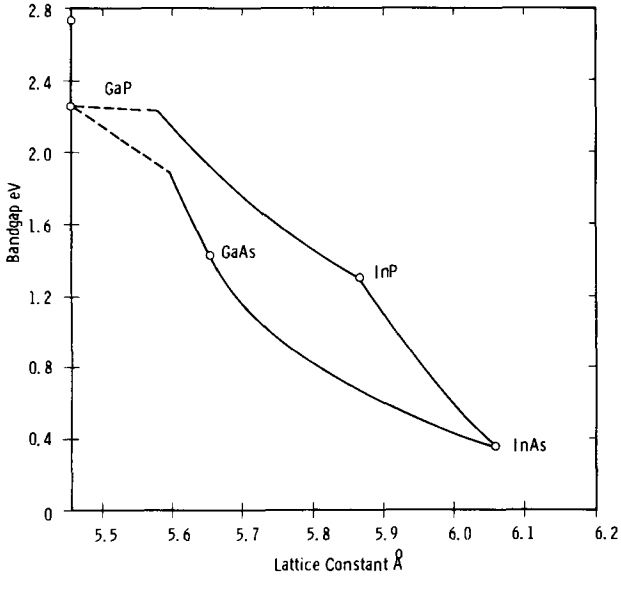

Fig. 1. Bandgap vs. lattice constant for the InGaAsP quaternary system. ——— Direct bandgap, - - - - - indirect bandgap.

tem reported by Burnham *et al.* (6), representing a series of systems covering practically the whole energy range of III-V semiconductors. We present here some experimental data on the growth properties of the InGaAsP system. The epitaxial layers were grown by liquid phase epitaxy on InP substrates. Although layers have been grown on both (100) and (111)A substrates, the results reported here are from layers exclusively grown on (111)B substrates. A horizontal growth system was employed, with a graphite boat similar in design to that reported by Rosztoczy *et al.* (7), in a palladium purified hydrogen environment. Epitaxial layers have been grown at temperatures as high as 750°C and as low as 580°C. These are considered practical limits due to the decomposition of the InP substrate at 750°C and the low solubility of P at 580°C. The layers for this study were grown in the interval of 650°-625°C. A variety of cooling rates have been tried varying between 0.1 and 2°C/min. The surfaces of the grown layers were mirror-smooth, with no apparent dependance of the cooling rate on the as-grown surface. Figure 2 is a photograph of the as-grown surface of a quaternary layer lattice matched to InP; layers of this quality can be routinely grown over 100% of the substrate with no liquid droplets remaining on the substrate following removal of the melt. This is certainly a very important feature since a portion of the solution remaining in contact with the substrate during cooldown to room temperature will result in local growth of material of different composition than that of the rest of the epitaxial layer. An interference photomicrograph is shown in Fig. 3 indicating the absence of gross growth features. The thickness variations of the epitaxial layer grown on ¾ in. diameter substrates are less than 10% across the diameter of the layers. Figure 4 shows a (110) cleave of the epitaxial layers having a bandgap of 1.17 eV and is lattice matched to InP. Figure 1 shows the quaternary region of the InGaAsP system bounded by the four ternary systems. The variation of the bandgap *vs.* lattice constant for a series of quaternary layers is shown in Fig. 5. In this figure the epitaxial layers were grown on a (111)B InP substrate in the 650°-625°C range under a cooling rate of 0.5°C/min. The melts were prepared with In, Ga, As (InAs was the As source, the As was always below the solubility limit) and were saturated with P from an InP substrate. The lattice constant was determined by x-ray diffraction of the Cu-Kα radiation, and the bandgap was determined by photoluminescence measurements at 77°K using a 0.5W argon ion laser with a dry-ice-cooled S-1 photomultiplier as the detector. The concentration in the solid was determined by microprobe measurements. Table I shows in detail solid and liquid concentrations, lattice constant, and bandgap. In this figure we can see that the increase in Ga in the liquid solu-

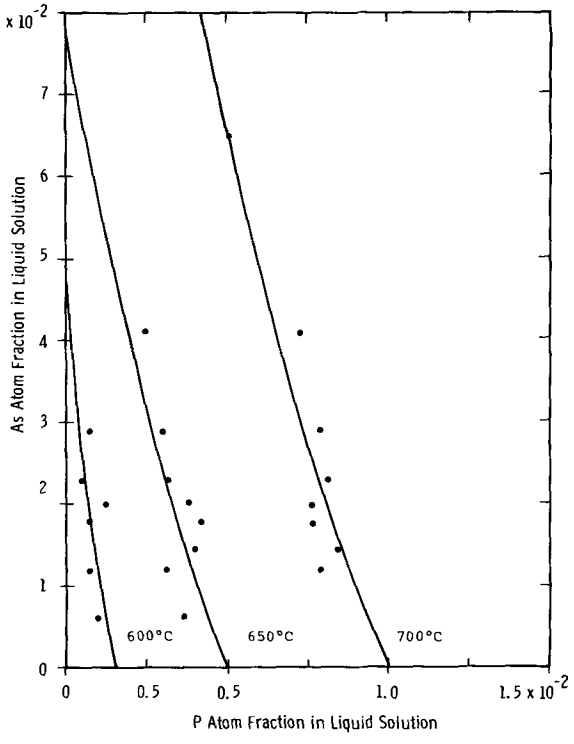

Fig. 6. Solubility of P as a function of As in liquid quarternary solutions for $X^{l}_{Ga}/X^{l}_{In} = 4.2 \times 10^{-3}$ at 600°, 650°, and 700°C. Curves are drawn through our experimental points.

tion is accompanied by a decrease in the lattice constant and an increase in bandgap energy. A number of series of runs as those shown on this figure were made in increasing As concentrations. In each series the first layer grown was with zero Ga to establish the InAsP boundary. In Fig. 5 we also show the InP point. The layer grown from solution No. 2 in Table I had a lattice constant of 5.864Å and a bandgap of 1.33 eV. InP, on the other hand, has a lattice constant of 5.868Å and a bandgap of 1.41 eV. Although no attempt was made to perfectly lattice match any layer to InP substrates during this series of runs, the lattice mismatch between epitaxial layer and substrate is 0.068% with a heterojunction barrier of 0.080 eV. In a similar manner, lattice matching has been achieved for layers having bandgap variation between 1.12 and 1.41 eV. No attempt has been made as yet to lattice match quaternary layers of lower bandgaps to InP, although no serious problems are anticipated.

Phase Diagram Investigations

The technique used in determining solubility parameters consists of preparing a liquid solution of In-Ga-As (InAs was used as the As source). The As concentration in the solution was always below the solubility limit determined by the X^{l}_{Ga} to X^{l}_{In} ratio in the solution. Solubility curves were determined at 600°, 650°, and 700°C by equilibrating the solution at the saturation temperature prior to contact with a single crystalline, chemically polished InP substrate. Following contact, the solution and InP substrate were kept at temperature for 2 hr which was experimentally determined to be of sufficient time for complete saturation. Subsequently the melt was separated from the InP substrate, and the substrate weight loss established the solubility limit of P. Figure 6 showed the solubility curves at 600°, 650°, and 700°C for a solution with a ratio X^{l}_{Ga} to X^{l}_{In} of 0.42×10^{-2}. The solid lines are drawn through the points and intersect the ordinate and abscissa at points coinciding with the extrapolated data of Antypas (8), Wu and Pearson (9) for the InGaAs system, and McVittie (10) for the InGaP system. A second series of solubility experiments was to investigate the dependence of P solubility on Ga, at constant As concentration. The results at 600° and 700°C are shown in Fig. 7. A comparison between Fig. 6 and 7 indicate that the solubility of P is decreased appreciably by the addition of Ga, while the presence of As has a less pronounced effect. This is very similar to the solubility of P in ternary solutions of InGaP and InAsP.

Since all the epitaxial layers grown were in the InP-rich corner of the quaternary region, the distribution of the solute Ga and As is certainly of primary interest. Figure 8 shows the distribution of Ga in layers grown in the temperature range of 650°-625°C from solution listed in Table I. In the region of X^{s}_{Ga} of zero to 0.055 the distribution coefficient K_{Ga} remains practically constant at 25. The distribution of As as a function of Ga in the solid solution, however, varies between 13.4 for zero Ga to 9.7 for 0.225% of Ga in the liquid solution. This variation is shown in Fig. 9, and it is obvious that such dependance will make the growth of a quaternary

Summary

Heterojunctions are useful for devices requiring either electrical confinement or a change in optical properties from one layer to another. Both requirements must be satisfied for efficient operation of electro-optical devices. In such devices dislocations at the junction between two nonlattice-matched materials may introduce nonradiative recombination centers which degrade device performance. We have reported here the preparation of lattice matched heterojunctions in the InGaAsP-InP system. Lattice matching has been achieved in the bandgap energy range of 1.12-1.41 eV, although this range can be extended between 0.8-1.41 eV. The photoemission properties of the quaternary layers were investigated resulting in the highest 1.06 micron quantum efficiency known. James *et al.* (11) have reported on the photoemission properties of a number of quaternary alloys. Investigation on the heterojunction properties of lattice-matched InGaAsP-InP structures based on photodiode measurements reported by Antypas *et al.* (4) indicates that low defect density heterojunctions can be fabricated in this system.

Minority Carrier Generation Studies in MOS Capacitors on N-Type Silicon

D. R. Young and C. M. Osburn*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The pulsed capacitance technique was utilized to determine minority carrier generation rates in MOS capacitors. The addition of HCl, Cl_2, CCl_4, or C_2HCl_3 to oxygen during thermal oxidation was effective in gettering trapping centers in the silicon and resulted in lifetimes greater than 150 μsec. Higher halide concentrations and high oxidation temperatures improve the gettering process. The capacitance-time plot showed that the generation rate in long-lifetime structures was proportional to the volume of carrier-depleted silicon and that the generation of carriers on the surface was very small, *e.g.*, $S \approx 10^{-2}$ cm/sec.

Minority carrier current in the depletion regions of semiconductor devices leads to various undesirable device characteristics such as high leakage currents in p-n junctions, excessive dark currents in photodetectors, and reduction of switching threshold in charge-coupled FET devices.

The theoretical or ideal generation rate of minority carriers in silicon is very small at room temperature. Hence, the much larger rates typically observed in most samples studied to date have been attributed to anomalous effects, the predominant process being carrier generation at impurity sites located in the depletion region (1,2). It can be shown that those sites (acceptor or donor) with levels close to the center of the gap are the most prolific in electron-hole generation; consequently, the temperature dependence of the generation rate indicates a thermal activation energy between 0.5 and 0.6 eV (3) or about half the bandgap of silicon.

In practice, it is found that large sample-to-sample variations exist in the minority carrier generation rate. The work reported here is part of a long-range program to gain added insights concerning the mechanisms responsible for minority carrier generation and to develop material technologies that will result in a significant reduction in the minority carrier generation rate as well as a decrease in its variability. The pulsed capacitance technique was chosen for measuring the minority carrier density and has been described earlier by Zerbst (4).

The gettering of metallic impurities from silicon is one technique previously used for reducing both minority carrier generation rates and diode leakage current (1, 5-12). Copper, iron, manganese, and gold have been shown (1, 2) to introduce recombination-generation centers in the forbidden energy gap of silicon and thereby reduce the lifetime of excess minority carriers. Actual gettering has been accomplished by KCN (1); P_2O_5 (1, 7, 9, 10, 12); B_2O_5 (1, 12); V_2O_5 (12); Ni (7); boron diffusion; and phosphorous diffusion (1, 5). Furthermore, reduced minority carrier generation has been obtained by Cl_2 annealing (5), precleaning oxidation tubes with HCl (13), and oxidation in Cl_2 (9, 11) or HCl (8, 9, 11).

In addition to improving the minority carrier lifetime, treatments have recently been shown to reduce mobile charge densities in SiO_2 (14-18), improve its breakdown strength (15, 16, 19), and enhance dielectric integrity under accelerated bias-temperature stress (20). Because of their simplicity of application and consequent technological advantages, HCl, Cl_2, CCl_4, and C_2HCl_3 oxidation processes were selected for this study.

Experimental Procedure

Metal-oxide-semiconductor capacitors were fabricated on 2 ohm-cm, p- and n-type <100>-oriented silicon wafers. Most measurements were made on n-type wafers to avoid surface inversion due to the positive space charge in the SiO_2. The wafers were ultrasonically cleaned using NH_4OH-H_2O_2, HCl-H_2O_2, and HF solutions. Oxides from 200 to 1000Å thick were grown in dry oxygen at 1000°C, using additions of 1-6% HCl (99.995% pure) or Cl_2 (99.99%) to the oxygen ambient; additions up to 3% CCl_4, 6% C_2HCl_3, or 9% HBr were also tested. By using reasonable precautions to insure pure SiO_2 films, mobile Na^+ ion concentrations in the SiO_2 were kept very low [$\approx 5 \times 10^{10}$/cm^2, as determined using the flatband voltage shift technique (21)]. One hundred aluminum electrode dots (10-50 mil diameter) were electron-gun evaporated through metal masks onto each wafer in a clean evaporation system; the samples were then given a 5 min anneal at 500°C in dry nitrogen to remove radiation damage.

Results

Processing.—The influence of processing on minority carrier generation was best determined from statistical measurements of inversion times of a large number of MOS capacitors, where the inversion time is defined as the time required for the capacitance to go from deep depletion to equilibrium inversion. In the absence of large surface generation Schroder and Guldberg (22) showed that these inversion times are directly proportional to the lifetime. Inversion times from less than 1 msec to over 1000 sec were observed, giving a wide range of measurable characteristics.

Dramatic improvements in inversion times are obtained with HCl or Cl_2 oxidations and are illustrated in Fig. 1, where statistical distributions of inversion

Key words: minority carrier generation, impurity gettering, metal oxide semiconductor (MOS), halogen oxidation.

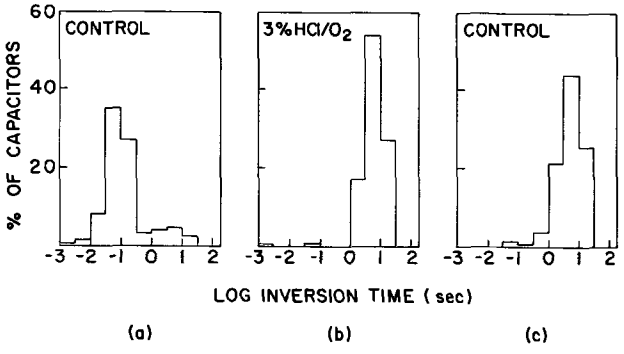

Fig. 2. Effect of sequential oxidation, after oxide stripping, on inversion time showing permanence of HCl gettering. (a) Initial control oxide; (b) after oxide strip and HCl oxidation; and (c) after strip of HCl oxide and regrown in control furnace.

times of halide-grown oxide capacitors are compared to normally grown ones. The halide oxidation not only improves the average time but also reduces the statistical variation. Increases up to two or three orders of magnitude in the inversion time were seen with the HCl treatment. Figure 2 shows the permanence of the HCl oxidation after additional processing; (a) is a histograph of the inversion times for a standard- or control-grown oxide structure; (b) indicates the characteristics when the control oxide is removed and then regrown in 3% HCl-97% O_2; and, (c) indicates the characteristics after the HCl oxide is stripped and regrown in the control furnace with no HCl present. A comparison of (a) and (b) shows the effectiveness of HCl while (b) and (c) are almost identical, indicating that once the impurities have been gettered from the silicon, they are not reintroduced by a later oxidation under very clean conditions. Merely growing an oxide by stripping and reoxidizing does not improve the lifetime and shows that the gettering effect is independent of a layer of silicon surface being oxidized away during preoxidation.

Both the oxidation temperature and the concentration were varied for the different halide additions in order to optimize the process. As seen in Table I, raising the temperature from 850°-1150°C for HCl oxides results in longer inversion times. Likewise, higher HCl concentrations (from 1 to 6%) yield improved properties. In practice, a lower HCl concentration is desirable in order to maintain close control over the oxidation rate and to prevent droplet formation and silicon pitting (8). Increasing the HCl/O_2 gas velocity during oxidation from 0.37 to 3.3 cm/sec did not improve the inversion time. Apparently the gettering process is dependent only on the HCl concentration and not on the flow rate. Measurements (23) of the silicon doping profile showing no enhanced phosphorus pile up at the surface confirmed that the longer inversion times were a result of the gettering and not because of additional dopant segregation. Both CCl_4 and C_2HCl were also seen to improve lifetime whereas HBr gave shorter storage times (Table I).

Table I. Effect of halide addition and oxidation conditions on average time for pulsed capacitance to reach equilibrium inversion (sec)

Halide	Oxidation temperature (°C)	Halide concentration 0%	½%	1%	3%	6%	9%
HCl	1000	3.75	—	68	77.2	79.7	—
HCl	850	—	—	—	16.4	—	—
HCl	1150	—	—	—	205.1	—	—
HCl	1150	8.0	—	—	97.2	—	84.9
Cl_2	1000	6.8	—	246	6.6	1.8	—
CCl_4	1000	7.2	4.1	50	46.1	—	—
C_2HCl_3	1000	4.6	—	61.2	118.6	99.4	—
HBr	1000	3.30	—	0.72	1.04	1.36	0.85

Additional processing variations were tested in order to evaluate more fully means for improving lifetimes. Some results are shown in Fig. 3. Figure 3c shows that a 30 min 1000°C HCl/N_2 anneal following oxide growth is detrimental to the quality of the capacitors since the inversion times after the anneal are considerably shorter than those for the control-grown oxide. An HCl/N_2 anneal at 1000°C before growth results in a very nonuniform attack or pitting on the surface of the Si wafer, and is therefore quite unacceptable. Surprisingly enough, the growth of 250Å HCl oxide after growth of a 250Å control oxide was found to be similar to oxides grown entirely in HCl (Fig. 3d). Apparently, the 250Å thick SiO_2 film is not sufficient to block the gettering action.

Attempts to optimize the chlorine oxidation conditions were not as successful as those with HCl. Wafer corrosion and nonuniform oxides often occurred when Cl_2/O_2 was used. Growth of a thin oxide before adding Cl_2 was helpful but not entirely effective in eliminating this etching. At 1000°C the Cl_2 concentration had to be kept below 2-3%; at higher temperatures even these concentrations gave poor results. Increasing the chlorine concentration from 1 to 6% during 1000°C oxidation resulted in an increased number of oxide shorts and shorter inversion times. This same effect was seen at the high concentrations of CCl_4 and C_2HCl_3 (Table I).

The postmetallization anneal (5 min at 500°C in N_2) given after the electron-gun evaporation of aluminum to reduce surface states and radiation damage was found to increase the inversion time. In some capacitors the inversion time increased by more than a factor of 100, and the average improvement was a factor of three. Apparently the surface-state generation component of the total generation can be dominant, at least in unannealed samples.

Electrode area.—In the course of the measurements a wide range (over six orders of magnitude) of inversion times was seen. In order to understand better the wide variation of results, inversion times were measured as a function of capacitor electrode area. Quite surprisingly, the fraction of capacitors having short inversion times was less for 32 mil diameter electrodes than for either 10 or 50 mil diameter ones. This

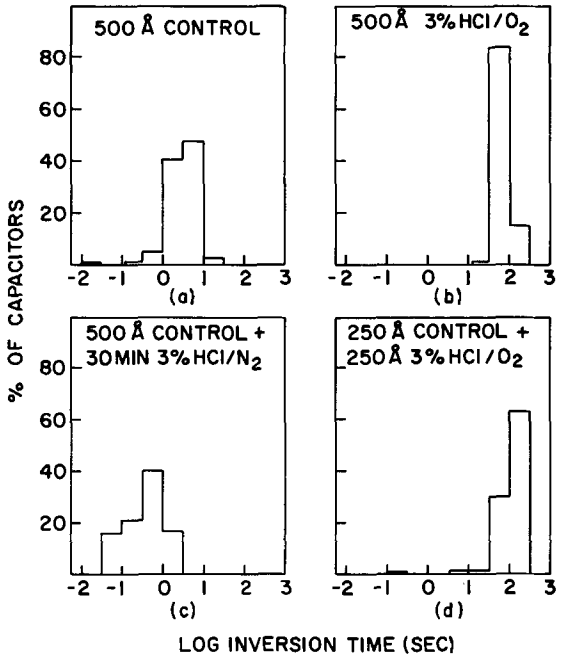

Fig. 3. Effect of processing variations on inversion time for (a) control oxidation; (b) normal 3% HCl/O_2 oxidation; (c) annealed in 3% HCl in N_2 at 1000°C following oxidation; and (d) 250Å of HCl grown after 250Å of control oxide was grown.

is in contrast to the behavior seen in dielectric breakdown in SiO_2 films on Si, for example, where the fraction of low electric field breakdown events is directly proportional to the electrode area (19, 24, 25). Apparently the capacitor area dependence of minority carrier generation is more complex than that of dielectric breakdown. Several different processes having different area dependencies that shorten inversion times can be considered:

(*i*) Generation centers. Since even the smallest capacitor covers many centers, the effect of these centers should be independent of electrode size.

(*ii*) Perimeter generation. If minority carriers were generated at the edge or surface of a capacitor dot, then the inversion time would be expected to vary directly as the electrode diameter.

(*iii*) Localized defects. If random defects are present, the generation rate would be proportional to the number of defects that a capacitor dot covered. In the case of defects under the electrode, this number varies as the capacitor area; for edge defects, this number varies as the diameter. In the case of a single defect, the inversion time should be proportional to the electrode diameter squared since the charge required for full inversion should vary with the area. Nevertheless, no one of these three mechanisms explains the phenomena we have observed.

Generation process.—A linear Zerbst (4) plot (Fig. 4) of a better sample signifies a generation rate proportional to the depletion volume. The intercept with $C_\infty/C = 1$ gave a surface generation velocity 1.06×10^{-2} cm/sec which was lower than the value of 1 cm/sec reported by Schroder (10) in phosphorous-gettered silicon. Minority carrier lifetime, using the technique of Heiman (26), was 168 μsec. This might be compared with a lifetime of 0.2 μsec quoted by Zerbst and 7.6 μsec, as reported by Heiman. Robinson and Heiman (8), also using an HCl treated oxide, obtained a lifetime of 100 μsec. Dumin and Henry (9) and later Schroder (10) reported lifetimes of nearly 1000 μsec in silicon gettered with $POCl_3$.

The temperature dependence of the generation rate has also been studied and the effect of the HCl treatment is readily apparent (*c.f.*, Fig. 5). It is observed that the old process resulted in an activation energy of 0.57 eV for the temperature range covered by the measurement (18°-120°C) whereas the HCl sample had an activation energy of 0.69 eV up to 55°C and 0.9 eV for higher temperatures. This is similar to the diode leakage studies discussed by Grove (3) and can be explained as follows. Impurity site generation ($d\sigma/dt$) is given by

$$\left(\frac{d\sigma}{dt}\right)_{\text{impurities}} = \frac{-\sigma_i U_{th} N_t N_i}{2\cosh\left(\frac{E_i - E_t}{kT}\right)} \qquad [1]$$

where σ_i is the cross section, U_{th} is the thermal velocity, N_t is the impurity concentration, N_i is the intrinsic carrier concentration, and $E_i - E_t$ is the position of the impurity level with respect to the intrinsic level. The temperature dependence is that of N_i with an activation energy approximately equal to one half the gap width if $E_i \simeq E_t$. The generation rate due to diffusion is given by

$$\left(\frac{d\sigma}{dt}\right)_{\text{diff}} = \frac{D}{NL} N_i^2 \qquad [2]$$

where D and L are the diffusion constant and diffusion length, respectively, for the minority carriers and N is the doping concentration. The temperature dependence of this goes as N_i^2 which has an activation energy of the full gap or 1.1 eV.

As a result, it can be seen that impurity generation is important at lower temperatures, and that diffusion becomes important at higher temperatures as seen by

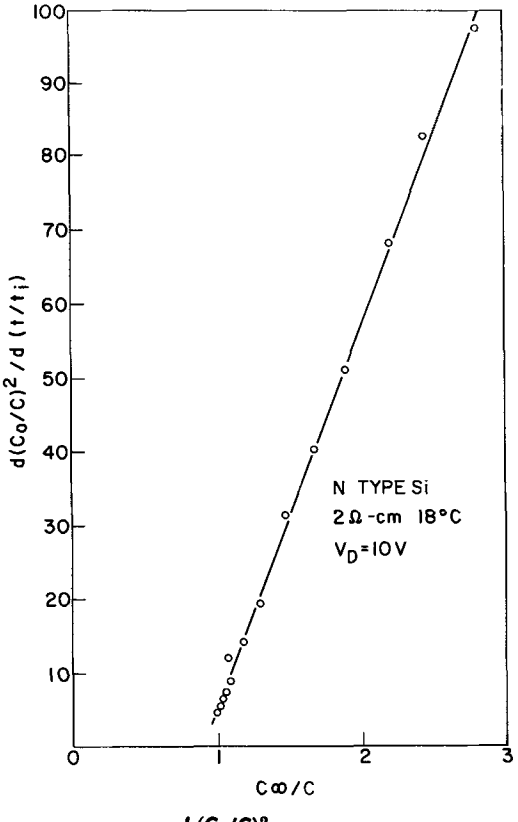

Fig. 4. Linear plot of $\frac{d\,(C_0/C)^2}{d\,(t/t_i)}$ vs. C_∞/C signifying a generation rate proportional to the depletion volume. The intercept at $C_\infty/C = 1$ gives the surface generation. t_i = time for full inversion.

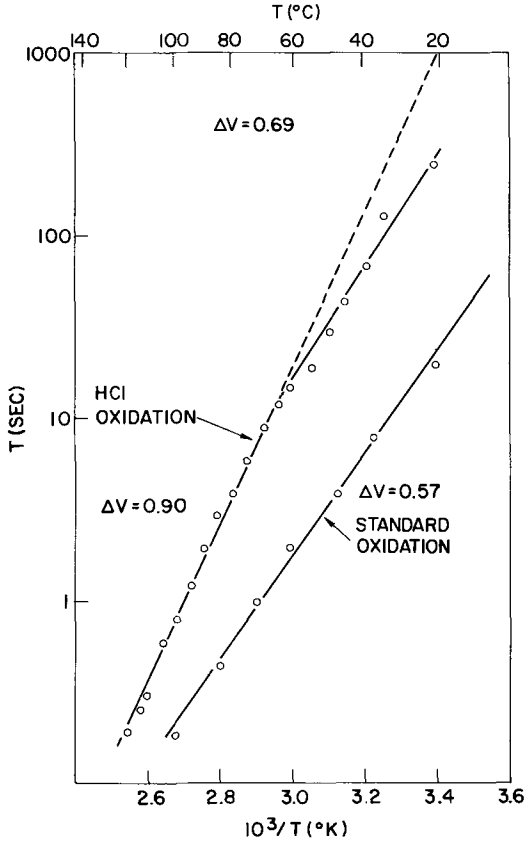

Fig. 5. Temperature dependence of inversion time of standard and HCl oxidized capacitors.

the data of Fig. 5. As the impurity concentration decreases, the onset of diffusion can be seen at lower temperatures.

Summary

The measurement of the capacitance buildup in an MOS capacitor following application of a depletion voltage was found to be a straightforward method to determine the surface generation rate. This technique avoids the problems associated with the measurement of low level leakage currents in diodes to obtain the generation rate.

The use of HCl, Cl_2, CCl_4, or C_2HCl_3 gas additions to oxygen during thermal oxidation of silicon was found to result in a very significant (up to two to three orders of magnitude) decrease in the generation rate; HBr slightly increased generation. Increasing HCl concentration from 0 to 6% and increasing oxidation temperature from 850° to 1150°C were seen to give improved properties. Experiments have confirmed that once HCl oxidation has occurred, subsequent oxide stripping and standard processing can also result in superior capacitors. The thermal activation energy for generation in standard capacitors was 0.57 eV or about half the silicon bandgap, while HCl oxidized ones had a 0.90 eV activation. Apparently the chlorine oxidation was effective in removing impurities such as Cu and Au that have states near the center of the silicon bandgap. The HCl gettering process was not diminished by the presence of a 250Å residual oxide on the silicon; however, the use of HCl/N_2 mixtures either before or after oxide growth resulted in either silicon pitting or a large number of shorted capacitors. The use of chlorine gettering was restricted because of substrate attack.

The variation of the inversion time with capacitor area suggests that several processes are important in addition to carrier generation at impurity centers. Evidence was also seen for localized defects and perimeter generation. Additional work is planned to describe these mechanisms.

Detailed analysis of the generation process in good capacitors shows that the generation rate is proportional to the depletion volume. A very small surface generation, $S = 1.06 \times 10^{-2}$ cm/sec, is observed along with a long lifetime of 168 μsec.

Acknowledgments

The authors would like to acknowledge many stimulating discussions with A. Berman and D. Kerr. The skillful measurements and sample preparation of E. Alley and D. Ormond are gratefully appreciated. W. P. Dumke contributed to the theoretical interpretation of the results.

ABSTRACT

In order to study electrical conduction at elevated temperatures in high purity, amorphous silicon dioxide films, emf and conductance measurements have been made on solid-state electrochemical cells incorporating films grown by thermal oxidation of phosphorus- or boron-doped silicon substrates in a double-wall fused silica furnace. No mobile ions were detected by capacitance-voltage measurements on MOS structures stressed at 150°C. Values of the ionic transport number, the ratio of ionic current to total current, were obtained as a function of temperature, oxygen partial pressure, and substrate doping by comparing the open circuit voltages measured for the cells with theoretical values calculated from the free energy of formation. On the basis of the experimental results and a theoretical model, it is proposed that the species primarily responsible for ionc conduction at elevated temperatures is a native defect, specifically, a doubly charged oxygen interstitial.

Electrical conduction in amorphous silicon dioxide films has been investigated at elevated temperatures by various workers. Either predominantly electronic or ionic conduction has been reported in most cases studied (1, 2); however, mixed conduction was reported by Jorgensen (3). The only well-established mechanism for conduction in SiO_2 films is the drift of mobile alkali ions as demonstrated by MOS measurements and chemical analysis (4, 5). In the absence of alkali ions, either electronic or ionic conduction occurs, depending upon the mechanism for creating electronic or native ionic defects.

Jorgensen (3) studied electrical conductance in SiO_2 films by observing the effects of an electric field on the growth of such films. He found that the growth could be stopped by applying a sufficiently high electrical potential, E_{stop}. The emf measured on a cell, Pt, Si/SiO_2/$_{Pt}O_2$ is related to E_{stop} by the expression

$$\bar{t}_i = E/E_{stop} \qquad [1]$$

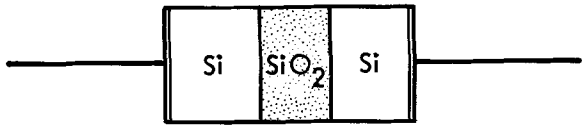
$\bar{t}_i$ is the average ionic transference number, defined as the ratio of the ionic conductance to the total conductance. Jorgensen used this expression to obtain values of $\bar{t}_i$ from the measured values of E and E_{stop}. By this method, he determined that at 1000°-1152°K, SiO_2 was a mixed conductor with $\bar{t}_i = 0.4$, and that the ionic conduction was due to a doubly charged species.

Similar results have been obtained by a different technique in our work. Transport number values were determined by open-circuit emf measurements on solid-state electrolytic cells incorporating SiO_2 films on Si substrates. The dependence of the emf and current-voltage characteristics of these cells on temperature, oxygen pressure, and substrate doping was interpreted in terms of a theoretical defect model in order to investigate the conductance mechanism and the identity of the conducting species.

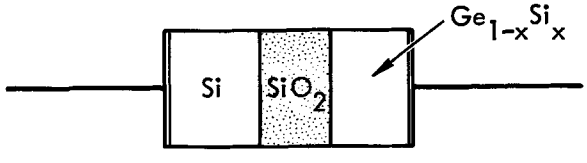
Experimental Procedure

Three types of electrochemical cells, as shown schematically in Fig. 1, were fabricated to study conduction in amorphous SiO_2 films: Type I (symmetrical, for current-voltage measurements), Pt, Si/SiO_2/Si,Pt; Type II (asymmetrical, for emf measurements), Pt,Si/SiO_2/(Ge,Si),Pt; and Type III (asymmetrical, for emf measurements), $_{Pt}^{O_2}$/Si/SiO_2/$_{Pt}^{O_2}$.

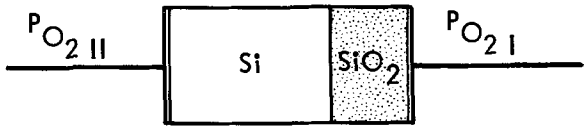
Type I and II cells had a fixed oxygen and Si activity at a given temperature. For Type I, the O_2 activity is established by the free energy of formation of SiO_2, while for Type II the Si activity is established



TYPE I. SYMMETRICAL CELL (LOW O_2 PARTIAL PRESSURES)



TYPE II. ACTIVITY CELL FOR EMF AT LOW OXYGEN PARTIAL PRESSURE



TYPE III. O_2 CELL FOR EMF AT VARIABLE OXYGEN PARTIAL PRESSURE

Fig. 1. Schematic diagrams of electrochemical cells used for investigating conduction in amorphous SiO_2 films.

Key words: emf measurements, ionic conduction, insulating films.

by the concentration of the Si at the (Ge,Si)/SiO_2 electrode. The oxygen activity at the Pt,O_2/SiO_2 electrode of the Type III cells is varied by changing the oxygen partial pressure, P_{O_2}. An electrochemical stabilized zirconia pump is used to establish P_{O_2} while the pressure is monitored with the aid of a stabilized zirconia electrochemical pressure gauge. Details of the pump and gauge will be given later.

Oxide films 3000Å thick were formed on 1.5 in. Si wafers by thermal oxidation at 1453°K using dry 99.999% oxygen in a clean double-wall furnace. The Si wafers, which were syton polished and chemically cleaned prior to oxidation, were doped with B or P at concentrations ranging from 10^{13} to 10^{16} atoms/cm^3.

Type I cells were formed by pressing two oxidized Si wafers together at 1100°C, while Type II cells were formed by pressing one oxidized Si wafer and a Ge-Si alloy wafer together at 900°C. The wafers were pressed at 1000 psi between pyrolytic graphite plates in a dry nitrogen ambient.

The Si-Ge alloys for Type II cells were formed by mixing the desired proportions of Si and Ge in a carbon crucible and heating to approximately 1100°C in argon, then permitting the melt to cool slowly. The Si and Ge in the alloy were virtually undoped, with impurity concentrations of the order of 10^{12} atoms/cm^3 and 10^{13} atoms/cm^3, respectively. The concentration of silicon in the alloy was determined by electron microprobe analysis. These concentrations were used to determine activities according to Hiskes and Tiller (6). This may be compared to the work of Thurmond and Struthers (7) where an ideal solution is assumed at low concentrations. (See Table I).

The oxide films were investigated for mobile alkali ions by using the techniques described by Deal *et al.* (4). Aluminum dots were deposited on the Si wafers through a metal mask, the contacts were annealed at 450°C for five minutes and C-V measurements made on an impedance comparator, employing a sweep voltage from a function generator. The data were plotted automatically on an x-y recorder.

Electrical contacts were made to the cells by sputtering −1000Å of platinum on each side of the thermally pressed wafer. The wafer was then diced into 1.0 × 0.5 cm segments for electrical measurements. Platinum leads were attached using a pressure contact.

The high-temperature electrical measurements were all made in a double-wall fused quartz furnace. The conductance and emf measurements were made on the Type I and II cells under dry N_2 ambient, while Type III cells were measured under various O_2 partial pressures. The emf was measured on a high impedance Cary voltmeter, as the open circuit potential across the cell. The emf was measured as a function of temperature and O_2 partial pressure. For the temperature dependence measurements, data were taken both with temperatures decreasing and increasing in increments of 50°C.

In the case of Type I and Type II cells, a fixed O_2 partial pressure is established at each half cell by the temperature and the free energy of formation of SiO_2, hence 30 min was allowed for stabilization at each temperature. (This will be discussed later.)

The O_2 partial pressure for the Type III cells was controlled and measured over the range of 10^{-3}-10^{-20} atm by using a pump and detector fabricated from stabilized zirconia (8). The pump was a ZrO_2 tube open at both ends with Pt electrodes formed inside and on the outside of the tube by using Pt paste and Pt foil. This tube was inserted in line with the gas flow as indicated in Fig. 2. Potentials of up to 3V, giving currents up to 13 mA, were applied across the Pt/ZrO_2/Pt pump cell. The O_2 partial pressures obtained were determined from the open circuit voltage E_a measured across the detector cell

$$\ln P_{O_2} = \frac{4F}{RT} E_a + \ln [P_{O_2}]_{ref} \quad [2]$$

The detector cell was a ZrO_2 tube closed on one end, with Pt electrodes formed on both the inside and outside of the tube. The closed end of the pump was inserted and sealed into the vacuum-tight, sampling furnace in close proximity with the cells to be measured. The open end of the tube was exposed to the room ambient. For the detector, the reference P_{O_2} was that of the room ambient, with the temperature of the detector cell being that of the sample. For efficiency in the O_2 pump, the pump was maintained at a constant temperature, 600°C, with a separate furnace.

Table I. Ge-Si alloy concentrations

Before alloying atom fraction Si	After solidification: Atom fraction Si (electron microprobe)	After solidification: Si activity (Hiskes and Tiller)[a]

Results

Figure 3 shows current density as a function of voltage for typical Type I cells, containing SiO_2 grown on P-doped Si. Approximately ohmic behavior is shown up to 3V; at higher voltages the current density is proportional to V^n, with $n \simeq 2$, which is characteristic of carrier injection.

Figure 4 shows values of log σT as a function of $(1/T)$ for SiO_2 grown on B- and P-doped Si as mea-

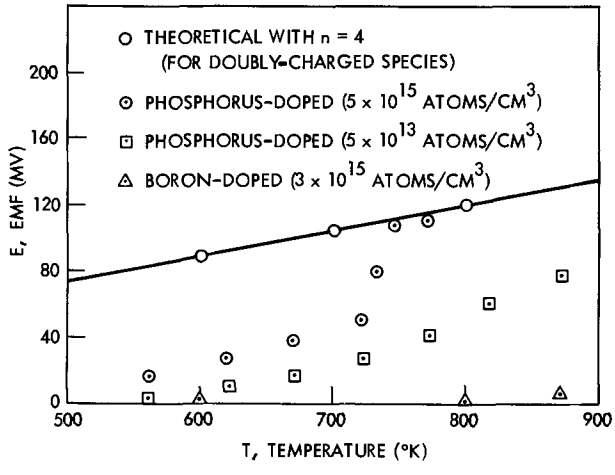

Fig. 6. EMF of Type II cells vs. temperature

sured in Type I cells. The conductivity σ is defined as $\sigma = IL/AV$, where A is the area and L is the thickness of the oxide. Typical values of A were 0.5 and 1.0 cm^2 and typical values of L were 3000-6000Å. The measurements were made at voltages in the range where the behavior is nearly ohmic. Data reported by Brander *et al.* (1) on cells with Al electrodes are shown for comparison with our Type III cells with Pt/SiO_2 electrodes. Brander's oxides were on B-doped substrates with 3 × 10^{15} atoms/cm^3.

The results of emf measurements at 600°C on cells containing SiO_2 films grown on P-doped Si with variable O_2 activities are shown in Fig. 5. It is assumed throughout this paper that the concentration of dopant in the SiO_2, both P and B, is proportional to the dopant concentration in the Si on which the oxide film is grown. The points at low P_{O_2} were obtained for Type II cells with (Ge-Si) alloys of various compositions. The points at higher P_{O_2} were measured on Type III cells.

Figure 6 shows emf as a function of T for Type II cells containing SiO_2 films grown on P- and B-doped Si. The method of deriving theoretical values of the emf will be described in the Discussion section.

Discussion

In this section, the emf data for Type II and III cells are used to obtain values for the ionic transference number (t_i), the ratio of the ionic conductance to the total conductance. These values are then used, together with the data for total conductance obtained for Type I cells, to provide evidence concerning the identity of the species primarily responsible for the ionic conductance.

For a cell with a gradient in the chemical potential of oxygen or a corresponding but opposite gradient in the chemical potential of Si between the electrodes on the right and the left sides of the cell, the emf is given by

$$E = \frac{1}{\mathbf{F}}\int_{I}^{II} (t_i/n)\, d\mu_{O_2} \qquad [3]$$

$$= \frac{RT}{\mathbf{F}}\int_{I}^{II} (t_i/n)\, d \ln P_{O_2} \qquad [4]$$

$$= \frac{RT}{\mathbf{F}}\int_{II}^{I} (t_i/n)\, d \ln a_{Si} \qquad [5]$$

Here t_i is the local value of the ionic transference number and n is the number of equivalents transported for a reaction involving one g-mole of O_2; $n = 4$ corresponds to transport by ions or ionic defects with conventional charges. Lower values of n correspond to abnormal charges (9). From Fig. 1, we see that Eq. [4] is applied to Type III cells and Eq. [5] to Type II cells.

Using Eq. [4] and [5], if we neglect the possible variation of t_i/n with P_{O_2} or a_{Si}, we can take this quantity out of the integral, replacing it by its average value, leaving only the integral of ln P_{O_2} or ln a_{Si}. For Type II cells of Si^I/SiO_2Si^{II}-Ge with $a_{Si^I} = 1$, we have

$$RT\int_{II}^{I} d\ln a_{Si} = RT\int_{I}^{II} d\ln P_{O_2} = -\Delta G^\circ \quad [6]$$

where ΔG° is the standard Gibbs Free Energy of the reaction

$$Si(s) + O_2(g) \rightleftarrows SiO_2(s) \quad [7]$$

Combining Eq. [6] with Eq. [4] and [5] gives the expression

$$E = t_i \Delta G^\circ / n\mathbf{F}_e \quad [8]$$

Theoretical values for the emf of a cell involving a completely ionic conductor with doubly charged ions have been obtained by using Eq. [8] and assuming $t = 1$, $n = 4$, and the literature values of ΔG° for the formation of crystalline SiO_2.

The theoretical emf values are plotted against temperature in Fig. 6.

It is seen in Fig. 6 that the experimental emf values for the higher P concentration at the highest temperatures are in good agreement with the theoretical values. This indicates that the conducting ionic species is doubly charged.

Based on an assumption that the ions are doubly charged, $\bar{t}_i$ for a Type II cell is given by the ratio E_{obs}/E_{the}.

Evaluation of this ratio for the data in Fig. 6 shows that the oxides grown on B-doped substrates exhibit predominately electronic conduction, while those grown on P-doped substrates are mixed conductors, with the ionic component increasing with increasing temperature and increasing P concentration in the substrate.

If the variable t_i/n is kept under the integral in Eq. 4 $\mathbf{F}E/RT$ can be differentiated with respect to P_{O_2} at side II to give the value of t_i/n at P_{O_2}II. The slope of a plot of $\mathbf{F}E/RT$ *vs.* ln P_{O_2} gives t_i/n over a given pressure range as shown in Fig. 5, where t_i/n varies from 0.145 at low P_{O_2} to 0.062 at medium P_{O_2} and 0.155 at high P_{O_2}. The values of t_i for the respective P_{O_2} ranges, assuming $n = 4$, may be compared with the $\bar{t}_i$ value of 0.4 measured by Jorgensen (3).

In an attempt to identify the species primarily responsible for ionic conductivity in oxides grown on P-doped substrates, the ionic conductance was calculated from

$$\sigma_i = t_i \sigma_t \quad [9]$$

where σ_t is the total measured conductance and t_i, the value obtained in Fig. 5. The activation energy for ionic conduction was then determined from the slope of a plot of $\sigma_i T$ *vs.* T^{-1}, as shown in Fig. 7. It can be compared with self-diffusion data by using the Nernst-Einstein relation. Since no measurable self-diffusion of Si in SiO_2 has been observed, the only data available for comparison are those for oxygen in SiO_2 (11). The activation energy of 1.2 eV derived from the high temperature region (673°-873°K) in Fig. 7 is close to the value of 1.3 eV derived from the oxygen self-diffusion data.

This agreement is consistent with the identification of oxygen as the major conducting ionic species in P-doped SiO_2. However, the activation energy data do not indicate whether the conducting species is an oxygen vacancy or interstitial. This may be investigated by comparing the observed dependence of the ionic transference ratio t_i/n on P_{O_2} and doping concentration with the dependence of the electronic and ionic defects on these parameters as predicted by a theoretical defect model.

Defect chemistry theory predicts that doping SiO_2 with foreign donors would cause an increase in O''_i and a decrease in $h^\cdot$, while it would cause a decrease in $V^{\cdot\cdot}_O$ and an increase in e'. Doping with foreign acceptors would have the opposite effect.

The defect notation is that of Kroger and Vink (12) where the species $h^\cdot$, e', $V^{\cdot\cdot}_O$, and O''_i refer to ionized holes, electrons, vacancies, and oxygen interstitials. The

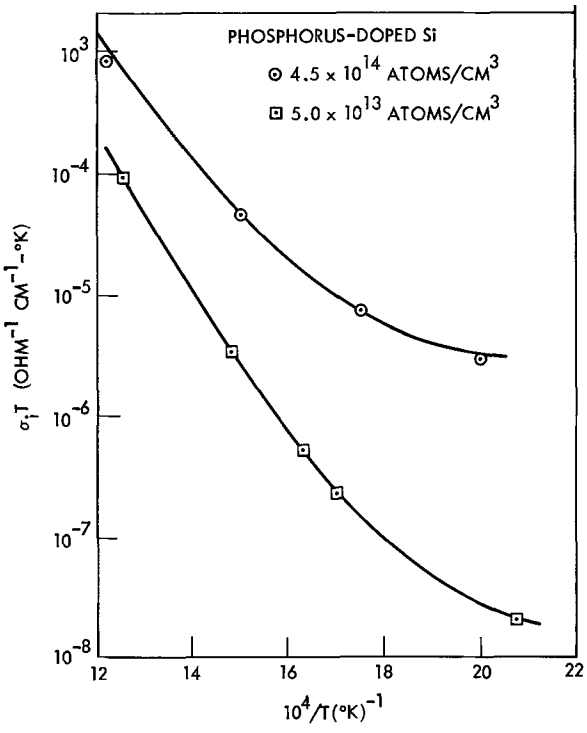

Fig. 7. Log $\sigma_i T$ vs. reciprocal temperature

superscript refers to the effective charge, with a dot positive and dash negative, while the subscript refers to the site; thus $V^{\cdot\cdot}_O$ is an oxygen vacancy with a net effective charge of +2.

It is observed (Fig. 6) that t_i/n is larger for SiO_2 grown on P-doped substrates than for SiO_2 grown on B-doped substrates.

Since it is assumed that P is a donor and B an acceptor in SiO_2, then the observed dependence of t_i/n on doping is consistent with O''_i, not $V^{\cdot\cdot}_O$, as the major conducting species.

If it is assumed that there is a mixture of abnormal and normal charges, the transference ratio (from Fig. 5) when plotted as a function of P_{O_2} gives the results as shown in Fig. 8. The trend of a decrease in t_i/n with increase in P_{O_2} follows the theory, while the magnitude of t_i/n favors a mixed charge model. The increase in t_i/n at high P_{O_2} is not explained by the theoretical defect chemistry model.

In summary, from this work we see an agreement of the measured emf with the theoretical emf if we assume normal charges. A correlation of the activation

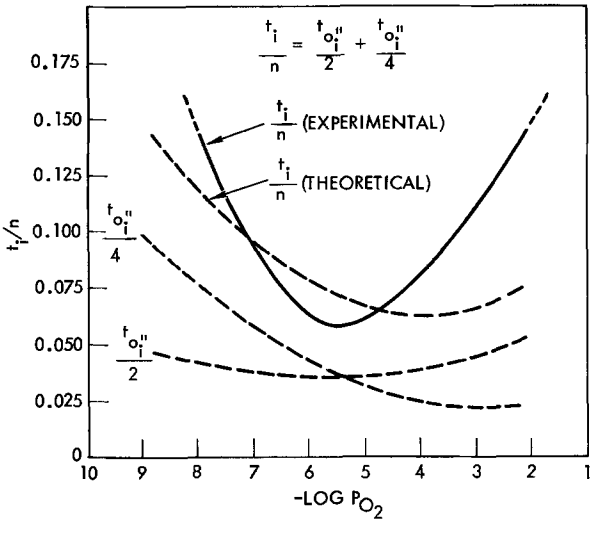

Fig. 8. Ionic transport ratio vs. $-\log P_{O_2}$

energy of the conducting species with the activation energy of self-diffusion of O_2 in SiO_2 is also shown. The agreement in the behavior of the t_i/n value as a function of P_{O_2} and of the P and B concentrations with that predicted for O''_i and $h^{\cdot}$ suggests the species to be a doubly charged oxygen interstitial. A more conclusive identification would require additional experimentation, including numerical calculation of the dopant and defect concentrations. The possibility of alkali ions as the conducting species was eliminated, in that the MOS C-V curves showed less than 0.1V shift on 1000Å test oxides stressed typically at 150°C but sometimes even as high as 300°C.

Growth of Polycrystalline Silicon Films: Grain Size

A. Emmanuel and H. M.-Pollock

Department of Physics, University of Lancaster, Lancaster, England

ABSTRACT

Transmission electron microscopy has been used to study the structure of polycrystalline films grown on silicon nitride and silicon dioxide substrates by chemical vapor deposition from silane gas. The effects of substrate temperature, type of carrier gas (nitrogen or hydrogen), and gas flow rate were examined. For substrate temperatures of 720°C (993°K) and above, the films were polycrystalline, and under certain conditions a uniform grain size of *ca.* 30 nm was obtained. At the highest temperatures (*ca.* 1040°-1100°K), the films were discontinuous and showed also a type of secondary structure. Results obtained by field emission microscopy have been used to show how incident flux and surface diffusion coefficient may affect grain size in polycrystalline films: it is likely that the observed noncrystalline/polycrystalline transition is affected by recrystallization, decrease in density of preferred sites for nucleation, and change in critical nucleus size.

Polycrystalline silicon films have recently become important in silicon device technology (1). The effect of the presence of grain boundaries is to enhance the diffusion coefficient of dopants, to reduce the active carrier concentration, and to lower the hole mobility. This paper describes research whose objects were as follows: to grow polycrystalline silicon films with a small, uniform grain size on silicon dioxide and silicon nitride substrates by chemical vapor deposition from silane gas; to use transmission electron microscopy to study the effect of substrate temperature, silane-to-carrier gas molar ratio, and type of carrier gas, on the structure of the deposit; and to relate the measurements of surface diffusion coefficients described elsewhere (2) to the observed grain sizes of the films. Preparation of the films was carried out at Ferranti Electronics Ltd., Wythenshawe, Manchester, in collaboration with Mr. R. Nuttall and Mr. J. R. Sowerby.

Polycrystalline silicon may be grown by chemical vapor deposition on the silicon dioxide or silicon nitride surface, using thermal decomposition of silane (3) in the approximate temperature range 920°-1300°K. As described below, we find that at temperatures below the lower limit the deposited silicon becomes noncrystalline; the upper limit, which depends on the particular carrier gas used, is marked by the onset of homogeneous decomposition (for gas pressures within the viscous range).

Key words: chemical vapor deposition, surface diffusion, nucleation, coalescence, amorphous-polycrystalline transition.

Experimental

It was considered important that the films to be examined should be grown under conditions similar to those prevailing during normal device fabrication.

Deposition apparatus.—A horizontal quartz tube with RF generator for substrate heating was used, the susceptor material being silicon carbide-coated graphite on a tilted quartz jig. The carrier gases used were nitrogen and hydrogen and their flow rates were respectively 26 and 30 liters/min (8.7-10.0 cm/sec). Silane, in the form of 3% silane in either hydrogen or nitrogen, was introduced at flow rates ranging from 5 to 210 cm^3/min. Facilities were included for the deposition of silicon nitride through the reaction between ammonia and silane at 1190°K (4).

Preparation of samples.—(111)-oriented 0.01 ohm-cm n-type silicon substrates were cleaned according to a schedule involving degreasing with toluene, a sulfuric acid-hydrogen peroxide dip, a deionized water wash, a hydrofluoric acid dip, a deionized water wash, and a hydrogen chloride gas etch. A 0.5 μm thickness of silicon dioxide was then grown by conventional thermal oxidation; 0.1 μm of silicon nitride was deposited with a substrate temperature of 1090°K, except in the ex-

Carrier: nitrogen; ×, "low" deposition rate (molar ratio 4.2 x 10^{-5}); ○, "high" deposition rate (molar ratio 2.1 x 10^{-4}); 1, "steeply rising" region; 2,"leveling-off" region; 3, "falling" region.

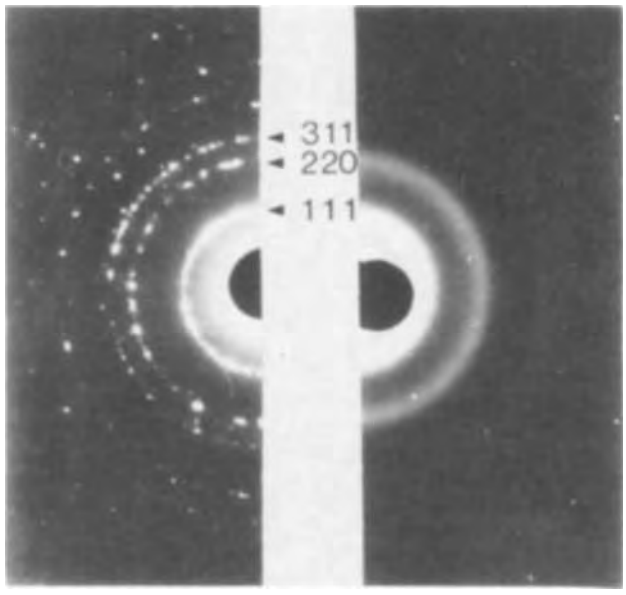

Fig. 2. Electron diffraction patterns: polycrystalline silicon (e.g., from film shown in Fig. 5, left) and noncrystalline silicon (e.g., from film shown in Fig. 3, right).

periments for which the silicon was to be grown directly onto silicon dioxide. The substrates thus pretreated were then introduced into the experimental chamber and the polycrystalline silicon layer was then deposited to a thickness of between 85 and 100 nm onto the substrate at the required temperature, at one of two different rates corresponding to molar ratios of silane to carrier gas of 2.1×10^{-4} and 4.2×10^{-5} (which will be referred to as "high" and "low" deposition rates, although the absolute rate does, of course, depend strongly on the substrate temperature, as shown in Fig. 1). The approximate layer thicknesses were estimated by means of the color of the interference fringes seen by reflected light, calibrated by "Talystep" measurements at intervals. A further 0.1 μm of silicon nitride was then deposited through the reaction between silane and ammonia, after which the slices were removed from the reaction chamber and introduced into another deposition system where a final 1.0 μm of silicon dioxide was deposited by oxidation of silane at a substrate temperature of 720°K. After removal from the deposition apparatus, the sample was glued face downward to a glass slide by means of a heat-resistant wax. The silicon substrate was then removed by an etch in a solution containing 11 parts nitric acid, 5 parts acetic acid, and 2 parts hydrofluoric acid (C.P. 4 etch), and the slide then dipped into hot toluene to dissolve the wax. The composite film then floated off and was further washed in toluene. A 40% hydrofluoric acid bath was then used to dissolve the silicon dioxide and nitride layers, leaving small pieces of polycrystalline silicon film which were washed and allowed to dry on electron microscope specimen grids.

Results

The effects of the film deposition parameters on the film grain size are summarized in Table I. Growth rates are approximate only, being estimated from the deposition time and the film thickness as judged from interference colors as described above. The following points were noted:

1. The films are always polycrystalline, as indicated by selected-area diffraction patterns (Fig. 2), except when deposited at temperatures as low as 923°K, in which case they were found to be noncrystalline, *i.e.*, with a grain size of less than 1 nm (see Fig. 2 and 3).

* Region (see text and Fig. 1): 1, steeply rising; 2, leveling off; 3, falling.
** Discontinuous film, with some "secondary structure."
† Assuming D has a similar value for Si on SiO_2 as for Si on Si_3N_4.
†† Dr. B. E. Watts and Dr. D. G. Barlow (6) have informed us that they observe the noncrystalline structure (for silicon growth under similar conditions at 650°C) on silicon dioxide substrates also.

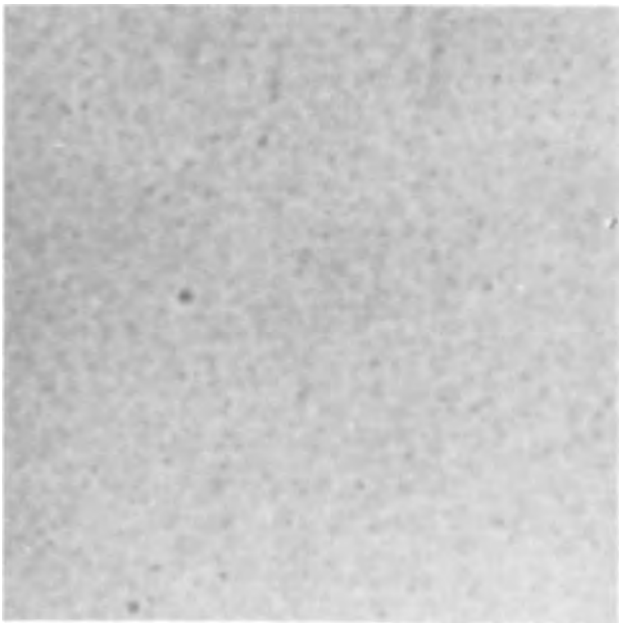

Fig. 3. Noncrystalline silicon film grown under conditions similar to those described for Fig. 5, but with the silicon nitride substrate at 898°K.

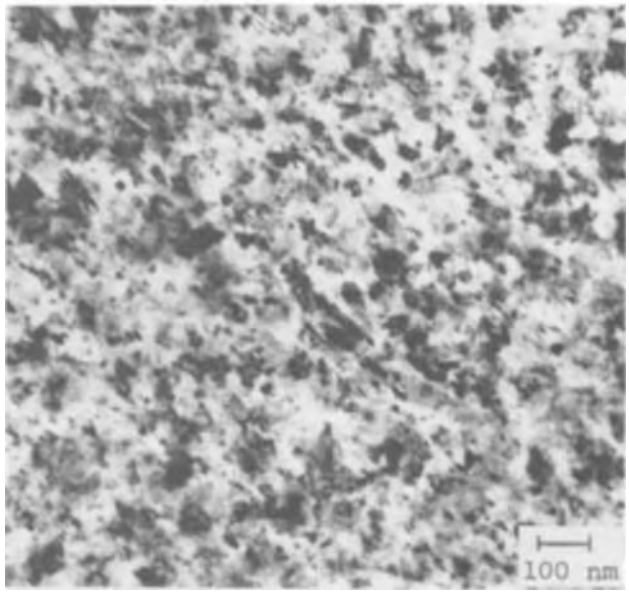

Fig. 4. Polycrystalline silicon film (thickness *ca.* 100 nm) originally deposited onto silicon nitride at 993°K (low molar ratio of silane, nitrogen carrier). The grain size is uniform and small (*ca.* 30 nm).

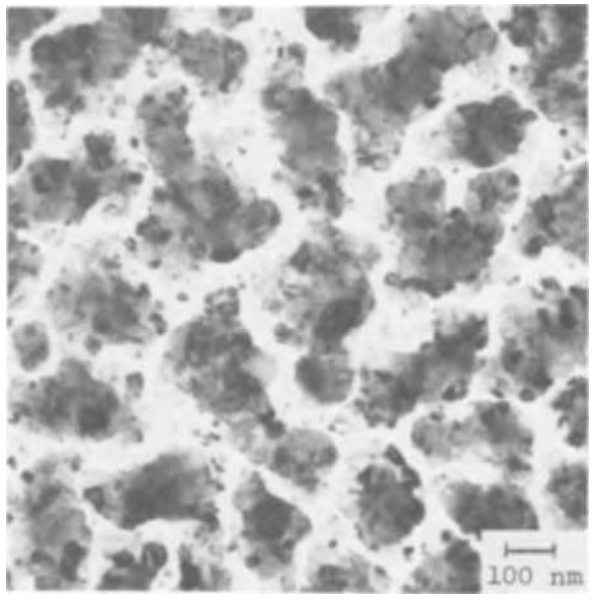

Fig. 5. Discontinuous film, with some "secondary structure" (thickness *ca.* 100 nm, high molar ratio, nitrogen carrier, silicon nitride substrate at 1103°K).

2. Curves for growth rates of silicon films as a function of substrate temperature may be divided into different regions of silane decomposition including a "steeply rising" region within which the rate increases rapidly with temperature, and "leveling-off" and "falling" regions within which the growth rate either increases slowly or decreases as the substrate temperature is raised (see, for example, Fig. 1). Provided that the deposition took place within the "steeply rising" region, and provided that the substrate was silicon nitride at 990°K or above, a typical small size of grain (up to 30 nm diameter) was obtained, the deposition being reasonably uniform over the full extent of the substrate. This type of film appears similar in structure to those grown by Cowher and Sedgwick (7) from SiH_4-H_2 and $SiBr_4$-H_2 mixtures. To the eye, the film presented a uniform reflecting surface (except that when a hydrogen carrier gas was used, the deposit was less uniform, the film causing certain areas of the substrate to show up in relief, such a cleaning residues or surface irregularities). Figure 4 shows a typical deposit of the uniform small-grained type. A phosphine-doped deposit [0.1% phosphine in hydrogen at a flow rate of 50 cc/min introduced into the reacting gas flow, the silicon nitride substrate temperature being 1043°K, the carrier nitrogen (26 liters/min), and the molar ratio 2.1×10^{-4}] also showed this typical small grain size.

3. At the two highest substrate temperatures used (1043° or 1103°K), the film was discontinuous (see Fig. 5 and 6). The micrographs suggest that in addition to the normal polycrystalline structure there is also an additional or "secondary" structure, although a dark-field image (Fig. 6) shows that most of the grains have the same size as before. To the naked eye these films presented a slight powdery appearance.

4. Some large grains were seen in films deposited onto silicon dioxide substrates or grown at a very low rate (0.033 nm/sec). These films presented a marked powdery appearance to the eye.

Discussion

The most striking feature of the structure of the polycrystalline silicon films is the abrupt change from the noncrystalline type of film to a structure with a grain size of *ca.* 30 nm as the substrate temperature is raised. It is possible that rapid crystallization would be aided by heat released during a true amorphous-crystalline transition such as that observed by Matthews and Mader (8) in their studies of certain two-metal systems. Although Brodsky *et al.* (9) state that amorphous silicon films, once deposited, crystallize on annealing at temperatures within the range 720°-920°K, Chopra (10) sets an upper limit of *ca.* 420°K for the amorphous-crystalline transition in silicon, considerably lower than the substrate temperatures used in this study. De Luca (11) has discussed the relation between deposition parameters and observed preferred orientations of silicon grown on fused silica substrates. In any case other deposition parameters besides temperature would be expected to affect the grain size in the film. Sloope and Tiller (12), in a discussion of their observations of an "amorphous"-crystalline transition for germanium films grown on calcium fluoride substrates, assume that the film becomes crystalline when the time for one atomic layer to form exceeds the mean time between jumps made by an adatom. In this discussion we attempt to see how the deposition param-

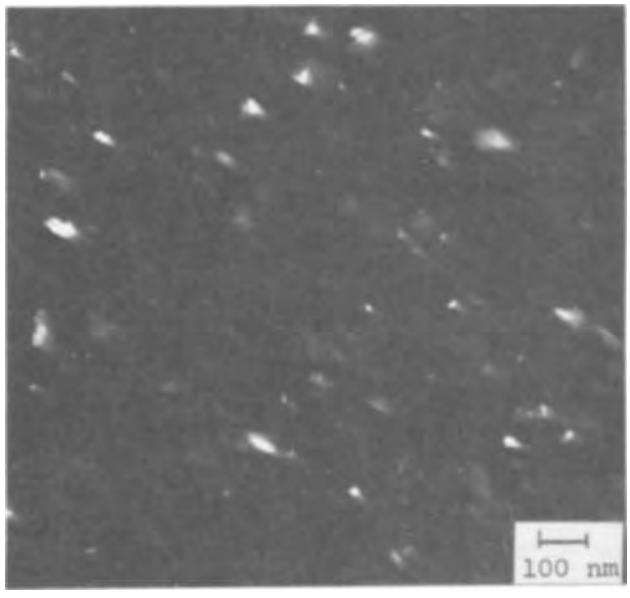

Fig. 6. Dark-field image of the film shown in Fig. 5

eters could affect the film structure, according to theories of nucleation kinetics and thin film growth as described by Stowell *et al.* (13-16) and to what extent the surface diffusion measurements described in ref. (2) are relevant to the observed grain sizes.

Since substrate temperature affects both the film deposition rate and the surface diffusion coefficient of silicon, it seemed appropriate to list the observed grain sizes in order of decreasing J/D, where J is the flux of silicon atoms/square meter/second condensed (calculated from the film thickness and deposition time, and provisionally assuming complete condensation of silicon atoms) and D is an upper limit for the surface diffusion coefficient of silicon on silicon nitride [estimated from the results of experiments described in ref. (2)]. Complete condensation has not been proved to apply, but it may be noted that Joyce *et al.* (3) justify the same assumption for their experiments with silicon substrates in which the substrate temperatures were higher than in the present study. In general, grain size could be expected to increase with decreasing J and increasing D, and Table I tends to confirm this expectation.

In analyses of the growth of silicon films on silicon substrates (5, 17, 18), the value of E_d has been unknown *a priori*, although Joyce *et al.* (3) and Henderson and Helm (17) deduced values of this quantity from their analyses. It can be more useful, however, to know absolute values of the diffusion coefficient D as well as its activation energy, since the pre-exponential D_o in the expression $D = D_o \exp(-E_d/kT)$ can vary over many orders of magnitude (19).

In this analysis, the quoted upper limits of D for diffusion of silicon on silicon nitride were calculated as follows: from the micrographs showing diffusion of silicon on tungsten emitters of known tip radius, the characteristic distance, x, for migration in the field emission microscopy experiments described in ref. (2) was estimated to be 300 nm. Since both the temperatures at which diffusion was measured, and the temperatures at which the flat films were grown, were lower than the minimum temperature for detectable evaporation of silicon (2), we assume that the diffusion equation

$$D = \overline{x^2}/(4t) = D_o \exp(-E_d/kT)$$

is valid: if we substitute the above value of x in this equation, using the observed values of t and E_d for silicon on tungsten, we obtain a pre-exponential, D_o, equal to 5.10^{-4} m^2 sec^{-1}. This is larger than the expected value of 3×10^{-6} as calculated from the expression νa^2, where ν is a typical atomic vibration frequency and a is the expected jump distance on the surface. The discrepancy may be due to a positive entropy factor, as observed in other work (19). The higher of the two values is preferred in this estimate of an upper limit for D. For each temperature, the diffusion coefficient for silicon on tungsten was that obtained from the expression $D = \overline{x^2}/(4t)$, using the values of t shown in Fig. 3 of ref. (2). The upper limit for D for silicon on silicon nitride was then taken as one tenth of this value, since the diffusion times were always at least ten times as long at a given temperature within the relevant temperature range.

We first see whether the observed numbers of grains per unit area N_g are explicable on the assumption that N_g is equal to N_s, the saturation nucleus density during initial nucleation of the film, *i.e.*, that each grain grows from one nucleus until the substrate is covered, after which the grain size is maintained throughout subsequent film growth. Grain growth through subsequent recrystallization is neglected on this assumption. It is shown in Appendix A that this assumption can possibly be justified for the noncrystalline films (with nucleation at normal sites on the silicon nitride lattice), but that even if we include the possibility of nucleation at surface defects or other preferred sites, the observed noncrystalline/polycrystalline transition cannot be explained.

It is therefore necessary to include the possibility of grain growth through coalescence and recrystallization. It is shown in Appendix B that crystallization or recrystallization can be expected over the whole range of conditions, as judged by a criterion involving J/D, and described by Stowell (16). We propose that the films deposited onto silicon nitride substrates grow as follows: at the largest values of J/D, nuclei form very close together ($\lesssim 1$ nm) on the silicon nitride substrate, at preferred sites with $i = 0$ and at normal sites with $i = 1$. (E_i is the binding energy of a critical nucleus containing i atoms, one less than the number of atoms in the smallest stable cluster.) The "preferred sites" formula (Table III) predicts that a lower density of nuclei is required at saturation under these conditions than does the "normal sites" formula (Table II), so that nucleation at preferred sites is probably predominant. After the substrate is covered, subsequent nucleation of silicon on silicon takes the same form so that a noncrystalline structure is obtained throughout the film. If J/D is lowered, there will be a tendency for the initial noncrystalline layer to crystallize as the gap between J/D and a critical value, $(J/D)_s$, widens (see Appendix B). Under these conditions, crystallites of silicon may appear upon which subsequent layers may nucleate, finding a much lower density of preferred sites (N_{do}) than was offered by the noncrystalline silicon nitride substrate. This decrease in N_{do} for the "preferred sites" nucleation will lead[1] to a decrease in N_s (Table III), again producing a larger crystallite size. If, moreover, the "preferred sites" nucleation rate is sufficiently reduced, it may, at the lower values of J/D, become swamped by "normal sites" nucleation with $i = 1$ (for which the calculated values[1] of N_s are not far from those predicted by the preferred sites formula even with sites separated by as little as 1 nm). This increase in the number of atoms in the critical nucleus will help to improve the crystallinity of subsequent layers. If, on the other hand, nucleation at preferred sites such as grain boundaries continues to predominate, recrystallization will not give a grain size larger than 30 nm owing to the reduction in the critical value $(J/D)_s$. As discussed earlier, a Mader-type of amorphous crystalline transition might be expected, at lower temperatures. Quite apart from this, it is possible that the abrupt onset of polycrystallinity observed here arises from the three co-operative

[1] An increase in the value of D appropriate to diffusion of silicon on silicon instead of on silicon nitride does not invalidate this statement.

effects, namely, recrystallization, decrease in density of preferred sites, and change in critical nucleus size. The calculations show that as the temperature increases, the increase in surface diffusion coefficient outweighs the increase in flux produced by the higher silane decomposition rate.

There is not enough evidence to say whether the larger grain sizes seen in films deposited at the lowest fluxes and on silicon dioxide substrates are produced by changes in J, D, or N_{dO}, or by other factors such as change in carrier gas. It is interesting to note that Cowher and Sedgwick (7), describing the structure of silicon grown on silicon dioxide, find that the particle size increases to up to 300 nm as the boron doping is increased to 10^{25} m^{-3}. The secondary structure seen in films deposited at the highest temperatures and in the "leveling-off" or "falling" regions of silane decomposition could be associated with silicon produced by homogeneous decomposition of silane in the gas phase, some distance from the substrate surface. The explanation of grain size given here is, of course, subject to the uncertainties underlying the theory of nucleation and growth. These include the assumptions that complete condensation of the arriving silicon atoms applies and that recrystallization occurs only before the film becomes continuous. If condensation is not complete, the values of J used in Table I will be affected as well as the nucleation process. Lewis (20) has suggested that a transition from complete to incomplete condensation, which would sharply reduce nucleation rate and density, may contribute toward the onset of polycrystallinity, although in this case an abrupt decrease in film growth rate as a function of substrate temperature would be expected, contrary to observation (5). In addition, as described in ref. (2) it is probable that the values of diffusion coefficient employed do not correspond to true surface diffusion of silicon atoms on a silicon nitride surface. However, in view of the similar deposition conditions used for the preparation of samples for the electron microscope and field emission studies, we are justified in using the numerical values to show how flux and diffusion coefficient may affect grain size in polycrystalline films.

Conclusions

1. Conditions have been established for the growth of polycrystalline silicon films with a small, uniform grain size on silicon nitride substrates.

2. Measurements of surface diffusion coefficients made by field emission microscopy can be used in support of a mechanism put forward to explain the observed transition from a noncrystalline to a polycrystalline structure.

APPENDIX A

Assumption of One Grain per Nucleus ($N_g = N_s$)

Nucleation at normal lattice sites.—We first see whether nucleation at normal lattice sites on the silicon nitride substrate can explain the observed grain sizes, using the expression

$$N_s = C(i)\,(J/D)^{2i/(2i+5)} \exp|2/(2i+5)\cdot E_i/kT|$$

with $i \geq 1$, $C(1) = 10^{7.2}$, $C(2) = 10^{1.2}$, $C(3) = 10^{-2.6}$, as derived by Routledge and Stowell (13) for all but extreme cases of incomplete condensation (21), modified by Stowell and Hutchinson (14), and converted to SI units with a silicon nitride surface site density of 10^{19}. Here E_i is the binding energy of a critical nucleus containing i atoms (one less than the number of atoms in the smallest stable cluster), and N_s is the saturation nucleus density. We make the same assumptions as the authors of these papers. Table II shows the calculated minimum values of $\log_{10}N_s$: for the polycrystalline films, the calculated minimum values of grain density exceed the observed values by a factor of at least 400 and, even allowing for the fact that the above expression is inaccurate for coverages of greater than 10%, the assumption of $N_g = N_s$ must be rejected. For the noncrystalline films only we have a straightforward explanation; it is, however, more likely that here $i = 0$ and that even in this case nucleation is not occurring at normal lattice sites, since at substrate temperatures so low that even a cluster consisting of $0+1 = 1$ atom must be stable, the same type of noncrystalline structure is obtained.

Nucleation at preferred sites.—The predicted values of N_s and nucleation rate for nucleation at normal substrate sites with $i = 1$ are so large that nucleation solely at surface defects or other preferred sites on the silicon nitride substrate can be neglected, unless we postulate $i = 0$. The appropriate expressions for "preferred sites" nucleation are then

$$N_s/N_{dO} = 0.1B \qquad \text{for } B \leq 10$$

or

$$N_s/N_{dO} = 1 \qquad \text{for } B \geq 10$$

with

$$B = \left\{ \sigma_i(i + 5/2) \left[\frac{N_0}{N_{dO}} \right]^{i+3/2} \exp\left[\frac{E_i + \Delta E_i}{kT} \right] \left[\frac{J}{DN_0^2} \right]^i \right\}^{1/(i+5/2)}$$

where $\sigma_0 = \sigma_1 = 1$, $\sigma_2 = 1.25$, N_0 is the density of all substrate sites (normal and preferred), N_{dO} is the density of preferred sites, ΔE_i is the additional binding energy of an i-sized cluster to a preferred site, and the other parameters have the same meaning as before. These expressions have been derived by Stowell and Hutchinson with certain assumptions (14) for the condition of complete condensation. Table III lists values of $\log_{10}N_s$ calculated for various possible values of N_{dO}, and for $i = 1$ and 2 as well as 0 for the sake of completeness. It shows that for the experimental conditions used, the value of B is very high (>40) and that saturation therefore occurs, with the calculated value of N_s equal to the assumed density of preferred sites N_{dO}, for all except very large values of N_{dO}. If we take a distance of 30 nm between preferred sites, formation of the polycrystalline films of grain size *ca.* 30 nm is explained on the original assumption that N_g becomes equal to N_s; but if the nuclei are always this far apart, then under the conditions for which a noncrystalline structure was observed, we would have $N_g > N_s$, *i.e.*, more than one grain per nucleus. If we assume a smaller distance (*e.g.*, *ca.* 1 nm) between preferred sites, a noncrystalline structure will be predicted throughout the range of experimental conditions; in any case we probably cannot neglect nucleation at normal sites which has already predicted a distance of this magnitude between nuclei at saturation (Table

Table II. Minimum values of $\log_{10}N_s$ assuming nucleation at normal lattice sites (N_s in m^{-2})

The calculation employs values of T, J, and D corresponding to conditions for the preparation of films with the different observed grain sizes.

Observed grain size →	Noncrystalline (~1 nm)	30 nm	50 nm	220 nm
$i = 1$	$\log N_s = 18.2$	17.7 to 18.1	17.6 to 18.0	17.8

* The ranges listed here correspond to the variation in T, J, and D for the different experimental conditions.

II). We must then seek some other explanation of polycrystalline film growth when observed.

APPENDIX B

Assumption of <1 or >1 Grain per Nucleus; Effects of Recrystallization and Coalescence

In order to explain the sharp transition from a noncrystalline to a polycrystalline structure, it is therefore necessary to include the possibility of grain growth through coalescence and recrystallization. Lewis (22) has given a general account of the relative importance of nucleation density and coalescence. It is interesting to compare the values of J/D for the condensing silicon atoms with the critical value, $(J/D)_s$, for which recrystallization is impossible before the growing film becomes continuous: $(J/D)_s$ may be estimated on the assumption that surface diffusion dominates over volume diffusion during any coalescence, from Stowell's formula (16)

$$(J/D)_s = 6\cdot10^6\,\gamma\,\Omega^{1/3}\,N_{sd}{}^{3/2}/(kT)$$

where γ is the surface energy of silicon and Ω is the atomic volume. If $J/D > (J/D)_s$, the initial nucleation density and orientation structure will be frozen into the film: if $J/D < (J/D)_s$, recrystallization may or may not be possible. It is important to note that this formula applies to the coalescence of crystalline islands only. Using a value of 1 Jm^{-2} for γ, we have the values of $(J/D)_s$ shown in Table IV. Thus we see that if the still discontinuous film were being formed from monocrystalline nuclei 30 nm apart, recrystallization would not be possible but that for the higher values of N_s predicted by nucleation theory, we would expect at least some recrystallization during the growth stage.

We have mentioned also the possibility that the initial nuclei are widely separated (*e.g.*, by *ca.* 30 nm), but that under conditions of high J/D the adatoms joining them do not assume crystalline packing, so that $N_g > N_s$. Although Table IV indicates that a film forming from nuclei 30 nm apart should not recrystallize under the experimental conditions used, this conclusion does not apply to noncrystalline nuclei. Thus crystallization or recrystallization can be expected over the whole range of conditions: there is, however, no need to assume an initial nucleation at widely separated preferred sites if we adopt the growth mechanism described in the discussion.

Table IV. Critical values of $\log(J/D)_s$ above which recrystallization should be impossible

Nuclei 1 nm apart at saturation	40.0	
Nuclei 10 nm apart at saturation	37.0	
Nuclei 30 nm apart at saturation	35.5	
Minimum values of $\log(J/D)$ employed	*ca.* 38 for noncrystalline films	36.0 to 37.8 for polycrystalline films

Correlation of Dielectric Dispersions with Electronic and Ionic Conduction Mechanisms in Glass

Mary Splann Mizzoni

Corning Glass Works, Research and Development Laboratory, Corning, New York 14830

ABSTRACT

Three iron oxide-containing glasses of different network formers, namely, a phosphate, a borate, and a silicate, were compared to an alkali-lime-silicate glass. Tests by the Tubandt method established the main conduction mechanism, whether electrons or ions, in each glass. The conductivity data and loss factor and dielectric constant data from frequencies of 10^{-2}-10^{5} Hz were measured as a function of temperature. As dielectric theory predicts, dispersions of the dielectric constant with associated relaxation peaks in the loss factor were observed in the four glasses. An analysis of these properties revealed that the same mechanism was responsible for the a-c and the d-c conductivity in each glass. The shape of the dielectric constant curves below the dispersion frequencies varied with the conduction mechanism. Interpretation of these data showed only the silicate glass to have mixed ionic-electronic conductivity.

The earliest papers written on the electrical conductivity of electronically conducting glasses were concerned with proving that the conduction mechanism was electronic (1-3). Mazurin *et al.* (4) employed the Tubandt method to show electronic conductivity in iron-containing silicate glasses. Several electrical properties were related in both vanadium and tungsten phosphate glasses by Ioffe *et al.* (5). Electrical resistivity and thermoelectric power on iron phosphate glasses were reported by Hansen (6). Later, Hansen and Splann (7) published the dielectric properties of these same glasses with 55% FeO_x-45% P_2O_5 and varying Fe^{3+}/Fe_{total} ratios. From the relaxation peaks in the loss factor, the activation energy of the a-c conduction mechanism was found to be equal to that of the d-c conduction mechanism. The "hopping" mechanism (8) was proposed for these related mechanisms. It was also observed that a measurable static dielectric constant, independent of temperature and frequency, was obtained well below the dispersion frequencies. To the author's knowledge, this phenomenon had not been reported previously for glasses. This was indicative of electronic conductivity only. The dispersion of the dielectric constant data gave support to the validity of the relaxation peaks.

Kinser (9) reported on this same glass system, relating dielectric relaxations to crystal formations in the glass. He was able to do this as he observed relaxation peaks only in samples with finely dispersed crystals (10). This work has been extended recently (11).

The dielectric behavior of vanadium phosphate glasses was published by Mansingh *et al.* (12) from frequencies of 10^{2}-10^{9} Hz and from temperatures of 80°-350°K. Isard (13) has shown, using published data, the similarity in the dispersion of conductivity of electronic and ionic dielectrics with random structures.

Because of the random structures of glass, theory (14) predicts that all glasses will have a dispersion in the a-c conductivity from which relaxation spectra are obtained. In many glasses, the peak in the relaxation is masked by the contribution of d-c conductivity to the measured a-c losses. Careful measurements over a suitably wide frequency and/or temperature range are required to locate them (15).

It is the purpose of this paper to show that low frequency dielectric relaxations are found in several glasses of diverse compositions. The relaxation peaks are associated with the dispersions in the dielectric constant. The behavior of three electronically conducting glasses, a phosphate, a borate, and a silicate, is compared to that of a common alkali-lime-silicate glass. Each of the electronically conducting glasses contains iron oxide, which is believed to be responsible for this conductivity. Tests by the Tubandt method substantiate the conduction mechanisms. From the activation energy data, it is shown that the same conduction mechanism is responsible for a-c and d-c conductivity in each glass.

Key words: dielectrics, glass, conductivity, dispersion, relaxation.

Experimental Procedure

The glasses were melted in 400-600g batches in fused silica crucibles at 1300°, 1250°, and 1400°C for the phosphate (glass A), the borate (glass B), and the silicate (glass C) iron containing glasses. They were poured on steel or graphite molds and annealed. The alkali-lime-silicate glass, Corning Code 0080 (glass D), was obtained from a production melt. The compositions of the glasses are given in Table I.

X-ray diffraction patterns and transmission micrographs showed no evidence of crystalline phases down to 30Å in glasses A, B, and D. Widely scattered crystals, about a micron in diameter, were observed in glass C.

Tests by the Tubandt method (16) were performed on each of these glasses. This precise method for determining the conduction mechanism is based on weight transfer during electrification. No weight is transferred if the conduction mechanism is electronic. The weight transfer can be calculated if no more than two species are involved in ionic or ionic-electronic conduction (17). Gold electrodes were evaporated on one face of each of two disks of each composition. The disks were 1½ in. in diameter and polished to a thickness of 2.00 mm. For some of the tests, a third disk was

Table I. Glass compositions in mole per cent

	FeO_x	P_2O_5

	FeO_x	Ce_2O_3	B_2O_3		
Borate* glass B	4.3	25.5	70		
	FeO_x	PbO	ZrO_2	SiO_2	
Silicate glass C	9.7	29.1	2.9	58.4	
	Na_2O	K_2O	CaO	MgO	SiO_2
Alkali-lime-silicate glass D	15.3	0.3	5.5	5.3	72.9

* Ref. (21). In varying compositions in this system, the iron oxide is believed to be the main contributor to electronic conductivity because (i) in decreasing the Ce_2O_3 and increasing FeO_x, the resistivity decreases; and (ii) in increasing the Ce_2O_3 and keeping the FeO_x constant, the resistivity is unchanged.

inserted between the electroded ones. The disks and combinations of disks were carefully weighed before and after testing to ±0.0005g. The disks were stacked between gold-plated stainless-steel electrodes, raised in temperature in a measurement furnace and the voltage applied. A known current was passed for a known period of time. Weight changes were calculated, assuming ionic conductivity by Na^+, by the equation

$$M = \frac{kIAt}{N} \qquad [1]$$

where M = weight change, g'; k = 6.281 × 10^{18}, charges/A sec; I = current, A; A = atomic weight of conducting ion; t = duration of electrification, sec; and N = Avogardo's number, 6 × 10^{23} molecules/mole.

Measurements of electrical properties, d-c and a-c, were made on similar samples. Three-terminal gold electrodes were evaporated on glasses A, B, and C. Hanovia Liquid Gold Bright electrodes were fired on glass D in the same configuration. The experimental procedures and theory were described previously (7). Briefly, the d-c conductivity γ_{dc} was obtained (18) with a potential of 20V with a Beckman electrometer. Two bridges were used to measure the a-c properties: a low-frequency bridge from 10^{-2} to 10^3 Hz, designed by Weingarten (19) [and used by Heroux (20)] and General Radio Type 1615A from 10^2 to 10^5 Hz.

The total conductivity γ_T was calculated from the following equations

$$\gamma_T = \frac{1}{R} \times \frac{t}{A} \text{ mho/cm} \qquad [2a]$$

where R = resistance (d-c or a-c), ohms; t = thickness of specimen, cm; and A = eff. area of electrodes, cm^2 and

$$\gamma_T = \frac{\tan \delta_T \times K' \times f}{1.8 \times 10^{12}}$$

$$= \frac{K''_T \times f}{1.8 \times 10^{12}} \text{ mho/cm} \qquad [2b]$$

where K' = relative dielectric constant = C × t/0.0885A; C = capacitance, pF; f = frequency, Hz; and K''_T = loss factor.

The total conductivity is the sum of a-c and d-c contributions. To obtain the relaxation peaks, the d-c contributions were subtracted, as

$$\gamma_{ac} = \gamma_T - \gamma_{dc} \qquad [3]$$

From this, the loss $factor_{ac}$ was calculated

$$K''_{ac} = \frac{\gamma_{ac} \times 1.8 \times 10^{12}}{f} \qquad [4]$$

Results and Discussion

Data from tests by the Tubandt method are tabulated in Table II. The temperature, current, voltage, and time of electrification are listed for each glass. The measured weights of each disk and combinations of them are listed before and after testing. A calculated weight transfer, based on ionic conductivity by sodium ions, is shown. For glasses A, B, and C there is no significant weight change. This indicates that most or all of the current was carried by electrons. Little adjustment of the voltage was required to maintain a constant current over a prolonged period of time. This lack of build-up of space-charge polarization further indicates electronic conductivity.

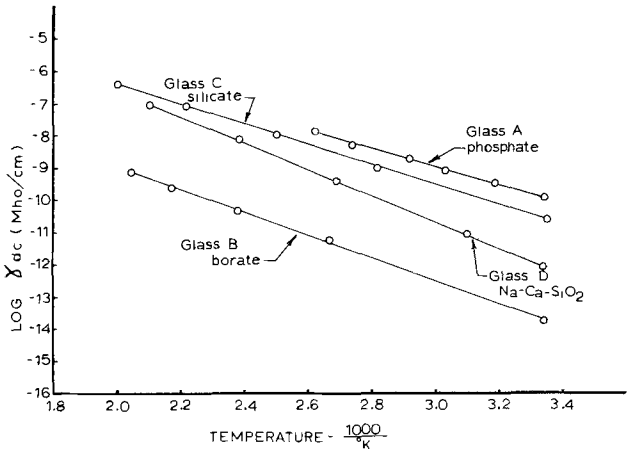

Fig. 1. D-C conductivity vs. temperature for glasses A, B, C, and D.

For glass D, the alkali-lime-silicate, the results were different. The Tubandt test was performed three times, each with essentially the same results. To prevent fusion to the contacting electrodes, weighed gold foil was placed between the electroded surface and the contacting electrode. The results of the last test are listed. The anode disk lost the amount of weight that was calculated. The middle disk did not change in weight. The cathode disk weighed more than the anode disk lost and continued to gain weight, as the additional active Na^+ in the cathode disk picked up water from the atmosphere. Because this glass is an ionic conductor, build-up of the space-charge polarization increased the resistance greatly. A constant current could not be maintained for 8 hr. The weight transfer calculation was dependent on four current levels, as the voltage and temperature were raised during the test.

From these tests it is shown that glasses A, B, and C are electronically conducting and that glass D is ionically conducting. With this difference established, the electrical behavior of the glasses will be compared.

Figure 1 shows the log of the d-c conductivity *vs.* 10^3/°K for each glass. In the temperature range shown,

Table III. Activation energy

	dc (eV)	ac (eV)
Phosphate (glass A)	0.54	0.57
Borate (glass B)	0.72	0.70
Silicate (glass C)	0.61	0.64
Alkali-lime-silicate (glass D)	0.84	0.89

the data establish straight lines. As the conductivity is represented by

$$\gamma_{dc} = \gamma_0 e^{-E/kT} \quad [5]$$

where E is the activation energy and γ_0 is a constant, the activation energies were obtained from the slopes of the lines. These are listed in Table III.

Figures 2-5 show the dispersion in the dielectric constant K' and the relaxation peaks in the loss factor K''_{ac} *vs.* log f for each glass. Data for typical curves are given at two temperatures.

Figure 2 is for glass A, the phosphate glass. These data were previously published, as glass 1 (7). The loss factor peaks at the same frequency that the midpoint of the dispersion of the dielectric constant curve occurs. The following relationship is observed

$$K''_{ac} < \tfrac{1}{2}(K'_s - K'_\infty) \quad [6]$$

which indicates a distribution of relaxation times. This is common for glasses because of their random structure. Both the dispersion of the dielectric constant and the relaxation peaks shift to higher frequencies with increasing temperature.

The dispersion of the dielectric constant, which is unaltered data, confirms the peak in the relaxation data. In this glass, unlike most glasses, the dielectric constant levels off below the dispersion frequencies and is independent of temperature, within experimental error. This static dielectric constant is also indicative of electronic conductivity. Heroux (20), in a study of lithium borosilicate glasses, showed that the interfacial polarization of ionic conductivity caused a rapid increase in the dielectric constant at frequencies below the dispersion.

Figure 3 gives similar data for glass B. Because this is a lower conductivity glass, the static dielectric constant was observed over a wider temperature and frequency range. For example, the dielectric constant is constant at 1 Hz, below the dispersion frequencies, over a span of 100°C.

Figure 4 gives comparable data for glass C. Again, a relaxation peak is seen at the frequency of the midpoint of the dispersion of the dielectric constant. However, no static dielectric constant is observed for this glass. This is interpreted as the effect of a mixed ionic-electronic conductivity. As gold electrodes were used for this test, it is assumed that this ionic conductivity is associated with tramp alkali in the glass. This slight ionic conductivity is possibly noted in the results of the Tubandt test. While the weight changes were insignificant, three disks were required for the test and two of them fused together. The behavior of the dielectric constant gives positive support to the interpretation of ionic as well as electronic conductivity in this glass. Similar behavior of the dielectric constant curves were previously reported for the iron phosphate glasses, using silver electrodes (7).

Curves for the ionically conducting glass D are shown in Fig. 5. They show a close resemblance to the electronically conducting glasses. Again, the peaks of the relaxation curves occur at the frequencies of the midpoints of the dielectric constant dispersions. However, the dielectric constant rises rapidly below the relaxation frequencies as a result of a build-up of the space-charge polarization. This is typical for ionically conducting glasses (20).

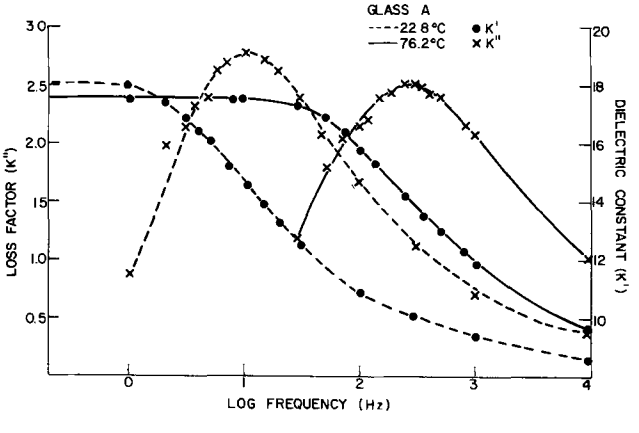

Fig. 2. Glass A, loss factor and dielectric constant vs. frequency

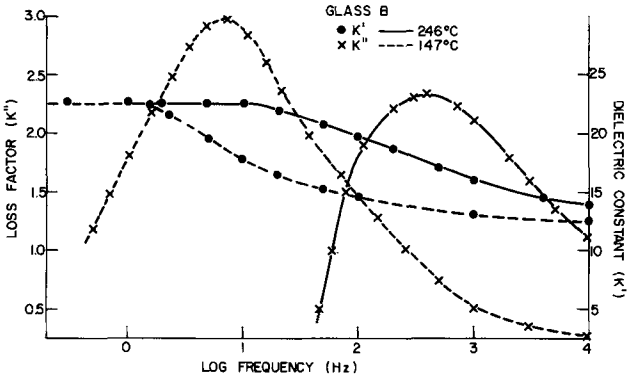

Fig. 3. Glass B, loss factor and dielectric constant vs. frequency

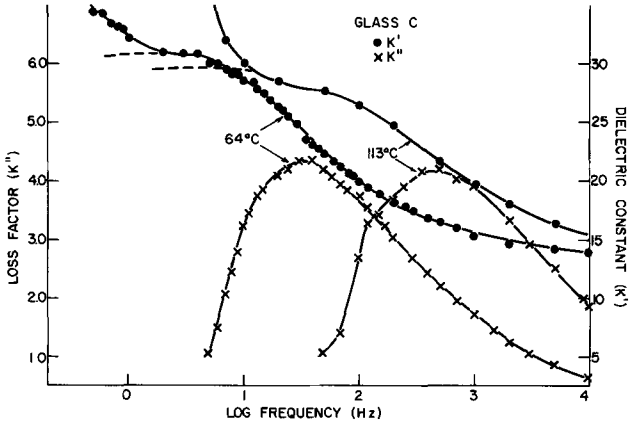

Fig. 4. Glass C, loss factor and dielectric constant vs. frequency

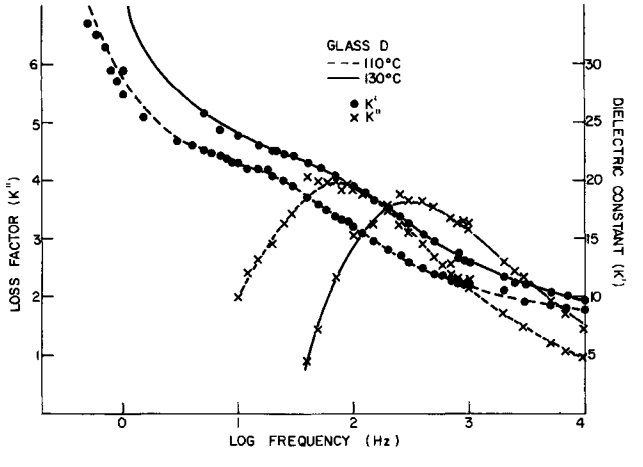

Fig. 5. Glass D, loss factor and dielectric constant vs. frequency

From the loss factor data on glasses A, B, C, and D, the activation energies of the a-c conduction mechanisms are obtained. A plot of the log of the frequency at which this maximum loss factor occurs *vs.* 1000/°K is shown in Fig. 6 for each glass. As the relaxation time $\tau = \tau_0 e^{E/kT}$, where $\tau = 2\pi f$, E is the activation energy, and τ_0 is a constant, the activation energies are obtained from the slopes of the curves. These are tabulated in Table III. The activation energies for each glass for the d-c and a-c conductivities agree well. This indicates that the same mechanism of conduction is responsible for d-c and a-c conductivity.

Conclusions

1. Based on the results of the Tubandt tests, the main conduction mechanism is electronic in glasses A, B, and C and ionic in glass D.
2. The loss factor$_{ac}$, for each glass, peaks in the frequency range in which the midpoint of the dispersion of the unaltered dielectric constant occurs.
3. From the slopes of the dielectric constant curves below the relaxation frequencies and the results of the Tubandt tests, it is deduced that the conduction mechanism is only electronic for glasses A and B, mixed ionic-electronic for glass C, and only ionic for glass D.
4. The agreement in the activation energy data indicates that the main conduction mechanism is the same for a-c and d-c conduction in each glass.

Kinetics of Thermal Growth of HCl-O_2 Oxides on Silicon

K. Hirabayashi and J. Iwamura

Toshiba Research and Development Center, Tokyo Shibaura Electric Company, Ltd., Kawasaki, 210, Japan

ABSTRACT

Growth kinetics at 1100°C are investigated as a function of HCl/O_2 mole ratio below 10% for (111), (100), (311), and (110) oriented wafers. It is concluded that the considerable increase of the oxidation rate in the presence of HCl is caused by three reasons: The first is enhanced diffusion of O_2 and H_2O molecules in the HCl oxide. The second is enhanced reactions at the Si-SiO_2 interface, resulting from a catalytic action of HCl. The third is the contribution of H_2O to the oxidation, which is formed by the reaction, $2HCl + \frac{1}{2} O_2 \rightleftarrows H_2O + Cl_2$. The diffusivity of O_2 and H_2O molecules in the HCl oxide was measured by a technique which is based on dry or wet oxidation after an initial HCl growth. Infrared spectroscopy of the output gas from the furnace and the observation of the Si-SiO_2 interface through a microscope and secondary electron microscope revealed the nature of the enhanced reactions, which are closely related to HCl gaseous etching of Si.

Recently it has been reported that clean SiO_2 films for MOS devices can be obtained by the addition of HCl to dry O_2 during the high temperature oxidation of silicon (1-6). The use of HCl reduces the number of Na^+ ions and surface states at the Si-SiO_2 interface. No significant change between standard and HCl oxide is observed in oxide charge, dielectric strength, dielectric constant, and index of refraction, but the oxidation rate and the diffusivity of Na^+ ions in the oxide are considerably increased in the presence of HCl. It has been suggested that a Si-O-Cl complex is formed

Key words: silicon dioxide, oxidation, HCl-O_2.

during the high temperature oxidation in the presence of HCl and that the actual position of chlorine is substitutional for oxygen, resulting in a nonbridging bond (4).

The increase of the oxidation rate cannot be explained only by the presence of H_2O molecules, formed by the reaction, $2HCl + \frac{1}{2}O_2 \rightleftarrows H_2O + Cl_2$. It is reasonable to suspect that the structure difference between standard and HCl oxide may explain the enhanced oxidation rate. In this paper we investigate the oxidation kinetics at 1100°C as a function of HCl/O_2 mole ratio below 10% for (111), (100), (311), and (110) oriented wafers. By the use of a kinetic model, the effect of diffusion of oxidizing species is separated from that of chemical reactions at the $Si-SiO_2$ interface. The diffusivity of O_2 and H_2O molecules in the HCl oxide is measured by a technique which is based on dry or wet oxidation after an initial HCl growth.

First in the analysis, we neglect the presence of H_2O. Assuming that the equilibrium concentration of O_2 molecules in the oxide and the number of O_2 molecules incorporated into a unit volume of oxide are not changed in the presence of HCl, it is concluded that the enhancement of the oxidation rate is induced not only by enhanced diffusion of O_2 molecules in the oxide but also by enhanced reactions at the $Si-SiO_2$ interface, resulting from a catalytic action of HCl. Second, the effect of H_2O is taken into account, and then the theory explains the experiment fairly well.

In order to clarify the nature of the reactions, infrared spectroscopy is applied to the output gas from the furnace. The structure of the $Si-SiO_2$ interface is observed through a microscope and secondary electron microscope. The roughening of $Si-SiO_2$ interface in the case of large HCl/O_2 mole ratio and large oxide thickness is discussed in relation to the HCl gaseous etching of silicon.

Kinetic Model

Consider a growing film of thickness X (Fig. 1). In the figure, F_1 is the flux of a oxidizing species across the oxide and f_1 is the HCl flux. The oxidizing species are O_2 and H_2O, formed by the reaction, $2HCl + \frac{1}{2}O_2 \rightleftarrows H_2O + Cl_2$. At equilibrium, the reaction for a 1:10 mixture of HCl and O_2 results in the O_2 partial pressure of 0.89 atm and the H_2O partial pressure of 0.016 atm at the total pressure of 1 atm and 1100°C (7). For such a small content of H_2O we may apply the concept of perturbation, and first we neglect the presence of H_2O.

The flux across the oxide is derived from Fick's first law

$$F_1 = D\frac{C_0 - C_i}{X} \quad [1]$$

$$f_1 = \delta\frac{\gamma_0 - \gamma_i}{X} \quad [2]$$

where C_0 and γ_0 are the concentration of O_2 and HCl, respectively, at the outer surface of the oxide. C_i and γ_i are the concentration at the oxide-silicon interface. D and δ are the diffusivity of O_2 and HCl, respectively.

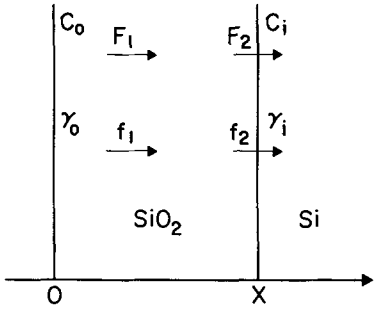

Fig. 1. Schematic representation of the growing film

As we see later the diffusivity, D, increases with the HCl/O_2 mole ratio, and at the $Si-SiO_2$ interface the reaction, $Si + O_2 \rightarrow SiO_2$, is apparently accelerated by the presence of HCl. The HCl molecule behaves like a catalyst. Then, for small concentration of HCl, the reaction constant, k, can be written in the first order approximation

$$k = k_0 + k'\gamma_i \quad [3]$$

where k_0 is the reaction constant for the dry oxygen.

The flux at the SiO_2-Si interface is given by

$$F_2 = kC_i \quad [4]$$

$$f_2 = \kappa\gamma_i \quad [5]$$

where κ is the reaction constant for HCl. The reaction relevant to HCl will be discussed later in relation to the HCl gaseous etching of Si. In a quasi-stationary state we obtain

$$F_1 = F_2 \quad [6]$$

$$f_1 = f_2 \quad [7]$$

The growth rate of the oxide film is then

$$\frac{dX}{dt} = \frac{k}{N}C_i \quad [8]$$

where N is the number of oxygen molecules incorporated into a unit volume of oxide. From Eq. [1]-[8] we get

$$\frac{dX}{dt} = \frac{DC_0/N}{X + \frac{D}{k_0} - \frac{Dk'\gamma_0/k_0^2}{\kappa X/\delta + 1 + k'\gamma_0/k_0}} \quad [9]$$

If we assume that both C_0 and γ_0 are independent of X, the integration of Eq. [9] with the initial condition, $X = 0$ at $t = 0$, leads to

$$2\frac{DC_0}{N}t = X^2 + \frac{2D}{k_0}X - \frac{2Dk'\gamma_0}{k_0^2}\frac{\delta}{\kappa}\log\frac{\kappa X/\delta + 1 + k'\gamma_0/k_0}{1 + k'\gamma_0/k_0} \quad [10]$$

This assumption is justified if the gas-phase mass-transfer coefficients of O_2 and HCl are large enough compared with the corresponding reaction coefficients (8). It is also assumed in Eq. [9] that D and δ are independent of X.

If X is small enough to be

$$\frac{\kappa}{\delta}X << 1 + \frac{k'\gamma_0}{k_0} \quad [11]$$

the growth law can be cast into the following linear-parabolic relationship

$$Bt = X^2 + AX \quad [12]$$

where

$$B = 2DC_0/N \quad [13]$$

$$A = 2D/(k_0 + k'\gamma_0) \quad [14]$$

This relation is readily obtained if the reaction constant is changed to be

$$k = k_0 + k'\gamma_0 \quad [15]$$

instead of Eq. [3].

Second, if we take into account the presence of H_2O, the same approximation as used in Eq. [A-10] of Appendix I leads to

$$(B_1 + B_2)\,t = X^2 + \frac{A_1B_1 + A_2B_2}{B_1 + B_2}X \quad [16]$$

that is

$$Bt = X^2 + AX$$

$$B = B_1 + B_2 \quad [17]$$

$$A = \frac{A_1B_1 + A_2B_2}{B_1 + B_2} \quad [18]$$

where B_1, B_2, A_1, and A_2 are defined as in Eq. [A-5]-[A-8] of Appendix I. The reaction constants, k_1 and k_2, in Eq. [A-7] and [A-8] increase with the concentration of HCl in the same way as Eq. [15] in the present case.

In the following section, we show the change of A and B for the (111), (100), (311), and (110) orientations when the HCl/O_2 mole ratio is varied from 0 to 10%.

Change of A and B

N-type 10 ohm-cm Si slices were used. All slices were cleaned immediately prior to oxidation. Slices were oxidized at 1100°C in various mixtures of HCl and dry O_2. Oxide thicknesses were determined using multiple-beam interferometric techniques. Accuracy of the measurement was ±25Å. For the case of HCl/O_2 mole ratios of 0 and 10%, the graphs of the oxide thickness *vs.* the oxidation time are shown in Fig. 2 and 3, respectively. It should be noted that for the dry oxygen, the growth rate of the (111) orientation is larger than that of the (100) orientation, whereas for the 1:10 mixture of HCl and O_2, they are in the reverse order. The inversion occurs between 2 and 3% of HCl mole ratios.

The oxide thickness as a function of oxidation time was fitted to Eq. [12] by the least square method in order to determine A and B. The values of A and B are summed up in Table I. In Fig. 4 and 5, B and B/A are plotted *vs.* HCl/O_2 mole ratio. The apparent orientation dependence of B may be explained by the inaccuracy in the determination of the oxide thickness. It may be concluded from Fig. 4, and Eq. [17], [18], [A-5]-[A-8] that the orientation dependence of the growth rate is owing to the orientation dependence of the effective reaction constant. The negative values of A, found in

Table I. Change of A and B

HCl/O_2 mole ratio (%)	$B(10^{-4}\ \mu^2/min)$ $A(10^{-2}\ \mu)$	(111)	(100)	(311)	(110)

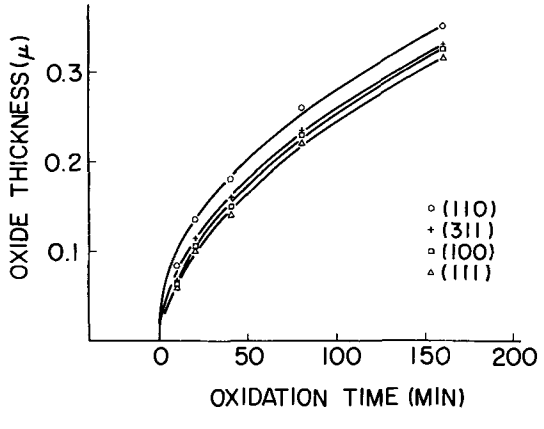

Fig. 3. Oxide thickness vs. oxidation time for the HCl/O_2 mole ratio of 10%. The fitted curves by the least square method are also shown.

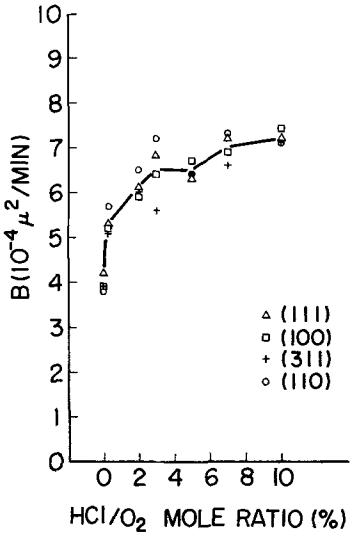

Fig. 4. B vs. HCl/O_2 mole ratio. The arithmetic mean value is shown by the solid line.

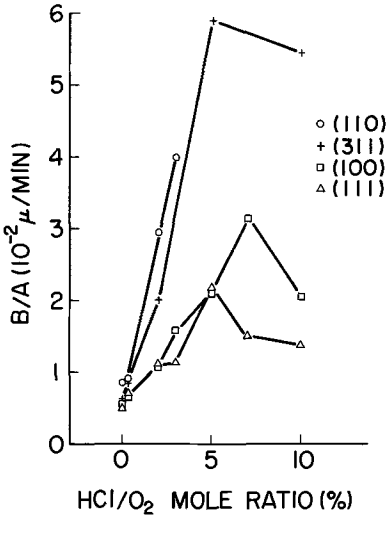

Fig. 5. B/A vs. HCl/O_2 mole ratio

Table I, cannot be expected from Eq. [18]. The growth as a function of time was found hardly to obey the linear-parabolic relationship for HCl/O_2 mole ratios beyond 10%. The approximations used to derive Eq. [12] are considered to be applicable only to smaller mole ratios. The occurrence of negative values of A could be avoided if the experimental data were fitted to Eq. [10] instead of Eq. [12]. For further investigation, higher degree of accuracy in the determination of oxide thickness is required especially for oxides thinner than 0.1μ, to which the values of A are sensitive.

The increase of B with the HCl/O_2 mole ratio may be attributed to the increase of the diffusivity of O_2 and H_2O in the HCl oxide if we assume that for both O_2 and H_2O, the equilibrium concentration in the oxide and the number of molecules incorporated into a unit volume of the oxide are equal to those of the standard oxide (see Eq. [17], [A-5], and [A-6]).

Diffusion of O_2 and H_2O in the HCl Oxide

In this section we determine the diffusivity of O_2 and H_2O in the HCl oxide grown at 1100°C in the 1:10 mixture of HCl and O_2, using a technique which is based on the dry or wet oxidation after the initial HCl growth. Wafers of the (100) orientation were used.

Theoretical relationship between the oxide thickness, X, and the oxidation time, t, in the dry or wet oxygen is expressed as

$$Bt = (X - X_0)(X + X_0 + A') \qquad [19]$$

where

$$A' = A + 2\left(\frac{D}{D_0} - 1\right)X_0 \qquad [20]$$

(see Appendix II). A and B are determined independently by the oxidation of bare silicon wafers. X_0 is the thickness of the initial HCl oxide. D and D_0 are the diffusivity of the oxidizing molecules in the growing oxide and the HCl oxide, respectively.

Diffusion of O_2 in the HCl oxide.—Values of X and t are shown in Table II. X_0 is 0.21μ. According to Table I, A and B are determined as $A = 7.4 \times 10^{-2}\mu$ and $B = 3.9 \times 10^{-4}\ \mu^2$/min. The values of D/D_0 obtained from Eq. [19] and [20] are also shown in Table II. Thus the diffusivity of O_2 in the HCl oxide is approximately 1.6 times larger than that in the dry oxide.

Diffusion of H_2O in the HCl oxide.—As the wet oxygen, where the bubbler temperature is 90°C, is used here instead of pure steam, the analysis is rather complicated. In this case, the oxidation in a mixture of H_2O and O_2 should be considered as in Appendixes I and II. Bare silicon wafers were oxidized in the wet oxygen, and then the oxide thickness as a function of time was fitted to Eq. [A-10], leading to $B^* = 0.47 \times 10^{-2}\ \mu^2$/min. If we take into account that for pure steam, $B = 0.917 \times 10^{-2}\ \mu^2$/min (9) and for dry oxygen, $B = 3.9 \times 10^{-4}\ \mu^2$/min, the value of B^* shows that the wet oxygen is a 1:1 mixture of O_2 and H_2O.

The oxide thickness, X, as a function of the oxidation time, t, after the initial oxidation of $X_0 = 0.21\mu$, is shown in Table III. Using the values, $A_1 = 0.074\mu$, $A_2 = 0.157\mu$ (9), $B_1 = 0.5 \times 3.9 \times 10^{-4}\ \mu^2$/min, $B_2 = 0.5 \times 0.917 \times 10^{-2}\ \mu^2$/min, $D_1/D_{01} = 0.64$ (assuming that the diffusivity of O_2 in the wet oxide is the same as in the dry oxide), and Eq. [A-21]-[A-23], we can determine the values of D_2/D_{02}, which are shown in Table III. The results are not strongly dependent on the value of D_1/D_{01}. Thus the diffusivity of H_2O in the HCl oxide is approximately 2.6 times larger than that in the wet oxide.

Next we compare the diffusivity of H_2O in the wet oxide with that in the dry oxide. Instead of the initial HCl oxide used in the above experiment, the dry oxide of $X_0 = 0.18\mu$ was used. The oxide thickness, X, as a function of the oxidation time, t, in the wet oxygen is shown in Table IV. Using Eq. [A-21]-[A-23] and assuming that the diffusivity of O_2 in the wet oxide is the same as in the dry oxide, we can determine the values of D_2/D_{02}, which are shown in Table IV. The results are not strongly dependent on the value of D_1/D_{01}. The gradual increase of D_2/D_{02} with the oxidation time suggests that the H_2O molecules are gradually incorporated into the network of the dry oxide in some form and the structure of the dry oxide is getting near to that of the wet oxide.

The diffusivity of H_2O in the dry oxide is approximately 1.5 times larger than that in the wet oxide, and thus the diffusivity of H_2O in the HCl oxide is approximately 1.7 times larger than that in the dry oxide.

Contribution of H_2O in the HCl oxidation.—The ratio of B for the HCl/O_2 mole ratio of 10% and for the dry oxygen is 7.4/3.9 = 1.9, which is larger than the ratio of the corresponding diffusivity of O_2 (= 1.6). The difference may be attributed to the presence of H_2O. In the reaction, $2HCl + \frac{1}{2}O_2 \rightleftarrows H_2O + Cl_2$, at equilibrium, the O_2 partial pressure is 0.89 atm and the H_2O partial pressure is 0.016 atm at the total pressure of 1 atm and 1100°C. Then, from Eq. [17], [A-5], and [A-6], we obtain by taking into account the increase in the diffusivity

$$B_1 = 0.89 \times 1.6 \times 3.9 \times 10^{-4}\ \mu^2/\text{min}$$

$$B_2 = 0.016 \times 2.6 \times 0.917 \times 10^{-2}\ \mu^2/\text{min}$$

$$B_1 + B_2 = 9.3 \times 10^{-4}\ \mu^2/\text{min}$$

which is too large compared with the actual value, $B = 7.4 \times 10^{-4}\ \mu^2$/min. Here we assumed that the diffusivity of H_2O in the steam oxide is the same as that in the wet oxide.

It may be doubted whether the H_2O partial pressure is lower than the equilibrium value, 0.016 atm. The initial O_2 pressure is 0.91 atm, which is little different from the equilibrium value, 0.89 atm. Let us denote the H_2O partial pressure as P_{H_2O} and use a tentative value, 0.9 atm, for the O_2 partial pressure. In order to explain the actual value of B, we should choose as $P_{H_2O} = 0.0075$ atm, which is approximately half of the equilibrium value.

As the final example, we show in Table V the results of the HCl oxidation after the initial dry oxidation of $X_0 = 0.21\mu$. The calculated thickness in Table V was obtained by assuming the O_2 partial pressure of

Table II. HCl oxidation followed by dry oxidation

0.9 atm, the H_2O partial pressure of 0.0075 atm, and $A_1 = A_2 = 0.036\mu$ in Eq. [A-22] and [A-23] (see Table I), and using Eq. [A-21]. The results are not strongly dependent on the values of A_1 and A_2.

Chemical Reactions at the Si-SiO_2 Interface

From Eq. [17] and [18], we obtain

$$\frac{B}{A} = \frac{(B_1 + B_2)^2}{A_1B_1 + A_2B_2} \qquad [21]$$

If the HCl/O_2 mole ratio is sufficiently small, B_2 becomes negligibly small. Then we get

$$\frac{B}{A} = \frac{B_1}{A_1} = \frac{C_0}{N}(k_0 + k'\gamma_0) \qquad [22]$$

where C_0, N, k_0, k' are for O_2 (see Eq. [13] and [14]). As C_0 is considered to be constant in the above range of the HCl/O_2 mole ratio and γ_0 is approximately proportional to the HCl/O_2 mole ratio, it is concluded that B/A is a linear function of the HCl/O_2 mole ratio. Actually, it is the case for the HCl/O_2 mole ratio below 5%, as we see in Fig. 5. The values of k' are dependent on the orientation

$$k'(111) \simeq k'(100) < k'(311) < k'(110) \qquad [23]$$

Thermodynamic analyses of an equilibrium Si-H-Cl system for the Cl/H ratio of 1 at 1100°C were made in the same approximation as used in the work of Lever (10). The result of the analyses indicates that H_2, HCl, $SiHCl_3$, $SiCl_2$, $SiCl_4$, and SiH_2Cl_2 need be considered. By the addition of O_2, $SiHCl_3$, $SiCl_2$, $SiCl_4$, and SiH_2Cl_2 are changed into SiO_2 and HCl. Silicon dioxide is hardly attacked by HCl as is shown later. If the rate of the two-step reactions mentioned above is larger than the rate of the direct oxidation

$$Si + O_2 \rightarrow SiO_2$$

the hydrogen chloride may be considered as a catalyst.

The reactions in the absence of O_2 are no other than those of the HCl gaseous etching of silicon. Then, we expect some parallelism between k' and the gaseous etch rate which is considered to be proportional to κ of Eq. [5]. The gaseous etch rate at 1100°C for the HCl/H_2 mole ratio of 5% is 0.5 μ/min for (111), 0.8 μ/min for (100), and 0.9 μ/min for the (110) orientation (11), and thus

$$\kappa(111) < \kappa(100) < \kappa(110)$$

In relation [23], $k'(111)$ is nearly equal to $k'(100)$. However, if we notice that for the dry oxygen, the growth rate of the (111) orientation is larger than that of the (100) orientation, whereas for the HCl/O_2 mole ratio larger than 2%, they are in the reverse order, we may conclude that $k'(111) < k'(100)$ and $k_0(111) > k_0(100)$. Then, the parallelism between k' and κ is complete. It should be noted that the orientation dependence of k_0 is different from that of k'

$$k_0(100) < k_0(111) < k_0(311) < k_0(110)$$

$$k'(111) < k'(100) < k'(311) < k'(110)$$

In the presence of H_2O, Si_2OCl_6 is produced in addition to SiO_2 (12). In order to verify the above reactions at the Si-SiO_2 interface, we exposed silicon wafers covered with the HCl oxide of 0.4μ thickness, to the HCl gas at 1100°C. The output gas from the furnace was introduced into a cell with KBr windows. The infrared absorption spectra of the output gas was measured by a Beckman's infrared spectrometer *IR* 10, in double beam operation. As shown in Fig. 6, H_2O, HCl, Si_2OCl_6, SiH_2Cl_2, $SiHCl_3$, and $SiCl_4$ were detected. For the HCl/O_2 mole ratio of 720, the same gaseous species were detected, but not for the HCl/O_2 mole ratios below 180.

The observation of the wafers through a microscope revealed triangle-shaped etch pits for (111), square-shaped pits for (100), and line-shaped pits for the (110) orientation. The shape of the etch pits is reasonable since the etch rate is largest in the <110> directions. Interference color was observed at the pits, which indicates that only Si is etched off at the pits and not SiO_2.

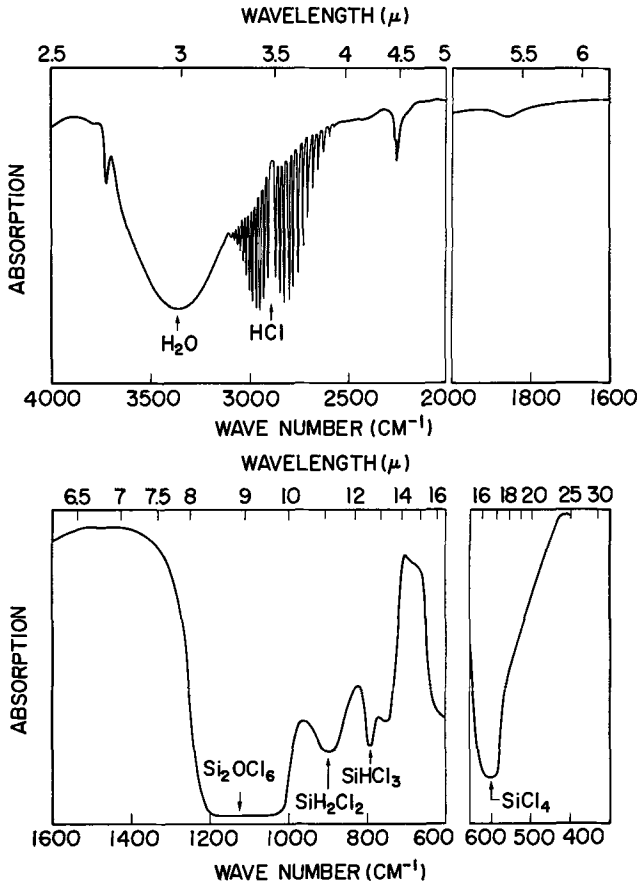

Fig. 6. Infrared absorption spectra of the output gas from the furnace. See the text.

Roughening of the Si-SiO_2 Interface

Especially in the case of large HCl/O_2 mole ratio and large oxide thickness, the color of oxide-covered silicon wafers becomes dirty. The observation through a scanning electron microscope indicates that this is because of the roughening of the Si-SiO_2 interface. Figure 7 is the SEM photograph of a (110) silicon wafer covered with the HCl oxide of 0.25μ thickness grown in a 7:100 mixture of HCl and O_2. The upper part in the figure is coated with an Al film of 300Å thickness. As the Al film prevents the penetration of electrons, the pattern in the Al-coated part is of the Al film itself and thus of the oxide. It is evident from the figure that many holes are at the Si-SiO_2 interface and the oxide film is curved along the wall of the hole. It should be noted, though not evident from Fig. 7, that there are no pinholes in the oxide over the silicon holes at the interface. This is also shown by the measurement of the dielectric strength (1). Figure 8 is the SEM photograph of the same wafer after the oxide film is removed. Line-shaped etch pits are observed in the figure. Figure 9 shows how large values of HCl/O_2 mole ratio and oxide thickness induce the roughening of the Si-SiO_2 interface for the (111), (100), (311), and (110) orientations.

From Eq. [1], [2], [4]-[7], and [15], we obtain for the concentrations of O_2 and HCl at the Si-SiO_2 interface

$$C_i = \frac{C_0}{1 + \frac{k}{D}X} \qquad [24]$$

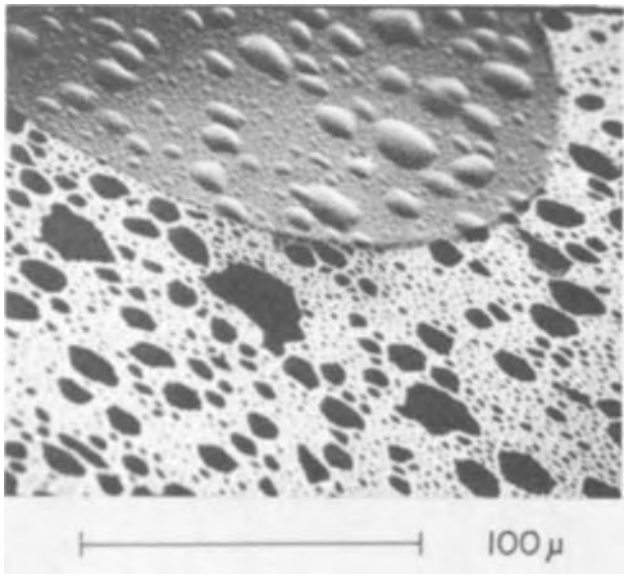

Fig. 7. SEM photograph of a (110) silicon wafer covered with the HCl oxide of 0.25μ thickness grown in a 7:100 mixture of HCl and O_2. The upper part in the figure is coated with an Al film of 300Å thickness.

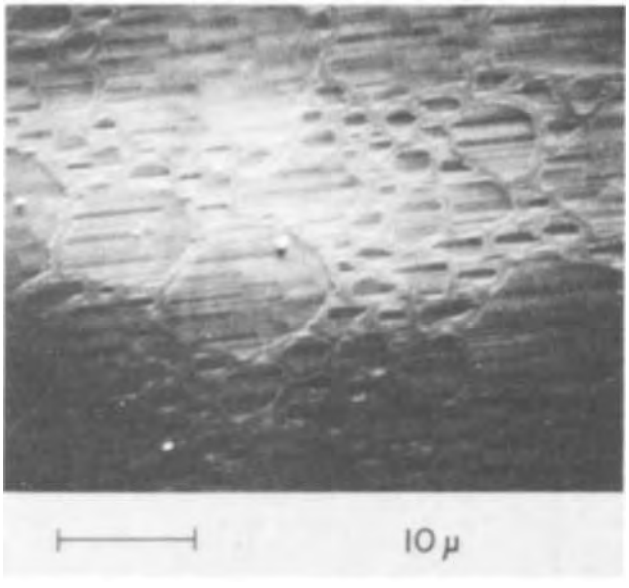

Fig. 8. SEM photograph of the same wafer as in Fig. 7 after the oxide film is removed.

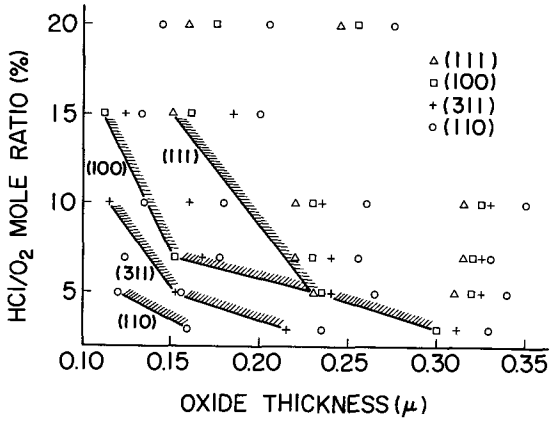

Fig. 9. Observed roughening of the Si-SiO_2 interface for various values of HCl/O_2 mole ratio and oxide thickness. Approximate boundaries between roughened and not roughened regions are shown by the hatched lines.

and

$$\gamma_i = \frac{\gamma_0}{1 + \frac{\kappa}{\delta} X} \qquad [25]$$

Then, if the relation

$$\kappa/\delta < k/D = (k_0 + k'\gamma_0)/D \qquad [26]$$

holds, γ_i/C_i becomes much larger than γ_0/C_0 for large values of X. Thus, for large thickness of the oxide, the deficiency of the oxygen may possibly occur in the oxidation of the intermediate products, $SiHCl_3$, etc., leading to the etching of the interface. This explanation is justified only when the relation [26] is verified. Another explanation is that the oxidation of the intermediate products are not always complete and the etching of the interface occurs slowly with increasing the oxidation time.

Conclusion

The considerable increase of the oxidation rate in the presence of HCl is caused by three reasons. The first is the enhanced diffusion of O_2 and H_2O molecules in the HCl oxide. This is consistent with the Kriegler's suggestion that the HCl oxide includes larger amount of nonbridging bounds than the dry oxide, which induces the enhanced diffusion of Na^+ ions.

The second is the enhanced reaction at the Si-SiO_2 interface, resulting from the catalytic action of HCl. The intermediate products of the reaction are the same as those for the HCl gaseous etching of silicon. The third is the contribution of H_2O molecules, formed by the reaction, $2HCl + \frac{1}{2} O_2 \rightleftarrows H_2O + Cl_2$. The effect of the H_2O molecule is thought to be minor for the HCl/O_2 mole ratio below 5%.

The roughening of the Si-SiO_2 interface is not desirable for device fabrications. It is probable that the roughening leads to the gradual increase of the surface state density observed in the case of (100) orientation for the HCl/O_2 mole ratio above 8% (1). The roughening is severer for the (100) orientation than for the (111) orientation.

Acknowledgments

We wish to thank Dr. Y. Takeishi for encouragement during the course of this work, Dr. Y. Nishi for helpful discussions concerning the HCl gaseous etching and the infrared spectroscopy, and Mr. H. Hara for suggestions on the effect of H_2O.

APPENDIX I.

Oxidation in Two Kinds of Oxidizing Species

Let us define relevant parameters as in Table A-I. For the sake of simplicity we assume that the concentration of oxidizing molecules at the outer surface of the oxide is equal to the equilibrium concentration in the oxide, which is proportional to the partial pressure of the oxidizing species. The flux of O_2 reaching the Si-SiO_2 interface across the oxide of thickness, X, is given by

$$D_1 \frac{C_{01} - C_{11}}{X} = k_1 C_{11} \qquad [A\text{-}1]$$

and the flux of H_2O is

$$D_2 \frac{C_{02} - C_{12}}{X} = k_2 C_{12} \qquad [A\text{-}2]$$

Table A-I. Relevant parameters in the oxidation in two kinds of oxidizing species

Oxidizing species	Reaction constant	Number of oxidizing molecules/unit volume	Concentration at the Si-SiO_2 interface	Concentration at the outer surface of the oxide	Diffusivity
O_2	k_1	N_1	C_{11}	C_{01}	D_1
H_2O	k_2	N_2	C_{12}	C_{02}	D_2

The growth rate of the oxide film is then

$$\frac{dX}{dt} = \frac{k_1}{N_1} C_{i1} + \frac{k_2}{N_2} C_{i2} \qquad [A-3]$$

From Eq. [A-1]-[A-3] we obtain

$$\frac{dX}{dt} = \frac{B_1}{2X + A_1} + \frac{B_2}{2X + A_2} \qquad [A-4]$$

where

$$B_1 = 2D_1C_{01}/N_1 \qquad [A-5]$$

$$B_2 = 2D_2C_{02}/N_2 \qquad [A-6]$$

$$A_1 = 2D_1/k_1 \qquad [A-7]$$

$$A_2 = 2D_2/k_2 \qquad [A-8]$$

Integrating Eq. [A-4] with the initial condition, $X = 0$ at $t = 0$, we get

$$(B_1 + B_2)t = X^2 + \frac{A_1B_1 + A_2B_2}{B_1 + B_2} X - \frac{B_1B_2(A_1 - A_2)^2}{2(B_1 + B_2)^2} \log\left[\frac{2(B_1 + B_2)X + B_1A_2 + B_2A_1}{B_1A_2 + B_2A_1} \right] \qquad [A-9]$$

When the condition, $A_1 \simeq A_2$, is satisfied, the last term can be neglected, and the linear-parabolic relationship is obtained

$$B^*t = X^2 + A^*t \qquad [A-10]$$

where

$$B^* = B_1 + B_2 \qquad [A-11]$$

$$A^* = \frac{A_1B_1 + A_2B_2}{B_1 + B_2} \qquad [A-12]$$

The condition, $A_1 \simeq A_2$, seems to be satisfied at 1100°C. For instance, the observed values are

$$A_1 = 0.086\mu \text{ and } A_2 = 0.083\mu \quad (9)$$

for the (111) orientation, and $A_1 = 0.074\mu$ and $A_2 = 0.157\mu$ (9) for the (100) orientation.

APPENDIX II

Diffusion in Double Layered Oxide

Consider the oxidation in the system schematically represented in Fig. A-1. The system is realized, for instance, when silicon wafers are oxidized in the dry or wet oxygen after the initial HCl oxidation.

The flux, F_0, of the oxidizing species across the initial oxide is

$$F_0 = D_0 \frac{C_0 - C_1}{X_0} \qquad [A-13]$$

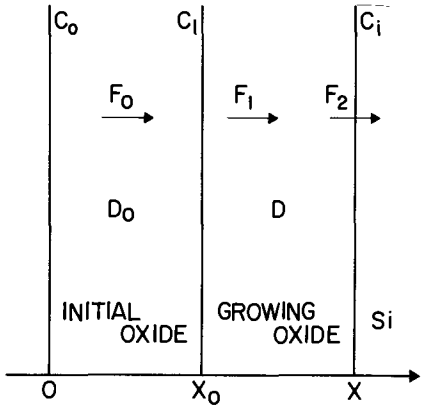

Fig. A-1. Schematic representation of the oxidation of silicon covered with a film of thickness X_0.

where D_0 is the diffusivity of the oxidizing species in the initial oxide, C_0 the concentration of the oxidizing molecules at the outer surface of the initial oxide, and C_1 is the concentration at the interface of the initial oxide and the growing oxide. The flux, F_1 across the growing oxide is

$$F_1 = D \frac{C_1 - C_i}{X - X_0} \qquad [A-14]$$

where C_i is the concentration at the Si-SiO_2 interface. In a quasi-stationary state we have

$$F_0 = F_1 = F_2 = kC_i \qquad [A-15]$$

where k is the reaction constant. The growth rate of the oxide film is then

$$\frac{dX}{dt} = \frac{k}{N} C_i \qquad [A-16]$$

where N is the number of oxidizing molecules incorporated into a unit volume of the growing oxide. Solving Eq. [A-13]-[A-16] with the initial condition, $X = X_0$ at $t = 0$, we obtain

$$Bt = (X - X_0)(X + X_0 + A') \qquad [A-17]$$

where

$$B = 2DC_0/N \qquad [A-18]$$

$$A' = A + 2\left(\frac{D}{D_0} - 1\right) X_0 \qquad [A-19]$$

and

$$A = \frac{2D}{k} \qquad [A-20]$$

As A and B are determined independently by the oxidation of bare silicon wafers, we can estimate the value of D/D_0 from Eq. [A-17] and [A-19].

When the oxidizing species are O_2 and H_2O, the same approximation as Eq. [A-10] leads to

$$(B_1 + B_2)t = (X - X_0)\left(X + X_0 + \frac{A'_1B_1 + A'_2B_2}{B_1 + B_2} \right) \qquad [A-21]$$

where

$$A'_1 = A_1 + 2\left(\frac{D_1}{D_{01}} - 1\right) X_0 \qquad [A-22]$$

$$A'_2 = A_2 + 2\left(\frac{D_2}{D_{02}} - 1\right) X_0 \qquad [A-23]$$

D_1 and D_{01} are the diffusivity of O_2 in the growing oxide and the initial oxide, respectively. Similarly, D_2 and D_{02} are for H_2O.

Technical Notes

Preparation of Ohmic Contacts to n-Ge by Diffusion from As-Doped SiO_2

James W. Holm-Kennedy and Tony P. C. Ku

Electrical Sciences and Engineering Department, University of California at Los Angeles, Los Angeles, California 90024

This note describes a rather simple and convenient procedure for fabricating ohmic contacts to lightly doped n-type Ge. The contacts are found to be ohmic at low electric fields over the range of temperature investigated (77°-300°K). They are noninjecting up to high fields at 77° and 195°K. At 300°K they begin to inject at fields above approximately 25 V/cm, presumably because the n-Ge used is nearly intrinsic at this temperature.

Previously reported techniques for fabricating ohmic contacts to n-Ge have included the use of indium amalgam (1) and alloying (2). It is not clear that the In amalgam contacts will remain noninjecting at moderate electric fields. These contacts are often on a surface previously damaged by sand blasting or lapping in order to achieve ohmicity. Damaged surfaces serve to kill lifetime and frequently will suppress injection at low applied voltages by simply causing rapid minority carrier recombination at the contact. Surface-damaged contacts, however, often inject at higher applied voltages. Further, it is difficult to define contacts to precise dimensions with In amalgam because the amalgam is liquid at room temperature. Contacts of Sb alloyed to n-Ge were investigated but these were found to be lightly injecting. Alloying with Sb-doped Au (0.1% Sb) has been reported to give a low-field ohmic contact to n-Ge (2).

We report here an alternative technique which employs an As-doped SiO_2 diffusion source to create an n^+ region. We chose to use As as the impurity because it supplies a shallow donor state (3) and has a relatively high saturation solubility at moderate temperatures (4). Sb or P might be expected to serve equally well. However, alloying of Sb dots and diffusion of Sb from an Sb-doped SiO_2 source did not provide high-electric-field ohmic contacts in the present case. This is presumably because Sb has a much lower saturation solubility in Ge than As (4). P was not tested but is expected to give results comparable to those obtained with As.

Doping with As can be achieved by heating a Ge wafer that has been sealed together with elemental As in an evacuated closed quartz tube. This closed-tube diffusion technique is awkward, however, because As oxidizes rapidly in air and has a vapor pressure considerably above 1 atm at the diffusion temperatures of interest. To prevent explosions, it is necessary to keep the weight of the As charge below maximum value determined by the volume of the quartz tube. These properties, coupled with the hazards of handling elemental As, make its use undesirable. We have circumvented the problem by using doped SiO_2 as an impurity source, a standard method used in Si technology (5).

Key words: semiconductor contacts, doped oxide, planar diffusion.

The following contacting procedure was used. A 22 ohm-cm (donor concentration $\sim 10^{14}$/cc) n-Ge wafer was lapped with No. 600 grit Al_2O_3, ultrasonically cleaned with Rustlick 660J detergent (Rustlick, Incorporated, Boston, Massachusetts), and thoroughly rinsed with deionized water (DI). The lapped surface was etched until shiny in CP4A (3:3:5:: conc glacial acetic acid: conc HF: conc HNO_3, by volume), dipped in methanol, rinsed in DI and dried with a dry nitrogen jet. Arsenosilica film (Emulsitone, Livingston, New Jersey) was applied to the surface of the wafer by spinning at 3000 rpm for 15 sec. After the film was cured at 200°C in air for 15 min or longer, the wafer was ready for shallow diffusion. The diffusion was performed in an open quartz tube at 650°C for 7 min in flowing forming gas (10% H_2, 90% N_2). (Diffusion temperatures to 850°C and times up to 30 min also produced good ohmic contacts.) The wafer was then slowly removed from the furnace to avoid the introduction of strain caused by thermal quenching. The arsenosilica film was etched away using HF acid leaving the wafer with an exposed n^+ surface having an estimated surface concentration (6) greater than $\sim 10^{20}/cm^3$ in an n^+ layer of less than 0.1 μm estimated thickness.

Metallization was accomplished by electroless Ni plating. A photoresist technique was then used to selectively mask the Ni. KMER photoresist (Eastman Kodak Company, Rochester, New York) was spun onto the n^+ side of the Ni-plated wafer at 1000 rpm for 10 sec. The wafer was dried in air at room temperature for an hour or longer and then cured in air at 100°-200°C for 15 min. The contact areas were then defined using standard planar techniques by exposing the KMER to ultraviolet light for 10 sec and developing the KMER in isopropyl alcohol. This was followed by a post bake in air at 120°C for 15 min to dry the remaining KMER. The unprotected Ni was removed with a Ni etch (1:1:1:: conc HNO_3: conc HCl: acetone, by volume). The exposed portion of the n^+ layer was removed by a quick dip in CP4A (mesa technique). Finally, the hardened photoresist was removed with J100 solution (IRCL, Richardson, Texas) leaving well-defined ohmic contacts under the Ni contacting pads.

Contacts made to lightly doped n-Ge (22 ohm-cm) following the above procedure were of low resistance, $< 5 \times 10^{-4}$ ohm-cm^2 at 300°K and $< 5 \times 10^{-5}$ ohm-cm^2 at 77°K (the lower limit which we could conveniently determine for our sample geometry using a Tektronix curve tracer.

The contacts proved to be non-injecting at 77°, 195° and 300°K. They maintained their ohmic integrity at

77° and 195°K to electric fields in excess of 1500 V/cm, the upper limit of the high voltage system used. The contacts did, however, inject minority carriers (holes) at 300°K for fields in excess of about 25 V/cm, probably because the Ge was so lightly doped that at room temperature a significant number of thermally generated holes were present. The contacting technique is expected to provide contacts which do not inject holes at 300°K even at high electric fields if the n-Ge is made sufficiently extrinsic.

Since the difficulty of obtaining ohmic contacts generally decreases with increasing extrinsic carrier concentration and increasing operating temperature, on the basis of our results for lightly doped samples we believe that the procedure described above is a simple, effective method for fabricating ohmic contacts to n-type Ge. The method should also provide a convenient planar diffusion technique for reliable n-type diffusion in Ge.

Thermal Oxidation of Silicon after Ion Implantation

C. R. Fritzsche* and W. Rothemund

Institut für Angewandte Festkörperphysik der Fraunhofer-Gesellschaft D-78 Freiburg, West-Germany

In semiconductor device technology ion implantation is applied to generate n- and p-type regions or special donor and acceptor profiles. It appears likely that ion implantation can also be used to influence technological processes, as for instance, thermal oxidation. This opens the possibility of selective oxidation and of the production of stress-free protective films. Normally selective oxidation is achieved using silicon nitride layers for masking during thermal oxidation, while stress-free films have been made with oxinitrides (1). Since the nitride as well as the oxide can be formed by implantation of nitrogen or oxygen ions, respectively, into silicon (2,3), we expected that these ions would influence the oxide growth. This paper reports on the growth of oxides after implantation of nitrogen, which was found to influence the oxidation strongly. Some information will also be given concerning the effect of implanted oxygen and carbon.

Experimental

Ions were implanted into polished (111) surfaces of 20 ohm-cm p-type silicon. The beam current depended upon the ion species and did not exceed 16 μA, which according to our beam sweep corresponds to a maximum current density of 5 $\mu A/cm^2$. The crystal axes were tilted by 7° to the beam axis. The distribution of ions is assumed to be close to the profiles calculated from LSS theory (4) at least at lower fluences and in the neighborhood of the concentration peak. The implanted species were N_2^+, O^+, and C^+. From the mass spectra obtained with N_2 or CO_2 in the ion source we conclude that about 5% CO^+ was contained in the beam used for N_2^+ implantations. We are sure that our results with N_2^+ are not due to CO^+ since the effects of C and O were investigated separately and found to be small.

During implantation, half of the sample was covered with an impermeable 0.1 mm steel sheet so that comparison of implanted and unimplanted material with otherwise identical processing was possible. The conditions of oxidation are given in the figures and tables. Three types of thickness measurements were made: Interferometric measurements of the surface step between the oxide layers grown on the implanted and the unimplanted part of the wafer, interference measurements of the oxide thicknesses after step etching with HF, and ellipsometric measurements.

Results

If 4×10^{15} N_2^+ ions per cm^2 are implanted with 30 kV, the oxidation proceeds as shown in Fig. 1 and 2. Consider first the results of oxidations at 1140°C in dry oxygen shown in Fig. 1. The unimplanted silicon shows the well-known square root relation between oxide thickness and time. However, only a very thin film with high refractive index is found on the implanted surface for up to 26 min of oxidation. Longer oxidation results in a substantial growth of films with a refractive index close to that of common thermally grown SiO_2, for which 1.46 is a typical value. With lower temperatures of oxidation, higher thickness differences can be achieved. Figure 2 shows the results of oxidations at 1010°C in dry oxygen. At this low temperature ex-

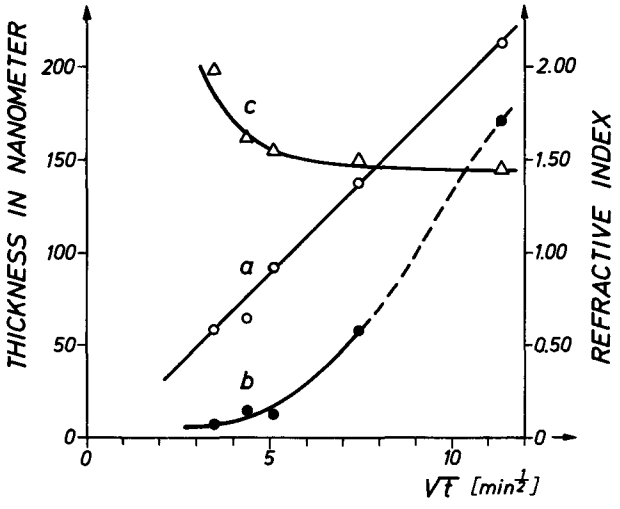

Fig. 1. Time dependence of oxide growth. Dry oxygen, 1140°C. N_2^+-implantation 30 kV, 4 x 10^{15} ions/cm^2. Ellipsometric measurements. (a) Thickness unimplanted, (b) thickness implanted, (c) refractive index implanted.

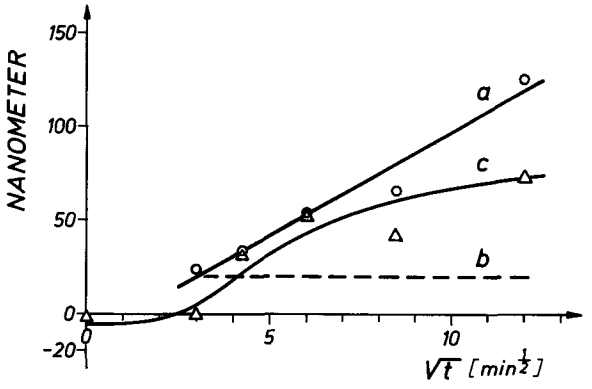

Fig. 2. Time dependence of oxide growth. Dry oxygen, 1010°C. N_2^+-implantation 30 kV, 4 x 10^{15} ions/cm^2. (a) Thickness unimplanted, ellipsometric measurements; (b) thickness implanted, upper limit of interferometric measurements; (c) surface step interferometric.

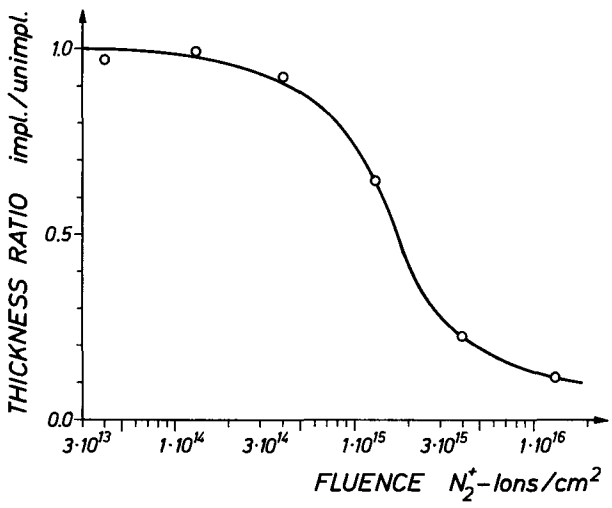

Fig. 3. Dependence of oxide growth upon fluence of 30 keV N_2^+-ions. Dry oxidation 18 min at 1140°C.

tremely thin films result on the implanted side, and we are not able to interpret the ellipsometric measurements in this case. If we assume a well-defined interface below a homogeneous surface layer on normal silicon, the measurements indicate initial layer thicknesses between 50 and 70 nm decreasing with oxidation times longer than 36 min. Apparently, these values are due to an implanted layer but not to a thermally grown layer. However, the suppositions for this evaluation are not adequately fulfilled. Therefore, we have plotted in Fig. 2 the surface step between the oxides on the implanted and the unimplanted side, which gives a lower limit for the difference in the thicknesses of the grown layers. The sign of the step is taken positive if the unimplanted surface is higher than the implanted surface. The negative value immediately after implantation is believed to be real, because we know from many other experiments that for silicon targets and energies higher than 20 keV lattice expansion is more pronounced than sputtering. Between 16 and 36 min of oxidation the surface step is only slightly smaller than the oxide thickness on the unimplanted side. Visually the implanted surface appears metallic for oxidation times up to 114 min. Practically no oxide growth was observed on this side.

Figure 3 shows the dependence of the oxide thickness ratio implanted to unimplanted upon the fluence of N_2^+ ions. On the unimplanted side the oxide thickness is 74.1 nm. The implantations have a distinct effect at 4×10^{14} N_2^+ ions/cm^2, but even at the lower fluences we always found thickness ratios smaller than 1. The impeding influence of implanted nitrogen was also observed after wet oxidation. This can be seen from Table I, sample 13c. Because of the larger thicknesses, higher ion energies and higher doses are necessary.

Table I also shows the effect of carbon and oxygen. Since in both cases the effect is weak, it is noteworthy that fluctuations of thickness within one single layer are mostly smaller than 1.0 nm and the accuracy of the ellipsometric measurement itself is still higher. Carbon implantation impedes the oxidation. Although somewhat higher thickness differences have been achieved with thinner layers, sample 1 was chosen for the table, because N_{max} and the thickness on the unimplanted side allow comparison with sample 3 and 42. The effect of oxygen depends even qualitatively upon dose and oxidation conditions. When the peak concentration was high, we observed an enhancement of oxide growth at 1140°C in dry oxygen (samples 2c and 42 in Table I). In other experiments, we implanted twice, first with 45 kV, 1.5×10^{16} ions/cm^2, and second with 30 kV, 1.0×10^{16} ions/cm^2, so that in spite of the high total fluence the maximum concentration was moderate. There, we observed an impeded oxide growth at 1010°C in dry oxygen (samples 22 and 24). The infrared absorption of sample 22 was recorded immediately after implantation and the experiment was repeated with sample 23. If absorbing Si-O oscillators are formed by the implantations, their number is limited by the total fluence, which is 2.5×10^{16} cm^{-2}. The number of oxygen atoms per cm^2 of a thermally grown layer with the same thickness as indicated in Table I for sample 22 unimplanted is 3.3×10^{17}. Thus, only very small bands can be expected after implantation. The result is shown in Fig. 4. Absorption bands sufficiently high above the background occur in both samples at 968 cm^{-1} and 888 to 895 cm^{-1}. A possible interpretation is given at the end of the next section.

Discussion

The effect of nitrogen implantation on oxide growth is pronounced even at fairly low concentrations. Let us assume that within the first impacts all the N_2^+ ions are split into two parts of equal mass with half the initial energy each. Then, from LSS theory [see Ref. (4)] a projected range $R_p = 41.0$ nm, a standard deviation $\Delta R_p = 18.1$ nm, and a peak concentration $N_{max} = 1.8 \times 10^{21}$ nitrogen atoms per cm^3 result for 30 kV implantations of 4×10^{15} N_2^+ ions per cm^2. To form a continuous layer of Si_3N_4 a concentration of 4.8×10^{22}

Table I. Dependence of oxide thickness on experimental conditions

is necessary. Although the calculated N_{max} of our implantations is more than an order of magnitude lower, the oxide growth is strongly impeded as shown in the figures. For the interpretation of our results it is important, whether the distribution of the implanted nitrogen remains constant inside the silicon during oxidation. If it remains, the concentration at the oxide silicon interface can be calculated from the oxide thickness, because the implantation profile is known from theory and the thickness of the silicon layer consumed by the oxidation is determined by the condition that the oxide contains as many silicon atoms as were contained in the silicon layer. We have performed this calculation from the data of Fig. 3, and found that at low fluences the interface concentration increases with increasing fluence and suddenly approaches the constant value of 3.2×10^{20} nitrogen atoms per cm^3 for fluences above 2×10^{15} N_2^+ per cm^2. From investigations of the solid solubility of nitrogen in silicon (5) and in silicon dioxide (1) it seems likely that during the oxidation the implanted nitrogen precipitates as Si_3N_4, but the growing surface film is truly an oxinitride polymer and not a mixture of SiO_2 and Si_3N_4. Qualitatively the refractive index indicated in Fig. 1 is consistent with this assumption, since after Tombs *et al.* (6) it varies continuously in oxinitrides and increases up to 2.2 with increasing nitrogen content. However, the high values obtained by short oxidations are inconsistent with the calculated interface concentrations. Perhaps, the precipitation does not take place inside the silicon. Since, according to the assumed Gaussian profile, 84% of the implanted atoms are located within the small distance of $R_p + \Delta R_p = 59$ nm from the surface, and are embedded in a lattice damaged heavily by the implantation, most of the nitrogen may be pushed out during recrystallization, which is known to take place within some minutes at about 600°C or less depending upon ion species and fluence (7). At the same time, the surface begins to cover with oxide which, after Tombs *et al.* (6), can form a continuous series of solid solutions with silicon nitride. A film, which impedes the oxidation substantially, should have a high nitrogen content and a thickness of at least a few interatomic distances. The Si-N distance in Si_3N_4 is 1.4 to 1.75×10^{-8} cm. Assume that after recrystallization most of the implanted nitrogen is contained in a 5×10^{-8} cm surface layer. Then, the fluence necessary to form Si_3N_4 is 1.2×10^{15} N_2^+ ions per cm^2, and this is just the value at which the curve of Fig. 3 falls most rapidly. We have no direct evidence that the nitrogen is pushed to the surface during heating, but the strong influence of low doses on the oxide growth becomes more plausible by this assumption. The time dependence of thickness and surface step in Fig. 1 and 2 is not only determined by the growth rate but includes contraction or expansion of the implanted as well as the growing layer. These effects have not yet been studied in sufficient detail.

The enhancement of oxide growth by implantation of high doses of oxygen is not surprising, since not all the oxygen needed for oxidation has to diffuse through the oxide in this case, and production of SiO_2 by implantation and annealing in inert gas is known to be possible (2, 3). More difficult to understand is the observation that a relatively slight change of the oxidation conditions results in an impeded oxide growth on the implanted area. In this connection, it is interesting that the absorption spectrum shown in Fig. 4 does not exhibit the band at about 1030 cm^{-1}, which was observed in our work on SiO_2 produced by ion implantation (3). The small band at 968 is very close to that reported by Ritter (8) at 980 cm^{-1} for SiO. Ritter also reports an Si_2O_3 band at 870 cm^{-1}, but in contrast to our band at 884 to 895 cm^{-1}, it was accompanied by a stronger band at 1050 cm^{-1}. The possible frequencies of the Si-O bond cover almost the full range between 800 and 1100 cm^{-1} and depend upon the sequence of silicon and oxygen atoms as well as the type of linkage between these groups (8-10). The arrangement will not be well-defined immediately after implantation, particularly as long as the fluence does not suffice to surround every silicon atom by four oxygen atoms. Therefore, we assume that under the conditions of implantation used in this work the oxygen atoms do not assemble to form the well known SiO_4 tetrahedrons of SiO_2, but remain distributed in the damaged silicon and form a mixture of lower oxides. Normally oxygen dissolved in silicon is indicated by a band at 1090 cm^{-1}, and it is likely that the implanted material can be converted to this solution when the sample is heated for oxidation. Should the lower oxides be volatile, and should they evaporate in noticeable amounts before conversion, this could indeed have a negative influence on the growth rate of SiO_2 layers.

Acknowledgments

We are indebted to K. Eisele for his suggestions concerning the manuscript and to R. Junghanns, J. Schaub, and K. Fruh for their assistance in the experimental work.

Solid-State Ionics: Studies on the Solid Electrolytes in the System Ag_2X-AgI-HgI_2

Takehiko Takahashi,* Katsumi Kuwabara, and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

Compositions exhibiting high ionic conductivity in the solid state at ambient temperature were determined in the system Ag_2X-AgI-HgI_2 (X = S, Se, or Te) to be $Ag_{2.0}Hg_{0.25}S_{0.5}I_{1.5}$ (N-1), $Ag_{1.85}Hg_{0.40}Te_{0.65}I_{1.35}$ (N-2), $Ag_{1.80}Hg_{0.45}Se_{0.70}I_{1.30}$ (N-3), or $Ag_{2.0}Hg_{0.5}Se_{1.0}I_{1.0}$ (N-4). The electrical conductivities of these compounds were measured by means of the 1000 Hz a-c bridge and the values obtained at 25°C were 1.47×10^{-1}, 9.40×10^{-2}, 1.00×10^{-1}, and 4.30×10^{-2} $(ohm\text{-}cm)^{-1}$ for N-1, N-2, N-3, and N-4, respectively. The activation energies for conduction were calculated from the conductivity curves to be 2.95, 3.24, 3.34, and 3.58 kcal/mole for the above four compounds. In order to interpret the high ionic conductivities and the low activation energies for conduction of these compounds, the crystal structure was analyzed in detail by means of powder x-ray diffraction, and it was found that N-1 had the same structure as that of α-AgI. The cations in N-1 were statistically distributed over forty-two sites of 6(b), 12(d), and 24(h) of the space group Im3m and the anions were randomly distributed at the corner and the center of the cell. N-2, N-3, and N-4 had somewhat different structures from that of N-1. The cations in N-2, N-3, and N-4 were statistically distributed over thirty sites of 6(b) and 24(h), and the anions were distributed in the same manner as N-1. The proposed crystal structures of the four solids were verified by comparing the calculated values of the relative intensities of the x-ray diffraction lines with the experimental values. The distribution factors were defined and were discussed together with the activation energies for conduction.

Studies on solid electrolyte devices have been made from various viewpoints. One of the most typical examples is solid electrolyte galvanic cells (1-3), and the other devices such as memory elements with variable resistance (4, 5) and solid electrolyte coulometers (6, 7) have also been studied.

Solid electrolytes used in these fields are required to have high ionic conductivity at room temperature. As the solids satisfying such a requirement, β-Ag_3SI and $RbAg_4I_5$ have been recommended for example (8-10).

β-Ag_3SI has a silver ion conductivity of 1.0×10^{-2} $(ohm\text{-}cm)^{-1}$ at 25°C and its activation energy for conduction is very small (4.0 kcal/mole) (8). This material has a so-called average structure, in which three silver ions are distributed statistically over twelve sites in the {100} plane of the cube (11). $RbAg_4I_5$ has a silver ion conductivity of 2.1×10^{-1} $(ohm\text{-}cm)^{-1}$ at 25°C and its activation energy for conduction is 1.7 kcal/mole (10). This electrolyte has an average structure like that of β-Ag_3SI: sixteen silver ions are statistically distributed over seventy-two sites in its unit cell (12, 13).

It is most significant in the above-mentioned fields to find various solid electrolytes which exhibit high ionic conductivities at ambient temperature and to consider a relation between crystal structures and electrical conductivities and activation energies for conduction.

In recent years, several materials possessing high ionic conductivities were found in the systems Ag_2X-AgI-HgI_2 (X = S,Se,Te) in the authors' laboratory (14-17). It is the purpose of this paper to determine their compositions, to analyze their crystal structures, and to make clear the relations between the crystal structures and the electrical conductivities.

Experimental

Preparation of the samples.—The starting materials were obtained as follows: Ag_2S was precipitated by passing hydrogen sulfide gas through a solution of silver nitrate; Ag_2Se was prepared by means of heating the mixture of silver powder (99.9%) and selenium powder (99.99%) in vacuo at 400°C for 36 hr; Ag_2Te was prepared by means of heating the mixture of silver powder (99.9%) and tellurium powder (99.99%) at 420°C for 24 hr in an evacuated sealed glass tube; AgI was precipitated by the addition of KI(aq) into $AgNO_3$(aq); HgI_2 was the powder of the guaranteed grade reagent.

In the Ag_2S-AgI-HgI_2 system, Ag_2S, AgI, and HgI_2 were precisely weighed, fully mixed, vacuum-sealed in a Pyrex glass tube, and heated in an electric furnace. Various conditions were examined beforehand and the reaction temperature and time were fixed at 400°C and 20 hr. As the reaction products had a tendency to be decomposed by moisture and light, they were kept in a dark desiccator.

The systems Ag_2Te-AgI-HgI_2, Ag_2Se-AgI-HgI_2, and Ag_2Se-HgI_2 were treated like the above system; the

* Electrochemical Society Active Member.

Key words: solid electrolyte, ionic conductivity, silver ion conductor.

reaction temperatures and times chosen were 300°C for 40 hr, 300°C for 20 hr, and 200°C for 48 hr, respectively.

Conductivity measurement.—The electrode was made of a mixture of the silver powder and the sample in order to reduce the contact resistance at the electrode-electrolyte interface (18). The composition was selected to obtain a high performance. A silver plate was used as an electronic collector of silver electrode. Samples were pressed by 4 tons/cm^2 pressure to form pellets 13 mm diameter and about 2 mm thick. A set of the pellet, the mixed electrode, and the collector was compressed by a stainless-steel frame with spring. This set was put in an electric furnace, the temperature of which was regulated within ±0.5°C by a thermistor-type automatic controller between 20° and 100°C.

The electrical conductivities were measured by the use of an a-c bridge using an oscilloscope as a zero-indicator. The frequency was fixed to 1000 Hz.

Measurement of transport number.—Transport numbers of ionic conductivity solids are measured by the methods proposed by Tubandt (19), Wagner (20), and Mitoff (21). In this paper, the Mitoff emf method was employed in which the theoretical emf was calculated from the free enthalpy change of the reaction $Ag(s) + \frac{1}{2} I_2(g) = AgI(s)$ (22). As shown in the previous work (23), the mercury ion conduction was not found.

X-ray diffraction.—A copper anode tube was operated at 15 mA and 35 kV. The goniometer scan speed was selected to 1°/min or ¼°/min. Powdered silicon was used as an inner standard material to correct diffraction angles. The observed diffraction intensities discussed later are the mean values of the diffraction lines obtained from a large number of samples.

Density measurement.—Density was measured to calculate the number of molecules contained in a unit cell. Toluene was used as a solvent since the samples had a tendency to be decomposed by a common alcoholic solvent such as n-butanol. The measurements were made using 5.00 cm^3 picnometer at 25°C.

Results and Discussion

Ag_2S-AgI-HgI_2 System

Total conductivity.—It was found in this system that a mixture of 33.3 m/o (mole per cent) Ag_2S, 44.4 m/o AgI, and 22.3 m/o HgI_2 showed a comparatively high conductivity (15, 24). The isoconductivity curves were drawn in the three component diagram, and it was recognized that a hill was formed near the composition of 30 m/o Ag_2S, 55 m/o AgI, and 15 m/o HgI_2. It was suggested that there was a new compound with a composition of about $(Ag_2S)_{0.30}(AgI)_{0.55}(HgI_2)_{0.15}$ in the Ag_2S-AgI-HgI_2 system.

X-ray diffraction and determination of composition.—X-ray diffraction patterns of the high conductivity sample showed simple lines corresponding to a body-centered cubic lattice. The composition range with the single phase of body-centered cubic structure was as follows; (number of sulfur atom)/(number of iodine atom) = 0.33-0.42 and (number of mercury atom)/(number of silver atom) = 0.12-0.19. In these ranges, the ratio of the number of the component atoms was determined on the basis of the total number of anions in a unit cell being integral as described in the latter section. This ratio was Ag:Hg:S:I = 8:1:2:6. The mole composition of Ag_2S:AgI:HgI_2 was calculated from the atomic ratio to be 28.6:57.1:14.3. This compound is designated N-1.

Ionic conductivity.—The Arrhenius plot of the total conductivity of N-1 is shown in Fig. 1. The value at 25°C is 1.47×10^{-1} (ohm-cm)$^{-1}$; this is higher than that of β-Ag_3SI by one order of magnitude and is comparable to that of $RbAg_4I_5$. The conductivity curve has a good linearity, and the activation energy for conduction is calculated from the slope to be 2.95 kcal/mole which is smaller than that of β-Ag_3SI. The open-circuit voltage of the galvanic cell Ag|sample (N-1)|I_2 was 680 mV at 25°C which was nearly equal to the theoretical value of 687 mV for Ag|AgI|I_2. It might be said from this that the contribution of electron to the total conductivity was very poor.

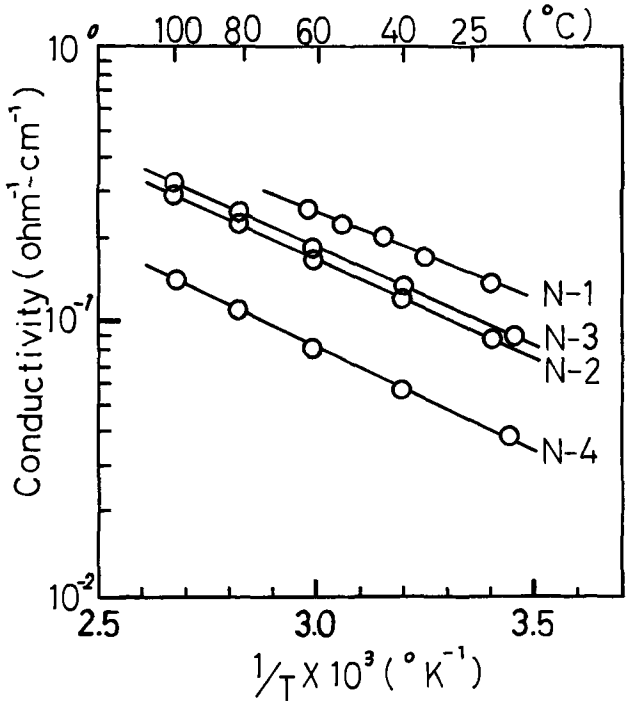

Fig. 1. Conductivity curves of the four compounds. N-1: $Ag_{2.0}Hg_{0.25}S_{0.5}I_{1.5}$. N-2: $Ag_{1.85}Hg_{0.40}Te_{0.65}I_{1.35}$. N-3: $Ag_{1.80}Hg_{0.45}Se_{0.70}I_{1.30}$. N-4: $Ag_{2.0}Hg_{0.5}Se_{1.0}I_{1.0}$.

Unit cell.—It was found from x-ray diffraction that the sample N-1 had a body-centered cubic lattice and that the lattice constant was 4.969Å. The interplanar spacings of N-1 were calculated by the use of the lattice constant. They are given together with the observed intensities in Table I. The observed density of N-1 was 6.5 and the x-ray density was 6.70.

The number of molecules in the unit cell was evaluated using the lattice constant and the density. With respect to N-1, one unit of $Ag_2Hg_{0.25}S_{0.5}I_{1.5}$ was contained in a unit cell. It should be noticed that the sum of the numbers of the anion is 2.00 and that of the cation is 2.25. It is a well-known fact that some compounds, such as silver chalcogenides, are nonstoichiometric and have electronic conductivity. The compound N-1 is, however, not nonstoichiometric and has high ionic conductivity. These facts might not be easily accepted by strict crystallographic theory but would be understood through the following information.

Rahlfs examined the distribution of x-ray intensity for α-Ag_2S and concluded that silver ions construct an average structure like α-AgI (25). This was confirmed by Boettcher *et al.* (26). According to them, α-Ag_2S

* S, strong; VS, very strong; MS, medium strong; W, weak; VW, very weak.

has a unit cell which contains two molecules; two anions occupy the sites of body-centered cubic lattice and four silver ions are statistically distributed over forty-two sites. On the other hand, Reuter and Hardel studied the structure of α-Ag_3SI and reported as follows (11): one sulfur and one iodine are statistically distributed at the corner and the center of the elemental cell, whereas three silver ions are also randomly arranged over forty-two sites. Their conclusion was that the structure of α-Ag_3SI was a disordered mix-phase of α-AgI and α-Ag_2S.

These average structures are generally characterized by the fact that the ions in a crystal can occupy many more lattice sites than their numbers and that they are statistically distributed over those sites. From this viewpoint, it might be proposed that the number of cations in a unit cell is not necessarily an integer.

As mentioned above, the sample N-1 has high ionic conductivity and low activation energy for conduction and the crystal system is body-centered cubic. It was suggested from these experimental results that the crystal structure of the sample N-1 was an average one.

Location of ions.—The space group Im3m was chosen among ten groups which were in a cubic system in the translation group I. Location of ions was assumed to be analogous to α-AgI; cations in the sample N-1 are statistically distributed over the sets of 6(b), 12(d), and 24(h) of the space group, as shown in Fig. 6, whereas sulfur and iodine ions are also randomly distributed at the corner and the center of the cube.

The intensities of the diffraction lines were calculated by the usual formula

$$I = A \cdot \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cdot \cos \theta} \cdot P \cdot F^2 \qquad [1]$$

where the fractional term contains Lorentz, polarization, and geometrical factors, P is the multiplicity term, and A is an absorption term which has been assumed to be proportional to θ (27). The structure factor term F includes arbitrary isotropic temperature factors. The temperature factor was neglected for α-AgI by Strock (28) and for α-Ag_2S by Rahlfs (25), but it was computed for α-AgI using the Debye factor $B = 8.0$ by Hoshino (29). Recently, the structure of MAg_4I_5 was analyzed by Bradley *et al.* (9); according to them, Debye factors for the anion and the cation were chosen to be 2.5 and 5.0, respectively. Referring to these data, the average Debye factor B was chosen to be 3.0 for the anions and 5.0 for the cations in the present calculation.

The calculated and the observed intensities are given for each diffraction line of N-1 in Fig. 2, which shows good agreement. The degree of agreement between the calculated and the observed intensities is quantitatively judged from the discrepancy factor

$$R = \frac{\Sigma||F_o| - |F_c||}{\Sigma|F_o|} \qquad [2]$$

where F_o and F_c are the observed and the calculated structure factors, respectively.

The factor obtained is listed in Table II. It might be said on the basis of the small value that the agreement is good and that the previous assumption with respect to the average structure is reasonable.

In the third column of the table, the distribution factor of cations is defined as a ratio of the real number of cations in a unit cell to the number of the available cation sites in the same cell (for example, in the sample N-1 the former is 2.25 and the latter is 42, so the ratio is equal to $2.25/42 = 0.054$). It might be said that the number of vacant sites of cations increases with the decrease of the distribution factor of cations and that the disturbance effect of divalent anions on the migration of cations increases with the increase of the number of divalent anions in a unit cell.

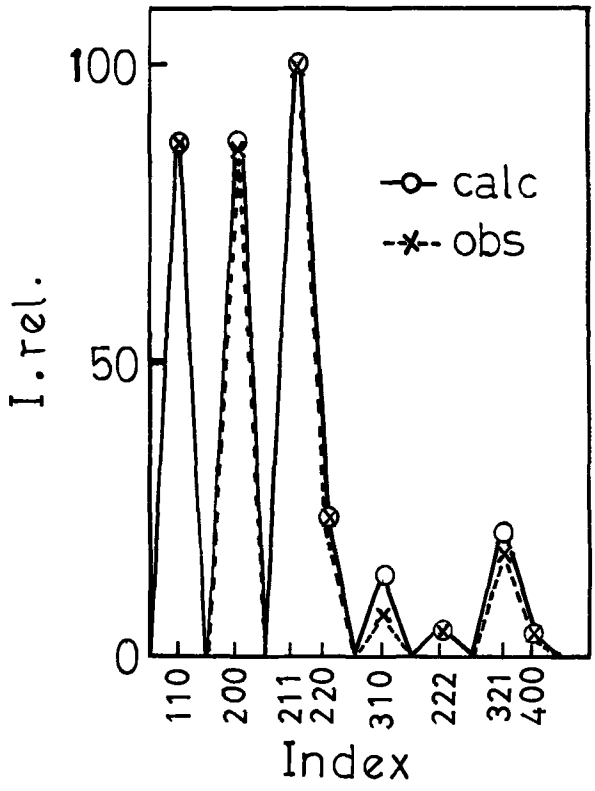

Fig. 2. Comparison of the calculated and the observed relative diffraction intensities of $Ag_{2.0}Hg_{0.25}S_{0.5}I_{1.5}$.

These tendencies correspond to the magnitude of the activation energy for conduction. For example, the activation energy for silver ion in AgBr (140°-250°C) is 16 kcal/mole which is larger than that of N-1 (30). The distribution factor of silver ion in AgBr is 1.0 which is also markedly larger than that of N-1. AgBr has a face-centered cubic lattice with rock-salt type. It has been interpreted that the activation energy for conduction in such a solid is equal to the sum of the energy for the production of the Frenkel defect and the energy for their migration. In contrast to AgBr, the compound N-1 has many structural defects. It can therefore be presumed from these data that N-1 has a negligibly small energy for the production of cation vacancies and that the activation energy for conduction consists of the energy for cation migration predominantly.

Ag_2Te-AgI-HgI_2 System

Total conductivity.—The electrical conductivities were measured with 5-10 m/o intervals and the isoconductivity curves were drawn in the three component diagram in a manner similar to the Ag_2S-AgI-HgI_2 system. It was observed that the curves made a hill near the composition of 40 m/o Ag_2Te, 35 m/o AgI, and 25 m/o HgI_2.

X-ray diffraction.—X-ray diffraction of the samples in the vicinity of $(Ag_2Te)_{0.40}(AgI)_{0.35}(HgI_2)_{0.25}$ showed a simple phase pattern which consisted of the lines corresponding to a body-centered cubic lattice. As in the case of the Ag_2S-AgI-HgI_2 system, the composition range with the body-centered cubic lattice in the

Table II. Discrepancy factors and distribution factors of cation in several compounds

Compound	Discrepancy factor	Distribution factor of cations
N-1	0.0706	0.054
N-2	0.0522	0.075
N-3	0.0692	0.075
N-4	0.0681	0.083

reaction products was examined and the ratio of the number of the component atoms in the above-stated sample was determined strictly and the mole composition of Ag_2Te:AgI:HgI_2 was evaluated from the atomic ratio to be 40.6:34.4:25.0. This compound is named N-2.

Ionic conductivity.—The total conductivity curve of N-2 is shown in Fig. 1. The value is 9.40×10^{-2} (ohm-cm)$^{-1}$ at 25°C. The conductivity curve has a good linearity and the activation energy for conduction is calculated from the slope to be 3.24 kcal/mole. The open-circuit voltage of the galvanic cell with N-2 as the electrolyte was 675 mV which suggested that N-2 had an ionic transport number of about unity.

Unit cell.—The compound N-2 had a body-centered cubic structure and the lattice constant was 5.081Å. Table III shows the interplanar spacings of N-2 together with the observed intensities. The observed and the x-ray densities were 6.6 and 6.76, respectively. The number of molecules in the unit cell was calculated by the use of the lattice constant and the density to be one unit of $Ag_{1.85}Hg_{0.40}Te_{0.65}I_{1.35}$. As in the compound N-1, the sum of the number of anions was 2.00 and that of the cations was 2.25.

Location of ions.—The space group Im3m was selected from the translation group I. A primarily assumed structure which was identical with that of α-AgI failed in agreement between the calculated and the observed intensities. It is therefore supposed that cations in the compound N-2 are statistically distributed in the sets of 6(b) and 24(h) of the space group as shown in Fig. 6 and that anions are distributed at the corner and the center of the cubic lattice. The calculated results are shown together with the observed intensities in Fig. 3, where good consistency is recognized between them. The discrepancy factor obtained by means of Eq. [2] is shown in Table II. The small value indicates that the above-mentioned assumption relating to the average structure is appropriate. The distribution factor of the cation is also given in Table II. It is larger than that of N-1 and corresponds to the relation in the activation energy.

Ag_2Se-AgI-HgI_2 System

Ionic conductivity.—The mole composition of Ag_2Se:AgI:HgI_2 in the highest conductivity compound was determined by the method used in the cases of N-1 and N-2. This single-phase compound, $(Ag_2Se)_{0.452}(AgI)_{0.258}(HgI_2)_{0.290}$ is designated N-3.

The total conductivity curve of N-3 is shown in Fig. 1 indicating a good linearity. The conductivity is 1.00×10^{-1} (ohm-cm)$^{-1}$ at 25°C and the activation energy is calculated to be 3.34 kcal/mole. The emf of the cell Ag|sample (N-3)|I_2 was 677 mV at 25°C which indicated that the ionic transport number was nearly equal to unity.

Unit cell.—The lattice constant of N-3 was 4.995Å. The calculated interplanar spacings are given in Table IV together with the observed intensities. The observed and the x-ray densities were 6.5 and 6.72, respectively. It was found by calculation of the number of molecules that one unit of $Ag_{1.80}Hg_{0.45}Se_{0.70}I_{1.30}$ was included in a unit cell.

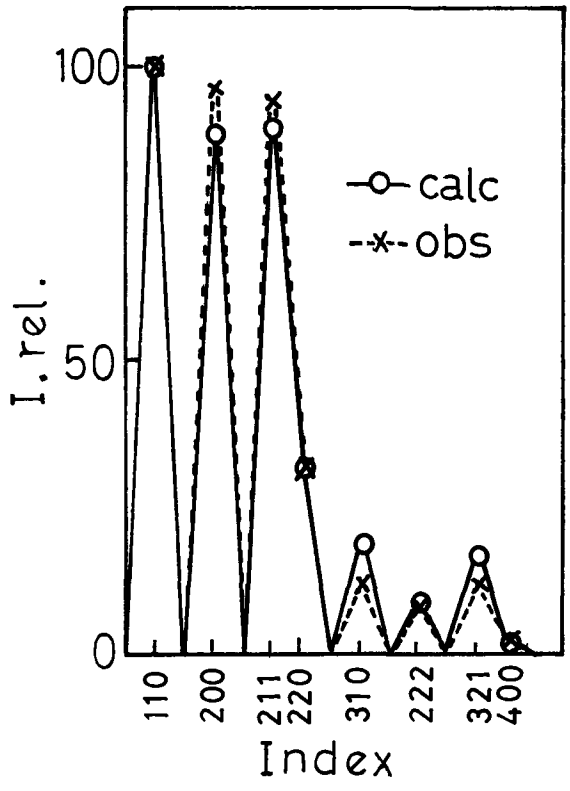

Fig. 3. Comparison of the calculated and the observed relative diffraction intensities of $Ag_{1.85}Hg_{0.40}Te_{0.65}I_{1.35}$.

Location of ions.—When the cations in N-3 are assumed to be statistically distributed as in α-AgI, the discrepancy factor is large which contradicts the above assumption.

In order to minimize the discrepancy factor, a second assumption was made as follows; cations and anions in N-3 were also randomly distributed in the same sites as N-2. The observed and the calculated intensities of the diffraction lines are shown in Fig. 4; they are consistent with each other. The discrepancy factor of 0.0692 given in Table II suggests that the proposed average structure is reasonable. The distribution factor of N-3 is shown in Table II; the factor of the cation is equal to that of N-2.

Ag_2Se-HgI_2 System

Ionic conductivity.—It was found by means of conductivity measurements and x-ray diffraction that another compound in the Ag_2Se-AgI-HgI_2 system was obtained. The single-phase compound was $(Ag_2Se)_{0.667}(HgI_2)_{0.333}$ which was named N-4. The total conductivity curve of N-4 is shown in Fig. 1. The activation energy for conduction is 3.58 kcal/mole and the emf of the cell Ag|sample (N-4)|I_2 was 675 mV at 25°C, comparable to the theoretical value of 687 mV for Ag|AgI|I_2.

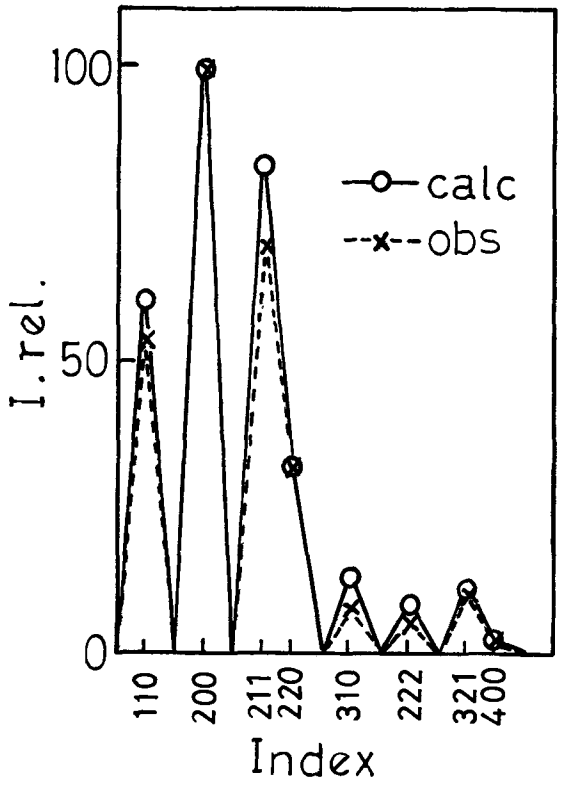

Fig. 5. Comparison of the calculated and the observed relative diffraction intensities of $Ag_{2.0}Hg_{0.5}Se_{1.0}I_{1.0}$.

Unit cell.—The compound N-4 had a body-centered cubic structure whose lattice constant was 5.000Å. Table V shows the interplanar spacings of N-4 together with the observed intensities. The observed and x-ray densities were 6.8 and 7.07, respectively. It was found that one unit of $Ag_{2.0}Hg_{0.5}Se_{1.0}I_{1.0}$ was contained in a unit cell.

Location of ions.—It was supposed that the cations of N-4 were statistically distributed over the sets of 6(b) and 24(h) of the space group Im3m and the anions were distributed at the corner and the center of the cube. The calculated intensities are shown together with the observed intensities in Table II. The small value of 0.0681 suggests that the supposed average structure is reasonable. The observed and calculated intensities of the diffraction intensities are shown in Fig. 5. The distribution factor of N-4 is given in Table II; it is the largest of four compounds.

Conclusion

The compounds described in this paper have high ionic conductivities at room temperature and have the average structures belonging to the space group Im3m. A typical compound which belongs to the space group Im3m and has the average structure is the high temperature phase of silver iodide, that is α-AgI. From various data the above-mentioned compounds have been seen to have modified structures of α-AgI. That is to say, these compounds have structures in which a part of the silver sites of α-AgI is substituted by mercuric ion and a part of the iodine sites of α-AgI is substituted by chalcogen ions.

The ionic radii and the electrical charges of the component elements have to be considered in these substitutions. Mercuric ion has nearly an equal size to the silver ion and both selenium and tellurium ions have approximately the same sizes as that of iodine, but the radius of the sulfur ion is considerably smaller than that of the iodine ion. N-2, N-3, and N-4 have, however, thirty sites with (b) and (h) of Im3m for cation distribution and only N-1 has a structure identical with that of α-AgI which contains forty-two cation sites with (b), (d), and (h).

When the lattice constant of the body-centered cube shown in Fig. 6 is a_o, the distances of (b), (d), and (h) from anion sites are 1/2a, $2\sqrt{5}/8a$, and $3\sqrt{2}/8a_o$, re-

Table VI. Interionic distances

Compound	Anion-Anion	Anion-Cation
$Ag_{2.0}Hg_{0.25}S_{0.5}I_{1.5}$	4.31	2.48-2.78
$Ag_{1.85}Hg_{0.40}Te_{0.65}I_{1.35}$	4.40	2.54-2.69
$Ag_{1.80}Hg_{0.45}Se_{0.70}I_{1.30}$	4.32	2.50-2.65
$Ag_{2.0}Hg_{0.5}Se_{1.0}I_{1.0}$	4.33	2.50-2.65
α-AgI	4.37	2.52-2.86
α-Ag_2S	4.23	2.44-2.74
α-Ag_2Se	4.33	2.50-2.79
α-Ag_2Te	4.38	2.52-2.82
β-Ag_6SI	4.24	2.51 (Ag-S) 3.11 (Ag-I)
$RbAg_4I_5$	4.56	2.83-2.88 (Ag-I) 3.63 (Rb-I)

spectively. The (d) site is farthest from the anion site and its appearance will be influenced by the size and the charge effect of the anion.

Table VI shows the interionic distances of these compounds together with those of other compounds possessing average structures. The distances of the anion-anion in these compounds correspond to the sum of Pauling's ionic radii, while those of the anion-cation are larger than the sum of their ionic radii. The latter indicates the partial covalency of the compounds. On the other hand, a simple correlation is found between the activation energy for conduction and the distribution factors of the cations and the number of divalent anions. From these facts, the compounds investigated in this paper are verified to have a modified crystal structure of α-AgI, which gives an important index to the study on solid electrolyte.

Manuscript submitted April 25, 1973; revised manuscript received July 2, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Lithium Anode Cells Operating at Room Temperature in Inorganic Electrolytic Solutions

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

ABSTRACT

Lithium anode electrochemical cells have been operated at room temperature using electrolytic solutions of lithium salts in inorganic solvents such as phosphorus oxychloride, thionyl chloride, and sulfuryl chloride. Lithium metal can be electrodeposited from these solutions accompanied, in the case of chlorine-containing electrolytes, by the simultaneous electrogeneration of chlorine at the positive electrode. The resulting lithium/chlorine electrochemical cells have open-circuit potentials of 4.0-4.3V, depending on the presence of excess Lewis acid in the electrolyte. The solvents are compatible with both lithium metal and with strong oxidants including chlorine (Cl_2), cupric fluoride (CuF_2), polycarbon monofluoride $(CF)_n$, and tungsten trioxide (WO_3) which can be used as cathode materials. The solvents themselves, while difficult to oxidize, can be electrochemically reduced at various catalytic surfaces (such as carbon black and metals) and act as cathode depolarizers. This catalytic solvent reduction process leads to cells with exceptionally stable voltages and energy densities in excess of 500 W-hr/kg.

We describe in this study a family of inorganic solvents with which room temperature lithium anode cells are made. The solvents, liquid oxyhalides of phosphorus and sulfur, are thermodynamically stable relative to their constituent elements, differing in this respect from organic solvents. Some of our solvents resemble fused salts in their stability to chlorine and other strong oxidants, the use of which (as depolarizers) becomes possible. Because of this stability toward oxidation, the solvents do not irreversibly decompose when the cells are charged at substantial overpotentials. Although lithium metal is stable in these electrolytic solutions, the solvents can be electrochemically reduced at catalytic surfaces and act as cathode depolarizers.

Experimental

Materials.—Phosphorus oxychloride ($POCl_3$) was purchased from Baker and Adamson. Commercial phosphorus oxychloride is purified by stirring over lithium metal in a dry nitrogen or argon atmosphere for 24 hr followed by distillation of purified phosphorus oxychloride from this mixture. The distillate contains <1 ppm moisture. Sulfuryl chloride (SO_2Cl_2) and thionyl chloride ($SOCl_2$) were purchased from Research Organic/Inorganic Chemical Corporation and purified by the same procedure. Lithium hexafluorophosphate ($LiPF_6$), lithium tetrafluoroborate ($LiBF_4$), fluorographite-A $[(CF)_n]$, and fluorographite-B $[(C_4F)_n]$ were purchased from Ozark-Mahoning Company; and aluminum chloride ($AlCl_3$), from Rocky Mountain Research, Inc. Other anhydrous materials used in these studies were purchased from their manufacturers and used without further purification. Southwestern Graphite Company Grade 1651 Microcrystalline Graphite and Ashland Chemicals Company XC-6310-4 Carbon Black were used as conductive additives to cathode materials not having sufficient electronic conductivity of their own. Shawinigan 100% Compressed Acetylene Black was used in catalytic cathodes containing carbon alone. Teflon 7C molding powder and Teflon 42 emulsion used as cathode binders were obtained from du Pont.

Electrolytic solutions.—The electrolytic solutions were prepared either *in situ* by adding lithium halide to stoichiometric quantities of $AlCl_3$, $SbCl_5$, $TiCl_4$, $ZrCl_4$, SO_3, $AlBr_3$, BCl_3, and BF_3 to make $LiAlCl_4$, $LiSbCl_6$, Li_2TiCl_6, Li_2ZrCl_6, $LiSO_3Cl$, $LiAlBr_4$, $LiBCl_4$, and $LiBF_4$, respectively, or by dissolving anhydrous salts such as $LiPF_6$ or $LiAsF_6$ in the purified solvents. All operations were conducted inside a fiberglass glove box flushed with argon.

Cell construction.—Cathodes were constructed by pressing a blend of active material (typically 80-90%) with a conducting additive (usually carbon or graphite) and binder (Teflon or polyethylene) onto an expanded copper or nickel screen in a heated square die 3.75 cm on each side at 2000 psig for 3 min. These cathodes were then heat sealed in a nonwoven polypropylene envelope and dried in a vacuum oven before being transferred to the argon glove box for assembly into a cell. The anodes were prepared in the argon glove box by pressing expanded nickel screen onto lithium foil, purchased from Foote Mineral Company. The anodes were folded to envelop the cathode on both sides. Later, carbon cathodes were prepared in a 4 × 8 cm configuration, enveloped with glass mat separator and lithium foil and folded in half. The electrodes were placed in polyethylene or Teflon rectangular jars of various sizes to contain from 8 to 25 ml of electrolyte. Open-circuit voltages and discharge characteristics were obtained with the cells in the argon glove box since they were not sealed but only covered with a tight fitting cap.

Results

Anodes: stability of lithium to phosphorus and sulfur oxyhalides.—Lithium metal appears visibly stable to attack by phosphorus oxychloride at 25°C. $POCl_3$ forms a brown layer on the surface of the metal upon boiling for several hours. Lithium is more stable to attack by thionyl chloride and sulfuryl chloride. The metal does not form an observable coating upon boiling for two weeks in either of these solvents.

Passage of current through phosphorus oxychloride solutions of $LiBCl_4$, $LiAlCl_4$, or Li_2ZrCl_6 results in simultaneous electrodeposition of metallic lithium and electrogeneration of chlorine at carbon, nickel, or platinum electrodes. The resulting Li/Cl_2 electrochemical cells have open-circuit potentials from 4.0 to 4.3V at 25°C, being higher when an aprotic Lewis acid (BCl_3, $AlCl_3$, or $ZrCl_4$) is present in excess. Prior to this observation Li/Cl_2 cells required the use of fused salt electrolytes.

[e] Reference (6).

Lithium is also electrodeposited upon passage of current through solutions of lithium salts in any of the other phosphorus and sulfur oxyhalides. The character of the deposits, although not dendritic, is soft and spongy.

Physical properties of the solvents.—The inorganic oxychlorides considered in this study are colorless liquids, some physical properties of which are listed in Table I. Phosphorus oxychloride, thionyl chloride, and sulfuryl chloride are miscible in all proportions. Phosphorus oxychloride is the stronger Lewis base and is a better solvent for many electrolytes. The melting point of this solvent (1.25°C) is higher than desired for many battery applications. A 1:1 mixture of phosphorus oxychloride and thionyl chloride, however, remains liquid to −40°C.

Electrolytes: solubilities and conductivities of solutions of lithium salts in phosphorus and sulfur oxyhalides.—Adequate solubilities of lithium salts in the covalent oxyhalides are reached only in salts with large anions. The solubility of LiCl in $POCl_3$ is only 0.005 g/liter (1). We find that the conductivity of the saturated LiCl solution is 2.4×10^{-6} ohm^{-1} cm^{-1} at 25°C. Lewis acids are usually soluble in covalent oxyhalides. Seidell (7) and Gutmann (2) list about 30 Lewis acids which dissolve at high (>1M) concentrations. In spite of these solubilities, the acid solutions are poor ionic conductors in sharp contrast with protic acids. We find that the conductivities of the Lewis acid solutions are in the 10^{-5} to 10^{-4} ohm^{-1} cm^{-1} range. (For example, the conductivity at 25°C of a 0.3M solution of $ZrCl_4$ in $POCl_3$ is 2.41×10^{-5} ohm^{-1} cm^{-1} and that of a 2M $AlCl_3$ solution in $SOCl_2$ is 1.74×10^{-4} ohm^{-1} cm^{-1}). While LiCl, a base in the solvent systems under consideration, is relatively insoluble in the pure solvents, it does dissolve in the acid solutions (Eq. [1] and [2])

$$POCl_3 + AlCl_3 \rightleftarrows POCl_3{:}AlCl_3 \rightleftarrows POCl_2^+ + AlCl_4^- \quad [1]$$

$$POCl_2^+ + LiCl \rightleftarrows Li^+ + POCl_3 \quad [2]$$

and the resulting neutral solutions are conductive. The concentration and conductivities of some of these solutions are shown in Table II. $LiBCl_4$ and $LiAlCl_4$ yield the most conductive solutions in $POCl_3$. $LiBF_4$, although more soluble in $POCl_3$ than either $LiBCl_4$ or $LiAlCl_4$, seems to be less dissociated. The most conductive inorganic oxyhalide systems are obtained with $LiAlCl_4$ solutions in $SOCl_2$ where the conductivity reaches 2.04×10^{-2} ohm^{-1} cm^{-1} at 1.73M. The conductivities of $LiAlCl_4$ solutions in $SOCl_2$ are shown as a function of electrolyte concentration in Fig. 1.

Some of the electrolytes which dissolve in $POCl_3$ are practically insoluble in $SOCl_2$. $LiBF_4$ and $LiPF_6$ are not satisfactory electrolytes in $SOCl_2$. BCl_3 solutions in $SOCl_2$ do not dissolve LiCl, showing that the equilibria analogous to Eq. [1] and/or [2] are displaced to the left. A 1.2M solution of $LiBCl_4$ can be prepared in 1:1 volume mixture of $POCl_3$ and $SOCl_2$, and the conductivity of the solution is only slightly below that of $LiBCl_4$ in $POCl_3$ itself.

Table II. Conductivities of solutions of lithium salts in phosphorus and sulfur oxyhalides at 25°C

Solvent	Electrolyte	Concentration (M)	Conductivity $\times 10^3$, ohm^{-1} cm^{-1}
$POCl_3$	$LiPF_6$	0.4	3.7
$POCl_3$	$LiAsF_6$	0.7	5.8
$POCl_3$	$LiAlCl_4$	0.9	7.8
$POCl_3$	$LiSbCl_6$	1.0	2.2
$POCl_3$	Li_2TiCl_6	1.0	5.7
$POCl_3$	Li_2SnCl_6	1.0	6.1
$POCl_3$	$LiSO_3Cl$	1.0	2.8
$POCl_3$	$LiAlBr_4$	1.0	6.3
$POCl_3$	$LiBCl_4$	1.2	8.7
$POCl_3$	$LiBF_4$	1.5	1.1
$SOCl_2$	$LiAlCl_4$	1.0	14.6
$SOCl_2$	$LiAlCl_4$	2.0	20.4
$SOCl_2$	$LiSbCl_6$	1.0	12.5
SO_2Cl_2	$LiAlCl_4$	1.0	7.4
$POCl_3$:$SOCl_2$ (1:1)	$LiBCl_4$	1.2	6.0

Cathodes and depolarizers.—A group of halogen/platinum, halogen/graphite, 38 nonmetallic solids. Sixteen metallic systems, and carbon were investigated. The nonmetallic solids included sulfur, selenium, metal oxides, metal sulfides, metal halides, and carbon fluorides. The insulators in the group were studied in mixtures with a conductive additive, usually carbon. The metals included mercury, titanium, platinum, palladium, nickel, cobalt, iron, 304 stainless steel, molyb-

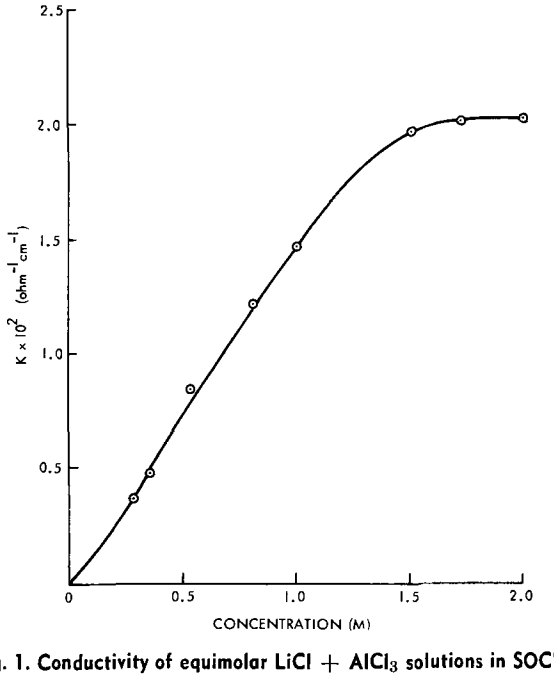

Fig. 1. Conductivity of equimolar LiCl + $AlCl_3$ solutions in $SOCl_2$

denum, tungsten, lead, niobium, tantalum, manganese, silver, and gold. Graphite and carbon black cathodes were also investigated.

Chlorine dissolves in phosphorus oxychloride to form a 10% solution (by weight) at 25°C and atmospheric pressure. Bromine is miscible with phosphorus oxychloride (at 25°C) in all proportions. The solubility of iodine was not determined but was found to exceed 10% (by weight).

Relatively few of the nonmetallic solids screened were stable to and insoluble in phosphorus oxychloride for the 60 day period of our tests, which were conducted at ambient temperature. Rapid reaction with the solvent followed by partial or complete dissolution was observed in SbF_3, BiF_3, CrO_3, V_2O_3, V_2O_5, and MnO_2. Pb_3O_4, PbO_2, Ni_2O_3, NiO_2, CuO, and CoF_3 reacted slowly and dissolved. NiF_2 and $PbCl_2$ reacted with the solvent. Chloranil and fluoranil dissolved. Nb_2O_5, AgI, CuCl, MoO_3, Bi_2O_3, HgO, $NiCl_2$, $CuCl_2$, CuF_2, and Ag_2S showed evidence of possible reaction or slight solubility. There was no conclusive evidence for instability or solubility of CuS, NiS, Ag_2O, AgBr, polycarbon monofluoride $(CF)_n$, or polytetracarbon monofluoride $(C_4F)_n$. HgS, $HgCl_2$, Hg_2Cl_2, S, and WO_3 were stable to attack and insoluble in phosphorus oxychloride.

Cell characteristics.—Li/Cl_2 cells.—The characteristics of the Li/Cl_2 system were investigated in a series of cells of varying configurations, having platinum, nickel, or carbon electrodes. Some of these utilized chlorine dissolved in the electrolytic solutions, while others operated like fuel cells using externally supplied chlorine.

The Li/$POCl_3$:$LiBCl_4$/Cl_2 cell appears to be reversible, as indicated by the electrodeposition of lithium and the electrogeneration of chlorine on platinum electrodes at potentials exceeding only slightly the open-circuit potential. The observed emf of the cell and the emf estimated from thermodynamic data are similar. In a typical experiment, a cell with platinum electrodes (1 cm^2 each, separated by 0.64 cm), filled with 1.8M $LiBCl_4$ (having an internal resistance of 84 ohms) was repeatedly charged and discharged. A 10 mA/cm^2 charging rate required a 5.35V external potential. Upon termination of the charging process the open-circuit potential of the unstirred cell was 4.30V, dropping to 4.186V in 5 min and remaining steady. The drop in potential could be associated with chlorine concentration differences, the chlorine forming a supersaturated solution on the cathode immediately following charging. The 4.186V potential could be reproduced in $LiAlCl_4$-saturated $POCl_3$ solution upon replacement of the electrogenerated solution in the cathode compartment by a chlorine-saturated solution.

Discharge of the Li/Cl_2 cells through varying external resistances shows a linear relationship between the cell polarization and the current density. This polarization is due predominantly to electrolyte (and separator) resistance. Similar results were obtained with a lithium foil and chlorine gas supplied through a cylindrical porous graphite cathode. Lithium/chlorine cells were also made with the other electrolytic solutions listed in Table II.

Li/Br_2 cells.—Cells similar to the Li/Cl_2 cells were made with bromides and bromine. Thus by charging a $LiAlBr_4$ solution in $POCl_3$, a Li/$LiAlBr_4$:$POCl_3$/Br_2 cell was made. At 25°C the open-circuit potential of the cell, which appears to be reversible, is 3.73V.

Cells with metallic cathodes.—The open-circuit potentials of Li/$POCl_3$:$LiAlCl_4$/Me cells with saturated $LiAlCl_4$ solutions at 25°C range from 2.05 to 2.92V. The values are: Pb, 2.05V; Ta, 2.30V; Ti, 2.50V; W, 2.50V; Nb, 2.60V; Pd, 2.70V; Ag, 2.70V; Fe, 2.70V; Mn, 2.70V; Mo, 2.75V; Co, 2.75V; 304 stainless steel, 2.80V; Ni, 2.80V; Pt, 2.90V; Hg, 2.90V; and Au, 2.92V. Current densities at 50% polarization based on geometric areas range from 0.053 mA/cm^2 (Ti) to 0.357 mA/cm^2 (Au). The current density for Hg is 0.175 mA/cm^2 at 50% polarization.

Lithium cells with solid nonmetallic cathodes.—The open-circuit potentials of the Li/CuF_2 cells in phosphorus oxychloride ranged from 3.7 to 4.0V, depending on the electrolyte. The potential was 4.0V with $LiPF_6$, 3.78V with $LiBF_4$, 3.63V with $LiBCl_4$, and 3.66V with $LiAlCl_4$. The discharge curves of these four cells are shown in Fig. 2. Current densities at 50% polarization reach 19 mA/cm^2. Cathode utilization efficiencies are moderate to high and depend on the electrolyte used. The efficiency in the Li/$POCl_3$:$LiBCl_4$/CuF_2 cell reaches 61%. Two voltage plateaus are observed in the discharge curve. A Li/$POCl_3$:$LiBCl_4$/$(CF)_n$ cell discharged at 1 mA/cm^2 exhibits a single, flat voltage plateau at 1.2V. The open-circuit potential of this cell is 2.86V. The utilization efficiency of the $(CF)_n$ cathode is 57%.

The open-circuit potential of the Li/$POCl_3$:$LiBCl_4$/WO_3 cell is 2.58V. The cathode utilization efficiency at 1 mA/cm^2 is 120% if reduction to WO_2 is assumed, an obviously wrong assumption. The current density at 50% polarization is 12 mA/cm^2. The discharge characteristics of this cell at 1 mA/cm^2 are characterized by a single voltage plateau at 2.3V.

The open-circuit potential of the Li/$POCl_3$:$LiBCl_4$/S cell is 3.3V with a sulfur-carbon cathode, and 3.1V with a sulfur-silver cathode. The cathode utilization efficiency is low (14%). Discharge characteristics of these cells are characterized by voltage plateaus at 2.3V for the carbon and 1.4V for the silver additive.

The open-circuit potentials of Li/$(C_4F)_n$ cells in $POCl_3$ range from 3.11 to 3.70V and depend on the electrolyte used. Their cathode utilization efficiency, assuming reduction of the cathode to carbon, substantially exceeds 100%, reaching 470% at 1 mA/cm^2 in $LiBCl_4$ in the experiment shown in Fig. 3. Typical current densities at 50% polarization are 4 mA/cm^2. The polytetracarbon monofluoride cathodes become inactive when discharged against lithium. They cannot be used over again with fresh lithium and electrolytic solution. Expended cathodes "swell" to about twice

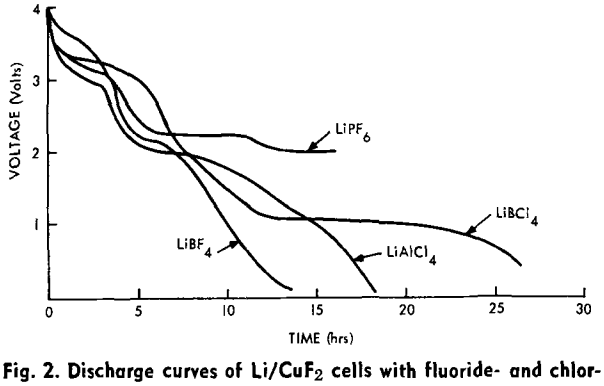

Fig. 2. Discharge curves of Li/CuF_2 cells with fluoride- and chloride-based saturated electrolytes. Solutions in $POCl_3$ at 25°C.

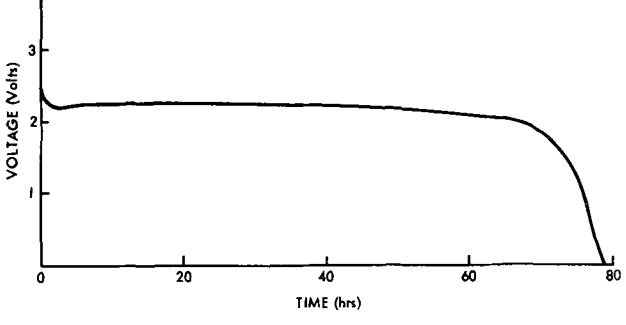

Fig. 3. Discharge curve of a Li/$POCl_3$:$LiBCl_4$/$(C_4F)_n$ cell at 1 mA/cm^2 (28 mA) rate.

their original thickness. Atomic absorption spectroscopic analysis shows that they pick up phosphorus and lithium. In ~1M $LiBCl_4$:$POCl_3$ solutions no boron from the electrolyte is detected in the spent cathodes.

Li/$(C_4F)_n$ cells made with a 1:1 $POCl_3$:$SOCl_2$ solvent and an acidic electrolyte consisting of 1M BCl_3 and 0.8M LiCl (0.8M $LiBCl_4$ plus 0.2M BCl_3) have open-circuit potentials from 3.90 to 4.05V. Current densities at 50% polarization (2V) range between 3-4 mA/cm². The cells exhibit flat voltage plateaus at 2.8-3.1V for 70-90% of their life when discharged at 1 mA/cm² (28 mA). A discharge curve typical to these cells is shown in Fig. 4. Energy densities of the cells range from 194-225 W-hr/kg, the weight including all cell components other than the case. Coulombic capacities of the cells exceed those expected from reduction of $(C_4F)_n$ to carbon by factors from 2.75 to 3.34.

Li/$SOCl_2$:$LiAlCl_4$/$(C_4F)_n$ cells, with 1-2M $LiAlCl_4$ solutions in thionyl chloride by itself exhibit flat discharge characteristics, high energy densities, and moderate power densities. The open-circuit potential of a Li/$SOCl_2$:$LiAlCl_4$/$(C_4F)_n$ cell with 1M $LiAlCl_4$ is 3.62V. The cell potential at a 1 mA/cm² discharge rate is 3.30V. The potential remains constant through the discharge of the cell and drops abruptly when the cell is exhausted. Ninety-six per cent (96%) of the cell's energy capacity can be obtained at a 1 mA/cm² rate above 3.0V. The discharge curve of this cell is shown in Fig. 5.

Substitution of high surface area graphite or carbon black for $(C_4F)_n$ in the thionyl chloride cells produces similar, and in some cases better, results. Voltage-current characteristics for 50% discharged $(C_4F)_n$ and acetylene black cathodes are shown in Fig. 6. The acetylene black cathode is capable of handling over five times the current density of $(C_4F)_n$ in this instance. Discharge curves of Li/$SOCl_2$:1.8M $LiAlCl_4$/C cells with folded 4 × 8 cm cathodes surrounded on both sides with lithium foil in 8 ml cases are shown in Fig. 7 at 1 mA/cm² (64 mA) and in Fig. 8 at 10 mA/cm² (640 mA). These particular cells exhibit energy densities of 578 and 408 W-hr/kg, respectively. These energy densities, like all reported here, include the mass of all cell components except the case.

Discussion

Stability of lithium in phosphorus oxychloride and in thionyl chloride.—It is evident from the Results section that the rate of reaction of lithium with the inorganic oxyhalides considered is very slow. Since lithium is sufficiently electropositive to be able to reduce any of the solvents, we conclude that upon contact with the oxyhalides a passivating layer is formed

on the surface of the metal. The nature and the stability of this passivating layer vary with the solvent and with the electrolyte. While lithium appears to be stable at room temperature for at least two weeks in any of the oxyhalides discussed, $POCl_3$ reacts with the metal at its boiling point to form a thick brown coating. Thionyl chloride is superior in its stability to reduction by lithium. Two weeks of boiling with this solvent has no visible effect on lithium, the metal retaining its metallic appearance. The addition of thionyl chloride to the phosphorus oxyhalides also improves the stability of the latter.

Lewis acids, such as BCl_3 or $AlCl_3$, exhibit a corrosive effect on lithium in boiling $POCl_3$ or $SOCl_2$. This suggests that the passivating coating is basic, possibly the lithium salt of a reduced oxyacid. Indeed both thionyl chloride and phosphorus oxychloride can be active as cathode depolarizers, being reduced in electrolytic processes.

Solvent stability.—The most significant difference between the present and the previously reported ambient temperature lithium cells in which organic solvents were used is in the stability of the solvents. The solvents described in the results are thermodynamically stable. All organic solvents used in lithium batteries are metastable in the thermodynamic sense. Because of this, when the systems are perturbed by application of a substantial overpotential or by intense local heating the change is irreversible in organic electrolyte solutions, but is reversible in the inorganic solutions. In phosphorus oxychloride, for example, charging overpotentials result in the formation of trivalent phosphorus compounds and dissolved chlorine. These recombine to regenerate the solvent.

Solubilities and conductivities.—The dielectric constants of the inorganic solvents under consideration are too low to be adequate to overcome the electrostatic lattice energies of salts consisting of small ions. However, if the solvents are sufficiently strong coordinating agents (electron pair donors), large solvated lithium ions can be formed. If the anions are also large the electrostatic attraction is sufficiently reduced for the lithium salts to dissolve, in spite of the low dielectric constants. In all of the presently considered systems the solubilities and conductivities depend on the sizes of the anions and on the donor strengths of the solvents.

The linear increase in the conductivity of $LiAlCl_4$ in $SOCl_2$ with electrolyte concentration (Fig. 1) shows that even in this solvent, having a dielectric constant of 9.05 (at 22°C), the ions are substantially dissociated. The addition of Lewis acids by themselves to the oxyhalide solvents leads only to conductivities of 10^{-4}-10^{-5} ohm^{-1} cm^{-1}, two orders of magnitude below the 10^{-2}-10^{-3} ohm^{-1} cm^{-1} conductivities of the lithium salt solutions. We explain this difference in dissociation by the ionic size, the acid cations $POCl_2^+$ or $SOCl^+$ being smaller than the solvated lithium ions $[Li(POCl_3)_n]^+$ and $[Li(SOCl_2)_n]^+$. As a result, the acid solutions consist predominantly of associated ion pairs (Eq. [3]). Neutralization of the acids by lithium salts leads to conductive solutions of dissociated ions (Eq. [4])

$$POCl_3 + AlCl_3 \rightarrow POCl_3{:}AlCl_3 \rightleftarrows POCl_2^+ + AlCl_4^- \quad [3]$$

$$LiCl + POCl_3{:}AlCl_3 + (n-1)\,POCl_3 \rightleftarrows [Li(POCl_3)_n]^+ + AlCl_4^- \quad [4]$$

The number of solvent molecules solvating the lithium cations is less than six and probably less than five as evidenced by the attainment of 2M $LiAlCl_4$ solutions in $SOCl_2$ and by the attainment of 1.8M $LiBCl_4$ solutions in $POCl_3$ (the ratio of solvent molecules to lithium cations is about 6:1 in the first and about 5:1 in the second). This value of n is consistent with the measurements of the stability constants for hydrated lithium ions in propylene carbonate (8), which show that the number of solvating molecules is three or more.

Thionyl chloride has a lower viscosity than the other oxyhalides (0.6 cp at 25°C) and is also substantially less viscous than water. The low viscosity and the dissociation of ion pairs account for the fact that the conductivity of 1.73M $LiAlCl_4$ solutions reaches 2.04×10^{-2} ohm^{-1} cm^{-1}.

Cathode and cell characteristics.—Li/Cl_2 cells.—Phosphorus oxychloride is stable to oxidation and is compatible with chlorine, bromine, and iodine. The observed open-circuit potentials of cells with differing electrolytes and varying Lewis acid concentrations range from 4.0 to 4.3V at 25°C. These values are in reasonable agreement with the available thermochemical data. The free energy of formation ($\Delta G°_f$) of LiCl at 25°C is −91.79 kcal/mole (9). The free energy of dissolution of chlorine in $POCl_3$ has not been reported; however, for carbon tetrachloride the value is +1.09 kcal/mole (10). Assuming a similar value for $POCl_3$ the calculated emf for a neutral solution, for the simple reversible reaction shown by Eq. [5], is 4.00V

$$Li(s) + \tfrac{1}{2}Cl_2(POCl_3) \rightleftarrows LiCl(s) \quad [5]$$

When an excess of a Lewis acid, such as $AlCl_3$ is present in the solution (and when the solution is saturated in the $LiAlCl_4$ electrolyte), the cell reaction is that shown by Eq. [6]

$$Li(s) + \tfrac{1}{2}Cl_2(POCl_3) + AlCl_3(POCl_3) \rightleftarrows LiAlCl_4(s) \quad [6]$$

Since the free energy of solvation of $AlCl_3$ and the free energy of formation of $LiAlCl_4$ are not available, we cannot calculate the emf. However, since the free energy of formation of $NaAlCl_4(s)$ from NaCl(s) and $AlCl_3(s)$ is −6.86 kcal/mole (11), an increase in the emf of our acidic cells by 0.30V to a maximum of 4.30V is not surprising.

The rates of electrode reactions at both the Li anode and the Cl_2(Pt) or Cl_2(C) cathodes are fast (>20 mA/cm^2), as expected for simple electron transfer reactions. Polarization of these cells is due to resistance of the electrolytic solution. At 50% polarization the cells deliver ~40 mW/cm^2.

Lithium cells with metallic cathodes.—The origin of the emf of our Li/$POCl_3$:$LiAlCl_4$/metal cells (with the cathode metal being any of the 16 listed in the Results section) can be either in electrochemical alloying or in catalytic reduction of the solvent at the cathode surfaces. However, the measured potentials of 2.05-2.92V are much above the potentials that have been determined for electrochemical alloying or in catalytic reduction of the solvent at the cathode surfaces. Lewis and Keyes determined the potential for the amalgamation reaction of lithium in propylamine in 1913 and found it to be 0.9457V (12), in agreement with the 1968 value of 0.947V of Cogley and Butler (13) who used a different solvent. Since the 2.90V of the Li/$POCl_3$:$LiAlCl_4$/Hg cell cannot be explained by formation of an amalgam, we conclude that the reduction of the solvent takes place at the cathode metal surface. This reduction leads to the formation of the observed LiCl precipitate and to the formation of soluble trivalent phosphorus compounds.

Li/CuF_2 cells.—Assuming that the reported free energies of formation for CuF_2 and CuF (−119.28 and −41.04 kcal/mole, respectively) (14) are correct, CuF_2 should be reduced directly to metallic copper, and only one voltage plateau should be observed in the discharge curve of the cell. The reversible emf for the reaction shown in Eq. [7] is calculated to be 3.46V as the free energy of formation of LiF at 25°C is −139.5 kcal/mole (9)

$$Li(s) + \tfrac{1}{2}CuF_2(s) \rightleftarrows LiF(s) + Cu(s) \quad [7]$$

However, the measured open-circuit potentials are higher, ranging from 3.63 to 4.00V depending on the electrolyte. The higher than theoretical open-circuit potentials suggest that reaction [7] is not the only cell reaction. A reaction which explains the observed cell potentials is the electrolytic reduction of solvent, catalyzed by the fresh porous copper surface formed upon reduction of the CuF_2.

The discharge curve of the $Li/POCl_3:LiBCl_4/CuF_2$ cell as well as the discharge curves of cells with the other electrolytes do not show a stable voltage plateau. The lack of such a plateau can be explained by the presence of at least two processes, solvent reduction and the reduction of cupric fluoride.

Li/S cells.—The open-circuit potentials of $Li/POCl_3:LiBCl_4/S$ cells are well above the 2.6V emf for reaction [8] (15)

$$Li + \tfrac{1}{2}S \rightleftarrows 1/2\,Li_2S \qquad [8]$$

Since our cathodes contained carbon or silver, reduction of the solvent at the metal surfaces could be a cause for the higher potentials. A reaction in which lithium chloride and thiopyrophosphoryl chloride are produced according to Eq. [9]

$$2Li + S + 2POCl_3 \rightleftarrows 2LiCl + P_2O_2SCl_4 \qquad [9]$$

may also explain the high emf. (Reaction [9] seems plausible in view of the known reaction of hydrogen sulfide with phosphorus oxychloride to form hydrogen chloride and thiopyrophosphoryl chloride (3).) We note that cells with selenium and metal oxide cathodes also have higher than expected open-circuit potentials probably for related reasons. Indeed, the formation of lithium chloride is observed in all of these cells.

$Li/(C_4F)_n$ and Li/C cells.—The $LiPOCl_3:LiBCl_4/(C_4F)_n$ cells as well as the $Li/POCl_3:LiBCl_4/WO_3$ cells exhibit greater coulombic capacities upon discharge than can be explained by reactions [10] and [11]

$$\frac{1}{n}(C_4F)_n + e^- \rightarrow 4C + F^- \qquad [10]$$

$$WO_3 + 2POCl_3 + 2e^- \rightarrow WO_2 + P_2O_3Cl_4 + 2Cl^- \qquad [11]$$

These cells also exhibit flat voltage plateaus at 2.2V in $POCl_3$ when discharged at 1 mA/cm^2. In some cells more than 5 faradays are passed per gram atom fluorine present in the $(C_4F)_n$. The only component present in our cells which can account for the added cathode capacity is the solvent itself. The reduction of the solvent is indicated by our experiments to be by at least a two-electron process. It is possible that the particular open graphite-like structure of $(C_4F)_n$ might act as a surface upon which the $POCl_3$ or $Cl_3PO:BCl_3$ adduct can be electrochemically reduced. A similar process occurred with $SOCl_2$ and SO_2Cl_2. $(C_4F)_n$ has a planar structure like graphite, but the distance between the planes of hexagonally arranged carbon atoms is 5.4Å (compared with 3.35Å in graphite) and the carbon planes are in identical positions one above each other (instead of offset as in graphite) (16, 17). Decomposition of $(C_4F)_n$ results in the formation of amorphous carbon; analysis of partially discharged $(C_4F)_n$ cathodes by x-ray crystallography revealed no structure, the cathodes behaving essentially like amorphous carbon. Substitution of carbon black for $(C_4F)_n$ in lithium anode cells operating in $LiAlCl_4$ solutions of $POCl_3$, $SOCl_2$, and SO_2Cl_2 confirmed our hypothesis for catalytic reduction of the solvents. The open-circuit voltages were similar to those observed with $(C_4F)_n$ and the discharge charcteristics improved, especially at the high rates, because of the increased electronic conductivity and surface area of the carbon electrodes. Solvent reduction explains the observed open-circuit potentials, as well as the exceptional voltage stability seen in the discharge curves (Fig. 3-5, 7, 8). Obviously the common mechanism that accounts for the increasing internal resistance or decreasing potential of conventional cells, the inbound movement of the reactive cathode layer, is inoperative in a cell in which the solvent is the depolarizer and the cathode is fixed.

The open-circuit potential of cells containing $SOCl_2$ (neutral solution) is 3.6-3.7V whether $(C_4F)_n$ or C catalytic cathodes are used. This potential increases to 3.9-4.0V in $SOCl_2$ solutions containing excess Lewis acid ($AlCl_3$ or BCl_3). The observed reaction products in discharged cells include lithium chloride, sulfite, and sulfur. These products as well as the observed emf of the cells suggest that the cell reaction is that shown in Eq. [12] for neutral solution

$$8Li + 3SOCl_2 \rightleftarrows 6LiCl + Li_2SO_3 + 2S \qquad [12]$$

The calculated emf for the reaction of Eq. [12] is 3.61V. The reactions in acid solution are similar except that $LiAlCl_4$ or $LiBCl_4$ rather than LiCl is formed.

Conclusion

Inorganic phosphorus and sulfur oxyhalides which are liquid at room temperature are useful solvents and depolarizers in lithium cells. Conductivities of lithium salts in these solutions reach 2.04×10^{-2} ohm^{-1} cm^{-1}. A broad range of cathodes is compatible with the solvents, including strongly oxidizing ones such as Cl_2(C) and sulfur. However, the best cathode electrodes are conductive materials, such as polytetracarbon monofluoride and carbon, which aparently aid the reduction of the solvent. With these electrodes, the solvent becomes the depolarizer. Unlike conventional solid cathodes the distance between the reactive zones of the electrodes remains constant upon discharge and the cells exhibit exceptional voltage stability. Since the electrolytic solution is also the depolarizer, the weight of the cathode does not burden the cell and energy densities of 570 W-hr/kg to 90% of the initial voltage are realized in simple cells. Furthermore, the problem of limitation of the shelf life by transport of the cathode depolarizer is altogether eliminated.

ABSTRACT

This paper describes a study of room temperature lithium cells employing solutions of $LiBCl_4$ in $POCl_3$ and $LiAlCl_4$ in $SOCl_2$ as electrolytes and polytetrafluoroethylene (Teflon)-bonded carbon black electrodes as cathodes. A novel feature of these cells is that during discharge the solvents, *i.e.*, $POCl_3$ and $SOCl_2$, are electrochemically reduced and behave as soluble cathodes. Sealed prototype cells were fabricated using a polyethylene-polyester laminated bag container. Based on total cell weight, a prototype cell yielded an experimental energy density of 244 W-hr/lb for a 57-hr discharge rate (20 mA constant current; 1 mA/cm^2 current density). The performance of these cells is also compared with the performance of prototype lithium-organic electrolyte-graphite monofluoride and lithium-inorganic electrolyte-tetracarbon monofluoride cells.

Recently, solutions of lithium-inorganic salts (*e.g.*, $LiBCl_4$, $LiAlCl_4$, etc.) in phosphorous oxychloride ($POCl_3$) and thionyl chloride ($SOCl_2$) have been reported (1) as electrolytes for room temperature lithium-chlorine cells. Attempts also have been made to use cathodes other than chlorine gas, *e.g.*, graphite fluorides (CF and C_4F), metal halides, metal oxides, etc. (2, 3). Among the various cathode materials studied (2, 3), cells with tetracarbon monofluoride (C_4F) cathodes yielded the highest energy densities. It was also reported that during discharge C_4F also catalyzes (3) the reduction of the solvents, *i.e.*, $POCl_3$ and $SOCl_2$, so that coulombic efficiencies far in excess of theoretical were obtained. In the present studies, it is demonstrated that both $POCl_3$ and $SOCl_2$ can be electrochemically reduced at an adequate rate on uncatalyzed carbon black electrodes and behave as soluble cathodes. Results are presented for prototype room temperature lithium-inorganic electrolyte cells using polytetrafluoroethylene (Teflon)-bonded carbon black electrodes as cathodes. Some new data on the performance of room temperature lithium-inorganic electrolyte-C_4F and lithium-organic electrolyte-CF cells at current densities of 1-10 mA/cm^2 are also presented by way of comparison with the newer systems.

Experimental Procedure

Chemicals.—The chemicals used in the experiments were purified as described. Reagent grade phosphorous oxychloride (Fisher Scientific Company) and analytical grade thionyl chloride (Matheson, Coleman and Bell Company) were refluxed over lithium metal for a period of 24 hr and then distilled. Propylene carbonate (Eastman Kodak Company, T_B = 121°-123°C at 17 mm pressure) was dried with 5A molecular sieves and submitted to vacuum fractionation at 7 mm Hg. The first fraction of 300 mliters was discarded. Reagent grade methyl acetate (Fisher Scientific Company) was used as received.

* Electrochemical Society Active Member.

Key words: carbon black cathodes, inorganic electrolytes, lithium anodes, lithium cells, phosphorous oxychloride, thionyl chloride, solvent reduction.

Reagent grade lithium chloride (Fisher Scientific Company) was further purified by heating at 100°-120°C for a period of 16-20 hr under a flowing atmosphere of hydrogen chloride (HCl) gas in a closed Vycor vessel. The temperature was then increased to 50° above the melting point of lithium chloride (610°C) and the bubbling of hydrogen chloride gas continued for another 4-5 hr. This was followed by bubbling chlorine gas for another 2-3 hr. The latter treatment with chlorine gas helped to remove the black organic impurities usually found after treatment with HCl gas. The excess of hydrogen chloride gas and chlorine gas was removed by bubbling argon gas and the temperature was gradually lowered to room temperature. The anhydrous lithium chloride, so obtained, was stored in Pyrex tubes in an inert atmosphere of argon gas. Anhydrous lithium tetrachloroaluminate ($LiAlCl_4$) was prepared by mixing weighed amounts [50:50 m/o (mole per cent)] of reagent grade lithium chloride with iron and water-free Fluka aluminum chloride (Columbia Organic Chemical Company) and then treated with hydrogen chloride gas and chlorine gas according to the prescribed procedure for the purification of lithium chloride.

Reagent grade lithium perchlorate (K&K Laboratories, Inc.) was vacuum dried and lithium hexafluoroarsenate (U. S. Steel Corporation) was used as received.

Preparation of electrolytes.—A 1M solution of lithium tetrachloroborate ($LiBCl_4$) in phosphorous oxychloride ($POCl_3$) was prepared by adding 21.196g of purified lithium chloride into distilled 200-300 ml of phosphorous oxychloride. Boron trichloride gas (Research Organic Inorganic Chemical Corporation) was then bubbled into the solution until the weight of the dissolved boron trichloride gas reached 117.17g. Lithium chloride is sparingly soluble in phosphorous oxychloride but as the requisite amount of boron trichloride gas is added, all of the lithium chloride dissolves and results in a clear solution. The volume of the resulting solution was increased to 500 ml by adding distilled $POCl_3$ to yield a 1M solution. It was found that

the addition of boron trichloride can be accomplished more easily by first liquefying the boron trichloride gas with an acetone-dry ice mixture so that it drips into the phosphorous oxychloride.

A 1.5M solution of lithium tetrachloroaluminate in thionyl chloride, 0.75M solution of lithium hexafluoroarsenate in methyl acetate, and 1M solution of lithium perchlorate in propylene carbonate were simply prepared by addition of requisite amounts of solutes into the solvents inside a Dry-Train, Dry-Lab (Vacuum Atmospheres Corporation) in pure dried argon atmosphere.

Preparation of electrodes.—Carbon black cathodes.—These electrodes were prepared by making a paste of 81 w/o (weight per cent) carbon black (XC-6310-4, Ashland Chemical Company) and 19 w/o Teflon binder (TFE-fluorocarbon resin dispersion No. 30, du Pont) in a small amount of water (5 mliters/g of carbon black-Teflon binder mixture). A 0.29-0.45g of the paste was then spread on two sides of a nickel grid (Exmet 3/0, 1.25 × 1.25 in.) which had a previously spot welded nickel wire lead. The electrode was sandwiched between two Whatman No. 42 filter papers and pressed between two stainless steel plates at a pressure of 8000 psi using a hydraulic press. The electrode was then removed and vacuum dried at 110°-120°C for a period of 24 hr.

Graphite fluoride cathodes.—Graphite fluorides were obtained from Ozark-Mahoning Company. The C_4F cathodes were prepared by making a paste of 72.53 w/o C_4F, 16.77 w/o carbon black, and 10.69 w/o Teflon binder in a small amount of water (2.5 mliters/g of cathode mixture). A 0.47-0.77g sample of the paste was spread on two sides of the nickel grid and pressed and dried as described above. The CF cathodes were prepared either by dry or wet processes. In the dry process method, a 1-1.47g sample of the cathode mixture (80 w/o CF, 15 w/o graphite, and 5 w/o Teflon powder) was put on two sides of copper foam metal (1.25 × 1.25 in.; 0.1 in. thick), having a previously spot welded copper wire lead, in a die and pressed between two stainless steel plates using a hydraulic press at a pressure of 10,000 psi. The CF cathodes in the wet process were prepared according to the procedure described by Watanabe and Fukuda (4). The electrodes so prepared, were dried at 120°C under vacuum for a period of 24 hr.

Lithium anodes.—The lithium anodes were prepared from commercial lithium ribbon (0.015 in. thick; Foote Mineral Company) stored in decahydronaphthalene. A 1.25 × 1.25 in. sample of this ribbon was pressed at 460 psi onto a nickel screen (Exmet 3/0; 1.25 × 1.25 in.), having a previously spot welded nickel wire lead, between two stainless steel plates greased with petroleum jelly (Snow White, USP, Fisher Scientific Company). The finished anodes were thoroughly washed with carbon tetrachloride before use.

Preparation of cells.—The cells were prepared by sandwiching the cathode between two Viskon nonwoven rayon separators and placing a lithium anode on the outside of each separator. The electrode assembly was then placed inside a polyethylene-polyester laminated bag (2.5 × 2.8 in.) containing 2-3 mliters of the electrolyte. The bag was then heat sealed so that approximately 2-3 in. of the electrode leads protruded out. All these steps were completed inside a Dry-Train, Dry-Lab (Vacuum Atmospheres Corporation).

Instrumentation.—The cells were discharged at constant currents up to 100 mA using a precision current source (North Hills Electronics, Inc., Model CS-11). For higher constant currents, a Kepco Power Supply (Model CK8-5M) was used in the current mode. For this purpose, the Kepco Power Supply was modified by placing a variable resistor in series to obtain the desired currents. The voltage-time curves were recorded on a Moseley Strip Chart Recorder (Model 7100B). The currents were read on a Weston Milliammeter (Model 901) placed in series with the cell.

Results and Discussion

Lithium-inorganic electrolyte cells.—The following lithium-inorganic electrolyte cells were investigated

Li | $LiBCl_4$-$POCl_3$ (1 molar) | Carbon black [I]

Li | $LiAlCl_4$-$SOCl_2$ (1.5 molar) | Carbon black [II]

Li | $LiAlCl_4$-$SOCl_2$ (1.5 molar) | C_4F [III]

Typical discharge curves for these cells at different current densities are presented in Fig. 1-4. The current densities are based on the geometric area of the cathode (including both sides) which in most cases was

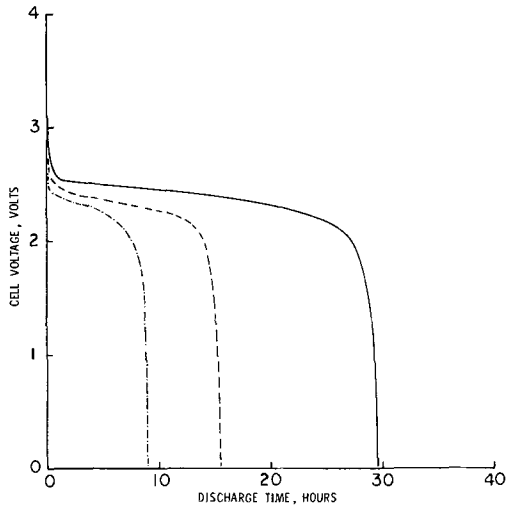

Fig. 1. Discharge curves for the cell: Li/$LiBCl_4$-$POCl_3$ (1M)/carbon black; ——— C.D. 1 mA/cm² (20 mA discharge current); - - - - C.D. 2 mA/cm² (40 mA discharge current); —·—·—·— C.D. 3 mA/cm² (61 mA discharge current).

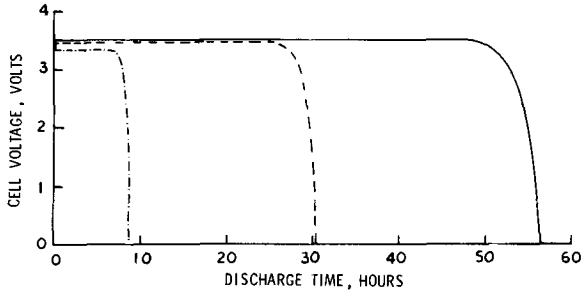

Fig. 2. Discharge curves for the cell: Li/$LiAlCl_4$-$SOCl_2$ (1.5M)/carbon black; ——— C.D. 1 mA/cm² (20 mA discharge current); - - - - C.D. 2 mA/cm² (36 mA discharge current); —·—·—·— C.D. 5 mA/cm² (100 mA discharge current).

20 cm^2. The open-circuit voltages for cells I, II, and III were 3.1, 3.65, and 3.65V, respectively, and showed a variation of less than ± 0.05V in a number of experiments. Upon discharge, cell I showed a large initial drop in voltage and exhibited a slightly sloping discharge plateau. In contrast to cell I, cells II and III showed only a small initial drop in voltage and exhibited exceptionally flat discharge plateaus. Toward the end of cell life, cell voltages for cells I, II, and III declined sharply to zero volt. The discharge curves for cells I-III were recorded at successively increasing current densities until either the cell voltage plateau fell below 2V or the 1-hr rate was reached. For cell I, the cell voltage plateau fell below 2V at current densities greater than 3 mA/cm^2 and thus no discharge curves are reported for higher current densities. For cells II and III, the 1-hr rate was reached at current densities of 20 and 10 mA/cm^2, respectively.

The electrochemical reduction of solvents, in solutions of triethylammonium chloride in phosphorous oxychloride and thionyl chloride, at platinum electrodes was first reported by Spandau, Beyer, and Preugschat (5). The cathodic product in the case of $POCl_3$ was found to have the stoichiometric formula PO and is believed to be polymeric. The cathodic products in case of $SOCl_2$ were found to be temperature dependent and, at temperatures above 0°C, predominantly consisted of SO_2, Cl_2, and S_2Cl_2.

The voltammetric reduction of the solvents in solutions of $LiBCl_4$ in $POCl_3$ and $LiAlCl_4$ in $SOCl_2$ at platinum, pyrolytic graphite and porous carbon electrodes was confirmed (6) in this laboratory using the techniques of cyclic and rotating ring-disk voltammetry. Assuming the cathodic reaction products to be the same as postulated by Spandau *et al.* (5), the net cell reaction in cell I may be given by the following equation

$$3Li + POCl_3 \rightarrow PO + 3LiCl \qquad [1]$$

Since SO_2 is known (7) to undergo further reduction in anhydrous nonaqueous solvents to dithionate ($S_2O_4^{--}$) and Cl_2 to chloride (Cl^-) (6) ions, the net cell reaction in cell II may be given by the following equation

$$8Li + 4SOCl_2 \rightarrow Li_2S_2O_4 + 6LiCl + S_2Cl_2 \qquad [2]$$

Assuming the net cell reactions given by Eq. [1] and [2] to be correct for cells I and II, respectively, the approximate free energy changes for reactions [1] and [2] are calculated from the open-circuit voltages to be, respectively, −214 kcal/mole of $POCl_3$ and −168 kcal/mole of $SOCl_2$. From these free energy of reactions, it would be expected that lithium metal would react spontaneously with both phosphorous oxychloride and thionyl chloride. However, in practice, lithium metal is extremely stable in solutions of $LiBCl_4$ in $POCl_3$ and $LiAlCl_4$ in $SOCl_2$. Lithium-inorganic electrolyte cells with these solutions have been stored for over two weeks without any appreciable loss of performance. The stability of lithium metal in $POCl_3$ and $SOCl_2$ solutions may be due to the formation of a passivating layer of the reaction products which protects it from any further chemical reaction.

The end of cell life in cells I and II is caused by the passivation of the carbon black cathodes by the accumulation of reaction products. Thus, attempts to regenerate the cells at the end of cell life by addition of more electrolyte were not successful. The energy densities and power densities for cells I and II were determined by discharging the cells to zero volt and the data are summarized in Table I. The amount of the solvent reduced at the carbon black cathodes was also determined from the total discharge time by use of Faraday's law and assuming the cell reactions given by Eq. [1] and [2] to be correct. From a knowledge of the initial amount of the solvent, the per cent solvent utilization was also calculated at various current densities. These data are also summarized in Table I.

In cell III, if C_4F is considered the active cathodic material, the electrode reactions would be given by the following equations

$$\text{Anode:} \quad Li \rightarrow Li^+ + e \qquad [3]$$

$$\text{Cathode:} \quad C_4F + e \rightarrow 4C + F^- \qquad [4]$$

$$\text{Net cell reaction:} \quad Li + C_4F \rightarrow 4C + LiF \qquad [5]$$

‡ Per cent solvent utilization, energy density, and power density determined by discharging cells to zero volt.

Considering the net cell reaction for cell III to be given by Eq. [5], the amount of C_4F reduced was determined from the total discharge time by use of Faraday's law. Knowing the initial amount of C_4F used, the per cent cathodic efficiencies at current densities of 1, 2, and 5 mA/cm^2 were calculated to be of the order of 402, 316, and 214%, respectively. Such high cathodic efficiencies indicate that even at C_4F cathodes, the main cathodic reaction is probably the reduction of the solvent. Taking the net cell reaction to be given by Eq. [2], the per cent solvent utilization at C_4F cathodes at various current densities was determined as described above. The energy densities and power densities for cell III were also determined. These data are also summarized in Table I.

From the data presented in Table I, it is seen that lithium-inorganic electrolyte cells employing $SOCl_2$ as the solvent yield higher energy densities as well as power densities as compared to the cells employing $POCl_3$ as the solvent. For cells based on $SOCl_2$, higher per cent solvent utilization as well as energy densities and power densities are obtained by using carbon black instead of C_4F as the cathodic material. Further, for cell II, 90% or more of the total cell capacities are delivered at cell voltages of 3V or higher at lower current drains (1-10 mA/cm^2).

Since the lithium-inorganic electrolyte cells discussed above are based solely on the reduction of the inorganic oxychloride solvent, *i.e.*, $POCl_3$ and $SOCl_2$, these cells do not require the use of any additional active cathode material. The reduction of the inorganic oxychloride solvent can presumably be achieved at other inert cathode materials. However, the highly developed surfaces of the cathodes used in this study are required for practical performances. The results reported in Table I were obtained by using carbon black (Ashland Chemical Company) as the cathodic material. However, several other types of carbon obtained from different sources were also used as cathodic materials in the Li/$LiAlCl_4$-$SOCl_2$ (1.5M)/C type cells. The preparative techniques for these cathodes were the same as those already described for carbon black cathodes. Due to the higher bulk density of some of these carbon powders, the weight of the carbon in the cathodes was 2-3 times higher than the weight of carbon black in cathodes of approximately identical size and thickness. The comparative performance of the various carbons was studied at discharge current densities of 1 and 2 mA/cm^2. The data are summarized in Table II.

It is clear from the data presented in Table II that the highest per cent solvent utilization as well as energy densities and power densities are obtained with carbon black cathodes (Ashland Chemical Company and Shawinigan Chemicals Ltd.). The reasons for the superior behavior of carbon black as the cathodic material as compared to other types of carbon are not yet understood in detail but probably involve such physical properties as porosity, wettability, and solvent absorption.

In the study of lithium-inorganic electrolyte cells discussed above, no attempt was made to optimize the weights of carbon black in the cathodes or the amount of electrolyte in the cells. The data presented in Table I, therefore, only demonstrate the feasibility of lithium-inorganic electrolyte cells as a viable power source and show the relative energy densities, power densities, and current carrying capabilities that can be achieved from these systems. It is believed that even higher per cent solvent utilization as well as energy densities and power densities can be achieved by a careful optimization of the weights of carbon black vis-a-vis the weights of the electrolyte in each of the cells studied.

Lithium-organic electrolyte cells.—The following typical lithium-organic cells were investigated to provide a direct comparison of their performance with the lithium-inorganic electrolyte cells under identical experimental conditions

Li | $LiClO_4$ — Propylene carbonate (1 molar) | CF [IV]

Li | $LiAsF_6$ — Methyl acetate (0.75 molar) | CF [V]

The electrode reactions in cells IV and V may be represented as

$$\text{Anode:} \quad Li \rightarrow Li^+ + e \qquad [6]$$

$$\text{Cathode:} \quad CF + e \rightarrow C + F^- \qquad [7]$$

$$\text{Net cell reaction:} \quad Li + CF \rightarrow C + LiF \qquad [8]$$

Typical discharge curves for cells IV and V at various current densities are presented in Fig. 5 and 6, respectively. Both cells showed an open-circuit potential of

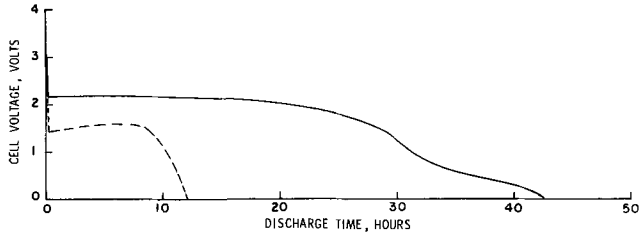

Fig. 5. Discharge curves for the cell: Li/$LiClO_4$-propylene carbonate (1M)/CF; ——— C.D. 1 mA/cm^2 (20 mA discharge current); – – – – C.D. 2 mA/cm^2 (50 mA discharge current).

3.45V and exhibited somewhat flat discharge plateaus. At current densities higher than 1 mA/cm², discharge plateaus for cell IV fell well below 2V whereas cell V could be discharged at cell voltages of 2V or higher, up to current densities of 10 mA/cm². The cathodic efficiencies, energy densities, and power densities for cells IV and V were calculated from the experimental data by discharging the cells to zero volt. The results are summarized in Table III. The cathodic efficiencies in cell V were close to 100% but were of the order of 124-135% in cell IV. The higher cathodic efficiencies in cell IV have been attributed (8) to a slight reduction (9) of propylene carbonate following the reduction of graphite fluoride. However, unlike the lithium-inorganic electrolyte cells I-III, the electrochemical reduction of the solvent, *i.e.*, propylene carbonate, in cell IV occurs (9) at a voltage of less than 1V and thus does not contribute significantly to the over-all energy densities.

From a comparison of the energy density and power density data presented in Tables I and III, it is seen that the lithium-inorganic electrolyte cells based on $SOCl_2$ yield higher energy densities as well as power densities and current carrying capabilities than those obtained from lithium-organic electrolyte cells.

Summary and Conclusions

The lithium-inorganic electrolyte cells were investigated and shown to possess higher energy densities and power densities as well as better current carrying capabilities as compared to the lithium-organic electrolyte cells studied. The lithium-inorganic electrolyte cells consist of a lithium anode, solutions of $LiBCl_4$ in $POCl_3$ or $LiAlCl_4$ in $SOCl_2$ as electrolytes, and polytetrafluoroethylene(Teflon)-bonded carbon black cathodes. It was also shown that the lithium-inorganic electrolyte cells are solely based on the electrochemical reduction of the solvents, *i.e.*, $POCl_3$ or $SOCl_2$, and thus do not require the use of any active cathode materials. The lithium-inorganic electrolyte cell, Li/$LiAlCl_4$-$SOCl_2$ (1.5M)/carbon black was found to be superior in performance to other lithium cells studied and yielded an experimental energy density of the order of 244 W-hr/lb for a 57-hr discharge rate (20 mA constant current; 1 mA/cm² current density).

Chemical and Electrochemical Behavior of Lithium Electrodes in Dimethyl Sulfite, Electrolytic Solutions

William H. Tiedemann*,[1] and Douglas N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Lithium has been shown to be chemically stable in dry $LiClO_4$-dimethyl sulfite solutions. If water is present above 20 ppm, the lithium reacts with the solution to form hydrogen gas and Li_2SO_3. Lithium electrodes are shown to exhibit two levels of electrochemical activity in $LiClO_4$-dimethyl sulfite solutions. The lower exchange current densities are attributed to film formation on the lithium due to trace water concentrations. For water concentrations below 500 ppm, the film can be removed by a 20 sec, 20 mA/cm^2 anodic pulse. The exchange current density, i_o, on a film free surface is 15 mA/cm^2 for a 1.12M $LiClO_4$ solution. The transfer coefficient, α, is 0.49.

Lithium metal is an attractive choice as a battery negative because of its low equivalent weight and its chemical behavior as a strong reducing agent. Beginning in the 1960's, studies were undertaken to find solvent-electrolyte systems in which lithium was stable and behaved electrochemically in a reversible manner (1, 2).

Studies in 1M $LiClO_4$-propylene carbonate (PC) by Burrows and Jasinski (3) indicate that the Li/Li^+ electrode behaves as a suitable reference electrode. Cogley and Butler (4) have shown lithium amalgam electrodes to be reversible in lithium chloride-dimethyl sulfoxide (DMSO) solutions. Butler *et al.* (5) have shown that in $LiClO_4$-PC solutions the exchange current density for the Li/Li^+ electrode decreases with increasing water content. They also observed that for constant water content the exchange current density decreased with time following a current pulse. These experiments did not allow a distinction between the effects of recrystallization of the cold-worked surface or film formation on the surface. Early studies of the effects of water in nonaqueous electrolytic solutions (6) dealt mainly with cathodic deposition of lithium.

Burrows and Kirkland (7) showed that strong complexing between Li^+ and water present in quantities below 500 ppm decreased the activity coefficient of the water. They also detected a film on the lithium surface which was postulated to be LiOH. Dey (8), working in $LiClO_4$-PC solutions, also observed a film on the lithium surface which could be removed by anodic polarization. Dey reports the film composition may be Li_2CO_3 and that the lithium ion has a transference number of one in the film. Scarr (9), also working in $LiClO_4$-PC solutions, has shown that, depending on pretreatment, lithium electrodes exhibit two levels of electrochemical activity. The observed behavior was believed due to a film which can be removed at high current densities and whose formation is sensitive to water concentration. Jackson and Blomgren (10) have also considered the effects of possible film formation on lithium electrode behavior.

Meibuhr (11, 12) examined the kinetics of the solid lithium electrode in $LiClO_4$-PC as a function of temperature. For the range of current densities, temperature, and $LiClO_4$ concentrations studied, the anodic and cathodic polarization data were symmetrical. No mention of film formation or dual activity was made.

The possible existence of a protecting film on the lithium surface suggests two types of stability. The film can protect the lithium from chemical reaction with the solvent during inactive times. However, electrochemical stability or lack of corrosion reactions during cathodic or anodic operation of a lithium electrode must be considered separately. The existence of this electrochemical stability might be demonstrated by (*i*) reversible or Nernst-type response to changes in lithium ion concentration, (*ii*) extended anodic and cathodic polarization tests in which no decomposition products can be detected, and (*iii*) cyclic tests which yield high coulombic efficiency for anodic dissolution and cathodic deposition.

It has been demonstrated (13-16) that dimethyl sulfite (DMSU) is a potentially useful, nonaqueous battery solvent. In the present study, two aspects of the behavior of lithium in electrolytic solutions in dimethyl sulfite have been investigated. The chemical stability of lithium in DMSU-$LiClO_4$ and DMSU-$LiCF_3SO$ solutions containing controlled amounts of water below 3000 ppm has been measured including analysis of reaction products. The electrochemical stability has been measured with special emphasis on the effects of trace amounts of water, the exchange current density, and characterization of film formation on lithium electrodes.

Experimental Equipment and Procedure

All experiments were performed in a VAC dry box equipped with oxygen, nitrogen, and water removal trains in an argon recirculating atmosphere. The temperature of the dry box was maintained at 28° ± 1°C with an auxiliary heater and controller. The chemical stability tests were run on six systems: (*i*) DMSU-lithium, (*ii*) DMSU-lithium-$LiClO_4$, (*iii*) DMSU-lithium-$LiCF_3SO_3$, (*iv*) DMSU-lithium-$LiCF_3SO_3$-H_2O, (*v*) DMSU-lithium-$LiClO_4$-H_2O, and (*vi*) DMSU-lithium-H_2O. The first three systems had water contents of about 50 ppm as determined by Karl Fischer titration (13, 17-19). Known amounts of water were added to the solutions and titration procedures standardized. The last three systems contained less than 3000 ppm water. Two types of cells and procedures were used to determine chemical stability. The first was a glass vessel from which liquid samples could be withdrawn periodically by inserting a syringe through a rubber port. The solution did not contact the rubber directly. No degradation of the rubber was observed. Water content of the samples was measured and recorded as a function of time. The second cell was also a glass vessel arranged so that gas evolution from the system could be monitored quantitatively with time. The gas was collected by displacement of vacuum pump oil in an inverted burette. The gas samples were analyzed using a mass spectrometer. The white precipitate which formed was analyzed as summarized in the Results section. The cells contained approximately 100 ml

Key words: batteries, lithium, dimethyl sulfite, nonaqueous electrolytic solutions.

of solution to which 2g of freshly cut lithium rod, diced to ⅛-in. cubes, were added.

The electrochemical polarization tests were made using a lithium wire as the reference electrode. Data of Burrows and Jasinski (3) and Meibuhr (11) indicated that lithium behaves as a suitable reference electrode in $LiClO_4$-PC solutions. It was also found to work well in DMSU solutions as shown in the Results section.

Lithium electrodes were prepared by inserting a freshly cut lithium disk into a heavy wall glass tube of about 1 cm ID. The tube containing the lithium disk was placed on a clean, polished, flat nickel plate. While the tube was firmly held against the plate, a rod was inserted from the top of the tube and pressed against the lithium disk. The pressure caused the lithium to flow to meet the wall of the tube providing a liquid tight seal and a flat lithium surface of well-defined surface area. The electrode was stored in a vacuum container inside the dry box until the experiments were run.

Some experiments were run by dipping the electrode holder directly into the electrolytic solution. However, nonuniform current distribution and difficulties in correcting for resistance losses in the solution arise for this geometry (20). In order to realize uniform current density and a negligible resistance loss, a special cell was built to hold the electrode as shown in Fig. 1. This cell is similar to one described by Kahan *et al.* (21). The reference electrode was in side compartment D. The liquid junction contact between the main compartment and the reference electrode compartment was in the plane of the test electrode along ledge F. In order to eliminate concentration polarization, pulse currents were applied. The pulses were long compared to double layer charging times and short compared to the time needed for significant concentration changes to occur at the test electrode face.

Lithium is known to attack glass at elevated temperatures. However, for the duration of these experiments at room temperature, no attack of the glass was noted.

Continuous polarization experiments were performed in a cell filled with 100 ml of solution containing previously measured concentrations of water and electrolyte. The solution was stirred with a coated, magnetic stirring bar. No significant temperature variations (less than ± 1°C) were observed when a thermometer was placed next to the cell. A Luggin capillary tube containing a lithium reference electrode was placed at the edge of the disk in the plane of the disk. The working electrode was pulsed with an anodic current of 20 mA/cm² for 10 sec to remove any film. The counter-electrode was a 0.5 × 0.065 in. lithium ribbon cylinder (Foote Mineral Company) at the bottom of the cell.

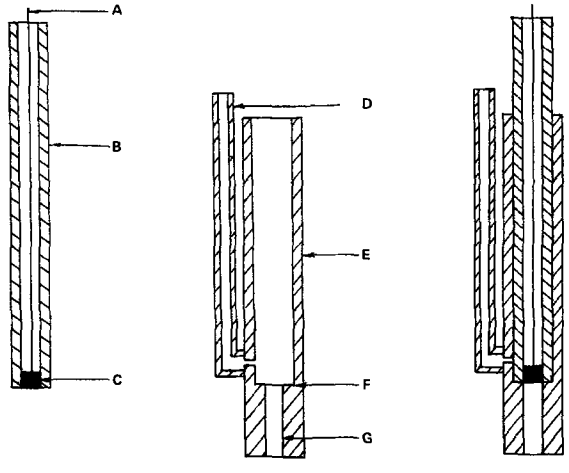

Fig. 1. Cell design for uniform current distribution and iR-free polarization measurements. A = electrode contact wire, B = electrode holder, C = electrode specimen, D = reference electrode, E = positioning tube, F = precision ground ledge, G = same diameter as specimen.

Current was increased anodically or cathodically and then decreased back to zero. Less than 30 sec were needed to establish steady state for each reading. Ohmic potential corrections were made as described elsewhere (20).

Micropolarization current pulse experiments were performed using the complete cell assembly shown in Fig. 1 dipped into a container holding about 100 mliters of solution. Galvanostatic pulses of 1-10 msec with a rise time of 5 μsec were applied. The potential between the reference and working electrode was observed on an oscilloscope. Clear separation between double layer charging and the beginning of concentration overpotential was obtained. No mass transfer effects were observed until times greater than 20 msec at 2 mA/cm². Prior to the test pulses, an anodic pulse of 20 mA/cm² was generally applied for 20 sec to remove any film unless behavior in the presence of a film was being examined.

Further details of the experimental equipment and materials are available elsewhere (22).

Results

The chemical stability of lithium in a 1.2M $LiClO_4$ solution in DMSU containing 1000 ppm water is characterized by the gas evolution rate following lithium addition to the solutions. The initially shiny lithium surface began to turn dull 2-8 hr after lithium was added, depending on initial water content, and a white precipitate began to form. After five days, the rate of gas evolution was too slow to detect. Freshly cut lithium was added to the solution at the end of 200 hr. No further reaction could be detected. The $LiClO_4$ solutions were colorless. Similar experiments with $LiCF_3SO_3$ produced solutions which were light yellow. A mass spectrometer analysis of the gas showed it to contain 80% hydrogen, trace quantities of ethane or a molecule which behaves similarly to ethane in a mass spectrometer, and the rest argon. The rate of gas evolution depends on stirring rate, suggesting a liquid phase diffusion step is rate limiting.

The quantity of gas collected as a function of the water initially present in the solution is shown in Table I. The nearly constant ratio of 22.4 liters of gas per mole of water indicates that one mole of water was producing one mole of hydrogen in the reaction which was being observed.

In separate experiments, the water content was measured as a function of time as shown in Fig. 2. After five days the water content was below the detection limit of 10-20 ppm.

A series of tests were run to determine the composition of the white precipitate. The results are summarized in Table II. In each case the test was specific for Li_2SO_3. It may be that the lithium sulfite was hydrated, the tests were not specific enough to determine water associated with the salt.

Solutions 1, 2, and 3 which initially contained less than 50 ppm water showed no observable reaction with the lithium except for a very light precipitate. One solution has been under observation for two years. No observable change has taken place; the lithium appears dull but metallic. For similar long-term tests with

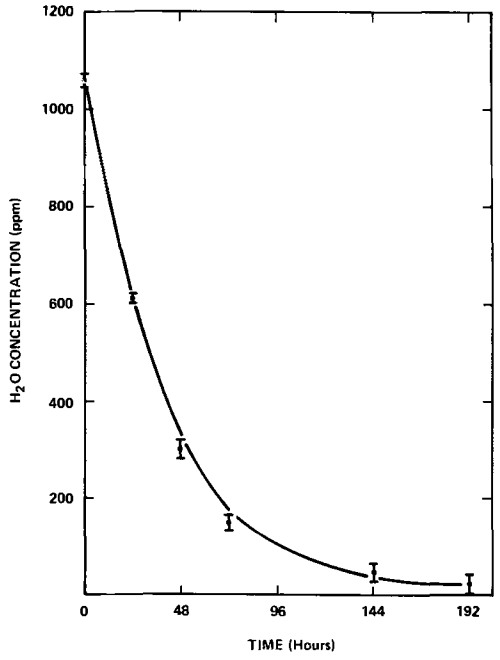

Fig. 2. H_2O content in 127g of a 1M $LiClO_4$ solution contacted with approximately 2g of lithium chips as a function of time. T = 28°C, solution volume = 100 ml.

$LiCF_3SO_3$ as the electrolyte, the solution turned a yellow-brown after a few weeks.

In a separate test, LiOH was added to pure dimethyl sulfite and stirred. Over a three week observation period, no gas evolution was observed, and Li_2SO_3 was subsequently identified in the precipitate.

Results of pulse, micropolarization tests for anodic current pulses at various concentrations are shown in Fig. 3; similar results for cathodic pulses are shown in Fig. 4. Results for the steady polarization of the plane electrode in a stirred solution are not shown. The large correction factor (20) made these results less accurate. However, to within the accuracy of those measurements, the results are in agreement with the more accurate results shown in Fig. 3 and 4.

Figures 3 and 4 are clearly within the linear polarization-current region

$$i = i_o \frac{\mathbf{F}}{RT} \eta \qquad [1]$$

The slopes of the curves in Fig. 3 and 4 as well as the plane disk electrode results were used to determine i_o as a function of concentration. The results are shown in Fig. 5 on a log-log plot. The importance in making a correction for nonuniform current distribution (20) is shown by comparison of the two triangular shaped points. The fact that the results for the electrode stored for ten days (the square point) falls within the error limits of the data taken with freshly prepared samples

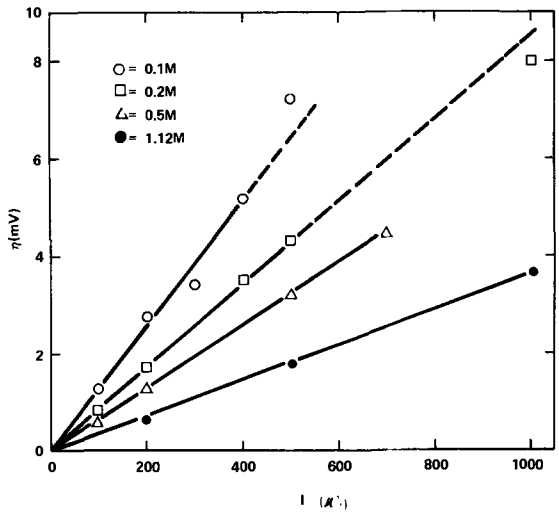

Fig. 3. Pulse, anodic, linear polarization for various concentrations of $LiClO_4$-$(CH_3O)_2SO$. Area = 0.486 cm^2, H_2O content < 20 ppm, T = 28°C.

indicates that effects of surface strain could not be detected.

If the reaction is a simple, one-electron transfer with the charge transfer step rate controlling, it can be shown (22, 23) that the transfer current density is related to concentration as follows

$$i_o = k_a^{(1-\alpha)} k_c^{\alpha} c^{\alpha}$$

where k_a and k_c are the kinetic rate constants for the anodic and cathodic rates, respectively, c is the concen-

tration of the lithium ion, and α is the transfer coefficient. From the least squares slope of the upper curve in Fig. 5, the transfer coefficient is found to be 0.49.

All of the electrochemical polarization data discussed above was taken in solutions with below 50 ppm water and using a 20 mA anodic, prepolarization pulse. In solutions with higher water content, comparing data taken with and without a prepolarization pulse, the apparent exchange current density increases when the prepolarization is omitted as shown in Fig. 6. In Fig. 7 is shown the variation of the overpotential with time for constant current pulses following a prepolarization pulse. Above 500 ppm water content a prepolarization pulse will no longer yield the higher exchange current density current-voltage behavior. A log-log plot of the apparent exchange current as a function of $LiClO_4$ concentration for a wet solution (500 ppm water) is shown as the lower curve in Fig. 5.

Discussion

The results of the chemical stability tests suggest that $LiClO_4$-DMSU solutions are stable with lithium or at least that reaction rates are not observable, except for a thin film formation or dulling of the surface, for up to two years provided the water content is below about 20 ppm. It appears that dry $LiCF_3SO_3$-DMSU solutions react slowly with lithium. Results of other workers (24-27) also suggest that such a conclusion is at least reasonable.

The chemical behavior of the aliphatic sulfides and the effects of water, various electrolytes, and alkali metals have been studied by numerous workers (28, 39). Cottrell and Mann (31) found that when perchlorates were present Cl^-, CO, and $NaCH_3SO_3$ were slowly formed. In our experiments, no Cl^- was detected in the precipitate and H_2 was evolved, not CO, indicating that the perchlorate was not involved in the reaction which we observed. Cottrell and Mann also observed different reaction products depending on water concentration. In the present study, the reaction product composition was independent of the water present, and the same product was observed in the absence of perchlorate ions implying that the perchlorate was not involved. Possibly the differences between this work and that of Cottrell and Mann are due to inherent greater stability of the sulfur bonds in dimethyl sulfite toward reaction with lithium compared to the compounds studied by Cottrell and Mann. Such variations in sulfur bond stability have been observed previously in this laboratory (40).

O'Connor and Lyness (36) observed that sodium and potassium appear to attack DMSO directly forming salts of methanesulfenate and methylsulfinyl carbanion along with methane and dimethyl sulfide. This type of attack does not appear to occur between lithium and dimethyl sulfite. The formation of hydrogen and subsequent decrease in water concentration indicates that it is the water which reacts directly with lithium to form hydrogen. Since no significant quantities of OH^- ions were found in the precipitate, it is reasonable to assume LiOH or Li_2O are at best intermediate species. It has been shown (29, 30) that the addition of dimethyl sulfite to aqueous KOH solutions results in the formation of K_2SO_3 (the reaction is complete). Our test of adding LiOH to dimethyl sulfite solutions yielded Li_2SO_3. From these results it is concluded that lithium first reacts with water, and an intermediate, possibly LiOH or Li_2O, reacts with dimethyl sulfite to form Li_2SO_3. This implies that in dry dimethyl sulfite solutions lithium is chemically stable, and such systems can be considered for secondary battery applications.

Film formation on lithium electrodes in $LiClO_4$-PC solutions has been considered by Dey (8), Scarr (9), Burrows and Kirkland (7), and Cogley and Butler

(4). Originally the composition of the film was considered to be LiOH (11). However, Dey (8) has suggested that in $LiClO_4$-PC solutions the film composition is more likely Li_2CO_3. The results of the present study indicate that a film formed in $LiClO_4$-DMSU solutions is probably Li_2SO_3.

Scarr (9) observed two levels of lithium activity in $LiClO_4$-PC solutions which were explained by the presence or absence of a surface film on the lithium. An anodic pulse of 3-5 mA/cm^2 or greater appears to remove the film. The lithium has a higher exchange current density with the film removed. Once removed, the film re-forms. These results in PC compare well with our observations for DMSU. The rate of film formation is implied in Fig. 7. The value of the exchange coefficient, α, of 0.55 in PC compares favorably with our observations of 0.49 in DMSU solutions. Scarr reports the higher value of the exchange current density, i_o, to be 1.22 mA/cm^2 in a 0.5M $LiClO_4$-PC solution. Our study in DMSU gives an i_o of 9.7 mA/cm^2 at 0.5M $LiClO_4$ (see Fig. 5). Scarr chose to locate his reference electrode near the edge and in the same plane as the working electrode. As shown by Tiedemann *et al.* (20), the observed overpotential for such a geometry can be four times as high as is characteristic of the average current density. If one attempts to correct Scarr's results for the nonuniform current density, reference electrode placement, and concentration polarization (22), a value of i_o equal to about 7 mA/cm^2 at a $LiClO_4$ concentration of 0.5M is obtained.

Butler *et al.* (5) performed experiments in $LiClO_4$-PC solutions on freshly cut lithium surfaces and obtained an i_o of 8 mA/cm^2 in a 0.257M solution. This value compares well with the results in DMSU (see Fig. 5). Butler *et al.* were concerned about possible recrystallization effects following slicing of the lithium. In our study, effects of recrystallization could not be detected; note the square point in Fig. 5. Comparing results of these experiments implies that recrystallization of fresh lithium slices occurs in a matter of seconds as is the case for lead and tin (41).

Stress Corrosion Cracking Behavior of Precracked 18-8 Stainless Steel

R. T. Newberg* and H. H. Uhlig†

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The critical potential is measured below which cracks in 18-8 exposed to $MgCl_2$, 130°C, no longer propagate. Some inhibiting ions, effective for crack initiation, are also evaluated with respect to crack growth. A surface oxide film is found to slowly form on stainless steels exposed to $MgCl_2$ solution; its role both in crack initiation and in crack growth is evaluated.

The importance of using precracked specimens to evaluate the stress corrosion cracking (SCC) behavior of titanium alloys in NaCl solutions at room temperature was first pointed out by Brown (1). He showed that cracks did not initiate in smooth stressed specimens, whereas cracks continued to propagate in specimens partially precracked by fatigue. The effect is usually ascribed to the stable passive film on titanium alloys which under normal exposure conditions in aerated neutral chloride solutions is not broken down, whereas, with continuing plastic flow, fresh metal is exposed. Furthermore, within a crevice, both low oxygen concentration caused by continuing uniform corrosion of metal, and acid anodic corrosion products induce breakdown of the passive film or prevent its reformation, and hence the crack process continues. It is of interest to learn whether similar conditions affect initiation and propagation of stress corrosion cracks in the stainless steels which also show pronounced passive behavior.

Results have shown that cracks in austenitic (2, 3) and ferritic stainless steels (4) initiate only above a well-defined critical potential. Pertinent questions are: does a critical potential also exist below which a crack stops propagating? Is such a potential the same as for crack initiation? Do inhibitors, effective for preventing initiation of SCC, also inhibit crack growth?

Experimental

Materials used for test specimens consisted of commercial Type 304 stainless steel of the following composition: 18.8% Cr, 9.2% Ni, 1.5% Mn, 0.06% C, 0.05% N, or Type 310 stainless steel of the composition: 24.8% Cr, 19.5% Ni, 1.7% Mn, 0.03% C, 0.05% N. The sheets originally 1/16-in. thick were cold rolled to 40-42 mil (0.102-0.107 cm) thick strip, and sheared to specimens measuring 1 3/4 × 3/16 in. (4.5 × 0.5 cm). After pickling in 15 v/o (volume per cent) HNO_3, 5 v/o HF at 90°C for 5 min, these were then tested as cold rolled or as heated in argon to 1050°C for 30 min and water quenched. They were stressed beyond the elastic limit to the shape of a C having a final span of 1 7/16 in. (3.7 cm), and held by porcelain insulators at constant flow stress by spring loading. Failure times were recorded by an electric clock. Electrical connection was made by means of a stainless steel wire of the same composition as the specimen, spot-welded to one end, and enclosed by closely fitting Teflon tubing.

The usual test solution was $MgCl_2$ solution boiling at 130°C, or LiCl solution boiling at 145°C. The electrolyte was contained in a Pyrex flask connected by means of a ground glass joint to a water-cooled condenser. Three side arms, separated from the main flask by glass frit separators, were filled with the same or more dilute electrolyte solution; two accommodated auxiliary electrodes and one a saturated calomel reference electrode, the latter being located near the surface of maximum stress in the test specimen. The detailed design of the apparatus was depicted in a previous publication (3). In general, failure times of stressed specimens were noted for a variety of fixed potential differences between the specimen and the saturated calomel electrode, the potential during the test being controlled by a potentiostat. The potential, determined within ± 3 mV, at or below which failure by SCC did not initiate for at least 100 hr was defined as the critical potential. It is reported on the standard hydrogen scale, neglecting small liquid junction and thermal gradient potentials. The applied potential required to stop crack growth was assessed by precracking a specimen for a fraction of an hour slightly above the critical potential, then polarizing the specimen up to 100 hr at various potentials below the critical value, followed by polarizing again to a potential slightly above the critical value until total failure occurred.

Results

Critical potential for crack initiation and crack propagation.—The critical potentials for crack initiation in smooth quenched 18-8 stainless steel exposed to $MgCl_2$ boiling at 130° and at 154°C are shown in Fig. 1. The value, −0.128 ±0.003V (SHE), is the same for the two concentrations of $MgCl_2$ within experimental variations of the test.

No cracks were found to initiate in stressed specimens polarized in $MgCl_2$ at 130°C for as long as 100 hr at or below the critical potential; for comparison the normal failure time of specimens not polarized is

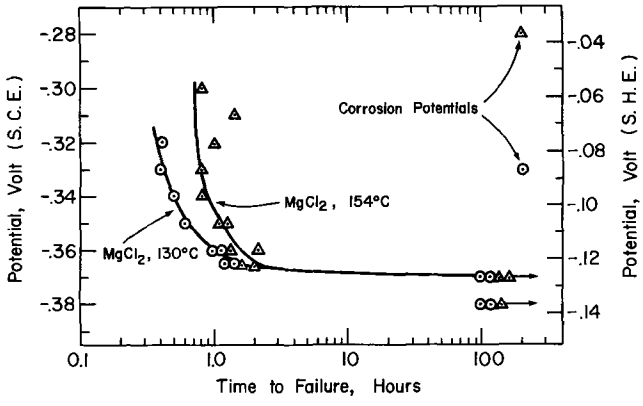

Fig. 1. Effect of applied potential on time to failure of 18-8 stainless steel, water quenched from 1050°C, in $MgCl_2$ at 130° and 154°C.

† Electrochemical Society Active Member.
Key words: oxide films on stainless steels, inhibitors of stress corrosion cracking, stress-sorption cracking, critical potentials for stress corrosion cracking.

1.4 ± 0.2 hr (3 specimens). Of importance is the observation that precracked specimens also polarized 5 mV below the critical potential do not fail within the maximum time of test equal to 100 hr. The specimens were precracked to a depth of 0.005-0.010 in. (0.013-0.025 cm) (as determined microscopically) by immersion for 0.2 or 0.3 hr in $MgCl_2$ at 130°C at a potential of −0.118V, which is 10 mV above (noble to) the critical potential (Fig. 2). This result means that even though visible shallow cracks have initiated, they will not propagate at applied potentials below the critical potential for crack initiation. Hence the critical potential for crack propagation is approximately the same as that for crack initiation.

It was observed that when smooth stressed specimens are prepolarized for several hours at 5 mV below the critical potential, the subsequent time to failure at a potential 10 mV above the critical value results in failure times that are longer than for specimens not prepolarized. The longer the time of prepolarization below the critical potential, the longer is the subsequent time to failure above the critical potential. The longer failure time following prepolarization is apparently the result of a prolonged induction time for crack initiation caused by slow build-up of a surface oxide (or basic chloride) film on exposure of stainless steels to the $MgCl_2$ solution. This explanation was supported by experiments in which specimens were pickled in the 15 v/o HNO_3, 5 v/o HF mixture at 90°C for 1 min after polarizing below the critical potential (without removing the specimen from the test apparatus) and noting the same short failure times as are observed for specimens not prepolarized.

The surface oxide film, which on long exposure times becomes thick enough to exhibit interference colors, also temporarily delays crack growth of precracked specimens, although not to the same extent as it delays crack initiation. The deeper the crack, the longer is the delay time caused by accumulation of oxide. But again, pickling the precracked specimens after polarization below the critical potential eliminated the observed delay in crack growth. Leckie (5) found similarly that prolonged cathodic polarization of a precracked Ti alloy in 3% NaCl increased subsequent failure time because of an accumulated surface oxide. The effects on 18-8 stainless steel are summarized in Table I.

Induction time for crack initiation.—Although an artificially produced thick surface film, as described, can appreciably slow down time for crack initiation or for resumption of crack growth, any thin oxide film formed on 18-8 or 25-20 stainless steel for a short time under normal exposure conditions at the corrosion potential has less effect. One of the properties of a growing surface oxide film resulting from normal exposure of stainless steels to $MgCl_2$ solution, as Lee and Uhlig showed (3), is to slowly shift the corrosion potential in the noble direction. At such time as the corrosion potential becomes equal to or noble to the critical potential, a crack is able to initiate. The time for the slow drift plus the additional time for crack initiation after critical and corrosion potentials coincide is the normal induction time.

* Critical potential for crack initiation = −0.128V (SHE).

For 18-8 stainless steel in $MgCl_2$ at 130°C, the initial corrosion potential and the critical potential are not far apart so that the induction time for cracks to initiate is short and in the order of 5 to 10 min. But for the same alloy exposed to LiCl at 145°C, the corrosion potential and the critical potential are farther apart and the induction time is longer. In absence of a thick surface oxide, but at a favorable potential, a crack initiates rapidly, as was shown by immediately polarizing pickled test specimens upon immersion in LiCl solution to a value either 5 or 45 mV above the critical potential and noting visible initiation of cracks within less than 2 min. The same situation applies to Type 310 stainless steel in $MgCl_2$ at 154°C which has an observed induction time for crack initiation of about 1 hr. The data are summarized in Table II.

Effect of inhibiting ions.—An inhibiting effect of nitrate ions on SCC of austenitic stainless steels in chloride solutions was reported by Phillips and Singley (6) and by several others (7-9). Uhlig and Cook (2) reported inhibiting effects of NO_3^-, acetate, I^-, and benzoate ions added to boiling $MgCl_2$ solution at 130°C. In accord with the latter results it was found in present measurements that 4% NaI added to $MgCl_2$ boiling at 130°C extends failure time of 18-8 to >200 hr. For the same concentration of $MgCl_2$ (approximately 36.5%) boiling at 130°C, but maintained at a lower temperature of 100°C, only 1.9% NaI was needed to extend failure time to >200 hr. The effect of I^- and other inhibiting ions is one of raising the critical potential for SCC to more noble values. In the case of I^-, the corrosion potential is simultaneously shifted in the active direction so that when the corrosion poten-

tial becomes active to the critical potential no cracks are observed to initiate. In the context of the present paper, it is also important to know the effect of inhibiting anions on propagation of cracks already initiated. Cracks about 0.005 in. (0.013 cm) deep were initiated in stressed 18-8 specimens by first immersing them (unpolarized) for 20 min in $MgCl_2$ boiling at 130°C, then transferring the specimens without removal from the test apparatus to a similar $MgCl_2$ solution at 130°C containing the NaI addition. It was found that up to 7.5% NaI very much slowed down but did not prevent failure of precracked specimens, whereas 4% NaI had effectively prevented crack initiation. Data are summarized in Table III.

Because of the lower transference number of I^- (slightly lower diffusion rate)[1] compared to Cl^-, it follows that within the narrow confines of a growing crack, the diffusing Cl^- ions always precede I^- ions to the crack tip which the inhibiting ions must reach in order to be effective. Although this situation has no influence on crack initiation, it makes I^- less effective as an inhibitor of crack growth. The question is: What would the situation be for a more rapidly moving inhibiting ion such as OH^- having a higher transference number than Cl^-? Such an experiment is not readily accomplished in $MgCl_2$ solution because of the limited solubility of $Mg(OH)_2$. In LiCl solution, however, the higher solubility of LiOH is more favorable. Normal failure time of 18-8 specimens in LiCl (saturated at room temperature) boiling at 145°C is 9.5 ± 2.3 hr (4 specimens) and 0.4% LiOH inhibits crack initiation. It was found that an addition of 0.8% LiOH to this solution was required to limit propagation of cracks 0.005-0.010 in. deep in precracked specimens assuring absence of failure for a period of at least 200 hr. Hence the faster moving OH^- ion is an effective inhibitor of crack propagation, but with more being needed for this purpose than to inhibit crack initiation.

The action of OH^- in LiCl solution, as for inhibiting anions in $MgCl_2$ solution, is to shift the critical potential in the noble direction. For example, 0.4% LiOH added to the above LiCl solution raises the critical potential of 18-8 by 15 mV from −0.153V (SHE) to −0.138V.

Discussion

The same approximate measured critical potential above which, but not below, cracks rapidly initiate in smooth specimens and propagate in precracked specimens indicates that the stress intensity factor is not a sensitive parameter governing the initiation of failure of 18-8 stainless steels by stress corrosion cracking. The results imply that either smooth or superficially precracked test specimens lead to the same results, and that notches or irregularities in the metal surface are not important. Since smooth and precracked specimens behave similarly it is also evident that fracture or breakdown of a passive film on stainless steels, unlike the situation for Ti alloys, is not an essential step in either crack initiation or crack propagation. Instead, the oxide film that slowly builds up in $MgCl_2$ solution, and which is obviously not the original passive film,[2] serves to delay both crack initiation and the continued growth of cracks that have already initiated only after it has attained appreciable thickness. The fact that the responsible oxide film forms visibly either below or above the critical potential for SCC can be taken as evidence that the critical potential is not that value necessary to inhibit corrosive attack, as in the usual cathodic protection of metals against corrosion. This fact is difficult to harmonize with any theory of SCC dependent on metal dissolution at the metal surface or at the base of a notch or crack. Similarly an initial corrosion potential that is active to the critical potential is inconsistent with the electrochemical model, interpreting the critical potential, in accord with the theory of cathodic protection, as the open-circuit anode potential of a corrosion cell. Instead, the critical potential, as has been discussed before (2-4), is better interpreted as the value above which damaging anions (*e.g.*, Cl^-) adsorb on appropriate defect sites causing disruption of metal bonds, and below which such anions desorb (stress-sorption cracking). On this model the action of inhibiting anions is to displace the damaging anions at the metal surface, making it necessary to polarize the specimen to a more noble value in order for damaging anions to reach the critical concentration necessary for crack initiation and growth.

The present results as reported for precracked specimens are valid only for cracks that are not deep. The limited throwing power of current in deep cracks or the limited surface diffusion of anions along deep crack surfaces alters the situation. Furthermore, differential aeration and analogous cells may appreciably change the composition and pH of electrolyte within a deep crack, thereby modifying the environmental factors acting to cause crack growth. These changes are less pronounced in shallow cracks of the order that are presently studied.

The effect of cold working a metal is to produce more defect sites on which damaging anions can adsorb, thereby making it easier for adsorption to occur, followed by a lowering of the critical potential to a more active value. This explains the more active critical potential for cold-worked 18-8 stainless steel (35% reduction of thickness) equal to −0.145V (SHE) as reported by Uhlig and Cook (2), compared to the value presently reported for the water-quenched alloy equal to −0.128V. Similarly, the critical potential for cold-rolled Type 310 stainless steel (35% reduction of thickness) (−0.123V) in $MgCl_2$ at 130°C is 10 mV more active than the value for the water-quenched alloy (−0.113V). This same trend of critical potential with cold work is also found for various nickel-bearing ferritic stainless steels, except for the 5% Ni, 18% Cr-Fe stainless steel which, because of its two-phase structure, is a special case (4).

The present interpretation of the induction time for crack initiation as being due to the time for the corrosion potential to reach the critical potential accompanying build-up of an oxide film and subsequent penetration of the oxide film, suggests a supplementary interpretation of the earlier results of Uhlig and Sava (11). They drew the conclusion that any oxide or so-called passive film on Type 310 (25-20) stainless steel in $MgCl_2$ solution at 154°C has no effect on failure times. This was based on tests of stressed cold-rolled specimens pickled at various times after previous immersion in $MgCl_2$ (0.5, 0.75, 1.25, and 1.5 hr) and then reimmersed in the same $MgCl_2$ solution. Their data showed that the failure times after pickling decreased linearly with time of previous immersion in the $MgCl_2$ solution, but that total failure times (including preimmersion times) for all specimens remained at 4.5 hr. The linear decrease is caused by metallurgical changes resulting from short-time heat-treatment at 154°C, as was further shown by tests on intentionally heat-treated specimens (in air). If we now take into account that the critical potential is unaffected by preimmersion (Table I), and, as subsequent measurements have shown, that the induction time for crack initiation (as observed microscopically) remains at about 1 hr for any of the pickled specimens whether preimmersed or not, the decrease in failure time with preimmersion time is then a measure of the rate of crack growth. In

[1] t_{I^-} for 0.05M ZnI_2 at 25°C = 0.618; t_{Cl^-} for 0.05M $ZnCl_2$ at 25°C = 0.635 (10).

[2] Anodic polarization curves of Type 304 stainless steel in $MgCl_2$ at 130°C show no passive region (2).

other words, the data of Uhlig and Sava show that heating of Type 310 stainless steel at 154°C for t_{Ht} in hours decreases the crack propagation time, t_{prop}, in accord with the equation

$$t_{Ht} = -0.96t_{prop} + 3.4$$

Since the total time to failure equals $t_{Ht} + t_{induction} + t_{prop}$ and taking $t_{induction} = 1$ hr, then substituting the equivalent of t_{prop} from the above equation $[3.4 - t_{Ht}]/0.96$, it is clear that within 4% experimental variation, total failure time for any of the intermediate pickled specimens preimmersed up to 1 hr is 4.55 hr. This value is close to what was observed.

It can be concluded, therefore, that a surface oxide film slowly forms on 25-20 stainless steel in $MgCl_2$ solution at 154°C, as it does on 18-8 stainless steel, and that its effect on the induction time is consistent with that described earlier in this paper.

The shift of corrosion potential of 18-8, and perhaps other stainless steels as well, with growth of an oxide film accompanies a gradually decreasing uniform corrosion rate in $MgCl_2$ solution (12). Lee and Uhlig (3) showed by weight loss measurements of a 19% Cr, 21% Ni stainless steel exposed 190 hr to $MgCl_2$ solution at 130°C and analysis of the solution for metal ions, that the surface oxide film is rich in iron (least soluble hydroxide) and is deficient in nickel.

The increased rate of crack propagation in stressed 25-20 stainless steel specimens following their heat-treatment at 154°C for 0.5-1.25 hr is presumably brought about by the favorable diffusion of impurities (*e.g.*, N atoms) to dislocations and similar imperfection sites taking part in the crack growth mechanism. Without sufficient alloyed nitrogen or similar specific impurities, the alloy is known to resist failure by SCC (13-16). An analogous effect of heat-treatment on crack propagation rates would be expected at 130°C.

Conclusions

1. The critical potential for crack propagation is approximately the same as that for crack initiation in 18-8 stainless steel. Hence the stress intensity factor, relating to an irregular, notched or precracked stainless steel surface, is not a sensitive factor in its stress corrosion cracking behavior.

2. The induction time for crack initiation consists in part of the time required for the corrosion potential to achieve the more noble value of the critical potential. For stainless steels exposed to $MgCl_2$ solution, the drift of potential accompanies slow build-up of a surface oxide film. A supplementary delay results from the time needed to penetrate the surface oxide.

3. Iodide ions in concentrations effective for inhibiting crack initiation, slow down but do not stop crack growth in 18-8 stainless steels in $MgCl_2$ solution. Hydroxyl ions, having a higher transference number than Cl^-, when added to LiCl solution more effectively inhibit crack growth as well as crack initiation.

Thermal and Mechanical Effects on the Corrosion Behavior of Ti-6Al-4V Alloy

D. L. Dull* and L. Raymond

Metallurgy Department, The Aerospace Corporation, Los Angeles, California 90045

ABSTRACT

Anodic and cathodic polarization behavior of Ti-6Al-4V alloy were determined by potentiostatic and galvanostatic techniques in deaerated 1, 5, and 10*N* sulfuric acid solutions. In the active region, metallurgical processing, which included cold rolling and thermal treatment, had no effect on the corrosion behavior. It is suggested that a titanium hydride film exists on the titanium alloy surface. In the passive region, plastic deformation, due to cold rolling, did increase the passive current density; whereas crystallographic texturing, did not have an effect. The introduction of an α'-phase due to thermal treatment produced an additional peak in the passive region.

Titanium alloys have found wide usage in commercial applications because of their high specific strengths and excellent corrosion resistance in aqueous solutions containing chloride ions. Most research studies have been directed at anodic and cathodic behavior of titanium alloyed with noble elements (1-4). Of the commercially used titanium alloys, relatively little data

Key words: material processing, titanium alloy, metal working, polarization.

are available discussing cathodic and anodic behavior. Levy (5) has studied the anodic behavior of Ti-6Al-6V-2Sn alloy (heat-treated to three strength levels), Ti-75A (annealed), and Ti-13V-11Cr-3Al alloy (annealed) in H_2SO_4 at various temperatures. Later research by Levy and Sklover (6) extended the study of anodic behavior to HCl solutions and included Ti-8Al-1Mo-1V alloy (single and duplex annealed) and Ti-6Al-4V alloy (annealed). Peters and Myers (7), again on the anodic behavior, have studied Ti-75A (annealed), Ti-6Al-2.5Sn (annealed), Ti-6Al-4V alloy (annealed), Ti-8Al-1Mo-1V alloy (duplex annealed), and Ti-13V-11Cr-3Al alloy (solution treated and aged) in H_2SO_4 solutions. It can be concluded that these titanium alloys do exhibit a typical active-to-passive transition in H_2SO_4 and HCl solutions in the concentration ranges studied. Increases in test temperature increased both the critical current density for passivity and the passive current density.

Tomashov and Ivanov (8) studied the effects of cold rolling and annealing on the corrosion of titanium in H_2SO_4 and HCl solutions. They identified effects of crystallographic texture and plastic deformation due to cold rolling. Their results showed that the effects of increasing the amount of cold rolling is to decrease the corrosion rate. This is contrary to corrosion studies of nontitanium-base materials where, generally, plastic deformation has an opposite effect or no effect; representative examples are summarized by France (9).

Heat-treatment of titanium alloys affects the microstructure and is expected to affect the anodic behavior. Levy (5) shows that the aging temperature of a solution-treated Ti-6Al-6V-2Sn alloy will change the critical current density for passivation. He postulates that this is due to the different α-phase-to-β-phase ratio resulting from the aging heat-treatment.

This study will determine the effects of cold rolling and thermal treatment on both the anodic and cathodic behavior of a Ti-6Al-4V alloy in 1, 5, and 10*N* H_2SO_4 solutions. Thermal treatments include annealed, and solution-treated and aged (STA) conditions. Cold rolling is used to bring about crystallographic texturing and an increased dislocation density.

Experimental Procedure

Characterization of material processing.—The starting material was 0.380-cm thick Ti-6Al-4V alloy sheet in the mill annealed (MA) condition (760°C, air cooled). Sheet stock material was processed by cold cross rolling to about 0.190-cm. The cold rolling was done in 20 passes, with initial reduction of 0.05 cm and the final reduction of 0.003 cm. An additional annealing treatment (700°C for 2 hr) was given to one section and another section was STA conditioned (940°C, water quench, 540°C for 4 hr, air cooled). A portion of the STA section was further cold cross rolled to 0.127-cm thickness. A list of the five processing sequences and the average Knoop hardness numbers are presented in Table I. The applied load of the Knoop Hardness Tester was parallel to the sheet normal. Metallographic examination of the processed material (Fig. 1) shows the annealed material contains a primary α-phase with an intergranular β-phase. The STA material contains primary α-phase in an α'-matrix.

Table I. List of material processes

Processing	Symbol	Knoop hardness number	Metallurgical phases present
Mill annealed[a]	MA	285	Primary α and β
Mill annealed[a] and 50% cold cross rolled	MAX	338	
Mill annealed,[a] 50% cold cross rolled, and annealed[b]	MAXA	328	
Solution treated and aged[c]	STA	335	Primary α and α'
Solution treated and aged and 30% cold cross rolled	STAX	351	

[a] 760°C, air cooled.
[b] 700°C for 2 hr.
[c] 940°C, water quench, 540°C for 4 hr, air cooled.

The sheet textures for the MA, MAX, and STA conditions that are represented by the (0002) basal quarter pole figures were determined with a General Electric Model 4968C autointegrating pole figure goniometer and are shown in Fig. 2. The details of the experimental procedure were reported in a previous work (10).

For the MA condition, the basal poles are primarily contained in the transverse direction with a small concentration in the rolling direction (RD). In the case of the MAX, the basal poles formed an annular concentration about the sheet normal with an absence of basal poles in the periphery. The rolling operation has caused the basal poles to rotate from the transverse and rolling directions to near alignment with the sheet normal. This allows one to compare the corrosion characteristics between the basal planes and the prismatic planes; *i.e.*, type I prism $(10\bar{1}0)$ and type II prism $(11\bar{2}0)$. In this study, an attempt was not made to resolve the more prominent prismatic plane. For the STA condition, a strong concentration of basal poles were found in the rolling and transverse directions. In addition, there was a strong concentration of basal poles at an angle of 40° from both the sheet normal and the transverse directions.

Electrochemical polarization.—Specimens (1.27-cm OD) were machined from the processed sheet, and each was mounted to a 1.27-cm-OD aluminum rod with silver epoxy paint. The specimen was then sealed with shrinkable Teflon tubing that encased the two materials and exposed only the titanium flat sheet surface to the solution. The electrochemical test cell basic design was from Greene (11). The following modifications were included: (*i*) a flat surface specimen holder was added, (*ii*) a saturated calomel electrode with a Luggin capillary probe replaced the salt bridge, and (*iii*) an enclosed platinum sheet electrode was used to eliminate oxygen in the test solution due to the oxygen evolution reaction.

An Anotrol potentiostat (Model 4700 M) was used for anodic polarization, and a Sorensen d-c power supply was used for cathodic polarization using galvanostatic techniques. A Keithley electrometer (Model 610B) was used to measure the potential *vs.* SCE. The H_2SO_4 solutions were prepared from reagent grade concentrated H_2SO_4 diluted with demineralized-distilled water ($>10^6$ ohm-cm). The solution was deaerated with 99.99% purity N_2 for at least 24 hr before a specimen was inserted into the test cell. Activation of the Ti-6Al-4V alloy specimen was performed by immersing in a 1:1:3 HF, HNO_3, lactic acid solution and rinsing with distilled water before inserting into the test cell.

Cathodic polarization was begun after a minimum incubation period of 24 hr for the 5 and 10*N* solutions and 48 hr for the 1*N* solution. During this incubation period, the corrosion potential increased in the noble direction. Reproducibility of cathodic data was not obtained unless these minimum immersion times were used. A steady-state potential was obtained within a 3-min interval with each incremental current increase. Anodic polarization was performed after cathodic polarization by increasing the potential in 20 mV increments and taking a reading after 3 min. In the passive region, larger incremental millivolt readings were taken.

Results

Cathodic polarization.—Cathodic polarization curves of the MA and STA materials in 1, 5, and 10*N* H_2SO_4 solutions are presented in Fig. 3 and 4. The cathodic polarization curves of the other processes can be readily superimposed on these curves (*i.e.*, MAX and MAXA on MA, and STAX on STA). Tafel regions were 1-2 decades in 1*N* H_2SO_4 solution. Corrosion currents were determined by extrapolating the Tafel slope to the measured corrosion potential. To obtain the corrosion

current density for the 5 and 10N solutions, the Tafel slope determined for the 1N solution was drawn tangent to the polarization curves of the 5 and 10N solutions and extrapolated to the corrosion potential. A summary of the cathodic polarization data is presented in Table II. From these results, there appears to be no effect on the electrode kinetics of the hydrogen evolution reaction due to either cold rolling or thermal treatment.

Anodic polarization.—Anodic polarization curves of MA, MAX, and STA material in 1, 5, and 10N H_2SO_4 solutions are presented in Fig. 5-7. The MAXA and STAX curves were similar in shape to the MA and STA anodic curves, respectively. Each material is shown to exhibit active to passive behavior. The annealed materials show a single active to passive be-

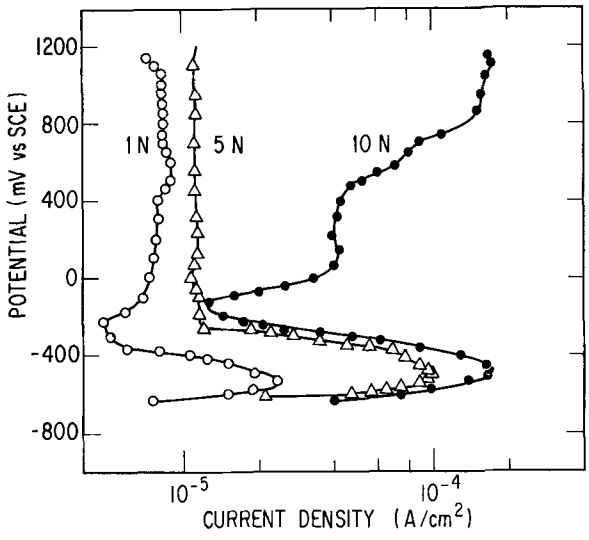

Fig. 5. Results from anodic polarization of MA Ti-6Al-4V alloy in H_2SO_4

havior, whereas the heat-treated material exhibits an additional peak in the passive region. The effect of cold rolling can be shown by comparison of Fig. 5 and 6. In the 1 and 5*N* H_2SO_4 solutions, the passive current density for the MAX is shown to increase with increases in noble potential, whereas it remains constant for the MA condition. A summary of anodic polarization data is presented in Table III. There appears to be no effect on the primary passivation characteristics due to either cold rolling or thermal treatment.

Discussion

Anodic and cathodic polarization.—The results from anodic polarization of the MA material are in good agreement with Peters and Myers (7) with the exception that in the 10*N* solution the passive film exhibits a form of breakdown.

Although data about cathodic polarization of commercial titanium alloy in H_2SO_4 is not readily available in the literature, a good comparison can be made with the work of Thomas and Nobe (12) on pure titanium. The observed Tafel slopes in our study ranged from 153-168 mV and agrees quite well with the reported value of 150 mV for pure titanium. The corrosion current density of the Ti-6Al-4V alloy, which contains two phases, are found to be slightly higher than those reported for pure titanium. The corrosion potentials of Ti-6Al-4V alloy measured in H_2SO_4 agree with Peters and Myers (7).

Effect of mechanical cold rolling and thermal treatment on cathodic polarization.—The processing methods used showed no significant effect on the corrosion potential, corrosion rate, or Tafel slope for the hydrogen evolution reaction (HER). Electrode kinetic studies have found that a film exists on the material surface in the active region. Thomas and Nobe (12) have studied the kinetics of the HER on titanium in the pH range of 0.25-2.25. To explain their experimental results, they assumed that a thin incipient film formed on the material surface. It was then possible to propose a mechanism for the HER based on the Temkin adsorption

tial and under cathodic polarization conditions. They showed that when the passive film is not stable, *e.g.*, in 5*N* HCl solution, a titanium hydride film will readily form. In a study of the electrochemical corrosion of titanium, Tomashov *et al.* (14) showed that the anodic polarization behavior of titanium is affected by prior cathodic polarization in a sulfuric acid solution. They demonstrated that after a forward-reverse anodic polarization run, the active corrosion potential became more active by approximately 0.1V. This effect was attributed to a titanium hydride film on the surface, which was produced by a prior cathodic polarization, that undergoes dissolution during the forward anodic polarization run.

In another study of anodic dissolution of titanium in sulfuric acid, Armstrong *et al.* (15) observed that after some time at a constant cathodic overpotential, the rate of hydrogen evolution increased and the metal dissolution decreased. This observed lowering of the hydrogen overpotential was attributed to the formation of a titanium hydride on the surface.

In a passivity study, Sukhotin and Tungusova (16) compared the anodic polarization of titanium and titanium hydride and found them to be similar in their transition from the active to passive state in a sulfuric acid solution. It was postulated that the passivation of titanium is due to the appearance of a passivating oxide on an already covered hydride surface. They further calculated the standard potential for the reaction, $Ti + 2H^+ + 2e \rightleftharpoons TiH_2$, to be 0.21V *vs.* SCE based on the free energy of formation being −20.9 kcal/mole to thermodynamically support the presence of titanium hydride layer on the titanium surface. The free energy of formation of TiH_2 has also been reported to be −25.13 kcal/mole by another source (17).

It is thus suggested from the literature, that in the active region where the titanium has been exposed to either concentrated acid solutions or cathodic polarization that the film which forms on the titanium surface is most likely a titanium hydride. This formation of a titanium hydride film on the Ti-6Al-4V alloy surface can explain why thermal treatment and cold rolling have no observable effects on the corrosion behavior. Further, it explains why an incubation period was required before the cathodic polarization data became reproducible. If a titanium hydride was not present, definite effects on corrosion behavior would be expected since the HER is markedly influenced by metallurgical variables (18). The various processing methods of the Ti-6Al-4V alloy in this study have considerably changed the metallurgical variables. These changes include: (*i*) crystallographic orientation, (*ii*) increased dislocation density due to plastic deformation, and (*iii*) metallurgical phases present (intergranular β in a primary α-matrix or primary α in an α'-matrix). However, since these effects did not change the corrosion behavior, either the various processing methods have no effect or the presence of a titanium hydride film on the surface in the active region conceals any influence of the various processing methods. The latter explanation is believed more reasonable. This titanium hydride film formation would also explain the differences between the results of our study and those of Tomashov and Ivanov (8) where they used weight loss techniques.

Effect of cold rolling and thermal treatment on anodic polarization.—Cold rolling and thermal treatment have been shown to have little effect on the active-to-passive transition. The effect of the metallurgical variables is apparently diminished by the presence of the titanium hydride film during the transition. It may be that the passive oxide film is forming directly on the titanium hydride film as suggested by Sukhotin and Tungusova (16).

Cold rolling and thermal treatment show significant effects in the passive region. The effects of cold rolling, in particular, rotation of the basal plane about the rolling direction and increased dislocation density, are shown in Fig. 8. The MA anodic polarization curve represents a material whose basal poles lie primarily in the transverse direction with a small concentration in the rolling direction (see Fig. 2). The dislocation density in MA material is considered minimal. The MAX curve represents a cold-rolled material in which the basal poles are rotated to form an annular concentration about the sheet normal with an absence of basal poles in the periphery. In addition, the dislocation density has been increased. The effect of cold rolling increased the passive current density at a given potential. To determine which of the cold rolling effects was more influential, the material was given the additional annealing treatment that produced a recrystallized structure without a loss of the crystallographic texture obtained from cold rolling. This caused the material to behave as the MA material. The MAXA represents this material. It can be deduced that crystallographic texturing is not as significant an influence as the dislocation density. Foroulis and Uhlig (19) during their study of the effect of cold work on iron and steel corrosion concluded that crystallographic orientation should have a more significant effect on corrosion behavior than dislocation density. However, our observations are being made on material that is in the passive region. It appears that the effect of the increased dislocation density is to increase the available active dissolution sites in the passive film. The crystallographic orientation does not play a dominant role because the corrosion of titanium in the passive region is limited by diffusion of the titanium ion through the passive film. When the material is given an annealing treatment, the dislocation density is decreased. This reduces the active dissolution sites and results in a decrease of the passive current density. This same behavior was also observed in the 5*N* H_2SO_4 solution; however, it was not observed in the 10*N* solution because the passive film exhibited a form of breakdown.

The effect of thermal treatment in the passive region is shown in Fig. 7. The introduction of the α'-phase appears to produce an additional peak in the passive

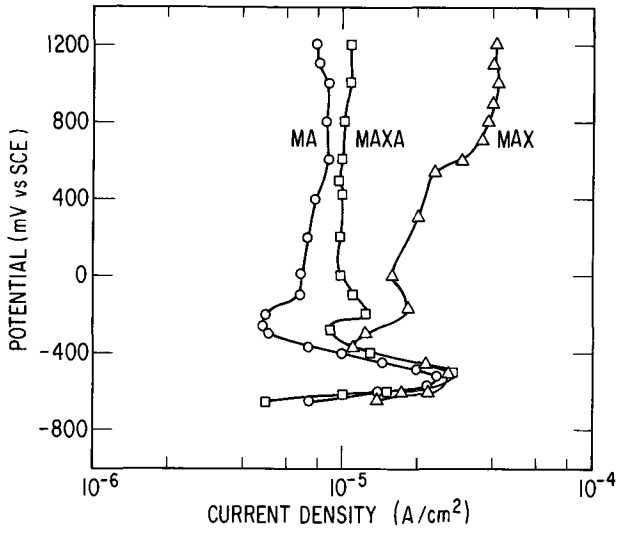

Fig. 8. Effects of cold rolling on Ti-6Al-4V alloy in 1*N* H_2SO_4; see text.

region. This additional peak has not been reported in the titanium alloy literature because most of the titanium alloys studied have been in the annealed condition. Levy (5) studied the effect of strength level on a Ti-6Al-6V-2Sn alloy and did not observe an additional peak although his microstructure is similar to ours for his highest strength material. The discrepancy is apparently due to the activation procedure and cathodic polarization testing conducted in our study prior to the anodic polarization. Cold rolling had no significant effect on the shape of the anodic polarization behavior of the STA material.

Conclusion

The metallurgical variables have shown no effect on the corrosion behavior of Ti-6Al-4V alloy in the active region. Neither of the effects of cold rolling, increased dislocation density and rotation of the basal pole from the transverse direction to a direction parallel to the sheet normal, influenced the corrosion current density or corrosion potential. The thermal treatment that changed the microstructure of the annealed condition from β-phase in a primary α-matrix to primary α-phase in an α'-matrix, *i.e.*, the STA condition, also showed no effects. It is thus suggested that a titanium hydride film exists on the titanium alloy surface.

The metallurgical variables do have an effect on the passive region. Cold rolling increased the passive current density of Ti-6Al-4V alloy consisting of β-phase in a primary α-matrix. This increase is attributed to an increase in the dislocation density and not to crystallographic texturing. Increased dislocation density is believed to increase the active dissolution sites in the passive film. Since the titanium ion transport through the passive film is rate determining, effects of crystallographic orientation are not observed. The thermally treated material, which consisted of primary α in an α'-matrix, exhibited an additional peak in the passive region. This peak is attributed to the introduction of the α'-phase. The cold rolling showed no significant effect on thermally treated material.

The Transient Behavior of Passivated Iron under Cathodic Potential Pulsing

Kotaro Ogura[*,1] **and Norman Hackerman**[†]

Department of Chemistry, Rice University, Houston, Texas 77001

ABSTRACT

Electrochemically reduced iron was first anodized in a basic solution at potentials in the passive region. The steady-state passivated iron then was subjected to a single cathodic potential pulse and then was cathodically reduced. In the initial stage of pulsing, the log of response current was linearly related with time at various preanodizing potentials. This relationship held at each temperature, but the slope depended on the solution temperature and the preanodizing potential. The shape of the cathodic reduction curve and the amount of charge needed for reduction were approximately the same whether or not the cathodic potential pulse was applied before cathodic reduction. Experimental results support the premise that cathodic potential pulsing does not influence the so-called bulk oxide but only the surface of passivated iron. In particular, the adsorbed oxygen on passive iron is influenced by the pulsing. The response current is explained by the cathodic reduction of adsorbed oxygen. Various kinetic parameters for the reduction reaction of adsorbed oxygen under cathodic pulsing were estimated from the experimental results, and it was found that appreciable coverage on passive iron by adsorbed oxygen appeared only at potentials far more noble than those in the Flade region.

It has been reported (1-5) that the electrode potential of passivated iron is controlled simply by the thickness of the surface oxide. However, it is questionable (6) whether a surface oxide such as γ-Fe_2O_3, which has to be assumed to be a good electronic conductor, can control the electrode potential. There is no agreement as to where the potential drop appears.

Recently it was reported that the potential of passivated iron is not a linear function of the film thickness (7) but is controlled by a small amount of electric charge accumulating in or on the surface film (8). Work from this laboratory (9-11) has emphasized that interface conditions between metal and solution are very important for producing or maintaining passivity and that the solid part of this interface cannot be treated simply as the bulk oxide-covered or clean surface metal (12, 13).

Experimental

Materials.—Zone-refined iron was supplied by Battelle Memorial Institute and had the following impurities: carbon, 10 ppm; oxygen, 23-28 ppm; nitrogen, 2 ppm; hydrogen, 0.1 ppm. The samples were 4-mm diameter rods which were inserted into a cylindrical Teflon plug, leaving one flat edge exposed. The plug was mounted in a glass support with a brass center rod screwed through the Teflon plug and into the iron rod to provide good electrical contact. After abrading with 4/0 emery paper, the specimens were electropolished in a mixture of glacial acetic acid and 70% perchloric acid at a current density of 0.45 A/cm^2 (14). The electropolishing was performed before each anodization, and the roughness factor was assumed to be approximately 1.0. All solutions used were 0.01M [0.5 w/o (weight per cent)] in $Na_2B_4O_7$ and pH of 9.20. According to Dulat (15), the specific conductivity of solution of borax in water at 20°C is: 1.72×10^{-3} mho/cm for 0.5 w/o borax; 3.17×10^{-3} mho/cm for 1 w/o borax; 5.79×10^{-3} mho/cm for 2 w/o borax. Solutions were prepared from analytical reagent grade borax and water redistilled from an alkaline permanganate solution. The solution was deaerated with nitrogen which had been passed through a column of active copper heated at 200°C, and the final solution was pre-electrolyzed for 48 hr at a current density of 80 μA/cm^2.

Cell.—The electrolytic cell was constructed of Pyrex and consisted of three compartments. The test cell was connected to the counterelectrode cell through a fine frit and to the reference electrode cell through a solution-lubricated glass stopcock. All three partitions contained the same solution. Potentials were measured with respect to the reversible hydrogen electrode (RHE). Both the counterelectrode and the reference electrode were of platinum. The three compartments were water-jacketed and temperature was maintained to ±0.5°C.

Electrical apparatus and procedure.—The passivation of iron was carried out potentiostatically at various anodizing potentials controlled by a Wenking fast-rise potentiostat. Potentials were measured on a Model 610B Keithley electrometer. Current was recorded as the ohmic drop across a standard resistance of 100 ohms on a Tektronix 535A oscilloscope equipped with a Type B calibrated preamplifier. The electrode was anodized for 20 min unless otherwise noted and then a single cathodic potential pulse of 5 msec was applied. The pulse generator was a Tektronix 160-series instrument and was triggered by an initiating pulse derived from the oscilloscope. After a single cathodic potential pulse was applied and the response current recorded photographically on the oscilloscope, the electrical circuit was quickly changed to a constant current circuit in order to reduce the passive film. Cathodic reduction was carried out at a current density of 20.9 μA/cm^2. The change in potential was followed by an X-Y recorder (Moseley Company, Model 2DR2) equipped with a Model 610B Keithley electrometer with gain of unity and an input impedance of 10^{13} ohms. In order to obtain the Q-values, the area of current *vs.* time curve was determined by a graphical integration using a planimeter.

Results

Current-time curves.—The cathodic potential pulse was applied to the steady-state passive electrode which had been preanodized at various potentials from 20 to 1690 mV (RHE). Typical response currents are plotted against time in Fig. 1 at pulse amplitudes of 50,

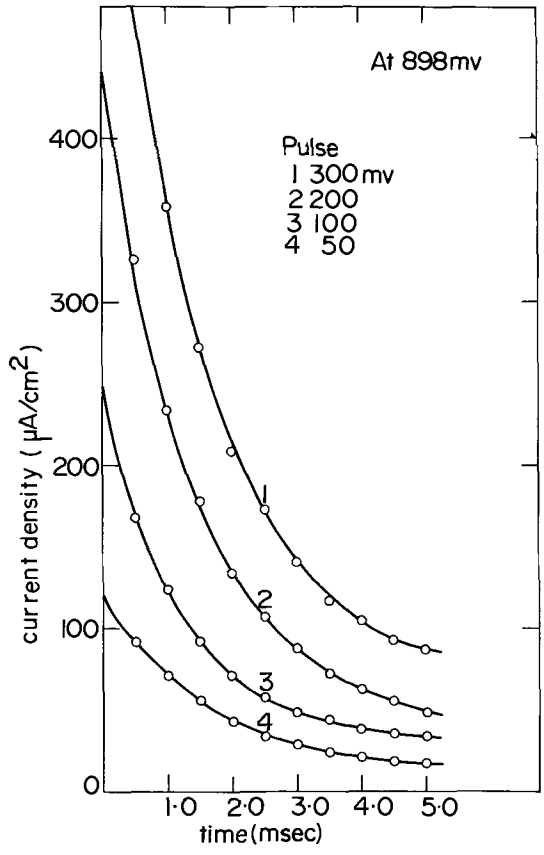

Fig. 1. Response current density of various cathodic potential pulses during preanodizing at 898 mV.

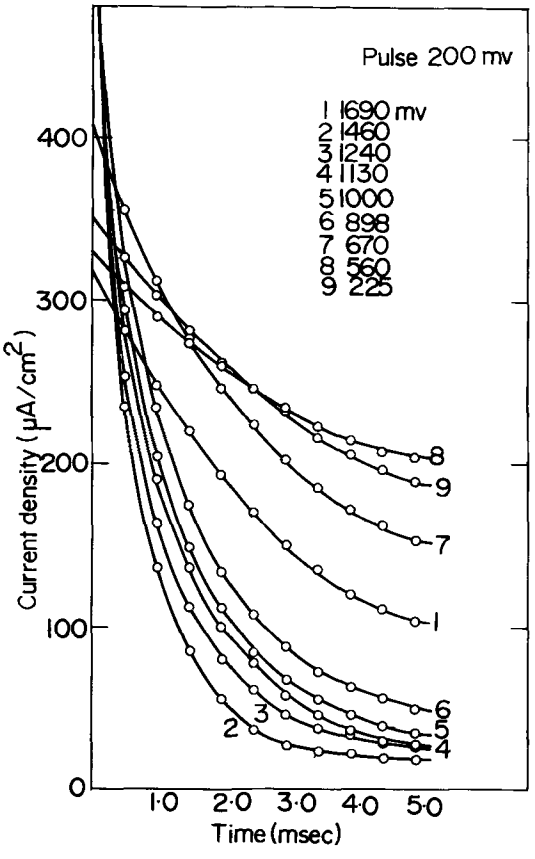

Fig. 2. Response current density of cathodic 200 mV pulse during various preanodizing potentials.

100, 200, and 300 mV. Response currents depended on preanodizing potentials and pulse amplitude. The drop of current with time was smaller in the less noble potentials than in the more noble potentials. Current density was significantly affected by the potential pulse amplitude, increasing with increasing pulse amplitude, especially at the less noble potentials.

Figure 2 shows the current-time relationship for various preanodizing potentials at a constant pulse amplitude of 200 mV. As preanodizing potentials were increased, current densities decreased except at 1690 and 225 mV. This can be also seen in Fig. 3.

Current-potential curves.—In Fig. 3, current densities at a pulse duration of 5.0 msec are plotted *vs.* preanodizing potentials. Except for the potential region more negative than 300 mV and more positive than 1600 mV, response current generally decreased as preanodizing potential, at each pulse amplitude, was increased. The potential regions more negative than 300

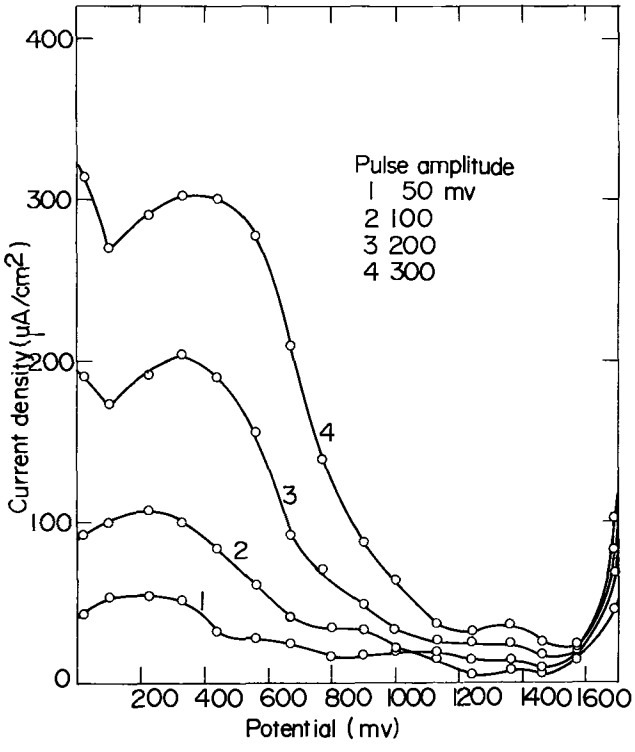

Fig. 3. Response current density at pulse duration of 5.0 msec vs. preanodizing potential.

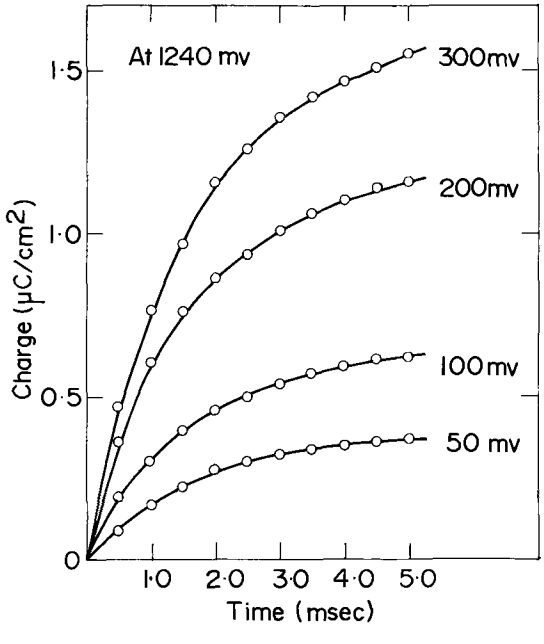

Fig. 4. Amount of charge passed under cathodic pulsing at various pulses vs. time.

mV and more positive than 1600 mV are discussed in a later section in greater detail.

Amount of charge passed under cathodic pulsing.—In Fig. 4, the amount of charge passed during cathodic pulsing is plotted against time at the constant preanodizing potential of 1240 mV. The amount of charge was calculated from the original current-time curves. Even at a pulse amplitude of 300 mV, the amount of charge passed during 5.0 msec was only 1.55 μcoulombs/cm^2. This value is small compared with that measured from the current after the potential was changed abruptly to the anodic side (about 1 mcoulomb/cm^2). This is in agreement with the data reported by Sato (7) and Cartledge (8).

Logarithmic current-time curves.—The logarithmic response currents of various pulses at various preanodizing potentials are shown in Fig. 5-8. In the initial stage of pulsing, the log of current is linearly related with time. This relationship held at each temperature, but the slope depended on the solution temperature and the preanodizing potential.

Cathodic reduction.—After the specimen was subjected to a cathodic potential pulse, the electrode was cathodically reduced. A typical chronopotentiogram is shown in the upper part of Fig. 9. The first arrest occurs at about +250 mV, the second at about −130 mV, and the third at about −200 mV. Q_A and Q_B are the amount of charge for the complete reduction and for the first wave, respectively. In Fig. 9, Q_A and Q_B are plotted *vs.* preanodizing potential for cases with and without cathodic potential pulsing before cathodic reduction. The plot of the amount of charge *vs.* the anodizing potential has been reported before (16). The amount of charge was approximately the same in both cases with and without potential pulsing before reduction. As shown in Fig. 10, the amounts of charge, Q_A and Q_B, are independent both of the length of preanodizing time and of potential pulsing, after 20 min anodization. Cathodic reduction of passivated iron is therefore independent of a previously applied cathodic pulse.

Discussion

In an alkaline solution, water molecules in the Helmholtz double layer at a passive iron surface tend to be oriented with the oxygen atom toward the passive film (17, 18). The water zone contributes to

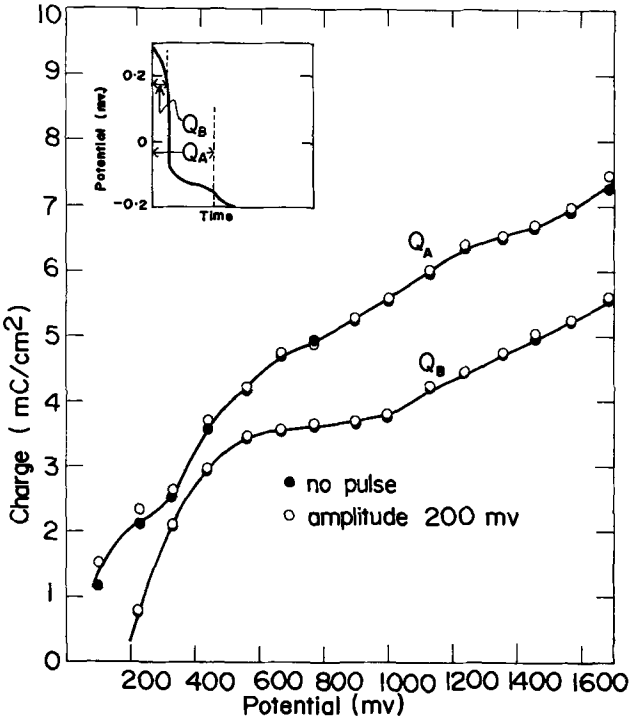

Fig. 9. Amount of charge needed for cathodic reduction vs. preanodizing potential.

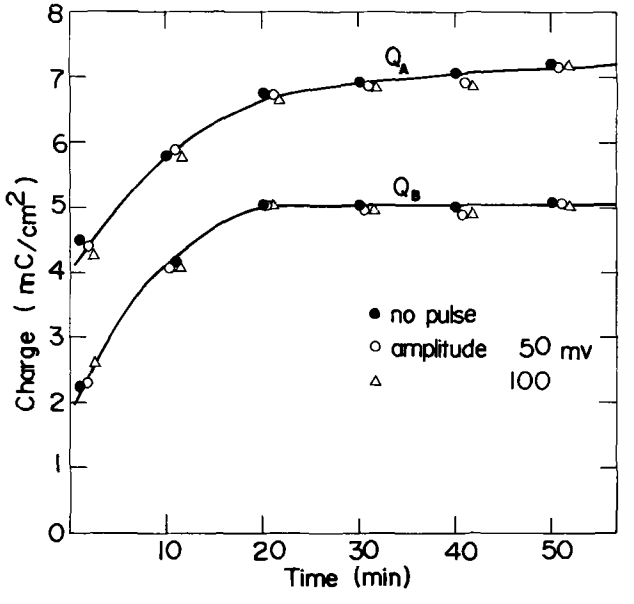

Fig. 10. Amount of charge needed for cathodic reduction vs. preanodizing time.

the anodic inhibition of iron or to the growth of a passive film. According to Bloom and Goldenberg (19) or Nagayama and Cohen (16), the outermost γ-Fe_2O_3 layer of the passive film may have a defect structure which involves cation vacancies or adsorbed oxygens.

As shown in Fig. 9 and 10, the amount of charge required for the reduction of the passive film was approximately the same whether or not a cathodic potential pulse had been applied before reduction. This means that the constitution of the passive film was not influenced by the potential pulse applied previously. Therefore, cathodic pulsing does not appear to control the so-called bulk oxide but only the surface on passivated iron. Further, with the fast-rise potentiostat, the electrical double layer capacity should be charged within microsecond order, whereas the current density was followed by an oscilloscope in millisecond order. Thus, the current density due to double layer charging or discharging could be considered to be zero.

This behavior appears to be explainable only by the cathodic reduction of adsorbed oxygen during the cathodic pulsing, since the transient current due to discharging the electric double layer can be neglected in a potentiostatic experiment using a high response potentiostat. The following reaction can be considered to occur under cathodic pulsing

$$Me_xO_y - O + H_2O + 2e \rightarrow Me_xO_y + 2\,OH^- \qquad [a]$$

where Me_xO_y is the passive film and $-O$ is the adsorbed oxygen on passive film. In other words, the response current of the potential pulse is due to the reduction of adsorbed oxygen and is represented by the following equation

$$i = n\mathbf{F}C_0k_0 \exp\left(-\frac{\alpha n\mathbf{F}V}{RT}\right) \qquad [1]$$

where C_0 is the surface concentration of adsorbed oxygen, and the other symbols have their usual significance. V is the electrode potential which was measured with respect to the reversible hydrogen electrode (RHE). The reverse reaction was neglected because of the large amplitude of the cathodic pulse.

If the response current is due only to the reduction of adsorbed oxygen, the rate of decrease of adsorbed oxygen can be expressed by Eq. [2]

$$-\frac{dC_0}{dt} = \frac{i}{n\mathbf{F}} \qquad [2]$$

From Eq. [1] and [2]

$$C_0 = C_0^* \exp\left(-k_0t\, e^{-\alpha n\mathbf{F}V/RT}\right) \qquad [3]$$

where C_0^* is the initial concentration of adsorbed oxygen. The time is calculated from the instant of applying the pulse. By substituting Eq. [3] into Eq. [1]

$$i = n\mathbf{F}k_0C_0^* \exp\left(-k_0t\, e^{-\alpha n\mathbf{F}V/RT} - \frac{\alpha n\mathbf{F}V}{RT}\right) \qquad [4]$$

Equation [4] is the expression for the response current under cathodic potential pulsing.

Transient behavior at room temperature.—Figures 5 and 6 show the logarithmic current *vs.* time plot. The logarithm of current is linearly related with time in the initial stage of pulsing. This relationship can be explained by Eq. [4]; that is, by differentiating the logarithm of Eq. [4] with time

$$\left(\frac{\partial \log i}{\partial t}\right) = -\frac{k_0}{2.303} \exp\left(-\frac{\alpha n\mathbf{F}V}{RT}\right) \qquad [5]$$

The initial slopes in Fig. 5 and 6 correspond to the right-hand side of Eq. [5]. The equation states that the plot of log i *vs.* time yields a straight line. The deviation from the line observed under the condition of long time as shown in Fig. 5 and 6 must be due to the contribution of the reduction of bulk oxide. Note that k_0 can be estimated from these experimental results and is discussed later.

Figure 3 shows the response current density at the pulse duration of 5.0 msec *vs.* preanodizing potential. Except for the potential region more negative than 300 mV and more positive than 1600 mV, response currents generally decreased as preanodizing potential was increased. The concentration of adsorbed oxygen in reaction [a] must be a function of the preanodizing potential, because the chemical force between the passive film and the adsorbed oxygen depends on the electrode potential. The shift of the preanodizing potential in the positive direction means an increase of the adsorbed oxygen concentration, and causes the initial potential of reaction [a] to become more noble. Here, the concentration of adsorbed oxygen can be con-

trolled only by the electrode potential since the pH of the solution was always constant. In Fig. 3, various potential pulses were applied to the electrode preanodized at a constant potential. In other words, the concentration of adsorbed oxygen was always constant before applying various pulses. The increase of the response current density with decreasing preanodizing potentials in the region between about 1600 mV and about 300 mV can be explained by the cathodic polarization of reaction [a].

When there is onset of oxygen evolution in the noble preanodizing potential, however, there will be the reduction of the molecules dissolved during preanodization

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O \qquad [b]$$

This may be the reason why the current density in Fig. 3 increased at potentials more noble than about 1600 mV. On the other hand, the decrease of current density at potentials less noble than about 300 mV, as shown in Fig. 3, may be due to the dissolution of bare iron. If the electrode potential passes through the Flade region by the applied potential pulse, the passivated iron would become active, and there should be dissolution of iron. The response current (which is negative) of the cathodic potential pulse will be reduced by the current for this reaction since it is anodic.

The amount of charge passed under cathodic pulsing shown in Fig. 4 corresponds to the decreased amount of adsorbed oxygen according to reaction [a]. For the 200 mV pulse amplitude, the amount of charge is about 1.6 μcoulombs/cm² at 5.0 msec at the preanodizing potential of 1240 mV. This corresponds to 9.9×10^{12} adsorbed oxygen atoms/cm², while for the 50 mV pulse amplitude, 2.2×10^{12} adsorbed oxygen atoms/cm² are obtained.

In Fig. 11, the logarithm of the current density at zero time in Fig. 5 and 6 is plotted *vs.* the electrode potential which was obtained by subtracting the pulse amplitude from the preanodizing potential. At each preanodizing potential, the logarithmic current density is linearly related with the electrode potential

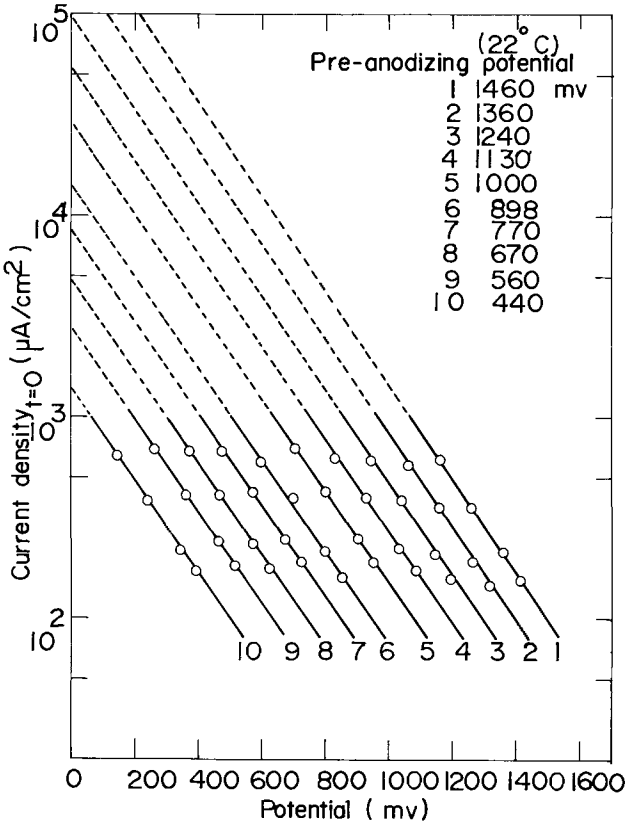

Fig. 11. Response current at the time of zero *vs.* electrode potential for specimen preanodized at various potentials.

Table I. Concentration of adsorbed oxygen on passivated iron before applying cathodic potential pulse at various preanodizing potentials

Preanodizing potential (mV)	i_o^* (mA/cm²)	C_o^* (10^{-10} mol/cm²)
1460	540	10.6
1360	180	3.52
1130	55	1.07
1000	29	0.56
898	14	0.27
770	8.5	0.17
670	4.8	0.09
560	2.8	0.05
440	1.4	0.03

(RHE), and the slope is always 2.27×10^{-3} (mV^{-1}).

If the logarithmic current of Eq. [4] is differentiated by V at zero time, Eq. [6] is obtained

$$\left(\frac{\partial \log i}{\partial V}\right)_{t=0} = -\frac{\alpha n \mathbf{F}}{2.303RT} \qquad [6]$$

The slope in Fig. 11 corresponds to the left-hand side of Eq. [6]. In the equation, α is an unknown parameter, and n is 2 according to reaction [a]. From the experimental results, α was estimated to be 0.1. The intercept of the line at electrode potential zero yields the logarithm of current density at zero time. From Eq. [4], the current density on this condition can be represented by Eq. [7]

$$i^*_{\substack{t=0 \\ V=0}} = n\mathbf{F}k_oC_o^* \qquad [7]$$

The value of i^* for each preanodizing potential is tabulated in Table I. If the value of k_o is known, the concentration of adsorbed oxygen at the preanodizing potential can be estimated from Fig. 11 and Eq. [7].

k_o was calculated by the following method. If the logarithm of the left-hand side of Eq. [5] is plotted against the electrode potential, the intercept at the potential of zero should give (k_o/2.303). Such a plot is shown in Fig. 12 and the intercept is 1.15×10^2 (1/sec). From this value, k_o was estimated to be 2.65×10^2 (1/sec).

The concentration of adsorbed oxygen on passivated iron at various preanodizing potentials was calculated by using k_o, and the results are shown in Table I.

Figure 13 shows the surface coverage θ of adsorbed oxygen which was obtained by assuming that the coverage at 1360 mV is 1.0. Appreciable coverage appears at about 300 mV, and increases abruptly at about

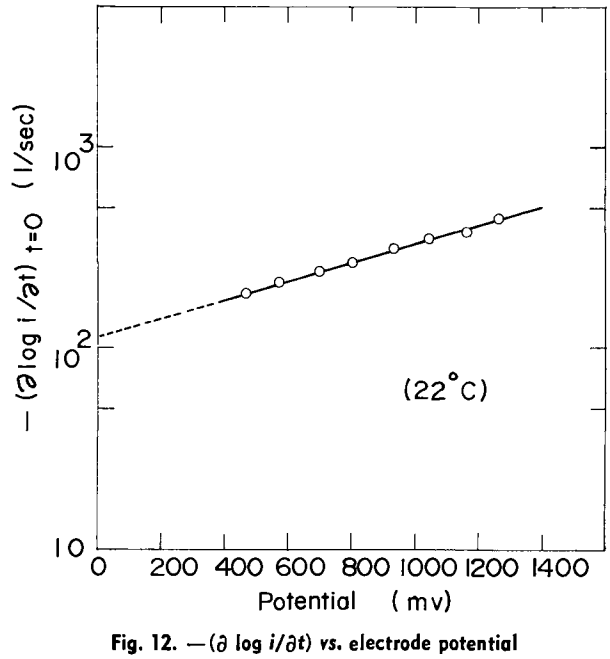

Fig. 12. $-(\partial \log i/\partial t)$ *vs.* electrode potential

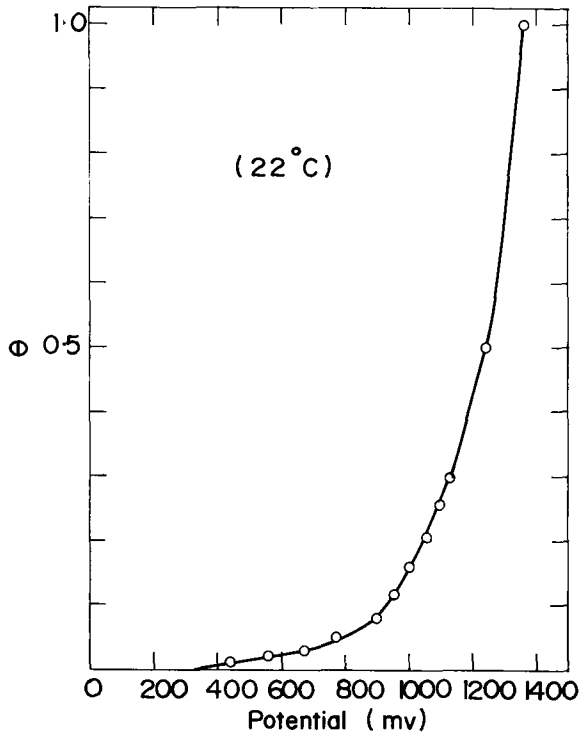

Fig. 13. Coverage vs. preanodizing potential

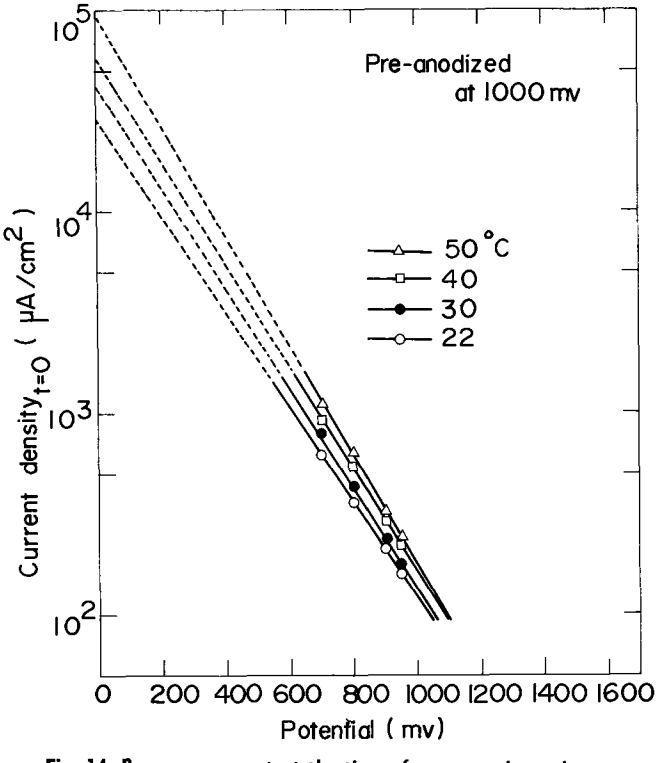

Fig. 14. Response current at the time of zero vs. electrode potential in various solutions. All specimens were preanodized at 1000 mV.

900 mV. It may be concluded that the adsorption of oxygen atom on passive film appeared only at potentials more noble than the Flade region, and that oxygen evolved effectively at more noble potentials than 1360 mV. In another experiment (20), a passive film was produced and the cathodic potential pulse was applied in a solution containing chelating agents. Reduction of the adsorbed oxygen by the cathodic pulse was depressed, presumably because adsorbed oxygen was replaced by the chelating agent.

Temperature dependence of the transient behavior.— In Fig. 7 and 8, the logarithmic current density is

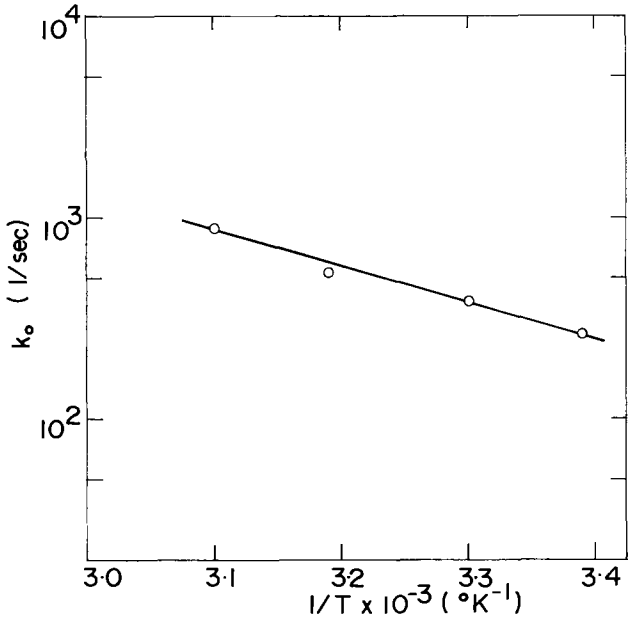

Fig. 15. Arrhenius plot of k_o

shown *vs.* time at the temperatures 40° and 50°C. The logarithm of the current density at zero time is plotted against the electrode potential in Fig. 14 according to the same procedure as that in Fig. 11. The intercept at the electrode potential of zero is $i^*_{\substack{t=0\\V=0}}$ of Eq. [7], and depends on the solution temperature. If the value of k_o is known, C_o^* can be evaluated. k_o was estimated by the same method as that employed above, and the result is shown in Fig. 15. Using these values and $i^*_{\substack{t=0\\V=0}}$ in Fig. 14, C_o^* was calculated according to Eq [7]. C_o^* was not influenced significantly by the change in the solution temperature, and was about 0.6×10^{-10} mole/cm^2 at the preanodizing potential of 1000 mV. However, a dependence of k_o on temperature was observed, and the logarithmic k_o is plotted against $1/T$ in Fig. 15. From this Arrhenius plot, the activation energy of reaction [*a*] was found to be 8.24 kcal/mole. Although there are no data in the literature for comparison, it should be noted that 8 kcal/mole is close to the activation energy often quoted (21) for an electrochemical reaction on metal.

The Nucleation with $SnCl_2$-$PdCl_2$ Solutions of Glass Before Electroless Plating

C. H. de Minjer* and P. F. J. v.d. Boom

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

It has been generally accepted that metallic palladium nuclei are formed by the nucleation procedure of nonconducting substrates with stannous chloride and palladium chloride solutions. However, results of experiments on glass using radioactive tracers and ellipsometry have shown that no metallic palladium is present after the nucleation procedure. The results indicate that presumably a tin-palladium complex, containing one palladium atom per two tin atoms is formed and that this initiates the nickel-phosphorus deposition from a suitable electroless plating solution.

Before a nonconductive substrate can be plated by an electroless process, it is necessary to nucleate the substrate. A widely used procedure for this nucleation involves "sensitization" and "activation" in a stannous chloride and a palladium chloride solution, respectively. The explanation widely accepted for this procedure [see for example Ref. (1) to (5)] is that the stannous ions reduce the palladium ions to finely divided metallic palladium nuclei on the surface of the substrate according to the equation

$$Sn^{2+} + Pd^{2+} \rightarrow Sn^{4+} + Pd \qquad [1]$$

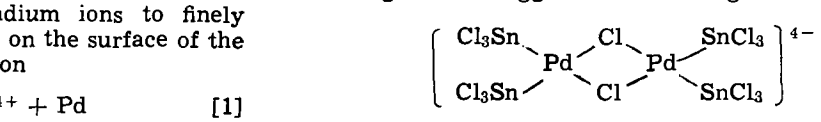
The palladium nuclei should then initiate the autocatalytic plating process.

Recently some doubt has been raised against this simple explanation. Goldie (6) concludes in a literature survey of the nucleation and activation process that the detailed mechanism is somewhat obscure. Chow and co-workers (7)[1] mention that Eq. [1] presumably leads to the formation of a Pd-layer on the substrate. However, irradiation of the sensitized and activated substrate with uv light inhibits the deposition of nickel or cobalt. The authors believe that this can be explained by a change in the crystalline structure of the Pd nuclei, but they also state that more information concerning the detailed chemistry is desirable. Tsukahara *et al.* (8)[1] conclude that the nuclei formed by the sensitization and activation probably consist of negatively charged $Sn^{II}Pd^{II}$ colloidal particles which by an intramolecular redox reaction may slowly decompose into palladium metal and Sn^{IV}.

On the other hand, Cohen and co-workers (9, 10) found, using Mössbauer spectroscopy, that on a sensitized Kapton substrate more Sn^{2+} ions and less Sn^{4+} ions are present than on a sensitized + activated substrate. They consider this as support for the reaction given by Eq [1]. A disadvantage of their technique is that the measurements were carried out in vacuum and therefore the sample had to be dried. This may have led to changes in the composition of the films.

A recent survey of the nucleation process is given by Feldstein (11).[1]

An argument against the likelihood of the reaction given by Eq. [1] is that in a solution containing $SnCl_2$ and $PdCl_2$ no palladium precipitates. It is known (12-15) that in this case complexes are formed. Khattak and Magee (14) suggest the following formula



with palladium in the univalent and tin in the bivalent state. Tsukahara (8) gives the formula $[Pd^{II}Sn^{II}{}_mCl_x]^{n-}$ with $m = 2$ or 6.

A commercial solution,[2] which is claimed to be a combination of sensitizer and activator, contains a palladium complex as well. This solution shows no Tyndall effect.[3]

During an investigation to achieve optimum conditions of the nucleation procedure we also studied the mechanism of this procedure, using radioactive tracer techniques and ellipsometry.

We obtained a very homogeneous nucleation by introducing an immersion of the substrate in a silver nitrate solution between the stannous chloride and the palladium chloride steps. In accordance with reaction [1] we expected the following reactions to occur

$$Sn^{2+} + 2Ag^{+} \rightarrow Sn^{4+} + 2Ag \qquad [2]$$

and

$$2Ag + Pd^{2+} \rightarrow 2Ag^{+} + Pd \qquad [3]$$

Due to the complication of the silver nitrate step our investigations into the mechanism of the nucleation procedure were performed with and without this step.

Key words: electroless deposition, nucleation, sensitization.

[1] Published between first and revised edition of this paper.

[2] Shipley catalyst 6F.

[3] After revision of this manuscript two papers dealing with $PdCl_2$-$SnCl_2$ solutions were published. Cohen and West (21), using Mössbauer technique, found that in concentrated acid solutions first a complex is formed and that this gradually decomposes whereby SnPd alloys could be detected. Rantell and Holtzman (22) found an indication that the active component of catalyst F6 is a complex chloride of Sn^{II} and Pd^{II} and that no colloidal particles could be detected larger than 5-10 nm.

Experimental Procedures and Results

Substrate.—Sheets of soda lime glass were used, 50 × 50 × 1 mm for examination with the electron microscope, 30 × 30 × 1 mm for the radioactive tracer techniques, and 100 × 25 × 1 mm for ellipsometry.

The sheets were carefully cleaned, first with trichloroethylene, followed by an immersion in a CrO_3-H_2SO_4 solution for several hours and an immersion in a 65 w/o (weight per cent) HNO_3 solution for at least 15 min. In this way the sodium ions are removed from the glass surface layer. Finally the glass sheets were rubbed with a slurry of $CaCO_3$ and MgO in water and dipped in a 16 w/o HNO_3 solution for 1 min.

Nucleation procedure.—As mentioned above two procedures were followed, one with and one without a $AgNO_3$ step.

With a $AgNO_3$ step.—The glass sheets were successively dipped in the solutions given in Table I. Freshly prepared $SnCl_2$ solutions were used. Between each step the samples were rinsed in running deionized water for 1 min.

During immersion in the silver nitrate solution the substrate darkens somewhat. This darkening disappears on immersion of the substrate in the palladium chloride solution.

Without a $AgNO_3$ step.—The same as the above, except that step b (Table I) was omitted.

Nickel plating.—Only electroless nickel plating was used in this investigation. The plating solution contained per liter: 30g $NiCl_2 \cdot 6H_2O$, 10g $NaH_2PO_2 \cdot H_2O$, 30g aminoacetic acid, pH 3.8 (measured at room temperature), temperature 95°C, and duration variable.

All chemicals used were of A.R. quality.

Checking of the homogeneity of the nucleation.—A homogeneous nucleation was very important for the interpretation of the results obtained from radioactive tracer and ellipsometric measurements. Therefore the homogeneity was checked by making a transmission micrograph of an approximately 80Å thick layer of nickel-phosphorus. This layer was deposited on a nucleated glass sheet and after evaporating a thin carbon film on it, the carbon + nickel layer was detached from the glass using hydrogen fluoride. The carbon layer acted as a support for the nickel-phosphorus film for examination with the electron microscope.

Figures 1 and 2 give the results, Fig. 1 of a layer obtained when a $AgNO_3$ solution was included in the nucleation process, Fig. 2 of a layer obtained without the $AgNO_3$ step. Figure 1 shows a regular pattern of small particles with sizes of 100-150Å. The pattern in Fig. 2 shows particles of the same size, but it is less dense; the number of particles is only about one half of that in Fig. 1. We were of the opinion that the nucleation was homogeneous enough to justify a quantitative analysis.

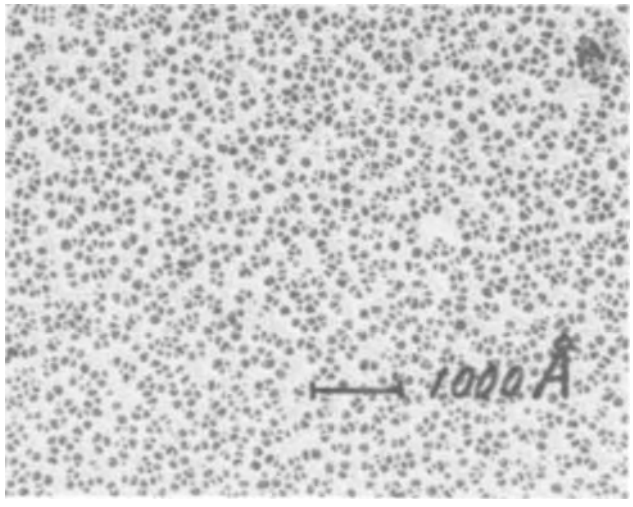

Fig. 1. Transmission electron micrograph of a NiP layer, about 80Å thick, nucleated with a $AgNO_3$ step included.

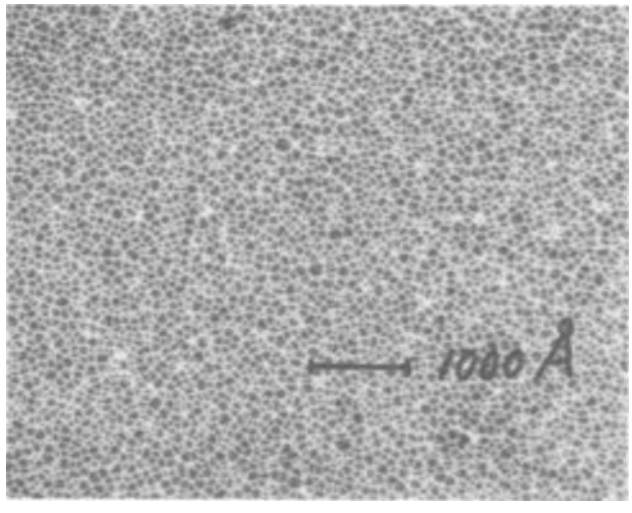

Fig. 2. Transmission electron micrograph of a NiP layer, about 80Å thick, nucleated without a $AgNO_3$ step.

Also, before and after each step of the nucleation procedure, replicas of the surface were made and examined in the electron microscope. They all showed the same appearance thus indicating that the nucleation process was homogeneous. No agglomerated clumps were found. Transmission micrographs of thin silicon oxide layers dipped in the $SnCl_2$ solution showed no clumps either. This is in contrast to the results of Sard (3). The high $SnCl_2$ concentration, used by Sard, may be responsible for this difference in results.

Analysis with radioactive tracers—The amounts of tin, silver, palladium, and chlorine left on the substrate after each step followed by rinsing, were determined by using radioactive isotopes of these elements. Some properties of the isotopes used are shown in Table II.

Table I. Solutions and conditions of nucleation procedure with a $AgNO_3$ step included

Step	Solution composition per liter		Temperature	Duration
a	$SnCl_2 \cdot 2H_2O$	100 mg	Room	1 min
	HCl sp. gr. 1.19	0.1 ml		
b	$AgNO_3$	1g	Room	1 min
c	$PdCl_2$	100 mg	~4°C	1 min
	HCl sp. gr. 1.19	3.5 ml		
d	Water, deionized		95°C	At least 15 sec

Table II. Isotopes used for analysis with radioactive tracers

Element	Isotope	Half life	Delivered as	Active conc. mg/ml	Active conc. mCi/ml	Peak measured, keV
Tin	Sn^{113}	115 days	Sn^*Cl_4 in 6M HCl	0.072 Sn*	1.0	393 (In^{113m})
Silver	Ag^{110m}	253 days	Ag^*NO_3 in 0.1M HNO_3	0.64 Ag*	1.0	658
Palladium	Pd^{109}	13.5 hr	Pd^*Cl_2 in 0.042M HCl	0.0605 Pd*	10^{-3}	88
Chlorine	Cl^{36}	3.1×10^5 years	HCl* in 0.38M HCl	10-12 Cl*	44×10^{-3}	—

The activities of Sn^{113}, Ag^{110m}, and Pd^{109}, all γ-emitters, were measured by means of a NaI(Tl) well-type scintillation detector and a single-channel spectrometer. The radiation of Cl^{36}, a β-emitter, was measured with a Philips Liquid Scintillation Analyser, using both the liquid scintillation and the Čerenkov method. The efficiency of the liquid scintillation method is about a factor of 20 higher than that of the Čerenkov method but the latter is less sensitive to "quenching." With each of the isotopes a solution was prepared, such that the same total concentrations of all components as given in Table I were maintained as far as possible. The final solution had to have a specific activity high enough to allow determination of the amount of the element on the glass substrate with a reasonable accuracy. This means that only small amounts of the radioactive Sn and Ag isotope solutions had to be added to the corresponding non-active solutions, whereas relatively high amounts of the radioactive Pd and Cl solutions were necessary. The accuracy of the method for Sn, Ag, and Pd is 10% (2s) or better, for Cl 30% (2s).

Radioactive tin was added in the stannic form.[4] Prerequisites for using this as radioactive tracer in our case are that the small amount of stannic ions added has no effect on the nucleation procedure and that there is a fast exchange between the isotopes of Sn^{2+} and Sn^{4+} ions. The first effect is negligible, because a small amount of stannic ions is always formed in a $SnCl_2$ solution by oxidation with air. We checked that an amount of Sn^{4+} ions up to a ratio of $Sn^{4+}:Sn^{2+}$ of at least 1:100 has no noticeable effect on the nucleation process, whereas the ratio of active Sn^{4+} to nonactive Sn^{2+} in the solution was approximately $1:25 \times 10^3$.

According to Haïssinsky's Handbook (16) Sn^{2+} and Sn^{4+} in a 9M HCl solution exchange their isotopes within several minutes. Though our solution contains only about 0.001M HCl, the extremely low concentration of Sn^{4+} ions causes a fast exchange. We checked this by varying the $*Sn^{4+}$ concentration and the time elapsed between adding the radioactive solution and immersion of a glass sheet. Within 15 to 20 min a constant amount of tin was found on the glass independent of the $*Sn^{4+}$ concentration, assuming a complete exchange.

Only the total amount of tin left on the glass could be measured.

The quantity of tin was determined by measuring the 393 keV peak of the daughter In^{113m} (half life 1.66 hr). The measurements were made the day after performing the experiments because an equilibrium had to be reached.

The radioactive silver was delivered as a $AgNO_3$ solution containing 0.1 mol HNO_3. Normally we use a solution of only $AgNO_3$. The ratio of active Ag* to nonactive Ag in the final solution was approximately $1:10^3$, therefore the concentration of HNO_3 in the final solution was only 10^{-4}M. This did not noticeably affect the nucleation procedure.

The radioactive palladium was obtained by irradiation of 10.1 mg $PdCl_2$ in a reactor in a flux of 3×10^{11} $nsec^{-1}$ cm^{-2} for 110 min. The activated product was dissolved in 3.5 mliters 1.2M HCl and this solution was diluted to 100 mliters. The experiments were carried out within a few hours after irradiation because of the short half life of Pd^{109}. The results were corrected for its decay. The Cl^{38} formed during irradiation of $PdCl_2$ has a half life of 37 min, much shorter than that of Pd^{109} and should not have affected our results.

The radioactive chlorine was delivered as a solution of HCl^{36} with a small amount of inactive HCl. The analysis of chlorine was less accurate than that of the other elements, due to the low specific activity of Cl^{36} as a consequence of its long half life and to the limited amount of HCl* that could be added to the $SnCl_2$ and $PdCl_2$ solutions to maintain the concentrations at their usual values. From earlier experiments we knew that a high concentration of HCl in the $SnCl_2$ solution results in a poor nucleation. After we found that only traces of chlorine were left on the glass after the treatment in the $SnCl_2$ solution, in both solutions the concentration of active chlorine was made as high as possible. The ratio of active Cl* to nonactive Cl in the $SnCl_2$ solution was about 1:1 and in the $PdCl_2$ solution about 1:0.23.

After a solution with one of the active elements had been prepared, a new glass sheet was used for each following step included. As an example, to determine the amount of tin left on the surface, a glass sheet was immersed in the $SnCl_2$ solution containing active Sn*, rinsed, and kept in water until the activity could be measured. Another glass sheet was also immersed in the same solution, rinsed, immersed in the $AgNO_3$ solution, rinsed, and kept in water until measuring, and so on.

Duplicate experiments were performed using the same solution and for most elements all the analyses were repeated with freshly made solutions.

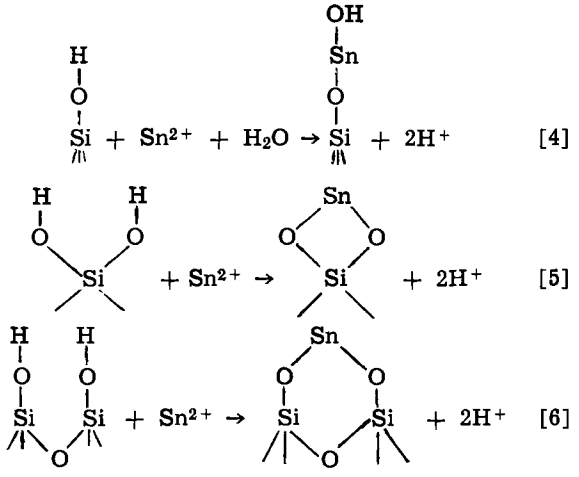
Instead of rinsing with running deionized water three beakers with fresh deionized water for each glass sheet were used. The test specimen was immersed in each beaker for 20 sec. This rinsing was sufficient, because in the third beaker no activity was found and rinsing six times instead of three times did not change the amount left on the surface.

The results are collected in Table III.

The amount of tin is strikingly constant during the whole procedure. Also the same amount of tin is present on the surface with and without an intermediate $AgNO_3$ step. The average of all the values, obtained with the $AgNO_3$ step included, is 0.109 μg Sn per cm^2. Assuming a homogeneous film, this corresponds to 1 atom Sn on approximately 18Å^2 or 1 atom per 4.2Å in a square arrangement, which is close to a monomolecular layer of a tin compound.[5] Only traces of Cl are left on the surface after immersion in the $SnCl_2$ solution. Sharp (1) assumes that a hydrated stannous complex is adsorbed on the surface. We suggest a chemical reaction between the stannous ions and the OH-groups present on the glass surface.

For simplicity we shall first consider the case of silica glass, characterized by a random network of interlinked SiO_4-tetrahedra. If this silica glass is brought into contact with an aqueous solution, each Si atom at the surface may be bonded to one, two, or even three OH-groups by chemisorption. Figure 3 gives an example.

Several reactions with stannous ions can be assumed. Examples are



[4] The Radiochemical Centre Amersham in England was unable to deliver Sn in the stannous form and we did not succeed in finding a simple method to reduce the $*Sn^{4+}$ to $*Sn^{2+}$ without contaminating the solution. In a paper published after revision of this manuscript Feldstein and Weiner (23) give results of a study using $*Sn^{2+}$ as well as $*Sn^{4+}$.

[5] Feldstein and Weiner (23), using aged combined $SnCl_2$ and $SnCl_4$ solutions on a hydrophobic substrate (Teflon), found values approximately a factor 20 to 30 higher.

[a] With activated Cl* in $SnCl_2$ solution.
[b] With activated Cl* in $PdCl_2$ solution.
[c] Liquid scintillation method.
[d] Not determined.

The Sn atoms on the surface will be surrounded by H_2O molecules. In silica glass the distance between 2 Si atoms in the Si-O-Si bridges is 3.02Å (17). However, the distance between Si atoms of neighboring $Si-O_4$ units not linked by oxygen atoms will be somewhat larger. According to Eq. [4]-[6] one Sn atom will be bonded to one or two Si atoms. Therefore the distance between the Sn atoms on silica glass may be expected to vary between 3 and 6Å.

The network of soda lime glass, in which about 15% of the oxygen ions are nonbridging, after extracting the metal ions from the surface, will be somewhat looser than that of silica glass. Thus the average distance between the Si atoms will definitely be somewhat greater than 3Å. Therefore, as a consequence of the calculated average distance of 4.2Å between the Sn atoms, the occupation of the Sn atoms might be close to one Sn atom per Si atom on the glass surface.

The amount of silver left on the surface after immersion in the $AgNO_3$ solution is *ca.* 0.16 $\mu g/cm^2$. This corresponds to 1.6 atom Ag per atom Sn.

During a subsequent immersion in the $PdCl_2$ solution no silver is removed. This contradicts reaction [3] according to which silver should be replaced by palladium.

After a dip in warm water the amount of silver is decreased to about half of its value and this reduced amount is maintained after nickel plating. We repeated these experiments with and without the step in warm water and also varied the duration of this step. Table IV gives the results. In all cases the amount of silver left after nickel plating is considerably lower than that after immersion in the $PdCl_2$ solution. However, without a dip in warm water the amount of silver left is higher than with this dip. A dip of 15 sec or 3 min in warm water makes hardly any difference. We know from earlier experiments that in our procedure a dip in warm water is essential for a homogeneous nucleation. Here again 15 sec or 3 min in water at 95°C gave the same results.

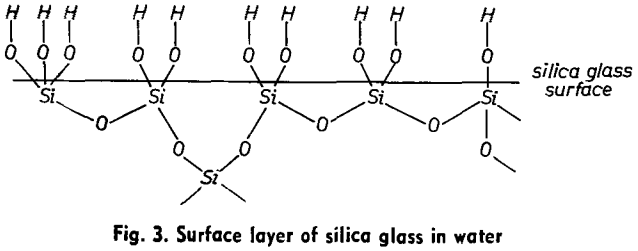

Fig. 3. Surface layer of silica glass in water

Table IV. Effect of rinsing in warm water before Ni-plating on the amount of Ag left on the substrate

The amount of palladium left on the surface after immersion in the $PdCl_2$ solution is 0.04-0.05 $\mu g/cm^2$, independent of whether a preceding step in a $AgNO_3$ solution is included or not.

No change of the amount of palladium occurs during dipping in warm water or during nickel plating.

The amount of chlorine left after the $SnCl_2$ step is negligible, as stated above. After immersion in the $PdCl_2$ solution, a relatively high amount of Cl is left on the surface, especially if a preceding step in a $AgNO_3$ solution is included. This amount is not reproducible. We repeated the experiments several times. The extreme values found were 0.2 and 1.4 $\mu g/cm^2$, corresponding to 6 and 40 Cl atoms per Sn atom, respectively. Although the chlorine analysis is less accurate than the analyses of the other elements, the spread in the chlorine values is much greater than can be attributed to the accuracy.

The large amount of Cl left on the surface makes it unlikely that Eq. [1] or [2] + [3] is representative for the mechanism of the nucleation process. The formation of a complex compound is more probable.

We found in the case of an intermediate $AgNO_3$ step

$$Sn : Pd : Ag : Cl = 1 : (0.4\text{-}0.5) : 1.6 : (6\text{-}40)$$

and without a $AgNO_3$ step

$$Sn : Pd : Cl = 1 : 0.4 : (1\text{-}5.5)$$

The ratio Sn : Pd is (2 to 2.5): 1. This is approximately the same as in the complex given by Khattak (14) and in the complex with $m = 2$ mentioned by Tsukahari (8).

After the dip in warm water the amount of chlorine on the surface is decreased to approximately 1 Cl atom per Sn atom, whether or not a preceding $AgNO_3$ step

is included. We assume that the Cl removed is replaced by OH groups. This hydrolysis might also occur at temperatures lower than 95°C but at a slower rate and might be an explanation for the poor reproducibility of the amount of Cl found after the immersion in the $PdCl_2$ solution.

Whether the chlorine left after the dip in warm water stays on the surface during nickel plating has not been determined.

Ellipsometry.—To obtain more evidence that no metallic palladium or silver is formed during the nucleation process, some experiments were performed using an ellipsometer.

Ellipsometry measures the change in the state of polarization of polarized light upon reflection from a surface. It yields two parameters, designated Δ and ψ, from which the optical constants, viz., refractive index and extinction coefficient of a film-free substrate, can be calculated. Formation of a layer on the substrate generally leads to changes in the ellipsometric parameters, and these changes give information concerning the thickness and the optical constants of this layer. The method is capable of detecting even small fractions of a monomolecular layer in many cases (18).

A layer which is optically nonabsorbing (low extinction coefficient) will give mainly a change in Δ and have only a negligible effect on ψ. Optically absorbing layers (high extinction coefficient), however, will show a significant change both in Δ and in ψ. The method therefore is well suited to an investigation of whether the films formed during the nucleation procedure are metallic or nonmetallic. As has been shown recently by Smith (19) a metallic film in submonolayer quantities still has metal-optical properties.

From the measurements with radioactive isotopes we know that *ca.* 0.16 $\mu g/cm^2$ silver and *ca.* 0.05 $\mu g/cm^2$ palladium are left on the surface. Assuming a homogeneous distribution these amounts correspond roughly with a monolayer of silver and 0.3 of a monolayer of palladium, or with *ca.* a 3Å thick layer of silver and a 1Å thick layer of palladium. We expect these values to be high enough to decide by ellipsometric measurements whether these elements are in the metallic or in the nonmetallic state.

The ellipsometer used was built in this laboratory. The sensitivity was ± 0.005 degree. A block diagram of the arrangement is shown in Fig. 4.

A He-Ne laser beam with a wavelength of 6328Å was used. The light of this beam is linearly polarized. The ¼ λ plate before the polarizer serves to obtain circularly polarized light, otherwise the intensity after the polarizer is dependent on the position of the polarizer. The value of Δ for a glass sheet immersed in water is somewhat temperature dependent. Δ changed by approximately +0.1 degree for an increase in temperature of 1°C. ψ showed no noticeable change.

Therefore the experiments were carried out at a constant temperature in a cell surrounded by a water

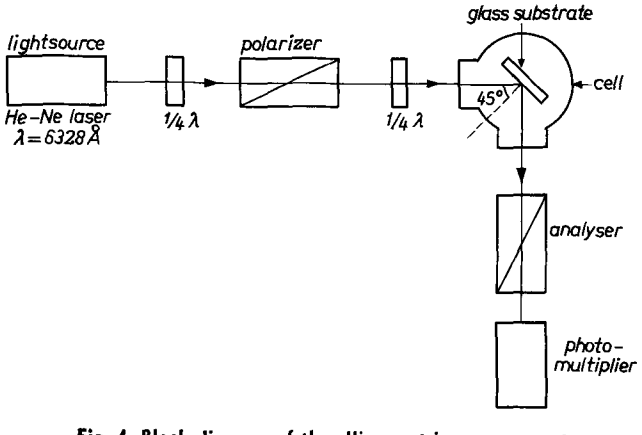

Fig. 4. Block diagram of the ellipsometric arrangement

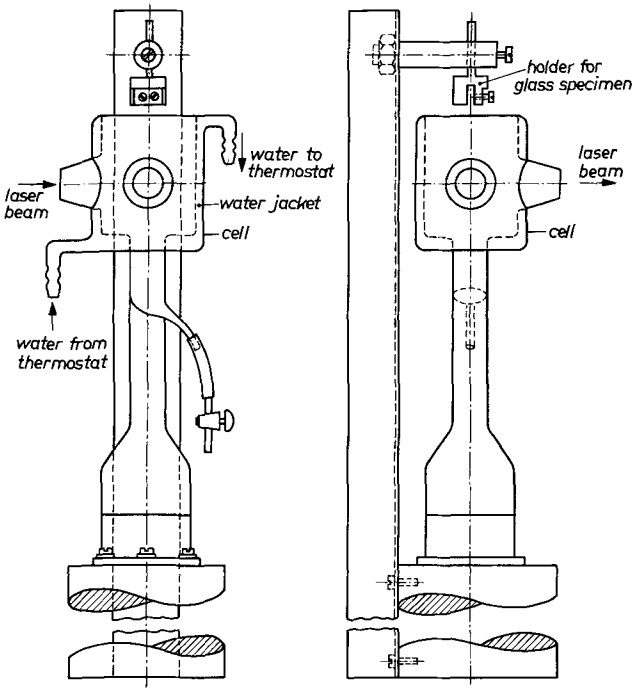

Fig. 5. Cell used for ellipsometric measurements

jacket except at the cell windows (see Fig. 5). Through this jacket water from a thermostat could be circulated to keep the temperature in the cell constant within 0.1°C. The temperature of the thermostat was chosen to be close to room temperature. All the solutions and rinsing water were kept in the thermostat before use, except those to be used at temperatures differing from room temperature, viz., the $PdCl_2$ solution (*ca.* 4°C), hot water (95°C), and the Ni solution (95°C).

Both the test specimen and the cell had to be rigidly mounted.

After cleaning the glass sheet, it was placed in the cell, which had previously been filled with deionized water and the ellipsometer was adjusted. For each test series the stabilities of the cell and the test specimen were checked by pouring hot and cold water into the cell; after the temperature was constant again, the readings of the ellipsometer had to be the same. Then the nucleation procedure was started by emptying the cell, pouring the $SnCl_2$ solution into it, removing the $SnCl_2$ solution after 1 min, and rinsing both glass sheet and cell by pouring deionized water into the cell for 1 min, after which Δ and ψ were read. Then the $AgNO_3$ solution was poured into the cell, and so on. If a solution at a low or a high temperature was used, the cell was rinsed until the temperature in it was again close to that of the thermostat before readings were made.

Several series were performed. Table V gives a summary of the results. All the values of $\delta\Delta$ and $\delta\psi$ are deviations from the initial values before immersion in the $SnCl_2$ solution, hence not per step.

As can be seen from Table IV, Δ has changed somewhat after each step, always in the same direction. The change in ψ is much smaller. For comparison a few calculated values of $\delta\Delta$ and $\delta\psi$ both for homogeneous films with high and low extinction coefficients are given in Table VI.

The values of the refractive indices (n) and extinction coefficients (K) are more or less arbitrarily chosen. The thickness has been varied to a maximum of 5Å for the strongly absorbing (metallic) and to a maximum of 25Å for the slightly absorbing films (nonmetallic). These values are more or less representative for monolayers of a metal and a metal-ion complex, respectively.

The small experimental values of $\delta\Delta$ and $\delta\psi$ (Table V) can only be interpreted in terms of nonmetallic

Table V. Changes in ellipsometric parameters Δ and ψ during the nucleation procedure on a glass substrate

films. The thickness of the films (for thin films $\delta\Delta$ changes linearly with the thickness) increases with each following step, except after the warm water treatment.

ψ changes rapidly immediately after filling the cell with the electroless Ni solution.

A sodium hypophosphite solution, either warm or cold, added to the cell after the nucleation procedure had been completed, caused no significant change in Δ or in ψ. This indicates that if a Sn-Pd complex is present on the surface, this is not reduced by hypophosphite to metallic palladium.

Our conclusion that no metallic Ag or Pd is formed during nucleation is further supported by recent ellipsometric measurements of Kelly (20), who followed the reduction of $PdCl_2$ on TiO_2 by illumination. He found changes in Δ and ψ, which indicated a metallic film. This could be proved for thicker films by reflection high-energy electron diffraction. The sensitivity of the ellipsometric measurements was high enough to detect 0.1 of a metallic Pd monolayer.

Experiments with mixed solutions of $SnCl_2$ and $PdCl_2$.—We also did some qualitative experiments by mixing various volumes of the solutions of $SnCl_2$ and $PdCl_2$, given in Table I. Yellow colored solutions were obtained. No palladium was formed. Heating gave in most cases a flocculent, nonmetallic precipitate.

If to the mixed solutions a sodium hypophosphite solution is added, no metallic palladium is formed. Upon heating a precipitate arises, which contains metallic palladium only if the ratio Sn^{2+} : Pd^{2+} in the mixed solution is low. This is in agreement with our finding that a nucleated substrate in a NaH_2PO_2 solution shows no light absorbing film in the ellipsometer.

By mixing solutions of $SnCl_2$ and $PdCl_2$ at higher pH's and with a small excess of chloride, dark colored solutions may occur. In such solutions a black precipitate is formed by oxidation with air. This precipitate is nonmetallic and consists of a palladium hydroxide or perhaps a basic palladium salt. If air is excluded the solutions are stable. This result might be in agreement with the opinion of Khattak (14) that a complex with univalent palladium is formed.

Discussion and Conclusions

The foregoing results can be summarized as follows. After immersion in a $SnCl_2$ solution a very reproducible amount of tin is left on the surface as a chlorine-free compound. This amount, corresponding closely to a monolayer, is maintained during all the subsequent steps, including the nickel plating. We suggest that the tin is chemically bonded to the Si-O groups of the pretreated glass surface.

The amount of palladium left after the immersion in a $PdCl_2$ solution, both with and without an intermediate dip in a $AgNO_3$ solution, is also reproducible and the same amount is also maintained during the subsequent steps. The ratio of Sn:Pd is approximately 2:1. After the $PdCl_2$ step a large amount of chlorine is found. This makes it unlikely that palladium metal is formed. The amount of Cl is not very reproducible, it varies from 6 to 40 Cl atoms per Sn atom when a $AgNO_3$ step is included and from 1 to 6 without a $AgNO_3$ step. A dip in warm water removes much of the Cl, but an amount is left corresponding approximately to 1 Cl atom per Sn atom. We expect that the Cl atoms removed are replaced by OH groups, consistent with the fact that the ellipsometric parameters change very little.

The amount of silver left after a dip in a $AgNO_3$ solution does not change during the following dip in a $PdCl_2$ solution. Thus, no exchange of Ag and Pd takes place. This gives evidence that the silver is not present in the metallic state either. The silver ions will be taken up by the Sn containing film in another way than the palladium ions, because the amount of palladium left on the surface is not affected by a previous dip in a $AgNO_3$ solution. An adsorption of the silver ions and a complex forming of the Pd ions is a very speculative assumption and has to be verified by further experiments.

Nearly half of the silver is removed by a dip in warm water. This indicates that the silver ions occupy two different sites on the surface presumably on Sn and on Si positions.

Ellipsometric measurements show clearly that no strongly light absorbing film is formed. This makes it very likely that the silver and palladium present on the surface are not in the metallic state.

Finally, a further support for the fact that no metallic palladium is formed, is that palladium either as bulk metal or as sputtered film is only a poor catalyst for electroless nickel deposition. It shows a long initiation period, much longer than a surface nucleated with a $SnCl_2$-$PdCl_2$ solution. The behavior of palladium metal as catalyst depends very much on its pretreatment, in many cases no nickel deposits at all.

The main conclusion from our results is therefore that during the $SnCl_2$-$PdCl_2$ nucleation process on glass, either with or without an intermediate $AgNO_3$ step, no metallic film could be detected. The formation of a Sn-Pd complex is more likely. The structure and

composition of such a complex cannot be deduced from our results. We only know that the Sn:Pd ratio is about 2:1 and that an excess of Cl is present before heating in water. Whether the Pd occurs in a univalent or a bivalent state is not known.

No suggestion can be made about the mechanism of initiation of the nickel deposition of the nucleated glass surface. We could not detect a metallic film after a treatment with a hypophosphite solution. Possibly the Sn-Pd complex reduces the nickel-ions. Further study is necessary to solve this problem.

Dimethylamine Borane as the Reducing Agent in Electroless Plating Systems

Mark Lelental

Research Laboratories, Eastman Kodak Company, Rochester, New York 14650

ABSTRACT

The interaction of dimethylamine borane (DMAB) with evaporated metal nuclei that exhibit catalytic and noncatalytic behavior towards nickel electroless plating baths has been studied. The adsorption of DMAB, followed by its catalytic decomposition, was found to be the initial step of nickel electroless plating. Elemental boron, deposited on the surface of the catalyst, was identified as a product of the latter reaction. The process of nickel deposition was shown to require a larger metal aggregate for catalysis than that necessary for the DMAB decomposition reaction. A mechanism for this reaction is proposed and possible sources of inefficiencies in the electroless-plating pathway are discussed.

Amine boranes are useful reducing agents for many types of electroless plating solutions. An advantage such systems have over solutions that use sodium hypophosphite as a reducing agent is the production of a relatively pure metal deposit and the ability to be catalyzed by a wide range of materials (1, 2). A properly formulated solution is thermodynamically unstable but kinetically stable, its decomposition being accelerated by the presence of a catalyst that leads to the deposition of metal. The mechanism of electroless deposition usually presupposes adsorption of the reducing agent onto the catalytic surface, followed by autocatalytic metal deposition. Metallic palladium is the catalyst most commonly used for the initiation of electroless plating. For some practical applications of this process, the minimum number of atoms (or critical size) of a given material able to form catalytically active centers is taken as a measure of its catalytic activity. Hamilton and Logel (3) have studied such catalyst-size effects in electroless plating deposition. This paper presents the details of a study of the interaction of an amine borane type of reducing agent with the surface of a catalyst.

Key words: amine, boranes, electroless, plating, palladium.

The interactions of dimethylamine borane (DMAB) solutions with vacuum-deposited Pd, Ni, and Bi films were studied by analytical techniques that monitored boron content on the metal surface. In the case of Pd, for which there is a considerable interaction with DMAB, the kinetics of this surface reaction were also studied as a function of DMAB concentration, temperature, and Pd coverage. On the basis of these studies, a mechanism of the catalytic decomposition of DMAB on palladium is proposed. A similar investigation of the interaction of hypophosphite and nickel ions on evaporated metal films has been carried out using radiotracer techniques and will be the subject of a later report (4).

Experimental

The palladium catalyst was prepared as a thin metallic film deposited on double-coated tape (3M Company, No. 665) by the vacuum-deposition technique of Hamilton and Logel (5). The Pd coverage was varied over the range 1.6-0.05 mg/ft^2. These values span the range of sizes and coverages above and below the critical size. This method of preparing the catalyst film allows the coverage of Pd film to be related to the size of the metal nuclei. Therefore, critical coverage represents a film of Pd nuclei of a critical size for catalysis in the appropriate electroless plating solution.

The electroless plating was carried out at room temperature and solution employed in these studies had the following composition:

$NiCl_2 \cdot 6H_2O$ (Baker and Adamson, reagent grade)	0.1M
Gluconic acid (Eastman Organic Chemicals, technical grade)	0.65M
NH_4OH	to pH = 9.0
DMAB (Callery Chemical Co.)	1%

A spectrophotometric method based on the formation of a boron-curcumin complex was used for the determination of boron (6). The complex is very stable and its high extinction coefficient makes it highly suitable for boron analysis. However, protonated curcumin in the acidic solution forms a strongly interfering complex, which must be destroyed before any measurement can be made. This was accomplished as proposed by Grinstead (7) by neutralization of the solution with ammonium acetate. For our studies, the determination of boron was carried out by modification of the procedures of Hughes and Metcalfe (8), and of Grinstead (7):

1. Introduce a dry sample containing 0.05–3.5 μg of boron into 125-ml polyethylene bottle.
2. Add 3 ml of curcumin (Eastman Organic Chemicals) reagent (0.125g of curcumin in 100 ml of glacial acetic acid).
3. Add 3 ml of acid reagent (equal volumes of 96% sulfuric acid and glacial acetic acid).
4. Mix and let stand for 2 hr.
5. Neutralize using 15.0 ml of ammonium acetate–acetic acid reagent (250g of ammonium acetate plus 300 ml of glacial acetic acid in sufficient water to make 1 liter).
6. Measure the absorbance at 555 nm in 1-cm cells against a boron-free blank.

For levels below 2 μg of boron, replacement of all glassware by polyethylene equipment was necessary to obtain reproducible results and low blanks.

The calibration curve was determined by placing 25, 50, and 100 microliters of solutions (containing 80 μg/ml and 10 μg/ml of boron as boric acid) on 0.5 in.^{2} of the double-coated tape mounted on a microscope slide. After drying, the tape was removed from the slide and placed in a polyethylene vial. The relationship between absorbance and boron content was determined (Fig. 1). For the studies of the interaction between catalyst and DMAB, the samples (metal nuclei-tape-glass slide) were immersed in aqueous DMAB solutions for the given period of time and then washed with water to remove excess DMAB. Then either 0.5 in.^{2} or 0.25 in.^{2} of the dried tape was analyzed by the same procedure as used for the standards. Four independent samples were analyzed for each boron determination. All determinations of absorbance were carried out using a Beckman DK-2A ratio recording spectrophotometer. The absorbance was calculated as follows

$$A = A_M - A_B$$

where A_M is the absorbance for a sample containing metal nuclei on tape (expressed as absorbance/0.5 in.^{2} of tape) and A_B is the blank absorbance for tape alone (expressed as absorbance/0.5 in.^{2} of tape). The amount of boron was read from the calibration curve.

Results and Discussion

Catalytic Nuclei (Pd)

Pd–DMAB interaction as a function of palladium coverage.—The films were immersed for 10 min in a 1% aqueous DMAB solution. The amount of "adsorbed" DMAB, as measured by the boron content, is shown in Fig. 2.

The results indicate that there is a much greater amount of boron on the palladium surface than would be expected assuming monolayer adsorption of the DMAB. For example, for Pd coverage of 0.5 mg/ft^2, the specific adsorption (Γ = number of moles of adsorbate/number of moles of adsorbent) is 9.83. This indicates that the mechanism of the interaction of

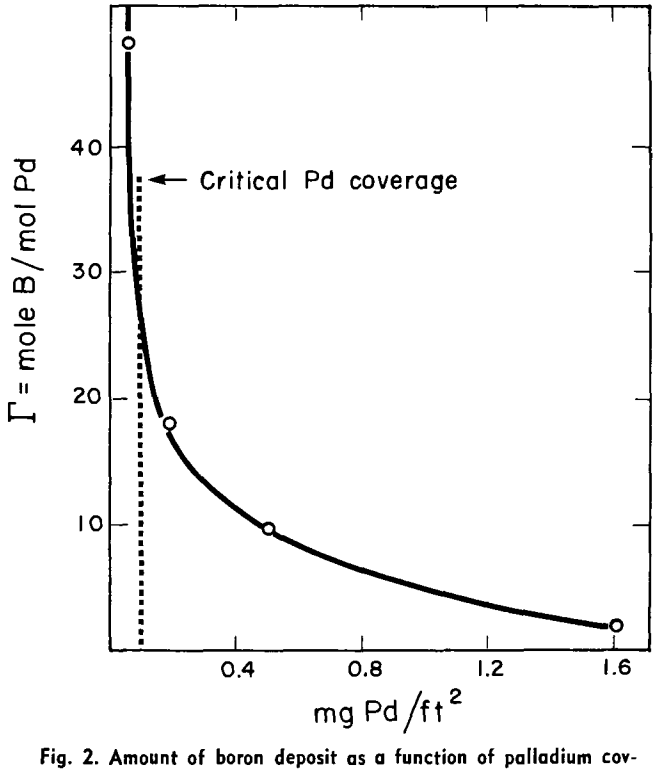

Fig. 2. Amount of boron deposit as a function of palladium coverage.

DMAB with the catalytic surface is different from that previously found for the hypophosphite system in which a monolayer adsorption was found (4). The results also show that even in the case of Pd coverages that are subcritical for nickel deposition, there is appreciable Pd–DMAB interaction. For example, a Pd coverage of 0.05 mg/ft² gives $\Gamma = 48.3$. The failure of the surface reaction between DMAB and Pd to terminate at subcritical Pd coverages indicates that another effect is responsible for the lack of nickel deposition in this region. A similar conclusion resulted from studies of adsorption of hypophosphite ions, where again no discontinuity of adsorption on Pd was observed below critical size.

Kinetics of the surface reaction between DMAB and Pd.—The results described above indicated that Pd-DMAB interaction is not a simple monolayer adsorption. To further elucidate this interaction it was studied as a function of time, concentration of DMAB, and temperature. Figure 3 illustrates the relationship between time and the amount of boron-containing species resulting from the surface reaction. Excess DMAB was used to keep the DMAB concentration essentially constant throughout the run.

The results indicate that the boron-containing product of this surface reaction is itself a catalyst for further reaction. This reaction is thus autocatalytic. The decrease of the rate of metal deposition with time is often observed in the electroless plating process for which autocatalytic behavior is well-established. This effect might be due to the accumulation in the solution of products of the reactions involved in electroless plating or to changes in the morphology of a metal deposit. The decrease of the rate of boron deposition with time might be due to the similar factors. Another possibility that must be taken into account is diffusion of palladium through the boron layer. Application of methods of surface examination, such as ESCA or Auger spectroscopy, could definitely establish the validity of this hypothesis. Such studies are in progress in these Laboratories. Studies of the rate of Pd-DMAB surface reaction as a function of DMAB concentration were carried out at two Pd coverages, one supercritical (0.5 mg Pd/ft²), and the other subcritical (0.04 mg Pd/ft²). Figure 4 illustrates the results of these studies.

A linear relationship exists between the amount of boron deposited as a result of surface reaction and DMAB concentration for the Pd coverages in both cases. The observation that even in the advanced stage of the process the rate varies significantly for the two Pd coverages indicates that in spite of the assumed coverage of the Pd nuclei by the boron-containing reaction product, the nature of the original Pd deposit still influences the course of the reaction.

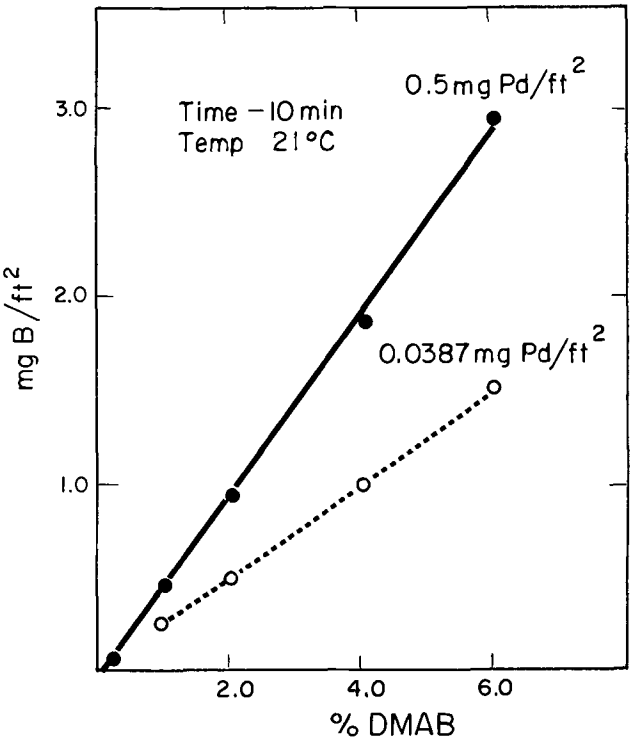

Fig. 4. Effect of DMAB concentration on boron deposition

The effect of temperature on the rate of boron deposition is shown in Fig. 5.

The increased rate of the surface reaction with increasing temperature is further evidence that the DMAB–Pd interaction is not a simple adsorption process. The activation energy of the over-all process in the temperature range 21°-32°C was estimated from

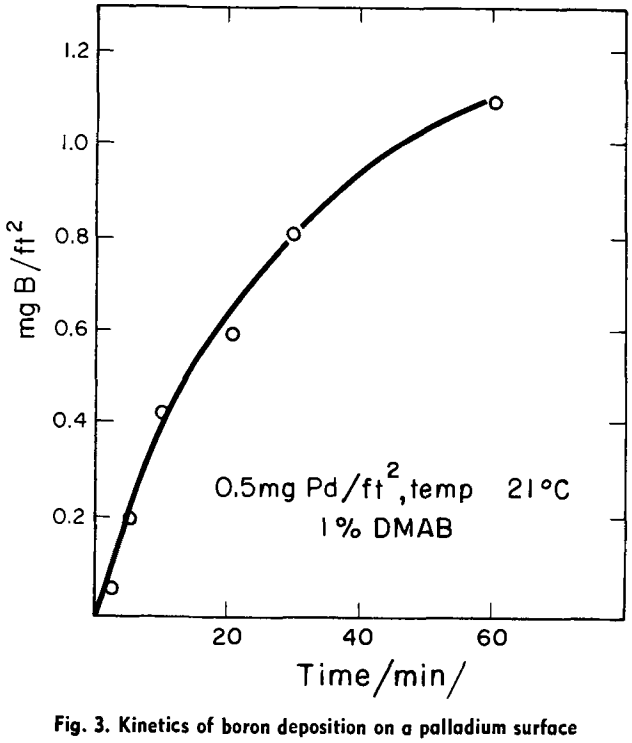

Fig. 3. Kinetics of boron deposition on a palladium surface

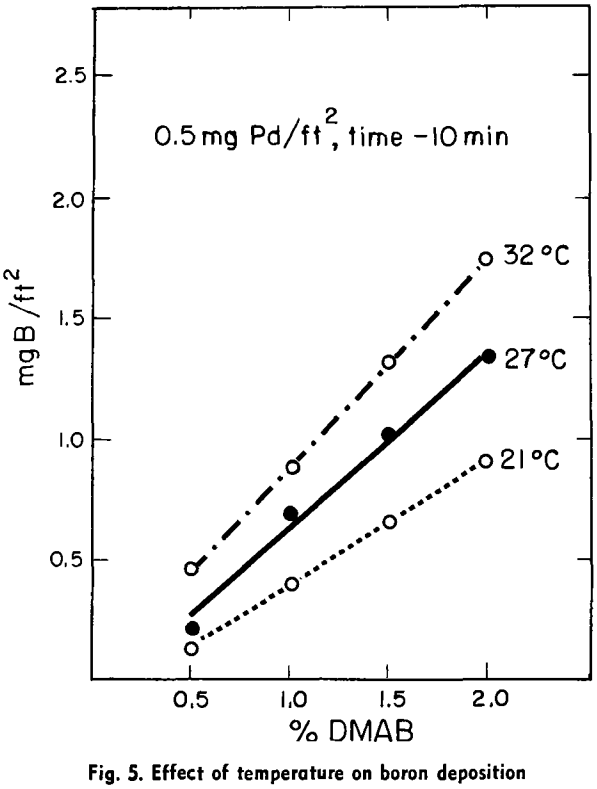

Fig. 5. Effect of temperature on boron deposition

the log k *vs.* $1/T$ relationship to be 12.2 kcal/mole. This applies to the reaction in the early (10 min) stage.

Products of the catalytic decomposition of DMAB on surface of palladium films.—Analysis by attenuated total reflectance (ATR) infrared spectroscopy of a Pd surface that had been treated with aqueous DMAB solution failed to detect the presence of any B-H-containing species on the Pd surface ($\nu_{B\text{-}H}$ = 1800-2400 cm^{-1}). Laser Raman spectroscopy also failed to detect the presence of any B-H-containing material on the Pd surface. The boron deposit was also investigated by x-ray diffraction methods.

A sample consisting of Ag foil on which Pd had been deposited by vacuum deposition was immersed into DMAB solution, washed, dried, and subsequently studied by the Debye-Scherrer method and diffractometry. Several successive scans were made under the conditions 45 kV, 24 mA, 3° tube Soller slit, 0.3° defining slit, 6° take-off angle, and a 3.5×10^{-6}-in.-thick beta filter in order to obtain the highest possible x-ray flux. The resulting diffraction patterns showed several low maxima between 3.5 and 7.5Å, which is the region of greatest diffracted intensity for both rhombohedral and tetrahedral boron. On the basis of these results, the presence of at least one crystallographic form of elemental boron on the palladium surface appears rather likely.

Nickel deposited from Ni–amine borane electroless plating bath always contains boron. It is possible that the boron in both cases (DMAB alone and electroless Ni) comes from the same mechanism of decomposition of amine borane.

Mechanism of the catalytic decomposition of DMAB on palladium.—In addition to elemental boron, the decomposition products of DMAB on metallic palladium are hydrogen, boric acid, and dimethylamine (9). On the basis of these products, the following mechanism is proposed

$$(CH_3)_2\overset{H}{\underset{|}{N}}\text{—}BH_3 + Pd^\circ \rightarrow \{[(CH_3)_2HN\text{—}BH_3]Pd\} \quad [1]$$

$$(CH_3)_2\overset{H}{\underset{|}{N}}\text{—}BH_3 \rightarrow Pd\cdots(BH_3) + (CH_3)_2NH \quad [2]$$
$$\vdots$$
$$Pd$$

$$Pd\cdots BH_3 \xrightarrow{3H_2O} \begin{cases} Pd\cdots B + 3/2H_2 \\ Pd + H_3BO_3 + 3H_2 \end{cases} \quad [3]$$

The cleavage of the B-N bond and formation of an adsorbed complex involving the borine radical [*i.e.*, $Pd\cdots(BH_3)$] could be facilitated by the initial adsorption of DMAB on the Pd surface. Borine is a powerful Lewis acid and would be hydrolyzed rapidly to produce boric acid and H_2. A competitive reaction is the reduction to elemental boron with the evolution of hydrogen. The suggestion of an adsorbed borine intermediate is consistent with electrochemical and chemical data for similar systems. Elder and Hickling (10) proposed the formation of a $Pt\cdots BH_3$ complex during the oxidation of aqueous $NaBH_4$ at a platinum electrode. Jones (11) has suggested that the reduction of organic carbonyl functions by trimethylamine borane proceeds by the formation of a $R_2\overset{+}{C}\text{-}O\text{-}BH_3$ species. Brown and co-workers (12) have proposed that diborane reduction of ketones most likely proceeds by an initial complexation of the BH_3 moiety with carbonyl oxygen followed by the intermolecular hydride shift. Kelly and Marchelli (13) postulated that the general acid-catalyzed hydrolysis of BH_3 adducts of a series of alkyl, aryl, and heterocyclic amines proceeded by a rate-determining electrophilic replacement of BH_3 from the nitrogen by the proton of the acid, followed by the rapid hydrolysis of the borane fragment. Formation of elemental boron by catalytic decomposition of BH_3 appears likely in view of the mechanism proposed by Machalov and co-workers (14) for the decomposition of $NaBH_4$ in $NiCl_2$ solution. The BH_3 formed as an intermediate can decompose, Eq. [4], or hydrolyze, Eq. [5]

$$BH_3 \xrightarrow{k_1} B + 3/2H_2 \quad [4]$$

$$BH_3 + 3H_2O \xrightarrow{k_2} H_3BO_3 + 3H_2 \quad [5]$$

The ratio of the two rate constants depends on the conditions under which the process is carried out, specifically, the composition of the electroless plating bath, pH, and temperature. Variations of these parameters lead to different boron contents in the deposited nickel.

Boron deposition on Pd surface and catalytic activity of Pd nuclei.—Pd metallic films were prepared by stepped vacuum evaporation using the method developed by Hamilton and Logel (5). The samples were divided into six sections varying only in Pd coverage. In the following experiments the Pd coverages varied in a geometrical progression so that each step differed from the preceding by a factor of ½.

The number of developable steps is related to the activity of a particular electroless plating solution. Such stepped deposits also allow the evaluation of a critical Pd coverage necessary for catalytic nickel deposition. Pd samples prepared by stepped evaporation were immersed in 1% aqueous DMAB solution for 10 min during which time 15–25 monolayers of boron were deposited on them, and were subsequently placed in the nickel–gluconic acid-DMAB electroless plating bath. The same number of active steps were observed for samples treated by the above procedure as in the case of identical samples that were immersed without pretreatment into an aqueous solution of DMAB. This indicates that the deposition of elemental boron, which is a product of DMAB decomposition on palladium, does not alter the catalytic activity of palladium towards nickel deposition.

Noncatalytic Nuclei

Nickel and bismuth metal nuclei prepared by vacuum deposition do not catalyze metal deposition from nickel–DMAB solutions. The interaction of DMAB with Ni and Bi metal nuclei was studied using the same technique as described for Pd. Table I contains results of these experiments. The level of sensitivity of the curcumin spectrophotometric boron determination does not allow us to conclude that DMAB is not adsorbed on the surface of Ni and Bi metal nuclei. But the analytical results indicate that if any adsorption of DMAB does take place it is not followed by catalytic decomposition of the adsorbed species. The fact that Ni and Bi metal nuclei do not catalyze the decomposition of DMAB (during our time scale) might be the main reason why these nuclei are not catalytically active towards nickel deposition. It is rather surprising that nickel nuclei prepared by vacuum deposition do not catalyze the initiation of nickel electroless plating, but chemically deposited nickel is catalytically active for the continuation of this process. However, it is often observed that the activity of catalysts varies depending

Table I. DMAB-Ni, Bi interaction

Metal nuclei	Coverage, mg/ft²	Deposited boron, mg/ft² (10 min)	$\Gamma = \frac{\text{mole of B}}{\text{mole of metal}}$
Ni	1.9	0.0006	below 0.06
Bi	2.0	0.0003	below 0.22
Pd	1.6	0.5356	3.10

upon the method of their preparation. The fact that nickel films prepared by vacuum deposition are not able to initiate the nickel electroless plating process might be caused by the presence of an oxide film. Nevertheless, other possibilities, such as impurities in chemically deposited nickel, as well as the presence of structural defects, also have to be taken into account.

Conclusions

These studies of the interaction of DMAB with palladium nuclei indicate that decomposition of DMAB takes place giving elementary boron in addition to the products previously reported: boric acid, hydrogen, and dimethylamine (9). The deposition of elemental boron on palladium in this reaction neither inhibits the reaction nor does it lead to a change of the critical Pd coverage necessary for subsequent nickel deposition. Since the DMAB decomposition occurs even in the cases of Pd coverages that were subcritical for nickel deposition, one must consider two different kinds of critical coverages: (*i*) critical coverage towards catalytic oxidation of reducing agent; and (*ii*) critical coverage towards the over-all nickel deposition process.

Hamilton and Logel (3) have found that two-atom Pd nuclei catalyze the decomposition of aqueous DMAB solution with the deposition of boron but larger Pd particles (4-20 atoms) are required for nickel deposition.

This leads to the conclusion that nickel deposition is dependent on processes complementary to the adsorption and decomposition of the reducing agent on the catalyst surface. Such processes may involve a catalyzed ligand dissociation reaction of the Ni^{+2} complex or electron transfer from the catalyst surface to some activated Ni^{+2} species. The actual electron-transfer reaction could involve Pd-H^-, Pd-H_2, or a Pd electrode mechanism. Proposed mechanisms of nickel deposition are based on these processes (15-21). It is also possible that adsorption of a complexing agent on the surface of the catalyst competes with adsorption of reducing agent. That might explain why the value of critical Pd coverage towards nickel deposition is highly dependent on the kind of complexing agent used in the formulation of the nickel physical developer. The fact that Ni and Bi metal nuclei are not able to catalyze the decomposition of DMAB might be the reason that they do not catalyze nickel deposition.

On the basis that cleavage of the N-B bond of the adsorbed amine borane occurs in the first stage of the process, we conclude that the energy of this bond and the ability of a catalyst to facilitate its cleavage are the critical parameters of the process.

Acknowledgments

I wish to thank Mr. Samuel Donley for x-ray diffraction examinations, and Drs. Joseph Yudelson and Henry Gysling for many helpful comments and suggestions.

Fabrication of Semitransparent Masks

N. Feldstein*,[1] and J. A. Weiner

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

A chemical plating technique has been devised for the preparation of semitransparent photomasks. The deposited thin film meets the optical requirement of being opaque in the ultraviolet range and transparent enough in the visible range for see-through applications. Suitable etchants are available to provide good edge definition of photolithographically delineated semitransparent films without deteriorating common resist compositions. Analytical characterization of the deposited films revealed that they are primarily composed of cuprous oxide. The major advantage of the present approach is the low cost. Masks made by the present system are more durable (harder) than emulsion-type masks, but less durable than iron oxide semitransparent masks.

In the manufacturing of electronic parts, photomasks are widely used in defining images on photosensitive materials. In the manufacturing of semiconductor devices, two main types of photomasks are used: (*a*) photographic emulsion on glass (silver in gelatin), and (*b*) chromium film on glass.

In both cases, the opaque regions absorb the incident light, allowing only selective areas of the photosensi-

* Electrochemical Society Active Member.

Key words: semitransparent mask, chemical plating, cuprous oxide.

tive material to interact with the light. Both masks have certain advantages and certain limitations, all stemming from the basic characteristics of such materials.

The following are some of the limitations encountered with the silver emulsion masks: (*i*) These masks are soft and hence are easily scratched. (*ii*) Dimensional changes take place due to moisture absorption by the gelatin. (*iii*) Due to the fogginess of the gelatin material, there is a significant optical density gradient at the edges. This gradient is due to the tapering of silver concentration. (*iv*) A limitation is encountered due to the excessive thickness of the emulsion mask (4μ thickness) for fine-line definition.

Although chromium masks overcome some of the above limitations, they too possess certain limitations: (*i*) Due to an aging phenomenon, the etch time varies even though the samples may have been prepared in the same batch. (*ii*) Due to the high reflectivity, multiple reflections can occur, resulting in a poor edge definition. (*iii*) Lack of resilience with growth spikes from epitaxial silicon layers.

Due to their opaqueness at the sodium D line (589 nm), registration of opaque masks with existing patterns is a difficult task, especially whenever positive photoresists are used. In meeting this difficulty, it has been recognized that the availability of semitransparent masks would overcome this registration problem. A typical semitransparent mask should have the following characteristics: (*a*) The film should have virtually zero transmission in the region below 450 nm. This region corresponds to the spectral range in which most commercial resists are sensitive (Fig. 1). (*b*) For the purpose of alignment, the film should be at least 30% transmitting in the 589 nm region. (c) The deposited film should be readily etchable in solvents which are compatible with commercial photoresists. (*d*) The deposited film should be abrasion resistant to ensure faithful transfer of the image on a repeated basis.

In recent publications, several materials and deposition techniques have been described for fabrication of semitransparent masks. Sinclair, *et al.* (1) have studied the spectral behavior and etch characteristics of various oxide films deposited by d-c reactive sputtering. They demonstrated that films of iron oxide, vanadium oxide, nickel oxide, iron oxide-vanadium oxide, and iron oxide-nickel oxide met the optical requirements. The iron oxide-vanadium oxide was best in view of its good etch properties in both acids and alkalis. Moreover, several oxides, including copper oxide, were found to be inferior because of their spectral absorption properties, and thus were eliminated as potential candidates. The copper oxide films were formed by the sputtering of copper in 100% O_2.

MacChesney *et al.* (2) characterized iron oxide films prepared by chemical vapor deposition using iron pentacarbonyl. Much of their investigation was focused on the deposition parameters and the etchability of the iron oxide films. Peters *et al.* (3) have devised a sputtering technique for iron oxide deposition; in CO-CO_2 mixtures resulting films could be properly delineated in 6M HCl solution. In the published work (3), data related to the scratch resistance values for the iron oxide films were found to be superior over those obtained using evaporated chromium films. More recently, a further comparison (4) of the merits of iron oxide *vs.* chromium film is available. More recently Janus (5) has presented a critical review of iron oxide masks in comparison to other systems. Taylor *et al.* (6) have studied the potential use of polycrystalline hexaferrite films for semitransparent masks. Although the films met the optical requirements to obtain pinhole-free films, a thickness greater than 2000Å was required. Loprest *et al.* (7) have also described the overall characteristics of the GAF Microline high resolution plates. These plates consist of a thin coating of a positive-working resist with a diazo dye as the sensitizer. By contrast to all other mask systems, the image development for this system is carried out using ammonia vapor at atmospheric pressure. The thickness of the light-sensitive layer is about 3.3μ and a line resolution of 2000 lines/mm was reported. Using a wide variety of photographic dyes, a method for the fabrication of see-through masks was described (8). Ables (9) has devised a process in which Lippman emulsions are exposed to light and, after conventional development, the black image is intensified according to the reaction

$$Ag^{o} + HgBr_2 \rightarrow (AgBr)(HgBr)$$

The product of the reaction is a white or bleached image which is then redeveloped in a saturated sodium sulfite solution. The resulting silver-mercury-sulfite image is sepia in color. In a slight variation, Drouge (10) redevelops the (AgBr)(HgBr) image in conventional developers or ammonia solution followed by a treatment in a dilute potassium dichromate-sulfuric acid solution. The resulting images are orange. Blome and Fok (11) have devised a selective process by which evaporated silicon oxide was deposited, providing hard and semitransparent silicon monoxide films. Diem (12) has also described a process for silicon semitransparent masks. Kiba (13) has described a process suitable for transparent masks. In his process copper is deposited by vapor plating and is subsequently oxidized at elevated temperatures. In a subsequent modification (14), a patterned film of aluminum is deposited prior to the copper deposition. With heat-treatment, oxidation and diffusion of the copper take place selectively. Unwanted aluminum and copper are subsequently etched. A commercial product (15) prepared by sputtering deposition was examined by x-ray diffraction and was shown to be primarily cuprous oxide.

In this paper, a chemical plating process for fabrication of semitransparent masks is described. The deposited films are based on a copper-containing compound which is readily deposited from aqueous solutions on heterogeneous interfaces, and provides the proper optical characteristics required for see-through mask application.

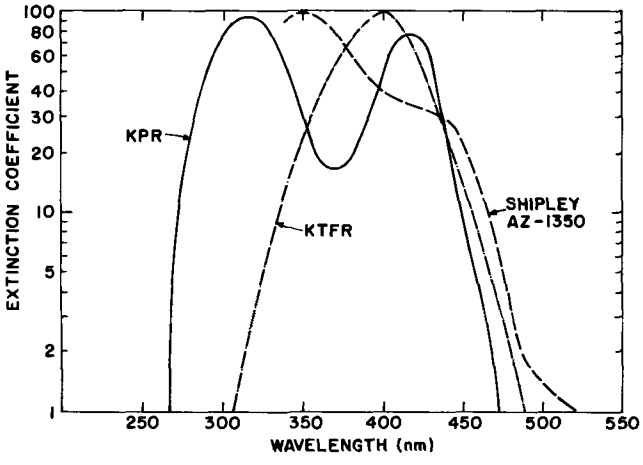

Fig. 1. Spectral sensitivities of commonly used resists

Experimental Procedures

In the current work, the glass substrates were pretreated in a fashion similar to the pretreatment of dielectrics prior to chemical (electroless) plating (16). Following an adequate cleaning procedure, the substrates were immersed in a sensitizer solution ($SnCl_2$/HCl) followed by an immersion in an activator solution ($PdCl_2$/HCl). Typical compositions used for the sensitizer and activator were as follows: sensitizer solution, $SnCl_2 \cdot 2H_2O$ 10 g/liter and HCl (conc) 30 ml/liter; activator solution, $PdCl_2$ 1 g/liter and HCl (conc) 1 ml/liter.

Due to a reaction (17) taking place between the adsorbed tin(II) and palladium(II), adsorbed palladium nuclei are present on the surface after the activation step. It is the presence of such nuclei that provides

Table I. Electroless copper plating bath

the catalytic sites required for the initiation of the autocatalytic plating process (16-18).

The "electroless copper" bath given in Table I is of typical composition which was used in the current process. In addition to sodium hypophosphite, other reducing agents were also found effective in producing the semitransparent films. Specifically, hydrazine sulfate $[(NH_2)_2SO_4H_2]$ and sodium hydrosulfite $(Na_2S_2O_4)$ provided films similar to those obtained when using hypophosphite. Following the plating cycle, a thin, adherent yellow film was present on the surface. The durability of the films was evaluated using a Tukon Microhardness Tester. In each case, the end point was defined as the required load to produce a break in the film.

Results and Discussion

Figure 2 shows the spectral characteristics of the current films in the visible and uv ranges. In a typical deposition cycle, the film thickness was found to be approximately 600Å. As seen, the deposited film shows a high degree of transmission in the visible range, with a substantial transmission decrease in the spectral region below 450 nm. As mentioned earlier, it is this optical property which is essential for see-through photomasks. The low transmission level in the spectral range below 450 nm provides good light absorption for the actinic light used to expose typical commercial resists.

In an attempt to characterize the deposited film, an x-ray diffraction technique was employed. Results show a diffuse pattern which closely resembles published diffraction patterns of cuprous oxide (Cu_2O). Furthermore, the visual appearance of the deposits (Cu_2O) is in agreement with reported observations. As reported previously (19, 20), cuprous oxide may range from yellow to red in color depending on the particle size. Wet chemical analysis of the deposited films showed a copper content of 82% by weight; the theoretical value of copper present in cuprous oxide is 89%. Using an attenuated total reflection method, the infrared spectra was found to be similar to a previously reported spectra (21) of cuprous oxide.

Figure 3 shows the variations in deposit weight as

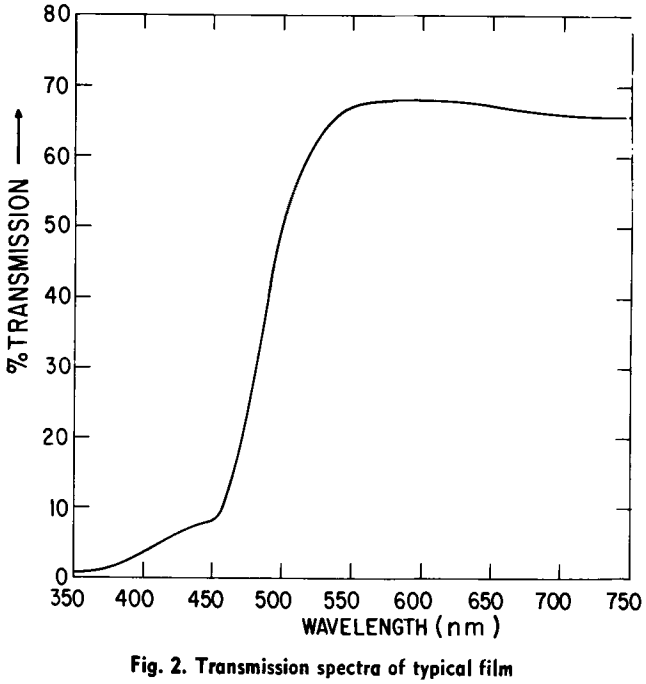

Fig. 2. Transmission spectra of typical film

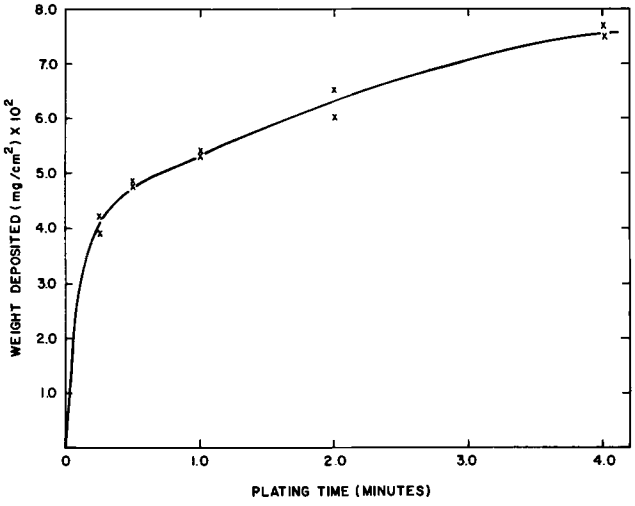

Fig. 3. Weight gain vs. immersion time

plating time was varied. As seen, the deposition phenomenon shows a leveling effect with deposition time, suggesting that the process is not a true autocatalytic plating process. In general, it was observed that prolonged deposition cycles (> 2 min) resulted in inferior uniformity. To account for the mechanism of deposition, Table II is provided. Although reactions [1] and [2] are similar to those proposed in electroless nickel plating (21, 23), the reduction of divalent copper is carried out to the monovalent ion. Due to the extreme insolubility of cuprous oxide in alkaline media, a heterogeneous precipitation takes place. The deposited cuprous oxide, however, does not provide sufficient catalytic activity for the continuation of the plating process, hence, cessation takes place with time. The disproportionation of copper(I) (reaction [4]) is generally prevented by the presence of strong complexing agents for copper(I).

In order to evaluate the efficiency of the copper reduction, a typical solution was thermally decomposed by boiling for about 30 min. The depletion in hypophosphite concentration was determined by an iodine/thiosulfate titration, and the precipitated Cu_2O was dissolved in ammonium hydroxide and analyzed for copper content. The molar ratio of the consumed hypophosphite to copper(I) formed was then calculated. Results based on several repeated runs showed a $Cu^+/H_2PO_2^-$ ratio of 1.95 ± 0.15. The value of 2.00 would be anticipated (see Table II) if only Cu^{+2} is reduced and no other specie(s) was reacting with the adsorbed hydride. Based on these results, it is believed that reaction [4] of Table II does not take place to any appreciable extent.

For the purpose of pattern delineation, it was found that alkali metal hydroxide solutions have virtually no effect, and this is consistent with the low solubility of cuprous oxide in such media. However, good edge definition has resulted with dilute hydrochloric acid, dilute ammonium hydroxide, or ammonium persulfate. In dilute solutions (5-10% by volume) of concentrated ammonium hydroxide (58% NH_4OH) an etch time of about 1 min was established. Figure 4 shows a typical test pattern of the current see-through mask as well as a developed resist pattern prepared from the see-through mask.

As mentioned previously, it is desirable to achieve films which are highly scratch resistant. Having this property, faithful replication can be carried out over many printings. The films deposited by the current method were found to be soft when compared to iron

oxide masks. Two approaches were undertaken to improve this limitation. In the first method, it was found that a baking for about 30 min at about 200°C provided increased durability for the film. In fact, it was found that this modification resulted in scratch resistant values better than those obtained for conventional silver-halide emulsion masks, however, not as good as the iron oxide. Alternatively, it was found that special commercial protective films (22) may be deposited on the copper oxide films. Typical materials used successfully were Scotch-Clad Strip Coating No. 2253, product of 3M Company, and Maskguard, product of Atomel Corporation, Mill Valley, California. These films do not affect the optical characteristics of the masks and they provide a "buffer zone" for abrasion. These films are conveniently deposited and removed, if necessary.

Conclusions

A process for the fabrication of semitransparent photomasks has been developed. The developed process utilizes chemical plating techniques for depositing thin cuprous oxide films. These films provide the necessary optical requirements and they can be readily delineated with common etchants. Using dilute ammonium hydroxide as a typical etchant, good edge definition was obtained. The heat-treated copper oxide film was found to be of greater durability when compared to emulsion masks, but of lower durability in comparison to iron oxide masks.

In comparing the current process with those reported on the same subject, it is apparent that the present technique is especially useful in the ease of preparation of both small- and large-size masks. Moreover, the present process does not require elaborate capital equipment. Hence, it is believed that the present approach may provide photomasks at reduced costs.

Activities of Organic Compounds in Aqueous Electrolyte Solutions

D. M. Mohilner,* L. M. Bowman,[1] S. J. Freeland, and H. Nakadomari

Colorado State University, Department of Chemistry, Fort Collins, Colorado 80521

ABSTRACT

A gas chromatographic method is described which permits the direct measurement of the activities of neutral organic compounds in aqueous electrolyte solutions. This method has a relative precision of about 0.5%; it is convenient and fairly rapid, and the apparatus required is relatively inexpensive. The significance of such activity measurements to electrosorption studies of organic compounds on electrodes is discussed. The method is equally applicable to organic compounds which are either liquid or solid in the pure state at the temperature of the electrosorption studies. It may also be used to determine the complete activity-composition phase diagrams of two component mixtures of the organic compound and water.

Determination of the isotherms for electrosorption of neutral organic compounds at electrodes from aqueous electrolyte solutions is always based in principle on the following fundamental equation derived from the thermodynamic theory of electrocapillarity (1)

$$\Gamma_{ow} = -(1/RT)\,(\partial\gamma/\partial \ln a_o)_{T,p,E,a_s} \qquad [1]$$

In Eq. [1], Γ_{ow} is the relative surface excess of the organic compound (with water as the reference component), R is the gas constant, T is the absolute temperature, γ is the interfacial tension of the electrode, a_o is the activity of the organic compound in the bulk electrolyte solution, and the subscripts T, p, E, and a_s indicate that the differentiation is carried out at constant temperature, pressure, electrode potential, and activities of all other solutes. In practice, however, although it is the thermodynamically correct relationship, Eq. [1] has almost never been used (2) because the activities of organic compounds in aqueous electrolyte solutions have not been generally available (3), and the measurement of these activities appeared too difficult. Instead, the following approximate equation has served as the basis of almost all published studies of electrosorption of organic compounds

$$\Gamma_{ow} = -(1/RT)\,(\partial\gamma/\partial \ln c_o)_{T,p,E,c_s} \qquad [2]$$

Equation [2] differs from Eq. [1] in two important ways. First, the differentiation is carried out at constant concentration, c_s, of the electrolyte. This means that the tacit assumption has been made that the activity of the electrolyte in the solution is unaffected by the presence of the organic compound. Recent work in this laboratory (4) has shown that this assumption is definitely false. Second, it is assumed that the differentiation may safely be carried out with respect to the concentration, c_o, instead of the activity, a_o, of the organic compound in the bulk solution. For a fixed activity of the electrolyte, this assumption would be valid if the activity coefficient of the organic compound were constant over the range of concentrations studied, *i.e.*, if the organic compound obeyed Henry's law over the entire concentration range. It will be shown below that this assumption is not generally valid. For comparison of adsorption data for the same organic compound from solutions of different electrolytes or from solutions of the same electrolyte at different electrolyte activities, the assumption that the concentration of the organic compound may be safely substituted for the activity is always very seriously wrong as was first shown by Frumkin (5) as early as 1919. Recently Bauer (6) has discussed this problem and has indicated a method of introducing activity corrections as the ratio of the solubility of the organic compound in the electrolyte solution to the solubility in pure water. Such a correction, however, is valid only if the organic compound obeys Henry's law in both the electrolyte and in pure water up to saturation, which is not generally true. Therefore it is apparent that from the standpoint of electrosorption studies there is a need for a convenient and precise method for determining the activities of organic compounds in aqueous electrolyte solutions.

This paper describes such a method. It is based on the use of a gas chromatograph equipped with a gas-sampling valve and a flame ionization detector. The apparatus required is relatively inexpensive.

Related prior work utilizing gas chromatography to measure the equilibrium vapor pressure of pure organic liquids at different temperatures for determination of heats of vaporization via the Clausius-Clapeyron equation was published by Mackle and co-workers (7-8), who gave a design for a gas-sampling valve. Wichterle and co-workers (9-10) described a gas chromatographic method for measuring equilibrium partial vapor pressures for two-component nonelectrolyte solutions such as hexane-toluene, and they also gave a design for a gas-sampling valve. Related measurements using a gas-tight syringe instead of a gas-sampling valve were reported by Klopstock and Rogozinski (11). Pollak and Cave (12) described a gas chromatographic method using a gas-sampling valve for measuring the activity coefficients of methanol and of ethanol in benzene. Maffiolo and Vidal (13) described a gas chromatographic method for measuring the equilibrium partial vapor pressures for two- and three-component nonelectrolyte mixtures such as acetone-hexane and aniline-benzene-hexane. None of this prior work was concerned with the measurement of the activities of organic compounds in aqueous solutions or in the presence of electrolytes, and in all cases a thermal conductivity detector was used, although Pollak and Cave (12) did refer to the enhanced sensitivity which would be expected with a flame ionization detector. The method described in the present paper is specifically designed to yield activities of organic compounds in three-component, aqueous electrolyte solutions, and it takes special advantage of the fact that a flame ionization detector does not respond to water.

Theoretical

The principle of the method is the measurement of the equilibrium partial vapor pressure, p_o, of the organic compound in the solution. The activity may then be calculated as the ratio of p_o to the vapor pressure, p_o^*, of the pure liquid organic compound at the same temperature as the solution. This means the standard state chosen is the pure liquid compound (14). The advantage of this choice of the standard state over that of a hypothetical solution obeying Henry's law is that it facilitates comparison of electrosorption data ob-

Key words: activity coefficients, gas chromatography, electrosorption, phase diagram.

tained from different electrolytes or from solutions with different activities of the same electrolyte (15). Vapor pressure may safely be used in the calculation in place of fugacities because at the low values of the pressures encountered the vapors behave nearly ideally, and, moreover, any slight deviation of the vapors from ideality tend to cancel in taking the ratio (14). Thus the activity of the organic compound in a given electrolyte solution will be taken as

$$a_o = p_o/p_o^* \quad [3]$$

In fact, the quantities actually measured are not p_o and p_o^* but rather the integrals of gas chromatograms produced by equal-volume gas samples of the vapor in equilibrium with solution or the pure liquid organic compound. These integrals, I_o, and I_o^*, respectively, are each directly proportional (with the same proportionality constant) to the corresponding vapor pressures. Thus the activity of the organic compound in the electrolyte solution will be given by

$$a_o = I_o/I_o^* \quad [4]$$

Experimental

General description of the apparatus.—A block diagram of the apparatus is shown in Fig. 1. Samples either of the solution or of the pure liquid organic compound are placed in glass tubes A and B. The bottom of each tube is a fine porosity glass frit which serves the dual purpose of holding the liquid sample in the tube and of dispersing the nitrogen gas which is passed through the liquids into very fine bubbles. Each of the tubes is provided with a jacket through which water from a thermostat is pumped. Prepurified nitrogen gas from a tank is bubbled at a rate of 3-6 cm³/min through the two tubes which are connected in tandem by glass tube C using stainless steel Swagelok unions with Teflon ferrules. The purpose of tube A is simply to presaturate the nitrogen with water and/or organic vapor. The gas bubbling through tube B then becomes saturated with water vapor and/or organic vapor at the equilibrium partial pressures corresponding to the thermostat temperature (25°C in the experiments described below). This means that each unit volume of gas passing out of tube B contains a quantity of water and/or a quantity of the organic compound which is directly proportional to the corresponding equilibrium partial vapor pressure. The thermostated portions of tubes A and B are 1/2 in. OD and are about 3 ft long. The tubes are filled only about 1/3 full to prevent the carrying over of spray. Tube B is connected to the gas-sampling valve by glass tube D. Tube D is wrapped over its entire length with a spiral of Chromel wire which is heated by passing an electric current from a variable transformer. It is very important that tube D be heated. Otherwise condensation could occur on its walls which would invalidate the measurements.

The gas chromatograph used is a Hewlett-Packard Model 700 equipped with a flame ionization detector.

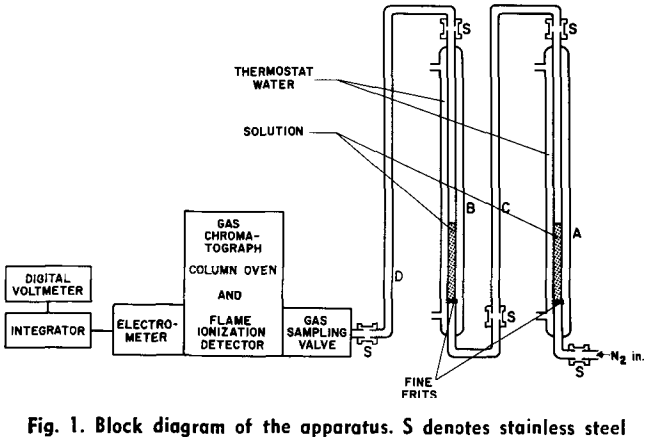

Fig. 1. Block diagram of the apparatus. S denotes stainless steel Swagelok union with Teflon ferrules.

The main reason a flame ionization detector was chosen is that it does not respond to water (or N_2). This insures that there is no interference from the water peak which for aqueous solutions is much larger than the organic peak. The enhanced sensitivity of a flame ionization over a thermal conductivity detector is a secondary reason for the choice. For the experiments described below which involved the determination of the activities of aliphatic alcohols, the chromatographic column was a 6 ft length of ⅛ in. OD stainless steel tubing packed with Porapak-Q,[2] 80-100 mesh. For other type compounds, column packings can be chosen as appropriate (16). For the experiments described in this paper the column oven was controlled at 220°C while the detector and injector port were controlled at 300° and 190°C, respectively.

The gas-sampling valve used was a Hewlett Packard Model 19021A heated dual-loop gas sampling valve whose temperature was maintained at 145°C by a Hewlett-Packard Model 19045A temperature controller. It is necessary to use a heated gas-sampling valve; otherwise errors due to adsorption or condensation in the sample loops will invalidate the measurements. The 1/16 in. OD stainless steel tube connecting the gas-sampling valve to the injection port of the chromatograph was also heated by wrapping it with a heating tape controlled by a variable transformer.

The Model 19021A gas-sampling valve contains two sample loops (5 cm³ in the experiments described here). Depending on the position of the control knob, one loop is connected to the helium carrier gas stream, and its contents are swept into the injection port and thence into the column. The other loop is connected to tube D (Fig. 1) and is thus being filled with vapor from the solution (or pure compound) in tube B. When the control knob is turned, the sample loop which was being filled is connected to the carrier gas stream, and its contents are swept into the column. At the same time the first loop is connected back to tube D, and it is refilled with a new sample of vapor.[3] The dual sample loops thus permit repetitions of measurements to be made at a maximum rate. In the experiments described in this paper the measurements could be made about every 4 min.

The entire organic sample eluted from the chromatographic column is burned in the hydrogen-air flame of the detector, and the resulting tiny electric current produced in the detector is transduced by the electrometer (Hewlett-Packard Model 5771A) into an analog voltage signal which is directly proportional to the instantaneous amount of organic sample being burned. Hence the time integral of this analog voltage is directly proportional to the total amount of the organic compound in the gas sample and therefore also to the partial pressure of the organic compound in the vapor phase in tube B which is in equilibrium with the liquid phase in the tube at the thermostat temperature (25°C).[4] The analog voltage signal from the electrometer is fed into an integrator circuit (Fig. 1), and the output of the integrator is read out on a digital voltmeter (Fluke Model 8300A).

Integrator and control circuit.—Figure 2 shows a typical chromatogram for an aliphatic alcohol (2-butanol) on the Porapak-Q column. The chromatogram is asymmetric and exhibits a considerable degree of "tailing." Integration of a peak with such tailing is troublesome because the integrator tends to drift slowly for a long period. This leads to irreproducibility in the results because one cannot be sure when to

[2] Manufactured by Waters Associates, Inc., Framingham, Massachusetts.

[3] The sample loop which is being filled with vapor from tube D exhausts to the atmosphere. Thus the total pressure in the sample loop and hence on the liquid in tube B is the ambient barometric pressure. However, the results of the activity measurements are independent of fluxuations in the barometric pressure because of the negligibly small influence which the total pressure on the liquid exerts on the vapor pressure (14).

[4] It is important to realize that this proportionality is exact in spite of the fact that tube C and the gas-sampling valve are at different temperatures from tube B. In fact, the temperature of tube C is immaterial. The only requirement is that the temperature of the gas-sampling valve be kept constant.

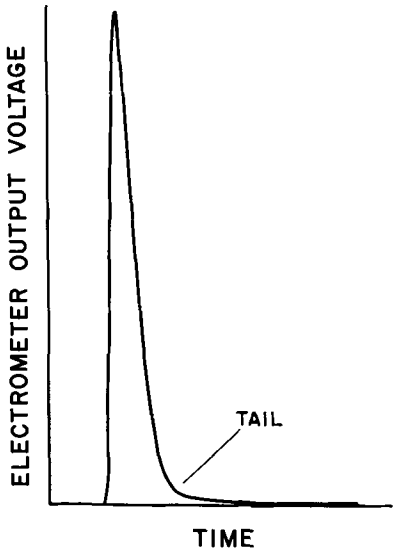

Fig. 2. Typical gas chromatogram of aliphatic alcohol on Porapak-Q.

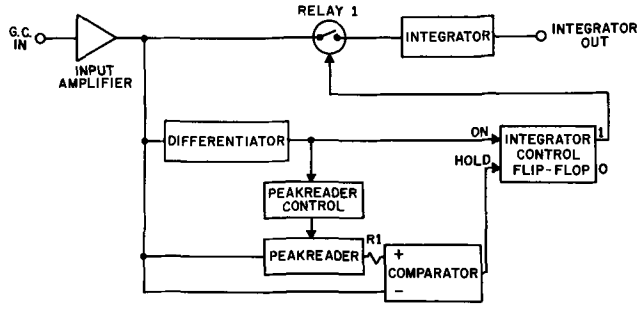

Fig. 3. Block diagram of integrator control circuit

stop the integration. It was found that a satisfactory solution to this problem was to stop the integration when the analog voltage from the electrometer had dropped to some preselected fraction of the peak voltage. For this purpose the circuit shown in block diagram in Fig. 3 and in detail in Fig. 4 was designed. This circuit automatically turns on the integrator when the chromatogram begins and then automatically stops the integration and causes the integrator to hold its voltage when the analog voltage output of the electrometer has dropped to the preselected fraction of the peak value (0.5% in the experiments described below). The actual value of this fraction is determined by the value of resistor R1 in Fig. 3 and 4.

The principle of operation of this circuit can be understood with reference to Fig. 3. The analog voltage signal from the electrometer (G.C. IN) is fed into an input amplifier which serves primarily for impedance matching. The output of this amplifier is then fed into a differentiator. When the derivative goes from zero on the base line to positive when the chromatogram begins, the integrator control flip-flop is switched to the "1" state. This causes mercury wetted relay 1 to close thereby connecting the integrator input to the output of the input amplifier. Simultaneously the positive going derivative causes the peak reader control which operates mercury wetted relay 2 (Fig. 4) to connect the peak reader amplifier, which then starts following the chromatogram. When the peak of the chromatogram occurs the derivative passes through zero. This causes the peak reader to hold the value of the peak voltage. The output of the peak reader is fed through resistor R1 into one input of a comparator, *i.e.*, the preset fraction of the peak voltage is fed into this input of the comparator. Simultaneously, the

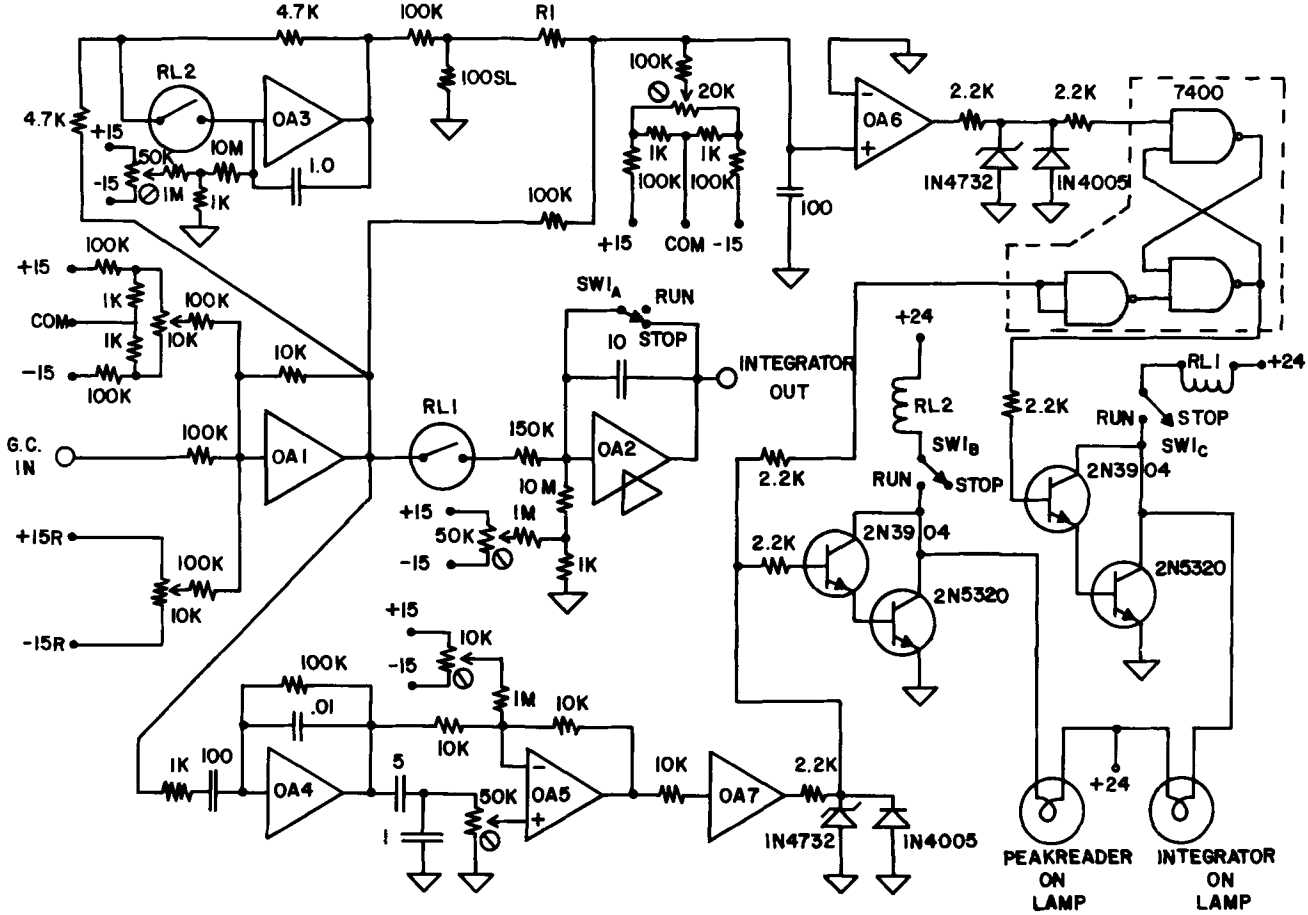

Fig. 4. Circuit diagram of integrator control circuit. The operational amplifiers used are: OA1, Philbrick 1020; OA2, Philbrick 1700, chopper stabilized; OA3, Philbrick 1023; OA4 and OA5, Philbrick SQ10A; OA6 and OA7, Model 741.

input amplifier which is following the chromatogram feeds into the other input of the comparator. When the voltage at this second input of the comparator drops to the value of the preset fraction of the peak voltage, the comparator changes state which in turn causes the integrator control flip-flop to switch to the "O" state. This action opens relay 1, and the integrator holds the integral of the chromatogram which is then read by the digital voltmeter. This circuit can be built for a very small fraction of the cost of a commercial gas chromatographic integrator. We have found it to be quite reliable, and it is convenient to use.

Operating Procedure.—In order to make precise measurements of the activity of an organic compound in a series of solutions, the following procedure has been found to be most effective. Two identical sets of tubes (Fig. 1) A, B, C, D, and A', B', C', and D' are used. The first pair of tubes, A and B, is filled with the pure compound. The first solution in the series is put in tubes A' and B'. Separate nitrogen tanks provide the flow of prepurified nitrogen into each of the two pairs of tubes. Tube D for the pure compound is connected to the gas-sampling valve. Successive samples of vapor from the pure compound are passed through the gas chromatograph, and the sensitivity of the flame ionization detector is adjusted until a suitably large integral is obtained (typically, 6.0-7.0V). The sensitivity of the flame ionization detector may be varied most easily by changing the output pressure at the air tank, keeping the output pressure at the hydrogen tank constant.[5] When the detector sensitivity has been set, a series of at least five samples of vapor from the pure organic compound are sent through each sample loop and the average value of the integral I_0^* for each loop is determined. Typical relative standard deviations of about 0.5% are obtained. Tube D is then disconnected and tube D' from the pair of tubes containing the solution is connected to the gas-sampling valve. Several samples of vapor are sent through each sample loop and the average value of the integral I_0 is obtained.[6] Then, in order to insure that the sensitivity of the detector has not drifted, tube D' is disconnected and tube D is reconnected to the gas-sampling valve, and several samples of vapor from the pure organic compound are again chromatographed. If the value of I_0^* now obtained lies within the confidence limits of the previous determination it may be assumed that the detector sensitivity was the same when the solution was chromatographed as it was when the value of I_0^* was first determined. If the detector has drifted, it must be reset so that the original value of I_0^* is obtained, and then the vapor from the solution is again chromatographed. This procedure is followed for each solution sample. It insures that the solution chromatograms are integrated at the same detector sensitivity as the pure compound and thus that the activities determined are valid.[7]

Results and Discussion

The quality of activity data which can be obtained with this apparatus using the procedure described above is illustrated by Fig. 5. This is a plot of the activity of 2-butanol at 25°C *vs.* its mole fraction in aqueous solutions of sodium sulfate in which the mean ionic activity, $a_\pm$, is held constant[8] at a value of 0.07087. The relative probable error in the activity was calculated not to exceed 0.5% for each of the seven concentrations (0.5, 0.6, 0.7, 0.84, 1.0, 1.2, and 1.4M) of the 2-butanol at which the activity was measured. The points for the three lowest concentrations fit quite accurately on a straight line passing through the origin. This means that for concentrations of 2-butanol up to 0.7M Henry's law is obeyed, and the activity coefficient of 2-butanol is constant. However, for concentrations of 2-butanol greater than 0.7M the true activity deviates negatively from the Henry's law line, and these deviations become quite serious in the high concentration region. For example, in the range of concentrations between 1.2 and 1.4M, it can be shown that the value of the relative surface excess Γ_{ow} calculated by Eq. [1] from the true activities is nearly twice as high as the Γ_{ow} values which would be calculated assuming Henry's law was still valid in this range. This result illustrates the fact that the assumption of a constant activity coefficient for the organic compound can produce very serious errors in the interpretation of electrosorption data.

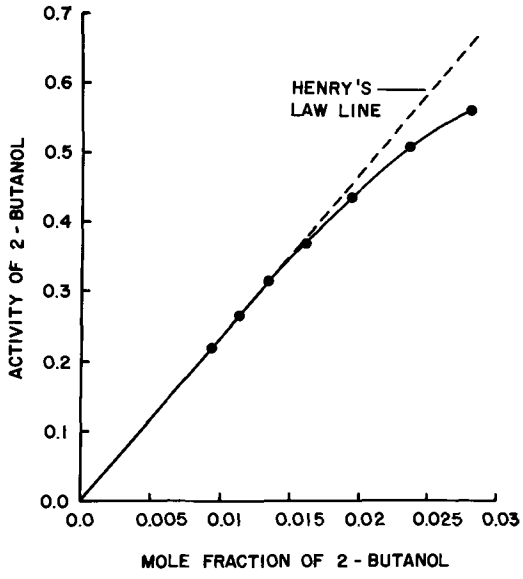

Fig. 5. Activity of 2-butanol in aqueous solutions of Na_2SO_4 in which the mean ionic activity, $a_\pm = 0.07087$.

It is strongly recommended that in future studies of the electrosorption of organic compounds on electrodes from aqueous electrolyte solutions two preliminary experimental steps not previously employed should always be taken. First, a preliminary study should be made to determine what concentration of the electrolyte is required for each concentration of the organic compound to yield a constant mean ionic activity (4) in the series of solutions to be used in the electrosorption studies.[9] After the recipe for preparation of the series of solutions has been thus established, the activity of the organic compound in each of the solutions should be determined by the method described above. Of course, it will not be necessary to make an actual measurement of the activity for every solution in the electrosorption study. It is only necessary to establish the activity-composition curve (such as Fig. 5) for the system. In most cases six to eight actual measurements will probably be sufficient to establish this curve.

It should be pointed out that a slight modification in the method described above will permit its extension to organic compounds which are solids in the pure

[5] It is very important for this purpose to use two-stage reduction valves such as the Matheson Model 8. Single-stage reduction valves do not permit a sufficiently sensitive pressure adjustment.

[6] The two sample loops have the same nominal volume, but their actual volumes may typically differ from each other by several per cent. It is therefore important when calculating the activity to divide the I_0 value by the I_0^* value for the same sample loop.

[7] An alternative procedure would be to use nitrogen which contains a suitable concentration of another gas which can serve as an internal standard. Besides the obvious requirement that the internal standard be detectable by flame ionization, it would have to possess the following three properties: (*i*) It would need a retention time which was sufficiently longer than that of the compound which was being studied that there would be time to take the integral of that compound, reset the integrator, and then take the integral of the chromatogram of the internal standard. (*ii*) It would have to be essentially totally insoluble in water. (*iii*) It would have to be essentially totally insoluble in the pure organic compound whose activity is being measured. Properties (*ii*) and (*iii*) seem very difficult to obtain with a single substance.

[8] This is the value of the mean ionic activity of a 0.1M (0.10045*M*) solution of sodium sulfate in pure water (17). In order to maintain $a_\pm$ constant in the presence of the organic compound the concentration of the Na_2SO_4 must be adjusted for each solution (4). For example, when the concentration of 2-butanol is 1.0M, the concentration of the Na_2SO_4 required to make $a_\pm = 0.07087$ is 0.0498M.

[9] The only time this step is unnecessary is when the solutions are to be saturated with a solid salt, in which case the mean ionic activity is automatically constant.

state at the temperature of the electrosorption experiments. The only change needed is to fill tubes A and B (cf. section on Operating Procedure) with a saturated solution of the solid organic compound in pure water. In the saturated solution, the fugacity of the organic compound in the solution, and therefore also of the compound in the vapor phase in equilibrium with the solution, will be equal to the fugacity of the pure solid compound. Therefore, the ratio of the integral of the chromatogram of the vapor sample from the electrolyte solution, I_o, to the integral, I_o^*, of the chromatogram of the vapor sample from the saturated solution of the compound in pure water will yield the activity of the organic compound in the electrolyte solution. In this case, however, the standard state will be the pure solid organic compound at the temperature of the electrosorption studies.

This same method can also be applied to the problem of determining the complete activity-composition phase diagram for two component mixtures of an organic compound and water. This application of the method is illustrated in Fig. 6. Here we have measured the activity of 2-butanol in two component mixtures with water over the mole fraction range of zero to unity for both components. This system exhibits phase separation into a water-rich and an alcohol-rich phase when the concentration of the 2-butanol reaches a value of 1.8M. The activity of the 2-butanol in each of the two saturated solutions should be the same. The measurements verified this fact. In addition it can be seen from Fig. 6 that the activity of the alcohol approaches the Raoult's law line as the mole fraction approaches unity, as it should. The very large deviations of the alcohol activity from the Henry's law line as the concentration of 2-butanol approaches that of saturation shows clearly that activity corrections based on solubility measurements assuming Henry's law is valid up to saturation will be seriously in error. The activity-composition curve for the water in this system could easily be obtained from the data in Fig. 6 by integration of the Gibbs-Duhem equation (14).

Conclusions

A gas chromatographic method for the measurement of the activities of neutral organic compounds in aqueous electrolyte solutions has been developed, and the importance of application of this method to electrosorption studies has been indicated. The measurements with the apparatus described are convenient and quite precise, and the apparatus is relatively inexpensive. The method may be applied to organic compounds which are either liquid or solid in the pure state at the temperature of the electrosorption experiments. In addition, the same apparatus can be used to determine the complete activity-composition phase diagram of two-component mixtures of the organic compound and water.

Electromotive Force Measurements on Cells Involving Beta-Alumina Solid Electrolyte

Nabendu S. Choudhury*[1]

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

Open-circuit emf measurements have been made to demonstrate that a two-phase, polycrystalline mixture of β-alumina and α-alumina could be used as a solid electrolyte in galvanic cells with reversible electrodes fixing oxygen or aluminum chemical potentials. These masurements indicate that such a two-phase solid electrolyte may be used to monitor oxygen chemical potentials as low as that corresponding to Al, Al_2O_3 coexistence ($P_{O_2} \approx 10^{-47}$ atm at 1000°K). The activity of Na_2O in β-alumina in coexistence with α-alumina was also determined by emf measurements.

Normally available polycrystalline beta-alumina (nominal composition $Na_2O \cdot 11Al_2O_3$) has been shown (1-4) to be really a two-phase mixture of beta-alumina (approximate composition $Na_2O \cdot 9Al_2O_3$) and alpha-alumina (Al_2O_3 with negligible or no doped sodium oxide). The three component, two-phase system has three degrees of freedom ($F = C - P + 2$; where F is the number of degrees of freedom, C the number of components, and P the number of phases) and at a particular temperature and pressure (which is nominally fixed at 1 atm), this is reduced to only one. Thus the thermodynamic state of the system at a particular temperature and pressure is completely defined if the chemical potential of any one of the components, *viz.* Na, O, or Al, is fixed.

The above considerations do not include electronic defects. However, if electronic defects are also considered, the local electroneutrality condition (together with the various chemical equilibria between electrons, ions, and neutral species) must also be taken into account in effect providing an additional constraint. Moreover, beta-alumina is known to be a good Na^+ ion conductor with negligible or no electronic conduction (5, 6) and alpha-alumina is an excellent insulator. Therefore, the measured open-circuit emf's, in an electrochemical cell with beta-alumina solid electrolyte, do not depart significantly from the thermodynamic emf's (6). These results were also confirmed by recent experiments conducted in this laboratory (7).

In all previous investigations (6-8), involving open-circuit emf measurements with beta-alumina solid electrolyte, the Na chemical potential has been controlled at both electrodes. The purpose of the present investigation is to determine if meaningful open-circuit emf's may be measured with electrodes fixing O or Al chemical potentials. If the phase rule applies as described above, fixing O or Al chemical potential is equivalent to fixing the Na chemical potential.

Experimental Technique

The beta-alumina solid electrolyte disks were prepared in this laboratory from beta-alumina powder (<325 mesh) supplied by Aluminum Corporation of America. The powder was pressed into ¾ in. diameter, ⅛ in. thick disks at 55,000 psi and sintered with β-alumina powder in dry air at 1690°C for 1 hr. The resulting material had 60-65% theoretical density and was kindly supplied by Dr. W. L. Fielder of this laboratory.

The cell for measuring emf's consisted of solid reversible electrodes and a beta-alumina solid electrolyte disk. The electrodes were held in contact with the beta-alumina disk by spring pressure applied through α-alumina tubes, which constituted the cell assembly. The design was similar to that described by Skelton and Patterson (9). Platinum lead wires were connected to the electrodes. The tip of a Pt-Pt, 13% Rh thermocouple, insulated by α-alumina tubes, was positioned close to the cell. The cell assembly enclosed in a closed-end α-alumina furnace tube formed a gas-tight system. Insulated feed-throughs were used to provide electrical connections external to the system. The heating system consisted of a wire (Kanthal) wound tube furnace with a controller to maintain the cell temperature to within ±1°C. The α-alumina furnace tube was shielded by a grounded stainless steel tube to minimize electrical noise. All electrical connections external to the furnace were made with shielded cables, with the shields appropriately grounded.

The cell emf's were monitored with an electrometer (input impedance 10^{14} ohms) or a digital voltmeter (input impedance 10^9 ohms). The temperature was monitored with a potentiometer in conjunction with a null detector. An electronic cold junction compensator was used to provide compensation for the cold junction temperature of the thermocouple.

At the beginning of each run, the system was evacuated to 10^{-2} Torr, flushed with helium and evacuated again. This procedure was repeated several times. The helium was purified by passing it through copper turnings held at 400°C and a liquid nitrogen cold trap before entering the system. Subsequent to the flushing and evacuation procedure the system was filled with helium and a slow and steady flow of helium was maintained through the system. The furnace was then brought to the measuring temperatures. The emf's were recorded after waiting for at least ½ hr at each temperature. The attainment of equilibration was indicated by reproducibility of the recorded emf's on cycling the cell temperature within the range of measurements.

Results and Discussion

Electrodes fixing oxygen chemical potential.—Stable and reproducible open-circuit emf's were obtained from the following cells with electrodes fixing oxygen partial pressures

$$\text{Fe,FeO}/\beta\text{-alumina/Ni,NiO} \qquad [\text{I}]$$

and

$$\text{Ni,NiO}/\beta\text{-alumina/Cu,Cu}_2\text{O} \qquad [\text{II}]$$

Figure 1 illustrates the data obtained from 689° to 990°C for cell [I]. Kiukkola and Wagner's (10) data for the cell $Fe,FeO/CaO,ZrO_2/Ni$, NiO are indicated in Fig. 1 as the solid line. The data for cell [II] are shown in Fig. 2 along with Lasker and Rapp's (11) estimated

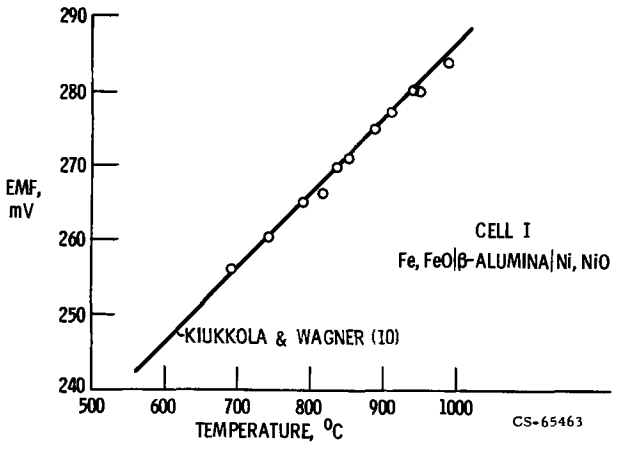

Fig. 1. Open-circuit emf against temperature for the cell Fe, FeO/β-alumina/Ni, NiO.

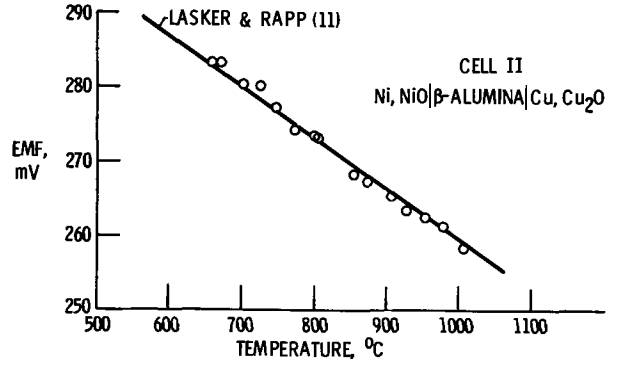

Fig. 2. Open-circuit emf against temperature for the cell Ni, NiO/β-alumina/Cu, Cu_2O.

thermodynamic emf for the cell. It is apparent that the open-circuit emf's observed with beta-alumina are in good agreement with the previously measured (with oxygen ion conducting solid electrolyte) and calculated thermodynamic emf's. It should be noted that the rate of equilibration at lower temperatures was progressively sluggish. For example, at 650°C cell [II] attained equilibrium only after waiting for 12 hr. In a few of the runs with Cu,Cu_2O electrodes, a considerable amount of Cu penetration was visually observed in the beta-alumina disks.

Determination of the Na_2O activity in beta-alumina.— Consider the reaction

$$Na_2O + xAl_2O_3 = Na_2O \cdot xAl_2O_3 \qquad [1]$$

where $Na_2O \cdot xAl_2O_3$ is the composition of β-alumina in coexistence with α-alumina. Because both β-alumina and α-alumina coexist in the standard state in the solid electrolyte, the standard free energy change for the above reaction is given by $RT \ln a_{Na_2O}$, where a_{Na_2O} is the activity of Na_2O in β-alumina in coexistence with α-alumina. This may be determined with a cell of the type M,MX_2,NaX/β-alumina/M', M'O provided M, MX_2 and NaX coexist in the standard state. The open-circuit emf for the above cell is given by

$$E = -\frac{RT}{F} \ln \frac{a_{Na}(R)}{a_{Na}(L)} \qquad [2]$$

The Na activities in the left- and right-hand sides of the cell are given by

$$RT \ln a_{Na}(L) = \Delta G^\circ_{NaX} - \frac{1}{2}\Delta G^\circ_{MX_2} \qquad [3]$$

$$RT \ln a_{Na}(R) = \frac{1}{2} RT \ln a_{Na_2O}$$

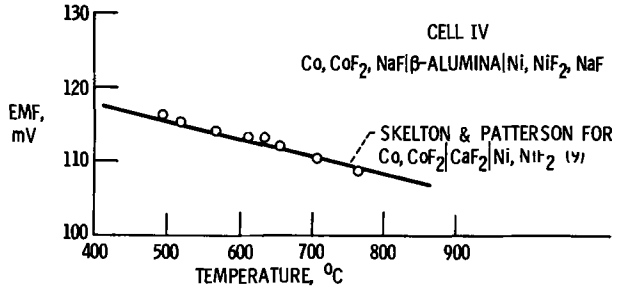

Fig. 3. Open-circuit emf against temperature for the cell Co, CoF_2, NaF/β-alumina/NaF, NiF_2, Ni.

$$+ \frac{1}{2}\Delta G^\circ_{Na_2O} - \frac{1}{2} 2\Delta G^\circ_{M'O} \qquad [4]$$

Combining Eq. [2], [3], and [4]

$$RT \ln a_{Na_2O} = -2EF + 2\Delta G^\circ_{NaX} - \Delta G^\circ_{MX_2} + \Delta G^\circ_{M'O} - \Delta G^\circ_{Na_2O} \qquad [5]$$

Ni,NiF_2,NaF/β-alumina/Cu,Cu_2O [III]

was the cell investigated in the present study. That Ni,NiF_2, and NaF coexist in the standard state at least up to 760°C was confirmed by measuring the open-circuit emf of the cell

Co,CoF_2,NaF/β-alumina/Ni,NiF_2,NaF [IV]

The observed emf's of cell [IV] between 490° and 764°C were in good agreement (Fig. 3) with those measured by Skelton and Patterson (9) with the cell Co,CoF_2/CaF_2/Ni,NiF_2. The solid line in Fig. 3 represents the least-square best fit of Skelton and Patterson's (9) data. It should be noted that NaF and NiF_2 form a eutectic at around 790°C (12), and this limits the use of Ni,NiF_2, NaF electrode to below this temperature.

Reproducible emf's were obtained for the cell Ni,NiF_2,NaF/β-alumina/Cu,Cu_2O between 576° and 725°C. The emf data for the above cell [III] is given in Table I and also illustrated in Fig. 4.

The least-square best fit of the data between 576° and 725°C is given by

$$E(\text{III})\ \text{mV} = (646.5 - 0.190T) \pm 1 \qquad [6]$$

where T is in °K. Above 725°C the emf's were low and irreproducible; presumably because of excessive evaporation of NaF affecting the Cu,Cu_2O electrode.

The standard free energies of formation of NiF_2 and NaF may be obtained from publications of Skelton and Patterson (9) and Steinmetz and Roth (13). The $\Delta G^\circ_{Na_2O}$ and $\Delta G^\circ_{Cu_2O}$ values may be obtained from JANAF tables (14). Using these values, the activity of Na_2O in β-alumina may be calculated from Eq. [4] and [5]. For example, at 1000°K $RT \ln a_{Na_2O} = -77.0$ kcal/mole, at 900°K $RT \ln a_{Na_2O} = -77.8$ kcal/mole, and at 800°K $RT \ln a_{Na_2O} = -78.7$ kcal/mole; the corresponding a_{Na_2O} values at 1000°, 900°, and 800°K are $10^{-16.83}$, $10^{-18.89}$, and $10^{-21.50}$, respectively.

In a review article on β-alumina electrolytes, Kummer (15) reported the thermodynamic data on β-alu-

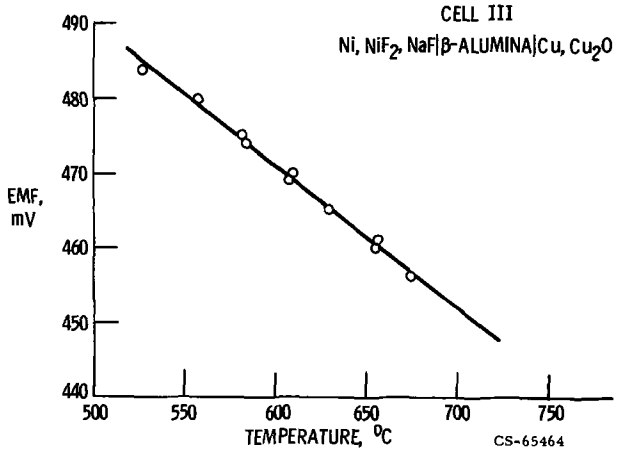

Fig. 4. Open-circuit emf against temperature for the cell Ni, NiF_2 NaF/β-alumina/Cu, Cu_2O.

mina obtained from emf measurements. The cell is schematically represented by $P_{O_2},Al_2O_3/\beta$-alumina (single phase)/$NaAlO_2,P_{O_2}$. In this work β-alumina was assumed to be a line compound in the analysis of the emf data. From the observed emf's between 1000° and 1600°C the standard free energy change per mole of β-alumina for the reaction

$$2NaAlO_2 + 10Al_2O_3 = Na_2O \cdot 11Al_2O_3$$

was calculated as −9.0 kcal at 1000°C and ≈0 at 140°C. $Na_2O \cdot 11Al_2O_3$ was the assumed stoichiometric formula for β-alumina; however, the observed emf's as well as the standard free energy change per mole of β-alumina is independent of the stoichiometry.

Beta-alumina is represented as $Na_2O \cdot xAl_2O_3$ instead of $Na_2O \cdot 11Al_2O_3$ in the following analysis. From the data reported by Kummer (15), the interpolated value of the standard free energy change per mole of β-alumina, at 1000°K, for the reaction

$$2NaAlO_2 + (x-1)Al_2O_3 = Na_2O \cdot xAl_2O_3 \quad [7]$$

is given by −6.14 kcal. The tabulated (14) free energies of formation of Na_2O, Al_2O_3, and $NaAlO_2$ may be combined to give the standard free energy change of −44.34 kcal, at 1000°K, for the reaction

$$Na_2O + Al_2O_3 = 2NaAlO_2 \quad [8]$$

Combining reactions [7] and [8] the standard free energy change at 1000°K for the reaction

$$Na_2O + xAl_2O_3 = Na_2O \cdot xAl_2O_3 \quad [1]$$

is given by −50.48 kcal.

However, as mentioned earlier the present work indicates a standard free energy change of −77.0 kcal, at 1000°K for reaction [1].

An attempt was made to resolve the apparent inconsistency by taking into account that β-alumina does in fact have a range of stoichiometry, from 1 to 4, rather than being a line compound. The cell reported in the review article (15) may then be represented as $P_{O_2},Al_2O_3/\beta(1),\beta(2)/NaAlO_2,P_{O_2}$, where β(1) is β-alumina ($Na_2O \cdot xAl_2O_3$) in equilibrium with Al_2O_3 and β(2) is β-alumina ($Na_2O \cdot yAl_2O_3$) in equilibrium with $NaAlO_2$. Thus the standard free energy change of −6.14 kcal at 1000°K corresponds to $RT \ln a_{Na_2O}(L)/a_{Na_2O}(R)$ where $a_{Na_2O}(L)$ is the Na_2O activity fixed by β-alumina ($Na_2O \cdot xAl_2O_3$) and Al_2O_3 coexistence and $a_{Na_2O}(R)$ is the Na_2O activity fixed by β-alumina ($Na_2O \cdot yAl_2O_3$) and $NaAlO_2$ coexistence. The value of $RT \ln a_{Na_2O}(L)$, at 1000°K, is given by −77.0 kcal/mole according to the present investigation. Therefore, combination of the previously reported results (15) with those of the present investigation yields $RT \ln a_{Na_2O}(R) = -70.86$ kcal/mole at 1000°K.

The thermodynamic stabilities of β(1) and β(2) toward decomposition into $NaAlO_2$ and Al_2O_3 are examined below. Reactions [1] and [8] may be combined to yield

$$Na_2O \cdot xAl_2O_3 = 2NaAlO_2 + (x-1)Al_2O_3 \quad [9]$$

Using the values of −77.0 kcal for reaction [1] and −44.34 kcal for reaction [8], the standard free energy change for reaction [9] is given by 32.66 kcal; which means that β(1) ($Na_2O \cdot xAl_2O_3$) is stable toward above mentioned decomposition at 1000°K.

Consider the reaction

$$Na_2O \cdot yAl_2O_3 + (y-1)Na_2O = 2yNaAlO_2 \quad [10]$$

The standard free energy change for the above reaction is given by $(y-1)RT \ln a_{Na_2O}(R)$ where $a_{Na_2O}(R)$ is the activity of Na_2O in a coexistent mixture of β-alumina ($Na_2O \cdot yAl_2O_3$) and $NaAlO_2$. Reactions [8] and [10] may be combined to yield

$$Na_2O \cdot yAl_2O_3 = 2NaAlO_2 + (y-1)Al_2O_3 \quad [11]$$

The standard free energy change for reaction [11] is given by

$$\begin{aligned}\Delta G^\circ_{11} &= (y-1)(RT \ln a_{Na_2O}(R) - \Delta G^\circ_8) \\ &= (y-1)(-70.86 + 44.34) \\ &= -26.52(y-1)\,\text{kcal} \qquad \text{at } 1000^\circ\text{K}\end{aligned} \quad [12]$$

Thus β(2) ($Na_2O \cdot yAl_2O_3$) is unstable toward decomposition into $NaAlO_2$ and Al_2O_3.

The apparent paradox of β(1) being stable and β(2) unstable toward decomposition may be resolved if an intermediate stable phase between β-alumina and $NaAlO_2$ in the Na_2O-Al_2O_3 system exists. Such a phase (*viz.* β″-alumina) is known to exist in the Na_2O-Al_2O_3 system (2, 4). Thus the coexistence of $NaAlO_2$ and β-alumina, as employed in the cell reported in the review article (15), must correspond to a thermodynamically metastable situation.

Electrodes fixing aluminum chemical potential.—Metallic aluminum was used as anodes fixing aluminum chemical potential in the following cells

$$Al/\beta\text{-alumina}/AlF_3,NiF_2,Ni \quad [V]$$

and

$$Al/\beta\text{-alumina}/NaF,NiF_2,Ni \quad [VI]$$

Emf measurements with compacted aluminum powder electrodes were not successful. However, reasonably stable emf's were obtained with Al electrodes in the form of a foil (1/16 in. thick). These cells had relatively short lives. It was further observed that the cell life could be prolonged when operated under vacuum instead of flowing helium. It is believed that rapid oxidation of aluminum at elevated temperatures is the cause of poor cell lives. However, under vacuum the cells lasted for 8 to 12 hr, during which the open-circuit emf data could be recorded.

The open-circuit emf of cell [V] is given by $E_V = -\frac{1}{3F} RT \ln a_{Al}$ where a_{Al} is the activity of aluminum at the cathode. Therefore, the emf E_V is also given by

$$E_V = -\frac{1}{3F}\left(\Delta G^\circ_{AlF_3} - \frac{3}{2}\Delta G^\circ_{NiF_2}\right) \quad [13]$$

Skelton and Patterson (9) have measured the open-circuit emf of the cell $Al,AlF_3/CaF_2/Ni,NiF_2$, which is also given by Eq. [13]. The data for cell [V] are plotted in Fig. 5, which also shows the least-square best fit line of Skelton and Patterson's (9) data. The agreement seems to be satisfactory at temperatures above 540°C. At temperatures below 540°C the observed open-circuit emf's of cell [V] fall significantly below

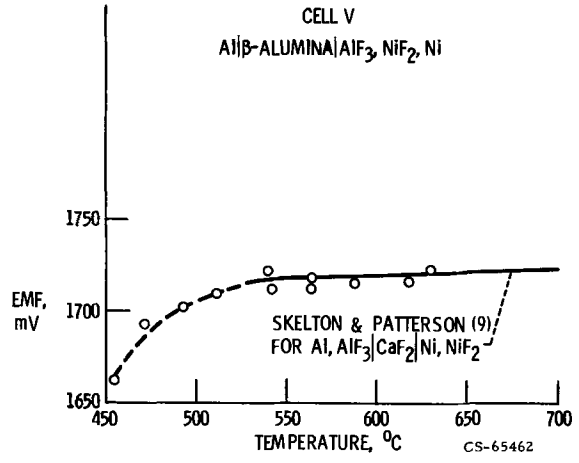

Fig. 5. Open-circuit emf against temperature for the cell Al/β-alumina/AlF_3, NiF_2, Ni.

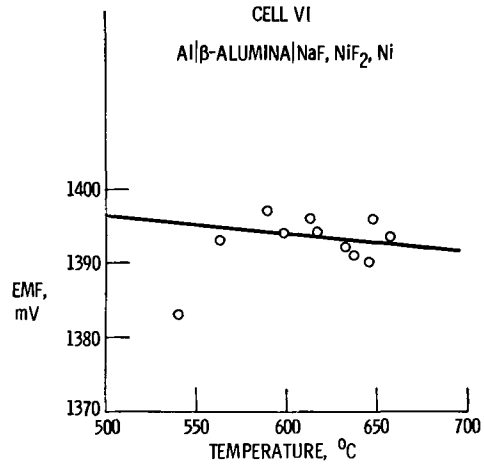

Fig. 6. Open-circuit emf against temperature for the cell Al/β-alumina/NaF, NiF_2, Ni.

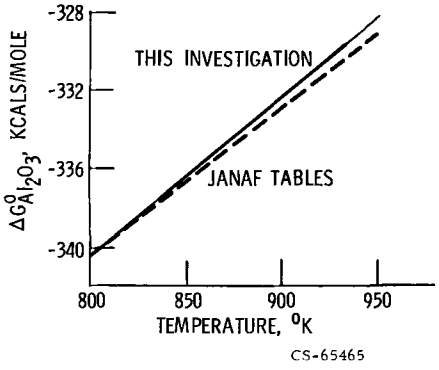

Fig. 7. Free energy of formation of Al_2O_3 against temperature plot comparing the values estimated in the present investigation with those tabulated in JANAF tables.

those observed by Skelton and Patterson (9). This may be due to sluggish electrode equilibration and/or departure from the proposed α-alumina, β-alumina equilibrium in the electrolyte.

Open-circuit emf data for cell [VI] are given in Table II and plotted in Fig. 6. The least-square best fit of the data from 563° to 656°C is given by

$$E(\text{VI})\,\text{mV} = (1414 - 0.023T) \pm 3 \qquad [14]$$

The departure of the observed emf at 540°C from the linear relationship is similar to that observed with cell [V] and may be accounted for in the same way.

Equations [6] and [14] may be combined to obtain the open-circuit emf between Al, Al_2O_3, and Cu,Cu_2O electrodes. Attempts were not successful to directly measure the open-circuit emf of such a cell below the melting point of aluminum (660°C). This is presumably because of the inability of the Cu,Cu_2O electrode to achieve equilibration in a relatively short time (8-12 hr) at these temperatures. Though not pursued in the present investigation, such measurements may be feasible at higher temperatures with different cell geometries. For example, the β-alumina solid electrolyte may be in the form of a flat bottomed cup with molten aluminum inside and the Cu,Cu_2O electrode contacting the outer flat surface of the electrolyte.

The free energy of formation of Al_2O_3 was calculated from Eq. [6] and [14] and the $\Delta G^\circ_{Cu_2O}$ (14) values. This is given by Eq. [15] below for the limited temperature range of 560°-660°C

$$\Delta G^\circ_{Al_2O_3} = (-404.8 + 0.081\,T) \pm 0.6\ \text{kcal/mole} \qquad [15]$$

Figure 7 compares the $\Delta G^\circ_{Al_2O_3}$ values, according to Eq. [15] with those given in JANAF tables (14). The agreement seems to be quite satisfactory in view of the scatter in the data of cell [VI] and the different methods of estimation.

The reaction between sodium and alumina.—Consider the reaction

$$6Na + Al_2O_3 = 3Na_2O + 2Al \qquad [16]$$

Table II. Emf of cell [VI]

Al/β-alumina/NaF,NiF_2,Ni	
Temperature (°C)	Emf (mV)
540	1383
563	1393
588	1397
598	1394
612	1396
616	1394
632	1392
636	1391
645	1390
646	1396
656	1394

The standard free energy change for the above reaction is given by

$$(3\Delta G^\circ_{Na_2O} - \Delta G^\circ_{Al_2O_3})$$

It has been discussed above that the standard free energy change of the reaction

$$Na_2O + xAl_2O_3 = Na_2O\cdot xAl_2O_3 \qquad [1]$$

is given by $RT \ln a_{Na_2O}$, where a_{Na_2O} is the activity of Na_2O in β-alumina in coexistence with α-alumina.

Combining Eq. [1] and [16] the standard free energy change for the reaction

$$6Na + (3x + 1)Al_2O_3 = 3(Na_2O\cdot xAl_2O_3 + 2Al \qquad [17]$$

is given by

$$\Delta G^\circ = 3\Delta G^\circ_{Na_2O} - \Delta G^\circ_{Al_2O_3} + 3RT \ln a_{Na_2O} \qquad [18]$$

Using the data from JANAF tables (14) for $\Delta G^\circ_{Na_2O}$ and $\Delta G^\circ_{Al_2O_3}$ and $RT \ln a_{Na_2O}$ value of −77.0 kcal/mole (see above), the estimated ΔG° for reaction [17] at 1000°K is −106.8 kcal. The value of ΔG° at 573°K is −129.3 kcal. The negative value of the ΔG° indicates that polycrystalline two-phase β-alumina (*i.e.*, a mixture of α-alumina and β-alumina) in equilibrium with Na is able to liberate free aluminum at the interface. This may have some implications concerning the development of electronic conductivity and blackening of β-alumina in prolonged contact with liquid sodium at 573°K observed Miles and Wynn Jones (16).

Beta-alumina and β″-alumina solid electrolytes are being actively considered for development of commercial Na-S rechargeable battery systems (15). These materials must be resistant to metallic sodium attack for such applications. Therefore, the thermodynamics of the reaction with Na need to be considered. The par-

ticular case of Al_2O_3 reacting with Na to form aluminum and the next Na_2O-rich compound (*viz.* β-alumina) in the Na_2O-Al_2O_3 system may be generalized to examine the criterion for the stability of any phase $Na_2O \cdot aAl_2O_3$ to attack by metallic sodium to form the next soda-rich phase $Na_2O \cdot bAl_2O_3$ and aluminum. The over-all reaction may be represented by

$$6(a-b)\mathrm{Na} + (1+3b)(Na_2O \cdot aAl_2O_3) = (1+3a)(Na_2O \cdot bAl_2O_3) + 2(a+b)\mathrm{Al} \quad [19]$$

The standard free energy change for the above reaction is given by

$$\Delta G^\circ_{19} = (a-b)[3(\Delta G^\circ_{Na_2O} + RT \ln a_{Na_2O}) - (\Delta G^\circ_{Al_2O_3} + RT \ln a_{Al_2O_3})] \quad [20]$$

where a_{Na_2O} and $a_{Al_2O_3}$ are the activities of Na_2O and Al_2O_3 in $Na_2O \cdot aAl_2O_3$ and $Na_2O \cdot bAl_2O_3$ coexistence. ΔG°_{19} may also be represented by

$$\Delta G^\circ_{19} = (a-b)\left[-\frac{1}{b}\Delta G^\circ_{Na_2O \cdot bAl_2O_3} + \left(3+\frac{1}{b}\right)RT \ln a_{Na_2O} + 3\Delta G^\circ_{Na_2O} - \Delta G^\circ_{Al_2O_3}\right] \quad [21]$$

where $\Delta G^\circ_{Na_2O \cdot bAl_2O_3}$ is the standard free energy change for the reaction

$$Na_2O + bAl_2O_3 = Na_2O \cdot bAl_2O_3 \quad [22]$$

For $Na_2O \cdot aAl_2O_3$ to be resistant to attack by metallic sodium ΔG°_{19} must be positive. ΔG°_{19} may be evaluated for any pair of coexistent intermediate phases with the help of Eq. [20] or Eq. [21] and [22]; but the relevant thermodynamic data are not completely available for the Na_2O-Al_2O_3 system. However, let us examine the case when $b = 1$, *i.e.*, $Na_2O \cdot bAl_2O_3 = 2NaAlO_2$. At 1000°K $\Delta G^\circ_{Na_2O \cdot Al_2O_3}$ for the reaction

$$Na_2O + Al_2O_3 = 2NaAlO_2 \quad [8]$$

is given by −44.34 kcal. Using the tabulated values (14) for $\Delta G^\circ_{Na_2O}$ and $\Delta G^\circ_{Al_2O_3}$ together with $\Delta G^\circ_{Na_2O \cdot Al_2O_3}$ at 1000°K in Eq. [21], ΔG°_{19} may be written as

$$\Delta G^\circ_{19} = (a-1)(4RT \ln a_{Na_2O} + 168.46)\ \text{kcal} \quad [23]$$

The phase diagram (2,4) for the Na_2O-Al_2O_3 system indicates that the alumina-rich phase next to $NaAlO_2$ is most likely β''-alumina. Thus for β''-alumina to be stable in contact with metallic sodium at 1000°K $RT \ln a_{Na_2O}$ should be ≥ -42.025 kcal/mole, according to Eq. [23]; where a_{Na_2O} is the activity of Na_2O in a coexistent mixture of $NaAlO_2$ and β''-alumina. The critical value of a_{Na_2O} may also be evaluated at other temperatures of interest and then compared with the actual value, if available.

Possible use of two-phase polycrystalline β-alumina in solid electrolyte P_{O_2} gauges.—The fact that β-alumina behaves as a solid electrolyte at the extremely low oxygen partial pressure of Al, Al_2O_3 coexistence ($P_{O_2} \approx 10^{-47}$ atm at 1000°K) suggests that it may be used to monitor very low oxygen chemical potentials. The commonly known oxygen ion conducting solid electrolyte P_{O_2} gauges are limited by the onset of electronic conduction to oxygen partial pressures of around 10^{-37} atm at 1000°K (17). Although the upper P_{O_2} limit in this investigation corresponded to Cu,Cu_2O equilibrium, it is probable that β-alumina may be used as a solid electrolyte at higher oxygen partial pressures without significant hole conduction. The low temperature limit for sufficiently fast equilibration in β-alumina for use as an oxygen monitor seems to be around 550°C. This temperature is lower than the operating temperatures of known oxygen ion conducting solid electrolytes in which the limiting factor is poor ionic conductivity. β-alumina being a much better conductor, by some three orders of magnitude, suggests the possibility of reducing the operating temperature below 550°C with better material and cell design. Thus P_{O_2} gauges constructed with β-alumina solid electrolyte may offer the advantages of lower operating temperature and wider response (especially at extremely low P_{O_2}) and may find applications in semiconductor and metallurgical industries.

A Solid-State Electrode for Reducible Gases

B. C. LaRoy, A. C. Lilly, and C. O. Tiller

Philip Morris Research Center, Richmond, Virginia 23261

ABSTRACT

The electrical properties of solid-state electrochemical cells using thin-film lanthanum fluoride electrolyte have been investigated as a function of the ambient atmosphere. The conductivity of the cells has been found to increase with the concentration of the reducible gases O_2, CO_2, SO_2, NO_2, and NO. Sensitivity to a given gas is observed when the cell's terminal voltage exceeds a "characteristic potential" which correlates with the electron affinity of the gas. With suitable choice of anode material a galvanic cell is formed which may be used as a "self-energized" O_2 electrode or as a low current battery or O_2 fuel cell.

Lanthanum fluoride has an unusually high anionic conductivity and polarizability at room temperature (1-3). Its Debye temperature is only ~360°K (4) although it melts at 1766°K. Thus the room temperature Schottky defect density is high. The lowest activation energy for F^- diffusion is ~0.4 eV in both single crystals (1) and thin films (5). Single crystals have a d-c electrical resistivity of 10^7 ohm-cm and a static dielectric constant of 10^6 at room temperature (2). Thin evaporated films of LaF_3 have higher resistivities (~10^{12} ohm-cm) and lower dielectric constants (~10^3) (5). But thin films are still good anion conducting electrolytes at ambient temperatures. The fact that thin-film LaF_3 is a good F^- anion conductor with low electronic conductivity made it reasonable to investigate it as an electrolyte for other anions.

Cell Description

The films were deposited by evaporation of 99.999% pure materials in an ion pumped ultrahigh vacuum system at pressures below 10^{-7} Torr. They were evaporated from W or Ta boats and deposited on glazed alumina substrates at substrate temperatures of 200°-300°C. A layered configuration was used. Cr metal was first deposited to promote adhesion. The anode metal was deposited next, followed by an electrolyte layer 0.2-1.2 μm thick and then by the cathode metal. To promote access of gas to the cathode-electrolyte interface, an open gridlike structure was used. (Figure 1 illustrates cell structure schematically.)

LaF_3 electrolyte was used for most investigations, but CeF_3, NdF_3, and PrF_3 gave similar results. Au and Ag cathodes and Bi, Al, La, Pr, and Au anodes have been used. All layers were deposited during one evacuation of the vacuum system by use of a mask changing arrangement. Twenty such cells were deposited on a 5 by 5 cm substrate. Each individual cell was about 5 mm square with an anode area of 0.14 cm^2 and a cathode area of 0.04 cm^2.

Other configurations, including coplanar, have been used with qualitatively the same results as are reported here. Linear dimensions have been made as small as 0.25 mm.

Key words: solid electrolyte, lanthanum fluoride, gas electrode.

Electrical Measurements

The cells were removed from the vacuum deposition system and placed in a hermetically sealed brass chamber. Tank gases were passed through $CaSO_4$ dryers, flow meters, appropriate valves, and into the chamber which was kept at a slight positive pressure (<2.5 cm of water).

Chamber response was determined for N_2 to O_2 transitions by using a Westinghouse Model 211 Pulmonary Function Monitor. Transition time to 90% of a mixture change was about 4 sec. Oxygen content in the chamber could be reduced to less than 3 ppm. The compositions of gas mixtures were determined from the ratio of flow rates of the gases entering the chamber.

The electrical circuit used for all measurements is shown in Fig. 2. The power supply furnished either regulated d.c. or a voltage ramp of variable rise rate. Terminal potentials were monitored with a Keithley 603 electrometer millivoltmeter having an input resistance of 10^{14} ohms. Currents were measured by a Keithley 417 high-speed picoammeter or (when a well-known shunt resistance was desired) by a Cary 31 vibrating-reed electrometer in parallel with an appropriate shunt resistor. System accuracy was ± 10% or better as determined by measuring known resistors in the 10^8-10^{12} ohm range. Current changes of ± 10^{13}A

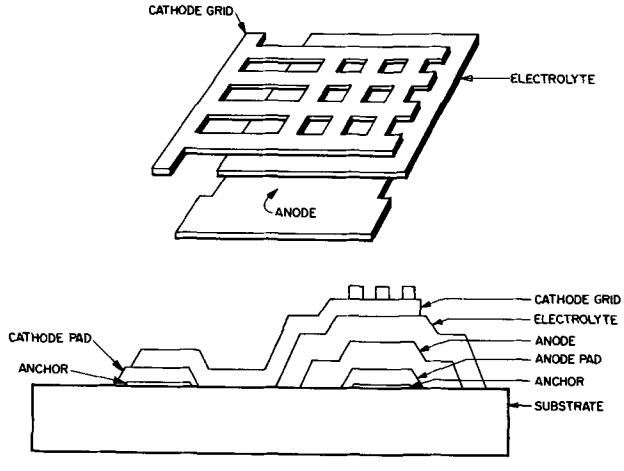

Fig. 1. Schematic of cell construction

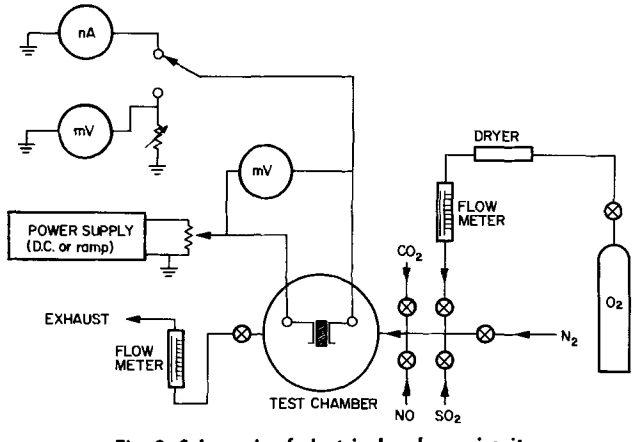

Fig. 2. Schematic of electrical and gas circuits

were easily resolved. By our convention "positive current" signifies anion transport from cathode to anode within the electrolyte.

Polarization and Initial Response

In 1 atm of nitrogen gas, typical cells exhibit d-c dielectric constants between 360 and 1100 and steady-state resistivities between 10^{12} and 10^{13} ohm-cm. The temperature coefficient of resistivity ($\Delta R/R/\Delta T$) is typically 0.1/°C below 100°C (5). Above 100°C conductivity increases strongly with temperature. When shunted by a small external resistance and biased to a fixed terminal potential, the initial current surge decays to a stable background current over a period of about 1 hr.

Upon exposure to a reducible gas the resistivity of a virgin cell decreases by two orders of magnitude or more. Then, during a "break-in" period in the reducible gas, the initial sensitivity decays in an exponential-like fashion, reaching a constant rate ($100\Delta I/I$/time ~0.1-0.5/hr) after about 2 hr. Figure 3 illustrates this initial period for a Cu(anode)/LaF_3(electrolyte/Au(cathode) cell which has been polarized with 0.3V for some time before the initial oxygen application at $t = 0$.

Changes in the electrode-electrolyte interfaces undoubtedly contribute to the initial decrease in sensitivity. However, another significant factor is the neutralization of a net positive charge (F^- deficiency) within the virgin cells. Fine gold probes deposited within the electrolyte layer at varying distances from the electrodes allowed the determination of internal potential profiles and, hence, the relative charge distributions. Upon the application of oxygen, the net internal charge became negative and the profile was indicative of injection and transport of negative carriers. When the O_2 atmosphere was removed after the break-in period, the net internal charge approached neutrality, but never again became positive. ...

Exposure of a broken-in cell to a different reducible gas requires an additional "break-in" treatment. In this case, the sensitivity changes much less than during the initial break-in period. Polarization by the reduced species or buildup of reaction products seems the most probable cause of this behavior. Background current is somewhat reduced during break in, again probably due to polarization, or reaction product buildup at the electrodes.

The current increase of a typical broken-in cell upon exposure to oxygen is characterized by two parts: an initial "fast" part where 25% of maximum amplitude is reached within 4 sec, followed by a "slow" part during which current rises to 90% of maximum in about 4 min. Upon removal of oxygen the current decrease has a similar "fast" part followed by a return to 90% of the baseline, in 5-10 min.

Equilibrium Response to Oxygen

When cells with copper or bismuth anodes are polarized and broken in as previously described, cell current becomes a relatively stable function of terminal potential and of the concentration of oxygen in the ambient atmosphere.

Figure 4 shows current *vs.* terminal potential for a Bi/LaF_3/Au cell in 1 atm of nitrogen and in 1 atm of oxygen. Each data point was recorded after allowing several hours for polarization. All data for nitrogen were taken first, followed by all oxygen data. As terminal potential is increased a particular potential, V_c, is noted below which the cells are rather insensitive to oxygen, but above which sensitivity increases strongly with V.

No classical half-wave potential is observed. Therefore, we conclude that diffusion is not a mobility limiting factor in these cells.

In the absence of a half-wave potential, V_c has been used as a characteristic potential. Since the cells have finite electrode potentials, V_c has been defined as the difference between the terminal potential giving zero current in oxygen and the terminal potential where the oxygen current begins its rapid increase (see Fig. 4). Defined in this way, V_c is largely independent of anode material. Static data from cells with Cu and Bi anodes yield $V_c = 230 \pm 30$ mV as characteristic for oxygen.

At a constant terminal potential above V_c cell current varies as the sum of linear and logarithmic terms in oxygen concentration. The variation is quite linear at concentrations above 20% of O_2 in mixtures of O_2 and N_2. Below 20% the logarithmic term causes significant curvature.

Figure 5 shows current sensitivity $(I - I_0)/I_0$ *vs.* per cent oxygen for cells having Bi, Cu, and Au anodes. Current (I) was monitored as the oxygen concentration was varied. I_0 is the background current in the absence of oxygen.

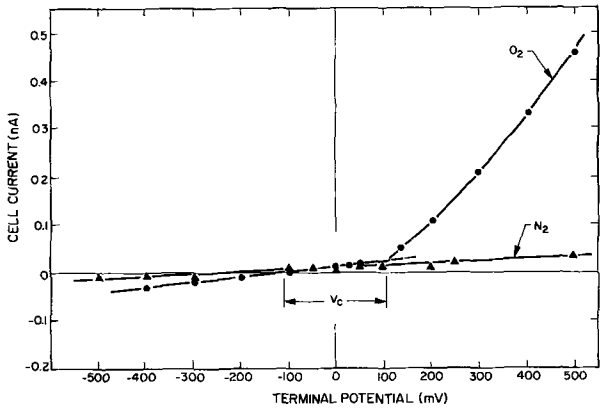

Fig. 4. Typical static current-potential relationship for a Bi/LaF_3/Au cell in 1 atm of O_2 and 1 atm of N_2.

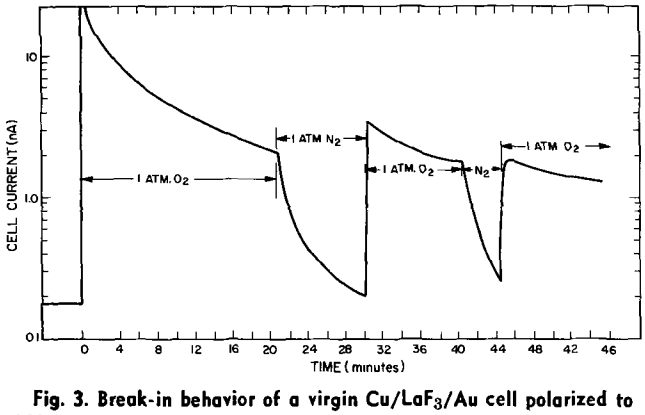

Fig. 3. Break-in behavior of a virgin Cu/LaF_3/Au cell polarized to 300 mV.

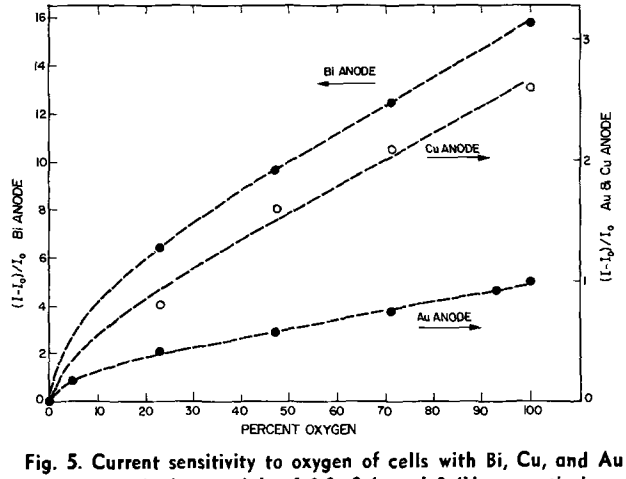

Fig. 5. Current sensitivity to oxygen of cells with Bi, Cu, and Au anodes at terminal potentials of 0.0, 0.4, and 0.4V, respectively.

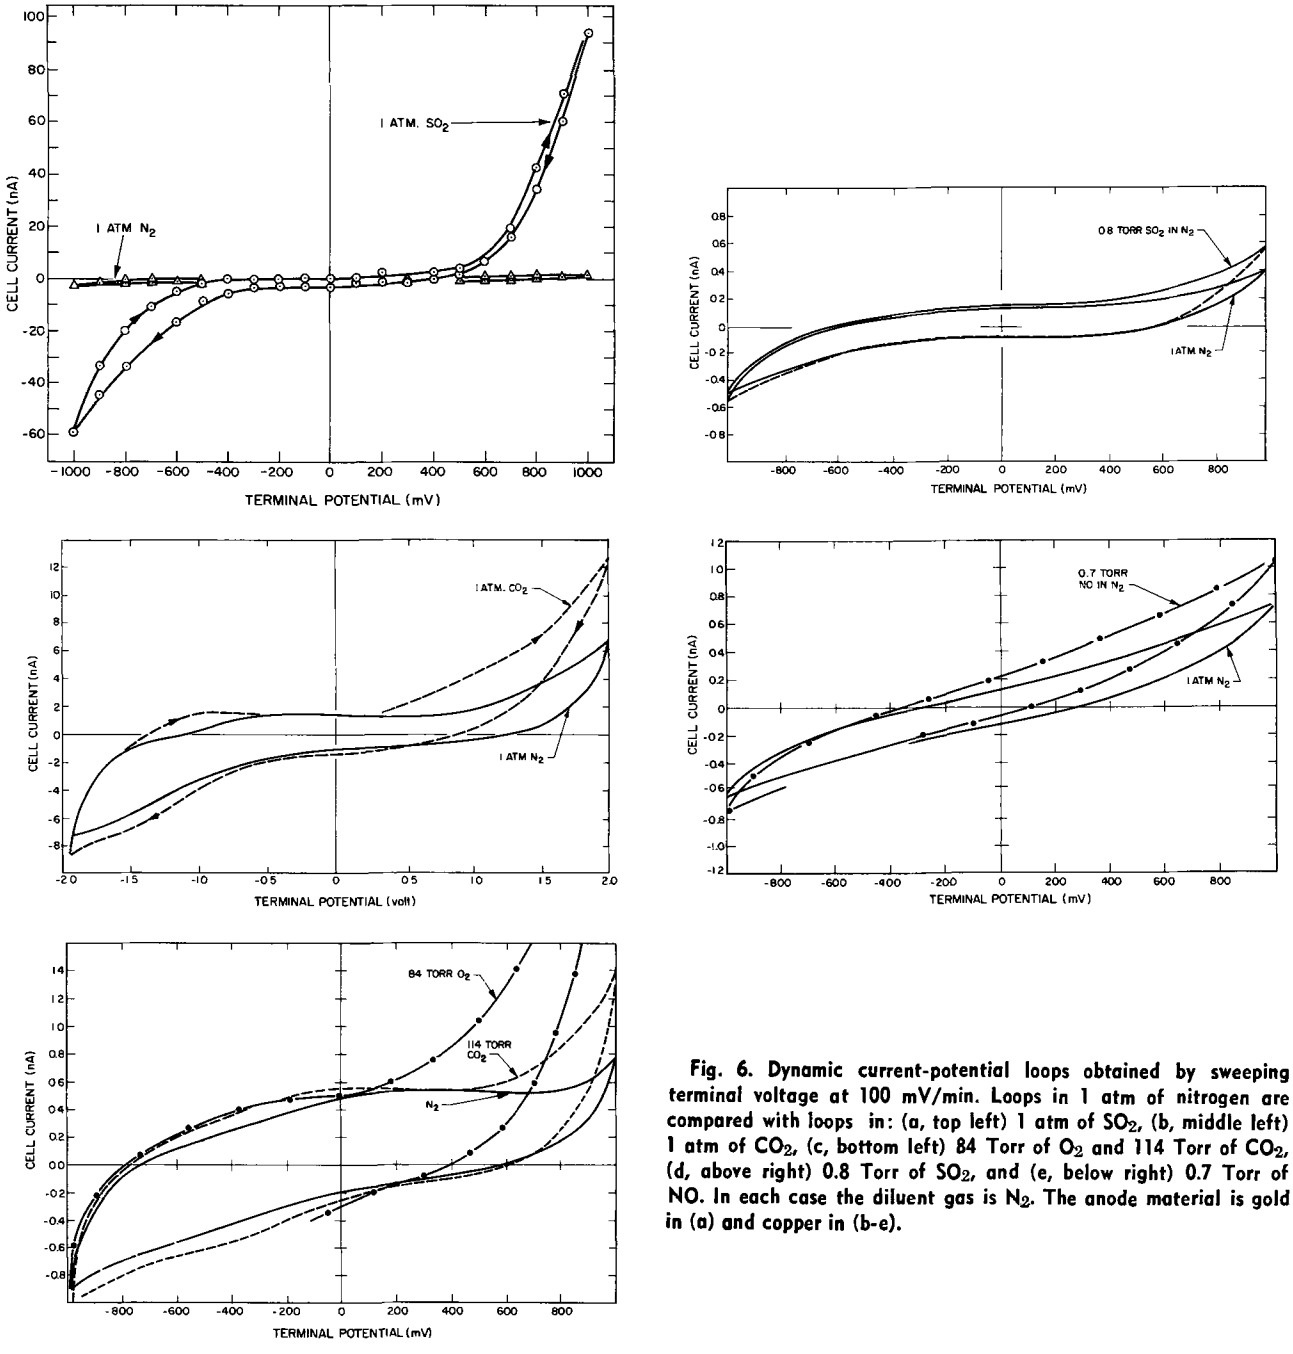

Fig. 6. Dynamic current-potential loops obtained by sweeping terminal voltage at 100 mV/min. Loops in 1 atm of nitrogen are compared with loops in: (a, top left) 1 atm of SO_2, (b, middle left) 1 atm of CO_2, (c, bottom left) 84 Torr of O_2 and 114 Torr of CO_2, (d, above right) 0.8 Torr of SO_2, and (e, below right) 0.7 Torr of NO. In each case the diluent gas is N_2. The anode material is gold in (a) and copper in (b-e).

Cells with Bi anodes are the most sensitive and have the greatest low concentration nonlinearity. Cells with blocking gold anodes respond more linearly. Probably, the logarithmic term arises from interfacial phenomena at the anode.

Cells made early in the program had higher background currents than cells produced recently. In the early cells, current variation was nearly linear with oxygen concentration (6). Evidently, the oxygen conductivity of these cells was shunted by a comparable oxygen independent conductivity. Thus, sensitivity to low oxygen concentrations was preferentially reduced.

Potential Sweep Data—Other Reducible Gases

By sweeping the terminal potential at a constant rate of 100 mV/min, data showing cell sensitivity to several additional reducible gases were obtained. The dynamic current-potential traces form loops due to the high polarizability of LaF_3. Even in this nonequilibrium situation, greater currents are observed (for a given potential magnitude) when anion flow is toward a reactive anode. However, "dynamic" sensitivity is also observed with a blocking anode material (*e.g.*, gold). Figures 6 (a and b) illustrates the current-potential data in 1 atm of SO_2 and CO_2. Figure 6 (a, d, and e) shows similar data for lower partial pressures of O_2, CO_2, SO_2, and NO.

For the dynamic curves we have taken $V_c = 1/2\,[V_+ - V_-]$ where V_+ and V_- are the forward and reverse bias terminal potentials at which the first significant sensitivity was observed. This procedure, which was necessitated by small gas-to-gas and cell-to-cell differences in curve characteristics, led to fairly large uncertainties in V_c. Still, the characteristic potentials were found to be indicative of the gas species (Table I).

Table I. Characteristic potentials and electron affinities of various gases

Gas	V_c (mV)	E_A (eV)	Reference
NO	<50	$0.024\ ^{+0.010}_{-0.005}$	(7)
O_2	230 ± 30	0.440 ± 0.008	(8)
CO_2	500 ± 50	1.2 ± 0.3	(10)
SO_2	400 ± 100	0.5-1.0	(9)
NO_2	<100	>2.04	(12)

In the case of nitrogen oxides, the dynamic current-potential curves show no region of insensitivity (Fig. 6e). Also, we were unable to locate a region of static bias where the cells were insensitive to NO or NO_2. Therefore, V_c is near zero. Table I shows upper limits set by the resolution achievable in the experiment.

$Au/LaF_3/Au$ cells were used to determine the approximate current-concentration curves for SO_2, CO_2, NO, and NO_2. For each gas the cells were polarized to a static potential above V_c and broken in until the time-rate of sensitivity decrease was small. All data were then taken within a few minutes.

Due to the blocking nature of the gold anodes, sensitivities were small. However, relative sensitivities could be obtained with less regard for electrode reactions.

Figure 7 shows current variation with the concentration of CO_2, SO_2, and NO. N_2 was the diluent gas in these cases. In the case of NO_2, current increased exponentially with concentration. Figure 8 shows data when a refrigerant gas of similar density (Genetron 12) was used as the diluent. Similar behavior was noted when the diluent was N_2, but noise was increased. This exponential sensitivity may be due to dissociation of NO_2 on the cathode (or on the specimen chamber walls) yielding NO.

In many cases, the solid-state cells have a shelf life of several months and maintain useful calibration for several days of use. However, the factors affecting lifetime are very complicated (*e.g.*, use lifetime depends on the rate of change of the oxygen current as well as on its magnitude) and are still under investigation.

Cells with like, gold, electrodes degraded by use or storage are easily "rejuvenated" by heating to 300°C in high vacuum for several hours.

Galvanic Cells

Cells with reactive anodes develop open-circuit potentials which presumably arise from the oxidation of the anode by F^- and the reduced species. These potentials range from 200 mV for Cu to about 1.5V for La.

Finite currents may be drawn from such a cell. Figure 9 plots current against the terminal potentials obtained at three oxygen concentrations by shunting a $Bi/LaF_3/Au$ cell with varying load resistors. As the load increases, current becomes increasingly sensitive to oxygen pressure, yielding a "self-energized" oxygen

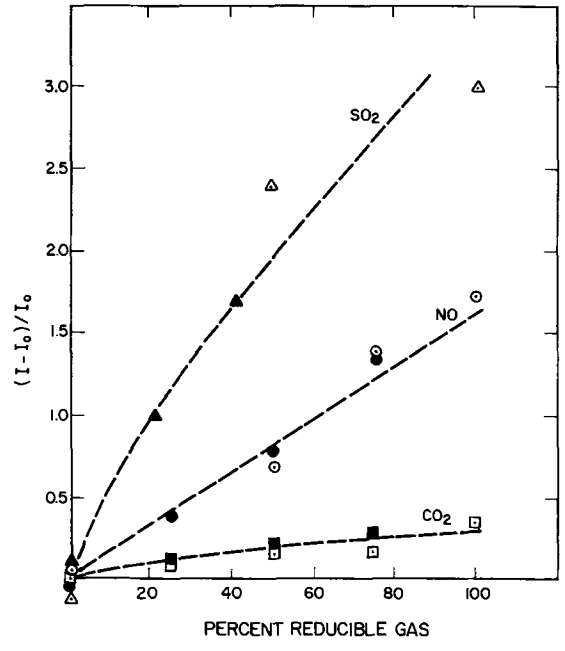

Fig. 7. Current sensitivity of $Au/LaF_3/Au$ cells to CO_2 at 1.1V bias, NO at 1V bias, and SO_2 at 1.6V bias. Open data points, concentration increasing; closed data points, concentration decreasing.

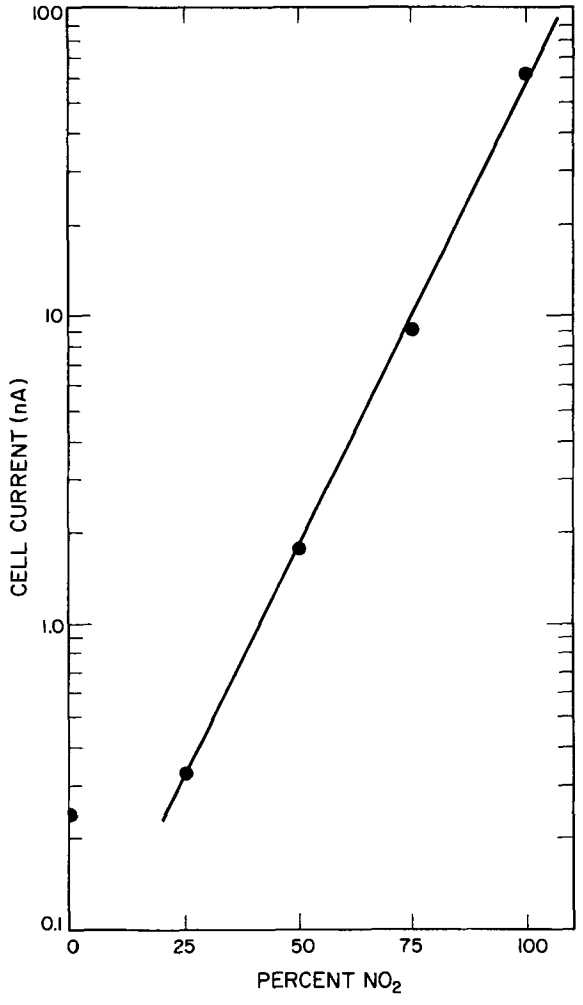

Fig. 8. Current variation with NO_2 concentration for a $Au/LaF_3/Au$ cell biased at 300 mV.

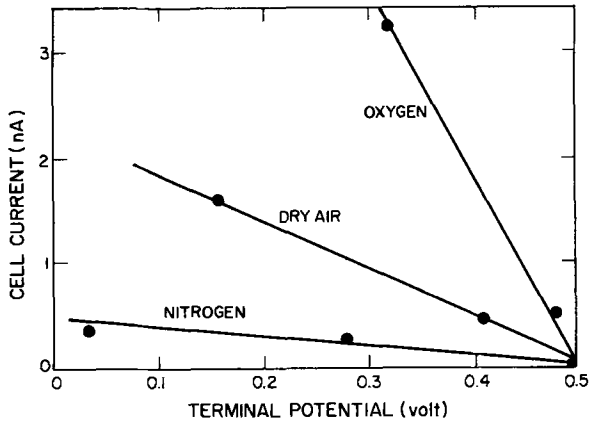

Fig. 9. Load characteristics of a galvanic $Bi/LaF_3/Au$ cell

electrode. Maximum oxygen sensitivity is obtained at zero terminal volts when the cell is short circuited and nearly the entire emf generated by the anode reaction is impressed at the cathode-electrolyte interface.

Although current is limited by cell resistivity, power densities of 1-10 Whr/kg have been estimated from discharge curves. This may indicate some utility for such cells as low discharge batteries.

Mechanisms

The observed behavior is consistent with a model constituted by (*i*) reduction of a gas at the ca hode-electrolyte interface, (*ii*) nondiffusion limited transport through the electrolyte, and (*iii*) oxidation of

the gas at the anode. That is, the cell constitutes a solid-state analog to the liquid reducible gas electrode.

Reduction.—Our potential probe measurements have shown strongly polarized layers less than 0.2 μm thick at the cell electrodes. Nearly the entire terminal potential appears across these polarization layers, giving ample electric field for reduction of a gas. In agreement with this, we observe little difference between the polarization and sensitivity of cells which have electrolyte thicknesses between 0.5 and 2.0 μm.

In Fig. 10 we have plotted literature values for electron affinity against V_c for the various gases. The electron affinities quoted for NO (7), O_2 (8), and SO_2 (9) are for the addition of a single electron to the entire molecule. The "electron affinity" of CO_2 is the same as that of O (10), probably due to dissociation on metallic surfaces (10, 11) ($CO_2 \rightarrow CO + O$).

The monotonic increase of characteristic potential (V_c) with the electron affinity of the incident gas (Fig. 10) indicates that the rate limiting reactions are

$$NO + e^- \rightarrow NO^-$$

$$SO_2 + e^- \rightarrow SO_2^-$$

$$O_2 + e^- \rightarrow O_2^-$$

$$O + e^- \rightarrow O^- \text{ (for } CO_2\text{)}$$

The electron affinity of NO_2 is uncertain, but it is greater than 2 eV (12) which is inconsistent with our V_c of <100 mV. This supports our previous speculation that NO_2 dissociates to yield NO which has a very low electron affinity.

Two gases, CO and N_2O, which do not form stable molecular anions did not alter cell conductivity.

Transport.—The apparent mobility of other ionic species in a solid fluorine ion electrolyte is surprising. We offer two possible models of the mechanism. The first depends on the high grain boundary area of the polycrystalline films (crystallite dimensions are 20-200Å). Large ions might carry significant current through defects at such boundaries.

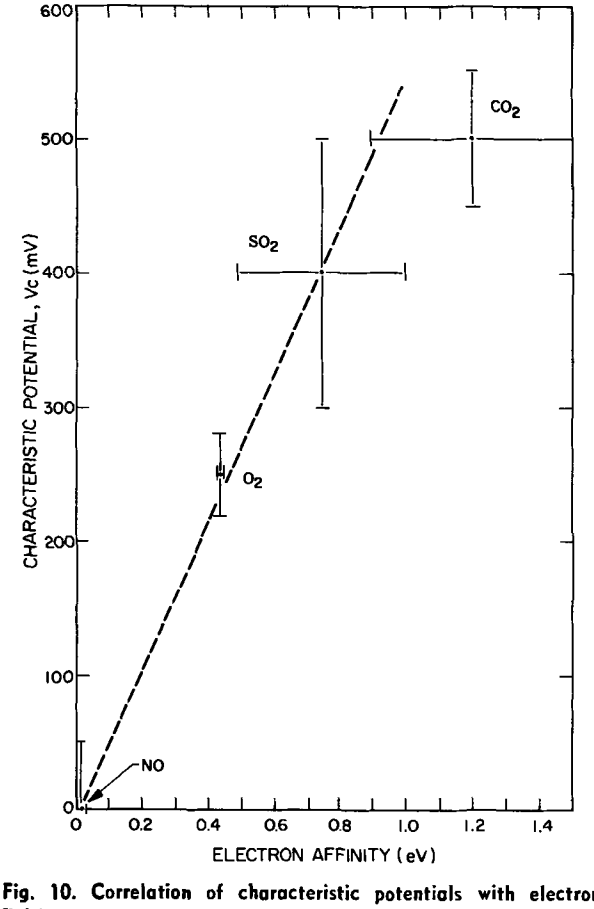

Fig. 10. Correlation of characteristic potentials with electron affinities.

The second possibility is mobility of other than fluorine ions through Schottky defects in the LaF_3 lattice. Fluorine in LaF_3 exists in three magnetically nonequivalent sites. Covalent bonding predominates in two of the sites. In the third site, the fluorines make up a layered array with approximately 60% ionic bonding and about 40% π-bonding (13). The high polarizability and conductivity of LaF_3 at room temperature is primarily due to motion through the latter sites.

From x-ray Debye-Waller factors, Zalkin *et al.* (14) find that the mean square displacement of the ionically bound fluorines is 1.7Å[2]. Therefore ions of widely varying size might substitute into F^- defects. Although large ions such as NO^-, SO_2^-, or O_2^- might not "fit" these defects, O^- with a radius of 1.76Å should substitute for the 1.33Å F^- (15) without significantly straining the lattice.[1] The proportions of π-bonding will be larger for O^- than for F^-, but ionic bonding should still predominate and lead to high O^- mobility. As previously noted, O^- is the probable product of the "reduction" of CO_2 (10, 11). We speculate below on the evolution of O^- in the cases of other gases.

In the case of oxygen, the creation of O_2^- is consistent with the observed characteristic potential. This O_2^- is probably created in an excited state which has a lifetime of 10^{-13} sec (17). In a solid a stabilizing collision within this time is probable. However, stabilization in the large fields at the polarized interface might also be accomplished through a reaction such as

$$O_2^- \text{ (excited)} \rightarrow O + O^-$$

Similar processes of varying efficiency might cause evolution of O^- in the cases of SO_2 and NO. Thus there are plausible sources of a species which should be mobile in the LaF_3 lattice. Experiments with films of varying grain size or designed to monitor the species arriving at the anode-electrolyte interface would do much to clarify the picture.

Anode.—A chemically reactive anode material is necessary to obtain appreciable steady-state sensitivity to oxygen. In light of the previous discussion we believe that the reduced species combine chemically with the anode material, thus diminishing further polarization of the interface and allowing continuing charge transfer.

Summary

Thin-film metal/rare earth fluoride/metal cells were found to constitute solid-state electrodes for reducible gases at ambient temperatures. Cell conductivity increases with gas concentration when the cell is biased above a characteristic potential which corresponds with the electron affinity of the gas.

The observed behavior fits a model where reduction and oxidation of the gas species occurs at the cathode and anode interface, respectively. Charge is transported through the electrolyte. Several different models for the mechanism are still considered possible.

We believe that the small size, sturdiness, and projected low cost of fabrication of these cells makes them potentially useful multigas selective electrodes for a variety of applications.

Acknowledgments

We are grateful to Mr. E. M. Gentry for his work in cell fabrication, to Mr. L. C. Bartlam for electrical measurement, and to Drs. D. A. Lowitz and D. T. Sawyer for many helpful consultations.

[1] One of the reviewers of this paper has pointed out that $O^=$ has almost exactly the same radius of F^-. Indeed $O^=$ should have good mobility in LaF_3. However, the attachment of the second electron would require the addition of an energy of 5.8 eV [the one electron affinity of O is +1.45 eV; the two electron affinity is −7.3 eV (16)] which could only be supplied by a very high surface polarization energy. We cannot rule out the existence of $O^=$ in the lattice, but the formation of O^- is a lower energy and more straightforward process.

Transport Properties of LaF_3 Thin Films

A. C. Lilly, Jr., B. C. LaRoy, C. O. Tiller, and Bruce Whiting[1]

Philip Morris Research Center, Richmond, Virginia 23261

ABSTRACT

Pulsed current-voltage measurements have been carried out on thin films of LaF_3 varying in thickness from 1000 to 10,000Å. The *I-V* data fit a relationship of the form $I = I_0 \sinh \alpha V$ normally associated with ionic conduction. If it is assumed that the internal field is equal to the externally applied field, the derived ionic jump distance is of the order of 20Å. However, potential probe measurements show a strong concentration of positive space charge near the cathode. When the effect of the space charge on the internal electric field is accounted for, a smaller value is obtained for the ionic jump distance, which is more in agreement with the crystal structure of LaF_3.

Lanthanum fluoride is a material that exhibits somewhat unusual electrical transport properties. Previous workers (1-3) have concluded that the electric current in LaF_3 single crystals is carried almost exclusively by F^- ions with negligible electronic conduction. As shown by Sher *et al.* (1) LaF_3 crystals are good ionic conductors at room temperature probably because of their low activation energy for formation of Schottky defects. Because of their good anionic conduction properties, we have used thin films of LaF_3 in chemical sensing devices. Since thin films in general have different properties than the bulk materials, we have examined the transport properties of ions in thin films of LaF_3 ranging in thickness from 1000 to 10,000Å.

Experimental Procedures

Since LaF_3 single crystals exhibit a large amount of polarization (2), it is important to measure currents a short time after a voltage has been applied to the films if transport properties free of interfacial effects are to be studied. In this work we have taken the high frequency model for the electrodes and the LaF_3 film as a parallel resistance and capacitance network. To measure the components of the network, we compared the current through a variable r-c parallel network connected to one channel of an oscilloscope. The resistance and capacitance of the network was then matched to that of the sample. This matching was determined by the coincidency of the current-time curves on a Tektronix 502 oscilloscope after a 200-500 μsec voltage pulse was applied. Steady-state current values were measured with a Keithley 417 picoammeter.

The thin films were evaporated in an ion-pumped ultrahigh vacuum system using 99.999% pure materials. They were thin-film sandwich structures consisting of an alumina substrate with LaF_3 between metallic electrodes (Al-Al or Au-Au). The evaporated films of LaF_3 are polycrystalline with crystallite sizes ranging from 20 to 200Å. The density of the films was not measured. Also the exact stoichiometry of the film is not known. Batsanova (4) reports the principal component of the gas phase over boiling LaF_3 at 2600°K to be LaF_3. However, mass spectrometer measurements also show ionic species La^+, LaF^+, and LaF_2^+ formed from dissociation of gaseous LaF_3. Undoubtably some fluorine is lost in the evaporation process as evidenced by the net positive change inside the films; however, all films are made under the same conditions and the electrical properties are reproducible.

A series of special samples was processed in order to establish a potential profile in the LaF_3 films. These samples had the normal Au top (cathode) and bottom (anode) electrodes, but also had a third Au probe inserted in the LaF_3 layer at various distances from the cathode. This probe was inserted by stopping the LaF_3 deposit during deposition, depositing the probe, and then completing the LaF_3 deposition.

In all potential probe experiments a constant potential difference of 300 mV was applied between the cathode and anode. The cathode was held at −300 mV

[1] Present address: Department of Physics, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15200.

Key words: transport properties, lanthanum fluoride, solid electrolyte.

and the anode maintained at essentially ground potential. The potential difference between one of the electrodes and the probe was measured with a Cary 31V vibrating reed electrometer.

Experimental Results

If the thin film of LaF_3 is an ionic conductor then the current-voltage (I-V) characteristics should follow a relationship of the form (5)

$$I = A \sinh (aq\ E/kT) \qquad [1]$$

where E is the electric field, a is one-half the ionic jump distance, q is the ionic charge, T is the absolute temperature, and A is a constant. A careful examination of the pulsed I-V data on several different samples disclosed that Eq. [1] gives the best fit to the data. For instance, in Fig. 1 and 2 are shown plots of the experimental points and the best fit $I = A \sinh (aq\ E/kT)$ curve obtained by fitting a and A. The fit is quite good over the entire range of the data. The calculated ionic jump distances from the data shown in Fig. 1 and 2, and in other cases, range from 15 to 25Å. However, it must be realized that this assumes that the internal field is the same as the applied field. In reality there are space-charge effects leading to an enhancement of the field near the cathode.

Even though scatter in the data was evident from sample to sample, the general trends of the potential profile measurements were clearly indicated and are shown in Fig. 3. The data in Fig. 3 show a potential profile as it occurs after a 30 min polarization in an N_2 or O_2 atmosphere. The samples were in the gas shown prior to charging and such profiles were obtained as a function of time. As charging time increased, the internal potentials became more positive with the major change having taken place after 30 min. Clearly the potential profiles are indicative of a large change in potential relative to ground at a distance of 1000Å from the cathode. The potential profile in O_2 shows a build-up of negative charge near the anode which is thought to be due to the reduction of O_2 molecules at the cathode and the subsequent movement of these oxygen anions into the LaF_3 film (6). Taking the modification of the internal field by charge accumulation into account when applying Eq. [1], the derived jump distance is approximately 4-5Å, or smaller, which is more in agreement with the 2-3Å expected from the trigonal crystal structure of LaF_3.

The experimental I-V results are independent of the electrodes used, in this case gold and aluminum. Solomon *et al.* (3) found the same electrode independence. In Fig. 4 a plot is shown of steady-state resistance *vs.* applied voltage in a 2400Å LaF_3 film. Note that the curve is of an ohmic character up to 1.6V, and is very nonlinear at higher voltage. In Fig. 5 the nonohmic

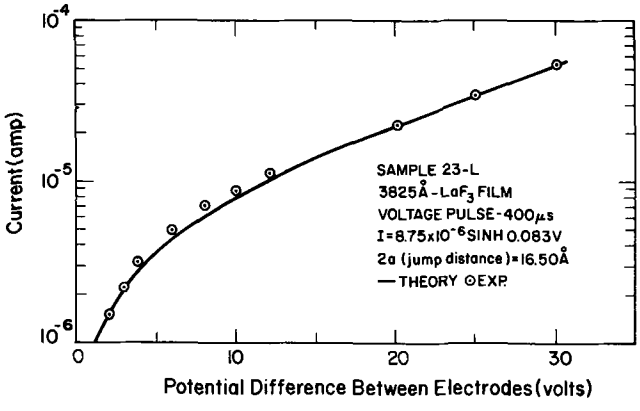

Fig. 1. Pulsed I-V characteristic for LaF_3 film of thickness 3825Å. The voltage pulse was of 400 μsec duration. The data has been fitted to an equation of the form $I = 8.75 \times 10^{-6}$ sinh (0.083V) and an ionic jump distance of 8.25Å.

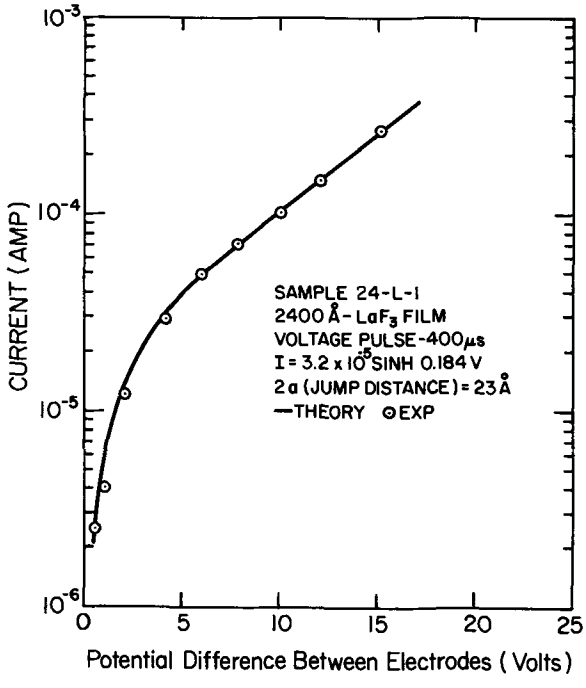

Fig. 2. Pulsed I-V characteristic for LaF_3 film of thickness 2400Å. The voltage pulse was of 400 μsec duration. The data has been fitted to an equation of the form $I = 3.2 \times 10^{-5}$ sinh (0.184V) and an ionic jump distance of 11.5Å.

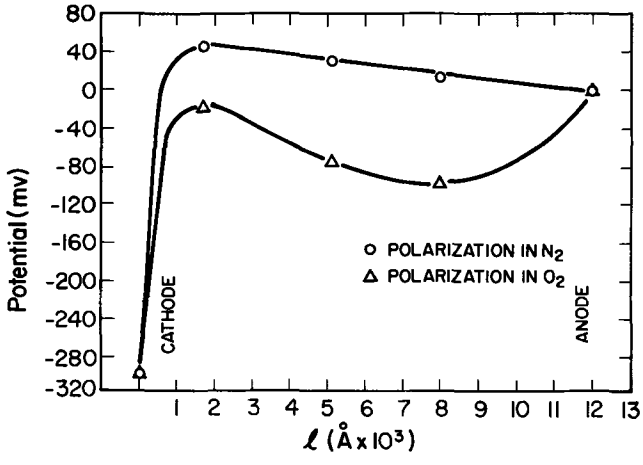

Fig. 3. Potential profile in the interior of LaF_3 films after 30 min charging in N_2 or O_2. The bias voltage is −300 mV applied to the cathode.

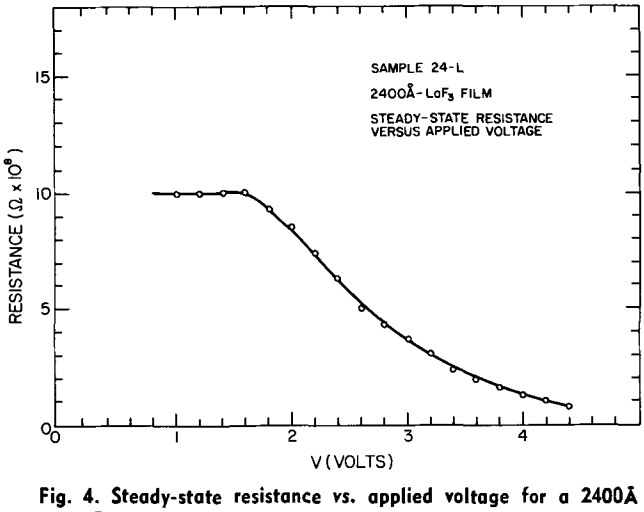

Fig. 4. Steady-state resistance *vs.* applied voltage for a 2400Å thick LaF_3 film.

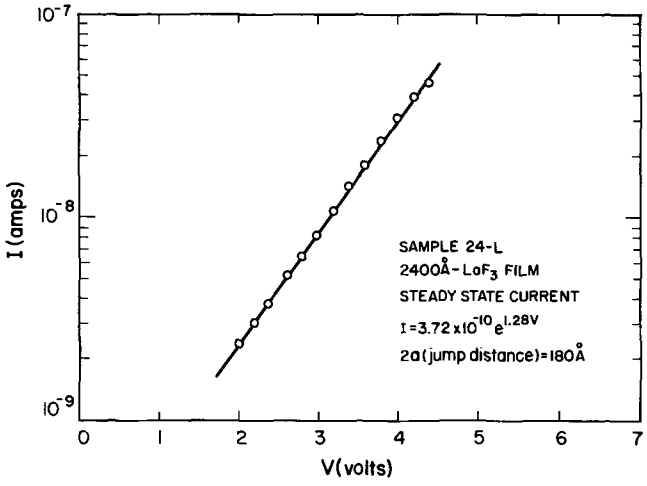

Fig. 5. Log I vs. applied voltage for a 2400Å thick LaF_3 film. Data is fitted to an equation of the form $I = 3.72 \times 10^{-10}$ exp (1.28V) which gives an apparent jump distance of 180Å.

portion of the I-V curve for the same sample is shown to fit Eq. [2]

$$I = 3.72 \times 10^{-10} e^{1.28V} \qquad [2]$$

which is another form of Eq. [1] with V, the potential difference between the electrodes, expressed explicitly. If we interpret the parameters as before, then a jump distance of 180Å can be derived. This value appears unrealistic and simply means that with the longer polarization time involved, the space charge layer has further enhanced the internal electric field near the cathode. In Table I a compilation is given of the pulse and steady-state electrical parameters, as a function of thickness of the LaF_3 film. The capacitance values for the pulse measurements are fairly constant with changing sample thickness indicating that the apparent dielectric constant is independent of inter-electrode distance. This indicates that the high polarization effect in LaF_3 is primarily an electrode effect. This is consistent with the potential probe data. The steady-state resistivity, is greater than the pulse resistivity by 10^2, and indicates the large effect of the interfacial polarization on the steady-state charge transport.

Discussion of Results

Single crystals of LaF_3 have previously been reported to have unusual electrical properties. For instance a small activation energy (0.069 eV) for Schottky defect formation has been measured and the defects are believed to be formed neutral (molecular holes). The interaction of LaF_3 in the crystal with a molecular hole to produce LaF_2^+ and F^- with a dissociation energy of approximately 0.40 eV (1) is thought to be the mechanism of carrier generation. Conductivity measurements by Sher *et al.* (1) and NMR experiments by Lee (7), Lundin *et al.* (8), and Goldman and Sher (9) all suggest that the electrical conductivity is due to ionic motion (F^-) with little electronic contribution. Solomon *et al.* (2) observed a large persistent polarization in LaF_3. They suggest the existence of a permanent double layer at the surface of the LaF_3 crystals, and potential probe measurements confirm this.

The results of thin films have many of the same features as the single crystal results. The measurements in this work certainly indicate a space-charge region near the electrodes plays a large role in the transport properties. The potential probe measurements given in Fig. 3 are similar to those obtained by Solomon *et al.* (2) on single crystals. Also, recent conductivity work on thin films of LaF_3 by Tiller *et al.* (10) agrees in the value of the conduction energy (0.43 eV) with conductivity (1-3) and NMR data (6-8) on single crystals of LaF_3.

The pulse resistivity of the LaF_3 thin films is of the order of 10^9 ohm-cm, or two orders of magnitude greater than the resistivity of the single crystal. However, the polycrystalline nature of the thin film and possible changes in stoichiometry could account for this difference. Lancaster (11) has observed that on heating CeF_3 films to 400°C in an ultrahigh vacuum system, fluorine gas was detected above the film. The I-V characteristics fit very well the $I \sim$ sine αV relationship that is indicative of ionic conduction over energy barriers controlled by the electric field. However, because of the strong positive space-charge region near the cathode, the internal electric field is different from the applied electric field. When this difference is accounted for, the ionic jump distances derived are more consistent with the values that would be expected in the LaF_3 structure.

The capacitance of the LaF_3 films is largely independent of the thickness, the I-V curves seem to be independent of the electrode material, and the potential probe measurements show a concentration of space charge near the surface. All of this evidence points to some form of persistent surface polarization in LaF_3 thin films. The same evidence exists for LaF_3 single crystals. The evaporation process probably leads to some degree of stoichiometry change if Lancaster's loss (11) of F_2 in CeF_3 can be assumed to happen in LaF_3 also. This plus the polycrystalline nature of the thin films must account for the two order of magnitude lower resistivity in the films.

Frenkel (12) has pointed out that a permanent double layer might exist in ionic crystals containing Schottky defects if there is a difference in activation energy for formation of vacancies between cations and anions. Frenkel's model predicts a charged layer of the ions that have the smaller activation energy. The evidence indicates that this phenomenon is active in both single crystals and thin films of LaF_3.

Conclusions

LaF_3 thin films exhibit the $I \propto \sinh \alpha V$ behavior characteristic of ionic conductors. The dominant charge carrier is thought to be an F^- ion hopping in vacancies created by the formation of Schottky defects. Because of the evaporation process there is probably a net loss of fluorine leaving a strong net positive space charge in the deposited LaF_3 with charge neutrality maintained by excess charge on the metal electrodes. An applied field enhances the positive space-charge layer in the vicinity of the cathode. The transport data

Table I. Electrical characteristics of LaF_3 thin films as a function of thickness

Sample	Thickness (Å)	Pulse time (400 μsec)			Steady-state

are consistent with the existence of persistent surface polarization in thin films. This permanent polarization has also been observed in single crystal experiments by other workers.

The Electro-Oxidation of Acetylene on Heterogeneous Au-Pt Alloys

J. W. Johnson,* C. K. Wu, and W. J. James*

Departments of Chemical Engineering and Chemistry and The Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri

ABSTRACT

The anodic oxidation of acetylene was studied in aqueous solutions (pH = 0.3-12.6) at 80°C on heterogeneous Au-Pt alloy electrodes. The results were interpreted in terms of parallel reactions occurring separately on the Au-rich and Pt-rich phases. The polarization behavior on the separate phases was very similar to that of the corresponding pure metals.

The electro-oxidation of acetylene has previously been studied on platinized Pt and Au (1, 2). On platinized Pt, CO_2 was produced with high coulombic efficiency. A suggested reaction mechanism was

$$C_2H_2 = C_2H_2(ads) \quad [1]$$

$$H_2O = OH(ads) + H^+ + e \quad [2a]$$

or

$$OH^- = OH(ads) + e \quad [2b]$$

$$C_2H_2(ads) + OH(ads) \xrightarrow{\text{r.d.s.}} \ldots \rightarrow CO_2, H^+, e \quad [3]$$

On Au, the CO_2 coulombic efficiency varied from 3-80%, depending on pH and acetylene partial pressure. Discontinuities in the Tafel curves were interpreted in terms of a "transition region," on either side of which different reaction sequences were operative. The mechanism below the transition region (b.t.r.) was proposed to be the same as that for Pt except for a change in the rate determining step (r.d.s.) and the appearance of a resinous by-product

$$C_2H_2 = C_2H_2(ads) \quad [4]$$

$$H_2O \xrightarrow{\text{r.d.s.}} OH(ads) + H^+ + e \quad [5a]$$

or

$$OH^- \xrightarrow{\text{r.d.s.}} OH(ads) + e \quad [5b]$$

$$C_2H_2(ads) + OH(ads) \rightarrow \ldots \rightarrow CO_2, H^+, e, \text{resin} \quad [6]$$

Above the transition region (a.t.r.), the sequence proposed was

$$C_2H_2 = C_2H_2(ads) \quad [7]$$

$$C_2H_2(ads) + H_2O \xrightarrow{\text{r.d.s.}} C_2H_2OH(ads) + H^+ + e \quad [8a]$$

or

$$C_2H_2(ads) + OH^- \xrightarrow{\text{r.d.s.}} C_2H_2OH(ads) + e \quad [8b]$$

$$C_2H_2OH(ads) \rightarrow \ldots \rightarrow CO_2, H^+, e, \text{resin} \quad [9]$$

The differences in these reaction sequences have been attributed to differing properties of the metals for hydrocarbon adsorption ,water discharge, and oxide formation. The pure metals differ greatly in these respects. On Pt it is believed that the unsaturated hydrocarbons absorb by the breaking of one C-C bond and the forming of covalent bonds between the organic radical and metal atoms The unpaired electrons of the radical and d-band vacancies of Pt apparently participate in this bonding. Pt has *ca.* 0.55 such vacancies, thus 4 adjacent atoms (sites) are required for acetylene adsorption (3). The equilibrium constant (K_p) for this case (Eq. [1]) has been estimated to be 10^4-10^6 atm^{-1}. The anodic discharge of water also appears to occur readily on Pt which leads to appreciable coverages of oxygen-containing species. In fact, the coverage of these latter species becomes so extensive that they prevent acetylene adsorption and stop its oxidation at potentials well below those required for oxygen evolution.

Au has no d-band vacancies available for covalent bonding. However, it does possess a uniquely small

* Electrochemical Society Active Member.

Key words: acetylene, oxidation, Au-Pt alloys.

energy for d-s promotion so that d-vacancies can be created rather easily to allow adsorption (4). Thus, 2 adjacent sites are needed to accommodate bonding with acetylene, but spacial and other mechanistic requirements may increase the number to 4 or more. Values of $n = 5$, $K_p = 10^4$ and $n = 8$, $K_p = 2.5$ were successful in correlating the kinetic data for acidic and basic electrolytes, respectively. No passivation region at the higher potentials was found on Au comparable to Pt.

A recent study of the anodic oxidation of ethylene on heterogeneous Au-Pt alloys (5) indicated qualitatively that the total current could be attributed to separate (parallel) reactions occurring on the Au-rich (α_2) and Pt-rich (α_1) phases.[1]

Therefore

$$I = I_{\alpha 1} + I_{\alpha 2} \qquad [10]$$

and in terms of current densities[2]

$$i = \beta_1 i_{\alpha 1} + \beta_2 i_{\alpha 2} \qquad [11]$$

Poor reproducibility of the experimental current-potential data prevented quantitative comparison. As very good reproducibility of data had been obtained earlier with acetylene oxidation on the pure metals, this study using the alloy electrodes was carried out hoping that a more meaningful test of the parallel reaction postulation could be made.

Experimental

The electrolytic cell, apparatus, reference electrodes, etc. have been described previously (1, 2, 5, 7). The studies were made potentiostatically and at 80°C except as noted. The gas flow rate (acetylene or acetylene-nitrogen mixtures) was kept constant to provide uniform stirring. The anion normality of the electrolyte was held constant at unity to insure good conductance.

Reagents.—Sulfuric acid, potassium sulfate, potassium carbonate, and potassium hydroxide, "Fisher Certified" reagents; acetylene, Matheson purified (>99.6% purity); nitrogen, Matheson prepurified (>99.997% purity); and conductivity water.

Anodes.—The anodes were prepared from the same Au-Pt alloy foils and wires as described previously (5). They were rectangular with geometric areas of 15.1 cm^2. Before each experiment they were cleaned by a brief immersion in boiling 1*N* KOH to dissolve any polymer film that may have formed during the previous run. They were subsequently activated by a cathodic polarization as also described previously. Repetitive runs showed the activity of the anodes to remain constant (within experimental error) during the course of the study.

Results

Rest potentials.—The open-circuit (rest) potentials in the presence of acetylene are shown in Table I. There is no consistent trend in the values, although for several *p*H's, they are intermediate to the values for Au and Pt. There was no noticeable effect of acetylene partial pressure.

Polarization behavior.—The current-potential relations are shown in Fig. 1-4. Individual points on the curves are steady-state values and could be reproduced within 5-10%. The curves for 80Au-20Pt and 20Au-80Pt are quite similar to those for pure Au and Pt, respectively. The other two alloys, 60Au-40Pt and 40Au-60Pt, have some regions of behavior similar to the pure metals and others with an intermediate behavior. Distinct discontinuities in the curves are observed as compared with a transition region (inflection point) for pure Au and the 80Au-20Pt alloy. The Tafel slopes and *p*H effects[3] are also tabulated in Table I.

With all the alloy anodes, the acidic anolytes became limpid amber in color and a brown resinous film formed on the anode surface after several hours of polarization. Basic anolytes became colored similarly, but no film was formed on the anode surface, apparently due to its solubility in these media.

Temperature effect.—The effect of temperature on the current at constant potential was determined for all the alloys in 1*N* H_2SO_4 and 1*N* KOH. Arrhenius plots are shown in Fig. 6 for the 60Au-40Pt anode and are typical of the others. The corresponding activation energies are summarized in Table II. In general, the latter are consistent with the observed Tafel slopes.

Pressure effect.—Studies with reduced acetylene partial pressures were also made in 1*N* H_2SO_4 and 1*N* KOH. The reduced pressures were obtained by mixing acetylene and nitrogen with a calibrated gas pro-

[1] A similar behavior has also been reported by Breiter [Ref. (6)] for Pt-Au alloys for oxygen-layer formation and reduction.

[2] β_1, β_2 = fractions of α_1 and α_2 phases in the alloys, respectively. Ratios of β_1/β_2 are shown in Table I.

[3] The effect of pH on current for the 60Au-40Pt alloy is shown in Fig. 5 and is typical of the relationships for the other alloys.

portioner. Figure 7 shows the results for the 60Au-40Pt alloy which are typical of the others. The pressure effects for all the alloys have been summarized in Table II.

Reaction products.—Faradaic efficiency studies for CO_2 production were carried out and the results are shown in Table III. The resinous films mentioned above appeared similar to those reported previously for Au (2). They were not soluble in ether, carbon tetrachloride, hexane, or benzene, but dissolved appreciably in warm 1*N* KOH. The anolytes were also extracted with the above solvents, but only ether showed any evidence of extraction by flame-ionization gas chromatographic analyses. Qualitative tests of the anolytes were negative for aldehyde and ketone groups. Infrared reflectance spectra of the films on the anodes indicated the presence of C—C and C=C bonds, but not O—H as reported previously for Au (2). *IR* analyses of extracts from the amber-colored basic

anolytes gave positive results for all three groups, C—C, C=C, and O—H. It thus appears that the OH group may have been introduced by the dissolution in basic media and that the film produced during polarization most likely has a polyacetylene-type structure.

Discussion

An examination of the experimental results[4] indicates that the Au-Pt alloys can be classified into three categories: (*i*) the high Au content alloy (80Au-20Pt) which behaves similarly to Au; (*ii*) the intermediate compositions (60Au-40Pt and 40Au-60Pt) which have distinct behaviors; and (*iii*) the high Pt content alloy (20Au-80Pt) which behaves similarly to Pt. As the Au-rich and Pt-rich phases are predominant at the opposite ends of the concentration range, this allows one to infer that the α_2 and α_1 phases have kinetic characteristics similar to the pure metals, Au and Pt. Thus the reaction sequence for the α_2 phase below the transition region should (*i*) involve species in addition to acetylene or its derivatives since $\partial i/\partial P < 0$; (*ii*) exhibit no *p*H dependence in acidic solutions and a unit dependence in basic solutions; and (*iii*) have a r.d.s. associated with the first electron transfer since the Tafel slope is $2(2.3\ RT/\mathbf{F})$.[5] Equations [4]-[6] satisfy these criteria and lead to the rate expression (2)

$$(i_{\alpha 2})_{\text{b.t.r.}} = n\mathbf{F}(k_{5a}a_{H_2O} + k_{5b}a_{OH^-})(1 - \theta_A) \exp(\alpha \mathbf{F}V/RT) \quad [12]$$

Above the transition region on the α_2-phase, the reaction sequence should (*i*) involve acetylene or species derived therefrom since $\partial i/\partial P > 0$; (*ii*) have a *p*H dependence approaching unity in basic solutions; and (*iii*) again have a r.d.s. associated with the first electron transfer since the Tafel slope is $2(2.3\ RT/\mathbf{F})$.[5] Equations [7]-[9] satisfy these criteria and lead to the rate expression (2)

[4] No mechanistic significance was attached to the rest potentials. In general they are 0.2-0.4V more positive than the corresponding reversible values for complete oxidation to CO_2. The lack of specific knowledge of by-products does not allow an exact calculation of the reversible values. This together with the absence of an acetylene partial pressure effect and the apparent low exchange current densities led to the rest potentials not being given further consideration. With such conditions they are often "mixed" values or possibly only remotely related to the reaction under consideration. The observations of this study are similar to several others involving hydrocarbons. Piersma (8) has summarized several interpretations of these potentials.

[5] Assuming Langmuir-type adsorption and low coverages of reaction intermediates.

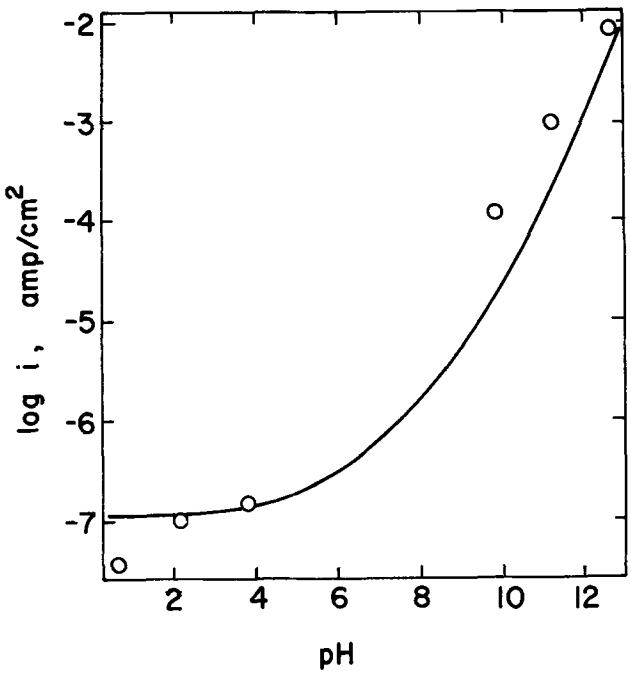

Fig. 5. Comparison of experimental and calculated effect of *p*H on current density for the anodic oxidation of acetylene on 60Au-40Pt alloy at 80°C ($P_A = 1$ atm, $V = 0.40$V). ○, experimental data points; ———, Eq. [11], [13], and [14] using constants evaluated for Pt and the 80Au-20Pt alloy.

$$(i_{\alpha 2})_{\text{a.t.r.}} = n\mathbf{F}(k_{8a}a_{H_2O} + k_{8b}a_{OH^-})\theta_A \exp(\alpha \mathbf{F}V/RT) \quad [13]$$

Similarly, the reaction sequence for the α_1-phase should (*i*) involve species in addition to acetylene or derivatives since $\partial i/\partial p < 0$; (*ii*) exhibit a *p*H effect of *ca.* unity; and (*iii*) have a r.d.s. involving a chemical reaction following the first charge transfer since the Tafel slope is 2.3 $RT/\mathbf{F}$.[5] Equations [1]-[3] satisfy these criteria and give the rate expression

$$i_{\alpha 1} = n\mathbf{F}k_3(K_{2a}a_{H_2O}/a_{H^+} + K_{2b}a_{OH^-})\theta_A(1 - \theta_A) \exp(\mathbf{F}V/RT)$$
$$= n\mathbf{F}k_3K_2a_{H^+}{}^{-1}\theta_A(1 - \theta_A) \exp(\mathbf{F}V/RT) \quad [14]$$

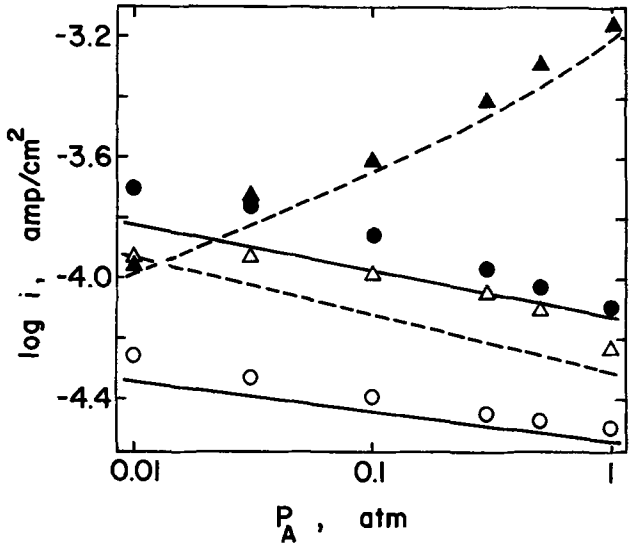

Fig. 7. Comparison of experimental and calculated effect of partial pressure on current density for the anodic oxidation of acetylene on 60Au-40Pt alloy at 80°C. Experimental data: ○, 0.70V, 1N H_2SO_4; ●, 0.75V, 1N H_2SO_4; △, 0.01V, 1N KOH; ▲, 0.26V, 1N KOH. Equation [11] using C.D. values for Pt and the 80Au-20Pt alloy: ———, 1N H_2SO_4; — — —, 1N KOH.

The 80Au-20Pt alloy was found to consist almost entirely of the α_2-phase (see Table I). Thus the C.D.'s for this electrode are the same as those indicated in Eq. [12] and [13] and can be used directly in Eq. [11]. The composition of the α_1 phase corresponding to the above α_2 composition is *ca.* 95% Pt (9). No alloy was available whose composition corresponded to this value, so the C.D.'s for smooth Pt have been substituted for those of the α_1 phase of Eq. [14] for use in Eq. [11]. There is some justification for this substitution in that the polarization characteristics of Pt and the Pt-rich alloy are similar and, of the electrodes available, the Pt composition of pure Pt is more nearly the same as that of the α_1 phase than any of the others. Equations [12]-[14] can now appropriately be combined with Eq. [11] to represent the polarization behavior of heterogeneous Au-Pt alloy electrodes for acetylene oxidation. In particular Eq. [12] and [14] substituted into Eq. [11] will represent current densities on Au, Au-rich (b.t.r.), Pt-rich, and Pt anodes. Equations [13] and [14] substituted into Eq. [11] will represent C.D.'s on Au-rich (a.t.r.) anodes. It is important to keep in mind that the α_1-phase will passivate (as also will Pt) when the potential becomes sufficiently positive, thus eliminating its contribution to the C.D. This is apparently responsible for the discontinuity region (d.r.) seen most markedly in basic solutions for the 60Au-40Pt alloys.[6] At potentials below the d.r., both the α_1 and α_2 phases are contributing to the current. Relatively speaking, the larger portion is contributed by the α_1 phase. As the potential is increased, the α_1 phase passivates, and further potential increases are necessary before the α_2 phase will contribute appreciable currents. The Tafel slope for either of the above cases reduces to the form

$$\partial V/\partial \log i = (2.3\,RT/\mathbf{F})\,i/(\beta_1 i_{\alpha 1} + \alpha\beta_2 i_{\alpha 2}) \qquad [15]$$

A comparison of the slopes calculated from Eq. [15] with the experimental values is shown in Table IV. Figure 8 shows the polarization curves for the two-phase alloys in 1N H_2SO_4 and 1N KOH as calculated using Eq. [11] and the experimental i-V data for the 80Au-20Pt alloy and smooth Pt. The curves correspond very closely to the experimental points as shown in the figure. The effects of electrolyte pH and acetylene partial pressure calculated in the same manner are shown in Fig. 5 and 7, respectively, for the 60Au-40Pt alloy. The experimental values are also shown for comparison. The agreement is fair and typical of that for the other alloys.

The resulting equation for the apparent activation energies for the two-phase alloy electrodes using the combined equations (Eq. [11]-[14]) is

$$E'_a = \beta_1(E_{\alpha 1} - \mathbf{F}V)\,(i_{\alpha 1}/i) + \beta_2(E_{\alpha 2} - \alpha\mathbf{F}V)\,(i_{\alpha 2}/i) \qquad [16]$$

The effect of potential on the activation energy is

$$\partial E'_a/\partial V = -\mathbf{F}(\beta_1 i_{\alpha 1} + \alpha\beta_2 i_{\alpha 2})/i \qquad [17]$$

Values for Eq. [17] are also shown in Table IV along

Table III. Coulombic efficiency of CO_2 production for the anodic oxidation of acetylene on Au-Pt electrodes at 80°C

Electrode	1N H_2SO_4 Current density (A/cm² × 10³)	1N H_2SO_4 CO_2 efficiency (%)	1N KOH Current density (A/cm² × 10³)	1N KOH CO_2 efficiency (%)

with the corresponding experimental values for comparison.

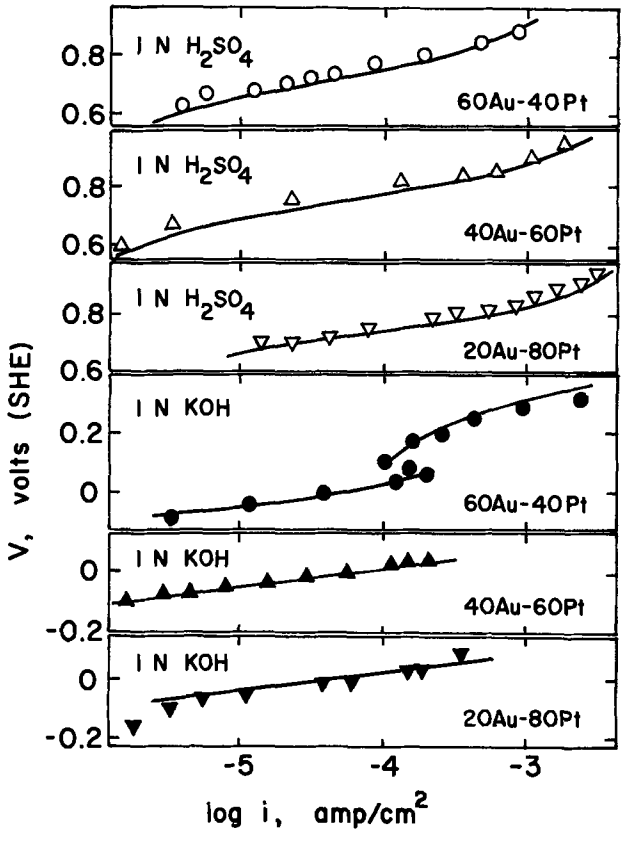

Fig. 8. Comparison of experimental and calculated polarization curves for the anodic oxidation of acetylene on heterogeneous Au-Pt alloys at 80°C (P_A = 1 atm). Experimental data symbols: ○, ●, △, ▲, ▽, ▼; Eq. [11], using C.D. values for Pt and the 80Au-20Pt alloy: ————.

It thus appears from an examination of Fig. 5 and 7 and Table IV that the behavior of the heterogeneous Au-Pt alloy anodes for the anodic oxidation of acetylene can be satisfactorily explained in terms of parallel electrochemical reactions occurring separately on the Au-rich and Pt-rich phases. It is also indicated that one phase can passivate while the other remains active.

Corrosion of an Iron Rotating Disk

Nader Vahdat and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The corrosion rate of iron rotating disks is studied by calculating the current and potential distribution on the surface of the disk. The results show that for rotation speeds high enough to create turbulent flow on the outer portion the rate of corrosion may be nonuniform. The surface toward the center of the disk can corrode with a maximum rate, while the edge of the disk remains almost unattacked. The effect of different parameters on the corrosion behavior of the rotating disk is studied.

LaQue (1) has conducted some corrosion experiments with copper and iron disks rotating in seawater. The copper disks corroded most rapidly at the periphery and remained almost unattacked at the center. But it is remarkable that the greatest attack on the iron disks occurred toward the center on the more slowly moving surfaces. LaQue's iron disks were 3, 4, and 5 in. in diameter and were rotated at 120 radian/sec (about 1146 rpm) in seawater at 15°C. The maximum corrosion rate might correspond to a local current density of 0.19 mA/cm^2. Under ideal hydrodynamic conditions, the flow would be expected to become turbulent at a radial position of about 5 cm or 2 in. at this rotation speed.

This particular corrosion system is attractive for analysis because the hydrodynamic flow (2, 3) is well known near a rotating disk, and one can calculate the current and potential distribution for this geometry. Levich (4) has found the limiting rate of mass transfer, and Newman (5) has given the current distribution below the limiting current.

In practice, usually the anodic and cathodic reactions occur on different parts of the same surface (or on two different surfaces which are in contact) and cause localized corrosion. The rotating disk seems to be an ideal case for studying localized corrosion because it is the simplest model that can be used to study this complicated situation (6).

It should be noted that velocity does not have a direct effect on the rate of corrosion; its only role is that it usually (but not always) increases the rate of transfer of corrosive species to the metal, and consequently it may increase the corrosion rate. In the case of a rotating disk in the laminar region, the limiting rate of mass transfer to the disk is not a function of linear velocity. Consequently, the disk should be corroded uniformly in spite of the fact that there is a velocity gradient on its surface.

The results for the copper disks can be explained by the fact that the surfaces towards the periphery of the disk move with a higher velocity (being in the turbulent region) and that the amount of oxygen that reaches them is higher. Consequently, the corrosion rate would be higher too. For the iron disks, the results can be explained when it is noted that iron is an active-passive metal and when a high oxygen concentration tends to produce a protective oxide coating on such metals. The surfaces towards the periphery of the disk are passivated because of the greater amount of oxygen that reaches them.

As stated in the Conclusions, the nonuniform rate of corrosion is not always achieved. For example, a very small or a very large disk could give a uniform corrosion rate. By the same token, the corrosive medium is also an important factor in determining the corrosion pattern.

* Electrochemical Society Active Member.

Key words: passivation, localized corrosion, potential and current distribution.

In the case of an iron rotating disk, the outer region of the disk, which is exposed to a higher oxygen concentration, acts as a cathode to the central portion. The reaction taking place on these cathodic areas would be the reduction of oxygen

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

and the anodic reaction (taking place on the inner region of the disk) would be the dissolution of iron

$$Fe \rightarrow Fe^{++} + 2e^-$$

These local anodes and cathodes form a corrosion cell and a current will pass through the solution. As there is no external current to the rotating disk, the total net current on the disk should be zero, *i.e.*

$$I_{net} = I_{Fe} + I_{O_2} = 0 \qquad [1]$$

Development of the Model

The current and potential distribution on the surface of a rotating disk are (5)

$$\Phi_0 = \frac{RT}{\mathbf{F}} \sum_{n=0}^{\infty} B_n P_{2n}(\eta) \qquad [2]$$

$$i(\eta) = -\frac{\kappa_\infty}{r_0 \eta} \frac{RT}{\mathbf{F}} \sum_{n=0}^{\infty} B_n P_{2n}(\eta)\, M'_{2n}(0) \qquad [3]$$

where Φ_0 is the ohmic potential, R is the gas constant, T is absolute temperature, $\mathbf{F}$ is Faraday's number, B_n is a constant, $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$, $i(\eta)$ is the current density, κ_∞ is the conductivity of the solution, η is the rotational elliptic coordinate, and $M'_{2n}(0)$ is a known constant [see Ref. (5)].

In the case of corrosion of the rotating disk, the current density, $i(\eta)$, in Eq. [2] would be the net current density which is the sum of anodic and cathodic current densities at each point on the disk, *i.e.*

$$i(\eta) = i_{Fe}(\eta) + i_{O_2}(\eta) \qquad [4]$$

If the relations between the iron and oxygen current densities and the potential are known, one is in a position to solve Eq. [1]-[4] to determine the current and potential distribution on the disk, and consequently find the corrosion behavior of the disk. The polarization curve of iron, which gives the relation between iron current density and potential, is a function of several parameters such as the ferrous ion concentration, the chloride ion concentration, and the *p*H of the solution. To simplify the problem, these composition effects have been neglected here. In most practical cases, the corrosive medium is neutral. Pourbaix (7) has given a set of iron polarization curves for the whole range of pH. From these results, the passivation current has the value 1.5 mA/cm^2 at

a pH of 7. Thus, we can construct the following equation to describe the kinetics of iron in a neutral solution

$$i_{Fe} = 1.5 \times 10^{-3} \exp[-5 \times 10^3 (V - \Phi_o + 0.2)^2] + 10^{-7} \quad [5]$$

for $V - \Phi_o > -0.25$ where $V - \Phi_o$ is the potential of the electrode relative to a hydrogen electrode close to its surface. (It should be noted that the concentration overpotential of iron has been neglected.) This equation shows a maximum current density centered at an electrode potential of -0.2V. At more cathodic potentials, the current density increases with electrode potential as is customary for anodic dissolution. At more anodic potentials, the electrode begins to passivate, and the current density decreases toward a value of 10^{-7} A/cm^2 in the passive region.

In the case of oxygen, one should consider both the concentration and surface overpotentials because both are important. The limiting rate of mass transfer to a rotating disk in laminar flow was calculated by Levich (4) and is given by the following equation

$$Nu_{lam} = C_1 Re^{1/2}_{loc} Sc^{1/3} \quad [6]$$

where Nu_{lam} is the local Nusselt number, Re_{loc} is the local Reynolds number, Sc is the Schmidt number, and C_1 is a function of the Schmidt number (8) approaching 0.6205 for large Schmidt numbers.

For the turbulent region there are some experimental correlations in the literature. Ellison (9, 10) has given the following expression for the rate of mass transfer to a rotating disk in the turbulent region for Reynolds numbers between 8.9×10^5 and 1.18×10^7 and for Schmidt numbers between 35 and 1350

$$\overline{Nu_t} = 1.17 \times 10^{-2} Re^{0.896} Sc^{0.249} \quad [7]$$

where $\overline{Nu_t}$ is the average Nusselt number and Re is the over-all Reynolds number. Equation [7] can be used to find the local rate of mass transfer to the disk in the turbulent region. By definition

$$\overline{N_i} \pi r^2 = \int_0^r 2\pi r N_i dr \quad [8]$$

where $\overline{N_i}$ is the average rate of mass transfer to the disk. Differentiation of this equation with respect to r and substitution of Re_{loc}, $\overline{Nu_t}$, and Nu_t (from their definitions) yield

$$\frac{d}{dRe^{1/2}_{loc}} (\overline{Nu_t} Re^{1/2}_{loc}) = 2Nu_t \quad [9]$$

From Ellison's correlation one can then get

$$Nu_t = 1.6332 \times 10^{-2} Re^{0.896}_{loc} Sc^{0.249} \quad [10]$$

where Nu_t is the local Nusselt number in the turbulent region.

Equations [6] and [10] yield the following expressions for the limiting current density on the surface of the rotating disk

$$i_{lim} = nFDc_\infty C_1 \sqrt{\frac{\Omega}{\nu}} Sc^{1/3} \text{ for laminar region} \quad [11]$$

$$i_{lim} = nFDc_\infty C_2 \sqrt{\frac{\Omega}{\nu}} \left(\frac{r^2\Omega}{\nu}\right)^{0.396} Sc^{0.249}$$

for turbulent region [12]

where Ω is the rotation speed (radians/sec), ν is the kinematic viscosity, and $C_2 = 1.6332 \times 10^{-2}$.

The kinetics of the oxygen reaction will be described by the following equation

$$i_{O_2} = i_o(c_o) \left[\exp\left(\frac{\alpha_a F}{RT}\eta_s\right) - \exp\left(\frac{-\alpha_c F}{RT}\eta_s\right) \right] \quad [13]$$

where η_s is the surface overpotential, α_a and α_c are the transfer coefficients, and $i_o(c_o)$ is the exchange current density. For the reduction of oxygen, the first term in Eq. [13] can be neglected (this is a good approximation for the potentials far removed from the equilibrium potential of oxygen). The concentration overpotential can be written as

$$\eta_c = -\frac{RT}{nF} \ln \frac{c_o}{c_\infty} \quad [14]$$

and the total potential is

$$V = \eta_s + \eta_c + \Phi_o + U \quad [15]$$

where U is the equilibrium potential of oxygen relative to a normal hydrogen electrode (about 1.229V).

The exchange current density depends on the concentration of reactants and products on the surface of the electrode. If the concentration variations of OH^- and H_2O are neglected, one can write the following equation for the oxygen exchange current density

$$i_o(c_o) = i_o(c_\infty) \left(\frac{c_o}{c_\infty}\right)^{1+\alpha_c/n} \quad [16]$$

where $i_o(c_\infty)$ is the oxygen exchange current density evaluated at the bulk concentration, c_∞. And the ratio of oxygen concentration on the surface to that in the bulk solution can be expressed as

$$\frac{c_o}{c_\infty} = 1 - \frac{i_{O_2}}{i_{lim}} \quad [17]$$

Substitution of Eq. [14], [15], [16], and [17] into Eq. [13] yields

$$i_{O_2} = -i_o(c_\infty) \left(1 - \frac{i_{O_2}}{i_{lim}}\right) \exp\left[-\frac{\alpha_c F}{RT}(V - \Phi_o - U)\right] \quad [18]$$

where $i_o(c_\infty)$ can be found from the polarization curve of oxygen reduction on iron. The kinetics of oxygen reduction on iron depends on the oxygen concentration and the pH of the solution, but unfortunately there are not adequate data in the literature to show the effects of these parameters. Delahay (11) has given a polarization curve for oxygen reduction on iron at pH = 7. From this result the following value is found for $i_o(c_\infty)$

$$i_o(c_\infty) \exp\left(\frac{\alpha_c F}{RT} U\right) = 7.4 \times 10^{-4} \text{ A/cm}^2 \text{ for } c_\infty = 10^{-7} \frac{\text{mole}}{\text{cm}^3}$$

To show the effect of oxygen concentration on the corrosion rate, the following value is assumed for $i_o(c_\infty)$ at $c_\infty = 5 \times 10^{-7}$ mole/cm^3

$$i_o(c_\infty) \exp\left(\frac{\alpha_c F}{RT} U\right) = 16.0 \times 10^{-4} \text{ A/cm}^2 \text{ for } c_\infty = 5 \times 10^{-7} \frac{\text{mole}}{\text{cm}^3}$$

Equations [5] and [18] give the desired relations that can be used in parallel with Eq. [1]-[4] to find the current and potential distribution on the disk. It should be noted that there are six equations with six unknowns, namely i_{Fe}, i_{O_2}, $i(\eta)$, Φ_o, B_n, and V. These

simultaneous equations are highly nonlinear and should be solved by numerical methods. The following iterative procedure is used to solve the equations. (*i*) A net current distribution is assumed for the disk. (*ii*) Equation [3] is used to find the coefficients, B_n. (*iii*) The ohmic potential, Φ_o, is calculated from Eq. [2]. (*iv*) A value is assumed for the potential, V, of the disk. (*v*) Iron and oxygen current densities are calculated from Eq. [5] and [18], respectively. (*vi*) The current densities found in step (*v*) should satisfy Eq. [1]; if they do not, another value is assumed for V, and the step (*v*) is repeated. (*vii*) The sum of iron and oxygen current densities should be equal to the net current assumed in step (*i*) at each point on the disk; if it is not, using a multidimensional Newton-Raphson method, another value is found for the net current, and the calculations enumerated in steps (*ii*) through (*vi*) are repeated until no significant changes occurred in the net current.

Limitation of the Model

The iron current density is a function of Fe^{++} concentration, chloride ion concentration, and *p*H of the solution, as well as potential. In general one can write

$$i_{Fe} = i_{Fe}(V - \Phi_o, c_{Fe^{++}}, c_{Cl^-}, pH)$$

In the case of corrosion of the rotating disk, the outer portion of the disk acts as the aerated cathode where oxygen is being reduced to water and/or hydrogen peroxide with an increase of *p*H, while the central portion of the disk, which is active, is the less well aerated anode where the metal undergoes corrosion and hydrolysis with decrease of pH. Thus, the *p*H does not remain uniform on the surface of the disk.

The concentration of iron ions and chloride ions are likewise not uniform on the surface of the disk. Fe^{++} is higher at the center and decreases towards the periphery. Migration may increase the concentration of the chloride ion on the central portion of the disk.

It should be noted that the variations of $c_{Fe^{++}}$, c_{Cl^-}, and *p*H are not large, and they are neglected in this work. They may, however, be crucial to the stability of a situation where part of the disk is active and part is passive.

Results and Discussion

The corrosion rate of the rotating disk depends principally on oxygen concentration, rotation speed, conductivity of the solution, radius of the disk, and a factor that takes into account the relation between the rates of oxygen and iron reactions on the surface of the disk. For the last variable, one can use the ratio of oxygen and iron current densities at a potential corresponding to the maximum of the iron polarization curve and for a high rate of oxygen transfer to the disk ($\Omega \to \infty$). That is

$$A = \left| \frac{i_{O_2}}{i_{Fe}} \right|_{\substack{\max i_{Fe} \\ \Omega \to \infty}} \qquad [19]$$

would be the last variable. This quantity is indicated in the graphical representation of the results.

Figure 1 shows the iron current density (which is proportional to the rate of corrosion), oxygen current density, and the ohmic potential on the surface of the rotating disk. The iron current density curve shows that the corrosion rate is high at the center, increases slowly with radial position, passes through a weak maximum, and then drops rapidly to a very low value at the periphery. This is in agreement with the experimental results (1). The curve for the oxygen current density has a flat part which is related to the laminar region of the disk, and a sharp increase of the current, that shows the transition from laminar to turbulent region. The ohmic potential is

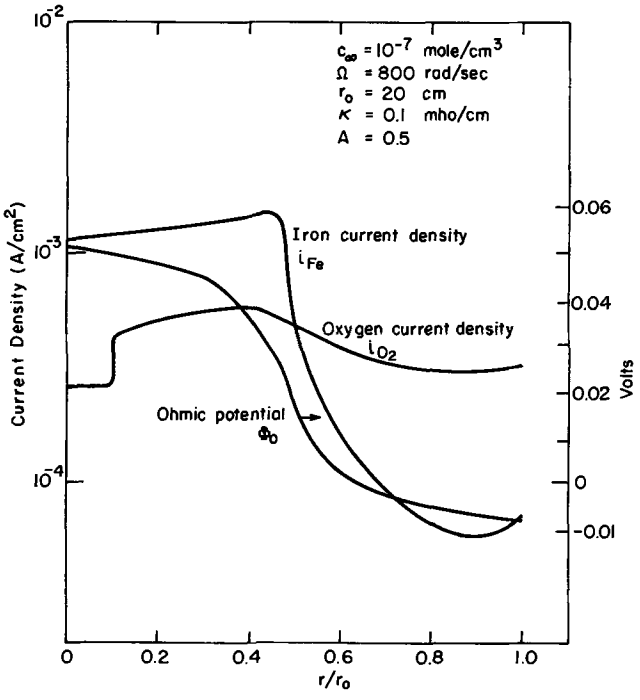

Fig. 1. Iron and oxygen current densities and ohmic potential distribution on the surface of an iron rotating disk.

high and positive at the center and decreases to negative values at the periphery. The net current would also be positive at the center and negative at the edge of the disk. This shows that in the central portion of the disk, anodic current has the larger contribution to the net current and that the cathodic reaction dominates on the outer portion.

The effect of rotation speed on the corrosion rate of the rotating disk is shown in Fig. 2 and 3. As it was mentioned earlier, the only effect of velocity is to increase the rate of transfer of oxygen to the disk (in the turbulent region). Thus, increasing the rotation speed has much the same effect on the corrosion as increasing the oxygen concentration. One

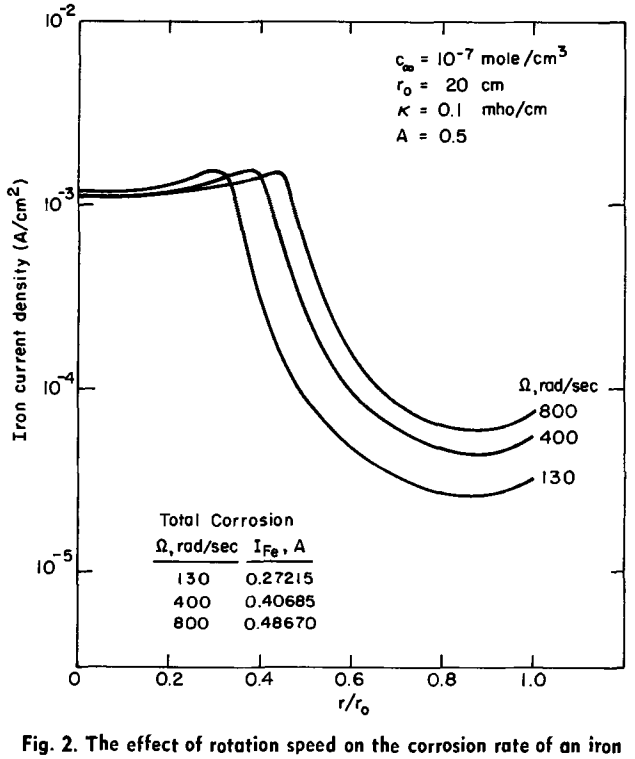

Fig. 2. The effect of rotation speed on the corrosion rate of an iron rotating disk.

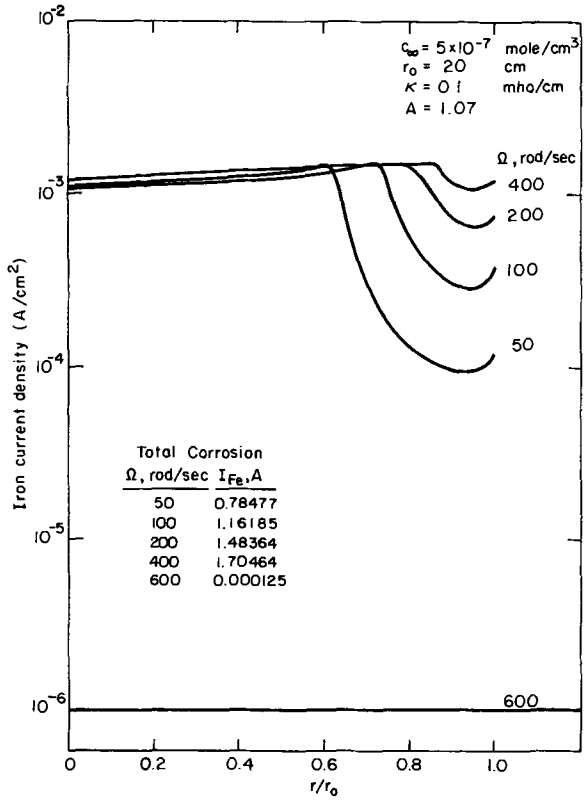

Fig. 3. The effect of rotation speed on the corrosion rate of an iron rotating disk.

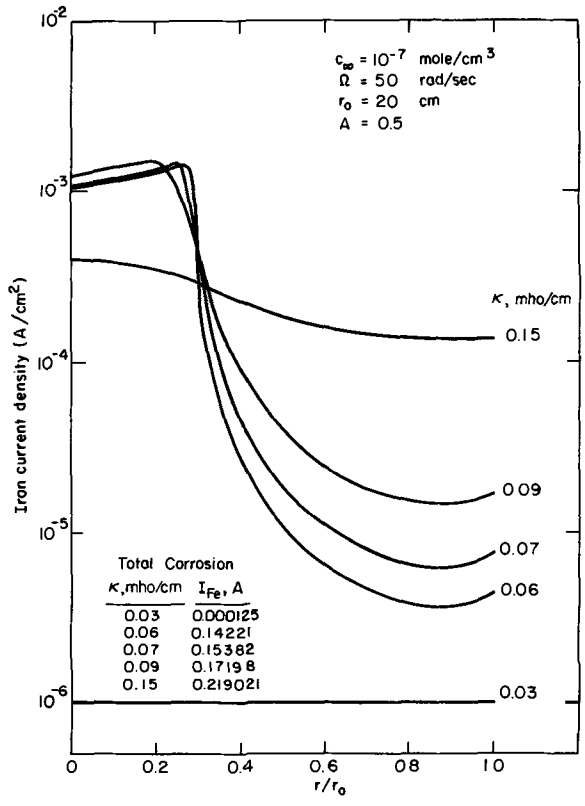

Fig. 4. The effect of conductivity of the solution on the corrosion rate of an iron rotating disk.

should, of course, note that changing the oxygen concentration will change $i_0(c_\infty)$. As the rotation speed is increased, the point of maximum corrosion on the disk moves toward the periphery, and the total corrosion of the disk increases. But if the rotation speed is increased to higher values, provided there is no limitation as far as the electrode kinetics of oxygen is concerned ($A > 1$), there will be a sudden change in the shape of the corrosion distribution, and the whole disk is passivated.

Figure 4 shows the corrosion behavior of the rotating disk when the conductivity of the bulk solution is a parameter. As the conductivity increases, the corrosion rate becomes more uniform. For the solutions with low conductivity, the nonuniformity in the corrosion rate increases, and the central region of the disk will have the maximum rate of corrosion, while passivation occurs at the edge. As the conductivity decreases, a larger area of the disk is passivated, and for very low conductivities, the whole disk would be in the passive region. It can be understood from Fig. 4 that for large values of conductivities, total passivity can also be achieved provided that rotation speed is high enough. Also, there will be no limitation for the electrode kinetics of oxygen.

The effect of the size of the rotating disk on the corrosion rate is given in Fig. 5. It shows that increasing the radius of the disk has a tendency to increase the nonuniformity of the corrosion rate, and for very large disks, the whole disk is passivated. For small disks, the whole area of the disk would be in the laminar region, and, consequently, the corrosion rate would be uniform, as is shown in Fig. 5. It should be noted that the size of the disk is an important factor in the corrosion rate, because it is not only a variable as far as the ohmic potential is concerned but also a factor that determines the limiting rate of oxygen transfer to the disk.

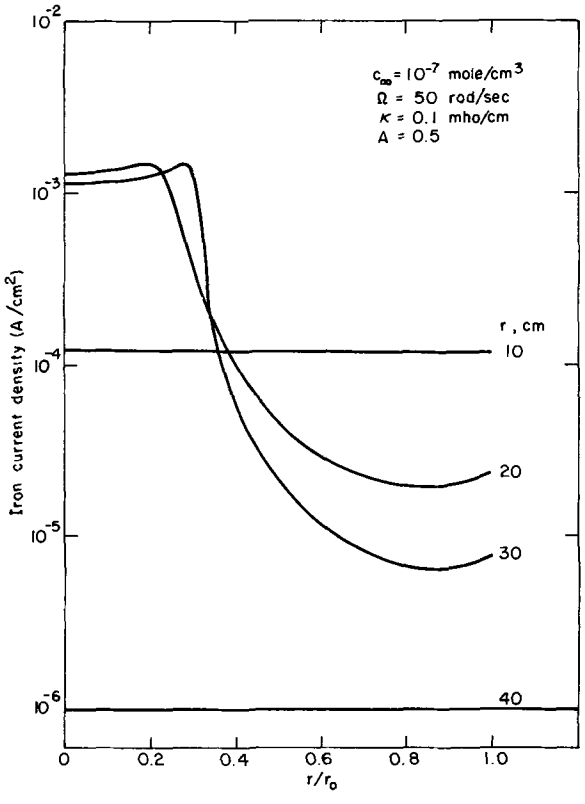

Fig. 5. The effect of the size of the disk on the corrosion rate of an iron rotating disk.

Conclusions

The development described in the preceding sections shows that the main reason for the peculiar corrosion behavior of an iron rotating disk is the passivation that occurs at the edge of the disk. Besides that, in order to have such a nonuniform corrosion rate on the surface of the rotating disk, the outer region of the disk has to be in the turbulent region. That is, if the size of the disk is small and/or the rotation speed is low so that the whole disk is in laminar region, one would get a uniform corrosion rate. The results also show that by changing the different parameters of

the system, one can get total passivity. It should be noted that in a system where the rate of transfer of corrosive species to the metal is high, the relation between the anodic and cathodic reaction rates is very important, because it is usually the electrode kinetics that limits the corrosion rate.

Because of the peculiar shape of the iron polarization curve, for a given condition of the system, it is possible to get three different schemes for the corrosion behavior of the rotating disk from the model developed above. Thus one would wonder which one of these solutions is physically meaningful. It should be noted that in the corrosion experiments of active-passive metals such as iron, one usually expects to obtain a hysteresis. That is, the corrosion rate of the metal at a given condition depends on the way the system approaches that specific condition. Thus, in the case of an iron rotating disk, one would also expect to get a hysteresis by increasing and decreasing the rotation speed, and the actual corrosion scheme of the disk would be one of the three solutions obtained from the calculations depending upon the way we approach a given condition.

LIST OF SYMBOLS

B_n	coefficients in series for potential
c_0	concentration at electrode surface, mole/cm^3
c_∞	bulk concentration, mole/cm^3
D	diffusion coefficient of oxygen, cm^2/sec
$\mathbf{F}$	Faraday's constant, coulomb/equivalent
i	net current density at electrode surface, A/cm^2
i_{Fe}	iron current density, A/cm^2
i_{lim}	limiting current density, A/cm^2
i_{O_2}	oxygen current density, A/cm^2
i_o	exchange current density, A/cm^2
I	total net current on the disk, A
I_{Fe}	total iron current on the disk, A
I_{O_2}	total oxygen current on the disk, A
M_{2n}	a Legendre function
n	number of electrons produced when one oxygen molecule reacts (−4)
N_i	flux of species i, mole/cm^2-sec
Nu	$N_i r/D(c_\infty - c_0)$, local Nusselt number
$\overline{\text{Nu}}$	$N_i r_0/D(c_\infty - c_0)$, average Nusselt number
P_n	Legendre polynomial of order n
r	radial coordinate, cm
r_0	radius of disk, cm
R	universal gas constant
Re	$= r_0^2\,\Omega/\nu$, over-all Reynolds number
Re_{loc}	$= r^2\,\Omega/\nu$, local Reynolds number
Sc	ν/D, Schmidt number
T	absolute temperature, °K
U	equilibrium potential of oxygen, V (~1.229 NHE)
V	potential of metal disk electrode, V
α_a, α_c	transfer coefficients
η	elliptic coordinate
η_c	concentration overpotential, V
η_s	surface overpotential, V
κ_∞	conductivity of bulk solution, ohm^{-1} cm^{-1}
Φ_0	external potential extrapolated to electrode surface, V
Ω	rotation speed, radians/sec

Technical Notes

Studies of $LiAlCl_4$ Solutions in Aprotic Solvents

M. Eisenberg,* K. Wong, and K-C Tsai*

Electrochimica Corporation, Mountain View, California 94040

Solutions of the Lewis acid, $AlCl_3$, coordinated with lithium chloride in nonaqueous aprotic solvents have been widely used in the lithium battery development work in recent years (1). The purpose of this study was to obtain basic information on the electrochemical stability of the LiCl-$AlCl_3$ solutions in aprotic solvents such as propylene carbonate, nitromethane, and their mixtures and to elucidate the mechanism of various redox processes pertaining to such electrolytes.

* Electrochemical Society Active Member.

Key words: nonaqueous electrolytes, lithium chloroaluminate, cyclic voltametry, propylene carbonate.

Cyclic voltametry was employed for the present study. This technique, involving a procedure of linear potential sweeps, is well established in electroanalysis for determination of reaction mechanisms in the oxidation and reduction of soluble species (2-6).

Experimental Procedure

Materials and electrolyte preparation.—Lithium chloride (LiCl) was vacuum dried at 150°C for 48 hr and the aluminum chloride ($AlCl_3$) was purified by sublimation just prior to its use. The solvents used were doubly distilled under partial vacuum (approx.

Table I. Compositions of the electrolytes employed in the cyclic voltametric studies

Electrolyte No.	Solutes, moles/liter		Solvents, %	
	LiCl	$AlCl_3$	Propylene carbonate	Nitromethane
1	0.8	0.8	100	—
2	0.8	0.8	—	100
3	0.8	0.8	50	50
4	0.4	0.8	100	—
5	0.4	0.8	0	100
6	0.4	0.8	50	50
7	—	0.8	50	50

50 mm Hg) and treated with a molecular sieve. All solutions were prepared in ground glass flasks inside a dry argon glove box. Karl Fischer titrations for water impurities gave a range of 20-50 ppm.

Seven solutions of varying concentrations of solutes and solvents were investigated. The compositions of these solutions are given in Table I.

Electrochemical cell and instrumentation.—The electrochemical studies were carried out in a typical three-electrode glass cell. A bright platinum rod with an exposed apparent surface area of 1 cm^2 was used as the working electrode. A concentric cylindrical platinum gauze (1 in. ID) with an exposed area much greater than the area of the working electrode was used as the counterelectrode. The reference electrode was Ag-AgCl(s) (immersed in the same nonaqueous electrolyte as under study) placed in a separate compartment with a Luggin capillary located about 3 mm away from the working platinum electrode. It was used to measure the potential between working and reference electrodes at both open-circuit voltage and under load conditions.

A Heath polarography Module EUA-19-2 with moderate sweep rates (0.05-2.00 V/min) was employed for all studies. The cyclic polarograms were recorded on a Houston Instruments HR-96T X-Y Recorder. The rest potential (at open-circuit voltage) was measured with a Keithley 621 Electrometer.

Two sets of experiments were conducted for the studies: (*i*) effects of solution compostiions on cyclic polarogram at a fixed slow scan rate of 2.0 V/min; (*ii*) effect of scan rate (0.2-2.0 V/min) on peak potentials.

Results and Discussion

All of the electrolytes tested yielded similar cyclic polarograms with the exception of electrolyte No. 7 containing no lithium chloride. The polarograms for the first six electrolytes were all similar to the two given in Fig. 1 for electrolyte No. 1 and No. 4. Figure 2 shows the polarogram for electrolyte No. 7.

In Fig. 1, the cyclic polarograms indicate an irreversible process for the oxidation and reduction reaction since there are no anodic current peaks corresponding to the observed cathodic current peaks $E_{pc(1)}$ and $E_{pc(2)}$.

Judging from the studies of Cauquis and Serve (2) and from the present results, it is very unlikely that the neutral organic solvents participate in the redox processes within the potential range studied. Therefore, we might assume the following.

(*i*) The anodic potential limit, E_{pa} (+1.6-1.7V) at the platinum electrode was caused by either the oxidation of Cl^- or of $AlCl_4^-$. The presence of $AlCl_4^-$ is due to the chemical equilibrium in this solvent system (1).

$$LiCl + AlCl_3 \rightleftharpoons Li^+ + AlCl_4^- \qquad [1]$$

(*ii*) The cathodic potential limit $E_{pc(3)}$ (−3.0 to −3.4V) was caused by the reduction of either Li^+ or Al^{+++} or the complex ion of aluminum, *i.e.*, $(AlCl_2 \cdot 2X)^+$ (1), where X = molecule of solvent.

The two-step reduction processes, namely $E_{pc(1)}$ at +1.1V and $E_{pc(2)}$ at −0.45V in Fig. 1 appear to involve an oxidized species which was produced previously at peak, E_{pa}. This was confirmed in separate experiments in which the range of potential scanning was limited to only ±1.5V. As shown in Fig. 3 (illustrated for solution No. 4) in this potential range the oxidation peak E_{pa} does not appear and neither do the cathodic (reduction) peaks $E_{pc(1)}$ and $E_{pc(2)}$.

(*iii*) Changes in solvents and their mixtures did not alter the curve shape of the cyclic polarogram. In other words, only the dissolved salts, LiCl-$AlCl_3$, participated in the observed redox processes.

(*iv*) In Fig. 2, the polarogram for electrolyte No. 7 with $AlCl_3$ as the only solute, indicates only a single peak, E_{pc} (−0.45V), in the cathodic polarization following the oxidation process at E_{pa} (+1.70V). The redox mechanism would presumably be

Chlorine formation:

$$AlCl_3 \rightleftharpoons \tfrac{1}{2}Cl_2 + AlCl_2^+ + e^- \text{ at } E_{pa} \qquad [2]$$

Chlorine reduction:

$$\left.\begin{aligned} \tfrac{1}{2}Cl_2 &\rightleftharpoons Cl^- - e^- \\ Cl^- + AlCl_2^+ &= AlCl_3 \end{aligned}\right\} \text{ at } E_{pc} \qquad [3]$$

The broad peak at E_{pc} could be explained by mass transfer effects due to the diffusion of dissolved Cl_2 away from the working platinum electrode. This was also the phenomenon observed in Fig. 1 for the second

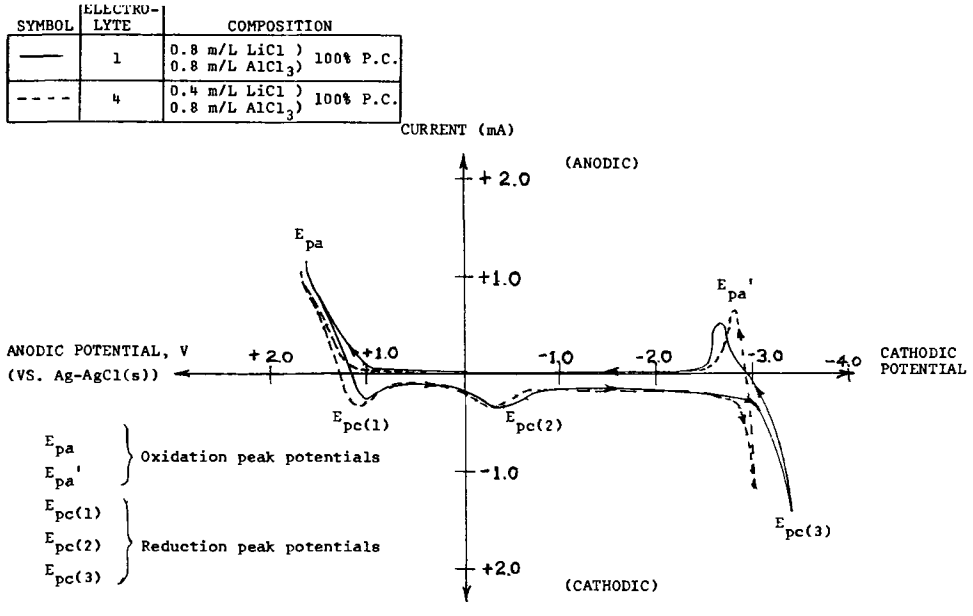

Fig. 1. Cyclic polarograms for electrolytes No. 1 and 4 at platinum electrode. A = 1 cm^2; scan rate = 2 V/min.

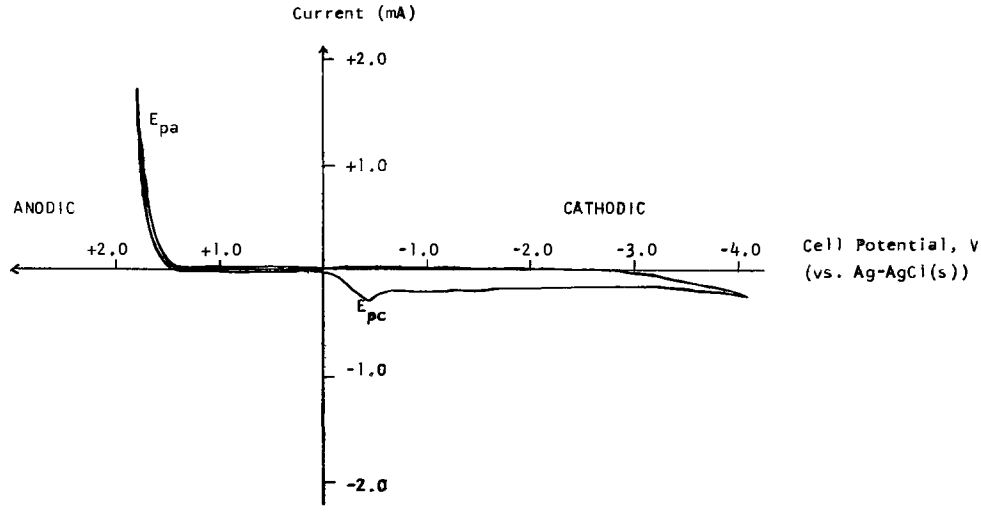

Fig. 2. Cyclic polarogram for the electrolyte No. 7 (no LiCl) at Pt electrode. $A = 1$ cm^2; scan rate = 2 V/min.

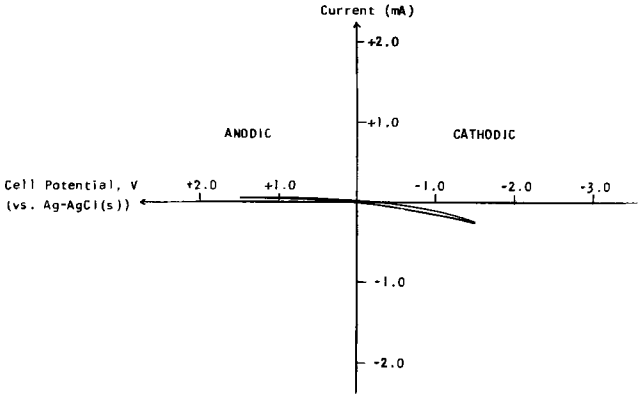

Fig. 3. Control cyclic polarogram for solution No. 4 at Pt electrode in the potential range +1.5 to −1.5V. $A = 1$ cm^2; scan rate = 2 V/min.

reduction peak at $E_{pc(2)}$ at lower scan rates. Figure 2 also points out that cathodic reduction of aluminum ions or its complex ions does not occur even up to potentials of −4V. By comparing results of Fig. 1 and 2, we conclude for solutions containing both LiCl and $AlCl_3$ that the anodic oxidation at E_{pa} (Fig. 1) is most likely due to $AlCl_4^-$, not Cl^-, and that the cathodic reduction of $E_{pc(3)}$, a reversible reaction, is due to Li^+, not Al^{+++} or $(AlCl_2 \cdot 2X)^+$.

(v) Scan rate studies on electrolyte No. 3 (0.8 moles/liter LiCl-$AlCl_3$ in 50% propylene carbonate and 50% nitromethane) shown in Fig. 4 revealed that the peak potentials corresponded to two-step reduction processes (involving the species generated at the same electrode at the previous anodic sweep in which $AlCl_4^- \rightarrow (AlCl_2^+) + Cl_2 + 2e^-$).

The two reduction steps are postulated as

$$(\text{at } E_{pc(1)}) \qquad AlCl_2^+ + e^- \rightleftharpoons (AlCl_2\cdot) \qquad [4]$$

$$(\text{at } E_{pc(2)}) \qquad (AlCl_2\cdot) + Cl_2 + e^- \rightleftharpoons AlCl_4^- \qquad [5]$$

The peak potentials corresponding to each of these two reduction steps were studied as a function of scan rate as shown in Fig. 4.

The apparent number of charge transfers corresponding to $E_{pc(1)}$ and $E_{pc(2)}$ were calculated by the equation for a totally irreversible process (3)

$$[E_{pc(1)}]_2 - [E_{pc(1)}]_1 = \frac{RT}{F} \cdot \frac{1}{\alpha n_1} \ln \left[\frac{v_1}{v_2} \right]^{1/2} \qquad [6]$$

where n_1 is the number of charge transfers, α is the transfer coefficient, and v_1, v_2 are scan rates. It was found that both reducing processes correspond to one charge transfer only.

Scan rate studies also indicated a possible ECE (electrochemical-chemical-electrochemical) mechanism (4-6). The kinetics of this mechanism are

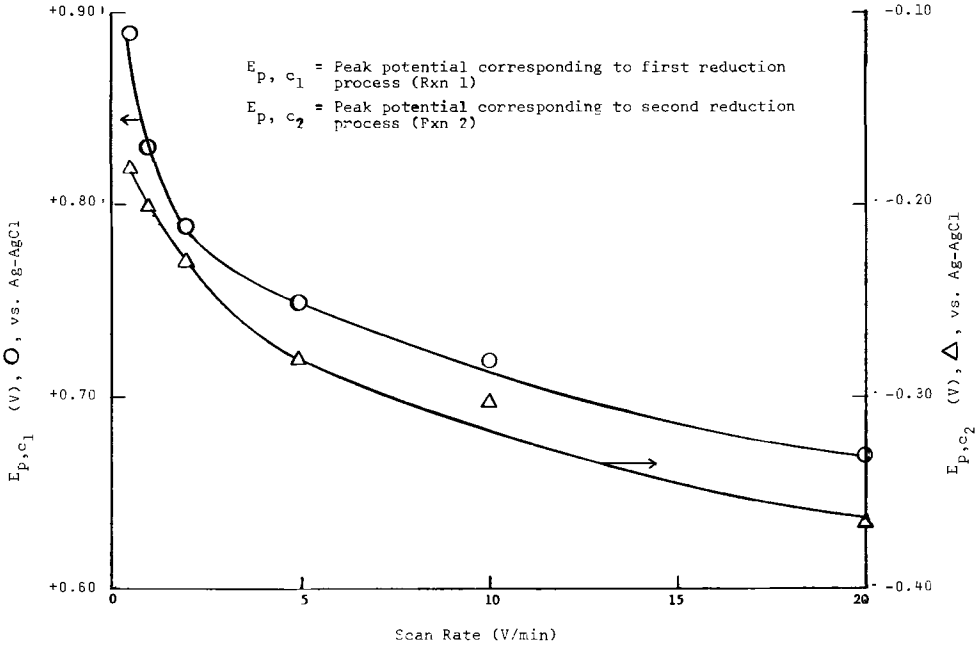

Fig. 4. Reduction peak potentials vs. scan rates for electrolyte No. 3.

$$0 \overset{ne^-}{\rightleftharpoons} R_1 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R' \overset{ne^-}{\rightleftharpoons} R_2 \quad [7]$$

i.e.

$$AlCl_2^+ \overset{e^-}{\rightleftharpoons} (AlCl_2\cdot) + Cl_2 \underset{K_b}{\overset{K_f}{\rightleftharpoons}} (AlCl_4\cdot) \overset{e^-}{\rightleftharpoons} AlCl_4^- \quad [8]$$

since, at lower scan rates, the peak corrsponding to the second reduction, Eq. [5], was significantly broadened. This indicates strongly that the diffusion of chlorine molecules away from the platinum working electrode significantly affects this process as would be expected for the chemical step in Eq. [8].

Conclusions

From the results of these studies, we propose the following as the most likely mechanisms for the redox processes involving aprotic solvent electrolytes containing both $AlCl_3$ and LiCl.

Oxidation: one step reaction

$$AlCl_4^- \rightleftharpoons AlCl_2^+ + Cl_2 + 2e^- \qquad \text{at } E_{pa}$$

Reduction: two step reactions

$$AlCl_2^+ + e^- \rightleftharpoons AlCl_2\cdot \qquad \text{at } E_{pc(1)} \quad [4]$$

and

$$AlCl_2\cdot + Cl_2 + e^- \rightleftharpoons AlCl_4^- \qquad \text{at } E_{pc(2)} \quad [5]$$

ECE mechanism:

$$AlCl_2^+ \overset{e^-}{\rightleftharpoons} AlCl_2\cdot + Cl_2 \underset{k_b}{\overset{k_f}{\rightleftharpoons}} AlCl_4\cdot \overset{e^-}{\rightleftharpoons} AlCl_4^- \quad [8]$$

Optical Evidence Concerning the Discharge of MnO_2 in Acid and Alkaline Electrolytes

Chin-Ho Lee,*[1] Boris Cahan,* and Ernest Yeager*

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

Optical transmission measurements have been made *in situ* on γ-MnO_2 during discharge in acid and alkaline solutions. The γ-MnO_2 was electrodeposited on a conducting tin oxide coated quartz flat. The optical data are compatible with disproportionation in acid media [MnIV $\overset{+e}{\longrightarrow}$ MnIII; 2MnIII $\rightarrow$ MnIV + MnII] and the stepwise reduction in basic media [MnIV $\overset{+e}{\longrightarrow}$ MnIII $\overset{+e}{\longrightarrow}$ MnII].

Yoshizawa and Vosburg (1) propose that the discharge of MnO_2 proceeds through a disproportionation reaction in acid media, *i.e.*

$$\text{MnIV} \overset{+e}{\longrightarrow} \text{MnIII}$$

$$2\text{MnIII} \rightarrow \text{MnIV} + \text{MnII}$$

For alkaline solutions, Kozawa and Yeager (2) have proposed the stepwise discharge mechanism; *i.e.*

$$\text{MnIV} \overset{+e}{\longrightarrow} \text{MnIII} \overset{+e}{\longrightarrow} \text{MnII}$$

According to these mechanisms, MnIV should be present in the oxide until virtually complete discharge in acid media. In alkaline media MnIV should no longer be present after ~50% discharge provided the first reduction step proceeds more readily than the second at the potentials of this electrode under polarization. Optical transmission measurements provide a means for verifying these predictions. The results of such studies are reported herein.

Key words: manganese dioxide, batteries, electrode behavior, optical absorption.

Experimental

Electrolytic γ-MnO_2 has been electrodeposited on a quartz plate which is optically flat and coated[2] with a conductive layer of SnO_2 with a resistance of ~40 ohm/□. Electronic contact was made to the SnO_2 transparent region by means of an insulated gold contact (Fig. 1). This arrangement minimized the nonuniformity of the current distribution arising from *IR* drop in the SnO_2 film. The niobium and gold layers in the opaque region of the electrode mount were laid down by sputtering and vapor deposition, respectively, and subsequently coated with a thin layer of polystyrene as an insulator. The thin niobium layer was required to obtain good adhesion of the gold. The MnO_2 was electrodeposited on the transparent SnO_2 region from 0.5*M* $MnSO_4$ + 0.5*M* H_2SO_4 solution at 90°C for 2 min at an apparent current density of 1 mA/cm^2, yielding a layer of ~0.1μ and of very uniform ap-

[2] The SnO_2 coated optical flats were prepared by Liberty Mirror, a subsidiary of Libby-Owen Ford Glass Company, Brackenridge, Pennsylvania.

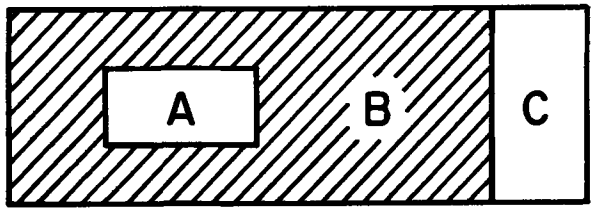

Fig. 1. Transparent electrode arrangement on quartz optical flat. A, transparent region: SnO_2/electrolytic γ-MnO_2, 2 cm^2 area; B, opaque region (insulated from electrolyte): SnO_2/Nb/Au/polystyrene; C, electrical contact area: SnO_2/Nb/Au.

pearance. Gamma-MnO_2 should be formed under these conditions (3).

The optical transmission measurements were carried out in a quartz electrochemical cell. The discharge was under galvanostatic control with a gold counterelectrode and a reference electrode consisting of a small bead of α-HPd, positioned close (1 mm) to the MnO_2 electrode just outside of the optical beam. The electrolytes used for the discharge were 0.1*M* H_2SO_4 + 0.9*M* Na_2SO_4 and 1*M* NaOH, prepared from reagent grade chemicals without further purification. The solutions were saturated with helium (purified with heated copper turnings and molecular sieves) and an atmosphere of helium maintained within the cell to eliminate O_2 from the solution.

The *in situ* optical transmission measurements were made using the tungsten source and monochromator of a Beckman Model DU spectrophotometer (single beam) in which the sample compartment was replaced with an assembly accommodating the electro-optical cell. The output of a 1P28 photomultiplier used as a detector was displayed on an x-y plotter. Some additional not *in situ*, absorption measurements were also carried out with MnO_2 electrodes using the Cary Model 15 spectrophotometer.

The potentials of the MnO_2 electrodes were measured relative to the reference α-HPd electrode with a Keithley electrometer, Model 610B. The optical-electrochemical measurements were made by following the change of the absorbance with charge; *i.e.*, $(1/I)dI/dQ = d\ln(I/I_0)/dQ = -(2.30)dA/dQ$. The first data points for a freshly prepared MnO_2 electrode were obtained by discharging at constant current (25 μA/cm^2) for 10 sec and recording the optical intensity change, followed by reversing the current and recording the change in intensity during 10 sec of charging at the same current. From these, data dA/dA with dQ corresponding to both charging and discharging were determined; both values of dA/dQ were always the same within a few per cent. The electrode was then discharged for a fixed time (4 to 8 min) at a constant current of 25 μA/cm^2 and then allowed to remain under open-circuit conditions until the voltage stabilized. This required typically a few minutes in acid solution and up to 20 min in alkaline solution. The 10 sec discharging and charging procedure was then repeated to obtain dA/dQ. This procedure of continuous discharge followed by evaluation of dA/dQ after voltage stabilization was repeated until the optical and potential measurements indicated complete discharge. The dependence of the absorbance on the state of charge was subsequently calculated by integrating the dA/dQ data.

This procedure minimizes problems of optical instability which might be encountered in continuous recording of the optical intensity with discharge. Furthermore, progressive changes in the electrode other than just the electrochemical reduction (*e.g.*, surface roughening and electrode nonhomogeneity) can seriously interfere with the use of the directly recorded optical intensity *vs.* time or total charge data to calculate dA/dQ. The derivative method used in the present work should be much less subject to this type of error. The values of dA/dQ evaluated by this procedure correspond to those of the electrode after reequilibration and not while on discharge. Thus the integral curves calculated from the derivative data dA/dQ correspond essentially to equilibrium conditions at each state of discharge.

Results

In Fig. 2 and 3 are plotted the open- and closed-circuit potentials, the open-circuit dA/dQ, and the integrated relative absorbance curves, the latter calculated from the dA/dQ data. The open-circuit potentials correspond to equilibrium values at designated states of discharge. The closed-circuit values are those at the end of 4 or 8 min intervals, just before the interruption of the current. In acid media, the potential and optical absorption data rather clearly indicate the

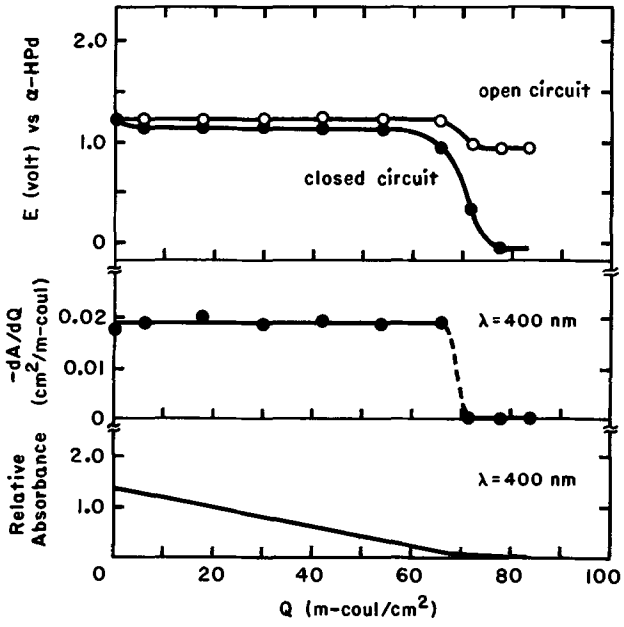

Fig. 2. Galvanostatic discharge of transparent γ-MnO_2 electrode (120 mcoulombs/cm^2, 0.1μ) in helium saturated 0.1*M* H_2SO_4 + 0.9*M* Na_2SO_4 solution at ~25°C. Discharge current density = 25 μA/cm^2.

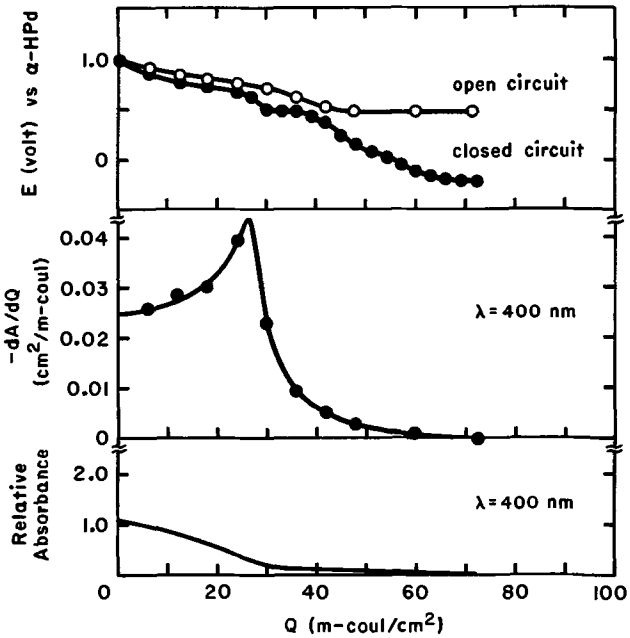

Fig. 3. Galvanostatic discharge of transparent γ-MnO_2 electrode (120 mcoulombs/cm^2, 0.1μ) in helium saturated 1*M* NaOH solution at ~25°C. Discharge current density = 25 μA/cm^2.

discharge to be effectively complete at ~70 mcoulombs/cm^2 as compared with 120 mcoulombs/cm^2 involved in the electrodeposition of the γ-MnO_2. This difference occurs principally because of the physical loss of material from the electrode surface during discharge and to some lesser extent because of coulombic inefficiency during the initial electrodeposition. In alkaline solution, the potential and absorbance data do not as clearly indicate the point of complete discharge but it still is ~70 mcoulombs/cm^2.

The potential curves shown in Fig. 2 and 3 exhibit the same charge dependence as reported by Yoshizawa and Vosburg (1) and Kozawa and Yeager (2). The relatively constant open-circuit potential found for the acid electrolyte has been interpreted by these authors as evidence for a disproportionation reaction involving two phases: an MnIV rich phase and MnII rich phase,

each of relative constant activity with respect to these ions. The more complex potential-charge curves for alkaline solution have been shown by Kozawa and Yeager (2) to be compatible with the stepwise discharge, the first portion of which involves a single solid phase with changing activities of MnIV and MnIII and the second two phases involving MnIII and MnII of relatively constant activities with respect to these ions.

The absorbance *vs.* charge data in Fig. 2 and 3 were measured at $\lambda = 400$ nm. This wavelength was chosen because it corresponds to a maximum value in the visible for dA/dQ. Only relative absorbance values were obtained from the integration of dA/dQ *vs.* Q and the final values of A in the discharge state were arbitrarily taken as zero. The electrodes used in both the acid and alkaline solutions had approximately the same initial thickness and initial apparent optical adsorbance. At the completion of discharge in the alkaline solution, the apparent absorbance of the electrode was still significantly greater than that of the transparent substrate, because of the presence of MnII oxide. In the acid solution all of the MnII entered the solution and the apparent absorbance of the electrode was essentially that of the electrode substrate. The decrease in absorbance is more rapid for the alkaline electrolyte and becomes essentially constant at approximately one-half of the complete discharge, in contrast to the acid electrolyte where the absorbance decreases linearly with discharge until discharge is complete.

The interpretation of the optical-electrochemical data is contingent on the absorption characteristics of MnO_2 and MnIV relative to the lower oxides and MnIII and MnII. The absorption spectrum of the electrolytically formed γ-MnO_2 was determined not *in situ* with the Cary spectrophotometer and is shown in Fig. 4 together with the corresponding spectrum for β-MnO_2 formed on the same SnO_2/quartz substrate by thermal decomposition of concentrated $Mn(NO_3)_2$. Spectral data for MnO_2 is lacking in the literature. Geschwind *et al.* (4), however, have examined the spectra of MnIV in an α-Al_2O_3 matrix (insert in Fig. 4). The Mn-O-Mn and Mn-Mn interactions in the pure oxides would be expected to modify very substantially the spectra compared to that for a dilute MnIV system. Nonetheless, there is some evidence of the absorption peak at ~480 nm in the MnIV-α-Al_2O_3 also in the spectrum for β-MnO_2. The specific absorptivity ($\epsilon = A$/thickness) of the γ-MnO_2 is much higher than that of the β-MnO_2 at $\lambda < 500$ nm, and the absorption edge is displaced to higher wavelengths.

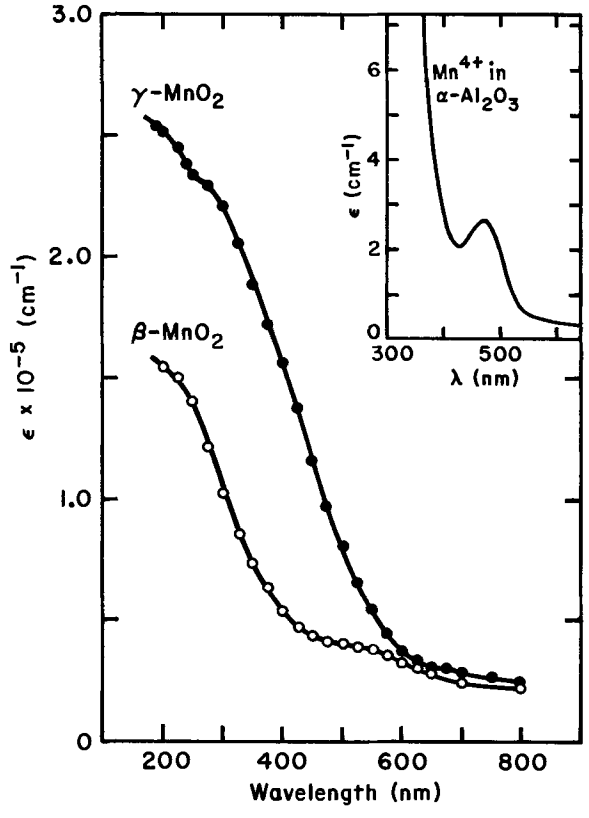

Fig. 4. Optical absorption spectra specific absorptivity of γ- and β-MnO_2 deposited on transparent substrate (present work). Insert figure: Mn^{4+} in α-Al_2O_3 matrix ($Mn^{4+} < 0.08$ w/o) reported by Geschwind *et al.* (4).

The absorption of the MnO_2 is much higher than that of the lower oxide. From Fig. 4, the molar absorptivity a_M based on the concentration in moles/liter of MnIV in the γ-MnO_2 is $a_M = A/bc \cong 10^3$ liter-cm^{-1} mole^{-1} where c is the concentration in moles/liter and b the thickness in centimeters. The concentration of MnIV in the α-Al_2O_3 matrix in the work of Geschwind *et al.* (4) was only known to fall in the range 10^{-3}-10^{-1} weight per cent (w/o). From their spectra, this would correspond to $a_M = 3 \times 10^1$ to 3×10^3 liter-cm^{-1} mole^{-1} at 400 nm. These values are to be compared with $a_M = 20$-100 for MnIII in various solid matrices at $\lambda = 476$-625 nm (5) and $a_M = 10^{-2}$-10^{-1} liter-cm^{-1} mole^{-1} for octahedrally coordinated MnII and 1-10 liter-cm^{-1} mole^{-1} for tetrahedrally coordinated MnII at comparable wavelengths (5). Thus, the decrease in absorbance of the γ-MnO_2 electrodes appears to be virtually entirely a consequence of the decrease in the concentration of MnIV in the electrode.

After discharge in acid solution, some pink color characteristic of Mn^{2+} was evident in the solution. The Mn^{2+} in the solution, however, does not contribute appreciably to the observed changes in adsorbance because of the low molar absorptivity of Mn^{2+} compared to the MnIV of the electrode phase. Loss of Mn^{2+} into the bulk of the solution, does result in the lack of rechargeability in acid solution.

The molar absorptivity, a_M, and hence dA/dQ, is not expected to be constant as the MnIV concentration in a particular oxide phase is reduced because of differences in the various Mn-O-Mn and Mn-Mn interactions involving MnIV and lower valency states. This explains the lack of consistency for dA/dQ in Fig. 3 for the alkaline solution where only one phase is believed to be present until the discharge is approximately one-half complete (2, 3). In acid media, two separate phases of invariant composition are proposed to be present over almost all of the discharge (1) and hence dA/dQ is essentially constant.

On the basis of this interpretation, the optical data for the acid electrolyte indicates the presence of MnIV until the discharge is virtually complete. In alkaline electrolyte, the MnIV is no longer evident after one-half discharge. These observations agree with predictions based on the disproportionation and stepwise reduction mechanisms in acid and alkaline solutions, respectively. They, however, should not be considered as confirming these mechanisms, but rather just as verification of thermodynamic expectation under open-circuit conditions at various states of discharge. In acid solution, the composition of the MnIV containing a solid phase must be constant on the base of the constancy of dA/dQ. Therefore, any appreciable amount of MnIII, if formed, would be expected to be in a separate solid phase. At pH < 3, however, pure Mn_2O_3 is not stable thermodynamically in contact with MnO_2 (6). Consequently, it would be very unlikely to find any significant amount of MnIII in the electrode in contact with acid solution. The reduction, as examined under essentially equilibrium conditions, should then proceed from MnIV to MnII with negligible build-up of MnIII. At pH > 3, Mn_2O_3 is thermodynamically stable in equilibrium with MnO_2 as well as $Mn(OH)_2$. Thus, under open-circuit conditions, MnIII would be expected to exist in the electrode at various stages of discharge. The large variation in dA/dQ during the first half of the discharge argues that the MnIV

and MnIII are probably in the same solid phase in contact with the alkaline solution.

Deposition of Silver on Platinum in Lithium Chloride-Potassium Chloride Eutectic

Wishvender K. Behl*

Power Sources Technical Area, U. S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

Recently, Hills and co-workers (1) reported a study of monolayer formation as well as metal deposition processes for Ni(II) and Ag(I) on platinum electrodes in lithium chloride-potassium chloride eutectic at 400°C using the chronopotentiometric, cyclic voltammetric, and potential step techniques. Cyclic voltammograms for the reduction of Ni(II) at fast scan rates ($\geq$8 V/sec) showed a prepeak corresponding to the monolayer formation at potentials ~0.5V positive to the main cathodic peak. Similarly, on the reverse scans at these scan rates, the main anodic peak due to the dissolution of the deposited nickel metal was followed by a small anodic peak due to the removal of the monolayer. At slow scan rates (<8 V/sec), only one cathodic peak and one anodic peak were observed due to the deposition and dissolution of nickel metal, respectively. The deposition of silver, on the other hand, was complicated by the presence of a prepeak at potentials ~0.1V positive to the main cathodic peak at all scan rates resulting in drawn out voltammograms. Further, on the reverse scans, only one anodic peak due to the dissolution of the deposited silver metal was observed at all scan rates.

The deposition of silver at platinum electrodes in lithium chloride-potassium chloride eutectic at 450°C was also studied in this laboratory employing the technique of cyclic voltammetry. Except for the temperature of 450°C [400°C in case of Hills *et al.* (1)], these studies were carried out at about similar Ag(I) concentrates as well as voltage scan rates. At slow scan rates (<2 V/sec), unlike Hills *et al.* (1), only one cathodic and one anodic peak were observed due to the deposition and dissolution of silver metal, respectively. At fast scan rates (>2 V/sec), a prepeak at potentials ~0.5V positive to the main cathodic peak was observed due to the monolayer formation. The deposition of silver in our studies was found to be similar to the deposition of nickel as reported by Hills and co-workers (1). This note summarizes our results and also examines in detail the applicability of theory of linear sweep voltammetry (2, 3) to the reduction of Ag(I) in lithium chloride-potassium chloride eutectic at 450°C.

Experimental

The cell assembly, the experimental details for the preparation and purification of the lithium chloride-potassium chloride eutectic, and the instrumentation have been described earlier (4). The eutectic solvent was compartmented by use of Pyrex tubes (10 mm diameter) with fritted-glass bottoms. A three-electrode system was used for all measurements. The Pt/Pt(II) system was used as the reference electrode and a graphite rod as the counterelectrode. The indicator electrode consisted of a 0.5 mm diameter platinum wire sealed into a 6 mm diameter Pyrex or soda-lead glass (Corning 0120) tubing so that a 5 mm length of the wire protruded from the seal. The exact length of the exposed wire was measured by optical micrometry. The Pt(II) concentration (0.02M) in the reference compartment and Ag(I) concentration in the indicator compartment were generated by anodic dissolution of high purity platinum foil and silver rod, respectively, at a current density of 2-3 mA/cm^2. The exact metal ion concentration was determined at the end of the experiment by weighing the eutectic in each compartment and was expressed in moles/liter. The density value (5) of 1.648 g/ml at 450°C for the lithium chloride-potassium chloride eutectic was used.

Results and Discussion

Cyclic voltammograms for Ag(I) concentrations of 7.44, 11.90, 14.88, and 18.60 mM were recorded at scan rates of 0.033-100 V/sec. Typical voltammograms for 11.90 mM solutions of Ag(I) at scan rates of 0.05 and 20 V/sec are shown in Fig. 1. The scans were started in the cathodic direction at the working electrode potential of −0.2V *vs.* Pt/Pt(II) reference, and the direction of polarization reversed at the working electrode potential of −1.2V *vs.* Pt/Pt(II) reference. At the end of each scan, the potential of the working electrode was held at −0.2V *vs.* Pt/Pt(II) reference for a few minutes and the solution stirred before taking the next voltammogram.

At scan rates of 0.033-2.0 V/sec, only one cathodic and one anodic peak were observed due to the deposition and dissolution of silver metal, respectively. Hills and co-workers (1) reported a prepeak at potentials ~0.1V positive to the main cathodic peak at similar scan rates and Ag(I) concentrations. In our experiments, no such prepeak was observed at scan rates less than 2V/sec. However, a small prepeak at potentials ~0.5V positive to the main reduction peak was observed at higher scan rates (>2 V/sec). The deposition of silver is thus similar to the deposition of nickel reported by Hills and co-workers (1), and the prepeak

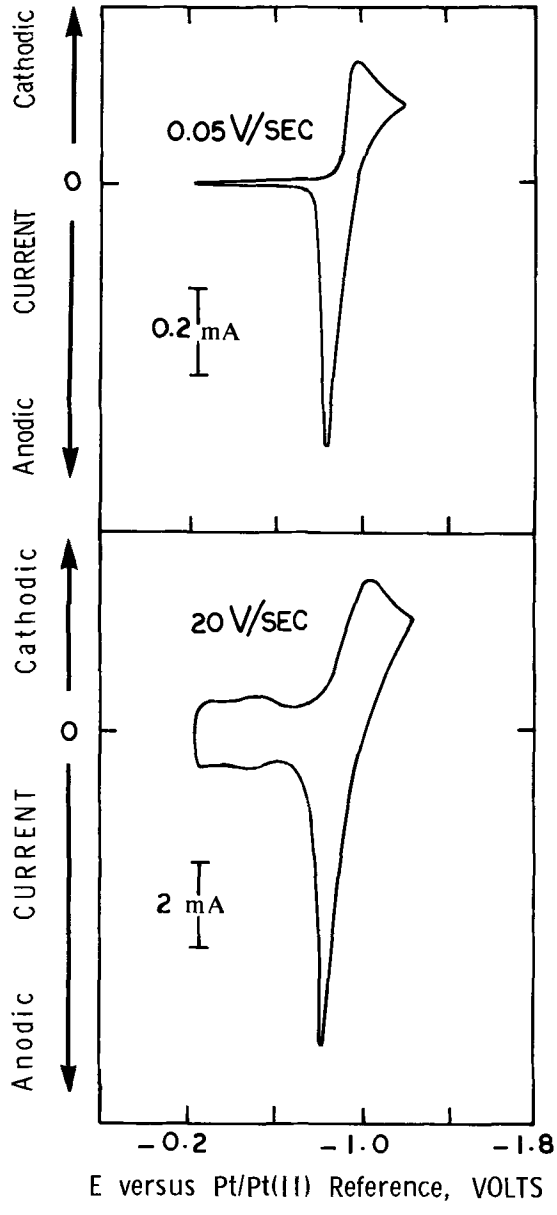

Fig. 1. Cyclic voltammograms for the reduction of 11.9 mM solutions of silver chloride at scan rates of 0.05 and 20 V/sec.

at fast scan rates may be regarded as due to the monolayer formation. Thus, analogous to the behavior of nickel (1), by reversing the direction of polarization after the main reduction peak, the main anodic peak due to the dissolution of deposited silver metal is followed by a small peak due to the removal of the monolayer. No such anodic peak for the removal of the monolayer was observed by Hills *et al.* (1) in the case of silver at all scan rates.

The peak currents for the reversible deposition of an insoluble substance at 450°C are given by the equation (2, 6)

$$i_p = 236n^{3/2}ACV^{1/2}D^{1/2} \qquad [1]$$

where i_p is the peak current (amperes), n is the number of electrons in the charge transfer step, A is the area of the electrode (cm^2), C is the concentration (moles/liter), V is the voltage scan rate (V/sec), and D is the diffusion coefficient (cm^2/sec).

Assuming that the activity of the deposited silver metal remains constant and equal to unity, the peak potential (E_p) (2, 6) and half-peak potential ($E_{p1/2}$) (7) are related to Ag(I) concentration and to each other by the following equations

$$E_p = E^\circ + \frac{RT}{n\mathbf{F}} \ln fC - \frac{0.854\,RT}{n\mathbf{F}} \qquad [2]$$

$$E_{p1/2} = E^\circ + \frac{RT}{n\mathbf{F}} \ln fC - \frac{0.0815\,RT}{n\mathbf{F}} \qquad [3]$$

$$\Delta E = E_p - E_{p1/2} = -\frac{0.7725\,RT}{n\mathbf{F}} \qquad [4]$$

where E° is the standard electrode potential, f is the activity coefficient of silver chloride in solution, and R, T, and $\mathbf{F}$ have their usual thermodynamic significance. Thus, the peak and half-peak potentials (E_p and $E_{p1/2}$) are dependent on Ag(I) concentration and shift to more anodic values as the concentration is increased. The difference between the peak and half-peak potentials (ΔE), on the other hand, is independent of the concentration. For a reversible process, E_p, $E_{p1/2}$, and ΔE are all independent of the voltage scan rate.

The reduction of Ag(I) leads to the deposition of solid silver metal and is thus similar to the deposition of an insoluble substance. The peak currents would, therefore, be given by Eq. [1]. The peak currents were determined by extrapolating the residual part of the voltammograms to the peak potential and measuring the height between this base line and the peak of the voltammograms. As predicted by Eq. [1], the plots of peak currents (i_p) *vs.* the square root of voltage scan rate ($V^{1/2}$) resulted in straight lines passing through the origin (Fig. 2). This linear relation was observed up to a scan rate of 0.5 V/sec. At higher scan rates, the peak currents tended to be lower than those predicted by Eq. [1]. Although Hills *et al.* (1) also observed straight line i_p *vs.* $V^{1/2}$ plots for the reduction of Ag(I), their plots did not pass through the origin.

The anodic dissolution of silver metal is unlikely (1, 8) to be diffusion controlled and thus the anodic current increases until all the deposited metal is stripped. The anodic peak is, therefore, very sharp and the anodic peak height is much greater than the cathodic peak height. However, from an integration of the current under the main cathodic and anodic peaks, it was found that the coulombs of charge deposited during the cathodic process were completely recovered during the anodic process.

The peak and half-peak potentials of Ag(I) reduction voltammograms were measured at all concentrations and scan rates and the data for one concentration are summarized in Table I.

The difference, ΔE, between the peak and half-peak potentials was found to be of the order of 45-50 mV up to a scan rate of 0.5 V/sec as compared to the theoretical value of 48 mV predicted by Eq. [4] for the reversible deposition of an insoluble substance at the electrode surface involving a one-electron change at

450°C. Further, up to a scan rate of 0.5 V/sec, E_p, $E_{p1/2}$, and ΔE were all found to be independent of the voltage scan rate. The peak and half-peak potentials shifted to more positive values with increase in Ag(I) concentration and a plot of $E_{p1/2}$ *vs.* log *C* (Fig. 3) resulted in a straight line with theoretical slope as predicted by Eq. [3]. The plot of $E_{p1/2}$ *vs.* log *C* shown in Fig. 3 was extrapolated to 1M concentration of Ag(I) and the $E_{p1/2}$ value so obtained was substituted in Eq. [3] to obtain the E° value for the Ag(I)-Ag(O) couple *vs.* the 0.02M platinum reference. It was assumed that the activity coefficient of silver chloride remains constant over the concentration range studied and the activity coefficient term in Eq. [3] is included as a constant in the E° value. The E° value so obtained was then converted to 1.0M platinum reference using the Nernst equation. The standard electrode potential, E°, for the Ag(I)-Ag(O) couple was found to be −0.771V *vs.* 1.0M platinum reference and is in fairly good agreement with the value of −0.743V obtained by Laitinen and Liu (9) from the equilibrium emf measurements.

From the results presented above, it can be concluded that the reduction of Ag(I) in molten lithium chloride-potassium chloride eutectic occurs reversibly up to a voltage scan rate of 0.5 V/sec. At higher scan rates, the voltammograms tend to be more drawn out so that the difference between the peak and half-peak potentials is larger than that predicted by Eq. [4]. Also, the peak currents tend to be lower than those predicted by Eq. [1]. At lower scan rates, Eq. [1] can be used to calculate the diffusion coefficient of Ag(I) in this solvent. For this purpose, the $i_p/V^{1/2}$ values were obtained from the linear i_p *vs.* $V^{1/2}$ plots and substituted in Eq. [1] to calculate the peak current constants ($K_p = i_p/V^{1/2}AC$) as well as diffusion coefficients (D) at various Ag(I) concentrations in the eutectic. These results are summarized in Table II. The constancy of the K_p values presented in Table II clearly demonstrates the linear dependence of peak currents on the Ag(I) concentration as predicted by Eq. [1]. The average peak current constant and diffusion coefficient were found to be 1.16($10^3 A$ $sec^{1/2}$ $V^{-1/2}$ cm/mole) and 2.39 × 10^{-5} (cm^2/sec), respectively. The value of the diffusion coefficient obtained in our study is in good agreement with the previously reported values of 2.5 × 10^{-5} (cm^2/sec) at 400°C (1), 2.6 × 10^{-5} (cm^2/sec) (10), and 3.2 × 10^{-5} (cm^2/sec) (11, 12) at 450°C.

Summary and Conclusions

The deposition of silver on platinum in lithium chloride-potassium chloride eutectic was studied at 450°C employing the technique of cyclic voltammetry. It was shown that at low scan rates (0.033-0.5 V/sec), the reduction of Ag(I) occurs reversibly and obeys the equations for the reversible deposition of an insoluble substance. The diffusion coefficient of Ag(I) in lithium chloride-potassium chloride eutectic was determined from the experimental data and found to be 2.39 × 10^{-5} cm^2/sec. At higher scan rates (>2 V/sec), a prepeak due to the monolayer formation was observed at potentials about 0.5V positive to the main reduction peak. On reversing the direction of polarizations after the main cathodic peak at scan rates of >2 V/sec, the sharp anodic peak due to the dissolution of the deposited silver metal was followed by a relatively smaller peak due to the removal of the monolayer. At scan rates below 2 V/sec, no peaks were observed for the formation or removal of the monolayer.

Electrogenerative Bromination

Alan D. Miller and Stanley H. Langer*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

As part of a program to identify and develop techniques for operating feasible electrogenerative processes (1-3), we describe here electrogenerative bromination in which bromine and an olefin are reacted with the aid of suitable electrodes and electrolyte to give dibromoethane and bromohydrin. (We define "electrogenerative processes" as those in which two or more materials react at electrodes so that favorable thermodynamic factors drive the reaction to give a useful chemical product with the generation of by-product electricity.) Bromine is reduced at the cathode to bromide ions which are transported through the electrolyte to the anode where they combine with olefin, while electrons are conducted through an external circuit to the cathode. Bromine vapor in a nitrogen gas stream and the olefin are introduced to cathode and anode chambers, respectively. The chambers are bounded by gas-permeable, liquid-impermeable electrodes separated by a free electrolyte phase. In contrast to earlier work on other electrogenerative systems (1-3), a diaphragm was needed to separate catholyte and anolyte. This limited the transport of free bromine, probably as Br_3^- and Br_5^- (4-6), which would give some direct chemical halogenation of olefin at the anode. Both electrodes operate at positive potentials relative to the standard hydrogen electrode. The rate of bromination and the potential of the cell are controlled by the electrical resistance of the external circuit.

Electrode reactions, based on product analyses, with bromide electrolyte appear to be

Cathode

$$Br_2 + 2e^- \rightarrow 2Br^- \qquad [1]$$

Anode

$$RCH{=}CHR' + 2Br^- \rightarrow \underset{\displaystyle Br}{\overset{\displaystyle |}{RCH}}\!\!-\!\!\underset{\displaystyle Br}{\overset{\displaystyle |}{CHR'}} + 2e^- \qquad [2]$$

or

$$RCH{=}CHR' + 2Br^- + H_2O \rightarrow \underset{\displaystyle Br}{\overset{\displaystyle |}{RCH}}\!\!-\!\!\underset{\displaystyle OH}{\overset{\displaystyle |}{CHR'}} + HBr + 2e^- \qquad [3]$$

No significant amount of glycol is formed in the electrolyte. Electrogenerative bromination requires no external power source.

Furthermore, we have also used chlorine gas instead of bromine vapor at the cathode where reaction is

$$Cl_2 + 2e^- \rightarrow 2Cl^- \qquad [4]$$

accompanied by

$$Cl_{2(aqueous)} + 2Br^- \rightarrow Br_{2(aqueous)} + 2Cl^- \qquad [5]$$

and

$$Br_{2(aqueous)} + 2e^- \rightarrow 2Br^- \qquad [6]$$

Chlorine gas sometimes can be used advantageously at the cathode because of ease of handling and convenience.

Experimental

A free electrolyte cell similar to that of Landi *et al.* (7) was used for all runs. It typically can be represented as

$$\underset{\text{Anode}}{\text{Olefin} \mid Br^-(aq.) \mid \text{Membrane} \mid Br^-(aq.) \mid Br_2}_{\text{Cathode}}$$

where the total free electrolyte chamber thickness varied from 0.25-0.5 in. The cell was constructed so that only the anode, Kel-F, and Teflon came in contact with the olefin. The free electrolyte chamber could be subdivided with diaphragms into two or three compartments. Kel-F inserts were used in the electrolyte chamber to thicken it and were sometimes fitted with inlet and outlet ports to permit electrolyte flow during operation.

The electrodes used were gas-permeable, liquid-impermeable commercial American Cyanamid Type LAA-1 (7). They have a platinum black loading of 9 mg/cm^2 on a 50 mesh tantalum screen and are wet proofed with Teflon. In later experiments, carbon-tetrafluoroethylene film electrodes (8), American Cyanamid LSE, were used on the halogen side of the cell. These electrodes were 95% graphitic carbon, 0.02 in. in thickness, had 45% porosity, and were supported on an open tantalum screen. All electrodes had an exposed area of 5.1 cm^2.

The electrolyte used in this study was generally 2 or occasionally 3M aqueous potassium bromide. A cell with electrolyte chamber ¼ in. thick and 2M KBr had an internal resistance of about 0.7 ohm in our cell configuration without a separator.

Diaphragms when used were either an AMFion Product anion with ion exchanger A60 (American Machine and Foundry Company) or an American Cyanamid TA-1 etched polytetrafluoroethylene flock. The former added considerably to cell resistance. For instance, a ¼ in. cell with 2M KBr electrolyte and membrane had a cell resistance of about 4 ohms. The (American Cyanamid) TA-1 membrane consisted of 95% polytetrafluoroethylene, 5% carbon. It is 0.63 mm in thickness and has an 80% porosity when wet with most pores having a diameter of 10 μm or less. A ¼ in. free electrolyte cell with 2M KBr electrolyte and a single TA-1 membrane gave an internal resistance of about 1.3 ohm. The A60 AMF ion exchange membrane was used as a separator, together with 3M KBr electrolyte, when electrode potentials were measured to minimize interference of molecular bromine or complexed bromide at the anode. This scheme is not desirable for ordinary cell polarization work because of the high internal resistance of the cell.

Cells were operated with continuous flow of reactive gases through anode and cathode compartments. Product analysis was by gas chromatography. Off gas from the anode compartment during operation at steady state was injected and the coulometric yield of 1,2 dibromoalkane was calculated from the chromatogram. The bromohydrin formed remained in the cell electrolyte because of its solubility in this aqueous phase. To close the material balance, a sample of electrolyte was converted to trimethylsilyl ethers and hexamethyldisiloxane (from water) with hexamethyldisilazane (9, 10). Conversion was effected by the refluxing of a 0.3 cm^3 sample of electrolyte with 5 cm^3 (50% excess) of hexamethyldisilazane for 13 hr. The reaction mixture was protected from the atmosphere with a drying tube attached to the reflux condenser. Ammonium salt that formed sublimed into the condenser. Acid is formed in the cell electrolyte during operation. When knowns for comparison were converted, a catalytic amount of acid, a few cubic centimeters of HCl vapor, was added to the reaction mixture.

The converted mixture was analyzed by means of gas chromatography (on silicone d.c. 550; chromosorb, W) to determine the yield of bromohydrin. Because electrolyte sometimes contained complexed bromine, it

* Electrochemical Society Active Member.

Key words: platinum electrodes, polarization, dibromoethane, bromohydrin.

was allowed to stand overnight to release this bromine before analysis was attempted. Closures of the material balance of 90% or generally better were obtained. This balance is important because it permits comparison of total product formed with coulombs generated by the electrogenerative cell. This permits identification of chemical reaction and of transport of molecular bromine from cathode to anode, probably complexed with bromide ion (4-6). Under conditions where bromine could be transported as a complex with bromide ion (in the absence of a diaphragm), product analyses indicated that such transport resulted in formation of dibromoethane.

Potentials of individual electrodes were measured on an operating ethylene-bromine cell with LAA-1 electrodes by referring the anode to a mercurous bromide (11, 12) electrode with a Luggin capillary. Other experimental details are given in our earlier description of electrogenerative chlorination (3).

Results and Discussion

Bromine-ethylene cells were operated with both an LAA-1 platinum electrode and an LSE carbon electrode at the cathode. The anode was always a platinum black electrode. When electrode potential measurements were made on an operating cell, the open-circuit potential for the cell was *ca.* 0.6V. This potential is reproducible with new cells but apparently is affected by the formation of Br_3^- ions and is not attained again after some operation of the cell. The bromine electrode was operated with nitrogen-saturated bromine (vapor pressure about 200 mm at 24°C). The potential of the bromine-bromide electrode under our operating conditions was 1.04V, in good agreement (within 0.002V) after conversion to standard-state conditions with the standard potential of 1.065V. The olefin electrode had a potential of 0.45-47V relative to the standard hydrogen electrode based on a mercury-mercurous bromide standard potential of 0.139V (11, 12).

The polarization curve for an ethylene-bromine cell with 2M KBr free electrolyte (5/16 in. thick) and a TA-1 membrane separator is shown in Fig. 1. This cell used an LSE carbon electrode as the cathode. An LSE carbon electrode was also operated as a bromide electrode with varying current, referenced to a mercurous bromide electrode, in a concentration cell arrangement

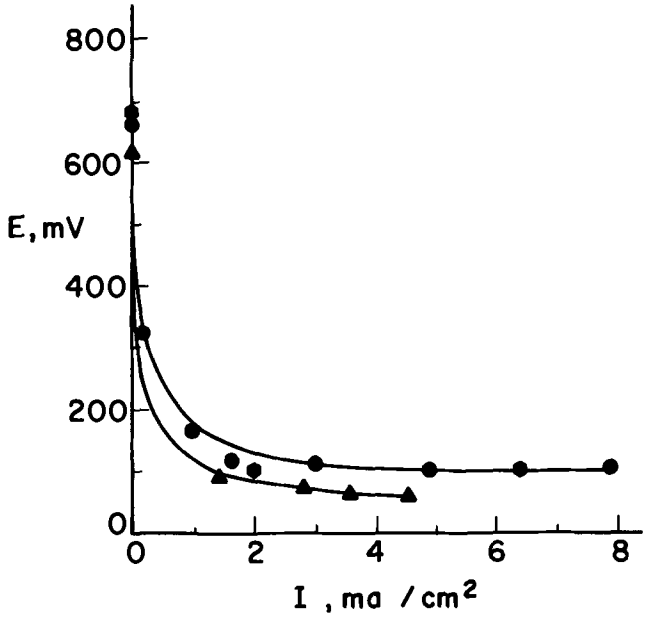

Fig. 1. Current density-cell voltage, E, curves (*IR* corrected), LAA-1 (platinum black) anodes, LSE (carbon) cathodes, TA-1 diaphram; 2M KBr aqueous electrolyte. ●, C_2H_4/KBr(2M)//KBr (2M)/Cl_2; ▲, C_2H_4/KBr(2M)//KBr (2M)/Br_2; ⬢, C_3H_6/KBr(2M)// KBr (2M)/Cl_2.

with an LAA-1 platinum counterelectrode and 2M KBr electrolyte. The carbon-bromine electrode showed polarization of less than 0.01V at currents up to 15 mA/cm². Considering this study, as well as results from the cell with LAA-1 electrodes, it is apparent that practically all polarization occurs at the anode or ethylene electrode.

Because of the ease of handling chlorine at room temperature and the fact that it is commercially significantly less expensive than bromine, we tested cells that incorporated a chlorine cathode, a 2M potassium bromide electrolyte, a separator, and an ethylene anode. These cells generally were operated either with flow or for a short enough period so that chloride ion was not discharged. The polarization curve for such a static cell run for a period of time of less than 1 hr is included in Fig. 1. The change in cell operating potential essentially is due to a shift in potential at the cathode. Under our conditions the cathode operated at a potential range of 1.09-1.11V relative to a standard hydrogen electrode. This potential rises with time toward the chlorine-chloride electrode potential, of course.

With the use of flowing electrolyte cells, it was possible to study, over a limited range, the effect of potential on reaction at the anode. In the potential region of 0.8-1.05V at the anode, and current densities of 0.2-10 mA/cm², dibromoethane was found to represent 20 ± 2% of the electrogenerated current. Both two-compartment and three-compartment cells were used in flow experiments which involved sweeping the center or cathode compartment with electrolyte so that the 2M KBr electrolyte was changed every 15 min. The remainder of the generated current resulted in the formation of ethylene bromohydrin. This was ascertained by collection of the electrolyte from a static cell run for a period of time less than 1 hr. Under these conditions, only bromohydrin was found in the electrolyte (*i.e.*, no chlorohydrin or glycol was detected), suggesting that the reaction proceeds through a $BrCH_2CH_{2Adsorbed}$ species.

With a mixed chloride-bromide electrolyte, dibromo-, bromo-chloro-, and some small amount of dichloro-compounds (after periods of operation greater than 2 hr) were observed in the off gas. The relative amounts of chloro-compounds could be controlled to some degree by variation of the ratio of chloride to bromide in the electrolyte. Under these conditions, as might be expected from the ethylene electrode operating potential, bromo-compounds tend to predominate. For instance, in a crude experiment with 1M KBr-1M KCl electrolyte, dihaloalkanes were separated in the ratio dibromoethane-2, chlorobromoethane-1, at a potential of 0.3V and 2 mA/cm².

Polarization data for a propylene-chlorine cell with 2M potassium bromide electrolyte and a TA-1 membrane are also represented in Fig. 1. This cell was somewhat more difficult to study because of the relatively low vapor pressure of dibromopropane. In order to insure vaporization of this compound, the propylene flow rate through the anode compartment was increased to the point where only 2% conversion took place. At 0.91V *vs.* S.H.E. and 10 mA/cm², 21% of the calculated amount of dibromopropane was recovered based on generated current. Within the accuracy of our material balance, the remaining corrected propylene apparently formed propylene bromohydrin. Some propylene glycol, of the order of 5%, was detected but this appears to stem from chemical hydrolysis of propylene bromohydrins during conversion to trimethylsilyl ethers; we found this glycol at the same concentration when analyzing a known commercial sample of propylene bromohydrin.

We are continuing work in this area with the objective of controlling the reaction product at the anode. Nevertheless, the high yield and facile formation of bromohydrin (of the order of 80%) is of interest since these materials are prospective intermediates for formation of olefin oxides (13). The selective formation of

alkyl bromides relative to chlorides suggests potential utilization of electrode reactions similar to those reported here as a means of selectively recovering bromide ion from mixed salts.

The Thermal Decomposition of Potassium Oxalate in Fused Nitrates

A. G. Keenan and Carlos G. Fernandez

Department of Chemistry, University of Miami, Coral Gables, Florida 33124

Electrochemical studies of oxide ion and of various oxide electrodes in fused salts have been of considerable interest for some time. Numerous methods for adding oxide ion to nitrate melts have appeared in the literature (1-3). Swofford and McCormick (4, 5) recommend potassium oxalate because of the purity and ease of weighing the chemical. In sodium potassium nitrate eutectic above 280° they give, for the decomposition, the equation

$$C_2O_4^{2-} \rightarrow CO_2 + CO + O^{2-} \quad [1]$$

Other workers (6-8), however, have given quite a different equation for the reaction, namely

$$C_2O_4^{2-} + NO_3^- \rightarrow CO_3^{2-} + CO_2 + NO_2^- \quad [2]$$

Carbonate ion is a product instead of oxide, and a second electroactive species, nitrite, is produced in addition.

A careful examination of the above references shows that in no case was an unequivocal quantitative confirmation of the respective stoichiometries carried out despite statements implying the contrary.

In the course of continuing our previous electrochemical studies in nitrate melts (9-11), we have now shown that reaction [2] is the correct one in potassium nitrate at 350°C. This stoichiometry is maintained for reaction times varying from 1 to 12 hr.

Experimental

All chemicals used were reagent grade and were oven-dried at 110°C at least 24 hr before being used. KNO_3 was vacuum-dried at 130° for 24 hr and then kept in oven at 110° until needed.

Carbonate determination.—To a test tube containing 5g KNO_3, which had been kept molten for 12 hr at 350°, a weighed pellet of $K_2C_2O_4$ was added and allowed to react for various times. The melt was then frozen, dissolved in boiled distilled water, and titrated with standard HCl, using phenolphthalein and methyl red as indicators.

The typical weak-base titration curve obtained with two distinct end points leaves no doubt that carbonate was the base present. The volume of titrant required for neutralization to the first end point was identical within experimental error to the volume from the first to the second end points. This shows that the only base was carbonate. In a series of four replicate experiments the mole ratio of carbonate obtained to oxalate added was 1:1 within 0.2%.

Nitrite determination.—A stock solution of $K_2C_2O_4$ in molten KNO_3 was prepared. After different reaction times, a sample was withdrawn, frozen, weighed, and dissolved in 50 ml of distilled water. This solution was then analyzed for nitrite, using the method of Wetters and Uglum (12). This consists of the determination of the absorbance of a solution of nitrite and nitrate at 355 nm. At this wavelength nitrate does not interfere with the nitrite absorbance. The molar absorptivity of nitrite is 23.3. A Cary Model 17 spectrometer was used.

Again, in a series of five replicate experiments, it was found that 1 mole of nitrite was produced per mole of oxalate added. The error of the analysis was shown to be about 3% using known mixtures of nitrite and nitrate.

Carbon dioxide determination.—KNO_3 melts containing known amounts of oxalate were allowed to decompose in an evacuated apparatus and the gas produced was expanded into a 10 cm *IR* cell. Qualitative analysis with a Beckman IR 10 spectrometer showed a strong CO_2 peak but no trace of CO. For a more sensitive test, samples of the gas were also run on a Consolidated Electrodynamics Corporation Type 21-103C mass spectrometer.

No trace of CO was found within the sensitivity of the spectrometer which is about 0.1%.

Carbon dioxide was determined quantitatively by expanding the product gas into a volumetric apparatus and measuring the temperature and pressure. Using standard gas laws, the 1:1 stoichiometry was checked within the experimental accuracy of about 8%.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 119, No. 7, 8, and 12; July, August, and December 1972; Vol. 120, No. 2 and 6; February and June 1973.

Corrosion Kinetics of Iron in Acid Sulfate Solutions. Effects of Impurities in the Metal

S. Barnartt (pp. 812-817, Vol. 119, No. 7)

W. J. Lorenz and A. A. El Miligy:[1] In the paper under discussion, Barnartt's investigations using nonsteady-state galvanostatic pulse measurements in the case of the anodic dissolution of pure zone refined iron and iron containing impurities are important, because they deal with the problem of superpolarization. It is well known that pure iron, with a low density of crystal imperfections, dissolves in oxygen-free acid solutions containing no surface active substances in accordance with the noncatalyzed (Bockris-) mechanism as described in the literature.[2,3] The appearance of anodic superpolarization in such a case of consecutive reaction mechanism was explained by (*i*) the diffusion of protons into the bulk of the solutions, which protons are formed in the first step of the noncatalyzed mechanism, which has a relatively high exchange current density;[4] (*ii*) the time-dependent formation of an intermediate in the case of a consecutive charge transfer-mechanism;[3,5-9] and (*iii*) crystallization steps, *e.g.*, formation of negative nuclei, kinks, or adatoms and the surface diffusion of adatoms.[10,11]

However, our investigations[12] using rotating-disk electrodes showed that the first explanation cannot be taken into consideration. Heusler arrived also to the same conclusion.[13] Also, the second possibility is not valid in the case of pure iron dissolution. We have found that the appearance of a steady-state anodic Tafel slope of $b_+ = +40$ mV implies that $i_{0,1} >> i_{0,2}$. Following the theory of the consecutive charge-transfer mechanism, anodic superpolarization cannot occur below a certain critical overpotential value.[3,5-9] This would contradict experimental results. Therefore the last explanation is the most probable one.

We think it is necessary to make some remarks regarding Barnartt's results as well as his conclusions in the paper being discussed.

(*i*) The considerable increase of the corrosion potential and the corrosion current density during the first 20 hr was not confirmed by our investigations in the systems of pure iron (various types)/H_2SO_4 or $HClO_4$. The steady-state corrosion current density agrees, however, with the reported data for pure iron. Therefore, it is possible that the pretreatment of the electrode in Barnartt's investigation produces some surface coverages with oxygen and/or anions.

(*ii*) Barnartt states that the superpolarization value $\Delta\epsilon_m$ is always greater than that corresponding to the open-circuit value $\Delta\epsilon_{oc}$. We have studied systematically the anodic superpolarization and open-circuit phenomena on iron in relation to pulse duration and pulse height. From this it has been found that Barnartt's statement is right for his applied pulse durations and current densities. However, Fig. 1 shows that the inverse relationship occurs for shorter pulse durations. These values were measured in the system pure ommet-iron (total impurities $\leq$ 300 ppm)/0.5M H_2SO_4 at 298°K using a multichannel pulse galvanostat (MEGA-PHYSIK, Rastatt, Germany) with a rise time of 10^{-7} sec. The charging of the double layer was completed and the maximum superpolarization value was reached in a time which is always smaller than the first point in each $\Delta\epsilon_{oc}$ curve of Fig. 1. The ohmic drop was always separately eliminated in these measurements.

(*iii*) The time necessary for reaching the maximum superpolarization value decreases with increasing pulse height. Whereas in the case of the open-circuit measurements, the time necessary to reach the minimum potential is longer and practically independent of the pulse height and pulse duration, *i.e.*, 50 ± 20 msec. An example is given in Fig. 2. The difference between this minimum potential and the steady-state corrosion potential increases with increasing pulse height and pulse duration. The slow attainment of the corrosion potential will be mainly due to surface diffusion processes of adatoms and diffusion of Fe^{2+} ions into the bulk of the electrolyte.

(*iv*) Barnartt's anodic Tafel slopes of $b_+ = +65 \ldots +69$ mV obtained from open-circuit measurements are

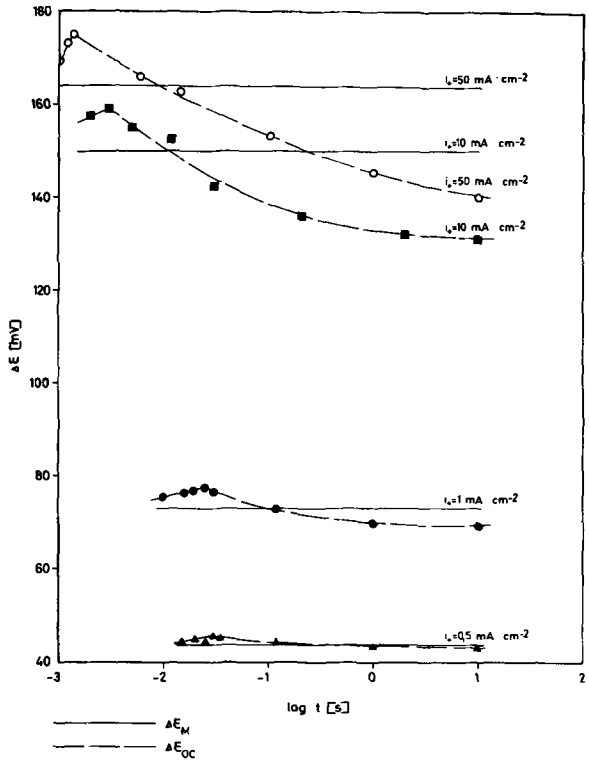

Fig. 1. Potential values of superpolarization maximum, $\Delta\epsilon_M$, and open-circuit minimum, $\Delta\epsilon_{OC}$, as a function of galvanostatic pulse height and pulse duration. System: Fe/0.5M H_2SO_4; $T = 298°K$.

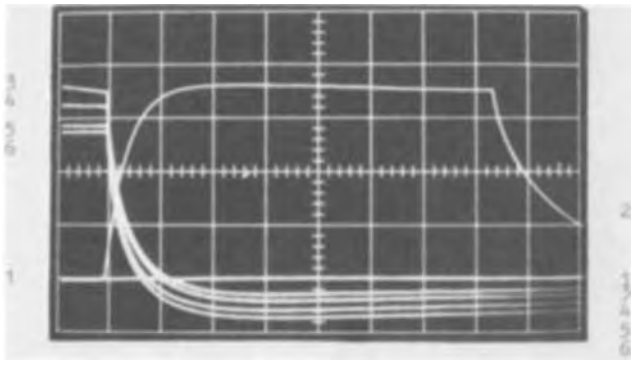

Fig. 2. Potential time dependence for galvanostatic pulse measurements with a pulse height of $i_+ = 1$ mA/cm^{-2} and various pulse durations. System: Fe/0.5M H_2SO_4; $T = 298°K$. 1, Steady-state corrosion potential ϵ_{corr}; 2, determination of $\Delta\epsilon_M$, $t = 37$ msec, ordinate is 20 mV/cm^{-1}, abscissa is 5 msec/cm^{-1}; 3, $t = 30$ msec, ordinate is 20 mV/cm^{-1}, abscissa is 20 msec/cm^{-1}; 4, $t = 120$ msec, ordinate and abscissa as in 3; 5, $t = 1020$ msec, ordinate and abscissa as in 3; 6, $t = 10{,}020$ msec, ordinate and abscissa as in 3.

typical of nonsteady-state values, which agrees with earlier results based on $\Delta\epsilon_m$ values.[2] This is due to relatively small variations between $\Delta\epsilon_m$ and $\Delta\epsilon_{oc}$ in the range of applied current density and pulse duration. If the pulse height and the pulse duration are relatively high, Fig. 1 shows that these variations would increase. In this case

$$b_{+,\,\text{steady-state}} < b_{+,\,\Delta\epsilon_{oc}} < b_{+,\,\Delta\epsilon_m}$$

However, in the case of shorter pulse durations the following sequence results

$$b_{+,\,\text{steady-state}} < b_{+,\,\Delta\epsilon_m} < b_{+,\,\Delta\epsilon_{oc}}$$

Therefore one must be careful in interpretations of results only based on galvanostatic, open-circuit measurements.

(*v*) The open-circuit technique and the interpretation of $\Delta\epsilon_{oc}$ implies that the reference state is of certain surface activity which corresponds to the charging conditions. Consequently for different charging conditions the reference point varies. Usually the surface activity of a metal electrode at the corrosion potential in the steady state is taken as the reference point. Under this condition the nonsteady-state $\Delta\epsilon_m$ values are related to a nearly constant reference point.

(*vi*) The roughness of the electrode surface is another factor which influences the reference state and the interpretation of the $\Delta\epsilon_{oc}$ values. Capacity measurement with rapidly galvanostatic pulses in the microsecond range can be used as an indication of the roughness of the electrode surface before and after anodic polarization at a certain potential. This has been carried out at the steady-state corrosion potential and after anodic polarization in the minimum potential value of the open-circuit measurement, whereby the pulse height and its duration were varied. The results show an increase of about 10-15%, *e.g.*, from 35 up to 40 μF/cm^{-2}. In other words, the electrode surface in the two mentioned states is not the same, but the differences are not very high. On the other hand, during anodic polarization the electrode capacity increases due to its dependence on the electrode potential.[14,15]

The conclusions from these remarks are that definite interpretations of $\Delta\epsilon_{oc}$ measurements are difficult as long as quantitative explanation of the observed superpolarization phenomena based on crystallization processes does not exist.

S. Barnartt: Studies of anodic pulses at relatively high current densities, such as the data in Fig. 1 of Lorenz and El Miligy's discussion above, are very helpful. Further studies at high current densities are necessary before a mechanistic interpretation of superpolarization, of the maximum potential change $\Delta\epsilon_m$, and of apparent steady-state potentials can be established.

In the paper under discussion a constant $\Delta\epsilon_{oc}$, independent of pulse length, was obtained up to $\Delta\epsilon_{oc} = 60$ mV. I observed also that at higher potentials $\Delta\epsilon_{oc}$ decreased with increasing pulse time, in agreement with Fig. 1 above of Lorenz and El Miligy. An important feature of such high current density pulses is that the corrosion potential ϵ^* drifts markedly with succeeding pulses, so that an anodic Tafel line corresponding to a fixed surface activity is unattainable.

Good agreement between $\Delta\epsilon_{oc}$ and $\Delta\epsilon_m$, as shown by Lorenz and El Miligy in the above discussion at $\Delta\epsilon \simeq 45$ mV, was found in my work only in the case of Ferrovac E iron, Fig. 2 of the paper under discussion. High-purity iron showed much poorer agreement at all times. It should be emphasized that $\Delta\epsilon_m$ cannot be a true measure of charge-transfer polarization, for $\Delta\epsilon_m$ data do not give consistent Tafel slopes when analyzed by the three-point method, a method which may be used as a stringent test for charge-transfer controlled corrosion.

I agree with Lorenz and El Miligy that the electrode pretreatment used possibly produced oxygen and/or anions tightly bound to the iron surface. The gradual increase in corrosion current density is probably caused primarily by removal of such surface films, and only secondarily by dissolution of the metal to produce a faceted surface of greater area. This view was supported by experiments in which the iron was corroded to a faceted surface and the specimen was removed; the original acid pretreatment was then repeated and the specimen replaced in the cell: the second corrosion period yielded essentially the same slow rise in i^* as was found in the first corrosion period.

Electrochemical Reactions with Consecutive Charge-Transfer Steps: Steady-State and Time-Dependent Behavior under Charge-Transfer and Diffusion Control

K. J. Bachmann (pp. 1021-1027, Vol. 119, No. 8)

V. V. Losev:[16] If an electrode process with consecutive charge-transfer steps is accompanied by formation of appreciable concentrations of low-valency intermediates, then the diffusion rate of these intermediates cannot be neglected in comparison with the rate of their further electrochemical reactions, and the elucidation of the mechanism and derivation of kinetic parameters on the basis of steady-state current density potential curves becomes a complicated problem. This conclusion has been clearly demonstrated in the paper under discussion. Bachmann has shown in his paper that at comparable values of the limiting current of intermediate diffusion and of the smaller exchange current even at intermediate concentrations, which are 2-3 orders of magnitude lower than the concentrations of initial substance and final product, the effect of intermediate diffusion should give rise to a noticeable distortion of the slopes of Tafel lines. In spite of this difficulty there exists, in our opinion, even under such conditions, some possibility of using steady-state curdent density potential curves for the elucidation of the mechanism and derivation of kinetic parameters of stepwise electrode processes.

First of all it should be noted that in the presence of appreciable intermediate concentrations a steady state can be realized under different conditions. Bachmann, in the paper under discussion, has derived the equation of the steady-state current density potential curve under the usual conditions; upon polarization, the concentrations of all reacting species at the electrode surface (including intermediates) differ from their equilibrium values existing prior to the flow of an external current, whereas in the bulk of the solution the initial equilibrium concentrations are maintained. This condition can be easily realized, particularly in the case of electrodes with a small ratio of electrode surface, S, to the cell volume, V (disk electrode, dropping mercury electrode), when the change of intermediate concentration in the bulk of the solution during the polarization measurements (*e.g.*, their accumulation under anodic polarization at $i_{01} > i_{02}$) is negligible.

But one can assume also a different steady-state condition, namely, that at any polarization, the bulk concentration of intermediates practically coincides with their concentration at the interface (as shown below this assumption can be easily realized under certain experimental conditions). Under such steady-state conditions, even at an appreciable intermediate concentration, the rate of their diffusion from the electrode (for the case mentioned above) should be negligible as compared with the rate of their further electrochemical oxidation on the electrode. Then the steady-state condition mentioned in Bachmann's paper

$$i_\nu = i_{\nu+1} \qquad [1]$$

will be satisfied and the results of polarization measurements can be described by the usual equation of the steady-state polarization curve for a stepwise process derived by Vetter. Of course, upon changing to a new polarization value during the measurement of a current density potential curve, when the new intermediate concentration at the interface is rapidly reached, and while their bulk concentration still corresponds to the previous value of polarization, a considerable gradient of intermediate concentrations arises between the interface and the bulk of the solution. But as the intermediates are accumulated in the bulk of the solution, this gradient will gradually decrease, and therefore the diffusion rate of intermediates from the electrode will decrease as well until the above-mentioned steady state is practically reached and the condition of Eq. [1] is satisfied. By choosing appropriate experimental conditions (a large ratio S/V) one can reach the steady state during a reasonable time interval.[17-19]

Finally, the steady state can also set in when the intermediate concentration in the bulk of the solution practically remains always equal to zero.[17] It is necessary to use such a steady-state condition, *e.g.*, in the important case where the intermediates are unstable and enter into a chemical reaction.

If the steady-state current density potential curve is obtained under conditions where an appreciable gradient of intermediate concentration exists, and their diffusion rate from the electrode is comparable with the rate of their further oxidation on the electrode (in the case of anodic polarization and $i_{01} > i_{02}$), then the results of polarization measurements can be corrected as follows: from the over-all current there can be singled out the fraction corresponding to the formation of such intermediate particles which do not enter into subsequent electrochemical reactions but diffuse into the bulk of the solution. The remaining current is distributed in equal parts between all electrochemical steps which makes it possible to apply Eq. [1] to this remaining current.[21] An equation of the current density potential curve including such a correction and expressed in terms of the experimental measurable value of effective valency, n_i,[23] enables us to use the results of polarization measurements for the elucidation of the mechanism and derivation of kinetic parameters of stepwise electrode processes.[21] This equation is applicable in the case of diffusion transport of intermediates between the interface and the bulk of the solution, as considered in the paper under discussion, as well as in the more general case when the intermediates are unstable and enter also into chemical reactions, *e.g.*, are partly oxidized to the stable final product by solution components.[21]

K. J. Bachmann: In Vetter's papers[28,29] concerning the steady-state current density overvoltage characteristics for the case of electrochemical reactions involving two consecutive charge-transfer steps, the assumption was made that at equilibrium, the concentration of the intermediate reaction product is small compared to the concentrations of both the most reduced and the most oxidized substance entering into the electrode reaction. When a current is passed through such an electrode, the concentration of the intermediate substance is assumed to remain small so that its diffusion flux from the interface into the bulk of the solution or

[19] The described steady-state condition has been briefly mentioned in a footnote to our paper[20] to which Bachmann refers in the paper under discussion. Apparently because of some misunderstanding, Bachmann attributes to us the statement that "the continuity condition $i_\nu = i_{\nu+1}$ is always satisfied even at high concentrations of the intermediate products." Meanwhile, as it follows explicitly from the said footnote to the paper,[20] as well as from our subsequent papers,[17,18,21,22] we stated that the condition of Eq. [1] is satisfied not always but only when, due to the gradual intermediate accumulation (*e.g.*, during anodic polarization at a constant potential), their bulk concentration becomes practically equal to their concentration at the electrode surface and hence their diffusion rate from the electrode becomes negligible.

vice versa may be neglected with respect to the rate at which the intermediate substance is produced and consumed in the two consecutive charge-transfer reaction steps. Under steady-state conditions, the continuity condition

$$i_1 \approx i_2 \qquad [1]$$

is established, where i_1 and i_2 are the C.D.'s carried by the two consecutive charge-transfer reactions. If there exists no other sources or sinks for the intermediate reaction products but consecutive charge-transfer reactions at the electrode interface, then this steady-state continuity condition is applicable to electrochemical reactions involving an arbitrary number of n consecutive charge-transfer steps, *i.e.*

$$i_\nu = i_{\nu+1} \qquad [2]$$

where $\nu = 1, 2, \ldots, n-1$. This case has been considered by Hurd.[30]

Referring to the work of Vetter,[28,29] Losev and Gorodetskii[20] have pointed out that the condition of small intermediate concentration is unnecessary. As I expressed in the paper under discussion my reservations concerning this point of view, I was indeed under the impression that Losev and Gorodetskii meant their comment to be true for the general case considered by Vetter. Losev's discussion of my paper and his recent publications[17,18,21,22] are most welcome. They give the special conditions, which Losev *et al.* assume to be adequate for using Eq. [2] above as a reliable basis for analyzing the current density overvoltage characteristics even at relatively high intermediate concentrations. These conditions are:

(*i*) The ratio of the electrode surface to the electrolyte volume is so large that during an electrolysis at constant potential rapid accumulation of the products of the electrochemical reaction in the bulk of the solution decreases any transient concentration gradients for the intermediate reaction products at the electrode surface within a reasonably short period of time to zero.

(*ii*) The intermediate concentrations in the bulk of the solution "remain always equal to zero," which may be the case when the intermediate products are unstable and enter into chemical reactions.

Knowing now the specific steady-state conditions considered by Losev, I still doubt that Eq. [2] above *i.e.*, the formalism derived elsewhere[20,28-30] provides a reliable basis for analyzing the current density overvoltage characteristics unless the intermediate concentrations are small compared to the concentrations of the most reduced substance (S_1) and most oxidized substances (S_{n+1}) entering into the consecutive charge-transfer mechanism

$$S_\nu \overset{i_\nu}{\rightleftharpoons} S_{\nu+1} + z_\nu e^-, \quad \nu = 1, 2, \ldots, n \qquad [3]$$

If condition (*i*) is satisfied, then the change in bulk concentration of all intermediate products must be generated in an anodic reaction from S_1 and in a cathodic reaction from S_{n+1}. Furthermore, not only the intermediate products are accumulated, but the concentration of S_1 decreases and the concentration of S_{n+1} increases in an anodic reaction (vice versa in the cathodic case) so that the equilibrium electrode potential rapidly approaches the externally imposed value, in which case the total C.D. approaches zero, *i.e.*, there is no true steady state under Losev's experimental condition.[28] A "quasi steady state" could be postulated if S_1 and S_{n+1} are available in much larger concentration than the intermediate products. In my opinion, the best and only way of characterizing the reliability of such an analysis of the current density overvoltage characteristics is to provide an error analysis for the deduced kinetic parameters.

Condition (*ii*) considered by Losev is not in conflict with what I have said in the paper under discussion, since I never objected to utilizing Vetter's analysis if the relative concentrations of the intermediate products are sufficiently small. I would like to point, however, to the fact that a finite equilibrium concentration of the intermediate products at the interface is required to establish an equilibrium potential characteristic of reaction [3] and to define the exchange C.D.'s of the various reaction steps. Since chemical reactions involving the intermediate products lead to branching in the equivalent mass flow at the interface, I do not believe that the interaction of consecutive charge-transfer reactions with chemical reactions is covered by the simple analysis given elsewhere.[20,28-30] In the general case, where the electrochemical reaction is controlled by charge-transfer, diffusion, and chemical reactions, the steady-state continuity condition Eq. [2] has to be replaced by

$$i_\nu = i_{\nu+1} + i^{D}_{\nu+1} + i^{R}_{\nu+1} \qquad \nu = 0, 1, 2, \ldots, n \qquad [4]$$
$$i_0 = i_{n+1} = 0$$

where $i^{D}_{\nu+1}$ and $i^{R}_{\nu+1}$ denote the equivalent C.D.'s with which the substance $S_{\nu+1}$ is consumed or produced at the interface via chemical reactions or by exchange with the bulk via diffusion. Note that no charge is carried across the interface by $i^{D}_{\nu+1}$ and $i^{R}_{\nu+1}$. I have treated in the paper under discussion the case of n consecutive charge-transfer reactions, when

$$i^{R}_{\nu+1} = 0$$

and

$$i^{D}_{\nu+1} = -FD_{\nu+1}\,(\partial c_{\nu+1}/\partial x) \qquad [5]$$

If $i^{R}_{\nu+1} \neq 0$, then not only the diffusion of $S_{\nu+1}$ but also the diffusion of the reaction products has to be taken into account. The relation between the concentration of $S_{\nu+1}$ and the rate of the chemical reaction depends on the specific nature of the reaction. In general, the current densities carried by the various charge-transfer reaction steps will not be equal in this case, *i.e.*

$$i_\nu \neq i_{\nu+1} \qquad [6]$$

except for the very special condition

$$i^{D}_{\nu+1} = -\,i^{R}_{\nu+1}$$

I agree with Losev that, in the absence of chemical reactions, the interpretation of the steady-state c.d. overvoltage curve is considerably simplified if the diffusion currents of all intermediates are known from an independent set of experiments.

The Kinetics of the p-Toluquinhydrone Electrode

F. Kornfeil (pp. 1674-1679, Vol. 119, No. 12)

J. C. Reeve:[31] The following comments may be of interest not only to those considering Dr. Kornfeil's valuable results in the paper under discussion concerning consecutive charge-transfer reactions, but to those interested in such reactions in general.

The term "pseudo-Tafel region" was introduced by Hurd[30] to describe what seemed, from a point by point calculation, to be a linear region of the Tafel diagram between two limiting anodic situations (where the steps are separately "rate-determining," rather than simultaneously "rate-determining" as in the transition region). This was unfortunate, since there is in fact no such special region,[32] and any apparent pseudo-Tafel behavior in such cases simply arises from experimental or graphical lack of precision. Vetter, in his classic works cited by Dr. Kornfeil in the paper under discussion, made no claim for such a region. In the paper being discussed an additional complication is introduced in that its Eq. [8] is said to have "pseudo-Tafel form." In fact, this not only has normal Tafel form (as usual ignoring small possible changes in α_2 with

The Kinetics of the p-Toluquinhydrone Electrode

F. Kornfeil (pp. 1674-1679, Vol. 119, No. 12)

J. C. Reeve:[31] The following comments may be of interest not only to those considering Dr. Kornfeil's valuable results in the paper under discussion concerning consecutive charge-transfer reactions, but to those interested in such reactions in general.

The term "pseudo-Tafel region" was introduced by Hurd[30] to describe what seemed, from a point by point calculation, to be a linear region of the Tafel diagram between two limiting anodic situations (where the steps are separately "rate-determining," rather than simultaneously "rate-determining" as in the transition region). This was unfortunate, since there is in fact no such special region,[32] and any apparent pseudo-Tafel behavior in such cases simply arises from experimental or graphical lack of precision. Vetter, in his classic works cited by Dr. Kornfeil in the paper under discussion, made no claim for such a region. In the paper being discussed an additional complication is introduced in that its Eq. [8] is said to have "pseudo-Tafel form." In fact, this not only has normal Tafel form (as usual ignoring small possible changes in α_2 with

[31] Chemistry Department A, Technical University of Denmark, Lyngby, Denmark.

[32] J. C. Reeve, *Coll. Czech. Chem. Comm.* (in English), 36, 757 (1971).

potential) but represents the normal anodic behavior complementary to the cathodic behavior indicated (the step $S_m \rightleftarrows S_o$ is "rate-determining" throughout). This behavior is marked as the "pseudo-Tafel region" in Fig. 4 of the paper under discussion but the short line shown at higher anodic overpotentials (where there has been a change of "rate-determining step") is very misleadingly called "the true Tafel line." Hurd[30] also called this region "the true Tafel-region," but only as opposed to the transition region, where there was supposed (incorrectly) to be an unexpected Tafelian behavior.

It is clear that terms such as "pseudo-Tafel behavior" and especially the term "pseudo-Tafel region" should be used with greater caution than hitherto.

Regarding the attainment of the steady state ($\gamma = 0.5$), it is said that (diffusion polarizations are to be supposed eliminated) "the stationary concentration of S_m can differ only slightly from its thermodynamic equilibrium concentration" for the given potential. In this statement it is not made clear between which solution species and S_m equilibrium is considered. In the here so-called pseudo-Tafel region, S_m will be in equilibrium with S_r. However, in the here so-called Tafel region, S_m can be in equilibrium with S_o at lower overpotentials and actually fall with increasing potential, but be nearly zero or again increasing at higher overpotentials (as in the present examples) depending on how closely α_1 approximates to α_2.[33]

It is possibly noteworthy that results, such as those used in Fig. 8 and 9 of the paper under discussion, can be used to determine i_o and both the sum and the difference of the reciprocal component current Tafel laws at $\eta \sim 0$ without making further suppositions.[34,35]

F. Kornfeil: I am grateful to the author of the above discussion for his interest and comments. I hope that the following arguments will help to remove at least the major part of any misunderstandings that may still exist.

First, and most importantly, it should be noted that, as a consequence of the experimental techniques used in the potential measurements, the transfer overpotential is the only component of the overpotential appearing in the experimentally determined values of the electrode potential. Since $\gamma \approx 0.5$, this means that all polarization curves presented are identical with the curves one would obtain from measurements in the steady state, if the diffusion coefficients of all reacting species and the rate constants of all chemical reactions involved in the reaction sequence were infinite. Therefore, the two charge-transfer steps clearly must proceed at equal rates over the entire range of overpotentials, irrespective of the sometimes very large difference between the individual exchange current densities $i_{0,1}$ and $i_{0,2}$.

Second, Dr. Reeve in the above discussion, is mistaken in his view that the phenomenon of the pseudo-Tafel lines is due to a lack of experimental or graphical precision. Inspection of Eq. [6] and [6a] of my paper under discussion reveals that, assuming $\gamma = 0.5$, at sufficiently large values of η, Eq. [6] simplifies to

$$i = 2i_{0,1} \exp\left(\frac{\alpha_1 \mathbf{F}}{RT}\eta\right)$$

with the intercept $2i_{0,1}$ in perfect analogy to the extrapolation of the Tafel line in a one-electron process. However, at intermediate values of η and the condition $i_{0,1} >> i_{0,2}$ the denominator of Eq. [6a] in the paper under discussion becomes unity and the numerator approximates $\exp(2\mathbf{F}\eta/RT)$ resulting, as pointed out by Vetter,[29] in another linear relationship between log i and η, namely

$$i = i_{0,2} \exp\left(\frac{1 + \alpha_2}{RT}\mathbf{F}\eta\right)$$

the pseudo-Tafel region, with the "wrong" intercept $2i_{0,2}$ (identical with the cathodic intercept), thereby raising the possibility of confusing an electrode reaction consisting of two consecutive charge-transfer steps with a single-step transfer of two electrons. What actually constitutes "sufficiently large" and "intermediate" values of the overpotential in this context depends on the kinetic parameters and their interrelations and has been clarified in Hurd's excellent analysis of this problem.[30]

If one remains faithful to the convention of referring to the linear portions as Tafel lines, then Hurd's terminology calling the straight line at the highest overpotentials the "true" Tafel line and the linear part of the polarization curve occurring at lower overpotentials the "pseudo"-Tafel line seems a most appropriate and logical choice. In view of the arguments presented above, it is, therefore, difficult to understand, both from the scientific and etymological points of view, why Dr. Reeve should find the term pseudo-Tafel region misleading. In fact, I fail to see any valid reason why electrochemists should, or the Ancient Greeks would, object to its continued use.

In regard to the last part of Dr. Reeve's discussion, the statement as to the small difference between the equilibrium and the steady-state concentrations of the intermediate should, in retrospect, have been presented in a more quantitative fashion. At any rate, a clear distinction should be made here between the steady-state concentration and the equilibrium concentration, a thermodynamic quantity governed by the equilibria existing among the quinone, meriquinone, semiquinone, and hydroquinone molecules. The assertion of the small concentration difference is based on considerations, via Faraday's laws, of the very small quantity of charge required for the observed rapid attainment of the steady-state condition.

The Kinetics of Chlorine Evolution and Reduction on Titanium-Supported Metal Oxides Especially RuO_2 and IrO_2

A. T. Kuhn and C. J. Mortimer (pp. 231-236, Vol. 120, No. 2)

G. Faita and G. Fiori:[36] Kuhn and Mortimer ascribe, in the paper under discussion, the differences existing between their data and those of our work[37] mainly to experimental procedures.

The first objection concerns the method used for obtaining the necessary ohmic drop correction.

Kuhn and Mortimer in their paper describe the method used by us[37] as "short-circuiting the working electrode to the counterelectrode." This procedure would be obviously incorrect and as a matter of fact was not applied. The actual experimental arrangement is sketched in Fig. 1.

The transistor-driven mercury switch is placed across the cell terminals: but the cell is electrically isolated

[36] Institute of Electrochemistry and Metallurgy, The University of Milan, 20133 Milan, Italy.
[37] G. Faita and G. Fiori, *J. Appl. Electrochem.*, 2, 31 (1972).

by a fast low-leakage silicon diode (*e.g.*, SGS EC-401 or BAY 73 with a 1 nA reverse current and a 8 pF capacitance). In view of this experimental arrangement the above mentioned criticism seems to be rather immaterial.

The second objection concerns the fact that in our work[37] the cell was purged with a slow nitrogen flow passing over the NaCl solutions. Kuhn and Mortimer in the paper under discussion suggest that the solution was not saturated with chlorine and consequently concentration polarization at the electrode surface may arise.

As a matter of fact, the potential values which is recorded just after switching off the current is given by the following equation

$$E = E_{rev} + \eta_1 + \eta_2$$

where E_{rev} is given by $E^\circ + RT/\mathbf{F} \cdot \ln (a_{Cl_2})$ sol/a_{Cl^-}; η_1 is the concentration polarization ($RT/2\mathbf{F} \cdot \ln (a_{Cl_2})$ surface/(a_{Cl_2}) sol; and η_2 is the activation polarization.

Now, (a_{Cl_2}) surface increases as the anodic current density increases and its upper limit is represented by the chlorine saturation solubility in the brine. This limit is probably reached, with the rotating disk equipment used by us,[37] in the 10 mA/cm^2 range, above which the chlorine activity at the electrode surface remains constant together with the concentration polarization.

The consequence is that the total overpotential is given by the sum η_1(constant) + η_2; hence our data at high current densities should be decreased by a constant value whose magnitude depends on the ratio (a_{Cl_2}) surface/(a_{Cl_2}) sol. (This will be a few millivolts in the operating conditions used in our work.[37])

The correct data (which were reported in Fig. 1 in our paper[37]) are independent of the chlorine concentration in the solution. In addition, it is important to stress that the Tafel *b* coefficient does not change for current densities above 10 mA/cm^2 and remains 32 mV/ decade of current in 4M NaCl at 20°C and *p*H = 2, up to 2 A/cm^2.

As far as the data below 10 mA/cm^2 are concerned, they are almost unaffected by the concentration polarization effects just opposed to what has been suggested.

That the situation is as above described is futhermore substantiated by Fig. 10 of the paper under discussion which shows that the anodic polarization curves for two different chlorine pressures (1 and 0.05 atm) are virtually identical above about 1 mA/cm^2.

Having stated this the most obvious conclusion is that the electrodes described in the paper under discussion of Kuhn and Mortimer behave in a different way with respect to those described in our paper[37] simply because they are different and not because of experimental procedures.

In fact the following points should have been taken into account:

(*i*) The coating tested in the paper being discussed is a solid solution of TiO_2, RuO_2, IrO_2 as has been demonstrated spectroscopically.

(*ii*) The coating tested in the paper under discussion has a (Ru-Ir) to Ti molar ratio of 0.1. An electrode with such a content of precious metal described in Kuhn's and Mortimer's paper (Fig. 7, curves e and f) is characterized by an overpotential of 0.6V at 1 A/cm^2 which seems to be too high for economic industrial operations. On the other hand, the coating prepared according to our work[37] (U. S. Patent 3,616,445, Appl. 690,407) exhibits an overpotential of only 125 mV; this value is confirmed by experimental measurements on actual chlor-alkali cells equipped with DSA (this is the commercial name for the anodes obtained by using the coating described in the above-mentioned U.S. patent).

An interesting feature of the RuO_2-TiO_2 electrodes obtained by Kuhn and Mortimer in their paper is represented in Fig. 2; the necessary data have been obtained from Fig. 7 of the paper under discussion and represent the limiting cathodic current densities ($\eta = -0.6$V). The relationship between current and Ru/Ti molar ratio is described by a straight line; a possible explanation of this linear dependence is that the chlorine discharge takes place only on Ru sites or RuO_2 islands (TiO_2 has a very low electrocatalytic effect).

If this mechanism holds, the high anodic overpotentials for the coatings with the lower Ru percentages can be readily explained; the observed apparent current density corresponds to quite larger actual current densities on the electrocatalytic centers.

S. Trasatti:[38] We have been working on RuO_2 film electrodes in this laboratory since early 1968 with particular regard to the intrinsic properties of such films to try to gain some insight into the rationale behind their undoubtedly peculiar behavior. Although, we have so far just published a preliminary note,[39] a number of papers is in preparation, and all of the aspects touched by the authors of the paper under discussion will be examined in detail there. We feel, however, that some discussion should be made here to clarify some points in the paper under discussion where the authors refer to results from this laboratory.

Roughness factor.—Although optical inspection gives evidence for compactness and microscopical homogeneity, recent BET measurements[40] in this laboratory give for the specific area of the films a value of about 14 m^2-g^{-1}. Since 2μ thick films were used (1.4 mg RuO_2 cm^{-2}), the roughness factor is as a result of the order of 200. This is in fairly good agreement with the value of 240 reported by Kuhn and Mortimer in the paper being discussed. Although this roughness factor should influence the charge associated with surface transformations, it is doubtful whether it could affect the value of reaction rates at potentials removed from the equilibrium value, due to the fact that sites available to rare gas in BET measurements are probably difficult to reach by particles in solution by diffusion. However, assuming for the roughness factor the possible value of 200, we will show that this cannot account for the charge measured by us[39] to change the potential of RuO_2 from oxygen evolution to about 0.4V.[41] Since 1 cm^2 of a 2μ thick RuO_2 film contains

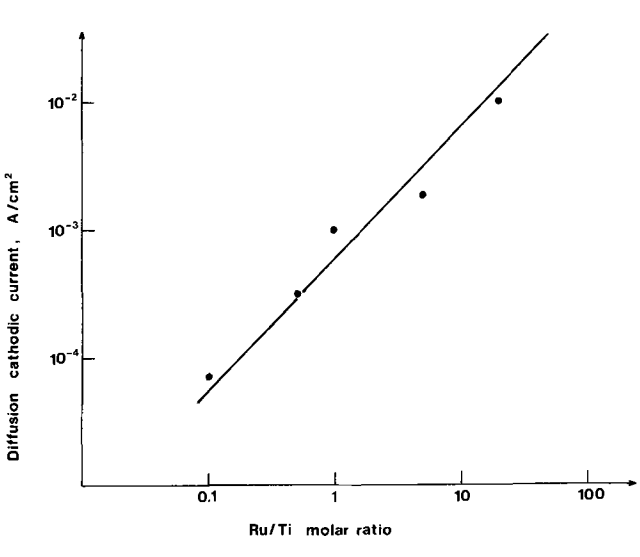

Fig. 2. Relationship between diffusion cathodic currents and Ru/Ti molar ratio (%).

6.3×10^{18} Ru atoms, the charge associated with a one-electron exchange reaction over all the film thickness would be about 1 coulomb/cm^{-2}. With reference to the (100) face of RuO_2, the number of surface Ru atoms is 0.5×10^{15} per cm^2.[42] With a roughness factor as above, the charge associated to a one-electron exchange surface reaction would be $80 \times 200 = 16$ mcoulombs/cm^{-2}.[43] Since the experimental charge[39] is about 70 mcoulombs/cm^{-2}, there are still 54 mcoulombs/cm^{-2} which cannot be accounted for by surface modifications. Thus, only about 5.4% of the Ru atoms in the bulk appear to exchange electrons during changes in potential. However, the problem is more complicated than it would appear at first sight. In fact, it should be reasonable to assume constancy in the roughness factor with change in film thickness. However, we measured[39] a charge of 17 mcoulombs/cm^{-2} for a ½μ thick RuO_2 film. In this case, all the charge could be accounted for by surface reactions, if the above roughness factor is adopted. Undoubtedly, the two results are contrasting and could be understood only if: (*i*) the BET surface area is not the electrochemical surface area; (*ii*) atoms in the surface are also reduced and oxidized in small fractions; and (*iii*) the roughness factor decreases with decreasing thickness of the film. Which of these models holds in practice cannot be established at the moment. We would like to emphasize here that chemical analysis[40] has given for the nonstoichiometry of RuO_2 the same order of magnitude and the same direction of change as those suggested in Table I of our paper.[39]

Electrical properties of RuO_2 films.—It is not completely clear which model is proposed by Kuhn and Mortimer in the paper under discussion as regards the nature of conduction in RuO_2 films. The authors seem prone to consider RuO_2 films as n-type semiconductors due to the low value of conductivity. This is, in principle, not really a correct argument since Bi is known to exhibit low conductivity while it is a metallic conductor. Further, reference to the dependence of conductivity on the firing temperature to support the above view does not appear to be relevant. In fact, measurements carried out by Pizzini's group[40] in this laboratory on RuO_2 films on silica show conductivity increases with increasing firing temperature. Opposite behavior would be expected if the semiconducting nature were related to the composition of the film, as Kuhn and Mortimer seem prone to think in the paper under discussion. In other words, a lower firing temperature would result in a higher nonstoichiometry which in turn would be responsible for a higher conductivity due to an increasing number of electrons. Results show that this is not the case. The positive temperature coefficient of conductivity[40] for temperatures higher than about 700°C is to be related to evolution of the structure towards the crystalline state rather than to semiconducting properties. Since the crystal has a higher conductivity, an increasing number of small crystals in the film as the temperature is increased accounts for the increase in conductivity. On the contrary, for T below 700°C the temperature coefficient of conductivity is practically zero which suggests rather a metallic behavior. On the other hand, if the number of electrons is reasonably high, a material could behave electrochemically as a metal even though it were rigorously a semiconductor. In fact, if the rate of the electron movement is higher than the rate of any step in the electrochemical reaction, the resulting whole process is not limited by the semiconducting nature. This may be the case of RuO_2 films. Our results with the Fe^{2+}/Fe^{3+} redox couple show that the activation energy is about 5 kcal-mol^{-1} for all types of films, which coincides with the value found for all metals investigated.[44] From this point of view, RuO_2 films can be defined with certainty as metallic in nature. Ti-Ru mixed oxides are more likely to be effectively n-type ionic semiconductors where Ru atoms should act as donors at least for Ru content below 20%.

Kinetics of Cl_2 evolution on RuO_2.—Kuhn and Mortimer in the paper being discussed observe that their results are in disagreement with those obtained by Faita and Fiori.[37] These authors give a detailed defense above in this Discussion Section. However, with reference to results obtained by us, the explanation given by Kuhn and Mortimer in their paper, in terms of different atmospheres above the solution during measurements, appears to us to be quite reasonable. In fact, we have carried out measurements in solutions saturated with Cl_2 and N_2, alternatively. The curve in N_2-saturated solutions is similar to that of Faita and Fiori with a Tafel slope of about 35 mV dec^{-1}, whereas the curve in Cl_2-saturated solutions exhibits a lower overvoltage at low current density (a few millivolts at 1 mA/cm^{-2}). The exchange current measured from linear i/η plots has been found to be about 5 mA/cm^{-2} in very good agreement with the value of Kuhn and Mortimer in the paper under discussion. However, in Cl_2-saturated solutions the i/E curve loses in definition and no definite Tafel line can be identified. In the paper being discussed the authors worked with stationary electrodes, whereas Faita and Fiori worked with rotating-disk electrodes. We are not of the opinion, as it appears in the paper under discussion, that the use of either type of electrode is irrelevant. In fact, in N_2-saturated solutions we obtained a quite definite Tafel line for current density up to 10 mA/cm^{-2} working with stationary electrodes. At higher currents, the overvoltage started to increase more rapidly in spite of vigorous stirring, whereas Faita and Fiori with the rotating-disk electrode were able to obtain a definite Tafel line at currents higher than 1 A/cm^{-2}.

A. T. Kuhn and C. J. Mortimer: The comments from Drs. Trasatti, Faita, and Fiori are, perhaps, best considered and replied to jointly, and their points fall into four categories: (*i*) problems relating to the removal of ohmic drops; (*ii*) the effect of Cl_2 concentration on the anodic i-V data; (*iii*) the catalytic activity of the anodes; and (*iv*) the nature of their electrical conductivity.

(*i*) Considering now the information (not originally proffered) that their circuit included a diode, and taking into account the other data now published, we are entirely satisfied as to the validity of the ohmic drop corrections of Faita *et al.*

(*ii*) Regarding the effect of dissolved Cl_2 concentration on the i-V data, we still have reservations regarding the explanation given by Faita *et al.* above in their discussion, since differences between N_2 and Cl_2 purged runs would be expected to disappear at high C.D.'s (as they do for N_2 and H_2 purged h.e.r. measurements) when plotted as E *vs.* log i (Fig. 10 in the paper under discussion). Indeed, the use of η/log i plots as seen in Faita *et al.'s* paper leaves quite open the question of what value of E_{rev} their η was based on. In an N_2 purged cell it may be suspected that the Cl_2 concentration increased (certainly in the diffusion layer) as the amount of electrogenerated Cl_2 increased from zero to the high C.D.'s used. In this context, Faita *et al.* will doubtless be considering the comments of Trasatti above. Taking Trasatti's reservations as to our statement that the use of rotating-disk electrode made no difference to the shape of the current-voltage plots, it should be borne in mind that our statement applied only under the conditions we reported in the paper being discussed (*e.g.*, Cl_2 saturated).

(*iii*) We agree with Faita *et al.* that our electrodes with 10% precious metal appear to show less activity than their samples, but the comments of Trasatti regarding differences in N_2 and Cl_2 purged data should here be borne in mind. If, this factor having been

eliminated, the difference persisted, it might indicate some merit in having a mixed precious metal system, or otherwise it could be a reflection simply on their and our preparative techniques. Further consideration of the activities of electrodes containing differing ratios of Ru:Ti have brought us to the same conclusion in the anodic sense, as Faita *et al.* have demonstrated on the cathodic side. We would not, however, refer to the cathodic limiting current as a diffusion limited one.

(*iv*) With regard to the type of conductivity shown by the oxide films, a-c impedance measurements on these films[45] in Cl_2 saturated brines at E_{rev} failed to show the behavior characteristic of a semiconductor, and reminding Trasatti that our suggestion of "η" type conductivity was clearly labeled as tentative, we would now agree with him.

The Thermal Power of the Solid Electrolyte Ag_4MI_5 and of Molten Mixtures of the Same Composition

K. E. Johnson, S. J. Sime, and J. Dudley
(pp. 703-707, Vol. 120, No. 6)

S. Chandra:[46] In the paper under discussion the authors have reported some very interesting studies on solid and molten $Ag+MI_5$ (M = K, Rb). Their values of the thermal power, θ, is lower than our values reported earlier[47] by a factor of three. Our measurements were made using massive silver electrodes which may not be reversible with the system as pointed out by the above authors in the paper under discussion. It is now well realized that obtaining a reversible electrode for such systems is very tricky. A value lower than our value is also expected on the basis of a recent theory given by Rice and Roth.[48] However, it has been our experience that the conductivity of Ag_4KI_5 depends upon the quenching rate, and a rapid quenching rate usually gives a higher conductivity sample. This is probably due to a higher degree of cationic disorder which sets in the lattice for rapid quenching rates. In obtaining their compounds, the above authors of the paper being discussed solidify the molten mixture by cooling it below the eutectic temperature without going through a rapid quenching sequence. Even though the thermopower reported by the above authors corresponds with the theory[48] better than our values,[47] it may be fortuitous. In my opinion a more confirmed value of thermopower would be obtained by using our system for pellets or single crystals but using better reversible electrodes. Two such electrodes may be: (*i*) silver electrode amalgamated with mercury and (*ii*) a pellet of powdered silver plus compound Ag_4KI_5.

K. E. Johnson, S. J. Sime, and J. Dudley: Chandra *et al.* made measurements only of the thermopower of solid Ag_4MI_5. Alhough silver electrodes could be reversible to these compounds in the solid state, we doubt if brass ones would be; the formation of a silver layer on the brass by a solid-state reaction

$$Ag^+ + Zn/Cu \rightarrow Ag + \tfrac{1}{2}Zn^{2+}/Cu^+$$

would be necessary to have a chance of creating a reversible system and other ions would be generated. A silver amalgam electrode may lead to better contact between electrode and compound but we would be reluctant to introduce mercury into the system for fear of mercury ion contamination of the compound when microcurrents flow. A pellet of powdered Ag + Ag_4MI_5 for an electrode does not seem to help either as one would still need to make a connection to it.

Since the values of thermal power obtained by us in the paper under discussion showed no sharp rise on going from liquid where contact is easy, to solid, we conclude that Chandra *et al.* had poor electrode/compound contact and measured some temperature-sensitive function of this. Rapid quenching would tend to preserve the level of disorder appropriate to high temperatures so we might expect their values for the solids to correspond more to ours for liquids which are even lower. As stated in the paper being discussed, the nonlinearity of the results of Chandra *et al.* also makes them suspect. Thermal power values of 300-700 $\mu V\ K^{-1}$ seem to be common for silver salts in the liquid state.

Hydrogen Overpotential on Zinc Containing Small Impurities in Concentrated Alkaline Solutions

T. S. Lee
(pp. 707-709, Vol. 120, No. 6)

F. Mansfeld:[49] The conclusion of the paper under discussion that "one can visualize that almost all the impurities, including mercury in the zinc, will make zinc more readily corroded in the alkaline medium" is in contradiction to many published results. Earlier studies of Vondracek and Jzak-Krisko[50] showed that alloying of zinc with Al, Pb, and Hg decreased corrosion rates (r_{H_2}) in 0.5*N* H_2SO_4, while Cd, As, Sn, Sb, Fe, and Cu increased r_{H_2}. Krug and Borchers[51] found that alloying with Fe (up to 310 ppm) increased r_{H_2}, but alloying with Pb up to 1% reduced this increase. Mansfeld and Gilman[52] prepared Zn-Pb and Zn-Al alloys [up to 1 weight per cent (w/o) Pb or Al] and showed that r_{H_2} values in 6*N* KOH were lower for these alloys than for pure zinc (99.999%). I found in addition that very pure zinc (99.999%) corroded faster in 6*N* KOH than zinc of lesser purity (99.95% and 99.9%) and attributed this to lead impurities, since similar r_{H_2} values were found for 99.5% Zn and a Zn-0.8 w/o Pb alloys prepared from high purity materials.[53]

T. S. Lee's conclusion in the paper under discussion is, therefore, not substantiated by experimental facts. In addition, it is well known that corrosion rates are determined by the interaction of oxidation and reduction reactions. An increase of the rate of the hydrogen evolution due to alloying might still not lead to an increase of corrosion rates because a still larger decrease of the rate of the metal oxidation reaction has resulted from alloying. For the case of zinc in KOH, the experimental evidence suggests, however, that alloying elements affect mainly the rate of the hydrogen evolution reaction.[51,53] More recent detailed investigations by Borchers and Krug[54] have shown that Cd and Pb accumulate on the surface of Zn during the initial corrosion period and then inhibit corrosion due to their higher hydrogen overpotential. Similarly from my results[53] it can be seen that the corrosion rate of pure Zn (99.999%) was constant over 160 hr after an initial decrease for 40 hr, while less pure zinc showed a longer period of decreasing corrosion rates. These results[53,54] also suggest that the beneficial effect of alloying elements can be entirely missed in short time experiments as it was apparently in the paper under discussion.

T. S. Lee: First of all, the main purpose of the paper under discussion was to present hydrogen overpotential data in concentrated KOH solution with uniformly prepared samples in clean environment. Mansfeld's comment above seems to have missed this point completely.

Second, the remarks the author made in the paper under discussion and quoted by Mansfeld were only intended to refer to the few impurities mentioned in the paper, *i.e.*, Cd, Fe, Ca, Mn, and Hg; this was not

[49] Science Center, Rockwell International, Thousand Oaks, California 91360.

[54] H. Borchers and H. Krug, *Metall*, 24, 952 (1970).

a general statement. It was also implied in the statement that impurities were present in the concentration range of 200-500 ppm and were uniformly distributed within the samples. It is general knowledge in electrochemistry that if sample A has a higher hydrogen overpotential than sample B, then sample A shows less corrosion than sample B in the same environment. The remarks in the paper under discussion were made following this kind of reasoning after comparing the hydrogen overpotential data. Mansfeld's comment above might be the result of misreading the paper.

Finally, the corrosion rate measurement by immersing a piece of the sample in the solution and letting the corrosion products accumulate on the surface of the sample with time is quite different from the hydrogen overpotential measurement. In the latter case, the surface of the sample at the beginning and the end of the experiment is, or is nearly, the same, while in the corrosion rate experiment, as mentioned by Mansfeld in his discussion, the surface of the sample at the beginning and the end of the experiment is quite different due to the corrosion reaction. The interpretation of data obtained from the same surface within a few hours is more easily or meaningfully obtained than from a different surface after 160 hr reaction. Besides, after certain lengths of time, the very minute amount of impurities in the solution may be readsorbed on the electrode surface which will effect the measurement.

As to the accuracy of correlating hydrogen overpotential data with those of corrosion rate measurements, there is a very nice correlation in our laboratory between my hydrogen overpotential measurements and J. C. Cessna's[55] corrosion rate measurements. In general, zinc containing Pb or Hg (in amounts greater than those discussed in the paper) has a higher hydrogen overpotential in concentrated KOH solution than pure zinc. In the corrosion rate measurement, it shows a lower corrosion rate which is completely agreeable with the published results. However, the result of the Zn-Al alloy in the work of Mansfeld *et al.* is quite different from the work obtained in this laboratory. Since it belongs in another subject of discussion, it will not be discussed here.

ABSTRACT

Al_2O_3 films, 200 nm thick, were chemically vapor deposited on (100) silicon substrates by hydrolysis of $AlCl_3$ at 900°C in a H_2-rich atmosphere of H_2 and CO_2. Heat-treatment in H_2 atmosphere produces no change in the charge state of the oxide. Heat-treatment in O_2, N_2, or Ar atmospheres produces only a redistribution of the negative charge grown in during deposition. Heat-treatment in H_2 subsequent to that in O_2, N_2, or Ar restores the original charge distribution. The flatband voltage characterizing these shifts approached a constant value with time (10V). The temperature dependence of the rate of approach to saturation is consistent with first-order kinetics and an activation energy of 1.42 eV. These results and the effects of annealing on optically active charge trapping centers are interpreted in terms of a simple phenomenological model. It is suggested that the charge trapping centers are due to a hydrogen-related species formed during film deposition.

A recent paper described an investigation of electronic charge trapping in chemically vapor-deposited thin films of Al_2O_3 on silicon (1). That investigation was carried out on evaporated metal-Al_2O_3 insulator-silicon MIS structures. The techniques used to study trapping phenomena were photoinjection-photodepopulation measurements (2) and high-frequency capacitance-voltage (C-V) measurements (3). The results of these measurements were interpreted in terms of two distributions of trapped negative charges within the insulator.

Electrons photoemitted into the insulator and trapped within the insulator accounted for most of the insulator charge.[1] This negative charge was distributed rather uniformly throughout the insulator. It was also determined to be a bounded distribution as a function of energy within the forbidden gap of the insulator, beginning approximately 2 eV below the conduction band edge. Some of this photoinjected trapped charge could thus be released by photons of energy 2.5 eV and removed from the insulator. In addition, a smaller negative charge distribution was incorporated into the Al_2O_3 films during deposition. This charge was concentrated near the metal electrode.

The present paper presents and discusses a program of postdeposition heat-treatments carried out on chemically vapor-deposited thin films of Al_2O_3 and their effect on the electronic trapping behavior of such films.

Key words: MIS structure, thin dielectric films, photoconduction in insulators, C-V measurements, chemical vapor deposition.

[1] The charging of insulator films by photoemission of charge carriers and subsequent capture into localized defect states is referred to as photoinjection. It was previously demonstrated that negative charging of alumina films could be achieved by photoinjection of electrons from both the silicon and metal electrodes [see Ref. (1)].

These measurements were undertaken to obtain some insight as to the nature and origin of the trapping centers responsible for capture of photoinjected electrons (4). Results have been interpreted in terms of a phenomenological model of hydrogen-related defects.

Experimental Procedure

Sample preparation.—All MIS specimens used in this investigation were prepared as previously described (1), with the insulator consisting of 200 nm of Al_2O_3. This thickness was selected on the basis of practical technological significance and on the basis of having thick enough film to obtain large measurable currents during photodepopulation measurements. Al_2O_3 was deposited by hydrolysis of $AlCl_3$ at 900°C in a hydrogen-rich mixture of H_2 and CO_2 (5). The volume fraction of gases entering the reaction zone were 0.02 CO_2, 0.005 $AlCl_3$, and the remainder H_2. Transmission electron diffraction on these films indicated a structure similar to bulk κ Al_2O_3 (6), with a grain size of 10-30 nm.

Measurement techniques.—The principal measurement techniques used were photoinjection-photodepopulation (2) and high frequency C-V measurements (3). The equipment and procedures used have been described in detail in the previous publication in this series (1). A brief technical description of the first technique is given in the Appendix to the present paper. The photoinjection-photodepopulation and C-V measurements were made in separate experimental facilities.

In general, flatband voltages, V_{FB}, as determined by C-V measurements (7, 8), are used to determine the

product $\bar{x}\,Q$, where $\bar{x}$ is the first moment (the centroid) of the charge distribution within the insulator and Q is the total charge within this distribution

$$\bar{x} = \frac{1}{Q}\int_0^L x\,\rho(x)\,dx,\quad Q = \int_0^L \rho(x)\,dx \qquad [1]$$

In these expressions $\rho(x)$ is the charge density within the insulator at some distance x from the metal electrode interface (L = insulator thickness, see Table I). As discussed in the section on Results and Discussion these measurements were performed at any desired stage of the fabrication and annealing processes on the insulator films. Also, these measurements have been made both before and after photoinjection of electronic carriers into the insulator (1).[1] In this case, the associated differences in V_{FB} were interpreted in terms of electrons captured in trapping states during transport across the insulator film.

The insulator charge was also investigated by electrometric measurements of trapped charge released by optical photons below the photoinjection threshold.[2] The measurement of primary interest was total released charge *vs.* applied voltage (Q-V), measured with fixed optical wavelength [480 nm in the present case, this being slightly below the silicon-Al_2O_3 photoinjection threshold (9)]. As discussed previously (1), these experiments were analyzed in terms of optically accessible trapped charge (*i.e.*, that fraction of the total insulator charge which can be optically excited into the Al_2O_3 conduction band by 480 nm light) and "fixed" insulator charge (*i.e.*, that fraction of the insulator charge which cannot be photoexcited to conducting states by 480 nm light). In these experiments, the centroid $\bar{x}$ and the total charge Q within the insulator charge distribution $\rho(x)$ can be separated (2).

The Q-V measurements, as the C-V measurements, can be performed at any desired stage of the oxide deposition-heat-treatment cycle. Also, C-V measurements were made before and after photodepopulation to determine the internal consistency of the basic experimental interpretation just described.

Heat-treatments.—All heat-treatments were carried out in a diffusion furnace and/or a closed reactor (the same unit used for film deposition) at temperatures at or below the deposition temperature. Transmission electron microscopy and diffraction data obtained on samples subjected to the most severe heat-treatments showed no measurable change in crystal structure or morphology from as-deposited samples. Thus, all specimens measured in the present program were structurally the same as polycrystalline bulk κ-alumina.

The following annealing sequences on Si/Al_2O_3 specimens were studied: (*i*) a series of heat-treatments was carried out in nitrogen atmosphere (3 lpm flow rate) as a function of temperature (450°-900°C) and time (0.25-48 hr); (*ii*) a series of annealing treatments was carried out at 900°C for 2 hr in N_2, Ar, O_2, and H_2 atmospheres; and (*iii*) a series of annealing treatments was carried out at 900°C for 2 hr in various mixtures of H_2 and N_2, in order to determine the effect of variations of the partial pressure of H_2 (p_{H_2}). High frequency C-V measurements were performed on specimens after each step in the sequences just described. On selected specimens, C-V measurements were also performed after photoinjection and after subsequent photodepopulation at 480 nm. Photodepopulation Q-V measurements were also performed at selected steps in the several annealing sequences.

Each of the measured data points to be described in the next section represents an average of at least six samples. Variations from sample to sample are shown by error bars or ranges wherever such variations were measurable. In the cases where these are not shown, the variations were within the experimental accuracy (better than ± 10%) of the particular measurement.

[2] Optical excitation of trapped charge carriers into mobile states and removal of the released charge from the insulator is referred to as photodepopulation.

Table I. Definitions of terms

MOS capacitor characteristics
- A = area of the metal electrode (0.1 ± 0.02 cm²)
- L = thickness of the dielectric (2.0 ± 0.1 × 10^{-5} cm)
- C = capacitance per unit area
- ϵ = dielectric permittivity of Al_2O_3 = 8.42 × 10^{-13} F/cm
- e = electronic charge (coulomb)
- N = charge density in the insulator (cm^{-3})

CV measurements
- V_{FB1} = flatband voltage of as-deposited sample (V)
- V_{FB2} = flatband voltage after photoinjection in as-deposited sample (V)
- V_{FB3} = flatband voltage after photodepopulation in as-deposited sample (V)
- V'_{FB1} = saturation flatband voltage value reached during heat-treatment in nitrogen (V)
- V'_{FB2} = flatband voltage after photoinjection in heat-treated samples (V)
- V'_{FB3} = flatband voltage after photodepopulation in heat-treated samples (V)

Q-V measurements (see Fig. 3a, 3b)
- q = total releasable charge = $q_+ - q_-$ (coulomb)
- $\bar{x}_1$ = distance of the centroid of the released charge from the metal-insulator interface = $\dfrac{q^+}{q_+ - q_-}$ (cm)
- Q_{f1} = part of the fixed charges having centroid $\bar{x}_1 = AC\dfrac{V_+ - V_0}{V_+ - V_-}$
- Q_{f2} = remaining part of the fixed charges (coulomb)
- $\bar{x}_2$ = distance of the centroid of Q_{f2} from the metal-insulator interface (cm)

Corresponding quantities in heat-treated specimens are designated by primed variable (*e.g.*, q', x', etc.)

Results and Discussion

In this section, the results of various experiments are presented and described. These results are analyzed in terms of a phenomenological model of hydrogen-related electron trapping defects in Al_2O_3 in the section on Model for Electron Trapping in Al_2O_3. The notation and terminology used to describe the experimental results and the analysis are listed in Table I. These notations are consistent with Ref. (1) and (7). Further simplification is made by using the centroid and the total charge to characterize the spatial distribution of the charges in the insulator (*i.e.*, $\bar{x}$ and Q as described in Eq. [1]). These are preferred to the integral expressions in Eq. [1], since this is the extent to which charge distributions can be specified using the present techniques.

As-deposited samples.—The photoinjection-photodepopulation and C-V measurements on as-deposited samples were described in the first paper in this series (1). A summary of the results of these measurements is given in Table II, since the measurements on heat-treated samples (described below) are to be compared with the results on as-deposited samples. It was shown in (1) that the thin films of chemically vapor-deposited Al_2O_3 on silicon have "grown-in" negative charges (denoted by N_{f2}) localized near the metal electrode interface. The centroid was found to be $0.14L$ measured from the metal-Al_2O_3 interface (4). These charges give rise to the initial flatband voltage, V_{FB1}, observed on the as-deposited samples. During photoinjection, additional charges N_T are trapped in the insulator, with centroid $\bar{x}_1 = 0.7L$. This increases the flatband shift to V_{FB2}. During photodepopulation, electronic charge of number density n_T is removed from the insulator, leaving behind a "fixed" negative charge N_{f1}. Thus, only a partial recovery in the flatband voltage occurs ($V_{FB3} > V_{FB1}$).

Heat-treated samples.—The heat-treatments were carried out on Al_2O_3 deposited on silicon, with time, temperature, and atmosphere as parameters, as described in the section on Experimental Procedure.

Figure 1 shows the results of flatband voltage measurements as a function of time and temperature of heat-treatment. These heat-treatments were carried out in an N_2 atmosphere. The curves are computer-plotted least squares best fit to the experimental data

Table II. Summary of results on as-deposited samples

Flatband voltage shifts (see Table I)

$V_{FB1} = 2.0 \pm 1.0V$ $V_{FB2} = 38.5 \pm 2.0V$ $V_{FB3} = 29.0 \pm 2.0V$

Equivalent charge densities (see Table I)
The numbers quoted are volume-average equivalent charge densities, related to net charge or voltage data from C-V or Q-V experiments by the defining relations

$$eLN = \frac{Q}{A} = CV$$

1. Fixed charges in as-deposited samples
$\bar{x}_2 N_{f2} = \frac{C}{e}(V_{FB1})$: $N_{f2} = 2.1 \times 10^{17}$ cm^{-3}, $\bar{x}_2 = 0.14L$
2. Trapped charges introduced by photoinjection
$\bar{x}_1 N_T = \frac{C}{e}(V_{FB2} - V_{FB1})$: $N_T = 6.4 \times 10^{17}$ cm^{-3}, $\bar{x}_1 = 0.70L$
$\bar{x}_1 N_{f1} = \frac{C}{e}(V_{FB3} - V_{FB1})$: $N_{f1} = (4.9 \pm 0.2) \times 10^{17}$ cm^{-3}, $\bar{x}_1 = 0.70L$
3. Trapped charges removed by photodepopulation
$\bar{x}_1 n_T = \frac{C}{e}(V_{FB2} - V_{FB3})$: $n_T = (1.5 \pm 0.2) \times 10^{17}$ cm^{-3}, $\bar{x}_1 = 0.70L$

From Q-V measurements:

$$n_T = \frac{q}{eLA} = \frac{q_+ - q_-}{eLA}$$

$$N_{f1} = \frac{Q_{f1}}{eLA} = \frac{C(V_+ - V_-)}{eL}$$

$$\frac{\bar{x}_1}{L} = \frac{V_+ - V_o}{V_+ - V_-} = \frac{q_+}{q_+ - q_-}$$

and the parameters are given in the figure caption. The following observations can be made from the results: (a) the flatband voltage as a function of time reaches a saturation value, V'_{FB1}; (b) V'_{FB1} is approximately independent of temperature; and (c) the rate at which V'_{FB1} is reached is determined by

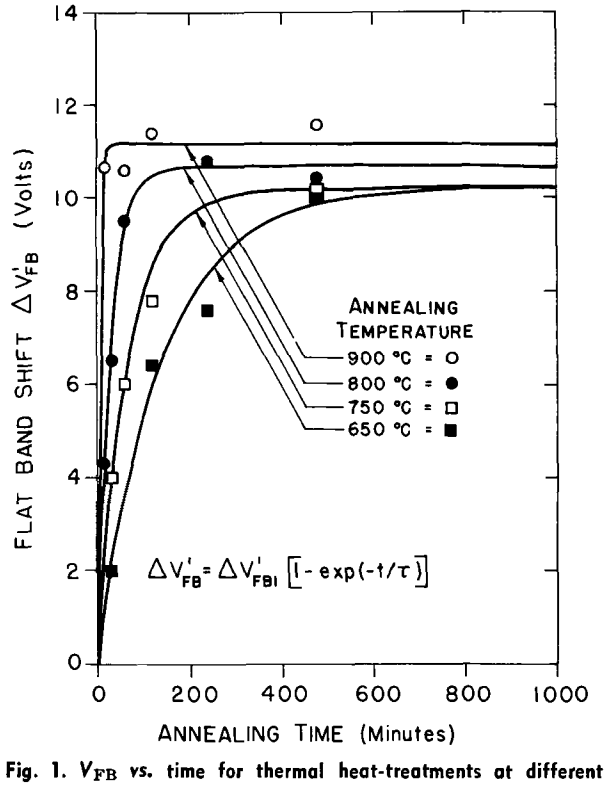

Fig. 1. V_{FB} vs. time for thermal heat-treatments at different annealing temperatures T. The solid curves represent least squares best fits of the data to the two-parameter exponential function indicated in the drawing. The root mean square deviation for the several curves range from 0.192 (800°C) to 0.419 (650°C). The average value of $V'_{FB1} = V_{FB1} + \Delta V'_{FB1}$ for the several curves is 12.5V. A 48-hr anneal at 600°C resulted in $V'_{FB} = 12.3V$, consistent with the data shown. A 48-hr anneal at 450°C produced no significant flatband shift [see Ref. (4)].

Table III. Results of heat-treatments in various atmospheres (900°C, 2 hr)

Atmosphere of heat-treatment	Flatband voltage V_{FB} after heat-treatment,* V
N_2	12.4 ± 2.0
A	10.0 ± 2.0
O_2	12.7 ± 2.0
H_2	2.9 ± 1.0
N_2 followed by H_2	2.9 ± 1.0

* Flatband voltage in as-deposited condition was 2.0 ± 1.0V.

$$\Delta V'_{FB} = \Delta V'_{FB1}(1 - \exp -t/\tau) \quad [2]$$

where

$$\Delta V'_{FB} = V'_{FB}(t) - V_{FB1}$$

$$\Delta V'_{FB1} = V'_{FB1} - V_{FB1}$$

and where the reaction time τ is a decreasing function of temperature.

In order to determine the effect of ambient atmosphere on V'_{FB1}, heat-treatments were carried out at 900°C for 2 hr in various atmospheres as previously described. The results are listed in Table III. There is essentially no change in V_{FB} produced by hydrogen annealing treatments. However, in all other atmospheres, the shift in V_{FB} after heat-treatment is the same. Therefore, the effect observed in these heat-treatments appears to be caused by a change in some hydrogen-related species rather than some oxidation-reduction process. Further, as indicated in Table III, samples which had been heat-treated in N_2 and subsequently heat-treated in H_2 at 900°C exhibited flatband shifts essentially the same as those observed in as-deposited specimens. Thus, the effect of heat-treatment in nitrogen is reversible by subsequent heat-treatment in hydrogen.

Assuming that a change in some hydrogen-related species was responsible for the observed shift in the flatband voltage, a dependence on H_2 partial pressure in the annealing ambient was anticipated. A limited number of heat-treatments were carried out in various mixtures of H_2 and N_2 at 900°C for 2 hr, and the results of these experiments are shown in Fig. 2. These data

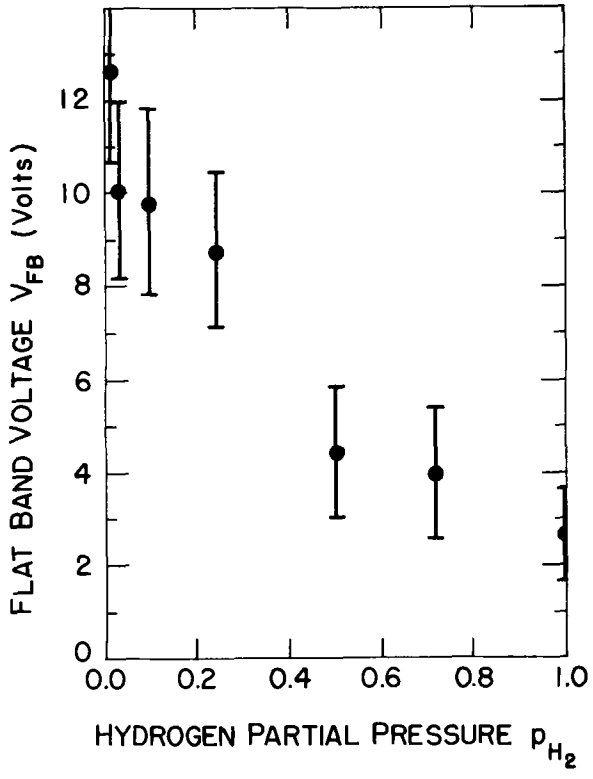

Fig. 2. V'_{FB} vs. p_{H_2}, for a 2-hr annealing treatment at 900°C. The indicated errors represent extreme values for the several specimens measured.

Table IV. Results of C-V measurements on heat-treated samples

Condition of sample (See Table I)	Flatband voltage, V
After heat-treatment, V'_{FB1}	12.0 ± 2.0
After photoinjection, V'_{FB2}	40.3 ± 3.0
After photodepopulation, V'_{FB3}	33.7 ± 2.0

are V'_{FB1} *vs.* p_{H_2}, the partial pressure of H_2 during the annealing treatment. It can be seen that V'_{FB1} increases monotonically as p_{H_2} is reduced.

In all of these measurements the observed flatband shifts are proportional to $\overline{xQ}$, as defined in Eq. [1]. Thus, an increasing V_{FB} may be caused by an increase in net negative charge Q during annealing, a shift in centroid of the initially existing charges in the as-deposited samples toward the Si/Al_2O_3 interface (*i.e.*, an increase in $\bar{x}$), or both. As described later, the results of C-V measurements after photoinjection on heat-treated samples showed that no charge had been added to the insulator during the heat-treatment. Therefore, the centroid of the as-deposited negative charges must have shifted toward the Si/Al_2O_3 interface.

Photoelectrical measurements.—On some samples which had been heat-treated to saturation (*i.e.*, to attainment of V'_{FB1}), the photoinjection and photodepopulation measurements were carried out, as described in Ref. (1) and in the section on Experimental Procedure. Table IV lists the results of C-V measurements after heat-treatment, after photoinjection, and after subsequent photodepopulation. It can be seen from these results that the flatband voltage after photoinjection on heat-treated samples, V'_{FB2}, is essentially the same as V_{FB2}, the flatband voltage after photoinjection on as-deposited samples (see Table II). Also, the recovery resulting from photodepopulation, $\Delta V'_{FB} = V'_{FB2} - V'_{FB3}$, is apparently less than the corresponding ΔV_{FB} on as-deposited samples.

Figure 3 shows the results of Q-V measurement on as-deposited and on heat-treated samples. From this data, the parameters $n't$, N'_{f1}, N'_T, $\bar{x}'_1$, etc., were calculated and the results are summarized in Table V. These results indicated: (*i*) the centroid of both fixed and optically released charges in heat-treated samples is essentially the same as the centroid of photoinjected charges in as-deposited samples, (*ii*) the density of the optically released charge is less in heat-treated samples than in as-deposited samples, and (*iii*) there are no charges in the heat-treated samples which correspond to the grown-in charges N_{f2} located near the metal-Al_2O_3 interface in the as-deposited samples (see Table II). It should be noted that the locations of the centroids were quite reproducible from sample to sample and, therefore, they may be related to the deposition process.

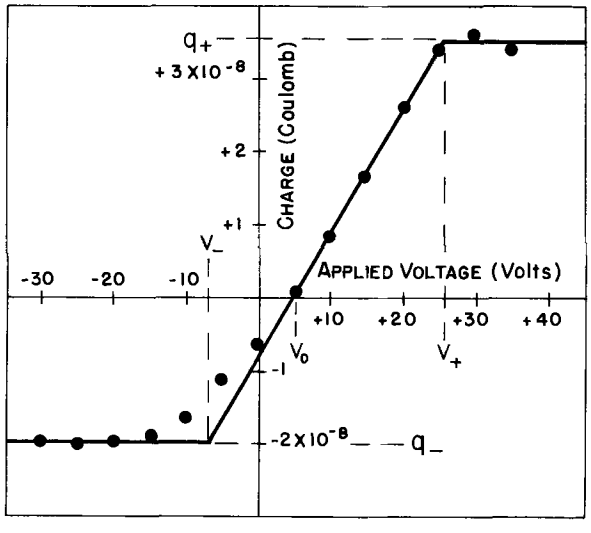

Fig. 3a. Photodepopulation Q-V data (solid circles) from as-deposited MIS specimen. The important quantities $q'_\pm$, $V'_\pm$, and V'_0 are indicated by dash lines on the diagram (see Tables I and II). The solid lines represent the idealized response expected from the distributions n'_T and N'_{f1} [see Tables I and II, Fig. 4(B-D), and Ref. (1)]. Deviations from this idealized curve are associated with the interfacial grown-in negative charge distribution N_{f2} [see Tables I and II and Ref. (1)].

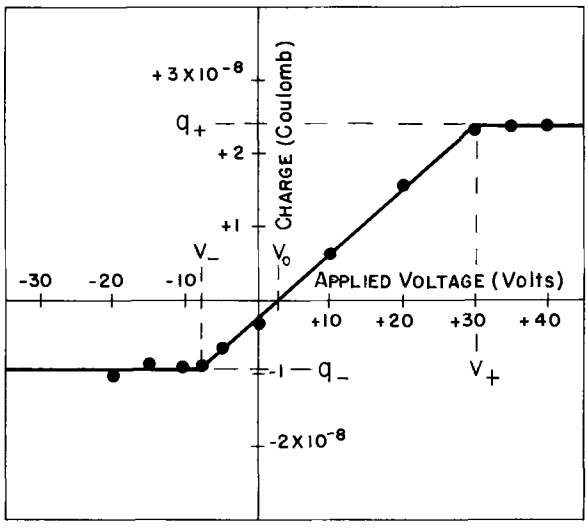

Fig. 3b. Photodepopulation Q-V data (solid circles) from MIS specimen heat-treated in nitrogen. The annealing time was sufficient to produce a saturated flatband shift V'_{FB1} (see Fig. 1). The important quantities $q'_\pm$, $V'_\pm$, and V'_0 are indicated by dash lines on the diagram (see Tables I and V). The solid lines represent the idealized response expected from the distributions n'_T and $N'_f = N'_{f1} + N'_{f2}$ [see Tables I and V and Fig. 4(E-H)]. The absence of significant deviation from the idealized response indicates that no interfacial distribution exists (*i.e.*, no charges corresponding to Q_{f2} or N_{f2} in as-deposited samples).

Model for Electron Trapping in Al_2O_3

The observed shift in the flatband voltage was apparently caused by a change in some hydrogen-related species in the Al_2O_3 films (see Table III). Incorporation of hydrogen in these films is consistent with deposition conditions, since hydrolysis of $AlCl_3$ is accomplished in nominally 98% by volume hydrogen atmosphere. The over-all deposition reaction, suggested by Tung and Caffrey (5), is

$$2AlCl_3 + 3H_2 + 3CO_2 = Al_2O_3 + 6HCl + 3CO \quad [3]$$

It can be shown that the thermodynamics of this reaction are favorable for formation of the stable phase α-Al_2O_3 (10). However, the deposit is a metastable phase, κ-Al_2O_3. In bulk materials, κ-Al_2O_3 is produced as one of the metastable products resulting from dehydration of AlO-OH (11). These metastable phases

Table V. Results of Q-V measurements on heat-treated samples (see Fig. 3b)

Numbers quoted are volume-average equivalent charge densities, defined in Table II.

Density of optically releasable charges, n'_T	(1.0 ± 0.1) × 10^{17} cm^{-3}
Density of fixed charges, N'_f	(5.7 ± 0.2) × 10^{17} cm^{-3}
Density of total charges, $N'_f + n'_T$	6.7 × 10^{17} cm^{-3}
Centroid of n'_T and N'_f, $\bar{x}'_1$	(0.75 ± 0.10) L

$$n'_T = \frac{q'}{eLA} = \frac{q'_+ - q'_-}{eLA} \qquad N'_f = \frac{Q'_{f1}}{eLA} = \frac{C(V'_+ - V'_-)}{eL}$$

$$\frac{\bar{x}'_1}{L} = \frac{V'_+ - V'_0}{V'_+ - V'_-} = \frac{q'_+}{q'_+ - q'_-}$$

As indicated in Fig. 3b, Q'_{f2} is zero in heat-treated specimens (see Table I). Thus, the interfacial charge distribution observed in as-deposited films (N_{f2}) is not observed in heat-treated films.

are reported to be nearly, but not completely, anhydrous. They retain some of the crystal structural characteristics of the parent phase (12). Thus, it is reasonable to expect some form of hydrogen-related "defect" species in these Al_2O_3 films.

The proposed model is summarized in Fig. 4 which shows a one-dimensional schematic representation of the spatial distribution of charge in Al_2O_3. It also demonstrates the variation of these distributions with specimen heat-treatment, and/or photoinjection and photodepopulation. Note that the distributions are represented by $\overline{x}Q$, *i.e.*, by total charge located at the distribution centroids. It is proposed that both negative charges near the metal electrode interface (N_{f2}, see Table II) and hydrogen-related defect centers exist in the as-deposited films, Fig. 4A, B, and E. The hydrogen species are presumed to be neutral (when unoccupied) trapping centers. During heat-treatment some of the neutral centers thermally decompose, consuming the initially existing negative charge from the N_{f2} distribution, Fig. 4F. One possible mode in which this process can occur is that the decomposition of the defect center releases an H^+ ion. This H^+ ion then diffuses toward the outer surface, combines with a negative charge, and escapes as part of a neutral H_2 molecule. The extent of this process would thus depend on the hydrogen content of the ambient. It should be emphasized that it is not necessary to postulate a detailed process such as described above for analysis of any result except the dependence of the flatband voltage on partial pressure of hydrogen. The over-all process may be described by a reaction

(Neutral defect) + (Negative charge from N_{f2})

= (Negatively charged defect) [4]

It is further suggested that the neutral hydrogen defect centers can also be converted to negatively charged defects by trapping electrons during the photoinjection process (Fig. 4C). The concentration of these centers is given by $N_T(x)$ (with centroid $\overline{x_1}$). At any given stage of the annealing cycle:

$N_d(x)$ = concentration of decomposed centers at x

$N_u(x)$ = concentration of undecomposed centers at x

where,

$$N_T(x) = N_d(x) + N_u(x) \quad [5]$$

If is is assumed that the total number of centers that will decompose at any position x, at saturation, is proportional to the total concentration of these centers at x, *i.e.*

$$N_d(x) = AN_T(x), \qquad A = \text{constant}$$

then

$$N_u(x) = N_T(x)(1 - A) \quad [6]$$

Therefore, $N_u(x)$, $N_d(x)$, and $N_T(x)$ will all have the same centroid $\overline{x_1}$, Fig. 4F. Although there is no prior justification for this last assumption, it is reasonable since the decomposition events should be thermally activated in a random manner. It is also consistent with the observed results of Q-V measurements on as-deposited as well as heat-treated samples, since the centroid of the charges N_T and N'_T and N'_{f2} is the same (see Tables II and V and Fig. 4B and G).

The maximum number of neutral grown-in centers that can decompose is limited by N_{f2} according to Eq. [4]. Thus, after heat-treatment, the saturation flatband voltage, V'_{FB1}, is given by

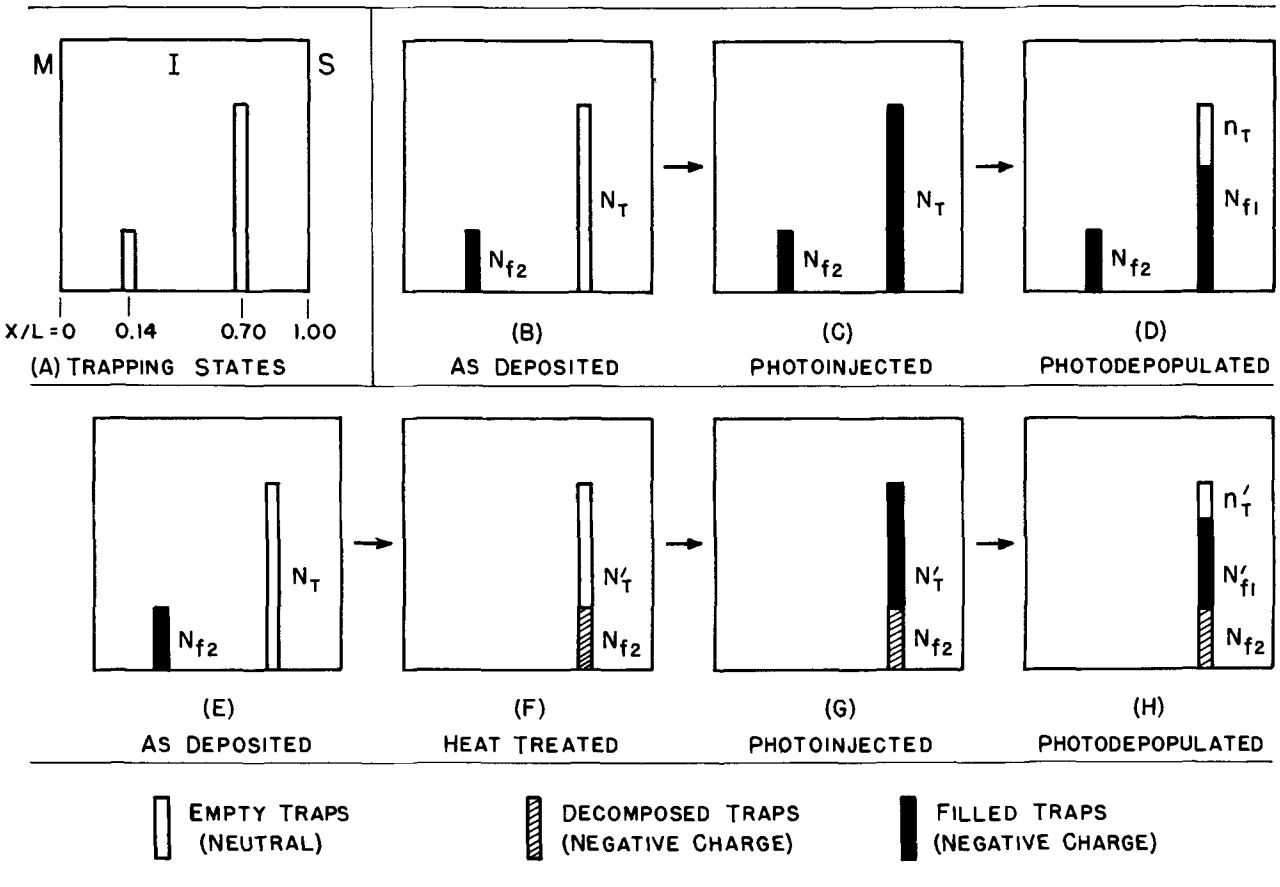

Fig. 4. Schematic representation of spatial charge distributions in MIS specimens incorporating CVD-alumina dielectrics. (A) Over-all geometry and equivalent negative charge distributions, represented by volume-average number densities N and centroids $\overline{x}/L$. (B-D) Photoinjection-photodepopulation sequence on as-deposited Al_2O_3 films [see Table II and Ref. (1)]. (E-H) Proposed heat-treatment-photoinjection-photodepopulation sequence on CVD Al_2O_3 films (see Tables III-V).

$$V'_{FB1} = \frac{\overline{x}}{L} BN_{dmax} = \frac{\overline{x_2}}{L} BN'_{f2} \frac{\overline{x}}{\overline{x_2}} = V_{FB1} \frac{\overline{x}}{\overline{x_2}}, \quad B = \frac{eL^2}{\epsilon} \qquad [7]$$

where $N_{dmax} = N'_{f2}$ the maximum concentration of decomposed centers and $V_{FB1} = \frac{\overline{x_2}}{L} BN_{f2}$ is the as-deposited flatband shift. Note that, as in Ref. (1), the work-function term and the surface-state term in the expression of the flatband voltage (7) are neglected since their contribution was shown to be within the range of reproducibility of the C-V measurements. Using the values of $V_{FB1} = 2.0$V, $\overline{x}_1 = 0.7L$, and $\overline{x}_2 = 0.14L$ for the as-deposited samples, the predicted value of V'_{FB1} is 10V. This value agrees with the observed value of $V'_{FB1} = (12 \pm 2)$ V (see Tables II and IV).

Time dependence of the flatband voltage during heat-treatment.— If N_d = concentration of centers decomposed at time t then $(N_{dmax} - N_d)$ equals the concentration of centers that remain to be decomposed, and if first-order kinetics are assumed

$$\frac{d(N_{dmax} - N_d)}{dt} \propto (N_{dmax} - N_d) \qquad [8]$$

and therefore

$$\frac{N_{dmax} - N_d}{N_{dmax}} = \exp(-t/\tau) \qquad [9]$$

where τ is a characteristic decay time for the decomposition reaction, Eq. [4]. The concentration of defect centers may be converted to flatband voltage, and the result is given by Eq. [2] and is fit to the data in Fig. 1.

A plot of $1/\tau$ *vs.* $1000/T$, T = absolute temperature, is shown in Fig. 5. From the slope of this plot, an activation energy E was determined from the decomposition reaction [4], $E = 33 \pm 1$(kcal/mole). According to the suggested mechansim of the decomposition process this energy can be related to either the decomposition of the center or the diffusion of the hydrogen ion. Diffusion data on hydrogen-related species in alumina are not available and, therefore, it is not possible at the present time to isolate the rate limiting process. We suggest that the kinetics of the postulated decomposition reaction, Eq. [4], are limited by diffusion of hydrogen.

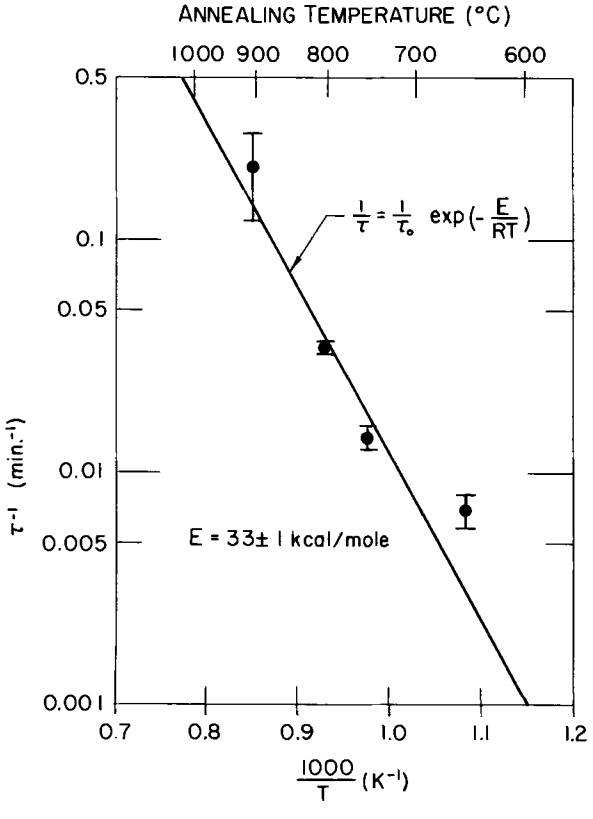

Fig. 5. $1/\tau$ *vs.* $1000/T$, where $1/\tau$ = statistically fit parameter from isothermal annealing data (Fig. 1) and T = annealing temperature. The error estimates on individual data points (solid circles) are obtained from the statistical fit of Fig. 1. The solid line is a statistically weighted least square fit of the data to the two-parameter exponential function indicated on the drawing. R is the gas constant. The quoted error on the resultant activotion energy represents the rms error of the weighted fit.

Photoinjection-photodepopulation in heat-treated samples.—The basic thesis, depicted in Fig. 4E and F, is that heat-treatment results in a reaction between some of the centers N_T and the charges denoted as Q_{f2}. These decomposed centers are negatively charged and cannot trap electrons during photoinjection. Thus, the maximum number of centers that can trap electrons in samples heat-treated to saturation is $N'_T = N_T - N_{f2}$ (Fig. 4F).

If it is further assumed that the distribution in energy of available trapping states (1) is diminished uniformly during decomposition (*i.e.*, the density of sites is diminished without altering the distributions in space and energy) it follows that

$$\frac{n'_T}{N'_T} = \frac{n_T}{N_T} \qquad [10]$$

Using the values of N_T, N_{f1}, N_{f2}, and n_T obtained for as-deposited samples (Table II), the predicted value of $n'_T = 1.0 \times 10^{17}$ cm^{-3}. This value is in excellent agreement with the observed value of $n'_T = 1.0 \times 10^{17}$ cm^{-3}. Similar calculations can be performed to predict the value of various measured parameters from both C-V and Q-V experiments, based on the proposed model of trapping defects and on the equivalent trapping state densities obtained for as-deposited films. Such predicted values are compared with the measured values of the important parameters in Table VI. It is clearly demonstrated that the proposed model is entirely consistent with the experimental results of this research.

Flatband shifts from heat-treatments in H_2/N_2 gas mixtures.—A brief series of heat-treatments in H_2/N_2 atmospheres was described in the section on Results and Discussion. The data show a monotonic increase in the saturation flatband shift with decreasing hydrogen partial pressure. This would be expected if the decomposition of these centers requires hydrogen to be removed from the film. Attempts have been made to develop an analytical expression for the functional dependence of the flatband voltage on p_{H_2} based on the thermodynamics of the reaction represented by Eq. [4] and are presented elsewhere (4). The reversibility of the charge redistribution resulting from subsequent hydrogen heat-treatments implies that no significant structural relaxation occurs upon decomposition. In view of the small "atom" fraction that these hydrogens constitute this seems reasonable. In this respect it should be noted that the very small grain size of these films (~20 nm) implies a rather large number of grain boundary related sites. Thus, the sites which decompose because the hydrogen can get away from them may be related to grain boundaries.

Table VI. Comparison of observed and predicted values of various parameters based on the proposed phenomenological model

	Observed value	Predicted value
n'	1.0×10^{17} cm^{-3}	1.0×10^{17} cm^{-3}
N'_t	5.7×10^{17} cm^{-3}	5.4×10^{17} cm^{-3}
Charges corresponding to N_{f2}	0	0
V'_{FB1}	12.0V	10.0V
V'_{FB2}	36.5V	40.3V
$\Delta V'_{FB}$ (= $V'_{FB2} - V'_{FB1}$)	6.3V	6.5V

Summary and Conclusions

The present experiments indicate that postdeposition annealing treatments in Ar, O_2, and N_2 atmospheres result only in a redistribution of the negative charge grown into chemically vapor-deposited films of Al_2O_3 on silicon. The flatband voltage shift after heat-treatment, which is a measure of this redistribution, reaches a saturation value of approximately 10V. This saturation value is independent of annealing temperature in the range of 600°-900°C. No flatband shift (and hence no charge redistribution) is observed after annealing in H_2 atmospheres. Also, the effect of heat-treatment in Ar, N_2, and O_2 is reversible by subsequent heat-treatment in hydrogen. The temperature dependence of the rate of approach to saturation is consistent with a first-order kinetic process with an activation energy of approximately 33.0 kcal/mole.

The total insulator charge after ultraviolet photoinjection of electrons into the Al_2O_3 films was the same in heat-treated specimens (for all annealing atmospheres) as in as-deposited specimens. The average number density of total negative charges was approximately 6×10^{17} cm^{-3}. The fraction of insulator charge which could be photodepopulated by 2.5 eV photons was approximately 25% in as-deposited films and 17% in films annealed in Ar, N_2, or O_2. In both as-deposited and annealed specimens, photoinjected electronic charge was distributed rather uniformly throughout the insulator film, with a distribution centroid located approximately $0.7L$ from the metal electrode (L = insulator thickness). Fixed charges which incorporated into the as-deposited specimens near the metal-Al_2O_3 interface (average density 2×10^{17} cm^{-3}) were not observed in specimens annealed in Ar, N_2, or O_2.

The experiments were interpreted in terms of a phenomenological model of hydrogen-related trapping centers in Al_2O_3. During the annealing treatments these centers decompose. This decomposition consumes the negative interfacial charges grown into the Al_2O_3 MIS specimens during initial deposition. Thus, the number of centers decomposing during subsequent heat-treatment is limited by the number of grown-in charges. The hydrogen-related defect, which is electrically neutral in the as-deposited sample, can also be negatively charged by trapping conduction electrons, and these centers are responsible for electron capture during photoinjection.

Acknowledgment

We should like to acknowledge many enlightening discussions with Dr. J. J. Curry of Bell Telephone Laboratories, Allentown, Pennsylvania. We also wish to express appreciation for Mr. V. Kapoor of Lehigh University for his help with computer analysis of some of the data. Partial support for S. R. Butler was provided by National Science Foundation.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

APPENDIX

The investigation of charge trapping behavior described in this work involved photoinjection-photodepopulation measurements. The technique of photoinjection-photodepopulation, and the equipment used in these measurements, are described in detail in previous papers (1, 2, 4). An outline of the principles involved in these measurements is presented here.

Figure 6(a) shows a schematic energy band diagram of a metal/insulator/silicon system. It also shows a discrete trap level in the forbidden energy gap of the insulator. Figure 6(b) represents the first step of the measurement cycle, *i.e.*, photoinjection. During photoinjection, electrons are excited out of the valence band of silicon (or, alternatively, from the metal) into states in the conduction band of the insulator by means of photons of energy $h\nu_1$. In simplest approximation this requires that $h\nu_1 > |E_{c\,ins} - E_{v\,Si}|$. If an external field is applied across the insulator, a large photocurrent can be observed in the external circuit. While this photocurrent is flowing through the insulator, some of the charges are captured into localized states with energies lying in the forbidden energy gap of the insulator. The fraction of available trapping states filled during the photoinjection step will be a function of the detailed balance between the capture of electrons in the traps and the re-emission of the trapped electrons due to simultaneous photoexcitation.

Photodepopulation is carried out subsequent to photoinjection. During photodepopulation, electrons are excited out of the traps into the conduction band of the insulator by photons of energy $h\nu_2$. This requires that $h\nu_2 > |E_{c\,ins} - E_T|$ (however, to avoid photoinjection, $h\nu_2 < |E_{c\,ins} - E_{c\,Si}|$). By applying the proper bias voltage, these charges can be collected in the external circuit. These charges are measured by high precision electrometry. The photodepopulation step is represented by Fig. 6(c).

The photodepopulation measurements can be used to determine the energy and spatial distribution of trapping states in the insulator by judicious choice of measurement variables (2). Most of the work described in this paper deals with the parameters representing the spatial distribution. These parameters are obtained

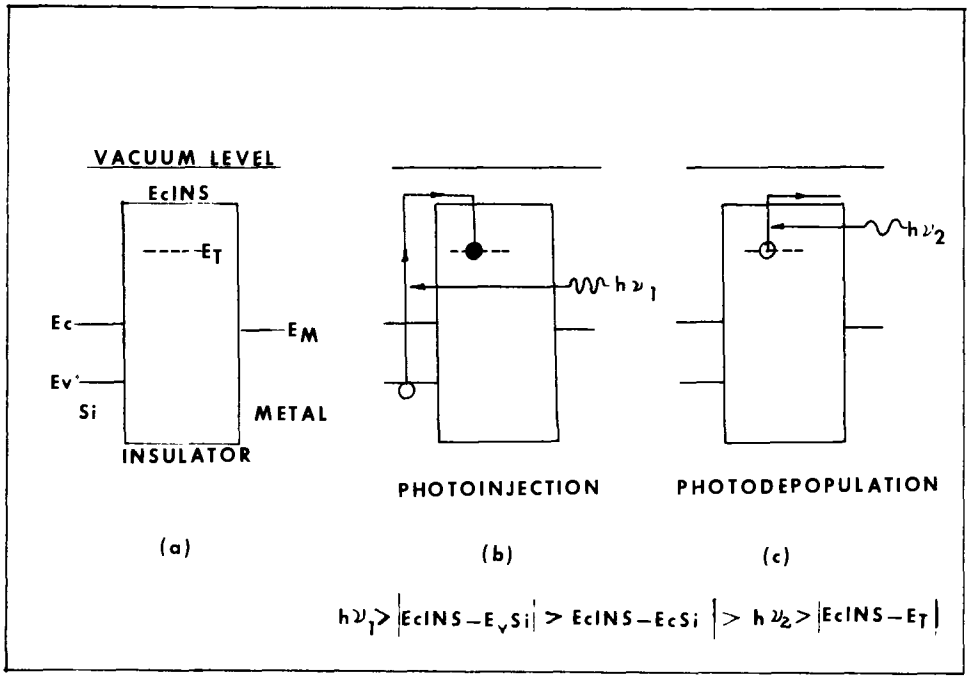

Fig. 6. Schematic representation of photoinjection and photodepopulation processes in MIS structures: (a) hypothetical energy band diagram, (b) photoinjection process, and (c) photodepopulation process.

from determination of the total charge transported through the external (electrometer) circuit during photodepopulation with fixed optical wavelength and fixed applied voltage (Q-V measurement). The wavelength used throughout this series of measurements was 480 nm, slightly longer than the wavelength threshold for photoinjection of electrons from silicon into Al_2O_3 at the applied voltages used (9). The released charge was measured for a time sufficient to reach a steady-state condition, *i.e.*, until the photodepopulation current stabilized at dark current value. The photodepopulation measurements were carried out on the same sample at various voltages while keeping the wavelength of the depopulation light source the same and populating the traps each time by photoinjection with uv light as previously described. The released charge, Q, in each case, was plotted as a function of applied voltage, V. The spatial distribution parameters were obtained from the analysis of these Q-V measurements (4).

New High Sensitive Electron Resist Materials

G. Paal,[1] U. D. Strähle, and G. Kielhorn

AEG-Telefunken, Research Institute Ulm, Germany

ABSTRACT

New negative-working electron resist materials have been synthesized, their sensitivities and technological properties were investigated and compared with the data of materials known from the literature.

Several electron-optical methods for the production of exposure masks and the exposure of wafers have become known in semiconductor technology recently, in addition to the customary light-optical procedures.

Basically, common photoresists may be used for exposure by electron beam, too. Their electron resist sensitivities, defined as the amount of charge per electron resist surface necessary for optimum exposure, are, however, insufficient for obtaining acceptable exposure times. At a maximum sensitivity of 10^{-5} coulombs/cm^2, for instance, a value often reported in the literature (see Table II), exposure times for various electron beam diameters result as listed in Table I, with beam current densities between 1 and 1000 A/cm^2 being possible today. If structure-writing is performed the exposure times quoted may be reduced by selection of advantageous electron beam paths, but they are still too high for commercial application. Therefore, the necessity arises for the synthesis of new materials which, while fulfilling the technical requirements, possess an increased sensitivity for electron beam exposure.

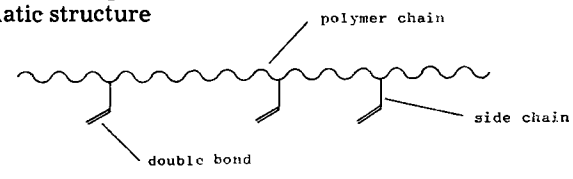
[1] Present address: IBM Laboratories, 703 Böblingen, Germany.

Key words: cross-linking, cross-linkable polymers, polymers, imaging, imaging on polymers, electron beam exposure.

Copolymer	R'	R''
M1	CH_3	CH_3
MG1	CH_3	CH_3 and $-CH_2-\underset{\diagdown\,\diagup\ O}{CH}-CH_2$
C1	H	CH_3
C2	H	CH_3

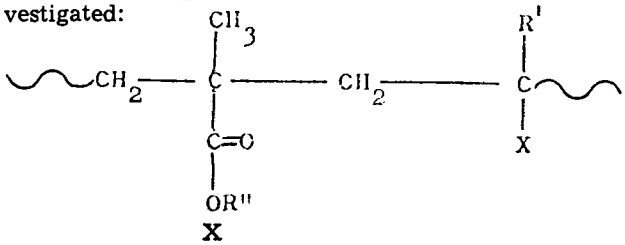
The newly developed materials described here are copolymers of methacrylate and acrylate esters, containing polymerizable double bonds.

These copolymers accord with the following schematic structure



They are obtained by modification of suitable copolymers containing either isocyanate or hydroxy functions, with reactive vinyl monomers like 2-hydroxyethylmethacrylate, 2-isocyanatoethylmethacrylate, or isopropenylisocyanate.

The following materials were synthesized and investigated:



X

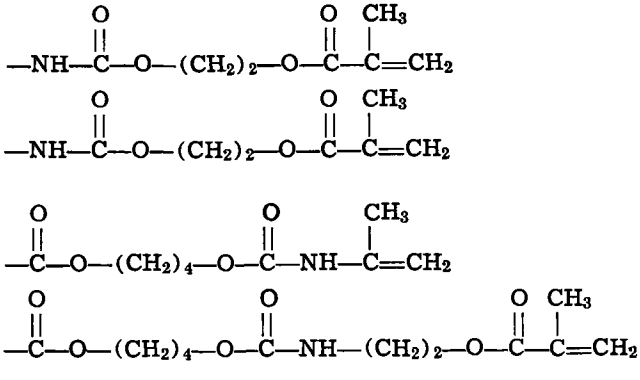


Table I. Wafer exposure times for an electron resist sensitivity of 10^{-5} coulombs/cm²

(The listed exposure times are valid for an exposure of the entire area of the wafer with a focused electron beam with scan-type deflection and an electron beam acceleration voltage of approximately 10 kV, without consideration of the attainable data flux of the data transmission and the speed of beam deflection through the deflection system)

Electron beam diameter (μm)	Exposure time per unit area at an electron beam density of 1 A/cm² (sec/cm²)	1000 A/cm² (sec/cm²)
0.01	10^7	10^4
0.1	10^5	10^2
1	10^3	1

At electron beam exposure of films of these materials the exposed areas become insoluble; the unexposed areas retain their solubility and can be removed.

Experimental

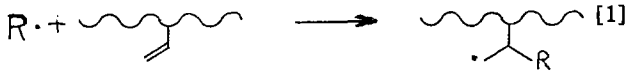
Preparation and exposure of the films.—Thin films 0.1 μm thick of the photoresists KAR-3, KTFR, KOR (Kodak), AZ 1350, and the copolymers M1, MG1, C1, and C2 are produced by centrifuging the filtered solutions onto Cr-plated glass substrates. As thinners or solvents, respectively, the original thinners were used for the photoresists, and acetic acid ethyl ester for the copolymers M1, MG1, C1, and C2. The films were dried in air for 10 min, then heated at 60°C for another 10 min. The development of the films exposed by the electron beam was performed with the original developers for commercial photoresists and with trichloroethylene for the copolymers M1, MG1, C1, and C2.

Several 1 × 1 mm² sections on a substrate were exposed in a scanning electron microscope (Cambridge Stereoscan). The line spacing amounted to 2 μm and the line width to about 0.5-0.7 μm at a 500-line scan.

The electron beam acceleration voltage of 20 kV and the exposure time of 20 sec per section was kept constant throughout the experiments. In order to obtain a step-function of the exposure the electron beam current was controlled from section to section within the range from 10^{-11} to 10^{-8}A. The sample current was conducted off through a chromium layer below the substrate, its amperage was measured for the calculation of the electron resist sensitivity. After exposure and development of the substrates the line structure was microscopically evaluated. From the data of the individual sections showing optimum exposure the sensitivity of the electron resist films was then calculated.

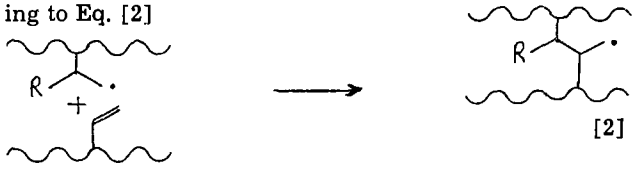
Results of the Measurements and Discussion

The values of electron resist sensitivities that were measured are listed in Table II and compared with literature values. It is seen from the table that sensitivity figures reported in the literature check with our measurements within the order of magnitude. These sensitivity values may be taken for a calibration of the measuring apparatus. The highest electron resist sensitivity of the materials measured was found in the newly developed copolymers M1, MG1, and C2 (negative working) with 4 × 10^{-7}, 2 × 10^{-7}, and 1 × 10^{-7} coulombs/cm². They possess, at the same time, good technological properties. For the (negative working) copolymer C1, a poor sensitivity was measured with 2 × 10^{-6} coulombs/cm². The cross-linking of these materials is initiated by a free radical symbolized by R· which is generated during the electron beam exposure. It is known that through the interaction of high energy radiation with organic polymers free radicals may be formed (6). A free radical is a chemically reactive species having an unpaired valence electron, and can react with the double bond of a polymer chain as shown in Eq. [1]



[1]

The product of this step is another free macro radical which in turn can react with a third molecule according to Eq. [2]



[2]

Again, the product is a free macro radical which continues to react in the same manner, thus producing a polymer network. We think that the high sensitivity of the novel materials can be explained by this chain mechanism of cross-linking.

Synthesis of the Polymers

Copolymer M1.—To 10g of dichloromethane, 5g methacrylic acid-methyl ester (freshly distilled), 5g isopropenylisocyanate, and 10g benzene are added. The dichloromethane is then distilled off in order to remove water traces. Now 20 mg α,α-azoisobutyronitrile is added and polymerized in nitrogen atmosphere for 24 hr at 50°C. Precipitation with petroleum ether and repeated re-precipitation from $CHCl_3$/petroleum ether

Table II. Electron beam sensitivity of macromolecular organic materials

Type	Material	Film thickness, μm	Acceleration voltage, kV	Electron resist sensitivity: Measured values, 10^{-8} coulombs/cm²	Electron resist sensitivity: Literature values, 10^{-8} coulombs/cm²	Literature reference[a]	Remarks
Positive resists	Cellulose acetate	0.5	10	—	50,000	3	Poor chemical resistance

[a] x is newly developed materials.

yields 2.6g of copolymer M. Then 2.6g copolymer M is dissolved in 30 ml dry dimethylformamide (DMF) and modified by reaction with 8.5g 2-hydroxy ethylmethacrylate at 50°C for 16 hr. After precipitation, dissolving in $CHCl_3$, drying with Na_2SO_4, precipitating with petroleum ether, and repeated re-precipitation, the copolymer M1 thus obtained is dried in vacuum.

Copolymer MG1.—To 10g of dichloromethane, 2.5g methacrylic acid methyl ester (freshly distilled), 2.5g methacrylic acid glycidyl ester (freshly distilled), 5.0g isopropenyl isocyanate, and 10g benzene are added. The dichloromethane is distilled off in order to remove water traces. After its removal from the mixture, 20 mg α,α-azoisobutyronitrile are added and copolymerized in nitrogen at 50°-55°C for 24 hr. After precipitation in petroleum ether, repeated re-precipitation from chloroform/petroleum ether and drying, 5.2g of copolymer MG are obtained.

The copolymer MG is modified by reaction with 16g of 2-hydroxyethylmethacrylate in dry DMF at 50°-55°C for 16 hr. After cooling off it is precipitated with water, dissolved in chloroform, dried with Na_2SO_4, and precipitated with petroleum ether. The copolymer MG1 is obtained after re-precipitation from chloroform/petroleum ether and drying in vacuum.

Copolymer C1.—4.4g copolymer C [composition 25 m/o (mole per cent) butanediolmonoacrylate and 75 m/o methacrylic acid methyl ester], 0.3g dibutyl-tin-diacetate, 0.1g hydroquinone, and 1.7g isopropenylisocyanate are dissolved in 20 ml dry DMF and heated in nitrogen atmosphere at 60°C for 14 hr. Precipitation is now performed with H_2O, the gluey sediment is dissolved in $CHCl_3$, dried with Na_2SO_4, precipitated in petroleum ether. The copolymer C1 is obtained after repeated re-precipitation from $CHCl_3$/petroleum ether and drying in vacuum.

Copolymer C2.—4.4g copolymer C (composition 25 m/o butanediolmonoacrylate and 75 m/o methacrylic acid methyl ester), 0.3g dibutyl-tin-diacetate, 0.1g hydroquinone, and 3.2g 2-isocyanatoethylmethacrylate are dissolved in 20 ml dry DMF and heated in nitrogen atmosphere at 60°C for 14 hr. Then it is precipitated with H_2O, dissolved in $CHCl_3$, dried with Na_2SO_4, and precipitated in petroleum ether. The copolymer C2 is obtained after repeated re-precipitation from $CHCl_3$/petroleum ether and drying in vacuum.

The Preparation and Properties of a Polysiloxane Electron Resist

E. D. Roberts

Mullard Research Laboratories, Redhill, Surrey, England

ABSTRACT

The preparation of polymethylcyclosiloxane (PMCS) is described. PMCS may be used as a resist in which siliceous film patterns may be formed by irradiation with an electron beam. These siliceous patterns are readily developed and may be used directly in semiconductor technology as diffusion barriers or as etch-resistant layers, and after suitable heat-treatment they may be used also as passivating layers. Transistors have been made using PMCS film patterns defined by electron beams as diffusion barriers and as passivating layers. The sensitivity of PMCS to irradiation may be increased by controlled condensation to give a higher molecular weight polymer, or by introducing vinyl groups to replace some of the methyl groups in the polymer. The chemical changes which occur in PMCS upon irradiation by electrons have been investigated and it is shown that at doses normally used in making film patterns of use in semiconductor technology, cross-linking occurs mainly through the hydroxyl groups present in the polymer. Subsequent treatment (thermal or radiation) can eliminate organic residues to produce a film which is identical to thermally grown silica.

In recent years, electron beam techniques have been studied extensively with a view to making solid-state electronic devices having geometrical features with dimensions less than about 2 μm. At these dimensions, normal photolithographic techniques for defining patterns become unreliable and yields of working devices rapidly diminish with the dimensions. It is believed that electron beam techniques will enable improved yields of devices with features down to 1 μm or less to be obtained.

Much work on electron beam technology has used otherwise conventional techniques, the electron beam merely replacing the ultraviolet lamp and mask normally used to obtain the desired film patterns. Conventional photoresists have been used (1-3) followed by chemical etching steps to produce patterns in silica

Key words: siliceous films, electron irradiation, diffusion barriers, passivating layers.

films, for example, though special resists appropriate particularly to electron beam technology have also been developed (3-8). Generally these electron resists are not photosensitive and do not require to be used in special lighting conditions.

In our application of electron beams to semiconductor technology, it was felt that in order to obtain the full advantage of the potentially high resolution which the method offers, steps involving chemical etching should be avoided so that film patterns produced by the electron beam should not be degraded by the undercutting which always accompanies chemical etching. The beam would be used to produce directly film patterns of any material required. Silica films are used extensively in silicon planar technology as diffusion barriers and as insulating and passivating layers, and the ability to define silica film patterns directly by an electron beam should be a useful process.

Earlier publications (5, 9) described our work on the preparation of siliceous films from various silicon compounds by electron beams, and it was concluded that the most satisfactory materials for this purpose were a range of solid siloxane polymers. These polymers are normally soluble, but become cross-linked and therefore insoluble when irradiated by electrons. Solutions of the polymers were applied to a substrate (usually silicon) which was spun rapidly to produce a film of polymer on the substrate. The spun films were irradiated by an electron beam, usually scanned to trace out the required pattern at a rate which produced sufficient cross-linking to render the polymer insoluble. Upon rinsing the film in a solvent, only the unirradiated polymer dissolved, leaving a pattern of cross-linked siliceous film upon the substrate. Subsequent treatment enables the film to be converted to silica, which may be used as a diffusion barrier (5), a passivating layer, or an etch-resistant mask.

This paper describes the preparation and use in electron beam technology of one of these electron resists—polymethylcyclosiloxane (PMCS)—and discusses the chemical reactions which occur during irradiation. Typically, films of this substance shrink in thickness by up to 8-9% during an exposure of 150 $\mu C/cm^2$ by 10-15 keV electrons. At exposures greater than about 140 $\mu C/cm^2$, no further loss in film thickness occurs during the solvent development process. Subsequent heat-treatment, including densification, results in further shrinkage, the silica film ultimately produced being about 60-65% of the thickness of the PMCS film originally applied to the substrate. Lateral shrinkage during these processes is negligible. PMCS required at least 140 $\mu C/cm^2$ to form a fully exposed image, and this exposure is rather high. Methods of making more sensitive resists of similar type are therefore also considered.

Preparation of Polymethylcyclosiloxane

It was shown by Wagner et *al.* (10) that some organotrichlorosilanes could be hydrolyzed to give soluble solid polymers if suitable precautions were taken to minimize the time of contact between the hydrolysate and the hydrochloric acid produced by the reaction. We have found that the procedure may be applied also to methyltrichlorosilane, though the risk of producing insoluble three-dimensionally cross-linked polymer is greater with this than with other organotrichlorosilanes, and some product is always lost by this side reaction.

Polymethylcyclosiloxane was prepared by hydrolyzing methyltrichlorosilane in a medium of diethyl ether and ice using a procedure similar to that described by Wagner et *al.* (10). Any insoluble gel which formed during the preparation was rejected. The resulting solution of methylsiloxane polymer in ether was evaporated to dryness, yielding a solid residue. The solid product can condense spontaneously through the hydroxyl groups present in it to an insoluble cross-linked form. It was, therefore, stored and used as a 25% w/w (weight in weight) solution in methyl isobutyl ketone, which remains stable for at least 9 months.

The polymer was found to contain no elements except silicon, carbon, hydrogen, and oxygen and no functional groups except hydroxyl. It is probable that each silicon atom has a methyl substituent group, for it is unlikely that during hydrolysis the silicon-methyl bond would be broken. The average molecular weights of the polymers (determined cryoscopically in acetic acid or in 1,4-dioxan) usually lie within the range 500-700, though it has been shown that fractions having molecular weights between 280 and 1200 are present. It seems likely that the polymer is a mixture of chains of cyclic methylsiloxanes (probably mainly cyclotetrasiloxanes) containing some silanol groups. It contains 40% by weight of silicon.

Irradiation of PMCS by Electrons

The apparatus in which PMCS films were exposed to electrons to produce patterns of siliceous film have been described elsewhere (5,9). Figure 1 shows the variation with exposure of the thickness of exposed and developed siliceous film on a silicon substrate. The thicknesses have been normalized to that of the unexposed PMCS film applied initially. The exposures were made in a machine (9) in which a focused beam of electrons of energy 15 kV and nominally 0.25 μm in diameter was scanned with overlapping lines in a TV-type raster to expose uniformly a 100 μm square area of the resist. The current was measured with a sensitive ammeter in series with the substrate to correspond with our practical application of this technique. No corrections for the effects of secondary electrons have been made. The exposure was calculated from the measured current, exposed area, and total exposure time and was varied by changing the scanning speed. The film thicknesses were measured with a Talystep 1 instrument, the interference colors observed in the films corresponding closely with those expected at the measured thicknesses.

Figure 1 shows that the film shrinks in thickness by about 8% when adequately exposed (140 $\mu C/cm^2$). This shrinkage occurs during irradiation and no material appears to be leached out during development. A film initially 4800Å thick was 4400Å thick after irradiation, and remained 4400Å thick after development in acetone.

Chemical Changes during Electron Irradiation

The changes occurring in PMCS films during electron irradiation and during subsequent heat-treatments have been studied by infrared spectroscopy. For this purpose, PMCS films on silicon substrates which had been polished on both sides were irradiated by an

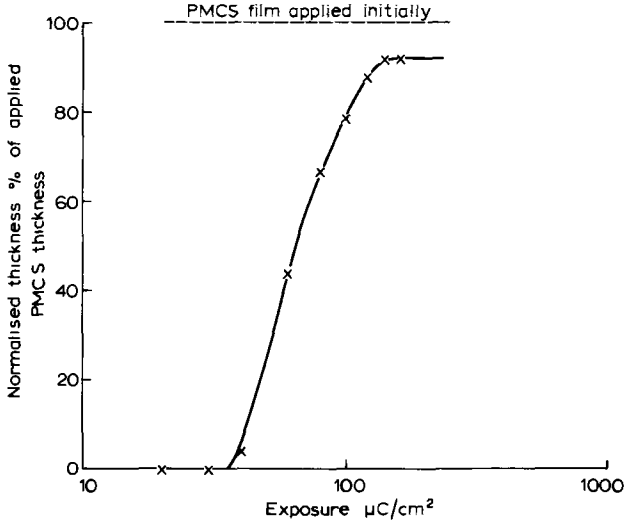

Fig. 1. Variation in thickness of irradiated developed PMCS patterns with exposure.

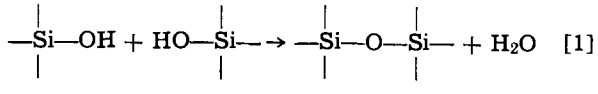
electron beam 1 cm in diameter (5), the exposed circular pattern being developed in acetone. The maximum electron energy available in this machine (5) is 10 keV. The exposure characteristics at this energy appear to be identical with those at 15 keV shown in Fig. 1, so the large area films for infrared spectroscopy were irradiated with 10 keV electrons. The exposure was determined by a purpose-built charge integrating instrument, which may be preset to deliver the desired exposure to the specimen. Although the current density in the large area flood beam (5) is less by a factor about 10^6 than that in the finely focused scanned beam described earlier (9), we have been unable to detect any difference in its effect on the resist when the average exposure is the same in each.

The infrared absorption spectrum of a film of PMCS is given in Fig. 2, together with assignments for the absorption bands (11). The band between 1000 and 1100 cm^{-1} is of most interest. The maximum absorption occurs at 1090 cm^{-1}, corresponding with the presence of tetrasiloxane rings. The changes which occur upon irradiation and subsequent heat-treatment of PMCS films may be seen in Fig. 3-5.

Figure 3 shows the effect of increasing exposure to the electron beam. The exposures used lie near the ends of the working range which is considered to be satisfactory for defining patterns of fine geometry in the resist (85-300 $\mu C/cm^2$).

The most noticeable change is the almost complete elimination of the absorptions at 3200-3300 cm^{-1} and at 900 cm^{-1}, which are due to the Si-OH group in PMCS. The peaks due to the Si-Me groups are also reduced and the shape of the broad band centered around 1090 cm^{-1} in PMCS is altered, the maximum absorption having shifted to about 1020 cm^{-1}. During irradiation at these exposures, PMCS becomes insoluble in solvents and infusible which means that cross-links are produced between molecules, and this process is accompanied by a reduction in thickness of the film by about 10%. The spectra suggest that cross-linking occurs extensively through hydroxyl groups, and to a lesser extent at these exposures through methyl groups, the over-all reactions probably being:



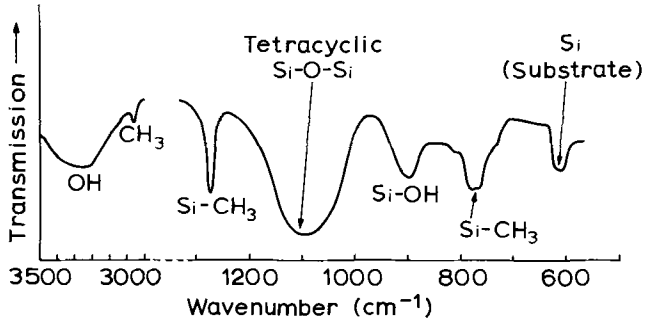


Fig. 2. Infrared absorption spectrum of PMCS film on silicon

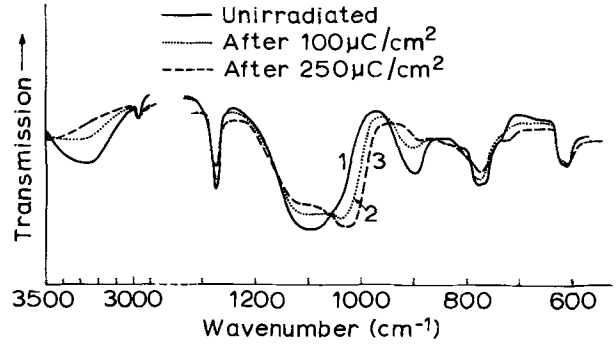

Fig. 3. Effect of electron irradiation on infrared absorption of PMCS.

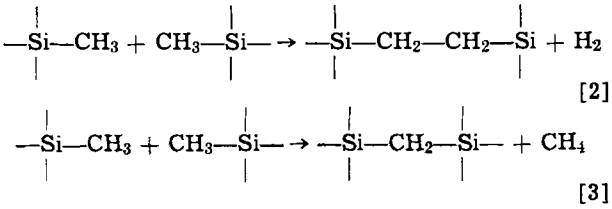

Although the absorption peaks which correspond to the siloxane and alkylene bridges produced all appear in the region 1000-1150 cm^{-1} where there is already a broad intense band, a small superimposed peak appears in Fig. 3 (curve 3) and Fig. 4 (curves 1 and 2) at about 1060 cm^{-1}, which could be indicative of the formation of alkylene bridges (11). It is noteworthy that this peak disappears again after subsequent treatment during which the organic residues are reduced markedly [Fig. 4 (curve 3)].

The broad band at 1000-1150 cm^{-1} shows a double absorption in the irradiated films which is not unlike that observed in both long chain and higher cyclic siloxane polymers (12). Cross-linking of PMCS molecules could be regarded as producing some large rings or long highly branched chains within a cross-linked network.

Figure 4 shows the effects of still higher exposures. The samples were prepared by irradiating PMCS films on silicon at 250 $\mu C/cm^2$ and developing the exposed pattern in acetone. The developed patterns were then re-exposed as shown in the figure. Direct irradiation with the total required exposure would result in loss of resolution of patterns, and if it were desired to give a large exposure to patterns in practice, it would be done in two stages, as was done with these samples. Continuation of the same trends as were observed with lower doses occurs, the absorption due to residual organic groups being markedly reduced, especially when the exposure has reached 2750 $\mu C/cm^2$. This must imply scission of many of the silicon-alkyl bonds within the film, the organic groups being eliminated as volatile fragments. The broad peak centered on 1020 cm^{-1} is tending to move back towards higher wave numbers at these higher exposures and the whole spectrum is approaching that shown by amorphous silica (13). It appears that the effect of very high exposures is to convert the siliceous film to a form resembling closely the thermal silica films commonly used in semiconductor technology.

Figure 5 is the spectrum of a film exposed at 250 $\mu C/cm^2$ which after development, has been heated in wet oxygen (saturated with water vapor at 95°C) at 650°C for 8 min. This treatment seems to eliminate all hydroxyl groups and virtually all organic residues and the spectrum is almost identical with that of amorphous silica (13). It has also been found that PMCS films defined by the electron beam and heat-treated in this way have after densification in nitrogen at 1000°C, the same refractive index and etch rate in hydrofluoric acid as amorphous silica has. The process is therefore a convenient method of converting PMCS film patterns to silica.

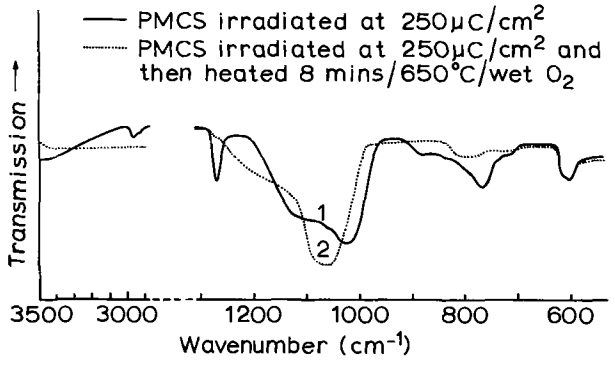

Fig. 5. Effect on infrared spectrum of heating electron beam defined film of PMCS in oxidizing atmosphere.

Preparation of PMCS of Higher Sensitivity

It was shown by Wagner (10) that silanol condensation in vinylcyclosiloxane polymers occurred in the presence of ammonia to produce higher polymers.

It was observed with a few early batches of PMCS that freshly prepared material required an exposure around 150 $\mu C/cm^2$ to produce a satisfactory image, while after a few weeks' storage an exposure around 30-40 $\mu C/cm^2$ only was required. It was found that the average molecular weights of the polymers had increased during storage from 500-700 to 700-1100, and that the polymer solutions contained ammonia equivalent to about 1 ppm by weight on the polymer. Until this was discovered, the ether extract of polymer had been washed during the preparation only until the washings were neutral to phenolphthalein, In subsequent preparations, a procedure using Nessler's reagent was introduced. It is estimated that after testing the washings in this way, the residual ammonia is less than 0.02 ppm on the polymer, and indeed the solutions have remained stable for periods up to 9 months.

The increase in sensitivity observed suggested that more sensitive PMCS might be made if the ammonia-catalyzed silanol condensation could be conducted in a controlled manner.

Methyltrichlorosilane was therefore hydrolyzed and was washed until free from hydrogen chloride (10). The ether extract was treated with dilute ammonia solution for various lengths of time, after which the ammonia was washed out as described above, and the polymer worked up to prepare a working solution (25% w/w in methyl isobutyl ketone). The ammonia concentration was calculated according to an equation, the derivation of which is given in the Appendix.

The results obtained on polymer treated with 0.2% by weight of ammonia are shown in Fig. 6. The increase in molecular weight of the polymer is accompanied by a decrease in the hydroxyl content as shown in Fig. 7. Clearly the ammonia treatment has caused further condensation of the polymer molecules through their hydroxyl groups. The expected increase in sensitivity has also occurred in the early stages (up to 3½ hr treatment) (Fig. 6). Continued treatment, however, produced an unexpected fall in molecular weight accompanied by a decrease in sensitivity to electrons. This must imply chain scission, but the end result cannot be due to simple hydrolytic fission of the chains, for this would produce an increase in the hydroxyl content of the polymer, which is contrary to observation (Fig. 7).

It is easy to understand that the larger molecules present after condensation would require a smaller number of cross-links to render them insoluble than would the smaller molecules originally present, resulting in the observed increase in sensitivity to electrons of the material of increased molecular weight.

The variation of residual film thickness with exposure for condensed PMCS of this type is shown in Fig. 8 (curve 1), together with curves for the two cyclo-

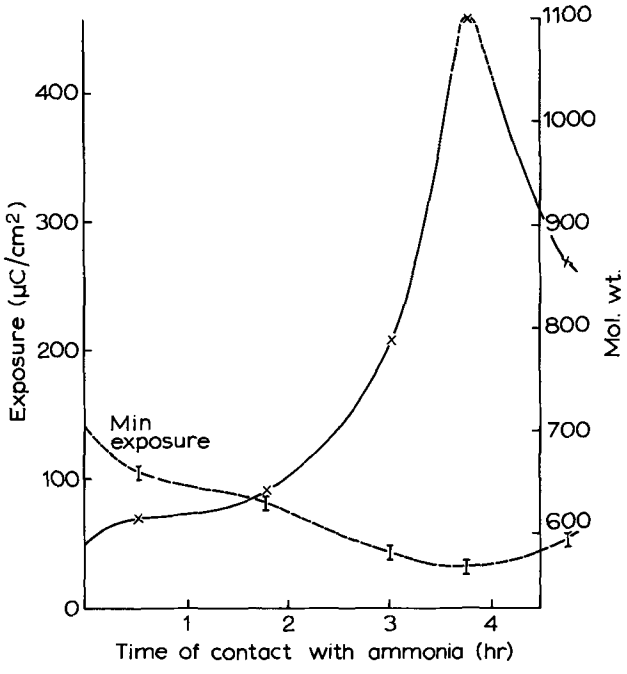

Fig. 6. Effect on properties of PMCS of ammonia-catalyzed condensation (0.2% NH_3 on PMCS).

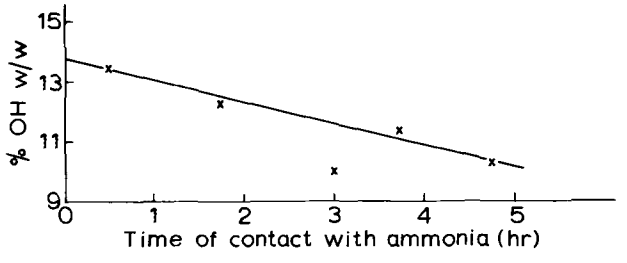

Fig. 7. Change in hydroxyl content of PMCS during ammonia-catalyzed condensation (0.2% NH_3 on PMCS).

siloxane polymers containing vinyl groups which are described below.

Other methods of increasing the electron sensitivity.—We have shown earlier (5) that a polymer made by hydrolysis of vinyltrichlorosilane has much higher sensitivity to electrons than PMCS does. Indeed the sensitivity appears to depend markedly upon the nature of the organic group present, as is shown by the values given in Table I. The great sensitivity of the vinyl polymer is almost certainly due to a chain reaction occurring through the vinyl group and initiated by the electron beam. Similar large increases in sensitivity have been observed in other systems when a vinyl group is introduced (14).

Table I. Variation of sensitivity of polycyclosiloxane electron resists with nature of organic group attached to silicon atom

Organic group attached to silicon	Minimum exposure required to form satisfactory image ($\mu C/cm^2$)
vinyl	4
methyl	130
ethyl	250
phenyl	800

Conversely, the low sensitivity of the phenyl compound is probably due to steric hindrance (shielding) of the hydroxyl group by the bulky phenyl group coupled with the known resistance of the phenyl group itself to the effects of ionizing radiation.

We have not investigated polyvinylcyclosiloxane extensively, but we have shown that fine geometrical patterns can be defined in it (detail <1 μm) and that it can be used as a diffusion barrier (5). It needs however, to be applied initially as a thicker film than PMCS to have the same ability to prevent diffusion of dopants into silicon. This may be the result of the larger amount of organic residues which could result in the film being rather more porous than PMCS films. This is one of the reasons why we have not favored it, believing that the more closely the structure of the polymer approached that of silica (*i.e.*, the smaller the organic radicals present) the better the system was likely to perform. We have found, however, that methyl-vinyl copolymers can be made which should enable the advantages of both materials to be brought together in one compound. Cohydrolysis of a mixture of 5 moles methyltrichlorosilane with 1 mole of vinyltrichlorosilane yields a polymer not very different in composition from PMCS but which enables patterns to be formed within the exposure range 10-80 $\mu C/cm^2$. Exposure curves for the two polymers containing vinyl groups are given in Fig. 8 (curves 2 and 3).

Use of PMCS in Semiconductor Technology

We have used film patterns defined in the resist PMCS by electron beams as a barrier against the diffusion of arsenic, boron, and phosphorus and satisfactory results have been obtained even in processes involving high doping levels such as those for emitter regions. In this method, the diffusion barrier pattern is formed by applying a film of PMCS to the silicon substrate, exposing it to an electron beam to produce the required pattern [generally using a scanned electron beam (9)] which is developed by rinsing the silicon slice in acetone for a few seconds. During development all the unirradiated PMCS is dissolved away leaving a pattern of siliceous film corresponding to the electron irradiation pattern. The siliceous pattern so produced may be used directly as a diffusion barrier, though it is beneficial whenever possible to densify the film before the diffusion process by heating in nitrogen at temperatures up to 1250°C (5). After diffusion, the siliceous diffusion barrier is completely removed from the substrate by treatment with hydrofluoric acid, and a fresh PMCS film is applied to provide a new pattern for the next diffusion stage. Thus in this method, none of the silicon substrate is used to provide the oxide diffusion masks.

We have also used PMCS film patterns defined in the same way by the electron beam as passivating layers in making bipolar transistors. For this purpose, it was found beneficial to heat the developed patterns for 10 min in wet oxygen at 680°C followed by densification in dry nitrogen for 30 min at 900°C. The heat-treatment in wet oxygen has been shown to eliminate almost completely any organic residues in the film (Fig. 5).

n-p-n Bipolar transistors with diffusion barriers and passivating layers defined by electron beams in PMCS have been made. Figure 9 is a photomicrograph of such a transistor before metalization showing the passivating layer produced by electron irradiation of PMCS. The outlines of the diffused base and emitter regions may be seen clearly, these areas having also been defined in PMCS films (which were subsequently removed) by the beam.

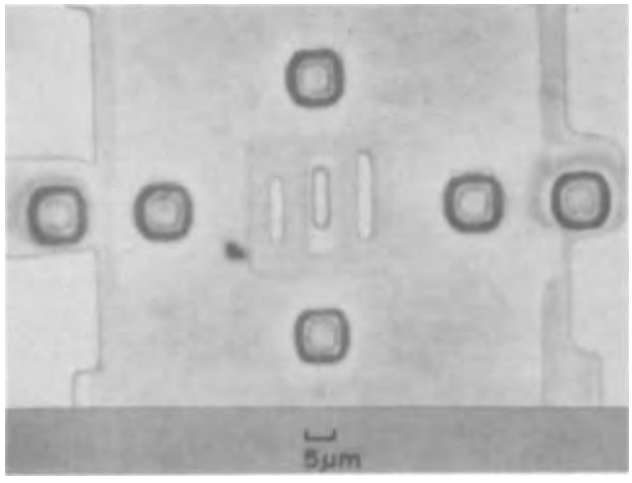

Fig. 9. Electron beam defined passivating layer on n-p-n bipolar transistor.

The preparation of transistors using PMCS will be described in more detail in a separate paper (15). We have yet made only transistors with emitters 5 μm wide, and these have had gains up to 100, but some have shown rather high leakage currents, sometimes being as high as 10 μA. The transistors had no phosphosilicate glass layers over the passivating layer, however, as in their method of fabrication any phosphosilicate glass which forms during the last diffusion is removed before applying the passivating layer. This is in contrast to some conventional processing. It is known that conventionally made transistors also can show high leakage currents if there is no phosphosilicate glass layer over the passivating layer. A method whereby phosphosilicate glass patterns can be formed by electron beam techniques over passivating layers similarly defined has been described recently, together with test results on the composite films (14). Tests of MOS capacitors having a dielectric of silica with a thin layer of phosphosilicate glass upon it, both layers being defined by electron beams in PMCS type resists, have shown that capacitance-voltage characteristics of the capacitors do not change when the capacitors are subjected to temperature-voltage stress, though there is a large change under these conditions if the phosphosilicate glass is not present. By analogy with conventional processing, it is expected that the application of an

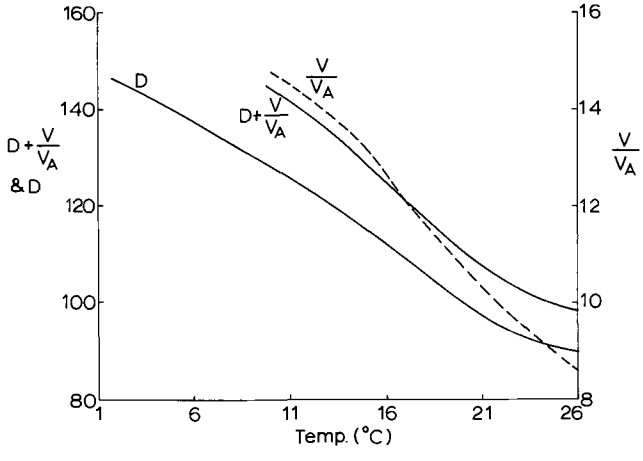

Fig. 10. Variation with temperature of terms required in calculating ammonia concentration during catalyzed condensation of PMCS.

electron beam defined phosphosilicate glass layer (14) to a passivating layer prepared from PMCS should stabilize the transistors, and the leakage current should then decrease to normally encountered values. This has yet to be confirmed experimentally, however.

PMCS film patterns have also been used as etch-resistant films, particularly for etching silicon with hydrofluoric acid/nitric acid mixture, and we have used them for etching patterns in metal films. The difficulty of removing the exposed PMCS film makes it less attractive for the latter application, however, unless the system is such that hydrofluoric acid may be used for removing the PMCS etch resist.

Summary and Conclusions

A method of preparing a polymethylcyclosiloxane has been described. It has been shown that upon irradiation by electrons, cross-linking between molecules occurs initially through silanol groups, while at higher exposures, this probably occurs also through methyl groups. At very high exposures or upon subsequent heat-treatment, organic residues are almost completely eliminated leaving a film with properties almost identical to amorphous silica.

A method whereby the average molecular weight of the polymer may be increased is described, and this leads to polymers having greater sensitivity to the effects of electron irradiation. Still further increases in sensitivity may be achieved by introducing vinyl groups into the polymer molecules.

Siliceous films may be produced in any desired pattern by irradiating films of the siloxane polymers described with electron beams which are masked or scanned to produce the desired pattern and then subjecting the irradiated films to a suitable development process. The siliceous films may be used in semiconductor technology as diffusion barriers, etch resistant layers, and, after suitable heat-treatment, as passivating layers.

APPENDIX

Calculation of Ammonia Concentration during Catalyzed Condensation of Cyclosilanols

Let W = wt of polymer used, V = volume of ether used, A_p = per cent by weight of ammonia on polymer in ether layer at equilibrium, A_w = per cent by weight of ammonia in ammonia solution used, V_a = volume of ammonia solution used, S_w = solubility of water in ether, g/100 ml, S_e = solubility of ether in water, g/100 ml, Δ_e = specific gravity of ether, and D = distribution coefficient of ammonia between water and ether.

At equilibrium

Net volume of ether layer =
$$V - S_eV_a/100\Delta_e + S_wV/100 = V_e$$
Net volume of water layer =
$$V_a - S_wV/100 + S_eV_a/100\Delta_e = V_w$$
Concentration of ammonia in ether layer =
$$WA_p/100V_e$$
Concentration of ammonia in water layer =
$$(A_wV_a - WA_p)/100V_w$$

$$\therefore \quad (A_wV_a/WA_p - 1)V_e/V_w = D$$

If $S_eV_a/100\Delta_e = S_wV/100$

then $V_e = V$ and $V_w = V_a$

$$A_wV/WA_p = D + V/V_a$$
$$V/V_a = S_e/S_w\Delta_e$$

The terms on the right of the last two equations are temperature-dependent, and Fig. 10 shows this dependency. The value of $D + V/V_a$ may be obtained by measuring the temperature of the solution and reading its value from the graph. V and W are predetermined, and A_w or A_p may be obtained by fixing the value of one of them.

In this work, A_p was specified and the value of A_w required to give this value was calculated. The ammonia concentration was adjusted to this value and V_a was calculated from the value of V/V_a appropriate to the temperature of the solution.

A New Family of Positive Electron Beam Resists—Poly(Olefin Sulfones)

L. F. Thompson and M. J. Bowden

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Poly(olefin sulfones) have been shown to represent a new class of positive electron beam resists exhibiting sensitivities in the region of 1-3 $\times$ 10^{-6} coulombs cm^{-2}. Processing variables have been evaluated and exposure characteristics determined. These materials can be used in two development modes, (*i*) as a conventional solvent-developed system and (*ii*) as a system which self develops during e-beam irradiation by depolymerization followed by vaporization. Limitations of this "vapor development" process are discussed.

Recent trends in microelectronic fabrication are towards reducing the size of large scale integrated circuits. Standard photolithographic techniques can be used to generate detail on a scale of ~3-5μ in both thin film conductor and dielectric materials. Structures with a 1-3μ resolution limit can only be fabricated with great difficulty using optical techniques. In contrast it has been shown (1) that electron beam lithography is capable of producing high resolution (<1μ) patterns with high yields.

Two primary competing reactions occur when a polymer is irradiated with a 1-30 kV electron beam, cross-linking, and chain scission. A polymer behaves as a positive resist if the rate of chain scission is substantially greater than the rate of cross-linking. Chain scission reduces the average molecular weight and increases the solubility of the polymer. When cross-linking is the predominant reaction, the converse is true and the polymer is termed a negative resist. A second reaction can occur to amplify the scission process, namely chain depropagation. This results when two polymer radicals, formed by chain scission, spontaneously split off monomer units. The extent of chain depropagation depends on the rate of radical termination and the rate of depropagation. If the polymer chain completely depolymerizes, the film will be totally removed thereby eliminating a solvent development step. We have termed this process vapor development.

The general use of electron beam fabrication techniques will require new classes of polymeric resist materials which have been designed for this process and optimized with respect to resolution, sensitivity, and etch resistance. The use of photoresists in e-beam lithography is not desirable since these systems are unnecessarily complex. Electron resists can be pure polymer systems offering significant advantages. Both positive and negative resists are desirable for a versatile lithographic system. However, most polymeric systems cross-link under irradiation and of the few which do degrade (notably polymethyl methacrylate), none have sensitivities high enough for economic fabrication of devices.

Poly(olefin sulfones) constitute a family of alternating copolymers of sulfur dioxide and an olefin. They have been reported to degrade rapidly under γ-irradiation (2), with a G(scission) of 10-12, far higher than any other existing positive resist. We have recently shown that they can be readily degraded in an electron beam and serve as good positive electron beam resists (3). These materials can be used in two development modes—firstly, as a conventional solvent-developed system and secondly, under proper conditions, as a solvent-free, vapor-developed system. The use of polysulfones as positive resists in both modes is described in this paper. The resists have been evaluated as chemical etching masks for silicon dioxide and tungsten and as a lift-off[1] mask for gold and aluminum.

Key words: electron resist, electron beam technology, electron photoresist, positive electron beam resist, aliphatic polysulfones.

Experimental

The preparation of the polysulfones has been described elsewhere (3). Table I lists the materials evaluated in this study and their pertinent properties and constants. The polymers were spin coated (4) onto either silicon dioxide or tungsten substrates from the solvents given in Table I. Silicon dioxide used in this study was thermally grown from steam to a thickness of 200-600 nm. The tungsten (6) was deposited on a SiO_2/Si substrate by a chemical vapor deposition technique and was nominally ~100-200 nm thick.

Resist films of 300-500 nm thickness were found to give optimum results for solvent-developed systems. Films of 100-200 nm were optimum for a vapor-developed system. All films were prebaked at 110°C for 0.1-1.5 hr. It should be noted that data in Table I were obtained in the course of a preliminary evaluation of a large number of materials, and hence some values may be less than optimum.

The polymers were subsequently exposed using a Cambridge Stereoscan Mark II scanning electron microscope (SEM) equipped with a beam blanker. The beam could be externally modulated to produce test patterns consisting of evenly spaced bars and spaces. The smallest structure that could be obtained using this system was ~1μ widths on 2μ centers. However, for smaller test patterns, the beam could be used in a single sweep mode which permitted structures of <0.4μ to be written. After exposure the sample was spray-developed (for solvent mode development) for ~15 sec using the developer given in Table I and postbaked for 0.5 hr at 110°C.

Two alternative processing steps may be used after the postbake. Firstly, the polymer resist pattern may be used as an etching mask. In this mode, buffered HF was used for etching the SiO_2 and a buffered $K_3Fe(CN)_6$/KOH solution was used to etch the W. In the second mode the positive resist image may be used as an evaporation mask in the lift-off or parting-layer technique described by Hatzakis (5).

The following method was adopted to evaluate the sensitivity of the positive resists. The electron beam was carefully adjusted to a known voltage and current. A resist film was prepared as previously described on 200 nm of SiO_2. Pads of known area (usually ~1 mm^2) were exposed for varying times at constant current. The exposed sample was developed and postbaked as described and then etched with buffered HF (2 min for 200 nm of SiO_2). The resist was stripped and the etched sample examined with the SEM. The critical dose was taken as the lowest dose which still allowed complete and clean etching of the SiO_2. This method was found to give reproducible critical dose values with good accuracy.

[1] A description of this technique is given in Ref. (5).

Table I. Evaluation parameters of polysulfone electron beam resists

All materials were prebaked and postbaked at ≥ 110°C for ≥ 0.5 hr.

Resist	Code number	T_c (°C) $[M][SO_2] = 27$ mol^2 l^{-2}	Solvent	Developer*	Sensitivity* coulomb cm^{-2}	Comments
Poly(propylene sulfone)	PPrS-M1	90	DMSO			Does not spin a film from DMSO at room temperature. Polymer is insoluble in all other solvents.
Poly(butene-1 sulfone)	PBS-M2	64	MEK	60% MEK 40% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Spins excellent films although preferably from less volatile solvents than MEK. Behaves as an excellent etch mask when prebaked at ≥100°C. Does not readily depolymerize, *i.e.*, very little evidence of vapor development below 10^{-5} coulomb cm^{-2}. Similar in this regard to PMMA.
	PBS-M20	64	MEK 60% Cyclohexanone 40%	85% MEK 15% 2-PrOH	$1\text{-}2 \times 10^{-6}$	
Poly(pentene-1 sulfone)	PPS-M1	63	MEK	50% MEK 50% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Similar to PBS.
Poly(hexene-1 sulfone)	PHS-M4	60	MEK	35% Xylene 65% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Xylene preferred spinning solvent. Partially vapor-develops at these doses. Erosion of the resist during etching was sometimes observed.
	PHS-M14	60	Xylene	35% Xylene 65% 2-PrOH	$1\text{-}2 \times 10^{-6}$	
Poly(octene-1 sulfone)	POS-M1		MEK	60% Heptane 40% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Poor etch mask. Partially vapor-develops.
Poly(cis butene-2 sulfone)	Pc-B-2S-M1	46	Dioxane	60% Dioxane 40% 2-PrOH	$2\text{-}4 \times 10^{-6}$	The 2-butenes do not spin good films from dioxane.
Poly(trans butene-2 sulfone)	Pt-B-2S-M1	38	Dioxane	60% Dioxane 40% 2-PrOH	$2\text{-}4 \times 10^{-6}$	
Poly(butene-2 sulfone)	PB-2S-M1		Dioxane	60% Dioxane 40% 2-PrOH	$2\text{-}4 \times 10^{-6}$	
Poly(hexene-2 sulfone)	PH-2S-M1		MEK	50% MEK 50% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Poor etch mask when film thickness is <200 nm. Can be completely vapor-developed at $2\text{-}4 \times 10^{-6}$ coulomb cm^{-2} for film thickness <150 nm.
Poly(heptene-2 sulfone)	PHp-2S-M1	−39	MEK	20% Xylene 80% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Poor etch mask. Completely vapor-develops at $1\text{-}2 \times 10^{-6}$ coulomb cm^{-2} for film thickness <150 nm.
Poly(cyclopentene sulfone)	PcycloPS-M1	102.5	Dioxane	60% Dioxane 40% 2-PrOH	$2\text{-}3 \times 10^{-6}$	No evidence of depolymerization at exposures $<10^{-5}$ coulomb cm^{-2}. Does not spin good films from dioxane. Improved by spinning from dioxane/chlorobenzene. Poor etch mask.
Poly(cyclohexene sulfone)	PcycloHS-M1	24	Dioxane	60% Dioxane 40% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Chlorobenzene preferred spinning solvent. Partially vapor-develops at these doses. Completely vapor-develops at 5×10^{-6} coulomb cm^{-2} for film thickness <150 nm. Good etch mask.
	PcycloHS-M1	24	Chlorobenzene	60% Dioxane 40% 2-PrOH	$1\text{-}2 \times 10^{-6}$	
Poly(2-methyl pentene-1 sulfone)	PMPS-M3	−34	Xylene	15% Xylene 85% 2-PrOH	$1\text{-}2 \times 10^{-6}$	Excellent etch mask. Can be completely vapor-developed at film thickness <150 nm with sensitivities of 5×10^{-7}-1×10^{-6} coulomb cm^{-2}.
Poly(2-methyl butene-1 sulfone)	PMBS-M1		MEK Dioxane			Material spins poor films from both solvents.

* The polysulfones exhibit very sharp contrast which requires careful adjustment of the developer for each polysulfone in order to maximize sensitivity. The developer solutions listed represent the average of several samples.

The effect of accelerating voltage on sensitivity and resolution on poly(butene-1 sulfone) (PBS) was evaluated. The sensitivity of PBS was determined at 5, 10, 20, and 30 kV. The resolution as a function of beam potential was evaluated by exposing a 400 nm film of PBS on 200 nm of SiO_2 with a 100 nm diameter electron beam operating in the single sweep mode. Providing care was exercised not to overexpose the resist, this mode gave the highest resolution attainable with a given set of operating conditions. The resist was then processed and the SiO_2 etched.

The width of the etched grooves was determined and taken to be the resolution for a particular exposure. The effect of overexposure was determined with a similar technique at 5 kV, by varying the sweep time between 0.4 and 0.02 sec; 0.04 sec being the correct time to expose the resist to its critical dose.

Results and Discussion

Solution development.—The sensitivity of all of the polysulfones, using optimum conditions and developer, was found to be ~1-3 × 10^{-6} coulomb cm^{-2}. There is a direct correlation between sensitivity and the magnitude of G(scission), the number of main chain bonds broken per 100 eV absorbed, as seen in Table II. This similarity in the sensitivities of the polysulfones indicates that they all have similar G(scission) values. This is in agreement with the results of Brown and O'Donnell (2) who reported similar G(scission) values (as determined from molecular weight measurements on γ-irradiated samples) for PBS and poly(hexene-1 sulfone). It is clear from these data that sensitivity will not be of major importance in the choice of a polysulfone as an electron beam resist.

From Table I several of the polymers can be eliminated because of poor film properties[2] and adhesion.

[2] *i.e.*, The film does not serve as an impermeable etching mask.

Table II. Sensitivity and G(scission) for several positive resists

Polymer	G(scission)	Sensitivity (coulombs cm^{-2})
Poly(α methyl styrene)	0.3	1×10^{-4} (4)
Poly(methyl methacrylate)	1.7	5×10^{-5} (4)
Poly(isobutylene)*	4.0	5×10^{-5} (4)
Poly(butene-1 sulfone)	11	2×10^{-6}

* We have obtained sensitivities of $2\text{-}3 \times 10^{-5}$ for this resist using the developing solutions quoted in Ref. (4).

This may well be a function of spinning solvent, the choice of which is limited by the individual solubility characteristics of the polymers. Of the remaining polysulfones, PBS, poly(pentene-1 sulfone) (PPS), poly(2-methylpentene-1 sulfone) (PMPS), and poly(cyclohexene sulfone) (PcyloHS) have adequate properties to be useful as positive resists. It was found that the polysulfones vapor-develop at rates dependent on the nature of the olefin, as discussed in detail later. When this process occurs, organic vapor and SO_2 are released into the column of the SEM, resulting in marked contamination after several exposures. Hence it is desirable that the rate of vapor development be a minimum in order to reduce contamination of the electron column. When the solvent development mode is being employed, PBS and PPS are the best choices for a solvent-developed positive resist system.

Detailed evaluation of PBS.—PBS was found to serve as a good electron beam resist with a sensitivity of 2×10^{-6} coulomb cm^{-2} (at 5 kV) when used as described.

Figure 1 shows the patterns obtained by etching SiO_2 and W through PBS delineated with an electron beam as described above. Figure 2 shows micrographs of Al/Au patterns evaporated through a PBS mask. The resolution is <800 nm with edge acuity of ±100 nm.

Effect of voltage and overexposure.—The sensitivity of PBS was found to increase with decreasing voltage as shown in Fig. 3. This is in agreement with previous findings for negative resists (7). For a 400-500 nm film of polymer resist, the most efficient energy absorption and hence the highest sensitivity occurs at ~5 kV. For negative resists, transverse electron scattering (coupled with backscattered electron) will increase the line width, with increased exposure, to approximately twice the diffusion range at any accelerating voltage (7, 8). Figure 4 is a plot of maximum line width as a function of accelerating voltage for epoxidized polybutadiene negative resist and PBS positive resist. The effect of voltage on resolution is more pronounced with a negative resist. The sulfone positive resists vapor-develop when overexposed and their scattering density decreases, minimizing line broadening.

Although somewhat material dependent, the best resolution has been obtained using a 5-15 kV electron beam with both positive and negative resists.

Vapor development.—The term vapor development refers here to the process of polymer removal during exposure—a process which eliminates the need for solution development. All the polysulfones investigated vapor-developed, but unlike solution development, the dose required was a function of olefin structure, *e.g.*, 10^{-4} coulomb cm^{-2} for 150 nm of PBS compared with 5×10^{-7} coulomb cm^{-2} for 150 nm of PMPS. Thermodynamic considerations lead one to predict that during irradiation *in vacuo* with product gases being continually removed, all positive resists should completely vapor-develop. The process is, however, complicated by several factors, *e.g.*, radical termination which can markedly decrease vapor-developed sensitivity (3).

When ~150 nm films are used, very high resolution patterns (<400 nm) with good edge acuity (±30 nm)

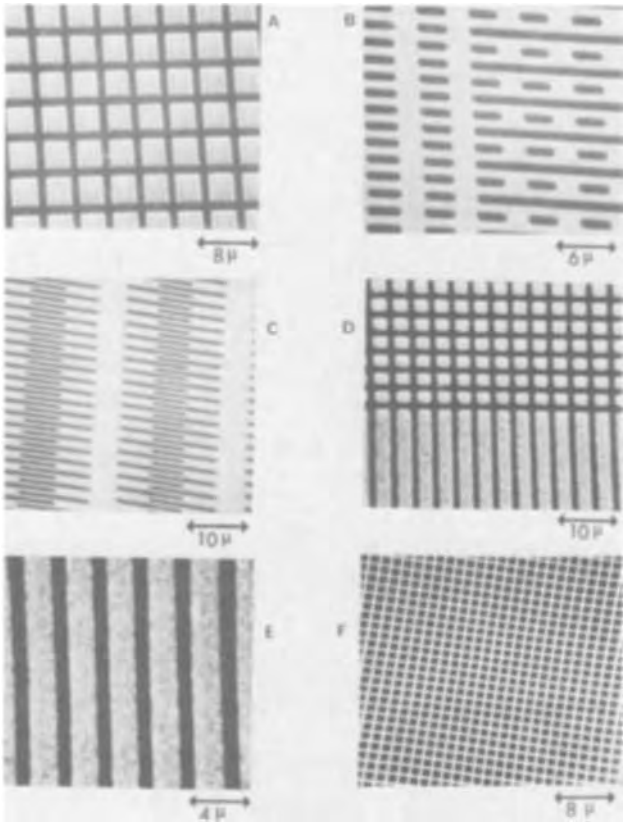

Fig. 1. Typical patterns etched through PBS masks in SiO_2 and W. Exposure 2×10^{-6} coulomb cm^{-2} at 5 kV. (A) and (B) etched in 200 nm SiO_2; (C) etched in 600 nm SiO_2; (D), (E), and (F) etched in 100 nm W.

can be made. Figure 6 shows several patterns etched in 200 nm SiO_2 through vapor-developed resists.

The vapor-developed sensitivity depends markedly on several other parameters, *e.g.*, film thickness and temperature, and will be described in detail at a later date.

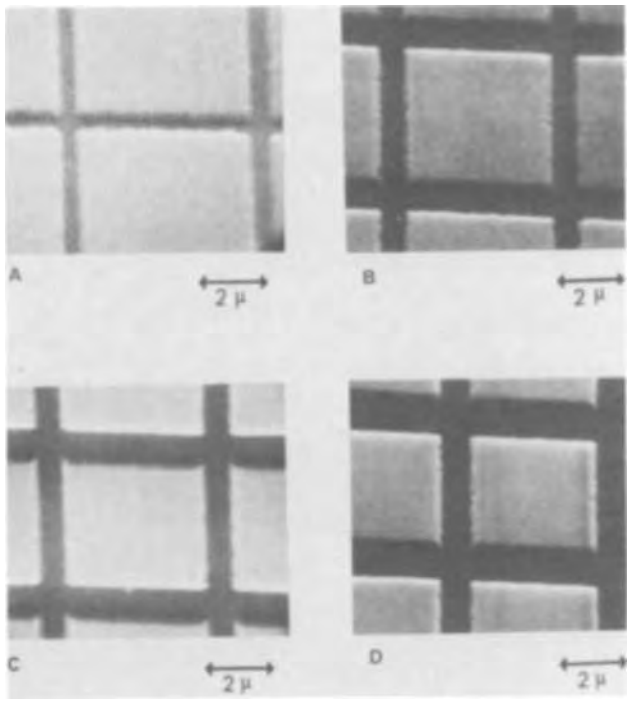

Fig. 5. Electron micrograph showing variations of resolution with dose (scan time at constant current) illustrating the effect of overexposure (A) 0.04 sec scan, (B) 0.1 sec scan, (C) 0.2 sec scan, and (D) 0.4 sec scan.

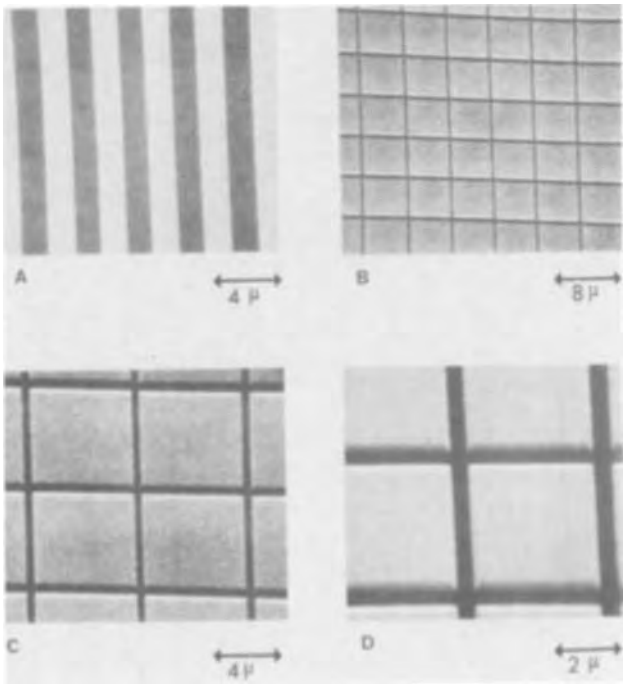

Fig. 6. Electron micrograph of typical patterns etched in SiO_2 through a vapor-developed PBS mask.

Conclusions

1. The family of poly(olefin sulfones) all undergo chain scission at about the same rate and can all serve as positive electron beam resists.
2. Poly(butene-1 sulfone) was found to exhibit best over-all resist properties.
3. All the polysulfones studied can be used in two development modes, *viz.*, solvent and vapor.
4. The optimum accelerating voltage to use is 5 kV for a 400-500 nm resist film.

Triboluminescence and Triboelectrification by the Motion of Mercury Over Glass Coated with Scintillator Dyes

Csaba P. Keszthelyi* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The conversion of mechanical energy into electrical energy and light (triboelectrification and triboluminescence) by the movement of mercury over glass surfaces coated with scintillator compounds was investigated. The motion of mercury over the coated glass involves the build-up of potential differences in excess of 20V; the nature of these triboelectric potentials differs significantly from those observed in the absence of scintillator coating. Twelve scintillator compounds were investigated with the observed luminescence being characteristic of the coating material.

Interfacial processes can generate potentials of varying magnitude, and from a fundamental aspect, these voltage-producing interfacial processes involve energy conversion. Scintillator compounds are characterized by a relatively efficient conversion of one form of energy into another; that is, in the usual experimental situation, the kinetic energy of high energy particles is converted into light energy. The study was concerned with the electrification, *i.e.* the separation of electrical charges, which occurs upon rubbing together dissimilar materials, a process termed "triboelectrification" or sometimes "static electrification." The related optical phenomenon is called triboluminescence (1), the emission of light when certain materials are rubbed or certain crystals are crushed. It has been known for a long time that triboelectrification and triboluminescence occurs when mercury moves over a glass surface in the presence of inert gases. For example, Picard (2) in 1675 observed a "whitish glow" in a Torricelli barometer. He attributed this to some "phosphors" ostensibly present as impurities. The explanation that is in general agreement with present thinking, namely, that a static electric charge builds up, was first put forth by Huksbee (2) in 1705. Recent workers in this field have observed chemical reactions in a triboelectric discharge (3, 4) and have studied the spectra of light generated by the relative motion of contiguous surfaces of mercury and glass (5-7). In related experiments, contact electrification potentials as high as 100V have been measured (8). While many details of the basic mechanism remain obscure, the process involves charge separation at the mercury-glass interface with the subsequent charge recombination reaction being energetic enough (>20 eV) to produce excited states of the inert gases, mercury and even of the silicon and boron of the glass, and to cause decomposition of such molecules as methane. We report here that coating the glass surface with a scintillator compound results in intense luminescence that is color-specific to the coating during movement of mercury over the surface and that this light emission is localized at the scintillator coating and does not extend into the interior volume as has been reported when only mercury and glass are involved (6). Other significant differences that can be attributed to the scintillator coating and potential difference measurements are also discussed.

Experimental

The structures and fluorescence maxima of the scintillator compounds that we used as coating with positive results are shown in Fig. 1. In our previous work involving scintillator compounds (9) we found that the commercially available samples are of a high quality and required no further purification. The FTD, ATD, APD, and BTD samples were sent to us by Prof. Richard L. Taber, Colorado College, who reported them to be extensively purified by column chromatography; these were used as received. The purity of the other compounds that were used as coatings (rubrene, phthalocyanine, $\alpha,\beta,\gamma,\delta$-tetraphenylporphin) was ascertained as described previously (9).

The glass surface to be coated was always cleaned first by rinsing with reagent CH_2Cl_2, hydrochloric acid, distilled water, ethanol, and methylene chloride (spectroscopy grade) several times. The last CH_2Cl_2 rinse was checked using an Aminco-Bowman spectrophotofluorometer and a quartz cuvette to make sure that no traces of luminescent impurities, especially those from a previous coating, were still evident. The glass was almost always coated by contacting it with a

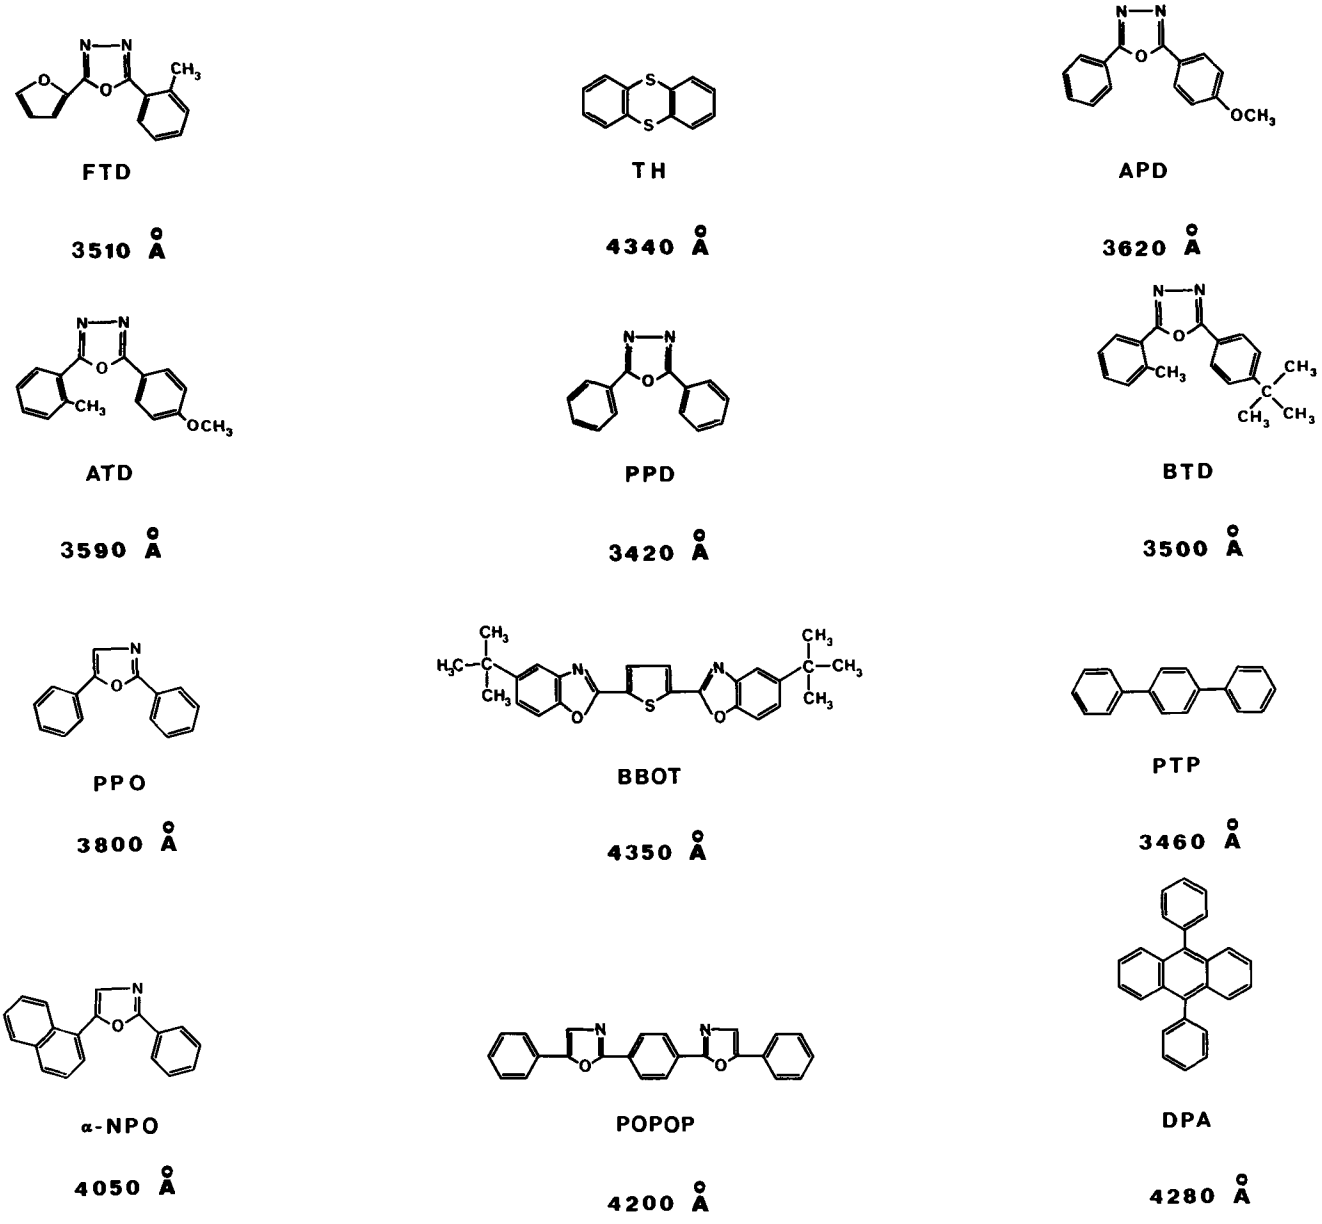

Fig. 1. Structures of the scintillator compounds that were used as coating. [Principal fluorescence or scintillation emission is indicated by λ (Å)].

CH_2Cl_2 solution saturated with the compound being investigated; using approximately 0.5 ml solution for the length of the tube indicated in Fig. 3; the liquid was slowly rocked back and forth in the horizontally held tube that was slowly rotated until all the CH_2Cl_2 had evaporated. Vapor deposition was also employed as a coating technique. By use of a "heat gun," it was possible to make the coating more homogeneous, melting the coating at either specific spots or along the entire surface. The observations were made either in hermetically sealed cells (Fig. 2) or in a detachable vacuum-line type arrangement using "Swagelock" couplings.

Potentials were measured in an arrangement resembling Debeu's (8) by using either an electrometer (General Radio Company, Type 1230-A) or a solid state operational amplifier (Philbrick-Nexus) in a voltage follower arrangement yielding an input resistance $>10^{12}$ ohms. A Moseley 7005-A XY recorder was used to obtain the potential-time plots shown in Fig. 4 and 5. The electrometer could measure voltages up to 10V, the Philbrick operation amplifier limits ~20V.

The rate of the rise and fall of the distilled Hg column could be controlled by the arrangement shown on the top of Fig. 3, whereby the vacuum pump or a noble gas source was alternately connected to the main coated tube. It was found impossible to achieve a steady rate of rise under our experimental setup, and recorded measurements were confined to the falling Hg column. The He, Ne, and Ar were a high purity, commercially available, grade, used as received. The imbedded electrodes (cf. Fig. 3) were of platinum wire.

Results and Discussion

For a preliminary investigation of the triboluminescence, the hermetically sealed cell arrangements shown in Fig. 2 were employed. These were coated tubes containing a small amount of mercury sealed under vacuum which produced light emission upon moving or shaking the mercury. Such closed cells functioned essentially without change over a period of several months when used intermittently. For a continuous test, a glass wheel, scintillator coated, and containing mercury, was rotated by connection to a motor revolving at 0.5-5 rpm; emission was observed for 48 hr in this arrangement before the test was terminated. In these cells, even the slightest movement of the Hg in the coated tube produced the characteristic luminescence.

We have made quantitative measurements of the triboelectric potentials generated at the scintillator interface by the movement of the mercury using the arrangement indicated in Fig. 3. In this apparatus,

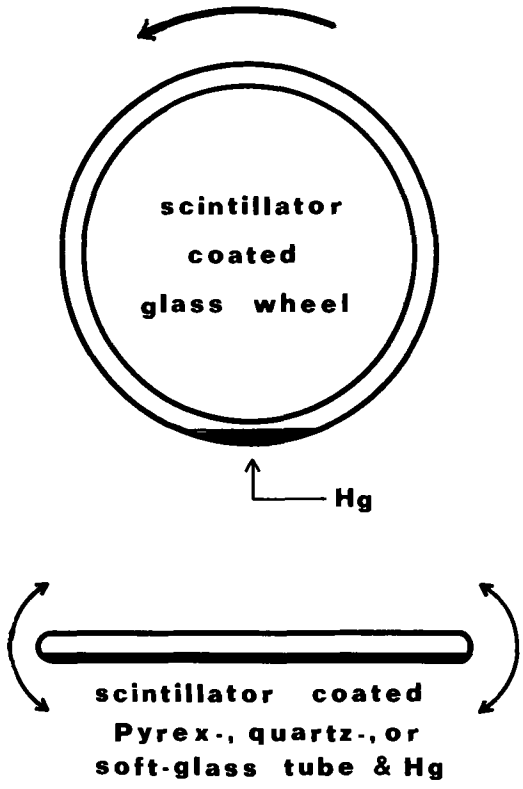

Fig. 2. Triboluminescence could be observed for prolonged periods of time in these hermetically sealed cells; the 9 in. diameter evacuated hollow wheel could be rotated by using an electric stirrer motor equipped with speed control.

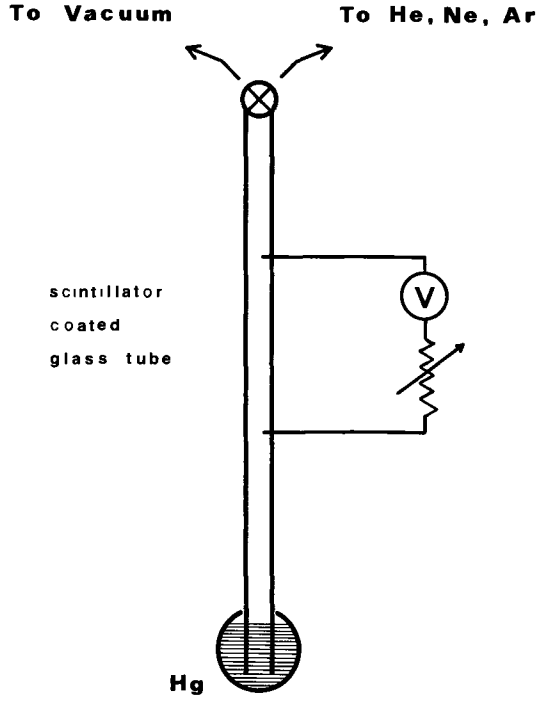

Fig. 3. Triboelectric potentials were measured accordingly (total length of the 6 mm OD tube was 34 in., separation of the imbedded electrodes was 10 in.).

which resembles an ordinary mercury-in-glass barometer except that here the glass has been coated with scintillator compound, the mercury in the reservoir can be made to rise and fall at a given rate in the tube by applying either vacuum or inert gas pressure at the inlet. The potential between the mercury and the glass can be measured by means of the two platinum wires sealed into the tube. In a typical experiment the mercury column, formed by applying a vacuum to the inlet, is allowed to fall by slow addition of inert gas. Flashes of light are observed at the mercury-coated glass interface. The potential-time behavior (termed here a "potentiogram") between the platinum contacts taken at various ohmic resistance settings of the electrometer is shown in Fig. 4. While the two electrodes remain shorted by the descending Hg column, the reading on the electrometer (or from the operational amplifier in the voltage follower arrangement) is, naturally, zero. There is a sudden increase in potential as the Hg level moves below the top platinum lead (with the lead contacting the mercury positive with respect to the upper glass lead); subsequent variations and the detailed shape of the potentiogram are highly reproducible for a given coating, but vary from coating to coating. This allows "finger-printing" a coating surface, and also checking for any bald spots, striations, etc. The maximum voltage generated by the triboelectrification process could not be determined in these experiments, but we did find it to be in excess of the amplifier limiting voltage of about 20V when the high impedance solid-state operational amplifier was substituted in place of the electrometer in Fig. 4. With the electrometer, the highest resistance setting corresponding to the vacuum tube impedance of the electrometer itself could not be applied for fear of damaging the instrument. Debeu (8) measured maximum voltages in excess of 100V on contact electrification using nickel as the stationary phase, and NaCl or quartz particles as the moving phase; our maximum voltages may well be in the same range.

The rate at which the mercury column was falling had an effect on the generated voltage; lower voltage readings occur at the slower flow rates probably because of leakage of the built-up charge, lateral migration processes inside the scintillator coating, etc. Tentative evidence of such losses is found in the generally declining shape of potentiograms as the Hg column moves farther away from the upper platinum electrode, making the effective scintillator column length being monitored by the electrometer increasingly longer.

The light pulses are quite irregular in their time distribution, and no correlation could be observed between certain positions on the coated tube and light emission either. The typical pulse length was between 0.2 and 0.5 sec; the rise time and decay characteristics have not been measured. By comparison to calibrated light sources with the aid of the photodiode we used in electrogenerated chemiluminescence quantum efficiency measurements (10) the number of photons emitted per cm^2 in these experiments is estimated to be certainly greater than 10^{15} in a pulse.

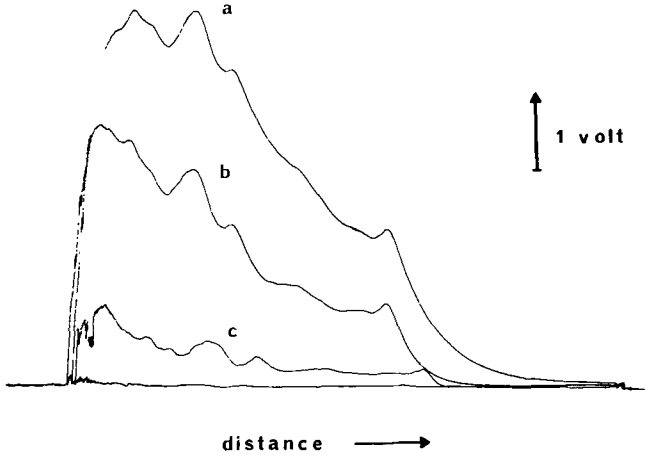

Fig. 4. Potentiogram of the triboelectrically generated voltages with apparatus of Fig. 3; constant recorder sensitivity is indicated by the "1 volt" scaler. The resistance settings of the electrometer were (a) 10^{11}, (b) 10^{10}, (c) 10^9 ohms. The rate of fall of the Hg column was 3 in./min.

Significantly different results are obtained in the same cells under similar conditions when the scintillator coating is removed. As Fig. 5 shows, now complete discharges occur, involving breakdown of the gas in the bulk volume. When a large number of potentiograms are examined, it is unmistakable that the voltage build-up and discharge pattern is quite random, in sharp contrast with the potentiograms taken in the presence of a scintillator coating, where the potentiograms are highly reproducible and also "fingerprint" minute details of the coating surface. In all the experiments when the type of glass varied, we found no specific or obvious differences in behavior. On the other hand, when other fluorescent (nonscintillator) compounds, such as rubrene, TPP, or PC were used as coatings, no intense orange or red triboluminescence resulted.

While a detailed mechanism of the phenomenon can obviously not be presented on the basis of the experiments here, these results combined with previous studies of static electrification and solid-state luminescent processes allow some possible schemes to be presented. The process of contacting mercury with glass causes the mercury to become positively charged and the glass negatively charged as a result of electrons from the mercury moving into unfilled surface states of the glass (6). The separation of the mercury and glass surfaces initiates a discharge, and based on the fact that emission from He has been observed under these conditions as well as decomposition methane and other hydrocarbons, the excitation energy produced by this discharge is greater than 20 eV (7). Thus, one mechanism for the luminescence of the scintillator would involve energy transfer from excited state species of the mercury or inert gas to the scintillator coating. However, the lack of luminescence of certain fluorescent dyes and the relative independence of the emission on the type or pressure of inert gas makes other mechanisms worth considering. The discharge process could lead to highly energetic electrons; the interaction of these "soft β-rays" with the scintillator could produce emission. Yet a third mechanism is suggested by experiments on charge injection into aromatic crystals (11, 12). In these experiments, the direct injection of electrons and holes into crystals, or injection via insulator crystal electrodes and solutions, leads to electron-hole combination in the crystal and light emission. The charge separation across the scintillator coating could lead to this kind of process in these experiments.

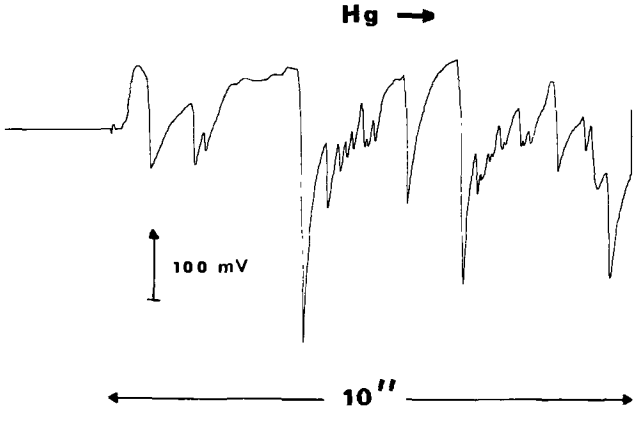

Fig. 5. Potentiogram of triboelectrically generated voltages under the same conditions as Fig. 4, except that the scintillator coat was completely removed; the resistance setting of the electrometer was 10^{11} ohms.

A Technique for Measuring the Saturation of Phosphors at High Current Densities

E. F. Gibbons, R. G. DeLosh, T. Y. Tien, and H. L. Stadler*

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

A technique is described which allows for the measurement of the saturation of luminous intensity of phosphors up to high current densities. The actual light intensity profile of the spot is measured and is related to the current density profile across the spot, the latter being obtained from measurements on a nonsaturating phosphor. This technique thus uses a point-by-point measurement of relative efficiency *vs.* beam current density, and therefore no assumptions concerning the beam current profile have to be made, and no averaging of beam current over spot diameter is required. Typical data are presented from several classes of materials. For the samples reported, La_2O_2S:Tb showed the least degree of saturation, (Zn, Cd)S:Ag the greatest degree, and Zn_2SiO_4:Mn was intermediate to these two.

Most phosphors, when excited by an electron beam, show a less than linear increase in brightness with increasing beam current density. This phenomenon is known as saturation and is indicated schematically in Fig. 1 where both intensity and efficiency are displayed as a function of beam current density. This effect can be particularly troublesome in multicolored cathode ray tubes using high current densities, *e.g.*, post deflection focusing (PDF) type color television tubes.

* Electrochemical Society Active Member.
Key words: luminescence, phosphors, saturation.

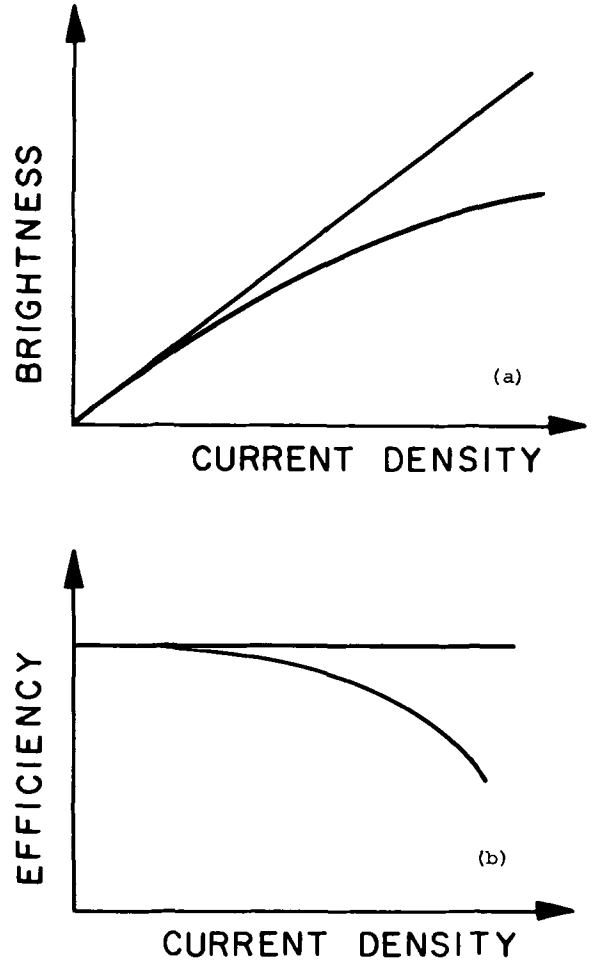

Fig. 1. Effect of current density on: a) brightness or b) efficiency of a nonlinear phosphor.

Two disadvantages will accrue if the phosphors chosen for this type of tube exhibit saturation in the current density range used by the tube: (*i*) the anticipated brightness increase will not be achieved, and (*ii*) the color balance and white field produced by color mixings will vary with beam current density. For these reasons, the intensity *vs.* beam current density data is an important factor in choosing the appropriate phosphors for these types of applications.

Measurement of the saturation of various phosphors has been reported by a number of authors (1-6), with the work of Meyer and Palilla (6) being most directly concerned with television tube application. In these previous works, some assumption was made about the current density profile across the electron beam and a calculated average current density was used in the saturation plots. The technique reported in this article determines the actual current density profile of the spot, and so provides a point by point measurement of intensity *vs.* beam current density.

Apparatus

Phosphors used in this experiment were either obtained commercially (so designated in the appropriate figures) or prepared in the laboratory. Samples were settled onto 2.5 × 7.5 cm microscope slides using a potassium silicate-barium acetate settling method. After lacquering, the slides were aluminized in a vacuum evaporator. Aluminum deposition was regulated by a quartz crystal thickness monitor such that all samples measured had an aluminum backing of 1000 ± 50Å. Saturation measurements were made in a demountable electron beam gun system shown in Fig. 2. The electron beam gun was a Raytheon Type QV-359 operated at 23 kV and with peak beam currents of 8 mA. The vacuum system was an oil-free system, using a sorption pump for roughing and an ion pump for high vacuum pump down. When samples were being changed, the electron beam gun could be isolated from the sample chamber by means of a gate valve. This allowed the gun to always remain under high vacuum after cathode break-in had been performed, and thus extending gun life indefinitely.

At the high beam currents used in these experiments, the coils located at the gun neck were not sufficient to prevent self-defocusing of the beam by the time it reached the sample plane. It was therefore necessary to provide auxiliary focusing coils closer to the sample plane and separate deflection coils just before the sample plane. A typical spot size for these measurements was 0.025 in. diameter at the 10% maximum intensity point. All these coils were operated from highly regulated constant current supplies.

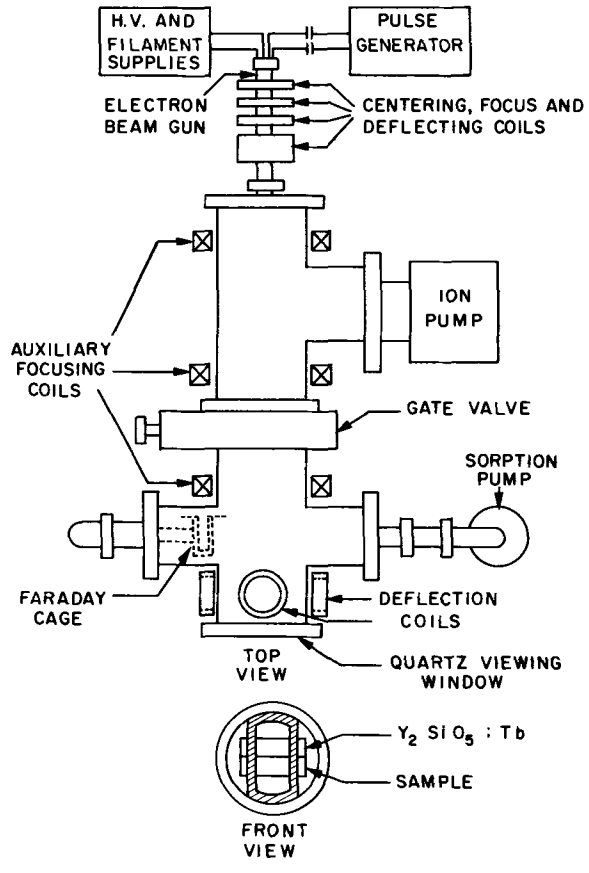

Fig. 2. Demountable electron beam gun system

The sample light spot intensity was measured using a photometer which observed a 0.002 in. diameter area of the spot. During the course of the measurement, the photometer remained focused on one spot and the electron beam was slowly scanned across it. The beam was swept horizontally by changing the current through the horizontal deflection coils. This was done by using a 1/6 revolution per hour motor to drive a ten turn potentiometer. The voltage across the horizontal deflection coil was then used as the signal for the x-amplifier on an x-y recorder. The signal from the photometer's photomultiplier was applied to the y-amplifier of the recorder. For each set of excitation conditions, a suitable neutral density filter was used so that the photomultiplier response was linear over the light intensities encountered. The resulting intensity profile of a nonsaturating phosphor is shown in Fig. 3.

The system was also provided with a Faraday cage mounted on a linear motion feedthrough for measurement of total beam current. The Faraday cage could be moved to the axis of the system for current measurement, and then withdrawn during the saturation measurements.

Current pulses were obtained by biasing the electron beam gun into cutoff, and turning it on by applying positive voltage pulses, obtained from a Hg-reed relay, delay line generator, to the grid. By this means the current pulse could be controlled from 0 to 8 mA and from 6 nsec to any desired duration. A typical current pulse is shown in Fig. 4.

Determination of the Current Density Distribution

Principle.—For a nonsaturating phosphor, the intensity is directly proportional to the current density. Therefore, the intensity profile shown in Fig. 3 is the same as the current density profile across the light spot. Hence, if the area under the current density curve and the total current are known, the current density at any point in the profile can be calculated. In this calculation the light intensity profile of the Y_2SiO_5:Tb is approximated by a series of annular steps, the ith step being of height h_i and radius r_i. The steps are taken at a uniform spacing of Δr. Since h_i is directly proportional to the current density at that point, J_i, for a nonsaturating phosphor

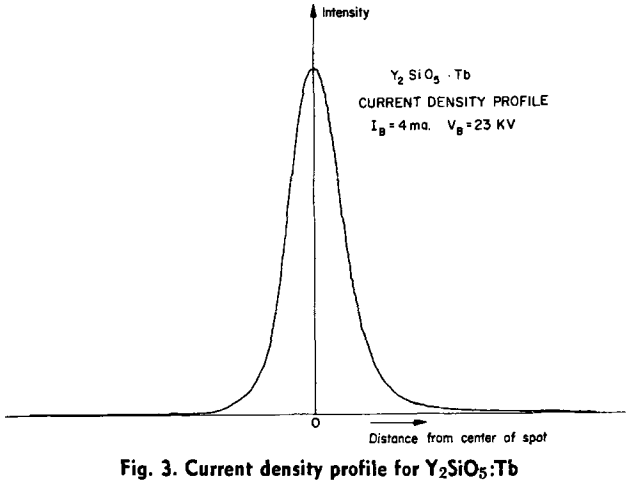

Fig. 3. Current density profile for Y_2SiO_5:Tb

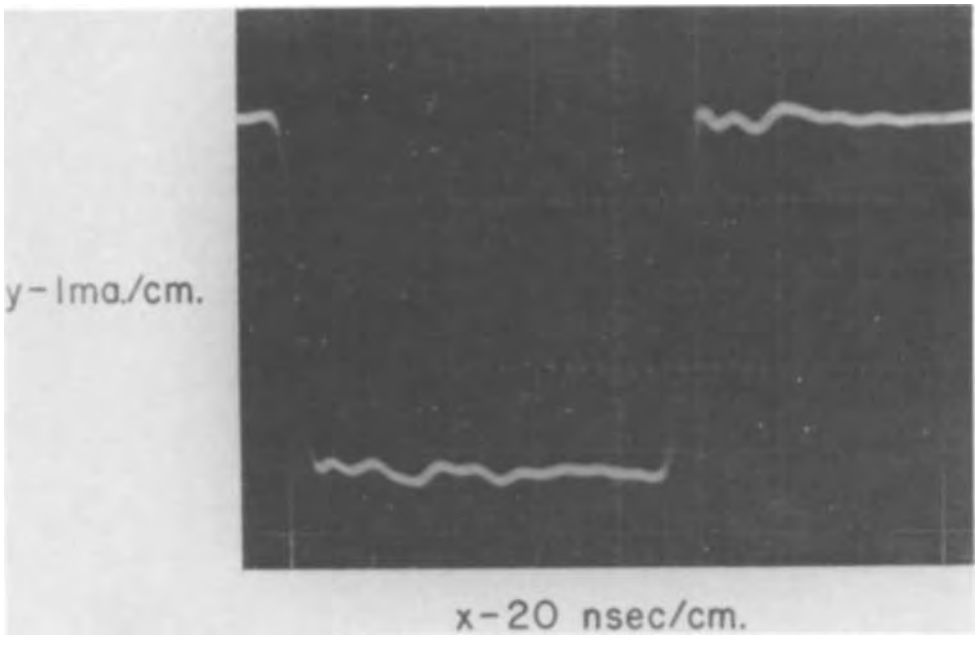

Fig. 4. Current pulse into the Faraday cage.

$$h_i = \alpha J_i \quad [1]$$

where α is a proportionality constant. Denoting the total current into the ith annular region as I_i,

$$I_i = (2\pi r_i \Delta r) J_i \quad [2]$$

Therefore, using [2] in [1] and solving for I_i

$$I_i = \frac{h_i}{\alpha} (2\pi r_i \Delta r) \quad [3]$$

The total current into the light spot is I

$$I = \sum_i I_i \quad [4]$$

or, using [3] in [4]

$$I = \frac{2\pi\Delta r}{\alpha} \sum_i h_i r_i \quad [5]$$

Therefore, the proportionality constant between light spot intensity and current density for Y_2SiO_5:Tb, α, is given by

$$\alpha = \frac{2\pi\Delta r}{I} \sum_i h_i r_i \text{ cm}^2/\text{A} \quad [6]$$

The intensity profile was approximated by using 20 steps. It was found that doubling this number provided no significant increase in accuracy.

It is therefore only necessary to measure the total current in the beam and to relate the dimensions of the x-y plot to the actual dimensions of the light spot to convert the intensity profile to a current density profile.

Technique.—The measurement of the total beam current is easily accomplished by means of the traveling Faraday cage. A 100 msec wide current pulse as recorded on a Tektronix 551 oscilloscope is shown in Fig. 4.

To relate dimensions on the x-y plot to actual dimensions of the light spot, advantage is taken of the optical system of the photometer. The spot photometer is constructed such that a lens system focuses the light from the sample plane onto the cathode of a photomultiplier tube. A mirror, with a precision aperture, intercepts the light beam and reflects all but the light passing through the aperture to an eye piece. The size of the aperture determines the cross-sectional area of the sample plane that is actually observed by the photomultiplier. A camera placed at the eyepiece will then photograph the light received from the sample plane, less that transmitted through the aperture. If the light spot is then positioned such that the photometer indicates an intensity of 10% of maximum, a photograph taken through the eyepiece will show a dark area at some distance from the center of the light spot. The diameter of the area will be determined by the diameter of the aperture chosen, thus the actual dimensions of the light spot can be determined. Also, since it is known that the dark area in the photograph is at the 10% intensity point, the dimensions of the light spot can then be correlated to the dimensions of the x-y plot. In practice, the negative of such a photograph is used and a microdensitometer trace is made from the negative. Such a trace is shown in Fig. 5 where a 0.006 in. aperture has been used for emphasis. A 0.002 in. aperture was used for the actual measurements. This would be an exact measurement in the limit where the ratio of photometer aperture to spot diameter is zero; with the 0.002 in. aperture, a 0.025 in. spot size, and assuming a Gaussian distribution of intensity, the error incurred in determining the 10% radius in this manner is about 2%.

The slope observed at the edges of the aperture spot is caused by the rounding of the mirror at the aperture opening. Microdensitometer traces were made through several different cross sections of the light spot to ensure that the beam was actually symmetric.

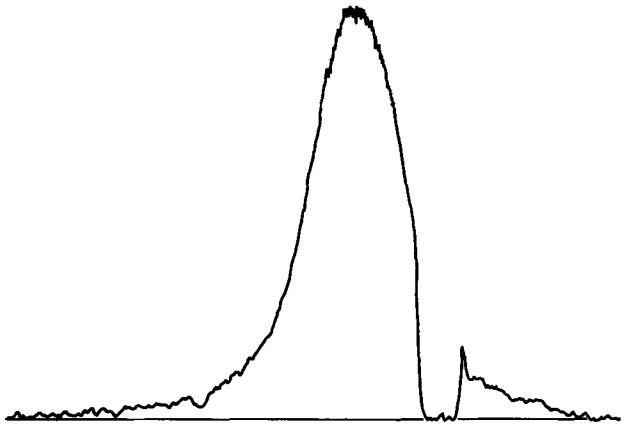

Fig. 5. Typical microdensitometer trace

Measurement of Saturation Characteristics

The procedure involved in measuring the saturation characteristics of a given phosphor is to mount a settled slide of this phosphor, along with a slide of a nonsaturating phosphor, in the demountable system. For a given set of excitation conditions—beam current, pulse width, and repetition rate—a light intensity profile is recorded for the nonsaturating phosphor. This is then converted to a current density profile as just described. The beam is then moved to the test slide and the same beam conditions are used to obtain a light intensity profile for the sample phosphor. Assuming that the same current density distribution pertains to the saturating phosphor as was determined for the Y_2SiO_5:Tb slide, an intensity (or efficiency) *vs.* current density plot can be derived.

The assumption that the electron beam did not change its shape when it was moved from the Y_2SiO_5:Tb reference slide to the test slide was checked by substituting a second slide of Y_2SiO_5:Tb for the test sample. The current density distribution for the second Y_2SiO_5:Tb slide was taken to be identical with that of the reference slide, as was done for measurements on saturating phosphors. If there were no change in the current density profile in moving the spot from one slide to the other, the relative efficiency *vs.* current density plot for the second Y_2SiO_5:Tb slide should be a straight line with zero slope. The results of several measurements are shown in Fig. 6. This shows a measurement error of less than ±5% except at the lowest current densities. These measurements were made periodically throughout the course of the experiment. Another check on the equality of the two current distributions was made by applying very small beam currents to the reference slide and a saturating sample. The current density at all points in the spot was below

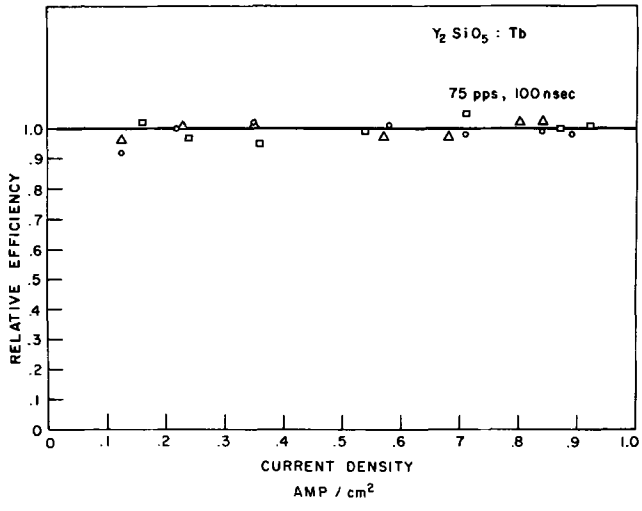

Fig. 6. Estimate of measurement error using an Y_2SiO_5:Tb sample

the level where saturation is noticeable. It was found that the two intensity profiles were proportional, thereby indicating equality of the two current distributions. Finally, the use of a grounded aluminum film on the back of the samples largely eliminates the importance of the electronic properties of the various materials.

The superposition of the light intensity profile of a saturating (Zn,Cd)S:Ag, and a nonsaturating, Y_2SiO_5:Tb, phosphor is shown in Fig. 7. The (Zn,Cd)S:Ag was a commercially obtained green television phosphor. From this plot it is evident that the (Zn,Cd)S:Ag is considerably brighter at the lower current densities, but at the highest current densities its relative brightness has fallen off considerably.

For a nonsaturating phosphor, Y_2SiO_5:Tb was chosen since it had been reported by Meyer and Palilla to have a luminous efficiency that was independent of current density. This was verified by measuring the total brightness from a defocused spot and then focusing the beam, producing current densities of several A/cm^2 in the center. Since no change in brightness was observed, it can be inferred that there was no change in luminous efficiency. There were conditions of sufficiently high beam current density where even the Y_2SiO_5:Tb showed saturation. This limited the useful range of current densities to approximately 3 A/cm^2 maximum current density.

The relative efficiency at any current density was obtained by taking the ratio of the intensity of the sample at that point to the intensity of the Y_2SiO_5:Tb and comparing it to the same ratio at low current density. The low current density ratio was obtained by using a raster scan and low beam current. A point-by-point comparison across a low current density spot could also be used to obtain the low current density ratio, and this technique gives the same results as the raster scan measurement, however, the raster scan measurement was much faster and easier to make.

Results

Relative efficiency *vs.* beam current density data are shown for several different phosphors in Fig. 8-10. In Fig. 8, the data for La_2O_2S:Tb, it is seen that although

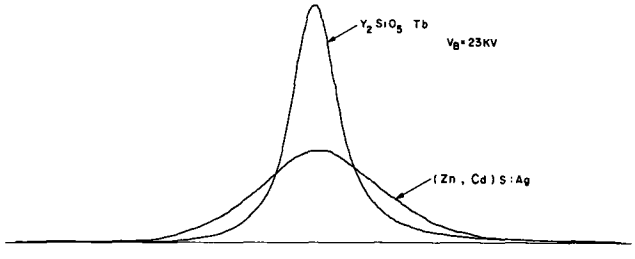

Fig. 7. The light intensity profiles of a saturating (Zn,Cd):Ag, and nonsaturating, Y_2SiO_5:Tb phosphor.

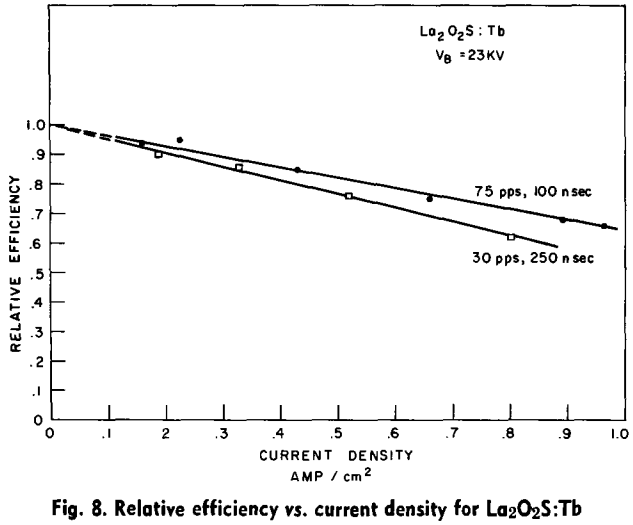

Fig. 8. Relative efficiency *vs.* current density for La_2O_2S:Tb

the two excitation conditions produce the same excitation time per second, the longer width pulse causes greater saturation. Also, this material shows the least saturation of the three samples shown. This is consistent with the results of Ref. (6) which showed that the rare earth doped oxides showed the least degree of saturation of the phosphors reported. ZnS:Ag and (Zn,Cd)S:Ag showed the greatest loss in relative efficiencies. Figure 9 shows the results for (Zn,Cd)S:Ag out to a current density of 3.2 A/cm^2. It is apparent that this phosphor loses efficiency very rapidly, even at low current densities, and at high current densities has less than 10% of its maximum efficiency. Therefore, even at moderate current densities a number of other phosphors would be brighter than (Zn,Cd)S:Ag.

Figure 10 shows the data for willemite which shows a degree of saturation intermediate to the rare earth activated phosphors and the sulfide phosphors. Also, the data show an increased effect for increasing pulse width. It should be pointed out that other authors (1, 2) have shown that the loss of relative efficiency for Zn_2SiO_4:Mn is very strongly dependent on manganese concentration, so the data of Fig. 10 should only be applied to the particular material studied, NBS standard phosphor 1021.

These data all show a greater saturation effect for a given current density than has been reported previously (6). We attribute this difference to the use of an average current density for the previous data. Because of the nonlinear relationship between light intensity and current density, the inner region of the light spot contributes far less, per unit current density, to the total spot brightness than do the outer regions. Hence,

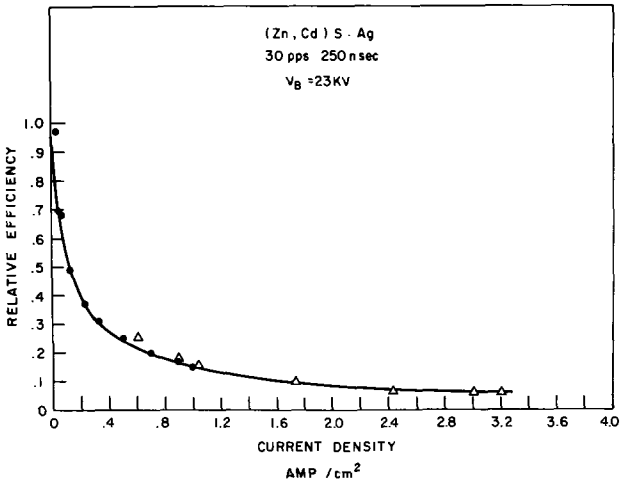

Fig. 9. Relative efficiency *vs.* current density for (Zn,Cd)S:Ag (sample obtained commercially).

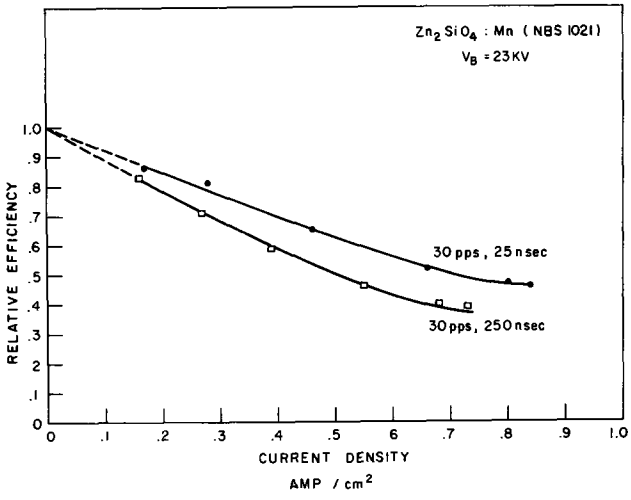

Fig. 10. Relative efficiency *vs.* current density for Zn_2SiO_4:Mn (sample obtained from NBS).

the low current density regions of the spot contribute a disproportionate fraction of the spot light, and the over-all saturation effect is apparently less. The difference between the average current density method and the point by point technique reported here is about a factor of two for high current densities.

Effects of Comminution on the Luminescence of Phosphors

S. Kuboniwa, T. Hoshina, T. Narahara, and M. Kanamaru

SONY Corporation Research Center, 174 Fujitsukacho, Hodogaya-ku, Yokohama, Japan

ABSTRACT

Luminescent properties of ball-milled $Zn_{0.97}Cd_{0.03}S$:Cu,Al and ZnS:Ag,Al phosphors have been measured. Particle size reduction, or the increase in the surface area, by comminution leads to a large luminescent loss of phosphors due to nonradiative recombination of the free carriers at the crystal surface. The milling condition adopted in this study does not have an appreciable effect on the surface or the bulk properties relevant to luminescence. The average width of the dead layer of the phosphors is estimated to be of the order of 0.1μ. The penetration range of the electron beams into the phosphor layers decreases with decreasing particle size. Particle-size effects on the parameters that determine luminescence are discussed.

Comminution of phosphor particles by means of milling or crushing leads to luminescent loss. Size reduction and lattice defects in the comminution process are caused by pressure, impact, or attrition, or by a combination of these. Size reduction of the phosphor particles leads to an increase in the surface area relative to the whole volume. The crystal lattice is strongly perturbed at and near the surface, and the dangling bonds formed can bind atoms from the ambient. As a result, energy levels of high density are formed in the forbidden gap near the surface. They act as nonradiative recombination centers for the free carriers. The size reduction due to comminution, therefore, increases the fraction of the less-luminescent parts of the phosphors. This is one of the possible causes for luminescent degradation and is regarded as a major cause in this report. Damaging of phosphor crystals in the comminution process can also produce recombination centers in the lattice. The increase in multiple reflection of fluorescent light at crystal surfaces may cause a loss of externally emitted light.

In this report, particle size effects on cathodo- and photoluminescent properties of $Zn_{0.97}Cd_{0.03}S$:Cu,Al and ZnS:Ag,Al phosphors are investigated. These phosphors are used as the green and blue primaries for color picture tubes.

Experimental Procedures

$Zn_{0.97}Cd_{0.03}S$:Cu,Al and ZnS:Ag,Al phosphors were ball-milled for up to 10 hr. The slurry consisted of phosphors (42g), methanol (50 mliters), and water (95 mliters) and was milled in a 500-mliter polyethylene pot with glass balls of 10 mm diameter at the rotation rate of 100 rpm. This milling condition is not so hard as to cause a large crystallographic change of the phosphors. The widths of the x-ray diffraction lines and the estimated lattice constants have shown only a small change caused by the ball milling. Nevertheless, the luminescent intensity is greatly reduced. The crystallographic investigation of the ball-milled phosphors and the study of the comminution mechanism will be reported in another paper (1). Some of the results are given in Table I.

Key words: phosphors; luminescence; (Zn,Cd)S:Cu,Al; ZnS:Ag,Al; comminution; ball milling.

For cathodoluminescent measurements, phosphors were packed in metal trays or sedimented on aluminum plates. The samples were placed in a demountable cathode-ray excitation apparatus. Luminescence was measured from the bombarded side. The current density of the electron beam incident on a sample was determined from the luminescent area measured by a cathetometer and from the beam current detected by a picoammeter, which was inserted between an electron-gun power supply and a pre-accelerating-voltage generator as shown in Fig. 1. The luminescence was detected by HTV-R376 photomultiplier tube through a SPEX-1700-II monochromator. The pressure was lower than 2×10^{-6} Torr.

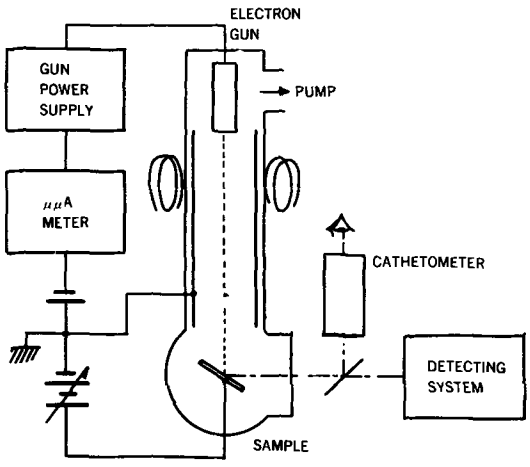

Fig. 1. Schematic diagram for the method of cathodoluminescent measurement.

The beam voltage dependence of the luminescent efficiency for steady excitation by the electron beam of 0.5 $\mu A/cm^2$ was measured. The beam current and the luminescent area were adjusted at each measuring voltage to maintain a constant current density. The measurements were made for the samples sedimented on aluminum plates. Comparison of the luminescent intensity of the sample phosphors was made for thickly packed samples at several voltages to eliminate the difference in reflectivity of the aluminum plates.

Decay-time measurements were carried out using the stroboscopic method (2). Phosphors sedimented on aluminum plates were excited by electron beam pulses of a 5-μsec duration at a frequency of 30 Hz. The time-averaged current density was 0.2 $\mu A/cm^2$, which was identical with the pulse height of 1.3 mA/cm^2. The triggering pulse from a pulse generator was delayed and supplied to a high voltage pulse generator which fed the gating pulses (−1.5 to −2 kV) to an HTV-R566 (S-20) photomultiplier. The gating-pulse width was varied from 0.1 to 10 μsec for initial and later stages of luminescent decay.

Excitation spectra were measured at room- and liquid-nitrogen temperatures. Exciting monochromatic light was obtained using a 150W Xe-lamp and a SPEX 1700-II monochromator equipped with a grating blazed at 3000Å. Phosphor particles were sedimented on a quartz plate to form an elementary layer of thickness equivalent to the surface mean diameter. The coating densities are given in the captions of Fig. 7 and 8. The quartz plate coated with the phosphors was placed on a black-coated holder to prevent the scattering of the emitted light. The samples were held in a vacuum for the room temperature measurements or directly immersed in liquid nitrogen. The exciting monochromatic light was swept from the shorter wavelength region at the rate of 50 Å/min.

Diffuse reflection spectra were measured for thickly packed samples using a double monochromator. The absolute reflectivity was determined by comparison with that of MgO and its published data (3). The measuring light was swept from the shorter wavelength region at the rate of 250 Å/min.

Experimental Results

The fluorescent spectra of the green- and the blue-emitting phosphors are shown in Fig. 2. The ball milling did not cause any appreciable change in the fluorescent spectra.

Figure 3 shows the dependence of the luminescent intensity on milling time for excitation by the 10 kV electron beam (0.5 $\mu A/cm^2$) and the above-bandgap radiation of 335 nm. The degree of the luminescent degradation is larger for $Zn_{0.97}Cd_{0.03}S$:Cu,Al than for

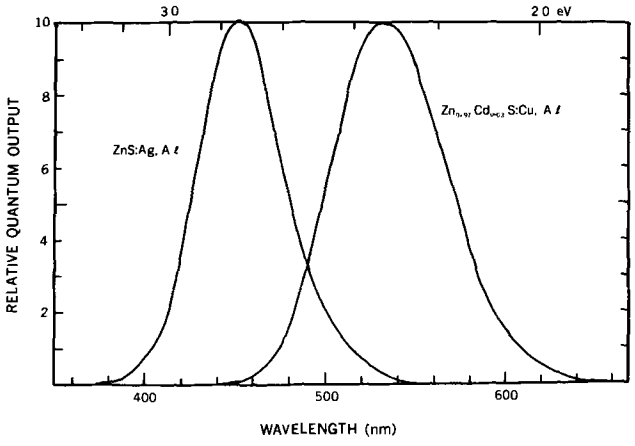

Fig. 2. Luminescent spectra of $Zn_{0.97}Cd_{0.03}S$:Cu,Al and ZnS:Ag,Al.

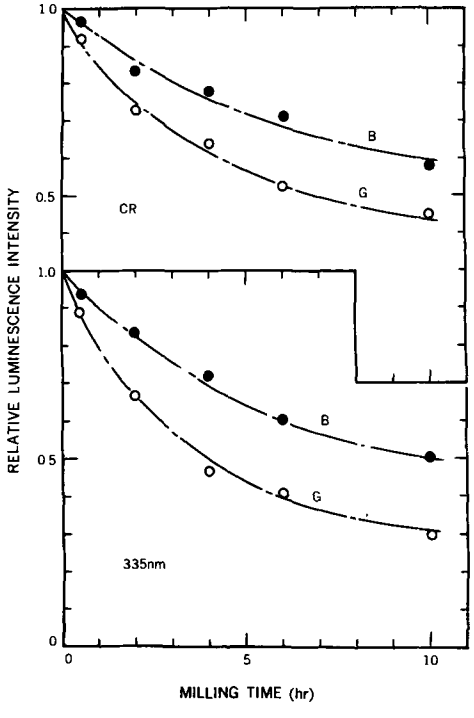

Fig. 3. Milling-time dependences of the luminescent intensities of $Zn_{0.97}Cd_{0.03}S$:Cu,Al (G, green) and ZnS:Ag,Al (B, blue) under the excitation of the 10 kV electron beam and the 335 nm light.

ZnS:Ag,Al, and larger for the uv excitation than for the cathode-ray excitation.

Figures 4 and 5 show the variations of the beam-voltage dependence of the luminescent efficiency of the green and the blue phosphors with milling time. The fluorescent efficiencies increase with the applied voltage and show a tendency to reach the limiting values. The solid curves are the theoretical ones calculated using Eq. [6] and the parameters in Tables II and III. The curves for the ball-milled phosphors are approximately scaled-down versions of that of the nonmilled phosphors except in the region of very low voltages.

Figure 6 shows the luminescent decay curves for the nonmilled and the 10-hr-milled phosphors. The decay curves are normalized for the intensity at the end of the 5 μsec-exciting pulse to be unity. The change of the decay curves is not so large as to make a contribution to the luminescent degradation. The fact that the short-term time decays are slower for 3 kV than for 10 kV excitation, in spite of the larger generation rate of electron hole pairs per unit volume for the former, is evidence of the large loss of the generated free carriers in the near-surface region. The short-term time decay for 20 kV was also slower than that

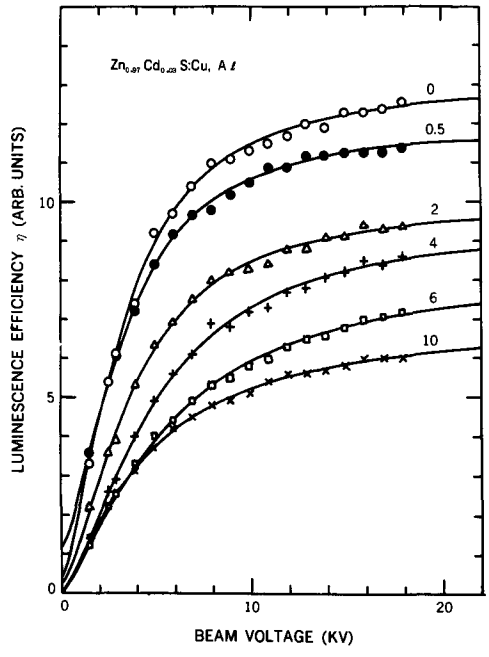

Fig. 4. Voltage dependences of the cathodoluminescent efficiencies of $Zn_{0.97}Cd_{0.03}S$:Cu,Al ball-milled for 0, 0.5, 2, 4, 6, and 10 hr.

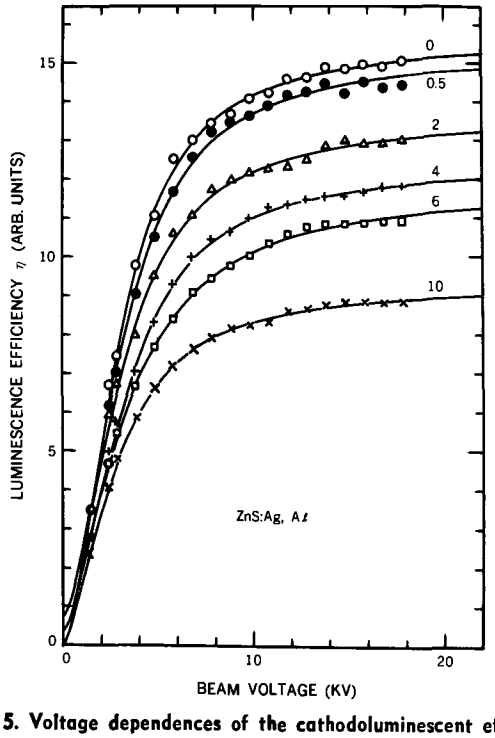

Fig. 5. Voltage dependences of the cathodoluminescent efficiencies of ZnS:Cu,Al ball-milled for 0, 0.5, 2, 4, 6, and 10 hr.

for 10 kV, which was caused by the decrease in the electron-hole pair generation rate per unit volume (see the next section).

Figures 7 and 8 show the excitation spectra at room and liquid nitrogen temperatures. The spectra are normalized with respect to their maxima. The spectra show no appreciable and no systematic change due to the milling in the region of the wavelength shorter than the bandgap light. The decrease in maxima with milling time is due to the decrease in the layer thickness, or the coating density of the phosphor. The layer thickness does not affect the shape of the excitation spectra in the region of the above-bandgap radiation, since the absorption coefficient is of the order of 10^5 cm^{-1}.

Figure 9 shows the diffuse reflection spectra. Little change in the reflection by the ball milling is observed

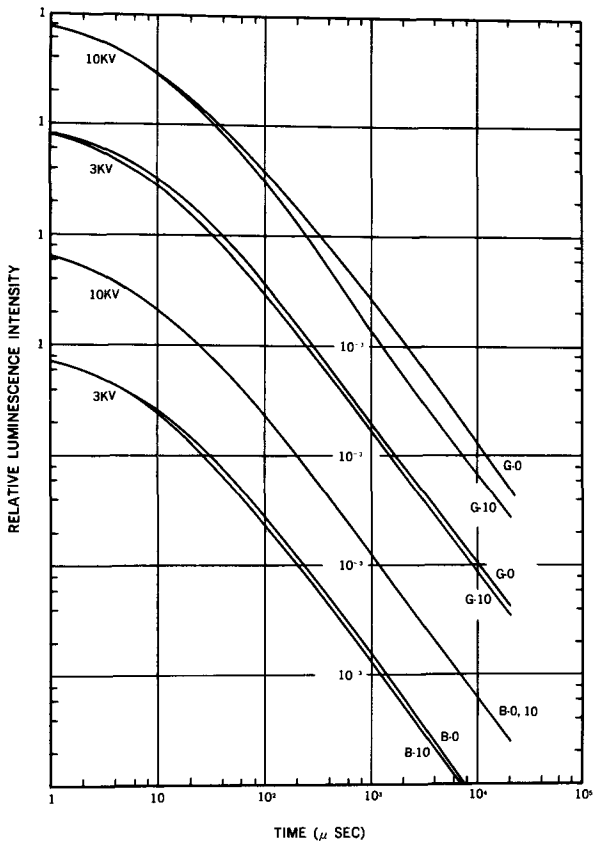

Fig. 6. Decay curves for the green (G) and the blue (B) emitting phosphors ball-milled for 0 and 10 hr at room temperature. The exciting electron beam pulse is of 5μ-sec duration with 30 Hz. The time-averaged current density is 0.2 μA/cm².

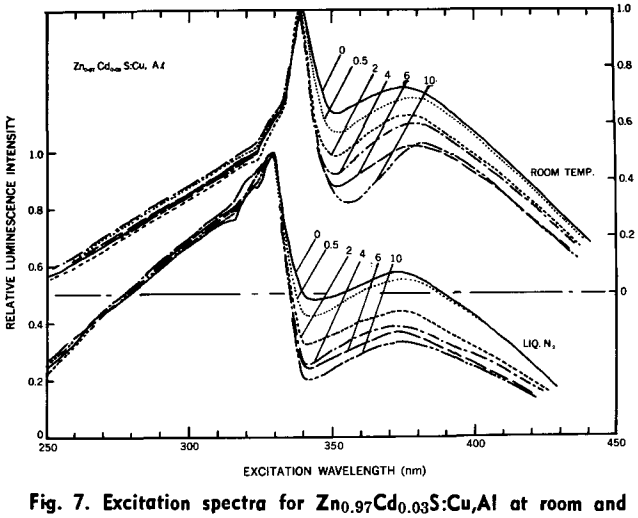

Fig. 7. Excitation spectra for $Zn_{0.97}Cd_{0.03}S$:Cu,Al at room and liquid nitrogen temperatures. The coating densities of the phosphor are 4.3, 3.6, 2.4, 1.8, 1.5, and 1.3 mg/cm² for 0, 0.5, 2, 4, 6, and 10-hr-milled samples, respectively.

in the region of the above-bandgap light and of the fluorescent light. In the region of the impurity absorption band for $Zn_{0.97}Cd_{0.03}S$:Cu,Al, the reflection increases with milling time due to the particle-size reduction.

Luminescence of Phosphor Particle Layers

In this section we shall follow the treatment of Gergely (4, 5) for phosphor luminescence and extend it to the case of phosphor particle layers, in which effects of particle size on luminescence are taken into account.

Donor-acceptor pair recombination causes green and blue luminescence in ZnS:Cu,Al and ZnS:Ag,Al

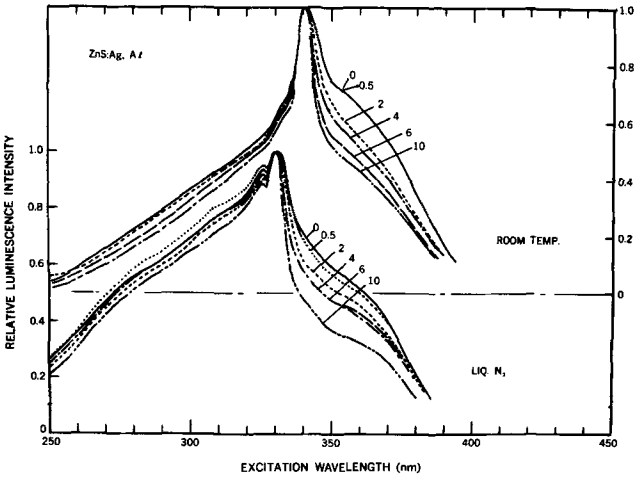

Fig. 8. Excitation spectra for ZnS:Ag,Al at room and liquid nitrogen temperatures. The coating densities of the samples are 2.5, 2.3, 2.1, 1.8, 1.6, and 1.3 mg/cm^2.

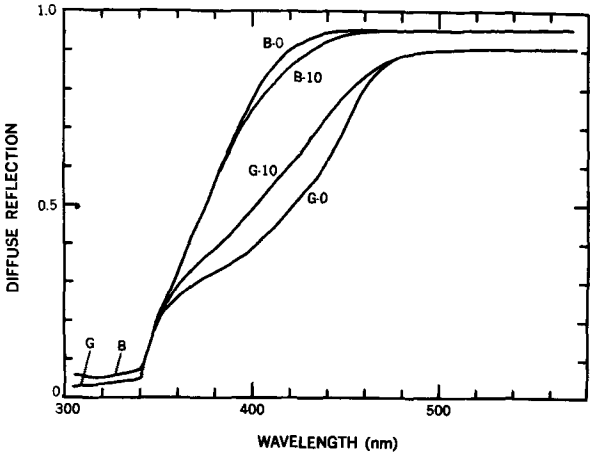

Fig. 9. Diffuse reflection spectra for the nonmilled and 10-hr milled green and blue phosphors.

(6), respectively. The acceptors with captured holes form energy levels high above the top of the valence band. The thermal activation of trapped holes occurs with negligibly small probability at room temperature and below compared with the recombination probability with electrons trapped at the donor sites. Under steady excitation, therefore, the rate for free holes to be captured per unit time by ionized acceptors is balanced with that for captured holes to recombine with electrons trapped at donors (see Fig. 10). The trapping rate for free holes is given by p/τ_p, where p is the density of free holes and $1/\tau_p$ is the probability for a free hole to be trapped by an ionized acceptor. Then the luminescent intensity, I, can be expressed in terms of the hole density p in the form

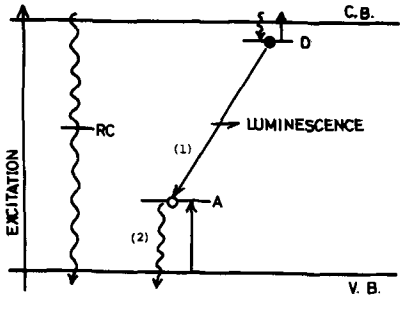

Fig. 10. Band diagram for ZnS phosphors. Arrows indicate electron transitions; the waved ones nonradiative. D, A, and RC indicate donor, acceptor, and nonradiative recombination centers, respectively. At equilibrium, the process (1) and (2) are balanced; thermal ionization of holes from the acceptor is neglected in the text.

$$I = \int_{V_c} \left\langle \frac{p}{\tau_p} E_r \right\rangle_{avg} dv \qquad [1]$$

where the average should be performed over all donor-acceptor pairs, E_r is the energy of the electronic transition in the pair of interest, and V_c the volume of the luminescent region.

The differential equation governing the generation and recombination kinetics of free holes under steady excitation is given by

$$g - \frac{p}{\tau} + D\Delta p = 0 \qquad [2]$$

where g is the generation rate of free holes by the excitation per unit time per unit volume, τ the lifetime of free holes, and D the diffusion constant of holes.

For electron beam excitation, g is assumed to be proportional to the energy dissipation rate of the electron beam in crystals. A simple model for the energy dissipation which is based on the observation by Young (7) was fairly successfully used to explain the secondary electron emission of solids by Lye and Dekker (8). It states that a constant amount of energy is dissipated per unit time per unit path length as an electron beam penetrates into solids until the electron beam consumes its entire energy in the effective penetration depth, R, which is called the range of electron penetration. Gergely also used this model, and g is given by

$$g = \frac{iV}{kR}, \quad 0 \leq x \leq R$$
$$= 0, \quad x > R \qquad [3]$$

where x is the distance in the solid from the bombarded surface, and k is the average energy consumed per generated low-energy electron-hole pair [about 10 eV for ZnS being estimated from the bandgap dependence of the radiation ionization energy which was measured for various semiconductors (9)], i the current density, and V the accelerating voltage.

Gergely has obtained the solution $p(x)$ of Eq. [2] using Eq. [3] for a semi-infinite crystal whose surface is bombarded uniformly by an electron beam (4). Substituting the solution into Eq. [1] gives the cathodoluminescent efficiency η in the form

$$\eta = \frac{I}{iV} = K\left(1 - Q\frac{1 - e^{-\beta R}}{\beta R}\right) \qquad [4]$$

where

$$K = \frac{C}{k}\left\langle \frac{\tau}{\tau_p} E_r \right\rangle_{avg}$$

$$Q = \frac{S}{D\beta + S}$$

$$\beta = \frac{1}{\sqrt{D\tau}}$$

C is the external efficiency of the luminescent light, and S is the nonradiative recombination velocity of free holes at the crystal surface.

Now, let us extend the above single-crystal treatment to the case of phosphor particle layers. Phosphor layers consist of particles of different sizes and irregular shapes. It is not advantageous to make a microscopic consideration on such particle layers. It seems better to regard the particle layers as a single crystal as a whole. Then Eq. [4] may still be used for phosphor layers. However, the parameters must necessarily have meanings or expressions different from those for a single crystal.

K is the ultimate efficiency at the high voltage limit. Luminescent loss increases with increasing surface area of phosphor, because of the high density of non-

radiative recombination centers for free carriers in the surface region of the particles. Therefore, the ultimate efficiency K is reduced by a factor of $(1 - S_A\rho l)$, going from the semi-infinite crystal to particle layers, where S_A is the specific surface area of the phosphor, ρ the specific gravity, and l a proportional constant. We consider the case where the particle size is not so extremely fine as the factor $(1 - S_A\rho l)$ and may be approximated by $\exp(- S_A\rho l)$. $S_A\rho$ can be also expressed as $6/d_m$, d_m being the average diameter, if the particles are spherical. Accordingly, K may be written as follows

$$K = \frac{C}{k}\left\langle\frac{\tau}{\tau_p}E_r\right\rangle_{avg}\exp(-S_A\rho l)$$

$$\frac{C}{k}\left\langle\frac{\tau}{\tau_p}E_r\right\rangle_{avg}\exp(-6l/d_m)$$

$S_A\rho$ and $6/d_m$ are usually connected by a shape factor due to irregular shapes of particles. The constant l takes different values for the above two expressions. It may be regarded as the average width of the "dead surface layer" of particles.

The hole lifetime τ in the case of particle layers should be considered as the one averaged over the whole volume of particles. Particle size reduction or increase in the surface area of the phosphors reduces the average lifetime of free holes because of the large contribution of the surface region of short lifetime to the average. The surface recombination velocity of holes S is not a function of the particle size but of the surface properties.

The electron range R should be considered also particle-size dependent for the following reason. R is related to the accelerating voltage V by the empirical formula

$$R = bV^n \qquad [5]$$

where b and n are experimental parameters characteristic of solids. Young's model states that the electron beam energy almost linearly decreases going into a solid and becomes zero at the distance R from the solid surface, as shown in Fig. 11a. The average slope is $-iV/R$ which is larger for larger V because $n > 1$. When the crystal is cracked into two parts, for example, at the distance $R/2$, the distance-energy line is deflected at the interface as shown in Fig. 11b. The resultant penetration depth R_1 is easily calculated as

$$R_1 = R\left(\frac{1}{2} + \frac{1}{2^n}\right) < R$$

Although this is a very simplified model, the probability that an electron beam, or part of it, experiences the second or the third surface increases as the particle size decreases, because electrons can penetrate through fine particles and also through the edge region of even larger particles. This tendency may be enhanced as the particle shape becomes complex. As a result, the average electron range decreases with decreasing particle size. In addition, the simple range energy relation of Eq. [5] may not hold for particle layers. We proceed, however, in this simple treatment on the assumption that the relation of Eq. [5] still holds for particle layers, but b and n are different from those for single crystal and are particle-size dependent.

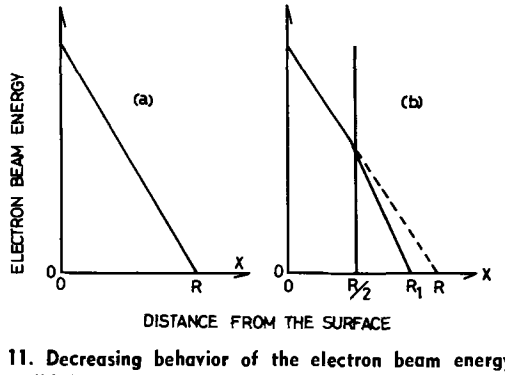

Fig. 11. Decreasing behavior of the electron beam energy in a perfect solid (a) and in a solid cracked into two parts at $R/2$ (b). x indicates the distance in the solid from the surface. R is the electron range.

In the case of excitation by above-bandgap light, the generation rate of electron hole pairs, $g(x)$, per unit time per unit path length is given by

$$g(x) = N_\lambda\,(1 - R_\lambda)\,\alpha_\lambda \exp(-\alpha_\lambda x)$$

where N_λ is the flux of the exciting light, R_λ the reflectance, and α_λ the absorption coefficient. Gergely has obtained an expression of luminescent intensity for such cases (5). A little modification of his expression [Eq. [14] of Ref. (5)] as we have done for cathodoluminescence leads to the following formula for photoluminescent intensity I_p

$$I_p = K_p\,N_\lambda\,(1 - N_\lambda)\left(1 - Q\frac{\alpha_\lambda}{\beta + \alpha_\lambda}\right)$$

where $K_p = kK$, and K and Q are formally the same as those in Eq. [4]. K_p does not have the meaning of the ultimate efficiency as K has in the case of cathodoluminescence. Considerations are to be confined within the region invaded by the exciting light, the depth of which is of the order of 0.1μ (inverse of α_λ). The ratio of the surface area to the volume in such a region is necessarily larger than that of the entire phosphor. Accordingly, K_p for bandgap excitation has a stronger dependence on the measured specific surface area S_A or on the mean diameter d_m than that of cathodoluminescence, as seen later (Fig. 12 and 13).

Let us summarize the formulas obtained for convenience of later discussion:
for cathodoluminescent efficiency η

$$\eta = K\left(1 - Q\frac{1 - e^{-\alpha V^n}}{\alpha V^n}\right) \qquad [6]$$

and for photoluminescent intensity I_p under bandgap excitation

$$I_p = K_p\,N_\lambda\,(1 - R_\lambda)\left(1 - Q\frac{\alpha_\lambda}{\beta + \alpha_\lambda}\right) \qquad [7]$$

where

$$K = \begin{cases} \dfrac{C}{k}\left\langle\dfrac{\tau}{\tau_p}E_r\right\rangle_{avg}\exp(-S_A\rho l) \\ \dfrac{C}{k}\left\langle\dfrac{\tau}{\tau_p}E_r\right\rangle_{avg}\exp(-6l/d_m) \end{cases} \qquad [8]$$

$$K_p = kK \qquad [9]$$

$$Q = \frac{S}{D\beta + S} \qquad [10]$$

$$\beta = \frac{1}{\sqrt{D\tau}} \qquad [11]$$

$$\alpha = b\beta \qquad [12]$$

The notations used are given at the end of the paper.

Discussion

Cathodoluminescence.—The values of the parameters K, α, n, and Q in Eq. [6] have been determined by the method of least squares, which minimizes the sum of the squared differences between the observed and the calculated efficiencies. They are given in Tables II and III, together with the resultant root mean square deviations.

The ultimate efficiency K at the high voltage limit should vary exponentially with the specific surface area S_A or with the inverse of the average diameter

$1/d_m$, as seen from Eq. [8], if the luminescent degradation is caused only by particle size. The variation of the factor $\left\langle \frac{\tau}{\tau_p} E_r \right\rangle_{avg}$ in K is not changed by the milling performed, since it little affects the luminescent spectra and the decay curves. The external radiation efficiency C may be considered to vary little because of the ball milling, since the luminescence is observed from the bombarded side and the diffuse reflectance in the luminescent region is affected little by the milling (Fig. 9). In such selected conditions of ball milling a linear relation is reasonably expected when log K is plotted against S_A or $1/d_m$, which is demonstrated in Fig. 12 and 13.

The value of l can be estimated from the slopes of the lines log K-S_A and $-1/d_m$. Silica applied to the phosphors as the coating makes a large contribution to the measured specific surface area in spite of its small quantity relative to the phosphor (Table I). However, the silica coating does not affect the slopes, since the surface area of silica does not change because of the ball milling according to our subsidiary measurement. A reasonable value of l as the dead layer width is obtained from the slope of log K-S_A but not

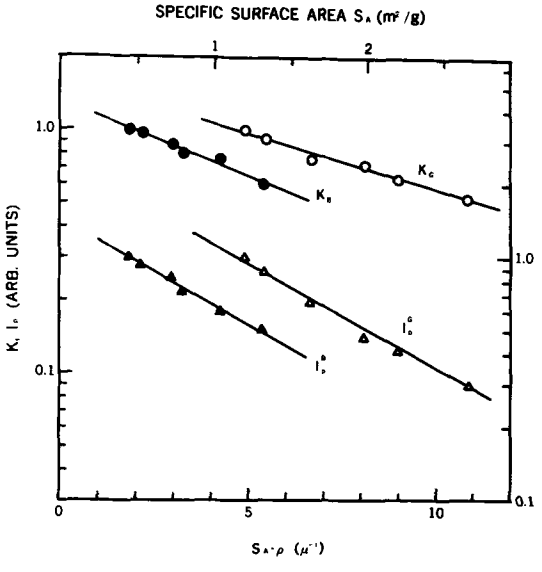

Fig. 12. Variations with the specific surface area S_A of the ultimate efficiency K for cathodoluminescent and of the photoluminescent intensity I_p under the 335 nm excitation.

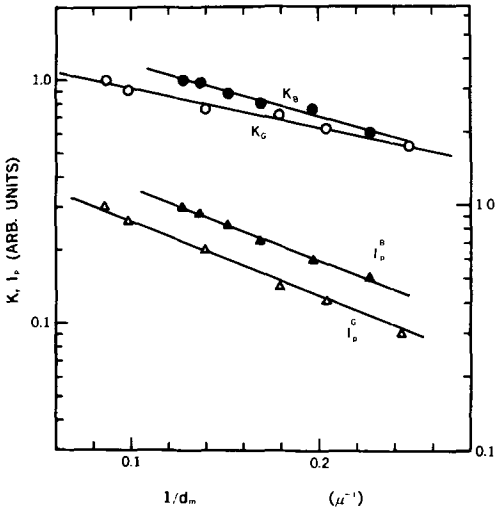

Fig. 13. Variations with the inverse of the mean diameter $1/d_m$ of K for cathodoluminescent and of the photoluminescent intensity I_p under the 335 nm excitation.

from log K-$1/d_m$, since the mean diameter is only a measure of the particle size without the irregularity of the particle shapes being taken into account. The values of l obtained are 0.10 and 0.14μ for the green and the blue phosphors, respectively. It should not be implied that each particle is covered by a dead layer of the width l, since l has only the meaning of the average over a whole particle group, which may include nonluminescent fine particles or particles less luminescent due to inhomogenous distribution of activators.

The variation of the exponent n of the range-energy relation with the mean diameter is shown in Fig. 14. The value of n for the nonmilled samples are approximately in agreement with those obtained by Ludwig and Kingsley (10). The exponent n decreases as the mean diameter decreases, especially rapidly below about 6μ. As described in the previous section, such tendency of n is caused by the decrease in the electron range R with decreasing particle size. Feldman (11) obtained $n = 2.4$ for transparent thin films of ZnS.

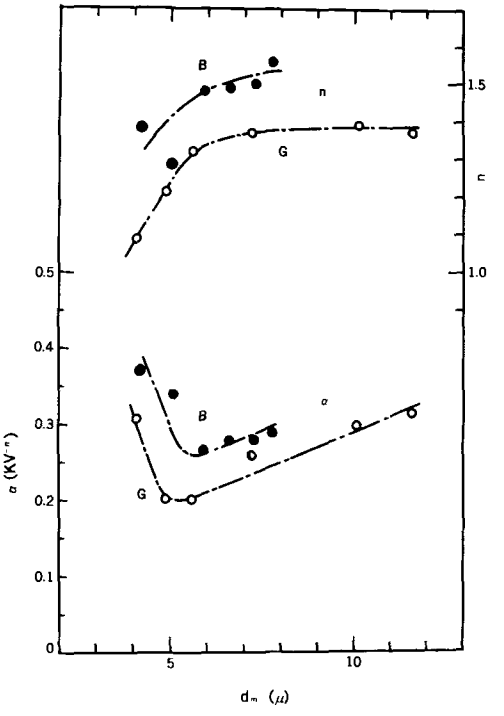

Fig. 14. Particle size dependences of n and α ($= b\beta$). d_m is the mean diameter. The approximate dependences are indicated by chained curves.

This large value of n compared with that obtained here may be considered to have been caused by the fact that the material he used was transparent without interface.

The value of α which is equal to $b\beta$ decreases with decreasing mean diameter and it rapidly increases also from near 6μ as shown in Fig. 14. β should increase with decreasing particle size, as discussed in the previous section, since the average hole lifetime decreases. The first decrease of α with decreasing mean diameter, therefore, indicates that b decreases much faster than β increases in this region. Such decrease of n and b with decreasing particle size is qualitatively consistent with the discussion in the previous section that the electron range R should decrease with decreasing particle size.

The "range" R used in this study may be different from the so-called range of electron penetration. The electron range R here means the range within which free holes and electrons are generated as the electron beam goes through into the phosphor. Generation and annihilation processes of elementary excitations such as plasmons, phonons, and excitons would affect the processes of electron-hole pair generation. Therefore, the electron range here is dependent on the properties of crystal structure, impurities, defects, and of the constituent atoms of the crystal, as well as particle size. In addition, it should be questioned for more rigorous treatment if the simple proportionality between the electron-hole pair generation rate and the energy dissipation rate of the electron beam holds in the wide range of the beam energy. Mayer has observed deviations from monotonic dependence of luminescent intensity on landing energy at x-ray levels of the constituent atoms for various phosphors (12). Young's model for energy dissipation of electrons is also questionable (13). However, it is convenient and not unreasonable in the simplified and semiquantitative treatment to see the gross features of the problem.

Photoluminescence.—The variation of the photoluminescent intensity under the excitation of the 335 nm light can be explained by Eq. [7]. The reflectance R_λ is not changed appreciably by ball milling as seen from Fig. 9. The parameter Q for cathodoluminescence takes values near unity almost independently of the milling time (Tables II and III). This fact means that the surface recombination velocity is much larger than $D\beta$ and that the variation of β does not much affect Q. Therefore, Q for photoluminescence must also have small milling-time dependences and take values near unity. The average lifetime of holes τ is considered extremely short because the bandgap light produces holes only in the surface region of high densities of recombination centers. Accordingly, it is reasonable to consider that $1/\beta$, or the average diffusion length of holes in the surface region, is much smaller than the penetration depth of the exciting light, or $1/\alpha_\lambda \cong 0.1\mu$. Thus, the variation of the photoluminescent intensity is ascribed to the variation of K_p. The plot of log I_p *vs.* S_A and $1/d_m$ shows linear relations as seen in Fig. 12 and 13, and the slopes are steeper than those of log K *vs.* S_A and $1/d_m$ for the cathodoluminescence. This steeper slope is, as discussed in the previous section, due to the fact that the ratio of the surface area to the volume in the region invaded by the exciting light is larger than that of the entire phosphor. Kremheller *et al.* (14) have also observed a linear dependence of the logarithm of photoluminescent intensity on measured surface area. They ascribed, however, the luminescent loss to the creation of trapping levels due to the exposure of internal surface chloride.

The voltage dependence of the cathodoluminescent efficiency has been found the most helpful in understanding the luminescent degradation in this study. The other measurements, decay curves, excitation and diffuse reflection spectra are complementary. Let us explain some of their meanings.

The short-term time decays of the luminescence for the ball-milled phosphors are little faster than those of the nonmilled ones. This may result from the higher densities of excited donor-acceptor pairs for milled phosphors than those for nonmilled ones. The decrease in the effective electron range R results in the increase in the average generation rate of free carriers per unit path length of the electron beam.

The average rate of generation of electron-hole pair per unit path length is larger for the smaller beam voltage according to Eq. [3], since $n > 1$. The slower initial decay for 3 kV in spite of the larger generation rate than for 10 kV is evidence of the large surface recombination loss of free carriers.

The excitation spectra in the region of wavelength shorter than the bandgap light do not show appreciable and systematic variation with milling time, in contrast to the spectra observed by Gergely *et al.* (15); their spectra for the ground samples show large decreases compared with the unground samples as the excitation wavelength becomes shorter. This is because the surface recombination loss is enhanced in the region of high absorption coefficient. Accordingly, the invariance of our spectra indicates that the particle surface is not seriously damaged by the ball milling adopted in this study.

Conclusions

1. The luminescent degradation of the $Zn_{0.97}Cd_{0.03}S$:Cu,Al and ZnS:Ag,Al phosphors by our ball milling is caused mainly by the particle size reduction, which increases the less-luminescent surface region relative to the whole volume of the phosphor. Bulk and surface properties relevant to luminescence are little changed by the ball milling adopted. The conclusion is mainly based on the fact that the linear dependences of log K and log I_p on S_A and $1/d_m$ are found. Other experiments also support this conclusion.

2. The average width of the dead layer of the phosphors is estimated to be of the order of 0.1μ.

3. The electron range in phosphor layers, or the average range of generation of electron-hole pairs, decreases with decreasing particle size.

4. Supplementary remarks: Effects of ball milling on phosphors depend on its condition, namely, sizes and materials of milling pot and balls, quantities of phosphors and balls, dispersion media and milling time. Under some conditions of ball milling, induced lattice defects may make a large contribution to luminescent loss. The authors have found that the linear dependence of log K on S_A is not obtained in such cases. Milling stability of phosphors also depends on the condition of synthesizing.

Acknowledgments

The authors are indebted to Mrs. T. Moriya and Mr. T. Abe for help with the sample preparation and measurements. They also express their thanks to Drs. S. Shima and T. Mitsuma for their encouragement throughout the course of this work.

Manuscript submitted Sept. 11, 1972; revised manuscript received *ca.* March 6, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

LIST OF SYMBOLS

τ	average lifetime of free holes
$1/\tau_p$	probability for a free hole to be captured by an ionized acceptor
E_r	radiative transition energy
k	average energy consumed per generated electron-hole pair
C	external radiation efficiency of luminescent light
S	surface recombination velocity of free holes
D	diffusion constant for free holes
S_A	specific surface area of phosphor

ρ	specific gravity of phosphor
d_m	average diameter of phosphor particles
l	average width of dead layer
V	accelerating voltage of the electron beam
b, n	parameters that determine the electron range as $R = bV^n$
N_λ	exciting light flux
R_λ	reflectance of the phosphor layer
α_λ	absorption coefficient of the exciting light

Indium Phosphide

I. A Photoluminescence Materials Study

E. W. Williams, W. Elder, M. G. Astles,[1] M. Webb, J. B. Mullin, B. Straughan, and P. J. Tufton

Royal Radar Establishment, Malvern, Worcestershire, England

ABSTRACT

Solution-, vapor-, and melt-grown InP have been analyzed with photoluminescence measurements over the temperature range 5°-300°K. Although undoped material is discussed, the main emphasis is on doped InP grown from an indium solution for use as LED material. Optical activation energies were determined for hydrogenic donors, 7-10 meV; simple acceptors, zinc −50 meV, cadmium −58 meV, and mercury −98 meV; the isoelectronic trap bismuth, −31 meV; transition metal acceptors, copper −60-73 meV and manganese −270 meV.

Indium phosphide lived in the shadow of gallium arsenide during the sixties and there was little interest in it. In 1970 it finally "arrived" on the semiconductor scene when the three level microwave oscillator was invented by Hilsum and Rees (1). The place of indium phosphide in semiconductor history was strengthened by the observation of Blom and Woodall (2) that the narrow line width of the spectra of indium phosphide light emitting diodes made them very efficient pumps for multiphoton phosphors so that brighter visible light output in a variety of colors was possible.

Light emitting diodes were the main motivation for the work described in this trilogy of papers on indium phosphide. The first paper is a review of some of the photoluminescence measurements made on indium phosphide prepared at this laboratory. Photoluminescence was used to analyze the material produced by solution growth (3), vapor growth (4), and by liquid encapsulation melt growth (5). The emphasis will be on solution-grown material since this was used for the preparation of the light emitting diodes. The technique of solution growth will be discussed in detail in the second paper. In the third, the subject will be double epitaxy light emitting diodes with efficiencies of 1.3% at room temperatures.

Earlier studies on indium phosphide photoluminescence concentrated on the study of undoped material. Two lines near 1.41 and 1.37-1.38 eV at 4.2°K were associated with excitons and with band to acceptor recombination (6-8). The 1.41 eV line consisted of several components at helium temperatures and these have now been more clearly resolved at 1.8°K to show free exciton, excitons bound to ionized and neutral donors, and excitons bound to neutral acceptors (9). Two-hole and two-electron transitions were also observed at this low temperature (9).

The present paper describes measurements made in the temperature range 5°-300°K and will stress the measurements made on the doped indium phosphide used in the light emitting diodes.

Studies of the half width and the peak position of the luminescence lines as a function of doping have proved particularly useful in understanding the mechanisms involved in heavily doped InP. The measurements of Roder *et al.* (10) on solution-grown InP doped with zinc and tellurium are compared with the present work and the tellurium results are reinterpreted. The optical activation energies of the dopants have been estimated and it is shown that for the group II elements, the acceptor activation energy increases with atomic size for the series zinc, cadmium, and mercury. The transition metals copper and manganese are also briefly mentioned.

Experimental Technique

The experimental setup was similar to the one described previously (11). A d-c 150W Atlas tungsten iodide lamp was used for excitation instead of a mercury lamp and a 230 Hz miniature Bulova tuning fork chopper replaced the old mechanical chopper.

The samples were glued with rubber solution onto the sample holder of a continuous flow helium cryostat (12) capable of giving temperatures from 5°K upwards. This cryostat worked simply by an immersion heater in the bottom of a 15 liter helium Dewar boiling off helium gas which flowed over the sample and cooled it. The faster the boil off, the colder the sample became.

The spectra were all corrected for the photomultiplier and optical system response.

Comparison of Growth Techniques for Undoped InP

Melt-grown material.—The InP crystals were grown in a pressure puller using boric oxide as a liquid encapsulant (5). The high temperature of growth (1050°C) means that more impurities and lattice defects can be incorporated into the material than when lower growth temperatures are used as in the case of epitaxially grown material. As was mentioned in a previous publication, when measurements were made at 77°K as many as six lines were observed in the photoluminescence spectrum of the bulk undoped material (13). Two lines at 1.41 and 1.37 eV were always observed but in addition two other lines at 1.32 and 1.16 eV were often observed, and less frequently, lines at 1.35 and 1.28 eV were seen.

The near band edge peak at 1.41 eV contains a large number of components (9) all of which were unresolved even when the temperature was lowered to 5°K. Most of these components are due to recombination associated with excitons bound to acceptors and donors. Mass spectrographic analysis (14) indicates that silicon is present, so silicon may be partly responsible for this line. But the role of other donors, sulfur and perhaps oxygen, for which this analysis is insensitive may perhaps be more important.

The peak near 1.37 eV was thought to be associated with zinc acceptors because of the zinc doping experiments with solution-grown material mentioned below, and the low temperature studies of zinc doped vapor-grown material (15) indicate that zinc acceptors produce a line at about 1.373 eV. Furthermore, mass spectrographic analysis (14) also clearly indicates the presence of zinc in the undoped pulled material.

Mercury is the likely cause of the 1.32-1.33 eV line. It was first suspected when it was found that the InP starting material was being treated with mercury. A typical spectrum of the highest purity crystals grown from this mercury-treated starting material is shown in Fig. 1(a). Notice the strong 1.33 eV line. These crystals were frequently p-type. The carrier concentration $N_A - N_D$ of the p-type sample shown in Fig. 1(a) was 3×10^{16} cm^3.

New crystals pulled from acid-treated starting material with no mercury present show very little emission at 1.33 eV as shown in Fig. 1(b). The small peak at 1.33 eV may be mainly caused by the first LO phonon replica of the 1.37 eV zinc acceptor-unknown donor pair line as the ratio of its size to the zero phonon line at 1.37 eV is similar to the phonon associated with the line seen in zinc doped samples. The carrier concentration of this second n-type sample was $N_D - N_A = 5.13 \times 10^{15}$/cm^3. All of the crystals grown from acid-treated material were n-type. Hence the above results imply that mercury produces a deep acceptor level which gives an emission line at 1.33 eV. This implication has been confirmed by (*i*) mercury diffusion into an epitaxial layer and (*ii*) mercury doping of the bulk material. The mercury diffusion will be discussed below but the doping experiments will be described elsewhere since they are not yet completed.

Lines at 1.35 and 1.28 eV have been observed in the 77°K spectra of undoped melt-grown indium phosphide and they were particularly strong in the less pure crystals. The 1.35 eV line is known to be associated with copper (see below), but the 1.28 eV line is of unknown origin.

A broad emission line at 1.16 eV was frequently observed and this has been discussed previously (13). It was always enhanced by the presence of excess indium so it was thought to be associated with phosphorus vacancies.

Vapor-grown undoped InP.—Over fifty samples grown by the PCl_3 technique (4) were run at 6°K. No deep level emission associated with the 1.16, 1.28, 1.33, or 1.35 eV lines was ever observed. This is probably because of the higher purity of vapor-grown material which normally has a much higher mobility than the bulk material. Mobilities as high as 60,000 cm^2/V-sec at 77°K were measured (4). The line at 1.37 eV was much sharper than with the melt-grown material and this enabled three other lines to be seen near to the 1.37 eV line. Two of these lines occurring at about 1.38 and 1.39 eV are shown in Fig. 2. This sample had a net carrier concentration of 2.4×10^{15} and a mobility of 23,000 cm^2/V-sec at 77°K. The third line occurs close to 1.36 eV but was never clearly resolved and just appeared as a weak shoulder. The LO phonon replica of the 1.37 line (Ac + LO) was also observed at 1.33 eV. The 1.39 eV line increased in intensity when the samples were heat-treated at 500°C in hydrogen for only 5 min; it also increased as the epitaxial layer was gradually etched off, and was very strong as the epi-

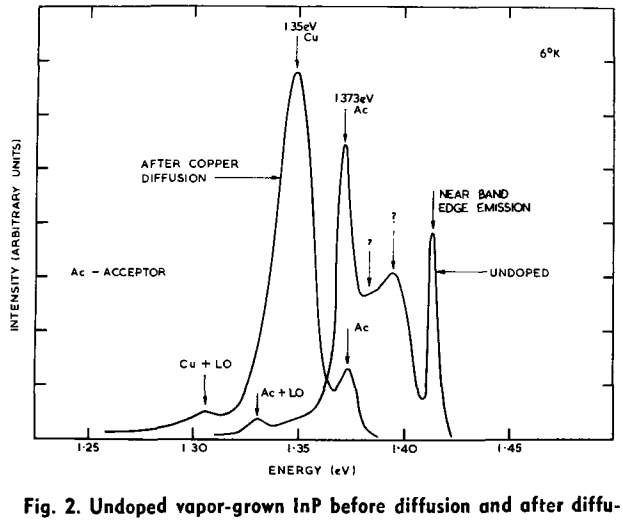

Fig. 2. Undoped vapor-grown InP before diffusion and after diffusion with copper for 5½ hr at 750°C. Photoluminescence spectra at 6°K.

taxial substrate interface was approached (16). Further work needs to be done before the origin of the 1.39 eV line can be ascertained and it would be pointless to speculate upon its nature at this stage of the work.

The ratio of the intensity of the two main lines at 6°K varied in a random manner for consecutively vapor-grown layers as did the carrier concentration and mobility.

At 77°K, however, the highest mobility samples all showed a very strong 1.41 eV line and an extremely weak 1.37 eV line, as has been mentioned previously by Joyce and Williams (4). The variation of the half width of the 1.41 eV line at 77°K as a function of $N_D - N_A$ which was reported in this paper is compared with doped samples grown by solution and by melt growth in Fig 3. This half-width variation can be used in place of Hall measurements as a measure of the carrier concentration. This is useful for epitaxial layer evaluation because the carrier concentration can be measured regardless of whether the substrate is semi-insulating or highly conducting and additionally it is a nondestructive technique. This was particularly useful for selecting good microwave device material for undoped layers grown on tin doped substrates. If the substrate quality was poor or had a doping level above $7 \times 10^{17}/cm^3$, impurities could be incorporated into the epitaxial layer during the growth. Gaseous interaction with the back of the substrate during growth was eliminated as a possible effect because layers grown on semi-insulating Cr doped substrates during the same run were uncontaminated by the substrate.

Finally, it should be mentioned that it was found that the presence of a strong 1.37 eV peak at 77°K correlated with strong compensation in the material and poor microwave device characteristics.

Solution-grown undoped InP.—Only a few photoluminescence measurements were made on undoped InP grown from indium solutions using phosphine saturation and a modified Nelson technique (3) because the main emphasis was on doped layers for light emitting diode studies. A series of six undoped layers grown sequentially and using the same growth conditions were all n-type and had carrier concentrations in the range 3×10^{15} to $2 \times 10^{16}/cm^3$ and mobilities at 77°K of between 12,000 and 19,000 cm^2/V-sec. The luminescence properties were very similar to the vapor-grown layers. The widths of the 1.37 and 1.41 eV lines were almost the same as for the vapor-grown material and the ratio of the intensities of the two lines varied in an arbitrary fashion from run to run. The 1.41 eV line was very slightly wider than for the best vapor-grown sample indicating a higher donor doping level. The 1.37 eV line was generally stronger and was once again believed to be due to contamination of zinc. None of the three extra lines sometimes seen in vapor growth were observed.

The first undoped layers were grown from indium solutions saturated with undoped single crystalline InP under a purified hydrogen flow and these also gave emission at 1.41 and 1.37 eV at helium temperatures but there was also a very strong 1.16 eV line. The electrical properties were much more variable and varied from 8×10^{15} to $4 \times 10^{17}/cm^3$. All the undoped samples were n-type and the highest mobility was 28,000 cm^2/V-sec for a carrier concentration of 8×10^{15} at 77°K.

Doping Studies

Group II impurities.—The addition of zinc, cadmium, and mercury to indium phosphide renders it p-type. Zinc and cadmium always gave p-type behavior but in the case of mercury the doping was much more difficult and p-type behavior is not always obtained due to the lower solubility of mercury in indium phosphide. The luminescence spectra at 50°K of these three group II acceptors is shown in Fig. 4. The zinc and cadmium samples were solution grown with doping levels of 1.2×10^{16} and 7.4×10^{16} holes/cm^3 at 300°K. The mercury doped sample was n-type with $N_D - N_A = 3 \times 10^{16}/cm^3$ at 300°K. The mercury doping was thought to be in the region of $2 \times 10^{16}/cm^3$ from a calculation of N_A from Hall measurements at 77° and 300°K. The temperature of 50°K was chosen for recording the spectra for two reasons. First, conduction band to acceptor recombination dominates at this temperature and second, the band to acceptor lines are clearly resolved from the near band edge peak at 1.40-1.41 eV. In the case of the zinc spectrum the peak occurs at 1.373 eV and this coincides with the peak most commonly observed in undoped solution-, vapor-, and melt-grown crystals. Cadmium on the other hand shows a peak at 1.362 eV and mercury shows a line at 1.324 eV. LO phonon coupling is observed for all three lines and the first phonon replica appears to be of equal relative strength for all three acceptors. However, in the case of cadmium and zinc, the phonon replica is unresolved from another impurity line. This was concluded from studies of the cadmium and the zinc line as a function of doping and as

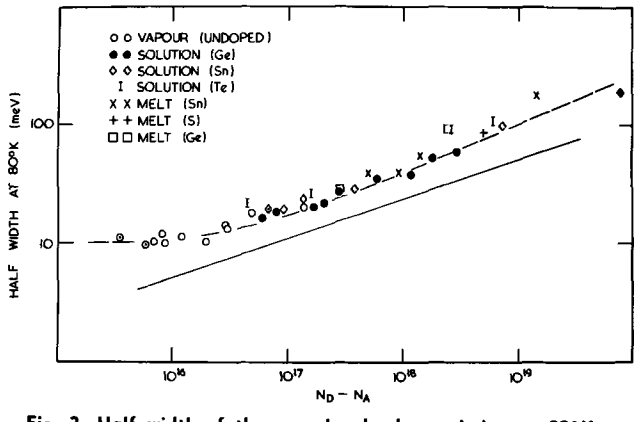

Fig. 3. Half width of the near band edge emission at 80°K *vs.* $N_D - N_A$ for n-type undoped vapor-grown and doped solution and melt-grown InP.

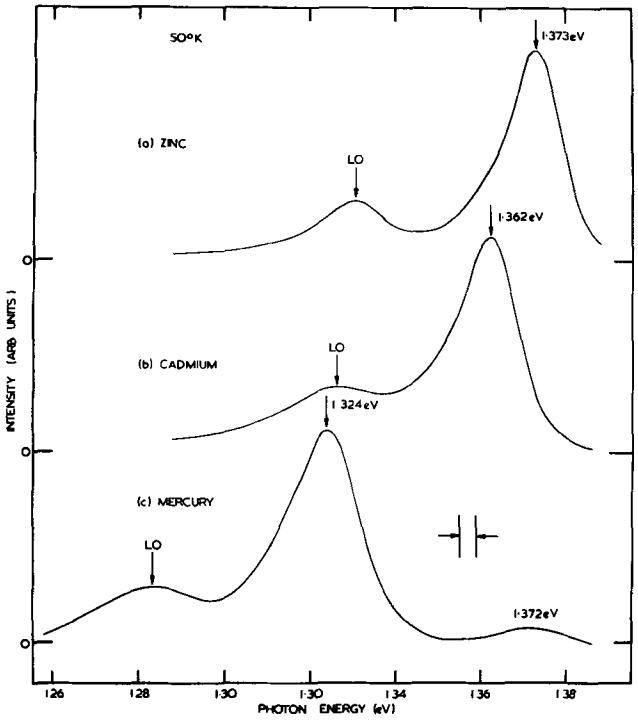

Fig. 4. Comparison of (a) zinc $N_A - N_D = 12 \times 10^{16}/cm^3$, (b) cadmium $N_A - N_D = 7.4 \times 10^{16}/cm^3$, and (c) mercury $N_A - N_D = 3 \times 10^{16}$ doping. Photoluminescence at 50°K. (a) and (b) are solution grown, (c) is melt grown.

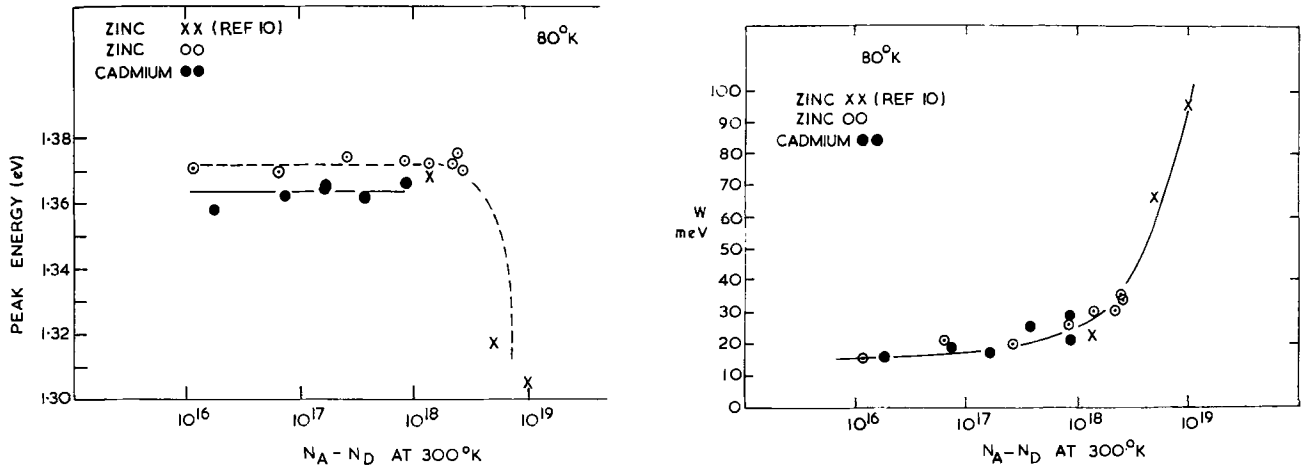

Fig. 5. (a, left) Variation of the peak energy of the band to acceptor luminescence line at 77°K with $N_A - N_D$ at 300°K for zinc and cadmium doped InP. (b, right) Half width of the band to acceptor luminescence line at 77°K vs. net hole concentration at 300°K for zinc and cadmium doping.

a function of temperature. The possibility of this extra impurity line being mercury is obvious from Fig. 4 since the mercury line almost coincides with the phonon replica of the zinc and cadmium.

The energy of the peak at 80°K of the zinc and cadmium lines as a function of doping is shown in Fig. 5(a). The results of Roder *et al.* (10) on heavily zinc doped solution-grown material are also plotted on the figure to show the expected shift of the peak as the impurity level broadens into a band as the doping increases. The half width of the emission is plotted in Fig. 5(b) for those samples shown in 5(a).

From the constant value of the peak at lower doping levels, the activation energy can be calculated by subtracting the peak energy from the bandgap. The activation energies are tabulated in Table I. They were corrected by $\frac{1}{2}kT$ to take account of the distribution of electrons in the conduction band. They compare very closely with those determined from measurements made on vapor-grown InP at 2°K on excitons bound to zinc and cadmium (15).

The activation energy was also found from temperature studies of the quenching of the luminescence. The activation energy is given by the equation

$$I = I_0 \exp(\Delta E/kT)$$

where I_0 is the intensity at 0°K and ΔE is the activation energy. Table I shows that the quenching activation energy for zinc and mercury was in reasonably close agreement with that found from the peak energy positions. An extensive study of the temperature quenching was not carried out because the peak position of the luminescence gave a more accurate determination of the activation energy.

The temperature variation of the position of peak energy of the luminescence for all three acceptors is shown in Fig. 6 and compared to the bandgap variation of Turner *et al.* (17). The zinc sample had a doping level of 6×10^{16} compared to 7×10^{16} for the one of the cadmium samples (Fig. 6, open circles) and 2×10^{16} for the second cadmium specimen (Fig. 6, shaded circles). The zinc and cadmium samples showed an increase in "optical" activation energy as the temperature was reduced from 80° to 6°K of about 7 meV. Here "optical" activation energy is the difference between the peak energy and the bandgap at a fixed temperature. The increase in "optical" energy was observed for all samples of zinc and cadmium doped samples in the doping range 1×10^{16} to $4 \times 10^{17}/cm^3$. The shift is accounted for by the change in electron recombination mechanism from conduction band to acceptor level at 80°K to donor to acceptor recombination at 6°K. The 7 meV shift is then reasonable because this is close to hydrogenic donor binding energy in InP which is 7 meV (using an effective mass of 0.078m) (18). The two mechanisms were not resolved as two separate peaks presumably because the doping level was too high.

The mercury doped sample had a doping level of about $2 \times 10^{16}/cm^3$ and followed the bandgap quite

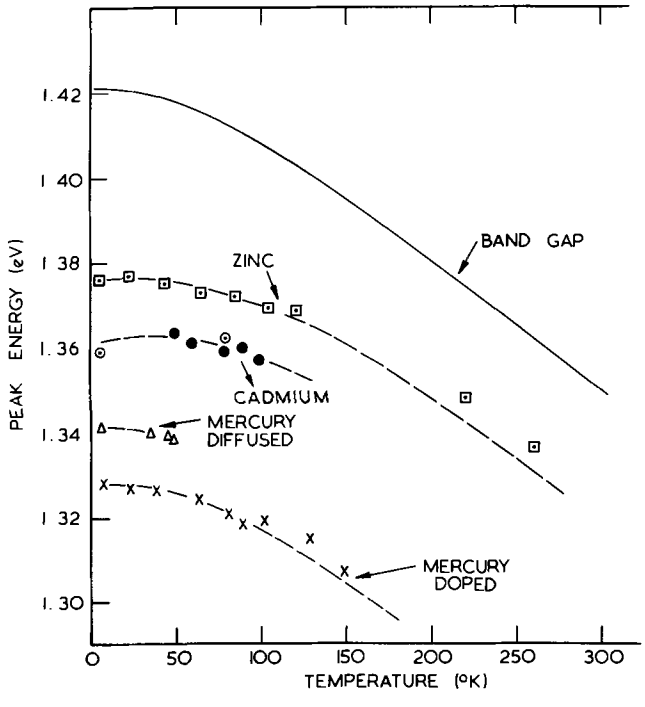

Fig. 6. Temperature dependence of the peak of the emission for zinc ($N_A - N_D = 1 \times 10^{18}/cm^3$), cadmium (open circles, $N_A - N_D = 1.8 \times 10^{16}/cm^3$; closed circles, $N_A - N_D = 7.4 \times 10^{16}/cm^3$, mercury diffused ($N_A$ unknown), and mercury doped ($N_A - N_D = 3 \times -0^{16}/cm^3$). The bandgap was obtained from absorption data (17).

Table I. Activation energy for group II acceptors in indium phosphide

Impurity	Photoluminescence at 50°K[a] (meV)	1.8°K exciton data (Ref. 15)	Intensity quenching (meV)
Zinc	50 ± 2	47.3	35 ± 5
Cadmium	58 ± 2	56.3	—
Mercury	98 ± 2	——	90 ± 5

[a] The bandgap used to calculate the optical activation energy was 1.420 eV at 50°K. This is 2 meV greater than the bandgap measured by Turner *et al.* (17). This 2 meV error in the Turner *et al.* bandgap was estimated from the position of the free exciton at 1.8°K (9).

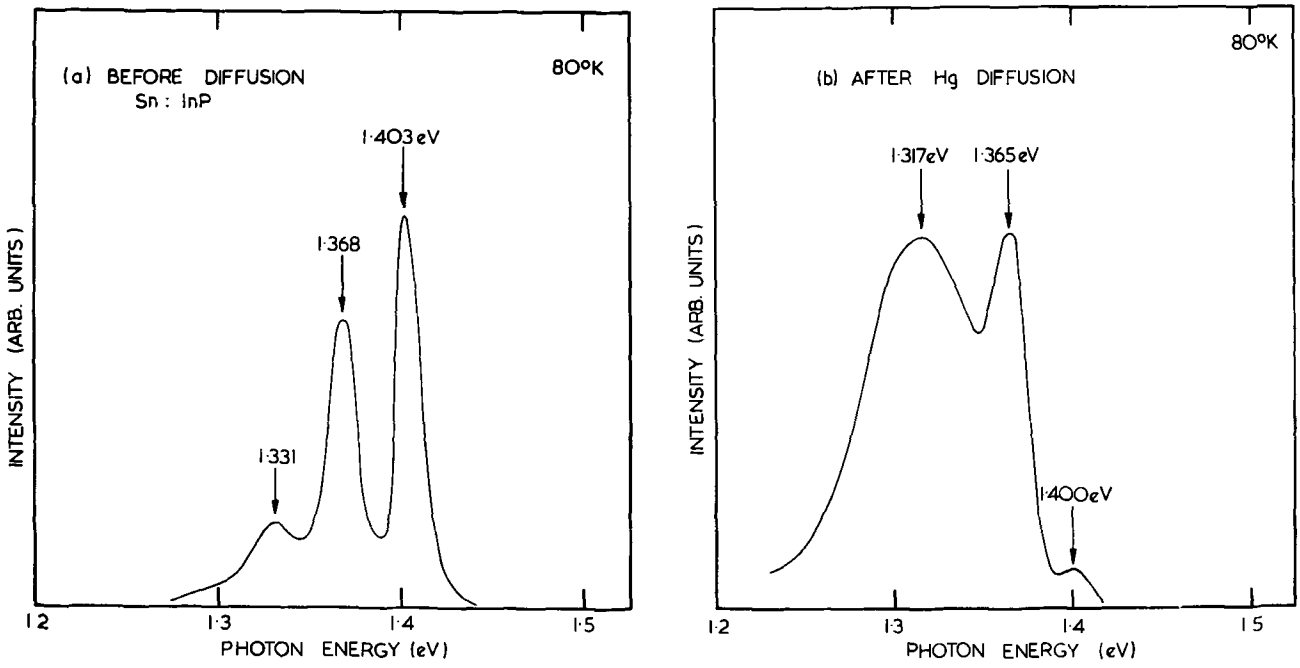

Fig. 7. Photoluminescence spectrum at 77°K. (a) A tin doped solution-grown layer ($N_D - N_A = 1 \times 10^{17}/cm^3$). (b) After diffusion of mercury into the tin doped layer at 750°C for 24 hr.

closely in the range 100°-6°K. In this case there appeared to be no change in mechanism.

The mercury diffused sample shown in Fig. 7 was prepared by mercury diffusion for 24 hr at 750°C into a tin doped epitaxial layer with a carrier concentration of 1×10^{17} electrons/cm³. A tin doped layer in preference to an undoped layer was used in an attempt to avoid the 1.37 line which was always present in the undoped samples. However the 1.37 eV always occurred at 80°K as is shown in Fig. 7 and it was very difficult to resolve the mercury line from the "zinc" line. This zinc contamination occurred even though the sample and the mercury were enclosed in a tantalum box within the quartz ampoule during the diffusion. At 6°K only one line was observed in the mercury diffused samples at 1.342 eV and its half width was just slightly larger than the mercury doped sample shown in Fig. 8 at the same temperature. The mercury diffused sample showed large changes in linewidth and peak position with changes in the exciting light intensity whereas the mercury doped sample showed none. For example, on reducing the magnitude of the intensity by two decades, the peak shifted from 1.342 to 1.334 eV and the half width changed from 23 to 35 meV. This change could possibly be interpreted as due to donor-acceptor pair recombination but such large shifts have never been observed in a direct gap III-V compound before. The shift observed for InP for the 1.37 eV line in undoped material is about 1 meV per decade of intensity change (6). It is therefore more likely that doping inhomogeneity may be causing the large peak shift for the diffused sample.

Group III isoelectronic impurities.—Boron doping of melt-grown crystals did not affect the electrical or the luminescence properties of the material. Local mode absorption studies of the boron doped crystal showed two absorption bands due to B^{10} and B^{11} and the concentration of boron was estimated to be about 10^{17} boron atoms/cm³ (19). The luminescence spectrum at 6°K of the same samples as used for the local mode studies was identical to the undoped spectrum shown in Fig. 1(a). From this it was concluded that boron did not produce any luminescence lines in the energy region 1.42-1.10 eV.

Preliminary results on an aluminum doped crystal indicate that aluminum produces a line close to the 1.32 eV line and further studies are in progress (14).

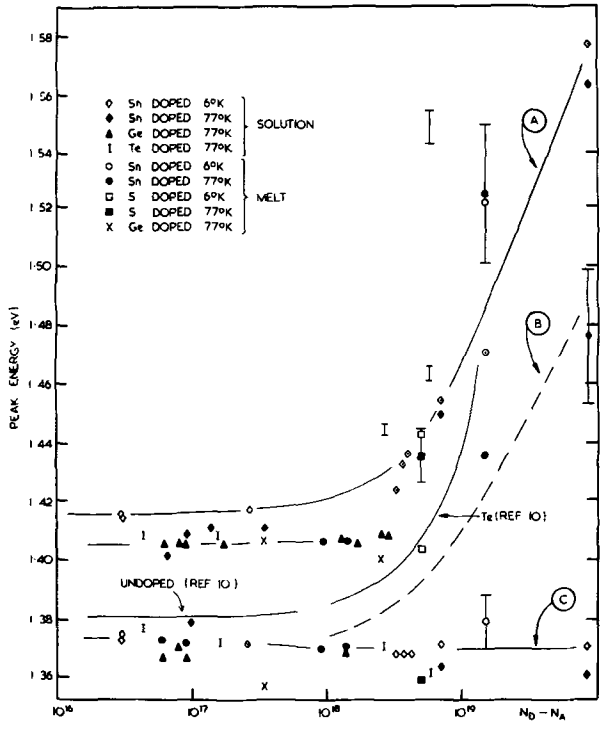

Fig. 8. Variation of the peak energy with doping of three lines seen in n-type indium phosphide grown from indium solutions and from the melt.

Group IV.—It is well known that silicon is an amphoteric impurity in GaAs and that the highest efficiency light emitting diodes have been made from silicon doped solution-grown GaAs (20). Consequently, it has been hoped that one of the group IV elements would also be strongly amphoteric in InP and that this characteristic could again be used for making efficient light emitting diodes. The many variations in the liquid epitaxial growth technique that were applied in an attempt to prepare p-type material with group IV elements were all unsuccessful (3). All the three elements attempted, *i.e.*, silicon, germanium, and tin, showed normal n-type behavior just like the group VI elements. The photoluminescence measurements on sili-

con, germanium, tin, and lead doping in melt-grown crystals have been reported previously (13) and will only be summarized briefly.

Silicon.—In the silicon solution-growth experiments, heavily doped n-type material was produced in contrast to the melt-grown crystals where no silicon was incorporated. However, the results were difficult to reproduce and the doping varied from 10^{16} to 10^{19} over the same epitaxial layer. The photoluminescence spectra of this inhomogeneous material is shown in the accompanying paper on materials growth (3). Although the 1.37 eV line associated with acceptors was observed in the lightly doped (less than $1 \times 10^{17}/cm^3$) samples it varied in a random manner and could not be correlated with silicon acceptors and could well have been due to zinc impurities.

Germanium.—In the solution-grown germanium doped samples, the 1.37 eV line was only observed when the doping level was below 1.5×10^{18} and above this up to carrier concentrations of 3×10^{18} only the 1.41 eV line was observed. The small variation of the peak energy of these two lines with doping is shown in Fig. 8 and the half width of the 1.41 eV line is plotted in Fig. 3. A typical spectrum at 80°K of a more lightly doped sample is shown in Fig. 9. The doping level was 6×10^{16} carriers/cm^3. Note the large 1.13 eV peak. A large 1.1-1.2 eV peak was observed in all the germanium doped samples both solution and melt grown. No correlation was observed between the intensity of the 1.37 and the 1.1 eV lines and the germanium doping level.

Tin.—The photoluminescence spectra of the tin doped solution-grown samples were similar to those of germanium in that the 1.41 and 1.37 eV lines were observed at 77°K over the same carrier concentration range (1×10^{16} to 3×10^{18}) that was studied for germanium. The 1.1 to 1.2 eV line was either very small or not observed in the solution-grown material and this was also typical of the melt-grown tin doped material.

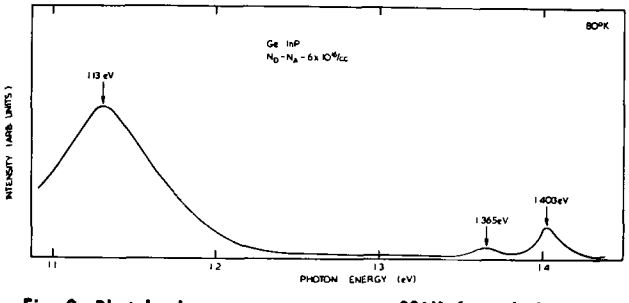

Fig. 9. Photoluminescence spectrum at 80°K for solution-grown germanium doped InP ($N_D - N_A = 6 \times 10^{16}/cm^3$).

The peak energies for the 1.37 and 1.41 eV lines as a function of doping are plotted in Fig. 8 for measurements made at 80° and 6°K. The half width of the 1.41 eV line at 80°K is plotted in Fig. 3. The change of approximately 10 meV in the position of the 1.41 eV line between these two temperatures is equal to the bandgap change. At carrier concentrations above 3×10^{18} the near band edge peak shifted to higher energies. This shift is a Burstein-Moss type shift and is due to the overlap of the donor impurity band within the conduction band and the consequent filling up of the (000) minima in the conduction band. This type of shift has also been observed for tellurium doped solution-grown InP and the results are summarized by the curve in Fig. 8 and they will be discussed below. The exact nature of the shift for the tin doped samples with concentrations above 1×10^{19} was complicated by the appearance of an extra luminescence peak above the intrinsic bandgap. Figure 10 compares two solution-grown samples. Figure 10(a) shows only one peak above the intrinsic bandgap E_G and the doping level of this sample was 7.1×10^{18}; in Fig. 10(b) however, with a doping level of 8.5×10^{19}, two peaks are observed above E_G. Two peaks were also observed in a melt-grown InP crystal which had a doping level of between 1 and 2×10^{19} electrons/cm^3. Figure 11 shows a plot of the spectrum obtained from the melt-grown crystal at five temperatures. The arrow under each curve indicates the bandgap at the temperature of measurements. The three peaks observed in the heavily tin doped spectra in Fig. 10 and 11 have been labeled A, B, and C and they have been plotted on Fig. 8. In the authors' opinion the mechanisms responsible for the three lines at 80°K are: A, band-to-band recombination (the tin donor states are merged with the conduction band); B, band-to-acceptor Ac1, where the concentration of Ac1 is less than 1×10^{18} carriers/cm^3 so that no acceptor band is formed; and C, band-to-acceptor Ac2 where the concentration of Ac2 is greater than 1×10^{18} carriers/cm^3 and increases proportionally to the tin doping. The variations with tin doping are consistent with this model and the curves on Fig. 8 have been labeled A, B, and C accordingly. The increase in half width of C for the solution-grown samples as a function of doping is clearly shown in Fig. 10 and this was observed for all solution-grown samples. From Fig. 5b it can be seen that the acceptor states begin to form a band at a carrier concentration of 1×10^{18} and Fig. 5(a) shows how the peak of the emission decreases in energy because most of the electron recombination occurs near to the top of acceptor band which is moving deeper into the forbidden gap. This decrease in energy is counteracted by the shift of the electron fermi level higher into the conduction band, hence there is little change in energy of line C. Line B, however, will follow line A because the concentration

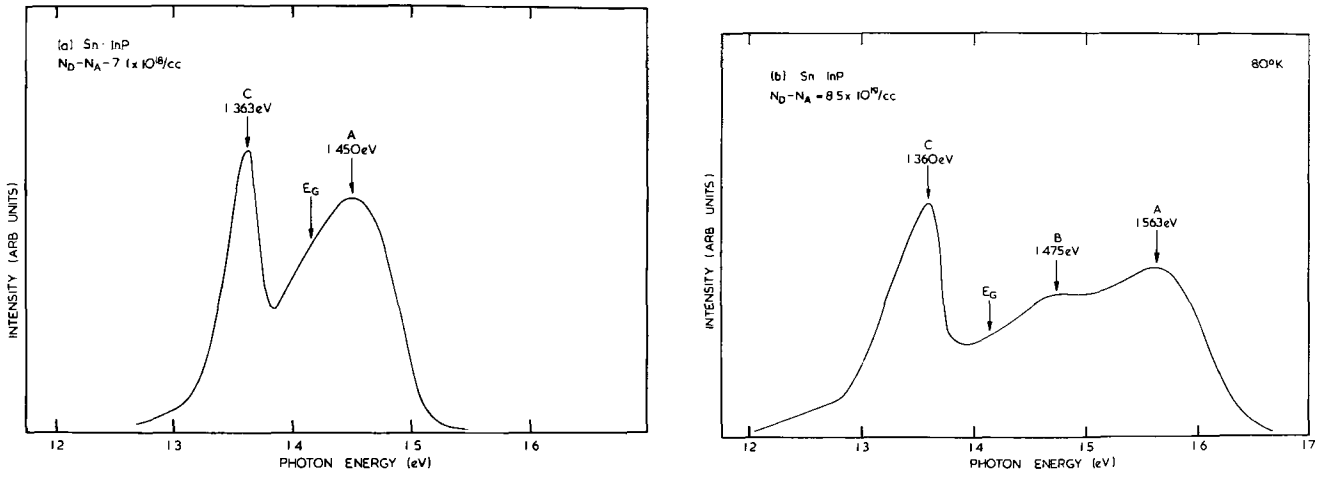

Fig. 10. Photoluminescence of heavily tin doped solution-grown InP at 80°K. (a) $N_D - N_A = 7.1 \times 10^{18}/cm^3$; (b) $N_D - N_A = 8.5 \times 10^{19}/cm^3$.

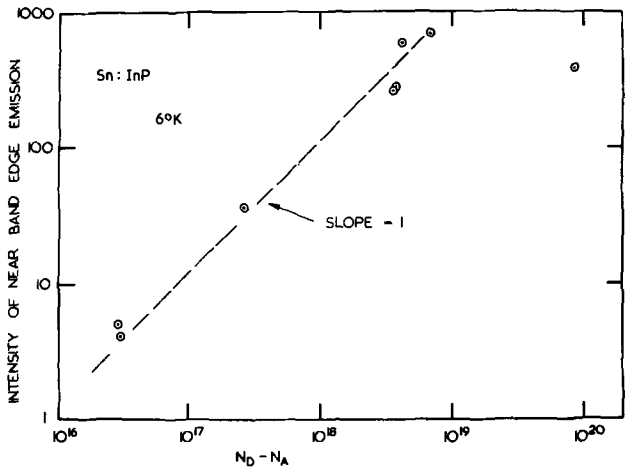

Fig. 12. Intensity of near band edge emission for solution-grown InP as a function of the tin donor concentration. The dotted line has a slope of 1.

of acceptor Ac1 is small in comparison to the donor concentration. The origins of Ac1 and Ac2 are unknown. Ac2 may be due to tin acceptors but one cannot be certain of this because a similar C line was observed for S and Te doped InP.

The temperature studies shown in Fig. 11 indicate that, assuming the proposed model is correct, band-to-acceptor recombination dominates at helium temperatures and that band-to-band recombination becomes dominant as the temperature is raised to 300°K. This behavior was also observed for the solution-grown samples. This is consistent with experimental observations for GaAs where donor-acceptor recombination often dominates at low temperatures.

The fact that the peak positions and half widths for these heavily doped (10^{19} to 10^{20}) samples do not lie exactly on the curves in Fig. 8 and Fig. 3 indicates that the carrier concentrations made by Hall measurements may be in error to some extent. This is hardly surprising since the Hall voltage is very small for these doping levels.

Of these three lines, A, B, and C, only the intensity of A which is thought to be associated with band-to-band recombination could be correlated with tin doping. This was expected because the half width of the A line was found to be proportional to the donor concentration (see Fig. 3). Figure 12 shows the intensity plot for line A at 6°K as a function of doping for solution-grown material. This shows that up to carrier concentrations of 5 to 7 $\times$ 10^{18} the intensity increase is directly proportional to the increase in the tin donor concentration and the accompanying paper (3) shows that this donor concentration is proportional to the quantity of tin going into the indium melt. This means that a large majority of the tin atoms which are electrically active act as donors and that there are extremely few acceptors present. This is confirmed by the Hall measurements which are summarized elsewhere (3). This also implies that the acceptor Ac2 proposed in the above model is not associated with tin.

A falloff at concentrations above 10^{19} is to be expected because carrier concentration quenching should set in. The mechanisms involved in the quenching cannot be discussed until more data have been assembled to derive the exact shape of the falloff in intensity.

Group V isoelectronic impurities.—Bismuth doping of solution-grown InP produces a luminescence line at 1.392 eV at 6°K whose intensity is proportional to the bismuth concentration. The luminescence line and its associated phonon replicas have been reported elsewhere (21). High concentrations of bismuth were required in order to produce 10-100 ppm of bismuth in the layers. As expected, bismuth did not show any electrical activity.

Group VI impurities.—The group VI impurities S, Se, and Te, all act as conventional donors in InP just as they do in GaAs.

The luminescence properties of four solution-grown layers doped with tellurium are summarized in Fig. 3 and 8. The half width at 80°K of the 1.41 eV line, or the A line at heavy doping levels, is plotted in Fig. 3. In each case the tellurium points appear to lie above the dotted line. Whether there is any significance in this larger half width is not known and further samples need to be studied before it is confirmed. In Fig. 8 the peak energy is plotted as a function of donor doping. For lower doping levels, below 2 $\times$ 10^{17} donors/cm^3, the tellurium points are close to those of the Group IV. At heavier doping levels there is some disagreement in that the peak positions of the two tellurium doped samples, with doping levels of 2.4 $\times$ 10^{18} and 5.8 $\times$ 10^{18} electron/cm^3 both lie appreciably above the A line for the tin doped samples. The reason for this is not understood and more samples need to be evaluated to see if this difference is confirmed. It is tempting to speculate that for some reason, perhaps because of heavy compensation, the Hall measurements always give a low reading for the carrier concentration. This would also explain the "apparent" larger half width seen in Fig. 3.

However, this still does not explain one result; in the heaviest doped sample with 5.8 $\times$ 10^{18} electrons/cm^3, an extra line is observed above line A at 1.55 eV. A spectrum of this sample at 80°K is shown in Fig. 13. The A line and the C line are observed as with the tin sample shown in Fig. 10 but in addition there is a shoulder centering at approximately 1.55 eV.

The tellurium doped solution-grown samples of Roder *et al.* (10) at 20°K are also summarized by the curve shown in Fig. 8. For doping levels up to 4 $\times$ 10^{18} they show a constant displacement from the estimated B line but they then move towards the A line at heavier doping levels. This could be explained by a gradual change in the mechanism from band-to-acceptor to band-to-band recombination at very high

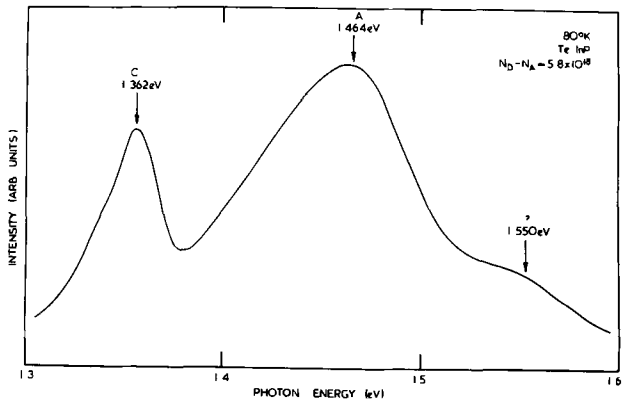

Fig. 13. Photoluminescence at 80°K of heavily doped solution-grown tellurium doped InP with $N_D - N_A = 5.8 \times 10^{18}/cm^3$.

doping levels. This is in disagreement with the interpretation of Roder *et al.* since they proposed that band-to-acceptor recombination dominated for all the tellurium doped samples because they were unable to resolve a band-to-band line at high doping levels.

Only one sulfur doped sample was evaluated and this was melt grown. The doping level was 5×10^{18} electrons/cm^3. Peaks A and C were observed, but B was not resolved. The peak energy is plotted for both 77° and 6°K in Fig. 8 and the half width is shown in Fig. 3. In both cases the agreement with the group IV elements is quite good.

Transition metals.—Copper.—Copper was evaporated onto the surface of an undoped vapor-grown layer of InP and it was diffused for 5½ hr at 750°C. The photoluminescence spectrum at 6°K of this layer both before and after copper diffusion is shown in Fig. 2 and the electrical properties are summarized in Table II. A new line is seen at 1.348 eV and this line does not occur if the heat-treatment takes place without copper. This disagrees slightly with the first results for copper diffused samples reported elsewhere by the authors when the spectrum at 80°K was shown and the copper line was at 1.355 eV (13). The first phonon replica of the copper line is clearly observed at 6°K in Fig. 1. The Hall measurements for the copper diffused sample are given in Table II. They clearly show that copper is an acceptor in indium phosphide. Inhomogeneities in the copper doping level are suspected because of the abnormally high mobility.

Whether the new copper luminescence level is due to a singly or doubly ionized copper acceptor or to a copper acceptor-donor complex is not known. Temperature studies indicate that more than one line may be present. Figure 14 shows the temperature dependence of the peak energy of the copper. At 80°K the luminescence was quenched and this was in contrast to earlier results in which the copper line was observed at 1.355 eV at 80°K on the first diffused samples. The difference between the two copper diffusion results is very confusing and indicates that more than one copper line is involved. It should be noted that the copper diffusions reported here were carried out on much better vapor-grown layers with a lower background doping than those used in the previous study.

Table II. Electrical properties of transition metal doped indium phosphide

Sample	Type	Temperature (°K)	Mobility (cm²/V-sec)	N/cm³
Undoped layer (used for copper diffused layer below)	n	300 77	3,204 22,800	7.2×10^{15} 2.4×10^{15}
Copper diffusion	p	300	707*	5.3×10^{15}
	p	77	1,435*	7.3×10^{15}
Manganese doped 32 mm	p	300	867	1.6×10^{16}
Manganese doped 58 mm	p	300	888	6.9×10^{16}

* Inhomogeneities in copper doping level suspected because of this abnormally high mobility.

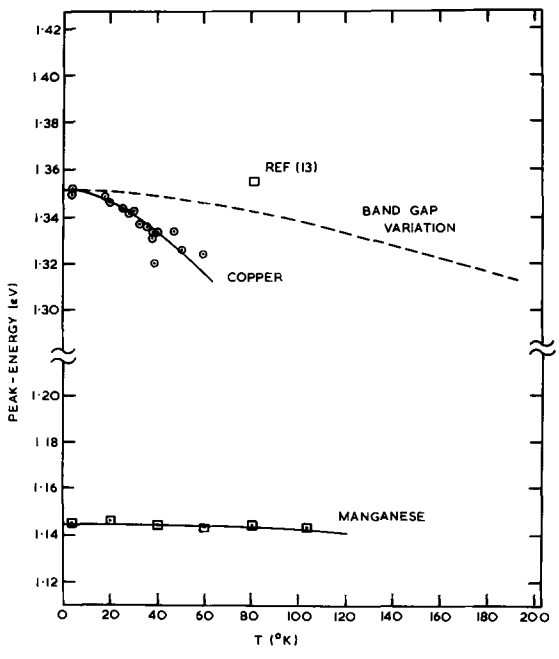

Fig. 14. Temperature variation of the peak of the emission associated with copper and manganese acceptors in InP compared to the bandgap (19)

Manganese.—The samples used in the photoluminescence measurements were cut from an InP crystal grown from a manganese doped InP melt. They were p-type and their electrical properties are summarized in Table II. The 58 mm sample was nearer the bottom of the crystal and had a concentration of manganese of $6.9 \times 10^{16}/cm^3$. The photoluminescence intensity was very weak for this sample and it could only be observed at helium temperatures. The spectrum is shown in Fig. 15. For the more lightly doped sample the

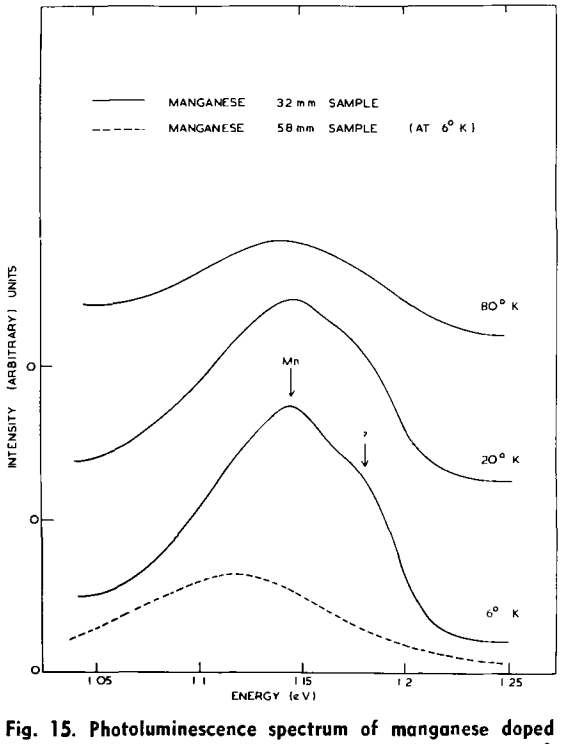

Fig. 15. Photoluminescence spectrum of manganese doped InP. Solid line, 32 mm sample, with $N_A - N_D = 1.6 \times 10^{16}/cm^3$; dotted line, 58 mm sample, with $N_A - N_D = 6.9 \times 10^{16}/cm^3$.

luminescence intensity was higher and it was studied as a function of temperature. Unfortunately, another line at about 1.18 eV is unresolved from the manganese line and this may have lowered the position of the manganese line. The spectrum for this sample with a doping level of 1.6×10^{16} is shown in Fig. 15 for three temperatures: 6°, 20°, and 80°K. The extra line is not associated with manganese since it was not present in the more heavily doped sample. The extra line appeared to be quenched at higher temperatures and only one line was observed at 80°K at approximately 1.14 eV. The peak position of the manganese line varied little with temperature as is shown in Fig. 14.

One attempt at manganese diffusion into an undoped vapor-grown layer of indium phosphide produced a line at 1.15 eV at 80°K of about half the width of the line observed at 80°K from the lightly doped manganese sample shown in Fig. 15. The manganese was diffused in at 650°C for 17 hr. The smaller half width indicated that the doping level was lower than 2×10^{16} but Hall measurements were not possible because of the nonuniform nature of the diffusion.

Conclusion

Zinc is the most common acceptor impurity in undoped melt-, vapor-, and solution-grown indium phosphide. This was confirmed by a comparison of the peak energy at 80°K and the temperature dependence of the zinc line in zinc doped solution-grown and undoped material. The temperature studies of the group II acceptors cadmium and zinc show a change in mechanism as a function of temperature from band to acceptor recombination at helium temperatures to band to band recombination at 50°K and above. Mercury, on the other hand, shows no change in mechanism. The optical activation energies at 50°K of zinc, cadmium, and mercury are summarized in Table I and Fig. 16. The optical activation energy was calculated by subtracting the peak energy from the bandgap at 50°K.

The optical activation energies for all the dopants studied are shown in Fig. 16. The exciton lines due to hydrogenic donors could not be resolved at 6°K which was the lowest measurement temperature used. The isoelectronic trap bismuth was reported previously (21) and is included for completeness. Copper was briefly reported in an earlier publication (13) and the spread in optical activation energy from 60 to 73 meV shown in Fig. 16 represents the difference between the present copper diffusion studies and those reported previously. The difference is indicative of copper forming more than one level, and the peculiar temperature results which show a large deviation from the bandgap temperature dependence is more typical of a copper complex than of a single copper substitutional acceptor behavior. The manganese luminescence line, on the other hand, follows the bandgap and indicates that manganese is a substitutional acceptor and is not forming complexes. The broad luminescence level in the region 1.1-1.2 eV is not shown on Fig. 16 because there is no strong evidence as to its nature. There is no doubt that it is always strongly enhanced in the presence of excess indium and this has led to the proposal that it may be associated with phosphorus vacancies. For some unknown reason it is enhanced by germanium doping but not with tin doping.

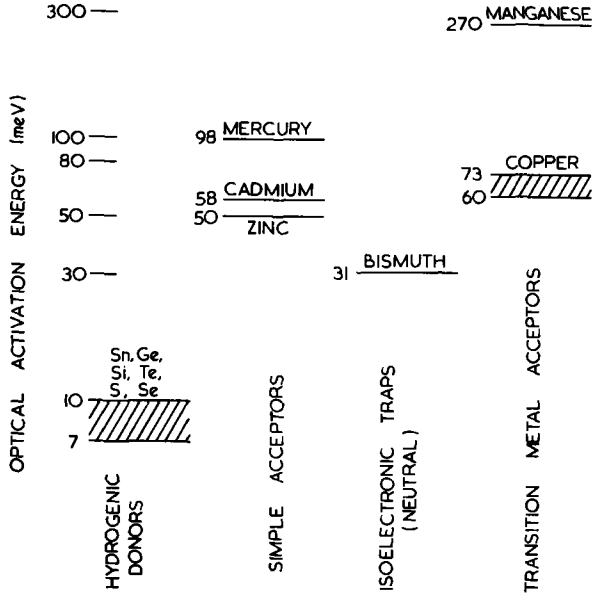

Fig. 16. Summary of optical activation energies of donors, simple acceptors, the isoelectronic trap bismuth, and transition metal acceptors [simple acceptors, see definition in Ref. (22)].

Indium Phosphide

II. Liquid Epitaxial Growth

M. G. Astles,[1] F. G. H. Smith, and E. W. Williams

Royal Radar Establishment, Malvern, Worcestershire, England

ABSTRACT

An improved technique is described for the growth of InP by liquid-phase epitaxy. The use of gold-plated reflector tubes in the furnace design has improved the control of layer quality, and background doping levels have been consistently reduced to $3 \times 10^{15}/cm^3$ by replacing polycrystalline InP by $PH_3(g)$ as a source of phosphorus. The behavior of the dopants Sn, Ge, Si, Te, Zn, Cd, and Bi in InP are discussed and the distribution coefficients "k" are found to be

$$k_{Sn} = 0.0019,\ k_{Ge} \triangleq 0.005,\ k_{Si} \triangleq 4,\ k_{Te} = 0.27,$$

$$k_{Zn} = 1.14,\ k_{Cd} \simeq 0.002,\ k_{Bi} \triangleq 0.002 \text{ to } 0.0002$$

The dopants Sn and Zn were found to be the most suitable for n and p doping for LED fabrication. The Group IV elements yielded n-type material only, although the mobility measurements indicated possible amphoteric behavior for Ge. The Hall mobilities at room temperature for the n-type samples show good agreement with theory.

In this paper, we describe improved techniques for the growth of InP by liquid-phase epitaxy (LPE), and the behavior of the dopants Sn, Ge, Si, Te, Cd, Zn, and Bi in InP.

We were particularly interested in the behavior of the Group IVB dopants because of the possibility of a similar amphoteric doping to that which has been found for Ge (1, 2) and Si (3) in GaAs.

The technique used throughout is the Nelson horizontal tipping method which was chosen for its simplicity of operation and ease of control (4). Also, at the normal growth temperatures for InP (600° → 700°C), loss of phosphorus from the substrate surface during the pregrowth stages is not a serious problem.

We had previously established that for flat, uniform interfaces between substrate and grown-layer, a controlled amount of etch-back before growth was necessary in addition to careful substrate preparation. It is also obviously important to be able to tip off the solution cleanly at the end of the growth cycle. The desired control could not be obtained in the type of furnace then used. This was a standard helically wound resistance furnace with concentric stainless steel radiation shields, with asbestolite outer casing and silica wool insulation. The visibility in such a furnace was very poor, which made proper equilibration of the solution before growth very difficult. The temperature profiles were also poor, having temperature plateaus much shorter than the length of the boats used, and often changed considerably with use.

In order to improve control, the furnace system was redesigned using gold-plated reflector tubes. The design is illustrated in Fig. 1. The golded tube reflects 95% of the incident *IR*, while allowing visible light in the green region to pass through. This enables the solution to be observed easily during the run. A longer temperature plateau is also obtained and this ensures that the temperature is constant to within ±2°C over the length of the boat (8 cm), and this profile can be maintained by cutting helical grooves in the silica former to hold the KANTHAL windings in place. All gas lines and fittings were of PTFE or stainless steel.

[1] Present address: Services Electronics Research Laboratory, Baldock, Hertfordshire, England.

Key words: indium phosphide, liquid epitaxy.

Materials

The growth solutions were prepared using 6 9's indium supplied in ingots under argon gas by Johnson-Matthey Chemicals. The indium was etched in 50% HNO_3 aq before use. Originally, polycrystalline InP was used as a phosphorus source but this was thought to be responsible for the large variations in the background doping levels in the epitaxial layers between 8×10^{15} and 1×10^{17} cm^{-3} n-type. So this was replaced by phosphine (PH_3) supplied as a 5% V/V mixture in high-purity hydrogen. Phosphine dissociates at temperatures above about 150°C as follows

$$4\,PH_3 \rightleftarrows P_4 + 6\,H_2$$
$$\uparrow\downarrow$$
$$P_2$$

The phosphorus then reacts with the molten indium until the solution is saturated with phosphorus and InP crystals start to form round the edges of the solution. A slight increase in temperature will then dissolve these crystals. Not only did the use of PH_3 bring down the background doping level to 3×10^{15} to 2×10^{16} cm^{-3}, but it also simplified the growth procedure. The presence of phosphorus vapor in the ambient during the pregrowth stages also helped to offset any loss of

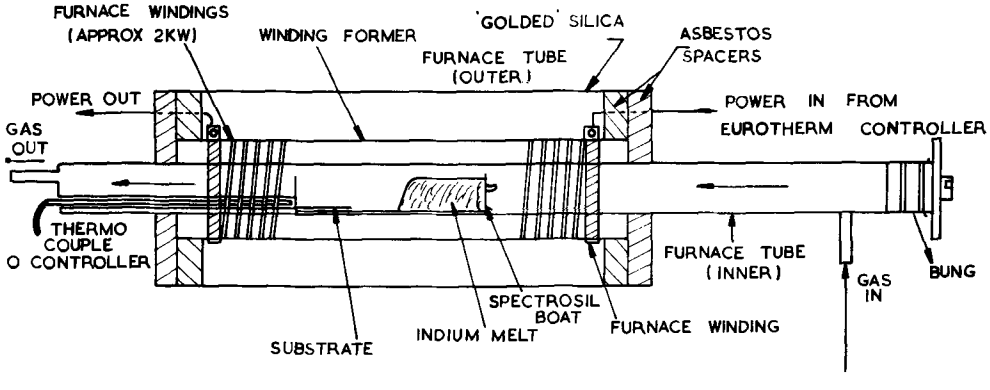

Fig. 1. Cross section of furnace, showing the position of the substrate and solution before tipping.

phosphorus from the substrate. With the earlier growth system, small indium inclusions could often be seen at the interface between substrate and layer when runs were done at 645°C or above. Since using the new system, this behavior has not been found. The dopants Bi, Sn, and Cd were used as 6 9's shot supplied by Cominco. The dopants Ge and Si were used as polycrystalline device grade. The dopants Te and Zn were used as 1% W/W alloys in indium metal (6 9's).

The InP substrates were grown by the liquid-encapsulation Czochralski method at RRE (5), and were used either on the (100) or (111) orientations. The substrates were chemi-mechanically polished with 2% bromine/methanol solution, followed by cleaning in a Soxhlet containing Propan-2-ol. For Hall measurements, the layer is grown on Cr-doped semi-insulating substrates.

Growth Procedure

When the materials have been loaded into the "Spectrosil" silica boat, this is placed in the furnace such that it is within the temperature plateau region. Having flushed the system with O_2-free N_2 gas for 15 min and Pd-diffused H_2 gas for 15 min, the furnace is brought up to the desired growth temperature. Above 600°C, any residual indium oxide on the solution surface is removed by reaction with the hydrogen gas. After passing the PH_3 at a rate of about 50 ml/min until saturation has occurred, the temperature is raised 1°C at a time, with gentle agitation of the solution, until residual InP crystals on the surface of the solution have dissolved. The temperature is then raised by a further 0.5° to 1°C to allow for etch-back before growth. This etch-back, which was estimated to be about 5 μm must be enough to remove any surface roughness from the substrate, but not enough to significantly back-dope the solution. The solution is gently tipped over the substrate, and the cool down commenced. After cooling at $\simeq$ 1°C/min for typically 20-30 min, the solution is tipped off, and this can usually be done without leaving any of the solution in contact with the substrate. When the furnace has cooled to room temperature, the sample is removed from the boat and any indium adhering to the slice is removed by ultrasonic treatment in a solution of mercuric chloride in dimethyl formamide. In most cases, however, the indium tipped off cleanly leaving a reasonably flat mirror finish surface.

Examination of Epitaxial Layers

Having cleaved the sample and stained with warm potassium ferricyanide/potassium hydroxide solution, the grown layer can be discerned under the microscope. The interfaces are usually straight and sharp, although with some dopants, particularly Zn and Cd, diffuse junctions can occur due to diffusion during growth. Having measured the layer thickness, Hall specimens are fabricated using indium dots for n-type and Pb/Cd dots for p-type material. Measurements were carried out at room and liquid-N_2 temperatures using the Van der Pauw technique.

Unfortunately, it is not yet possible to make reproducible impurity profile measurements by Schottky-barrier methods as is possible with GaP and GaAs (6). However from electron microprobe analysis on Sn-doped layers it appears that there are no significant doping gradients through the grown layers. This is not surprising as the rates of growth are quite low (0.5 to 1 μm/min), and the cooling range is quite small ($\simeq$20° to 30°C).

For the dopants Sn, Ge, Si, and Zn, growth on the (111)A, (111)B, and (100) faces was compared and found to yield very similarly doped material whatever the orientation. An exhaustive study as a function of growth temperature and cooling rate was not carried out. A solubility limit was seen for only one of the dopants examined. This will be discussed later.

Background Doping Levels

It is obviously necessary before commencing a series of controlled doping experiments, to ascertain that the background level is fairly low and repeatable. As mentioned above, the change to PH_3 as a phosphorus source gave a great improvement, the level being consistently in the range 1-2 $\times$ 10^{16} cm^{-3} (n) for a starting temperature of 650°C, using (111)B orientation and without baking the indium beforehand.

The possible sources of this residual impurity concentration were thought to be: (*i*) impurities in the indium starting material, (*ii*) contamination from the silica boat, (*iii*) leaks in the apparatus, e.g., through PTFE tubing and seals, (*iv*) impurities introduced with the PH_3 gas which could not be purified by normal means, and (*v*) impurities from the substrate introduced during the "etch-back" stage. It was found that baking the indium for 1 hr at 670°C after saturating with PH_3 gas at 650°C improved the background doping level from 1.8 $\times$ 10^{16} cm^{-3} to 8 $\times$ 10^{15} cm^{-3} (n). However, similar baking before passing the PH_3 had no effect on the background level. This suggests that the PH_3 gas is a source of impurities, although the nature of these impurities is not known. The extent of contamination from the boat was difficult to ascertain. After a few runs in a silica boat, a discoloration could be seen on the walls where the solution had been in contact, and after considerable use slight devitrification was found. But the rate of attack was very slow and was not thought to be a significant source of impurities at these low temperatures. Growth in vitreous carbon boats was found to have no significant effect on background doping.

It was hoped to overcome the problem of leaks in the apparatus by working at a pressure slightly above atmospheric. However, since the PTFE tubing used on the gas inlet was known to be slightly porous to oxygen, it was replaced by flexible 1/16 in. stainless steel tubing and a very slight improvement in background level was obtained.

The effect of introduction of impurities into the solution during the back-etching of the substrate is calculated to be negligible for a 5μ etch-back of the substrates used.

A marked temperature dependence of background-doping level was found, as illustrated in Fig. 2. An undoped run at 660° → 640°C produced n-type material with a doping level of 2 $\times$ 10^{16} cm^{-3}, whereas a run in the same furnace using a cooling range of 580° → 500°C produced a doping level of 2 $\times$ 10^{17} cm^{-3}. The Hall measurements implied that shallow donor impurities were involved and this was confirmed by photoluminescence studies (7).

The highest purity n-type material was obtained with growth temperatures in the range 780°-660°C. The carrier concentration was in the range 3 to 5 $\times$ 10^{15}/cm^3 and the mobility was 20,000 to 27,000 cm^2/V-sec at liquid nitrogen temperatures.

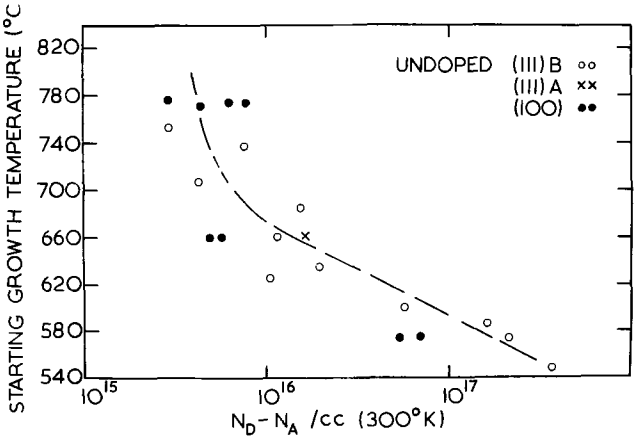

Fig. 2. Plot of starting growth temperature against (N_d — N_a) at room temperature.

Doping Experiments

Tin-doping.—We have done most work on tin doping, as it emerged as an easily controllable n-type dopant. There was also the possibility that Sn might behave amphoterically in InP. A wide range of dopings and growth temperatures was studied, and in all cases, only n-type material was obtained. Figure 3(a) shows a plot of log ($N_d - N_a$) against log (atomic per cent Sn in solution). The starting growth temperature was 650°C. The figures have been corrected for background doping levels. The gradient of the line in Fig. 3(a) is approximately 1. If the data is plotted linearly as ($N_d - N_a$) *vs.* weight per cent tin in solution, then the gradient can be used to calculate the distribution coefficient "k" under these growth conditions:

Since k is defined as $k_{Sn} = \dfrac{[\text{Sn in solid}]}{[\text{Sn in liquid phase}]}$

where the [ ] brackets denote concentration in gram atoms of tin per gram of solid or liquid, then this can be written as

$$k_{Sn} \simeq \frac{(N_d - N_a)}{W_{Sn}} \times \frac{AW_{Sn} \times 100}{N \times \rho_{InP}}$$

where W_{Sn} = weight per cent of tin in the growth solution, AW_{Sn} = atomic weight of tin, ($N_d - N_a$) = net donor concentration assumed equal to the concentration of tin atoms in the solid (cm^{-3}), ρ_{InP} = density of InP = 4.80 g cm^{-3} (8), and N = Avogadro's number. The value of k_{Sn} calculated in this way is 0.0019.

There is no significant orientation effect at these temperatures, the data for (111)A, (111)B, and (100) all lying very much on the same straight line shown in Fig. 3(a).

Germanium doping.—Work on Ge doping in GaAs has shown Ge to be capable of amphoteric doping. Rosztoczy *et al.* (1) have prepared p-type Ge-doped GaAs while Whelan *et al.* (2) prepared n-type material by melt growth. We have grown Ge doped InP using a wide range of doping concentrations and as wide a range of temperatures as possible. All material was n-type. The results are shown in Fig. 3(b). The gradient of this line is $\simeq$ 0.71. This contrasts with all the other dopants studied, (with the possible exception of Si) where the gradient was $\simeq$ 1. Whether this is due to a compensation of Ge donors by Ge acceptor centers which increases with increasing Ge concentration, due to a complex center or some other mechanism is not yet clear.

The value of the distribution coefficient calculated at low germanium concentrations was $\simeq$ 0.005.

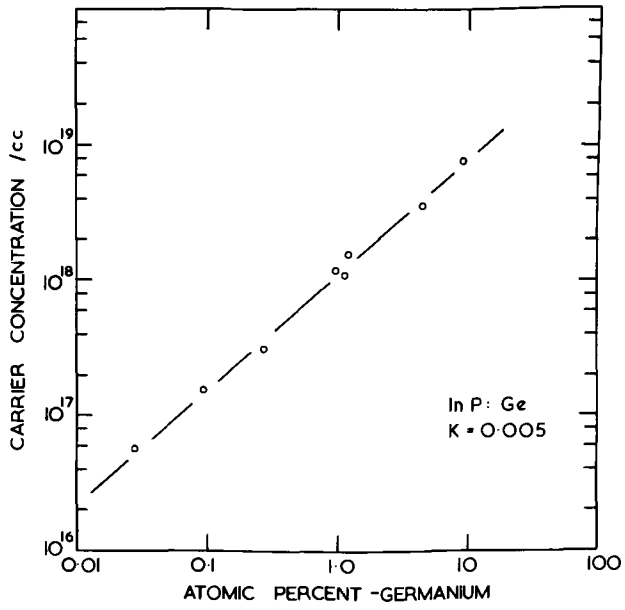

Fig. 3(b). Log ($N_d - N_a$) at room temperature against log (atomic per cent Ge in solution).

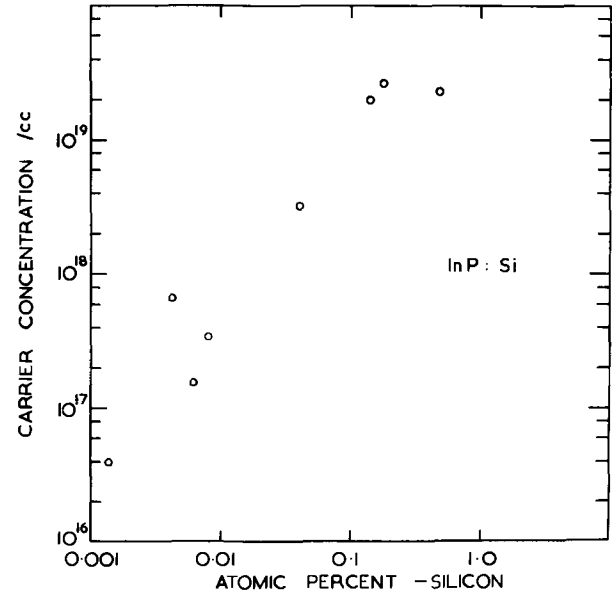

Fig. 3(c). Log ($N_d - N_a$) at room temperature against log (atomic per cent Si in solution).

Silicon doping.—We have investigated Si-doping in InP under a wide range of growth conditions. There are several practical difficulties involved. The main one is the rather low solubility of silicon in indium in the operating temperature range, for example, 0.1 atomic per cent (a/o) at 700°C and only 0.03 a/o at 610°C. Also great care must be taken to ensure that the indium solvent is entirely free of any residual oxygen before allowing the silicon dopant to come into contact with the solution otherwise small white flakes of SiO_2 form on the surface of the solution and remain there throughout the run. Rather erratic results were obtained as is shown in Fig. 3(c) where the carrier concentration ($N_d - N_a$) is plotted against log (atomic per cent of silicon in the indium solution), but the following points emerged. In spite of the scatter the distribution coefficient is obviously quite high but it was not estimated in view of the inhomogeneity of some of the samples (see below). Doping concentrations in the solution above 0.1 a/o yield n-type material with $N_d - N_a$ = 2 to 3 $\times$ 10^{19} cm^{-3} when grown at about 680°-640°C. This could represent either the solubility limit of Si in InP or correspond to the solubility limit of silicon in the indium solvent. Local mode absorption

studies on some of these heavily silicon-doped samples confirmed that the concentration of silicon donors, Si_{In}, was in the region of 10^{19} but there was no evidence for silicon acceptors Si_p, or for nearest neighbor Si_{In}-Si_p pairs (9). It should be pointed out however, that Si_p is more difficult to detect by local-mode absorption than Si_{In}.

Ahn *et al.* have recently shown that the transition temperature from n- to p-type in silicon-doped solution grown GaAs can be increased by over 100°C by changing from (111)B substrates to (111)A substrates (10). This gave rise to the hope that p-type material might be produced in InP if the right orientation of substrate were used. Several attempts with (111)A and (100) substrates at growth temperatures in the region 600°-700°C were all unsuccessful in that n-type material was always produced and the results were not too different from those for (111)B substrates.

On cleaving and staining the layers distinct subinterfaces, SI, running parallel to the surface across the whole layer were observed as shown in Fig. 4. That these interfaces are due to sudden changes in silicon doping was shown by electron microprobe analysis. A scan of Si counts across the layer is also shown in Fig. 4. It can be seen that there are two distinct zones of concentration, the transition point coinciding almost exactly with the visible boundary seen in the photomicrograph of the cleave. The microprobe analysis also showed the presence of silicon-rich precipitates in the grown layers. From the results of microprobe analysis on one of the homogeneous Si-doped samples, we have estimated k to be $\simeq 4$.

The photoluminescence spectra from the heavily doped silicon layers also indicated that there were inhomogeneities present. Figure 5 shows a comparison of a heavily doped silicon layer (full line) with a doping level of 1.1×10^{19} and a lightly doped layer (dashed line) with $N_d - N_a = 2 \times 10^{16}$ cm^{-3}. The lightly doped layer shows no emission above the bandgap E_G at 6°K (1.423 eV). The heavily doped layer however shows a broad line well above the bandgap and a sharp cutoff of the luminescence in the region of the bandgap. Both of these features are also observed at nitrogen temperatures but in this case it is seen from Fig. 5 that the cutoff has shifted to lower energies by an amount which is the same order as the change in bandgap. With the prior knowledge that the microprobe results on the same heavily doped sample show doping fluctuating from 10^{19} to 10^{17}, it appears possible that these fluctuations could cause the cutoff. The low carrier concentration regions would absorb some of the emission and produce the distorted luminescence curve that is observed. These inhomogeneities also explain why no similar sharp cutoff was observed for the heavily doped Sn and Te samples of InP; the spectra for Sn and Te were shown in a previous paper (7).

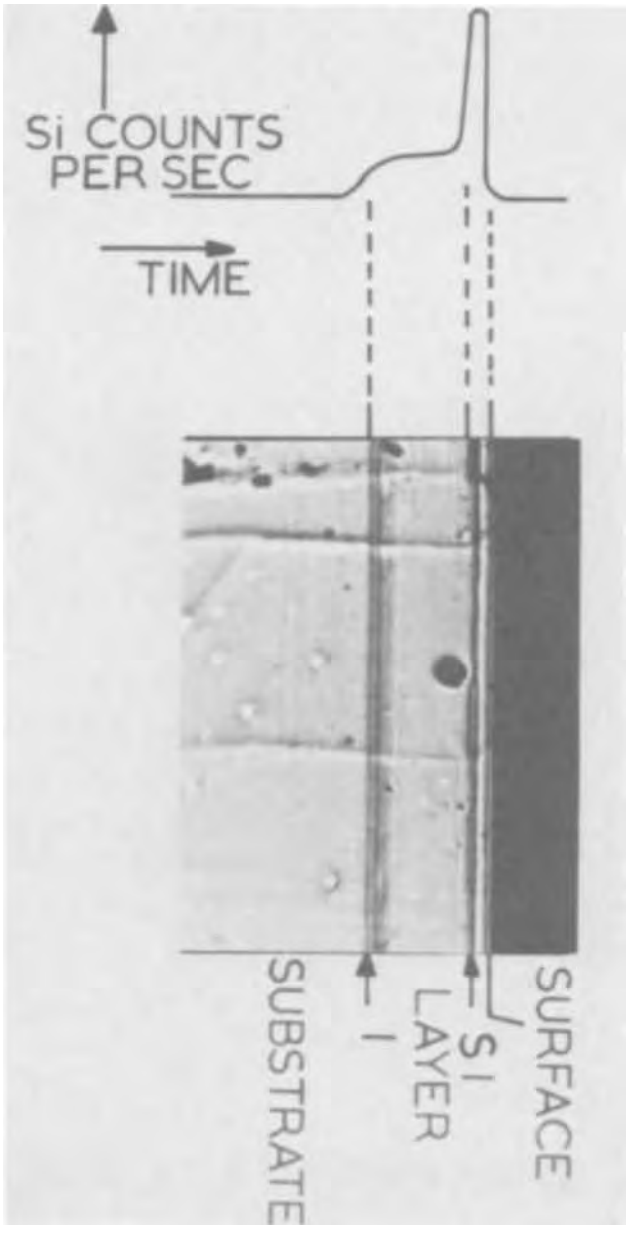

Fig. 4. An electron microprobe scan of a cleaved silicon doped layer compared to a photomicrograph of the same layer. The subinterface (SI) which is 4 μm from the surface separates a low doping region from a high doping region which is revealed by a large increase in the number of silicon counts/sec on the microprobe. The layer was 18 μm thick and on close examination it appears to be full of striations.

Tellurium doping.—Tellurium is a familiar n-type dopant in III/V compounds. In InP, we have been able to dope up to 1×10^{19} cm^{-3} using tellurium. It is a convenient dopant in that it substitutes exclusively on P-sites, dissolves readily in the indium solvent and is nonvolatile at our growth temperatures. It has however a fairly high distribution coefficient, and we found it necessary to use a 1% tellurium in indium alloy as the dopant source in order to weigh the desired amounts accurately. The results of Hall measurements on Te-doped layers grown on Cr-doped substrates are shown in Fig. 6. The results have again been corrected for background doping. The gradient of the plot is again approximately 1. The value of "k" is calculated to be 0.27.

Cadmium doping.—Cadmium was investigated as a possible alternative to zinc as a p-type dopant in InP, as the latter has a rather high distribution coefficient and is hence difficult to control. Although p-type material was grown using Cd-doping, the high vapor pressure of Cd at the growth temperatures (100 mm Hg at 611°C) led to rapid loss of Cd from the solution. The use of lower growth temperatures to overcome this difficulty led in several cases to n-type material. This is thought to be due to contamination with shallow donor impurities from the phosphine since we have already mentioned that growth at low temperatures yields higher background n-type doping levels. These background levels were thought to be high enough to overcompensate the cadmium doping. The plot of log $(N_a - N_d)$/log (atomic per cent Cd) is shown in Fig. 7(a). Again the gradient is approximately 1. From the gradient of the plot of weight per cent Cd against $(N_a - N_d)$, the value of "k" is calculated to be $\simeq 0.002$.

Zinc-doping.—In order to accurately weigh out the required weights of zinc over the range of doping studied, a 1% alloy of zinc in 6 9's indium was used. None of the problems encountered above with cadmium doping were found here. The results are shown in Fig. 7(b). It can be seen that above about 3×10^{18}

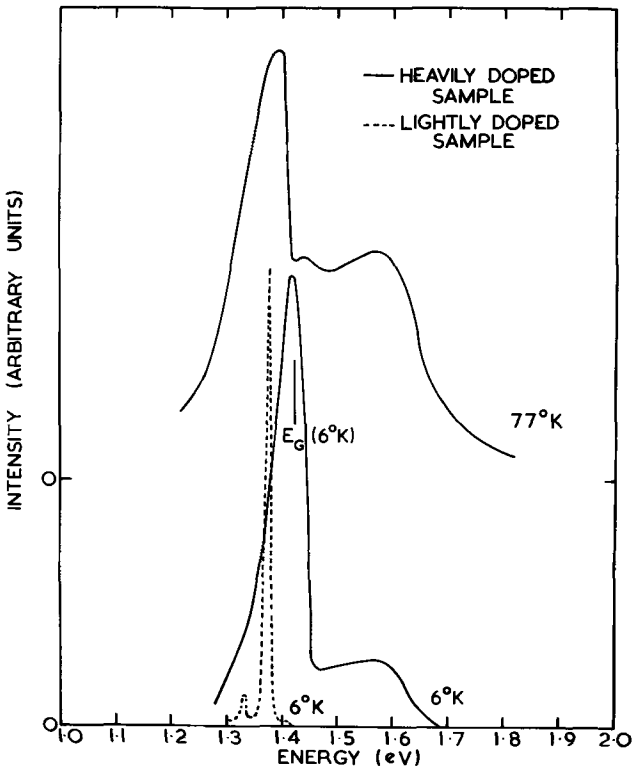

Fig. 5. Photoluminescence spectrum (full line) at 77° and 6°K of the heavily silicon doped sample shown in Fig. 5 compared to a lightly n-type silicon doped sample (dotted line) with a carrier concentration of 2×10^{16}/cc.

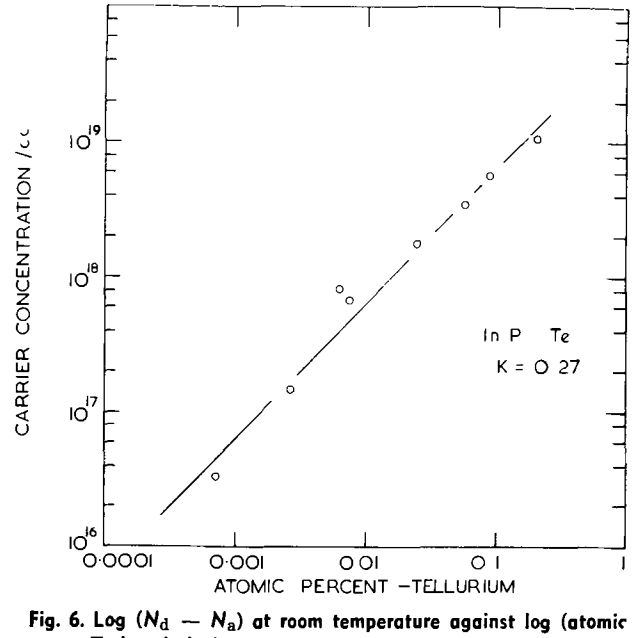

Fig. 6. Log (N_d — N_a) at room temperature against log (atomic per cent Te in solution).

cm^{-3}, the carrier concentration levels off. It is possible that this represents the solubility limit of zinc in indium phosphide at these temperatures. The gradient of the plot of weight per cent zinc/(N_a — N_d) yields a value of "k" of 1.14.

Bismuth doping.—Several Bi-doped epitaxial layers were grown to investigate the behavior of iso-electronic impurities in InP. The results of this work have been recently reported (11). Since bismuth is electrically neutral in InP, it is impossible to deduce the bismuth concentration from electrical measurements. However, it was estimated from x-ray fluorescence measurements that the bismuth was present in concentrations of between 10-100 ppm when the atomic per cent of bismuth in the solution was ≏ 3%. This information gives limits of "k" between ≏ 2×10^{-3} to 2×10^{-4}.

General Properties of the Epitaxial Layer

Surface features.—One surface feature which was found on all layers grown on (111) oriented substrates was the "overlapping scales" or "sea-shore ripples" effect illustrated in Fig. 8. The ripples are less than 0.5 μm in height.

The ripple density can be reduced by careful optical orientation of the substrates to make sure they are exactly (111). Figure 8 shows a zinc-doped layer grown on a substrate which was optically aligned over part of its area. A large flat region was obtained on this optically oriented section and all the ripples appear to be originating from it. The ripples on the optically oriented section are much more widely spaced than those on the section that was not optically oriented.

The (111) surface quality was generally superior to the (100) surfaces and optically oriented slices gave near "mirror" layer quality with very few features. The (100) surface varied from run to run and from dopant to dopant in a seemingly arbitrary fashion. The surfaces were sometimes pitted with holes up to 1 μm in depth. Figure 9 shows three of the different types of (100) surfaces obtained for (a) zinc, (b) tellurium, and (c) silicon doping.

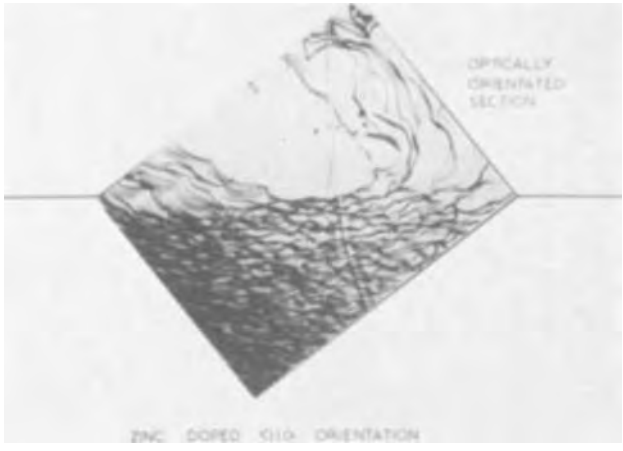

Fig. 8. Photomicrograph of a layer grown on a (111) partly optically orientated substrate.

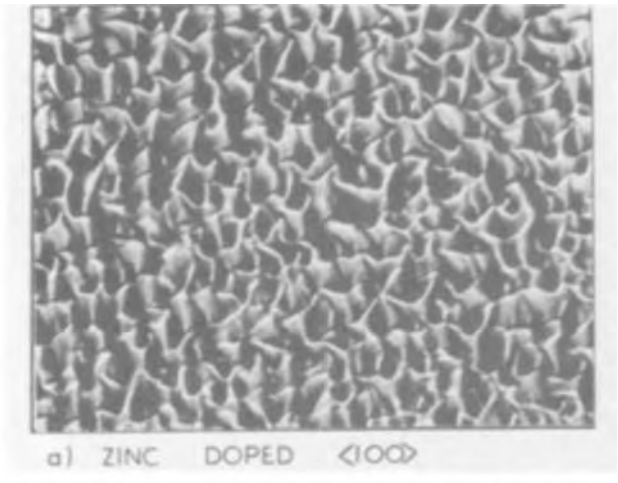
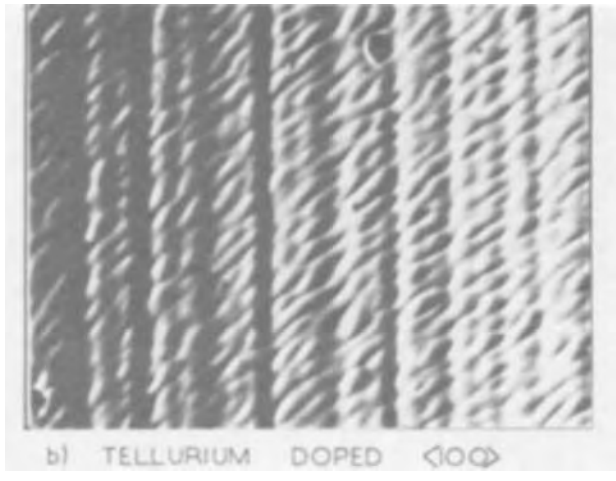
The importance of etch-back.—It has been mentioned earlier that it is vital to ensure a controlled etch-back of the substrate surface before growth commences. Figures 10(a) and 10(b) show how the amount of etch-back affects the appearance of the interface between substrate and layer. In Fig. 10(a) it can be seen how irregularities at the interface produced by insufficient etch-back cause holes and poor quality layers. In Fig. 10 (b), the etch-back has produced a good interface and the layer quality is much superior. The thickness of the interface shown in Fig. 10(b) is estimated to be about 0.5 μm.

Layer thickness.—As well as controlling the layer and surface quality, the thickness must be carefully controlled for most device applications. The technique used here is not suitable for the growth of very thin layers of less than 2 μm in which case the Rupprecht dip system (12) or the sliding pot system are more suitable. However for LED devices where layers between 3 and 30 μm are required, our method is quite suitable since reasonably flat layers can be grown in this region.

The growth cycle can be considered as 3 stages: (*i*) etch-back phase, (*ii*) growth before nucleation in the solution takes place, and (*iii*) growth after nucleation in solution has occurred until tip off. As mentioned earlier, we intentionally imposed approximately 1°C of undersaturation and in addition there was possibly unintentional etch-back due to temperature fluctuations in the furnace. So, cooling at 1°C/min, the etch-back phase could last for 1 to 2 min.

In most runs in the temperature range 630° → 660°C, it was observed that after cooling about 15°C from the starting temperature small crystals would start to appear round the walls of the boat which would then grow until the end of the run. It is quite likely therefore that the rate of deposition on the substrate is greater in phase (*ii*) than in phase (*iii*) due to "competition" from crystal growth in the solution. Thus when measuring the growth rate, an average over these three phases is being taken, and it is difficult to draw any conclusions about the effects of substrate orientation and dopant concentration on the growth rate because of the scatter of the data. In Fig. 11, we have plotted the measured growth rates (μm/min) against median growth temperature $\left(\frac{\text{Tstart} + \text{Tfinish}}{2}\right)$ for several dopants on (111)B material. At the temperature of 640°C where most layers were grown, the spread of growth rate is from about 0.45 to 0.75 μm/min. The main trend evident is the increase in growth rate as a function of increasing temperature corresponding to the increase of solubility with increasing temperature.





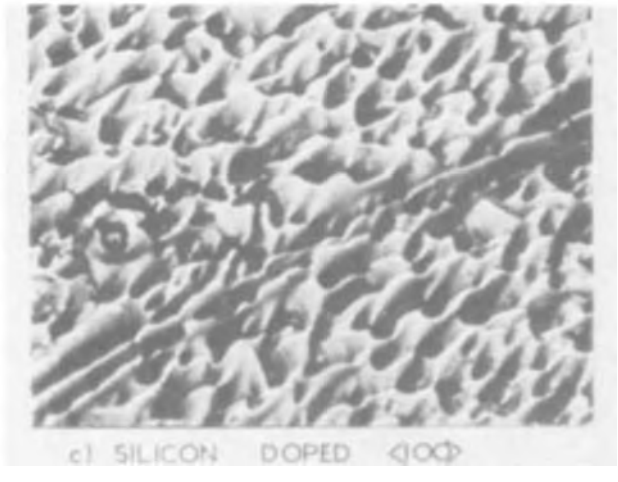


Fig. 9. Layers grown on (100) orientated substrate. (a) Zinc doped, (b) tellurium doped, (c) silicon doped (Magnification 90×).

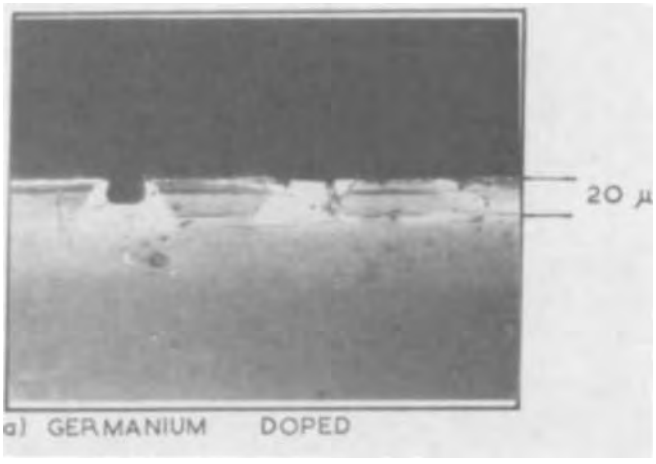

Fig. 10(a). A cleave of an epitaxial layer with insufficient etch-back of the substrate. (Magnification 400×).

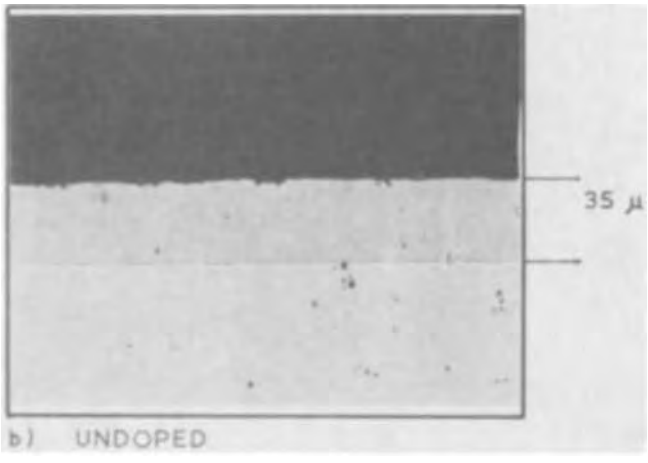

Fig. 10(b). A cleave of an epitaxial layer with the correct amount of etch-back of the substrate. (Magnification 400×).

For growth on other orientations, it was generally found that growth rates on (100) orientation were similar to those on (111)B, while (111)A growth rates

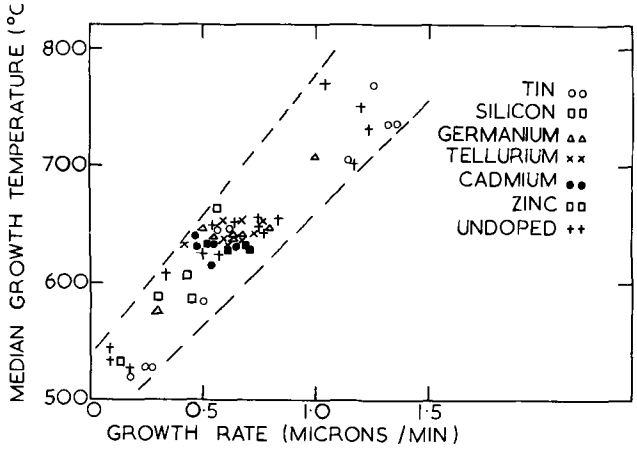

Fig. 11. The variation of the growth rate of epitaxial indium phosphide with the median growth temperature.

in the few cases we studied were significantly higher.

Fluctuations in growth rate much higher than normal were found for Zn-doped layers which were mainly grown on (100) orientation. This is possibly due to diffusion of zinc into the substrate during growth. In fact there was evidence in some runs that zinc was diffusing into the substrate before the growth cycle via the vapor phase.

Mobilities.—The Hall mobilities at room temperature of n-type samples are plotted against $(N_d - N_a)$ in Fig. 12. The theoretical curve due to Moore (13) for ionized impurity scattering is plotted on the figure assuming Ehrenreich's value of 4700 cm^2/V sec for the limiting mobility due to lattice scattering (14). It can be seen that the fit is quite good at low doping levels but deteriorates at higher doping levels. The divergence from Moore's curve is greater for the heavily doped Group IV doped samples (Si,Ge) than for the tellurium-doped samples, which is possibly an indication of compensation occurring with the Group IV elements, particularly Ge. Although the scatter of the mobilities at 77°K was greater, a similar trend was seen at high doping levels in that the Group IV doped samples have much lower mobilities than the Te-doped samples with similar values of the carrier concentration.

Conclusions

The distribution coefficients, k, for all the dopants studied are summarized in Table I and compared to the

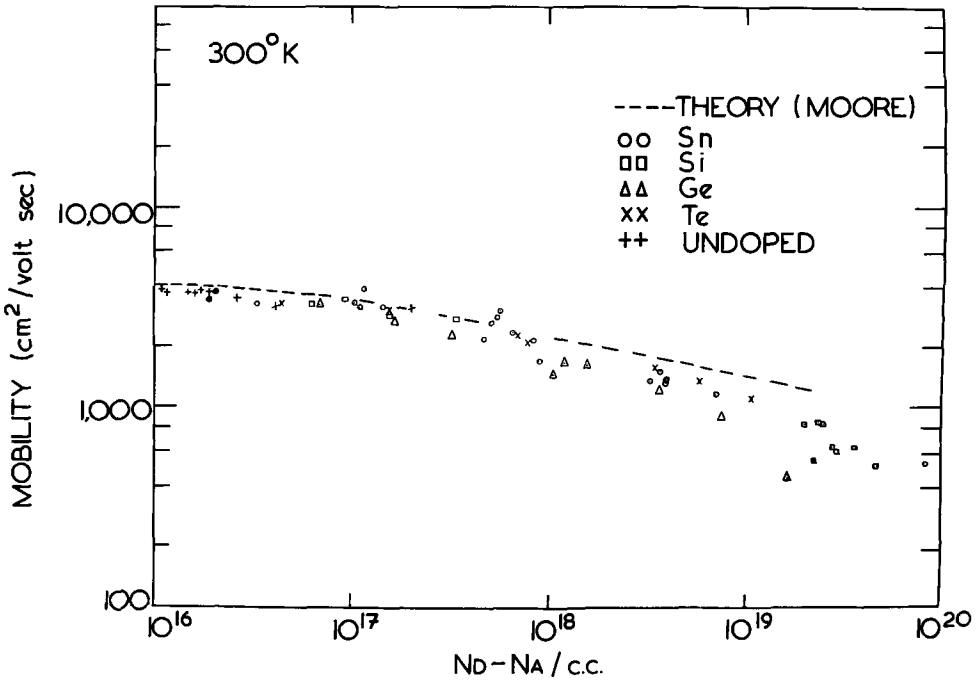

Fig. 12. The Hall mobilities of n-type samples compared to theory [Ref. (14)].

Table I. InP distribution coefficients

Dopant	Solution		Melt	
	k	k [Ref. (16)]	k [Ref. (17)]	k [Ref. (18)]
Tin	0.0019	0.0022	0.021	0.03
Germanium	0.005	0.011	0.024	—
Silicon	Approx: 4	—	—	—
Tellurium	0.27	0.4	—	0.05
Sulfur	—	—	—	0.5
Selenium	—	—	—	0.4
Zinc	1.14	—	—	0.008
Cadmium	Approx: 0.002	—	—	—
Bismuth	0.002 to 0.0002	—	—	—

results of Rosztoczy *et al.* (15). Rosztoczy used similar growth temperatures to ours but his indium solutions were saturated with polycrystalline InP feed material and not with phosphine. The tin values agree very closely but the germanium and tellurium results differ by a factor of two. These latter differences are probably due to differing degrees of electrical compensation in the material, since the assumption is made that the concentration of donor impurity, N_d, is approximately equal to $(N_d - N_a)$.

As expected, the melt growth values (16, 17) of the impurity distribution coefficients which are shown in Table I differ from the solution growth values because of the large difference in growth temperature. In the case of zinc there is an enormous difference and this can be explained as a large loss of zinc from the melt in the melt growth process since the vapor pressure of zinc is so high at the melting point of InP.

The vapor pressure of cadmium is higher than zinc and this makes its use as a p-type dopant in solution grown InP more difficult. Hence zinc was chosen as the most suitable p-type dopant for LED material since none of the Group IV elements appeared to form p-type material. The high distribution coefficient of zinc makes it necessary to dilute the zinc with indium before adding it to the indium solution.

Tin and germanium were both useful n-type dopants and could be added directly to the melt without dilution because of their low distribution coefficients. Tin was used in preference to germanium for LED material because of the higher photoluminescence efficiency of the layers.

Finally, the modified Nelson technique using phosphine and a gold-plated reactor was very suitable for LED double epitaxy for the following reasons:

(*i*) Good interfaces can be obtained provided there was sufficient etch-back. (*ii*) High quality flat layer surfaces were obtained with (111) optically oriented substrates. (*iii*) Reproducibility from run to run was much better than with the old reactor system using polycrystalline InP. (*iv*) The photoluminescence efficiency of the layers was good for both tin and zinc doping. (*v*) 1.3% power efficiency at 300°K was achieved with several double epitaxy diodes.

Acknowledgments

The authors are particularly grateful to P. J. Dean for his many constructive comments. Experimental assistance was provided by P. Porteous, Mrs. M. Webb, and W. H. E. Wilgoss. Substrates were grown by B. W. Straughan and P. J. Tufton. The microprobe measurements were made at Harwell by D. M. Poole under contract.

Indium Phosphide

III. Double Epitaxy Light Emitting Diodes with 1.5% Efficiency at 300°K

E. W. Williams, P. Porteous, M. G. Astles,[1] and P. J. Dean

Royal Radar Establishment, Malvern, Worcestershire, England

ABSTRACT

Indium phosphide double epitaxy light emitting diodes with a 1.5% quantum efficiency and 1.3% power efficiency at 300°K are reported. The emission spectrum half width is 50% of the amphoterically doped GaAs diode spectrum and this makes the diodes four times more efficient as infrared pumps for the two-photon phosphor green emitting diodes. The peak of the diode emission varies from 1.29 to 1.30 eV at 300°K.

Indium phosphide infrared light emitting diodes can be made into green lamps by coating them with two photon phosphors (1). These green lamps are potentially more attractive than gallium phosphide nitrogen doped diodes because the peak of their emission at 5500Å coincides with the maximum of the eye response

[1] Present address: Services Electronics Research Laboratory, Baldock Hertfordshire, England.

Key words: indium phosphide, light emitting diode.

[b] n side up.

curve giving a pure green color. The gallium phosphide lamps appear yellowy green because their maximum intensity is at 5650Å, and they have a broad spectral distribution. However, by filtering the emission can be narrowed a little and made to look greener.

The three requirements for an infrared light emitting diode that would be best suited to the two-photon phosphor made from lanthanum trifluoride (2) doped with Yb and Er are: (*i*) a narrow emission spectrum, (*ii*) output peaking at 1.271 eV, and (*iii*) a high efficiency. The first is fitted by InP and not by GaAs, whereas for the third GaAs leads the way since efficiencies of 32% have been realized at room temperature (3).

The highest efficiency so far reported for InP diodes is 0.75% at room temperature (1). These diodes were prepared with a vertical dip solution growth system. The solution was saturated with solid indium phosphide at 750°C in a reactor flushed with forming gas. A cool rate of 0.22°C/min was used to grow, first, a tin-doped layer, then a zinc-doped layer.

Blom and Woodall (1) tried no other dopants, but their choice of tin and zinc was fortuitous since these appear to be the best dopants, as has already been explained in previous papers. Using tin- and zinc-doped double epitaxy diodes prepared in the manner described below a 1.5% quantum efficiency with 1.3% power efficiency has been achieved. In this paper we briefly discuss the electrical and optical properties of these double epitaxy diodes and compare them with gallium arsenide silicon-doped diodes.

Materials Preparation

The horizontal liquid-epitaxial growth technique for single layers was described in previous papers. For double-layer growth, three different methods were used.

Method I. The n-type Sn-doped layer was grown on the Sn-doped substrate, and then in a separate run, a zinc-doped p-type layer was grown on this to form a p/n junction.

Method II. Having grown the Sn-doped layer, the solution is tipped off, and an amount of 1% zinc/indium alloy is dropped into the solution from a quartz spoon, sufficient to overcome the n-type behavior of the Sn in the solution. The solution is brought back to the saturation point with approximately 0.5°C added on to allow for a small amount of etch-back before growth. A compensated p-type (Sn + Zn)-doped layer was then grown.

Method III. The procedure is similar to Method II, except that after the growth of the Sn-doped layer, the temperature rundown is stopped (no tip-off of solution) and the zinc/indium is added as above. After 5 min the rundown is recommenced.

Cooling rates were always 1°C/min over a range 675°-610°C. Table I gives specific examples of the growth conditions under which some of the best double layers were grown. It should be noted that the material grown by Methods II and III (with compensated p-layers) gave consistently higher diode efficiencies. Figure 1 shows a photograph of a stained, cleaved cross section of two of the layers. Figure 1(a) shows a double layer grown on a (111) tin-doped substrate. The interface between the tin and zinc epitaxial layers is flat and the layer thickness was constant across the slice. The tin doping level was $6 \times 10^{16}/cm^3$ and the zinc doping was $4 \times 10^{18}/cm^3$. The junction is about 1 μm wide. The wide junction is almost certainly due to the indiffusion of zinc into the tin layer during the growth of the zinc layer. In Fig 1(b) for the double-layer grown on a (100) tin-doped substrate the interface is not perfectly flat, and this is because of insufficient etch-back prior to the growth of the second layer. The stain used to reveal the junction for 1(b) was an iron and nitric stain, and this gives a large color difference between n- and p-type layers. The more n-type the layer is, the darker is the stain. The p-type zinc layer has a doping level of $4 \times 10^{18}/cm^3$. The tin substrate which has a doping level of $1 \times 10^{18}/cm^3$ shows up darker than the tin epitaxial layer which has a doping level of $6 \times 10^{16}/cm^3$. The striations in the substrate are thought to be caused by doping fluctuations since they appeared most frequently on the heavily doped substrate where solubility problems occur.

Diode Properties

The first double epitaxy diodes were made with alloyed contacts, using tin for the n-type substrate and tin-2% zinc alloy for the p-type layer. These diodes were generally soft and leaky but nevertheless effi-

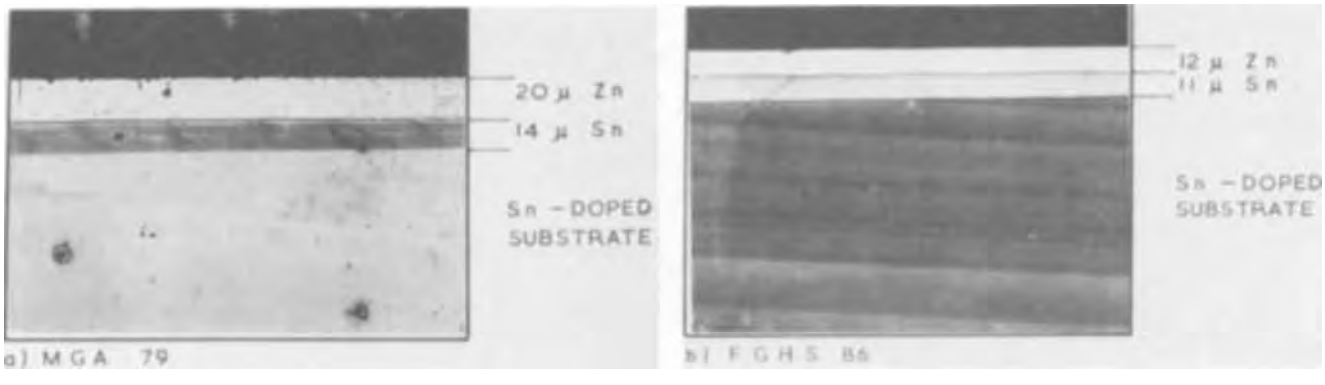

Fig. 1. Photomicrographs of a cleave of two double epitaxy growths on InP. Tin is the dopant for the first layer and zinc for the second. In (b) the etch-back after the growth of the first layer was not sufficient so the interface between the layers is not flat. (Magnification 440×).

ciencies up to 1.0% were realized on some of the diodes. However, diodes made from one slice often varied in efficiency by as much as ten times.

More recently evaporated contact diodes have been used with gold-germanium for the n-type substrate and gold-zinc for the p layer. These diodes generally gave much better I-V characteristics, and the leakage current in the reverse direction was often two or three orders of magnitude less than for the alloyed contact diodes. Diodes made from the same slice sometimes showed identical efficiencies but more usually they varied by up to a factor of three or four. Two characteristics are shown in Fig. 2 for diodes T2 and T3 shown in Table I. The upper curve (a) is for T3 with the p layer uppermost and the n-type substrate mounted on the header. The lower curve is for T2 which was a "flip chip" diode made from the same double layer as T3 with the n-type substrate uppermost and the p layer next to the header. The reverse breakdown is slightly better for (a) but the forward characteristics for (b) show a much sharper knee. The better forward characteristics are typical of the highest efficiency diodes. In this case T2 has a 1% efficiency at 300°K compared to 0.3% for T3. The large difference in efficiency is thought to be the result of the difference in absorption in the two cases. Due to the wide difference in doping of the two layers, $6 \times 10^{16}/cm^3$ for the tin layer and $4 \times 10^{18}/cm^3$ for the zinc layer, the light emission would be expected to be on the n side of the junction and with the much lower doping level on the n side the light transmission through the n layer will be much higher than through the p region, as has been shown from recent absorption studies (4). This is borne out not only by the efficiency difference but also by the uniform emission of light that is observed under an infrared microscope from the "flip-chip" diode.

Figure 3 shows a typical detailed forward characteristic for diode T2. Over seven orders of magnitude of the current the slope is constant and from the diode equation

$$I = I_0 \exp (V/nkT)$$

n is calculated to be 2.3. This value of n indicates that the majority of the recombination occurs in the space charge region of the diode.

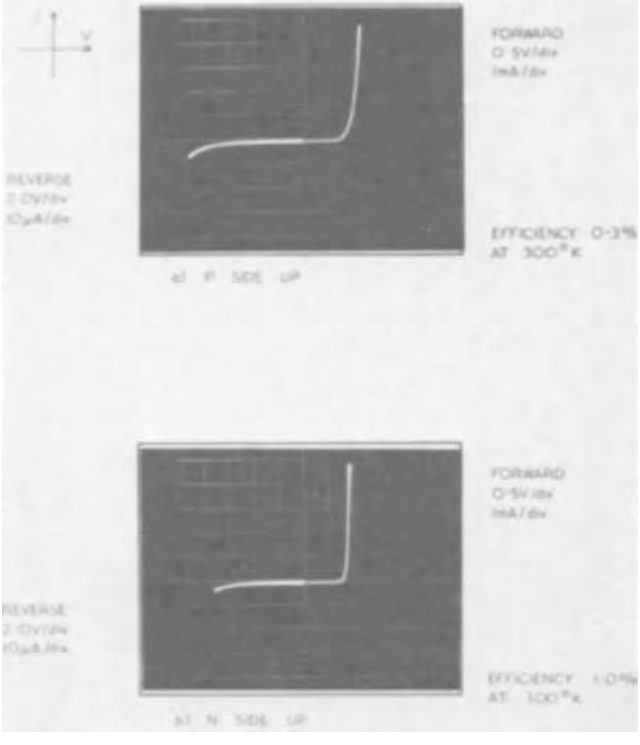

Fig. 2. I-V characteristics for the double epitaxy diodes (a) p side up, (b) "flip-chip" or n side up.

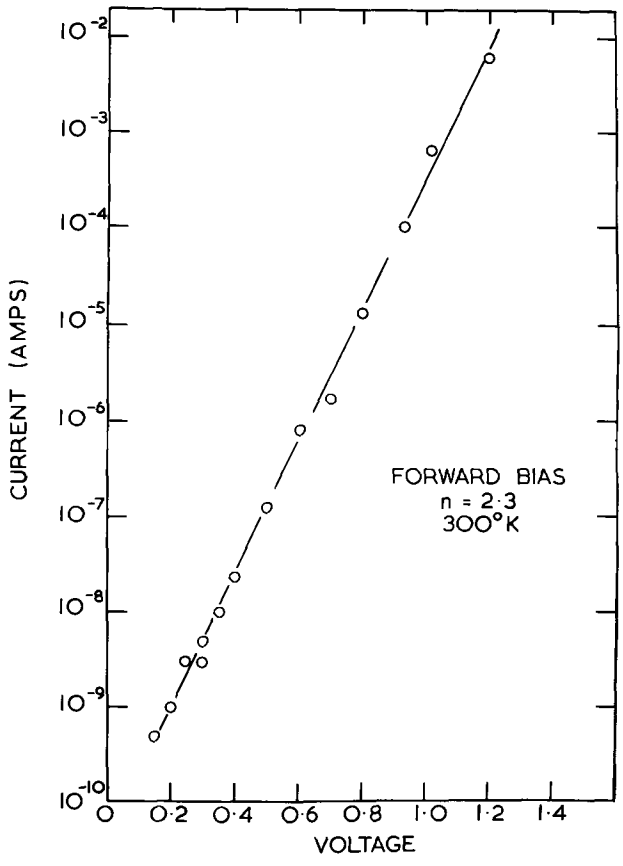

Fig. 3. A detailed forward characteristic for a "flip-chip" diode plotted as log I against V. From the equation $I = I_0 \exp V/nkT$, the slope of the graph gives $n = 2.3$.

Figure 4 illustrates the power efficiency, the quantum efficiency, and the diode integrated emission intensity as a function of current for the "flip-chip" diode T2. The power efficiency for the best diodes generally peaked at about 100 to 150 mA (current density 40-60 A/cm^2). The highest power efficiency was 1.3% at 300°K with a quantum efficiency of 1.5%. As expected the intensity was proportional to the current and only saturated at very high currents.

The room temperature spectral emission of the two types of diodes whose characteristics were shown in Fig. 2 are shown in Fig. 5. As expected, because of the smaller absorption the diode with the n side up, or the "flip-chip" diode, has a narrower emission line. The narrower spectrum is about half the width of a GaAs:Si diode spectrum, as is shown in Fig. 5.

Conclusion

The InP diodes described here and the GaAs:Si diodes were both required to match the peak of the excitation curve of the two-photon LaF_3:Yb;Er phosphor which is shown by the arrow at 1.271 eV on Fig. 5. This clearly indicates that neither diode gives a perfect match to the phosphor. The GaAs:Si spectrum can be made to peak at 1.271 eV by increasing the silicon doping (3). Unfortunately, this also increases the half width so that net gain is very small since it can easily be shown that the infrared to visible conversion efficiency is inversely proportional to the half width. The smaller half width of the spectrum of the indium phosphide diodes and the fact that the visible light output from the phosphor is proportional to the square of the infrared diode power that is absorbed, means that the green phosphor coated diodes are four times better than gallium arsenide coated diodes when the two diodes have the same infrared power efficiencies.

Consequently the InP cleaved diodes with a 1.5% efficiency described here are almost equivalent to the

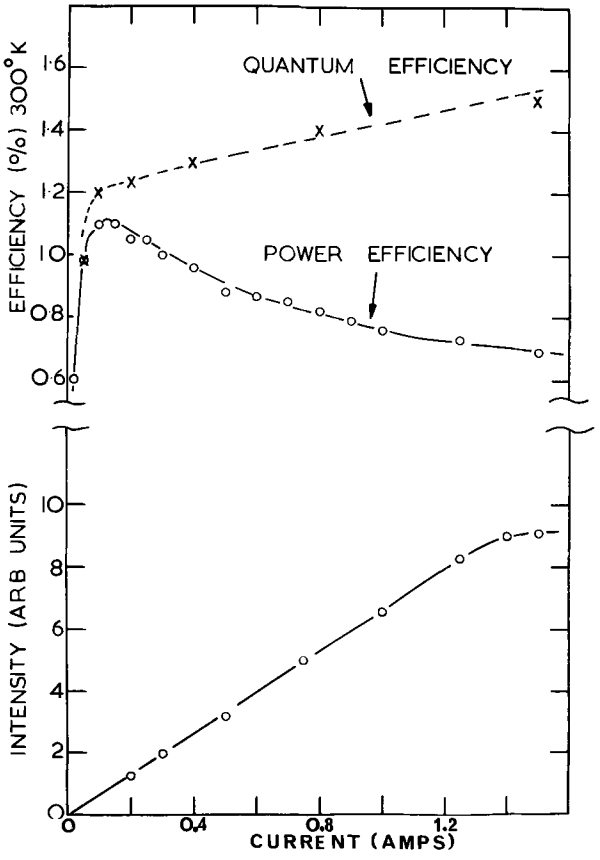

Fig. 4. The power efficiency, quantum efficiency, and diode integrated emission intensity ot 300°K as a function of current for a "flip-chip" diode.

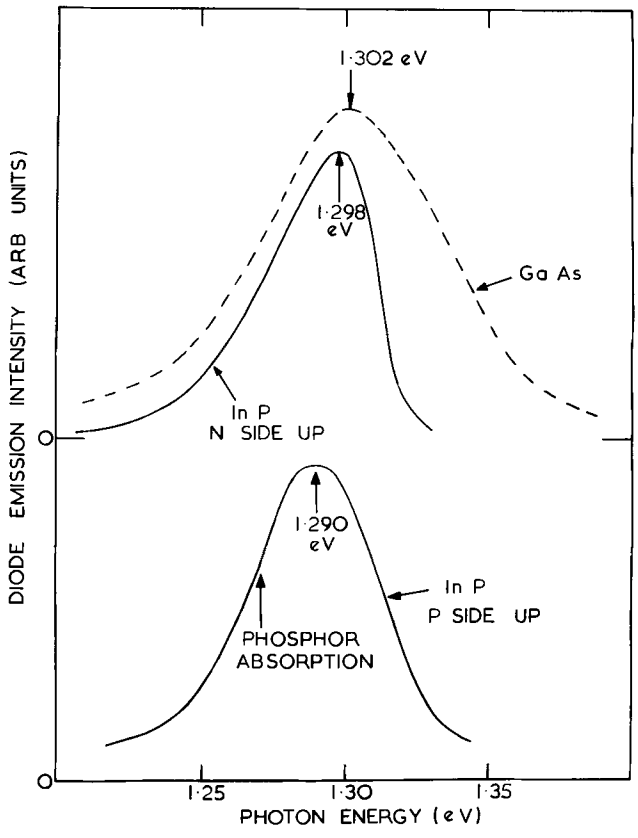

Fig. 5. The room temperature spectral emission of the two types of diode shown in Fig. 2. The "flip-chip" diode spectrum is compared to a GaAs:Si diode. The arrow at 1.271 eV indicates the peak of the excitation curve of the LaF_3:Yb;Er two-photon phosphor.

best GaAs:Si cleaved diodes with efficiencies in the range 6% to 10%, and the InP doping levels were not optimized.

Since amphoterically doped diodes of InP could not be fabricated (5) the obvious next step is to try doming or coating with high refractive index glass domes so that the efficiencies can be increased. Provided efficiencies of 10% or greater can be achieved with InP then the narrower half width of the emission will mean that InP would be preferred to GaAs for the two photon phosphor diode.

Acknowledgments

The authors are particularly grateful to Dr. R. Hall and to Mr. K. Brown of the Thorn Lighting Company for many helpful discussions and for the fabrication of some diodes from our epitaxial layers. Technical support was provided by Mr. F. G. H. Smith and Mrs. M. Webb. Dr. A. M. White and Mr. W. Elder provided many useful comments and helped with the first efficiency measurements. This series of three papers on indium phosphide are published with the permission of the Director of RRE.

Manuscript submitted Dec. 4, 1972; revised manuscript received May 29, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Growth and Characterization of Polycrystalline Silicon

P. Rai-Choudhury* and P. L. Hower

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Polycrystalline silicon is deposited by pyrolysis of silane in an rf heated epitaxial reactor. The grains exhibit a fibrous microstructure having an <110> preferred orientation in the growth direction. Growth is inhibited in the presence of excess arsine and accelerated in the presence of diborane. The results are explained in terms of catalysis and poisoning of surface adsorption sites responsible for reaction. A simple model for current conduction in polycrystalline silicon is described based on grain size, grain doping, and effective barrier height due to the grain boundary. This model satisfactorily explains the observed temperature dependence of the resistivity of undoped films and also the large values of resistivity which are observed for dopant concentrations $\lesssim 10^{15}$ cm^{-3}.

Polycrystalline silicon is finding increasing applications in dielectrically isolated structures for high speed and radiation hardened circuitry, silicon gate MOS technology, and field plate structures (1, 2). In addition, some potential applications as solar energy collectors in the harnessing of solar energy are being proposed (3). Therefore, a better understanding of the processing technology, as well as the electrical and optical properties of polycrystalline silicon, is needed.

By controlling the parameters of the deposition process, polycrystalline silicon having a wide range of properties can be produced. The properties of the silicon can be tailored to make it behave as a dielectric, a resistive, or a semiconductive film. However, no satisfactory model exists which predicts the resistivities of these films as the grain size or the doping level is varied. Phenomenologically, the carrier mobility in polycrystalline silicon may be represented by four contributions; namely, the lattice, impurities, dislocations, and the grain boundary effects (4). Optical properties can also be affected significantly by grain size and doping.

Cowher and Sedgwick (5) have recently grown polycrystalline silicon from pyrolysis of SiH_4 as well as from the $SiBr_4$-H_2 system. They have observed a slight deterioration of surface quality of the films deposited from SiH_4 with increasing dopant concentration at 650°C. The mobility of carriers in their films is lower than the single-crystal bulk value by a factor of about 2 to 3. The acceptor concentration in their boron-doped films seems to increase very rapidly to the mid 10^{18} cm^{-3} region with only a slight increase of the B_2H_6 concentration in the gas phase. Ford *et al.* (6) have also reported that the acceptor concentration of the boron-doped layers was always high ($\geq 2 \times 10^{19}$ cm^{-3}) and suggested the possibility of grain boundaries acting as acceptor centers. Their films were grown on an oxidized silicon surface at about 300 Å/min at 600°C. Recently, oxidation characteristics of polycrystalline silicon were studied by Kamins and MacKenna (7). The oxidation rate in the reaction-rate-limiting region is found to be between those of (100) and (111) single-crystal silicon. The orientation dependence, of course, becomes unimportant when high temperature ($\sim$ 1200°C) is used or thicker oxide is grown.

In this study the effects of dopant concentration in the gas phase on the film resistivity, growth rate, and grain size are examined. Also a simple model for current conduction is described which explains the observed temperature dependence of the resistivity of undoped films as well as the consequences of doping.

Experimental Procedure

Substrates used were (111) silicon, oxidized silicon, silicon nitride coated silicon, and ($1\bar{1}02$) sapphire. One of the reasons for selecting these different substrates was to find out the importance of the substrate orientation in establishing the microstructure of the deposit at low growth temperatures. Silicon was deposited by pyrolysis of SiH_4 in hydrogen carrier gas, and the layer doped to the desired level by controlled injection of AsH_3 or B_2H_6. The reactor used was a horizontal rf heated system having a silicon-coated graphite susceptor. The doping results at low temperature (680°C) from SiH_4 pyrolysis were compared with those at high temperature (1200°C) from H_2 reduction of $SiCl_4$.

The resistivity and thickness of the doped films were determined by measuring the spreading resistance along a beveled surface (8). The undoped film resistivities were determined by measuring the resistance for a known geometry. Using the same geometry the temperature dependence of the conductivity was also measured. The concentrations of the dopants were measured using a spark source mass spectrometer. The microstructure and the orientation of the films were determined using transmission electron microscopy and reflection electron diffraction.

Results

The results are presented in three sections dealing with the microstructure of the films, effects of doping on growth rate, and the electrical properties of the films. However, it must be emphasized that the results from these three sections are interrelated in a rather complex manner. An effort is made to present the relevant data in each section without unduly complicating the text through use of descriptive figure captions and cross-referring wherever it seems necessary. Discussion of experimental data in all three sections are, at best, semiquantitative. The energetics and kinetics of the growth and microstructure of films, the nature of absorption sites and its dependence on impurities (*e.g.*, catalysis and catalyst poisoning), and the charge carrier transport through various crystal defects, are all subjects difficult to treat analytically.

Microstructure of the films.—Films were normally grown at temperatures between 650°-680°C at a silane partial pressure of 5.4×10^{-3} atm. Simultaneous growth on different substrates indicates that the microstructure and the orientation of the films are essentially dictated by the growth conditions, rather than the substrate orientation. Figure 1 shows the reflection electron diffraction patterns of silicon grown at 680°C on different substrates. The <110> preferred

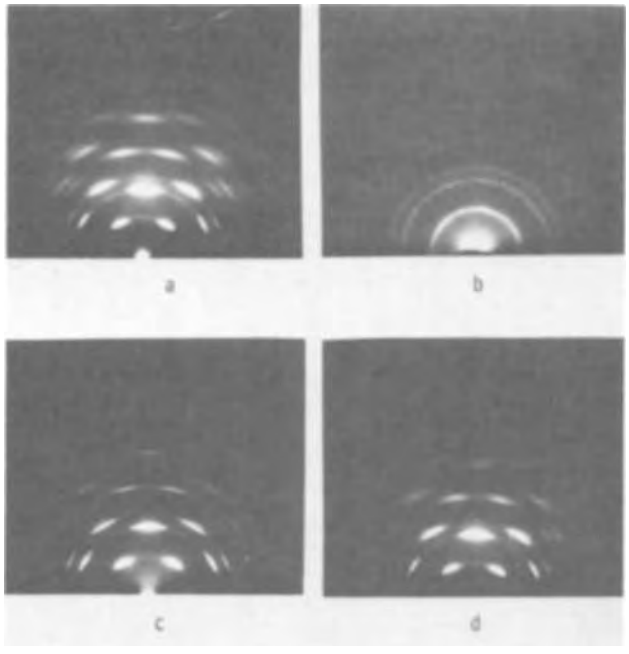

Fig. 1. Reflection electron diffraction of deposited silicon on different surfaces. (a) Si/Si, (b) Si/Al_2O_3, (c) $Si/SiO_2/Si$, (d) $Si/Si_3N_4/Si$.

orientation, seen in films grown on (111) silicon is also present in films grown on SiO_2 as well as Si_3N_4-coated silicon substrates. The films grown on $(1\bar{1}02)$ sapphire, on the other hand, show only random orientation. Since the layers on (111) silicon did not follow the substrate orientation, the initial nucleation as well as the growth of these films are essentially independent of substrate orientation (9). These results can be explained by considering the ease of nucleation on {110} and the energetics of growth in <110> direction, and are discussed in more detail later. The growth habit of the silicon films on sapphire substrates is complicated by the presence of mechanical damage, interfacial strain, and by unknown factors that results in the heteroepitaxial growth of silicon on sapphire (10).

In layers several micrometers thick, the grain size is a function of temperature, doping level in the film, and the substrate surface preparation. At and below about 850°C the grain size of films deposited on oxidized silicon is comparable to those on bare silicon substrates, and has only a slight temperature dependence. In the temperature range of 650°-750°C the grains of the undoped films, grown on both oxidized and bare silicon substrates, may be described as fibrous, having an <110> preferred orientation and grain size of the order of 0.2 μm. The grains also tend to grow in preferred directions in the plane of the wafer. At about 950°C, while the grains in the films on oxidized silicon are still comparable to those grown at lower temperatures, the films on bare silicon consist of very large grains showing evidence of epitaxy. It should be mentioned that when submicron thick layers are grown, the grains are of the order of 0.02 μm. In thicker films ($\geq$ 1 μm) the grain size seems to have stabilized at about 0.2-0.5 μm. Further work is required to establish the thickness dependence of the grain size. The larger grains in thicker films usually consist of several crystallites. The boundaries between these crystallites also probably form effective barriers to current transport. Thus, a mere increase in the observed grain size does not necessarily decrease the resistance to current flow.

At a given growth temperature, the grain size is affected only at high doping levels (for both boron and arsenic), and the films show a strong preferred orientation in the growth direction at high growth rate. Figure 2 shows the effect of arsenic doping on the microstructure. The films remain fibrous until the arsenic concentration in the solid exceeds about 10^{19} atoms/cm^3. At higher doping levels the fiber-type grains change to rods and platelets and the deposition rate decreases rapidly.

The results of boron doping are somewhat different. At high boron doping ($>10^{19}$ atoms/cm^3) the grains tend to lose the fiber-like texture as shown in Fig. 3 without losing the <110> preferred orientation. At very high B_2H_6 partial pressures ($\geqq 10^{-5}$ atm) the growth rate increases significantly and the films exhibit a strong <110> orientation in the growth direction. However, the orientation of the grains is quite random in the plane of the (111) wafer. Note again that the films do not follow the orientation of the substrate. Figure 4 shows a comparison of the reflection electron diffraction patterns of undoped films, heavily boron-doped films grown rapidly, and heavily arsenic-doped films grown slowly (see also Table I). Arsenic doping tends to weaken the preferred orientation which is present in the undoped films, whereas, boron doping enhances the preferred orientation.

Effects of doping on growth.—The presence of dopant atoms in the gas phase above a certain level influences the nucleation and growth behavior of the deposits. In this regard boron and arsenic behave in striking contrast. The effects of dopant partial pressure in the gas phase on the growth rate of the polycrystalline silicon is shown in Fig. 5. As may be expected, at low dopant partial pressures the growth rate is independent of the amount of dopants present in the system. Presence of AsH_3 above a certain partial pressure causes a significant decrease in the growth rate of silicon, whereas, the reverse is the case with B_2H_6. Considering the effects of AsH_3: substituting SiH_4 by $SiCl_4$ and using a higher temperature (1200°C) for single crystal growth also produces similar effects as shown in Fig. 6. A significant decrease in the growth rate of silicon is observed above about 0.1% AsH_3. In order to maintain high enough arsenic concentrations on the silicon surface (as adsorbed species) so that growth inhibition is effective, it is necessary to increase the AsH_3 partial pressure with increasing temperature. Recently Farrow and Filby (11) have also observed similar effects using a molecular beam growth system. These results may be explained using the concept of catalyst poisoning by Group VB elements which is a common occurrence in systems containing metal catalysts (12). Poisoning occurs be-

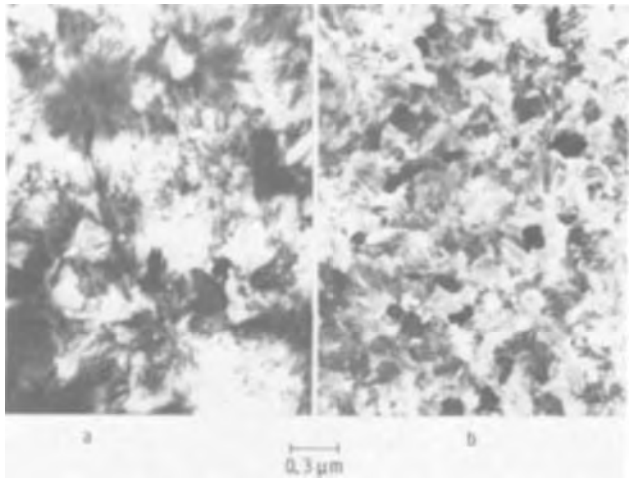

Fig. 2. Micrographs showing the effect of AsH_3 partial pressure on the microstructure of the films grown at 680°C. (a) $P_{AsH_3} = 9.6 \times 10^{-8}$ atm, $N_{As} = 2.5 \times 10^{19}$ atoms/cm^3; (b) $P_{AsH_3} = 9.6 \times 10^{-6}$ atm, $N_{As} = 1.6 \times 10^{20}$ atoms/cm^3.

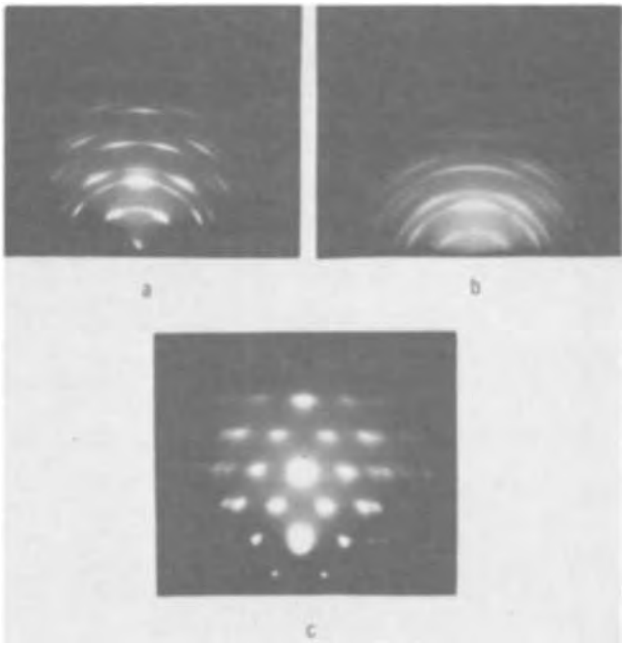

Fig. 4. Reflection electron diffraction patterns of silicon films deposited at 680°C showing preferred orientation. (a) Undoped film, growth rate = 0.13 μm/min; (b) heavily arsenic-doped film, growth rate = 0.018 μm/min; (c) heavily boron-doped film, growth rate = 0.4 μm/min.

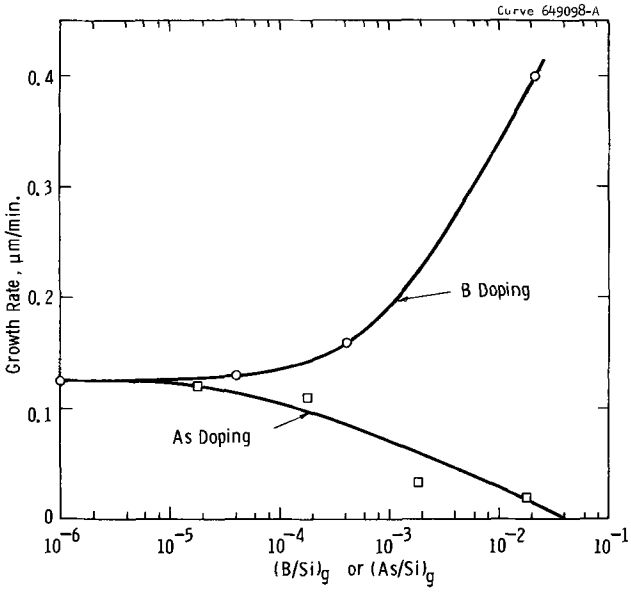

Fig. 5. Effect of dopant concentration in the gas phase on the growth rate of silicon at 680°C; $P_{SiH_4} = 5.4 \times 10^{-3}$ atm.

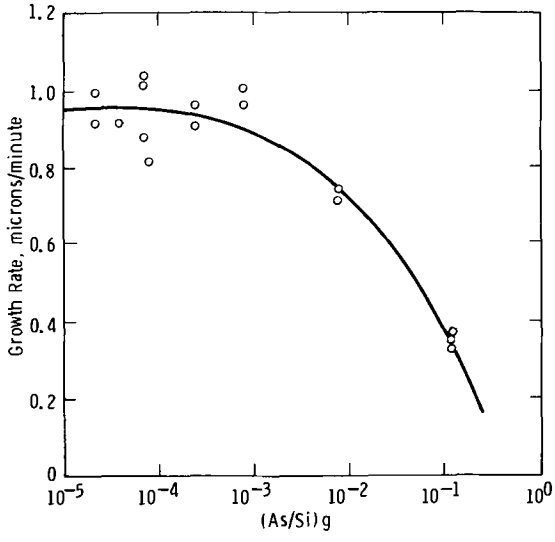

Fig. 6. Effect of arsenic to silicon ratio in the gas phase on the deposition rate of silicon from $SiCl_4$-H_2 system at 1200°C.

cause of a strong adsorptive bond between catalyst and poison. On the basis of their results, Farrow and Filby postulated that arsenic atoms become strongly bound to certain surface sites which are active in inducing silane pyrolysis. In spite of the fact that the SiH_4 pyrolysis is energetically more favorable (*i.e.*, having a large negative free energy change) compared to the H_2 reduction of $SiCl_4$, the arsenic poisoning is equally effective in both cases. This is due to the fact that at low temperature the SiH_4 pyrolysis is essentially a surface reaction and the growth rate is limited by the number of available adsorption sites.

The presence of B_2H_6, on the other hand, results in increased adsorption of SiH_4, and probably decreases the size and increases the number of stable nuclei. This would, of course, increase the growth rate with increasing B_2H_6 partial pressure (see Fig. 5) as long as pyrolysis of SiH_4 is not a limiting factor. Similar increase in the growth rate of the borosilicate films from SiH_4-O_2-B_2H_6 system were observed with increase in the B_2H_6 partial pressure (13). The increase in the growth rate is more than that which could be accounted for by a simple linear combination of SiO_2 and B_2O_3 deposition rates. Another example is found in the growth of II-VI compounds (14); addition of Group III elements enhances the growth whereas Group V elements poison the growth.

Electrical properties of the films.—Although boron can be trapped in the growing films in excess of its solid solubility limit, it is considerably more difficult to incorporate excess arsenic (15). Moreover, at doping levels above 10^{19} atoms/cm^3 the resistivity of the films and the number of dopant atoms in the silicon matrix do not bear a simple relationship, especially in polycrystalline silicon. Heavy doping tends to decrease the grain size (see Fig. 2 and 3), which in turn, effects the resistivity. Thus in examining the dependence of the film resistivity on the impurity concentration it is difficult to hold the grain size constant at high doping levels.

The resistivity of undoped films grown on oxidized silicon substrates was comparable to that on bare silicon substrates at growth temperatures up to about 850°C. At 950°C the films on oxidized substrates were still of very high resistivity. Table I shows some of the doping data for both n- and p-type films deposited on silicon substrates at 680°C along with the corresponding deposition rates. Control of the film resistivity was difficult above about 0.2 ohm-cm for both boron- and arsenic-doped layers. These results are explained using the barrier conduction model, a detailed discussion of which appears in the next section.

Discussion

Development of a preferred orientation.—The development of <110> preferred orientation in the direction of the film growth on differently prepared silicon substrates (see Fig. 1) clearly indicates the absence of any influence of the substrate orientation (under the present experimental conditions). Thus nucleation of {110} islands is kinetically favored. This is not unexpected when the ease of nucleation on various planes is considered. Atoms in {110} surfaces are arranged in planar zigzag chains, each atom being bonded to two nearest neighbors in the chain with the remaining two bonds extending diagonally out on each side. If the first depositing atom makes only one bond to the existing surface then three dangling bonds are created. Once the first atom is in place, other atoms can deposit adjacent to it without change in the number of unsatisfied bonds, and consequently, without any increase in the energy barrier. In the case of oxidized silicon wafers heating in hydrogen tends to reduce the surface oxides and the depositing silicon atoms will attach themselves to surface silicon atoms with minimum steric hindrance (16). {110} planes, once nucleated, might be difficult to extinguish by the slow growing {111} faces, since four of the six {111} are at right angles to a growing (110) plane while the other two {111} are at 35·36°. Since the surface energy of the (110) plane (1510 ergs/cm^2) is relatively high (17, 18) the crystallites tend to grow in the [110] direction rather than in the (110) plane.

The other possible preferred orientation in the film growth direction is the development of <100>. This is less likely since a depositing atom needs to bond to two adjacent surface atoms. Moreover, the four bonding {111} faces are at 54·74° from the (100) and will extinguish the (100) face easily (18).

Table I. Doping results of polycrystalline silicon

Doping compound	Dopant partial pressure, atm	Film growth rate, μm/min	Film type	Film resistivity, ohm-cm	Dopant concentration in films by mass spectroscopy, atoms/cm^3
None	0	0.13	p	6.5×10^6	5×10^{18} boron
B_2H_6	9×10^{-9}	0.13	p	4.5	—

$P_{SiH_4} = 5.4 \times 10^{-3}$ atm. $T = 680$°C, $V = 30$ cm/sec.

Barrier model for conduction in polycrystalline silicon.—The major electrical characteristics of polycrystalline silicon films can be described in terms of three film parameters; namely, grain size l_g, grain doping N_D or N_A, and an effective barrier height ϕ_B due to the interface state density at the boundary. A one-dimensional band diagram similar to that considered by Kamins (19) is shown in Fig. 7. It is assumed that $\phi_B > \phi_n$, and therefore there will be a depletion region of positive space charge over the distance l_2. It is also assumed that current transport across the depletion regions is similar to that of two Schottky barrier diodes connected as shown in the figure. These diodes appear in series with a resistor, which is due to the neutral portion of the grain.

When an external voltage is applied to the sample, a current density J will flow and the voltage will divide among the grains. Within each grain there will be a component V_1 across the neutral region and a component V_2 across the depletion region. Since $V_2 << kT/q$, we can write the film resistivity ρ as

$$\rho = \frac{1}{l_g}\frac{V_1 + 2V_2}{J} = \left(\rho_1 l_1 + \frac{2kT/q}{J_o}\right)\Big/ l_g \quad [1]$$

$$= \rho_{bulk} + \rho_{barrier}$$

where J_o is a factor which is exponentially dependdent on ϕ_B and also the built-in field, as we shall describe further.

From Eq. [1] we can see that bulk resistivity values can be approached either by growing very large grains or by increasing J_o. The latter can be accomplished by reducing ϕ_B or by increasing the built-in field to the point where the barrier tunneling probability is significant. For the latter case we can adapt Yu's analysis (20) for the contact resistance R_c of metal-Si junctions. The barrier resistivity is then

$$\rho_{barrier} = 2R_c/l_g \quad [2]$$

where R_c has dimensions of ohm-square centimeters and is a function of ϕ_B and N_D that behaves as $\exp(\phi_B/\sqrt{N_D})$ for large N_D.

If we consider the case of decreasing N_D, with ϕ_B and l_g fixed, there will be a value of N_D for which tunneling is no longer significant (20). This defines the lower limit of the heavily doped range. For smaller N_D, barrier transmission is due entirely to thermionic emission and the barrier resistivity is given by

$$\rho_{barrier} = \frac{2k/q}{l_g A^* f_p T}\exp(q\phi_B/kT) \quad [3]$$

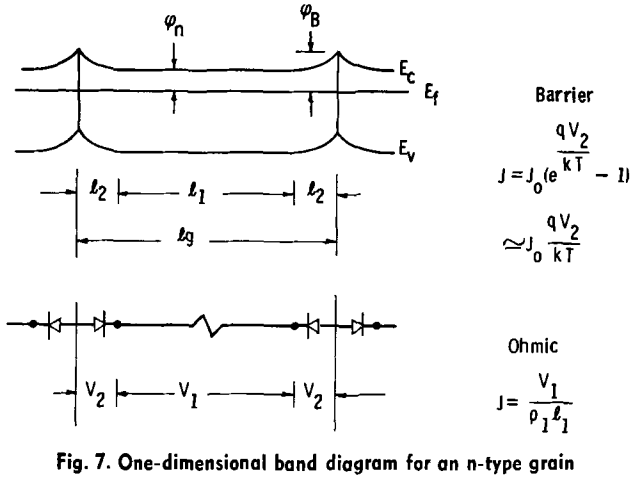

Fig. 7. One-dimensional band diagram for an n-type grain

where A^* is the effective value of the Richardson constant and f_p is the probability that an electron will be emitted over the potential energy maximum associated with the barrier. As the built-in field is reduced, f_p will decrease due to the increasing probability that an electron will be backscattered due to an electron, optical-phonon collision (21).

For the middle range of doping, Eq. [3] applies with $f_p \cong 1$. In this range, $\rho_{barrier}$ is independent of N_D and changes only with ϕ_B and l_g. Equation [3] indicates that $\rho_{barrier}$ (as a function of T) should show an "activation energy" $= q\phi_B$, if we ignore the slight temperature dependence due to the terms preceding the exponential term. This fact is used later in the experimental check of the model.

As N_D continues to decrease, the depletion layers will widen and eventually they will fully deplete the grain. For further decreases in N_D, the built-in field decreases rapidly and can lead to large increases in barrier resistivity. The third or "lightly doped" range is defined by

$$N_D < 8 \frac{\epsilon}{q} \frac{\phi_B - \phi_n}{l_g^2} \qquad [4]$$

In this range f_p can be approximated by (21)

$$f_p = \exp\left[1/(2\lambda\sqrt{2\pi N_D l_g})\right] \qquad [5]$$

where $\lambda (\cong 60\text{Å})$ is the mean-free-path for electron, optical-phonon collisions. In this range $\rho_{barrier}$ is again dependent on N_D, and because of the exponential dependence introduced by [5], resistivity will increase rapidly with decreasing N_D.

Applicability of Hall data.—To check the model against experiment we wish to compare measured resistivities against those predicted by the model. It might appear that Hall sample data would also provide a check, and while Hall data has been shown to be in qualitative agreement with the barrier model (19), the data require some interpretation. In particular the Hall coefficient is largely determined by the neutral portion of the grain (22) for the case where the resistivity is dominated by the barrier. Combining resistivity and Hall coefficient measurements in the usual manner then gives a Hall mobility and a Hall concentration that is not directly interpretable in terms of the model parameters. For this reason, and also because Hall measurements are difficult on high resistivity samples, we have elected to check the model using ρ *vs.* concentration and ρ *vs.* temperature data.

Comparison with experiment.—The solid curves of Fig. 8 are theoretical plots of resistivity *vs.* concentration with l_g fixed at 0.2 μm and ϕ_B as the parameter. As noted earlier, resistivity for the experimental points was determined from spreading resistance profiles and also by fabricating resistors using an aluminum surface electrode pattern. Concentrations were obtained from mass spectrometer measurements of boron and arsenic.

The dotted curve is a plot of measured resistivity *vs.* concentration of n- and p-type polycrystalline Si/SO_2 films as reported by Fripp and Slack (23). Their data is in close agreement with that of Kamins (19), which was obtained over a smaller doping range. These workers obtained concentration values from simultaneously grown epitaxial films on single-crystal substrates. The discrepancy between our data and that of Ref. (19) and (23) may be due to the different methods of determining the concentration. In either case the value obtained can only be regarded as an estimate to the electrically active grain doping.

If we ignore this discrepancy for the moment, the data suggests that ϕ_B is not constant, but is dependent on impurity concentration and decreases to small values at large doping values. This is in agreement with

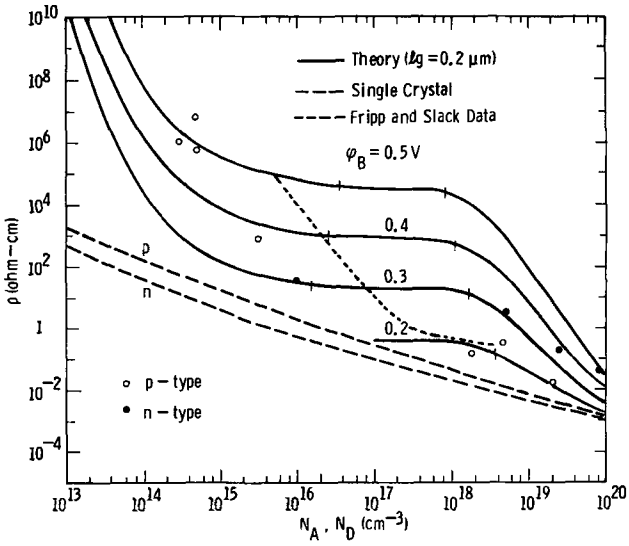

Fig. 8. Resistivity vs. concentration with ϕ_B as the parameter. The vertical bars indicate the three doping ranges of the model.

Kamin's observation that ϕ_B may decrease due to a "saturation" of the interface states as doping increases. The relatively large resistivity values of the heavily doped ($N_D > 10^{19}$ cm^{-3}) n-type films are attributed to a significant reduction in l_g from the typical 0.2 μm value.

We have measured ρ *vs.* T for a p-type film ($N_A = 2 \times 10^{18}$ cm^{-3}) and in comparing the data with the model, we find $\phi_B \cong 0.1$V, which is in agreement with Fig. 8. Data was also taken for a lightly doped sample ($N_A = 5 \times 10^{14}$ cm^{-3}) and is shown in Fig. 9. From Fig. 8, the model predicts that $\phi_B = 0.5$V which is good agreement with the observed value of 0.55V.

At low temperatures ϕ_B is observed to have a second, smaller value, $\phi_B = 0.126$V. Approximately the same value has been reported for amorphous films which were annealed at temperatures in the range 550°-750°C, and are therefore likely to have many properties in common with polycrystalline films (24). We have no explanation for this smaller value of ϕ_B

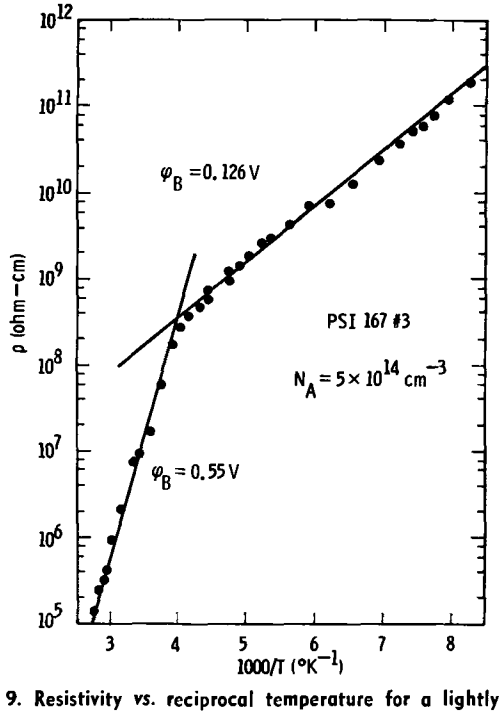

Fig. 9. Resistivity vs. reciprocal temperature for a lightly doped film.

except to ascribe it to the temperature behavior of the interface states.

The decreasing of ϕ_B with concentration does suggest that the density of interface states is less than that of a free silicon surface, for which ϕ_B is very nearly independent of concentration. In addition the similarity of ρ *vs.* concentration data for p- and n-type polycrystalline films suggests that interface donor and acceptor states have energy density profiles which are reflected with respect to the center of the band, which is also in contrast to a free silicon surface; however, this is somewhat speculative and additional work is required to elucidate the detailed behavior of the interface states.

Summary

At temperatures of 850°C or below, polycrystalline silicon films grown on differently prepared silicon substrates have comparable grain size. The microstructure is fibrous with grains growing in preferred <110> as well as some preferred directions in the plane of the substrate. Initial nucleation and growth of thin films are essentially independent of substrate orientation. The preferred orientation is enhanced in heavily boron-doped films accompanied by an increase in the deposition rate. In heavily arsenic-doped layers the preferred orientation tends to disappear along with a sharp decrease in the deposition rate.

A simple model has been described which can be used to estimate film resistivity as a function of grain size, grain doping, barrier height, and temperature. Comparison of the model with experimental ρ *vs.* concentration data indicates that the barrier height increases as doping decreases, with ϕ_B reaching a level near mid-gap for lightly doped films. Resistivity *vs.* temperature measurements on lightly and heavily doped films confirm this behavior of ϕ_B and provide a self-consistent check of the model.

Electrical Characteristics and Thermal Stability of Platinum Silicide-to-Silicon Ohmic Contacts Metalized with Tungsten

A. K. Sinha*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The present work was undertaken in order to determine the effect of various thermal treatments up to 800°C and of CVD Si_3N_4 encapsulation on the electrical characteristics of PtSi-to-Si contacts containing an overlay of W-metalization. Ohmic PtSi contacts were made to four sets of p-type Si samples doped in the 10^{18}-10^{20} cm^{-3} range and three sets of n-type Si samples doped in the 10^{19}-10^{20} cm^{-3} range. The measured contact resistivities, $\rho_{c,s}$, contain large spreading resistance contributions, but they establish useful upper limits to effective impedance at contact areas having dimensions of the order of 20 × 20 μm. The measured $\rho_{c,s}$ values range from 1.1×10^{-6} to 7.1×10^{-5} ohm-cm^2 for p-type Si samples and from 9.4×10^{-7} to 8.4×10^{-6} ohm-cm^2 for n-type Si samples. No significant degradation of contacts was observed at 600° or 700°C, or upon 680°C Si_3N_4 deposition. At 800°C (½-hr anneal) an excessive amount of WSi_2 is formed in the contact areas. Its effects may range from no change in contact resistance to an electrical "open." A large disagreement exists between the measured contact resistivities and those predicted by calculations based on one-dimensional electron tunneling through a potential barrier at the metal-semiconductor interface. A major part of the discrepancy results from extending the theory to very small (<150Å) depletion widths for alloyed interfaces that are physically not sharp. A three-dimensional micromodel that includes effects of nonuniform current flow and mobility differences between n- and p-type Si may be more appropriate.

The importance of ohmic contacts to diffused (doped) silicon layers is generally recognized in integrated circuit technology. In recent years, much interest has centered on PtSi-to-Si contacts, and there have been several reports of experimental (1-5) and theoretical (4, 6, 7) investigations. However, the exact situation does not appear to be clear yet. Most of the measured contact resistance values (1-3, 5) differ significantly from those predicted by the usual theoretical model, namely, tunneling of electrons through a potential barrier at the metal-semiconductor interface.

Also, since the original proposal of PtSi as the ohmic contact material in beam-lead technology (8), which utilizes Ti/Pt (or Pd)/Au metalization, there have been several investigations concerning the use of single-layer refractory metalizations such as W (9-11) for Si integrated circuits. Tungsten is potentially better able to withstand high-temperature processing steps such as chemical vapor deposition (CVD) of dielectrics (12) in the large scale integration (LSI) and multilevel metalization technologies.

The present study was made in order to provide new contact resistance data on ohmic PtSi/Si contacts metalized with W, and, in particular, to evaluate the electrical and metallurgical stability of these contacts as a function of various thermal treatments, including CVD Si_3N_4 encapsulation, in the range 600°-800°C. Some earlier results on high-temperature metallurgical stability of PtSi thin films were described in Ref. (13).

Experimental Procedure

Contact fabrication.—Bulk-doped n- and p-type Si samples, (100)-oriented and 0.25 mm thick, were used. The dopant was either As or B, and the dopant concentrations, $N_{D,A}$, were deduced from the supplied resistivity data, ρ_{Si}, by using published ρ_{Si} *vs.* $N_{D,A}$ plots (14). The Si wafers were cleaned and then steam-oxidized at 1050°C to give 3000Å thick SiO_2. Contact windows, having dimensions of 20 × 20 μm at 2.5 mm spacing, were etched through the oxide on one-half of the slice by standard photolithographic techniques. The oxide was completely removed from the other half. A layer of PtSi, 900Å thick, was formed on the exposed Si areas by backsputter cleaning the Si, sputtering 450Å of Pt, and then sintering *in-situ* at 700°C for 10 min (13). The unreacted Pt over SiO_2 was removed by etching in hot aqua regia. It was possible to ascertain the effectiveness of PtSi sintering by microscopic observation, supplemented by x-ray diffraction, on the control-half of the slice. The PtSi/Si samples were then metalized with an approximately 3000Å thick W film by low-voltage rf-diode sputtering (15) or by electron-beam evaporation (11) at about 300°C substrate temperature. Isolation pads were etched around the contact windows, and W was left unetched over the PtSi in the control-half of the slice. Various contact samples were annealed in H_2 or vacuum at 600°C (1 hr), 700°C (1 hr), or 800°C (½ hr). To evaluate the effect of Si_3N_4 encapsulation step on the W/PtSi/Si contact, approximately 1200Å of CVD Si_3N_4 (16) was deposited at 680°C and then etched away in a constant boiling (160°C) aqueous solution of H_3PO_4. Finally, contacts were made to the back side of the Si slices by first removing any residual oxide with dilute HF and then evaporating 5000Å of Al over the entire area.

Four sets of p-type Si samples and three sets of n-type Si samples were processed in this manner. Each set, with a given doping level, consisted of five to eight wafers.

Measurements.—Contact resistance measurements were made with an Electroglas Auto Probe Model 190 tester. Figure 1 illustrates the measurement procedure. The sample current was maintained a 1 mA. The probe was positioned on the contact area so that the voltage drop V_{xz} from X to the aluminized back Z was minimum. This was done in order to minimize contributions to the measured V_{xz} from the sheet resistance of the W film. Next, the probe was moved to a point Y in the middle of the control-half, which has an area of ~3.5 cm^2, approximately 10^6 times that of the contact area. The voltage drop V_{yz} contains mainly contributions from the "probe resistances" as Y and Z as well as any wire resistances in the measurement circuit. The area is too

Key words: thin films, metal-semiconductor contact, heat-treatment, device fabrication.

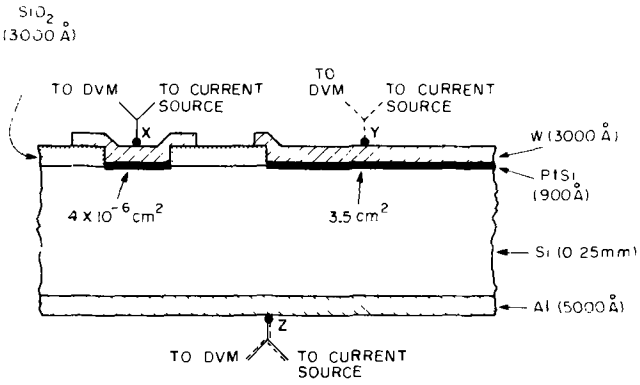

Fig. 1. Schematic of ohmic contact resistance measurement procedure.

large for any appreciable contribution from spreading or ohmic contact resistance. V_{yz} was always found to be less than 1 mV (for 1 mA current) and stayed constant within 5% for several scans of the probe from X to Y to X′ to Y′ to X″ to Y″, etc. indicating a reproducible "probe resistance."

It is important here to emphasize the distinction between the apparent contact resistance, $R_{c,s}$ (ohms), which was directly measured, and the apparent contact resistivity, $\rho_{c,s}$ (ohm-cm^2), which was derived from it. These quantities are defined as follows

$$R_{c,s} = I^{-1}(V_{xz} - V_{yz}) \quad [1]$$

$$\rho_{c,s} = AR_{c,s} \quad [2]$$

where I is the sample current and A is the area of the contact, which in the present case was equal to 4×10^{-6} cm^2. The subscript c,s means that the quantity includes both contact and spreading resistance contributions. Thus, the true contact resistance and the true contact resistivity will be represented by R_c and ρ_c, respectively. The ohmic nature of contact was verified by determining the I-V profile with a Tektronix Type 576 curve tracer, as shown in Fig. 2. Here, line A represents the resistance XZ and line B represents the resistance YZ so that the difference between their slopes is a measure of $R_{c,s}$. At least 20 contacts were measured on each wafer and then a logarithmic distribution plot was made (Fig. 3). As might be expected, samples with smaller $R_{c,s}$, which were obtained by subtracting two numbers (V_{yz} and V_{xz}) of comparable magnitude, tended to show a greater variation than those with larger $R_{c,s}$.

For diagnostic studies, the as-prepared or heat-treated samples were examined using optical microscopy, scanning electron microscopy, and x-ray diffraction on the control-half of the sample.

Experimental Results

Table I summarizes the median values of the apparent contact resistance, $R_{c,s}$, as a function of Si doping level and thermal treatment. Also listed for comparison (see Discussion section) are the expected values for the spreading resistance contributions, R_s, which were estimated using the formula (17)

$$R_s \approx \rho_{Si}/4r \quad [3]$$

where ρ_{Si} is the resistivity of the Si sample and r is the effective contact radius, assumed in the present case to be equal to 10 μm. Values of R_s obtained using the above formula are known to differ from the true spreading resistances by factors which may range from 0.8 to 3 (18). These, however, were not determined in the present case.

It may be seen in Table I and Fig. 4 that annealing at 600° or 700°C or Si_3N_4 deposition at 680°C did not cause any significant change in the $R_{c,s}$ values. This is reflected in cosmetically clean appearance of contact areas after, *e.g.*, 600°C anneal (Fig. 5a) or after a typical Si_3N_4 deposition and subsequent Si_3N_4 etch (Fig. 5b). Some roughness in the surface of W in Fig. 5b was caused by a slight attack on W by the H_3PO_4 etch used

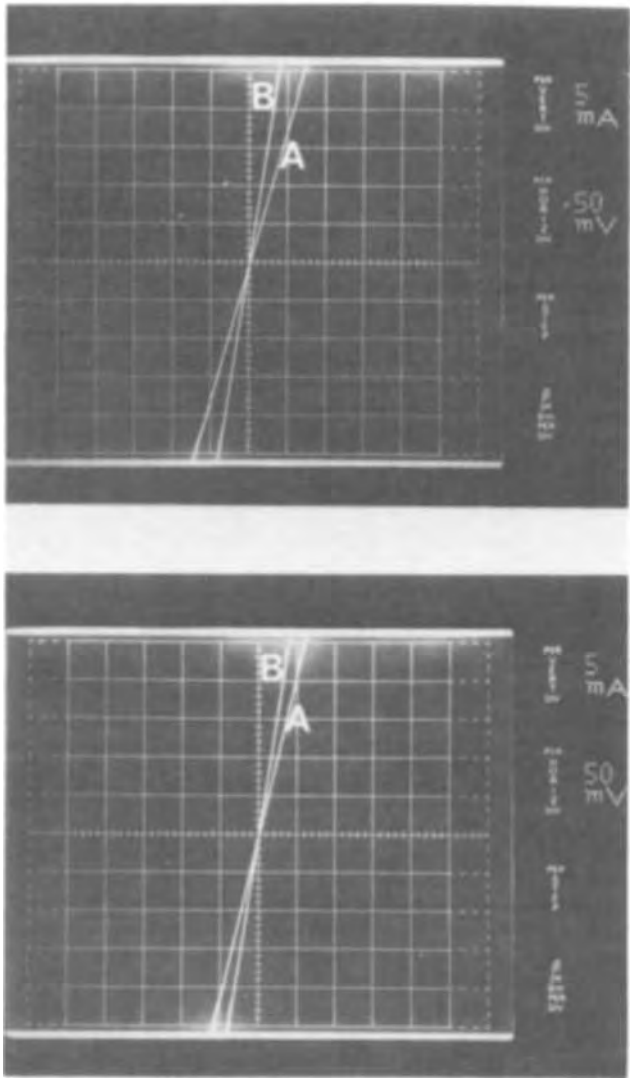

Fig. 2. Current-voltage profile for W-metalized PtSi/Si contacts with Al on the back side of Si. for Si_3N_4. In one Si_3N_4 deposition run, however, there was partial formation of WSi_2 at the edges of the contact window (Fig. 5c). This was probably due to an inadvertent and momentary rise in temperature during Si_3N_4 deposition. Such partial WSi_2 formation does not cause any significant increase in the contact resistance.

Annealing at 800°C (1/2 hr) results in unpredictable behavior. The contacts on various slices ranged from those with essentially unchanged $R_{c,s}$ to those which had become highly resistive and nonohmic or were electrically open (Table I). Such variability in contact resistance correlates with excessive WSi_2 formation illustrated in Fig. 6. WSi_2 possesses a rough texture, and the higher diffusivity of Si at the walls of the contact windows results in an apparent "spill-over" of WSi_2 outside the contact window. Although WSi_2 has several desirable properties, *e.g.*, metallic conductivity and oxidation resistance in air at 900°C, its formation in contact areas is clearly undesirable. It can be concluded from lattice parameter data (19) on WSi_2 (tetragonal, 6 atoms/cell, a = 3.211Å, c = 7.868Å) that its formation involves a 27% decrease in volume with respect to the components W and Si. This can cause development of large internal stresses especially near edges of contact windows, and can thereby lead to microcracks and electrical "opens." Therefore, it appears likely that the observed increases in contact resistance upon 800°C anneal primarily involve poorly reproducible mechanical/metallurgical effects and not the creation of any additional potential barrier between WSi_2 and PtSi.

Figure 7 shows the variation of median contact resistivity $\rho_{c,s}$ as a function of doping level of n- and p-type Si substrates. Also shown are two sets of previously published theoretical curves for ρ_c which have considered tunneling and tunneling/thermionic emission (7) processes.

Discussion

An examination of Table I shows that the spreading resistance contributions, R_s, are large and comparable in magnitude to the measured contact resistances, $R_{c,s}$. Therefore, the true contact resistances, R_c, are much smaller than the measured $R_{c,s}$ values. However, since all small area ohmic contacts to Si layers are associated with some spreading resistance, $R_{c,s}$ does provide a useful estimate of the effective impedance at contact areas having dimensions of the order of 20 × 20 μm. Contact resistance data reported by most of the previous investigators (1-5) also contain relatively large spreading contributions, but these were obtained on contacts having different sizes and shapes. Since the spreading resistance decreases as the first power of the

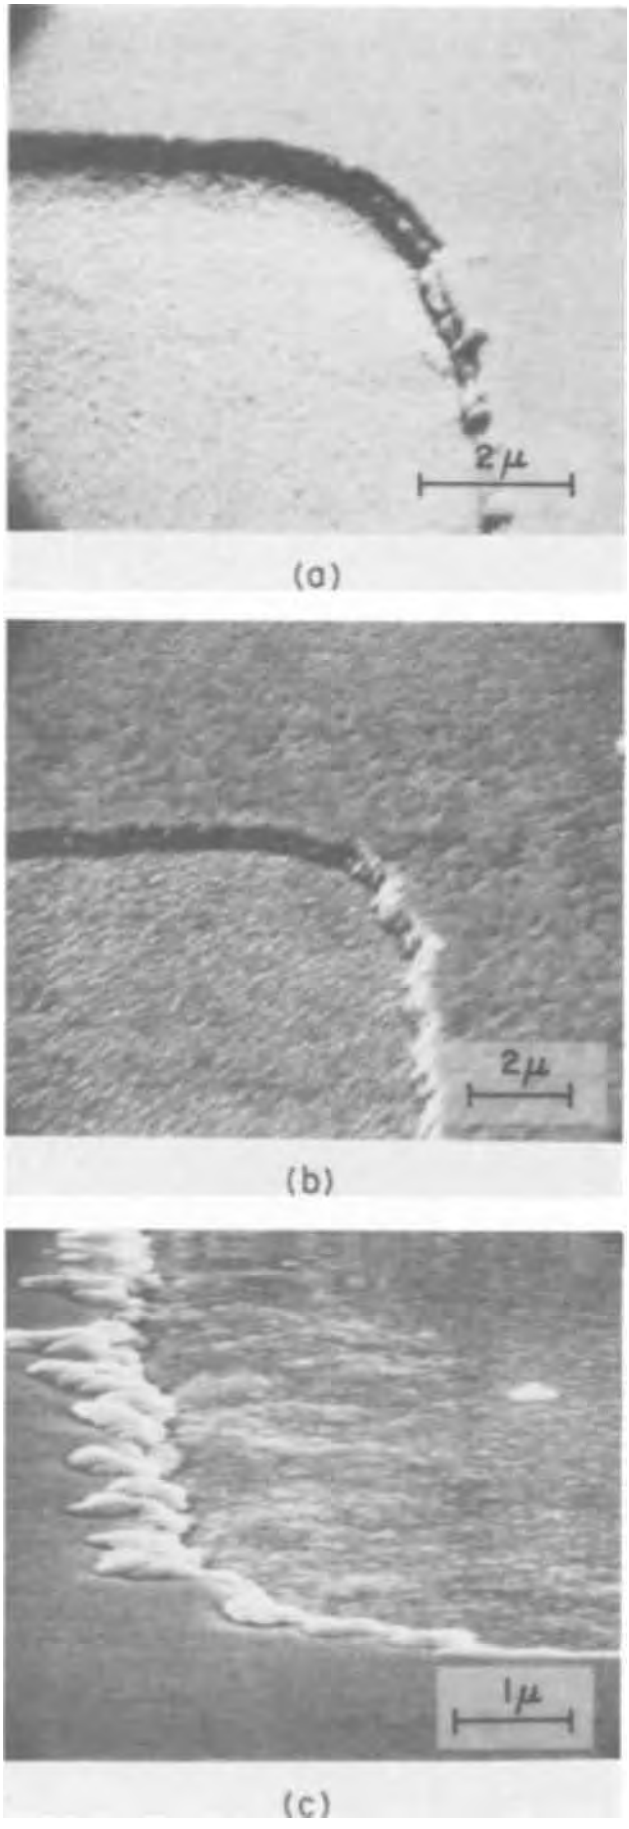

Fig. 5. Microstructures of W-metalized PtSi/Si contact areas: (a) after 600°C anneal, (b) after 680°C Si_3N_4 deposition and subsequent H_3PO_4 etch to remove Si_3N_4, and (c) after Si_3N_4 deposition with probably an inadvertent temperature rise during deposition.

contact radius (Eq. [3]) whereas the true contact resistance decreases as the square of the radius, comparisons between $\rho_{c,s}$ values obtained by different investigators are not meaningful unless the measurements are made on contacts of very nearly the same size and shape. There is, however, enough qualitative agreement between the present results and those of most previous investigators (1-3, 5) so that several of the conclusions (see below) reached on the basis of comparison of presently obtained data with predictions of the tunneling model are applicable to a wide range (with respect to sizes and shapes) of alloyed PtSi contacts in silicon integrated circuits (SIC's).

Since theoretical analysis of the contact resistance problem yields only ρ_c values (in ohm-cm^2), in order to compare the experimental results with theoretical ones (Fig. 7) it is necessary to obtain values of $\rho_{c,s}$ by multiplying the measured values of $R_{c,s}$ by the contact area. It should again be emphasized that the very large spreading resistance contributions make the values of $\rho_{c,s}$ obtained in this way only upper limits to the values of ρ_c. Therefore, it is significant that the experimental values of $\rho_{c,s}$ for n-type samples are much smaller than the theoretical values, since correcting for the spreading resistance would make the discrepancies even larger, However, no definite conclusion can be drawn from the comparison between the experimental $\rho_{c,s}$ values for p-type samples and the theoretical ρ_c values of Chang, Fang, and Sze (7); since the latter are lower than the former, the discrepancies would be reduced by correcting for the spreading resistance.

In view of the large disagreement between the experimental data and the contact resistivities predicted by the tunneling model (6, 7) especially for n-Si, it is important to examine the possible reasons for the inapplicability of this model to the PtSi/Si contacts studied in the present investigation. The tunneling theory predicts the resistance of a potential barrier, at the metal-semiconductor interface, as a function of the depletion width. Simple calculations show that the depletion width for the PtSi/Si interface is less than 150Å for doping levels (n- or p-type) exceeding the mid-10^{18} cm^{-3} range. The fact that the depletion widths for Si samples used in the present work are so

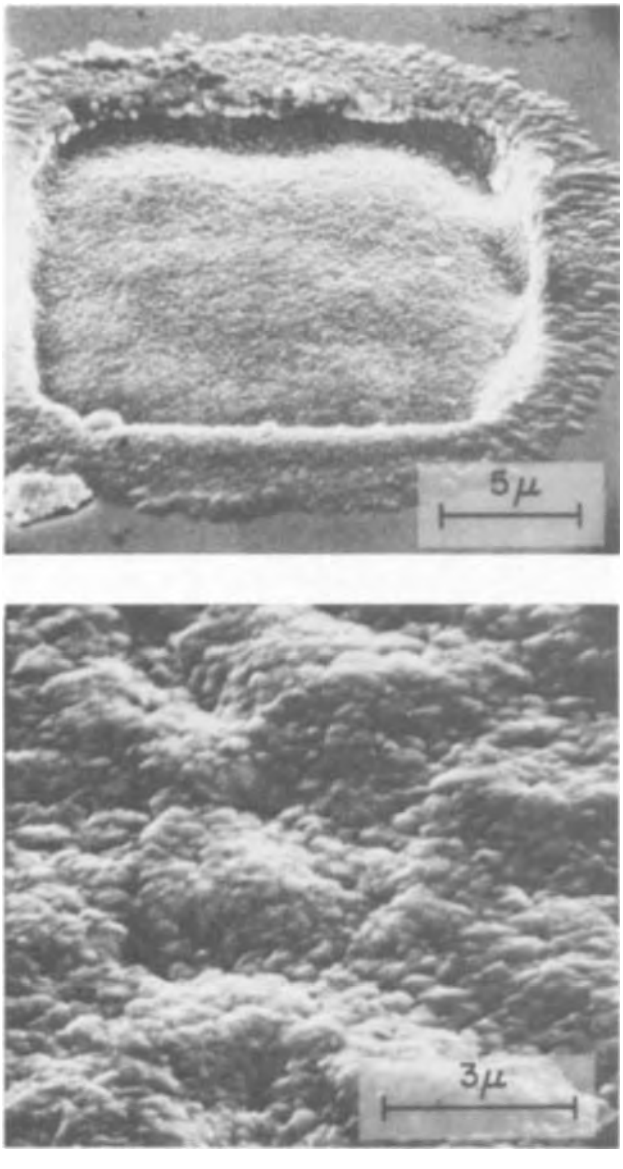

Fig. 6. Microstructure of contact samples annealed at 800°C. (a, upper) WSi_2 formation and "spill-over" outside the contact areas and (b, lower) surface texture of WSi_2 on PtSi on Si.

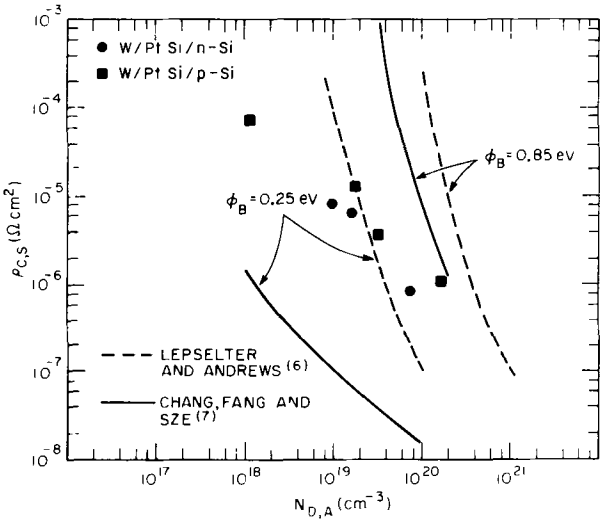

Fig. 7. Measured contact resistivity, $\rho_{c,s}$, vs. dopant concentration, $N_{D,A}$. Also shown are theoretically calculated curves for n- and p-type Si with PtSi/Si barrier heights of 0.85 and 0.25V, respectively.

small is very significant. It has been previously shown (13) that our as-prepared PtSi films contain surface irregularities of the order of a few hundred angstroms, distances which are greater than the estimated depletion widths. In addition to the roughness at the interface, there is a lattice mismatch between the diamond cubic Si and orthorhombic PtSi, and it is probable that the distribution coefficients of As and B between PtSi and Si are not exactly equal to unity. These factors, which are present in most alloyed ohmic contacts, preclude the possibility of any ideally sharp metal-silicon interface. Under such conditions, then, the idealized one-dimensional tunneling model (6-7) loses its validity. A three-dimensional micromodel that includes the effects of nonuniform current flow and mobility differences between n- and p-type Si may be more appropriate in the case of alloy-type ohmic contacts to semiconductors.

Summary and Conclusions

1. PtSi ohmic contacts were made to four sets of p-type Si ($N_A = 10^{18}$-10^{20} cm^{-3}) and three sets of n-type Si ($N_D = 10^{19}$-10^{20} cm^{-3}) samples. Each set consisted of five to eight different wafers, and at least 20 measurements were made on each wafer.

2. Measured contact resistances, $R_{c,s}$, for 20 × 20 μm contacts include large spreading resistance contributions.

3. Annealing at 600° or 700°C (1 hr) or Si_3N_4 deposition at 680°C does not cause any degradation of the ohmic contact or any significant metallurgical interaction.

4. At 800°C (1/2 hr), WSi_2 forms in the contact areas. Its effects may range from no change in contact resistance to an electrical "open."

5. Wide disagreement exists between the presently measured ohmic contact resistances and theoretical values based on a model of one-dimensional electron tunneling through a potential barrier. It is questionable whether such an idealized one-dimensional tunneling model is applicable to metal/highly doped semiconductor contacts containing irregular interfaces.

The Etch Rate of Gadolinium Gallium Garnet in Concentrated Phosphoric Acid of Varying Composition

D. C. Miller

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The etch rate of $Gd_3Ga_5O_{12}$ in concentrated phosphoric acid between 140° and 180°C was found to vary directly with the square of the H_3PO_4 concentration when dilution of the H_3PO_4 with higher acids of the type $H_{n+2}P_nO_{3n+1}$ ($n = 2,3,4\ldots$) occurs as a result of dehydration. When the H_3PO_4 concentration is reduced by dilution with water, however, the etch rate continues to increase reaching a maximum value at a dilution of approximately 50 mole per cent (m/o) H_2O at 140°C. For any given acid composition the etch rate varies exponentially with temperature.

Phosphoric acid above 250°C has been used to chemically polish a number of oxide single crystals (1-4), and between 160° and 170°C to reveal defects (5) in nonmagnetic garnet substrates (6, 7) and magnetic garnet epitaxial layers (8-10) used in bubble domain devices (11, 12). When heated, phosphoric acid dehydrates resulting in changes in the etching properties of the acid. These changes are especially deleterious at polishing temperatures but can be overcome by stabilizing the water content of the acid by bubbling steam through the bath (4). In the 140°-180°C range the selectivity of the acid is not affected by dehydration (5) but the etch rate is. Hence, precision etching of epitaxial garnet layers for thinning and circuit delineation, and the process-related etching of substrates for cleaning and defect analysis, requires that the etching properties of the acid be understood and controlled.

Key words: garnets, etching, phosphoric acid.

The changes which occur in the chemistry of phosphoric acid upon heating and the effect these changes have on the etch rate of $Gd_3Ga_5O_{12}$ are presented below.

Chemistry of Concentrated Phosphoric Acid

Commercial 85% phosphoric acid consists of orthophosphoric acid (H_3PO_4) and H_2O. Upon heating, the acid loses the excess water by boiling which commences at about 170°C and continues until the temperature reaches about 250°C. Upon further heating, dehydration will continue until essentially P_2O_5 remains at around 1000°C (13). However, as a result of dehydration, different acids form having the general formula $H_{n+2}P_nO_{3n+1}$ where $n = 2, 3 \ldots$, each representing an increase in the P_2O_5/H_2O ratio (14, 15). The equivalent concentration of P_2O_5 governs the ratios of the different phosphoric acids present and is related to the density, d, of the solution by the following empirical relationship (15)

$$d = 0.0167 \text{ (weight per cent } P_2O_5) + 0.66 \quad [1]$$

The per cent of the total P_2O_5 present in the solution in the form of each of the polyphosphoric acids has been determined for mixtures having P_2O_5 concentrations between 68.8 and 86.3 weight per cent (w/o) (16). These results and Eq. [1] have been used to calculate the mole per cent (m/o) H_3PO_4 present in the solution as a function of the density and this is shown graphically in Fig. 1. The maximum H_3PO_4 concentration attained is less than 100% (17, 18) at the stoichiometric composition (72.44 w/o P_2O_5). This solution has a density of 1.87 g/cm³ and contains a few per cent of equal amounts of water and pyrophosphoric acid ($H_4P_2O_7$).

The decreasing concentration to the left in the figure represents dilution with water and to the right dilution with acids having higher P_2O_5/H_2O ratios. Dehydration and the accompanying compositional changes are reversible, though re-establishment of the equilibrium composition after dehydration may take weeks. The equilibrium composition (density) depends upon the temperature and partial pressure of water in the ambient and is about 1.90 g/cm³ at 160°C in an open system, for example. If kept sealed, the composition characteristic of the conditions prevailing before sealing will be maintained upon heating or cooling (15, 17).

Experimental

Commercial 85% orthophosphoric acid with an mitial density of about 1.68 g/cm³ was used for all of the etching experiments reported here. The acid was contained in platinum beakers. However, below about 200°C Teflon and Pyrex (which dissolve at the rate of approximately 0.05 μm/min at 150°C) may also be used. Specimens were held with Teflon forceps.

Samples were dipped directly into the acid at the etching temperature for 1-15 min. Following etching, the samples were quenched in vacuum pump oil at 75°C to stop the etching action yet minimize the chances of thermal cracking. Then the samples were cleaned in consecutive hot Alconox solutions, the first containing 15 w/o KOH to aid in neutralizing any acid remaining on the specimens. The specimens were then rinsed in distilled water and blown dry.

The etch rates were determined in two ways. For short etching times (1-4 min), regions of the substrates were masked with SiO_2 deposited by electron beam evaporation. Then, after phosphoric acid etching, the SiO_2 was removed with dilute HF and the resulting steps measured with the Tally-Step machine. For long eching times (1-2 hr) when 50 μm or more was removed from both sides of the substrate, the over-all thickness change was measured with a micrometer. Results obtained using both techniques on the same specimen were in close agreement. The acid bath temperature was monitored with either a platinum-platinum 10% rhodium or a platinum encased chromel-alumel thermocouple immersed in the bath.

The water content or composition of the acid was determined by measuring its density for which volumetric flasks and hygrometers were used before and after etching at 25°C, the temperature to which all of the densities reported here have been normalized. In order to avoid error caused by either the gain or loss of moisture by the acid between the time of etching and measurement, the density was also determined during etching by a weight loss method. The method consists of first measuring the density of the fresh acid at 25°C in a volumetric flask or by use of a hygrometer. This was normally found to be between 1.625 and 1.685 g/cm³. The fresh acid is then weighed in the etching beaker at 25°C and again weighed during etching. Then, by assuming all weight loss is due to loss of H_2O ($\simeq$ 1 g/cm³ at 25°C) and that the density of the acid is the result of a simple mixing of H_2O and acid, the density of the acid during etching corrected to room temperature is given by

$$\frac{w_f}{\frac{w_I}{\rho_I} - (w_I - w_f)/\rho_{H_2O}} \cong d \quad [2]$$

where w_I is the initial acid weight, w_f is the acid weight during etching, ρ_I is the initial density of the acid, and ρ_{H_2O} is the density of water at 25°C. This approximation was found to be inadequate for precise measurement of the density and thus a calibration curve was determined that relates the density measured using this relationship to the "true" density. The true density was measured by overfilling volumetric flasks with the hot acid, sealing them until cooled to the measurement temperature, and then releveling them by removing excess acid. The calibration curve is shown in Fig. 2.

The surfaces of the specimens were polished with diamond followed by Syton,[1] which leaves the surfaces damage free. This is important because damaged surfaces etch faster than perfect surfaces and over-all

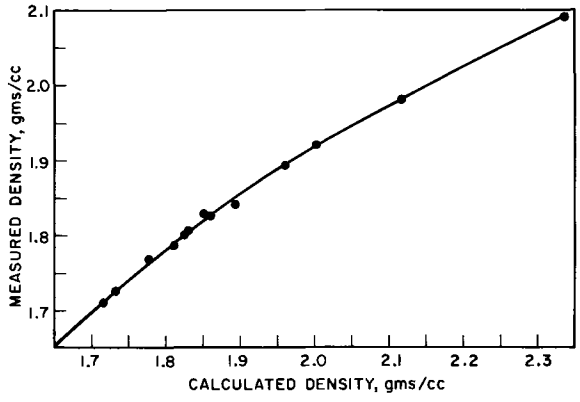

Fig. 2. Density of phosphoric acid measured using volumetric flasks and hygrometers vs. that calculated using the weight loss method.

falsely high etch rates would have been measured had as-sawn or rough polished substrates been used. Furthermore, the etch rate of garnet in the 140°-180°C temperature range is affected by small changes in composition (5). In order to minimize the possibility that small differences in stoichiometry and impurity concentration could introduce a source of error in the measurements, one (111) slice of $Gd_3Ga_5O_{12}$ was cut into 50 pieces and used in determining all of the data reported here.

Results

The etch rate of $Gd_3Ga_5O_{12}$ in the <111> direction as a function of acid density for four different temperatures is shown in Fig. 3. Every point on the curves is the average of at least three determinations at the specified temperature and density, and can be relied upon to ± 5%. Note that the etch rate continues to increase linearly as the acid is diluted with water until about 50% dilution is reached at 140°C (~ 1.70 g/cm³) whereupon the rate decreases.

This behavior cannot be readily related to the chemistry of the acid. Even though there is some disagreement about the maximum H_3PO_4 concentration attainable (18), it is unlikely that the reported H_3PO_4 concentrations (17) are enough in error to account solely for the observed behavior. It is most likely that dissociation of the acid must occur before etching can proceed and the concentration of the dissociated species reaches a maximum at some level of dilution (50% at 140°C, for example). Unfortunately, knowledge of the dissociation equilibria of concentrated phosphoric acid is limited to lower temperatures (18, 19) and more dilute solutions (20). Because of the large deviations from ideality present, neither Raoult's nor Henry's law can be applied or sensible extrapolations made of existing data.

Using the results of Huhti and Gartaganis (17) and Eq. [2] the etch rate data for solutions diluted with higher acids can be replotted as a function of H_3PO_4 concentration and this is shown in Fig. 4 for 150° and 170°C. If indeed the etch rate is a function of the ionized species present, then in view of the small etch rate

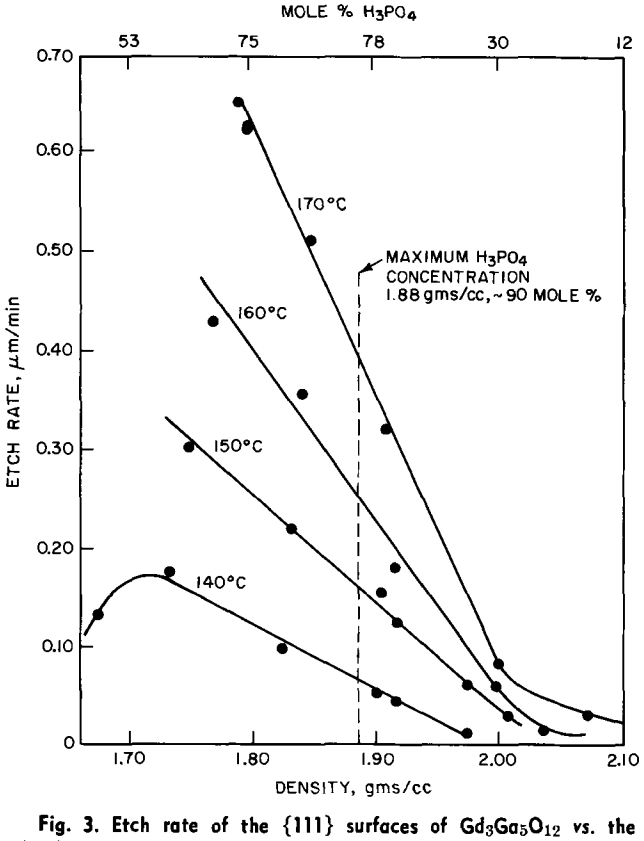

Fig. 3. Etch rate of the {111} surfaces of $Gd_3Ga_5O_{12}$ vs. the density of phosphoric acid.

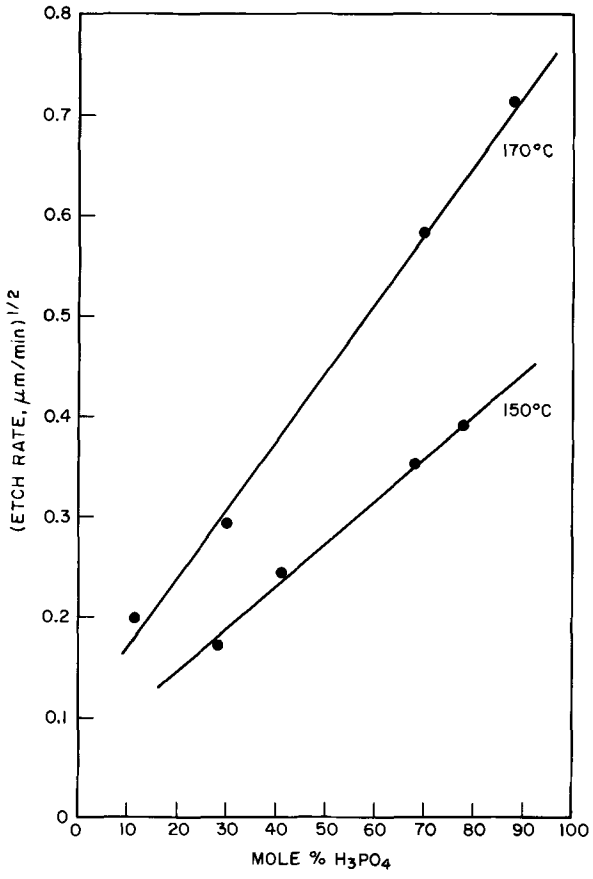

Fig. 4. Square root of the etch rate of the {111} surfaces of $Gd_3Ga_5O_{12}$ vs. mole per cent H_3PO_4 in phosphoric acid at 170° and 150°C.

indicated at 0% H_3PO_4, it is probable that the higher acids are only slightly dissociated and therefore serve to dilute the partially dissociated H_3PO_4. The square law dependence of the etch rate on concentration may indicate that the ionized species is formed by a reaction, such as

$$2H_3PO_4 \leftrightarrow H_2PO_4^- + H_4PO_4^+$$

and

$$\text{etch rate} \propto [H_4PO_4^+] = K'[H_3PO_4]^2$$

The variation of the etch rate as a function of temperature for the different densities is shown in Fig. 5. The variation is exponential with an activation energy of 25.5 kcal/mole for all three compositions. This suggests that the same component of the acid etches the garnet independent of the over-all acid composition. The negative deviation from exponential behavior at 140°C, which is largest at 1.980 g/cm³, probably arises from the development of a diffusion boundary layer at the crystal surface. The boundary layer thickness, and hence the etch rate, is controlled by the viscosity of the acid, which increases rapidly with decreasing temperature and increasing density.

It is also important to note that all of these data were taken from the same 0.030 in. thick by 0.8 in. diameter <111> slice of $Gd_3Ga_5O_{12}$ sectioned into many pieces. When attempts were made to measure etch rates on samples having different orientations that were cut from other $Gd_3Ga_5O_{12}$ boules, and (111) samples from these different boules were etched in order to correlate the data with that of Fig. 4 and 5, not only were they found to have considerably different absolute etch rates but large differences in activation energy as well (as high as 42.1 kcal/mole in one case). In addition, etch rate variations of an order of magnitude were observed to occur with magnetic garnet films of different compositions. Therefore, it must be concluded that etch rates are extremely sensitive to small variations in stoichiometry and impurity concen-

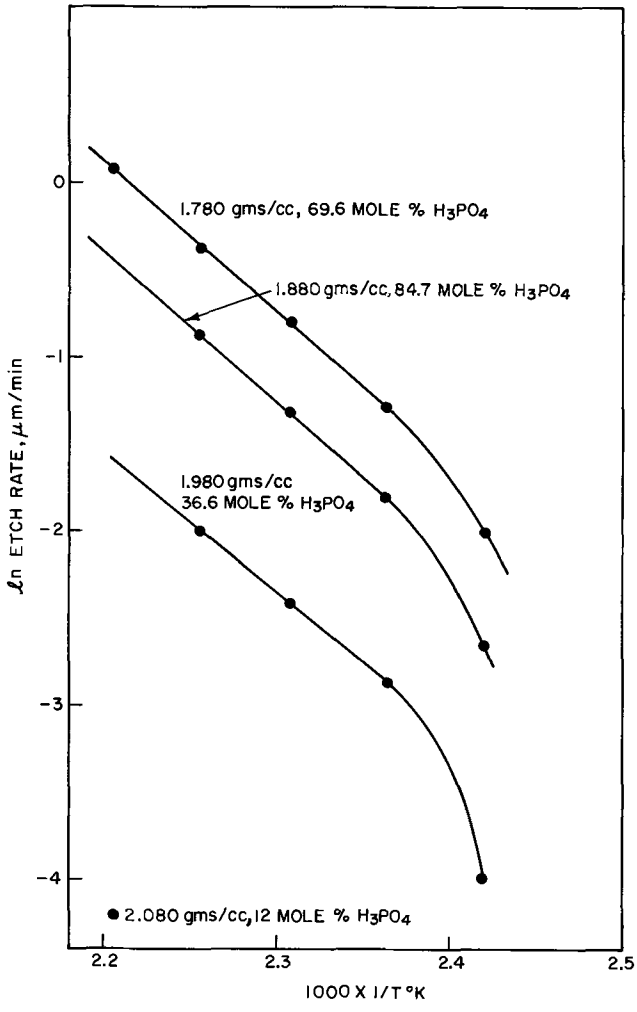

Fig. 5. Ln of the etch rate of the {111} surfaces of $Gd_3Ga_5O_{12}$ vs. inverse temperature at different densities.

tration. Such variations in the composition of $Gd_3Ga_5O_{12}$ can be caused by Ga_2O_3 evaporation during growth, growth atmosphere composition, starting material purity, and other variables (7). In view of this sensitivity, it may also be concluded that the etch rates will be extremely anisotropic. This was observed here qualitatively and is suggested by other results (21).

The great selectivity of the acid can be very useful in a variety of applications in addition to defect studies. For example, the steps produced by the SiO_2 mask were quite sharp, with no undercutting. This can be used to good advantage, since steps, grooves, and other configurations with possible circuit applications can be easily delineated. Despite the large differences observed in the absolute etch rates of the various garnets studied, the functional dependence of the etch rates on the phosphoric acid composition appeared to be the same as that of $Gd_3Ga_5O_{12}$.

Conclusions

The etch rate of $Gd_3Ga_5O_{12}$ in concentrated phosphoric acid varies directly with the square of the H_3PO_4 concentration when the H_3PO_4 is diluted with higher acids of the type $H_{n+2}P_nO_{3n+1}$ ($n = 2, 3, 4 \ldots$) formed as a result of dehydration. When the H_3PO_4 is diluted with water the etch rate continues to increase, reaching a maximum at a dilution of 50% H_2O at 140°C. The activation energy for etching is independent of acid composition but extremely dependent on the stoichiometry and impurity concentration of the $Gd_3Ga_5O_{12}$.

Silicide Formation in Tungsten and Other Refractory Metalizations on PtSi on Silicon

A. K. Sinha,* Mildred H. Read, and T. E. Smith

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We have evaluated the alloying behavior of W and other refractory metal films on PtSi on Si at temperatures ranging from 700° to 900°C. Nearly complete WSi_2 formation is observed in the case of W/PtSi/Si samples annealed above 750°C (1 hr). Si appears to be the diffusing species, and PtSi provides an unpassivated interface between W and PtSi/Si. WSi_2 is a metallic conductor with a resistivity of ~54 μohm-cm. Unlike W, WSi_2 does not oxidize upon heating in air up to 900°C. Its formation in the ohmic contact areas is, however, undesirable because of the volume changes accompanying its formation. In the case of other refractory metalization systems, M/PtSi/Si where M is Ti, V, Cr, Ni, NiCr, Mo, and Ta, PtSi also offers little resistance to M-silicide formation at high temperatures (800°-900°C).

Information on the high-temperature metallurgical compatibility of various thin-film materials systems is of considerable importance in the design of certain LSI (large scale integration) processing schemes. It becomes a critical factor when postmetalization steps such as Si_3N_4 encapsulation by CVD (chemical vapor deposition) (1) are involved. A refractory metal metalization such as tungsten on SiO_2 is generally able to withstand temperatures in excess of 900°C. However, a potential problem area lies in the ohmic contact regions of the LSI circuits. Here the reliability and performance of the device would depend rather critically on the metallurgical interactions involved.

In the present work, we have studied the alloying behavior of thin W-films over the ohmic contact material PtSi (2, 3) at temperatures ranging from 700° to 900°C. In addition, the nature of intermetallics formed during high-temperature annealing of other thin-film metalizations of type Si/PtSi/M (where M is Ti, V, Cr, Ni, NiCr, Mo, and Ta) and Si/PtSi/M/W has been also determined.

Experimental

PtSi was deposited (3) on n-type Si having (100) orientation and doped with As to 7-14 ohm-cm resistivity. Some of the Si wafers were steam oxidized at 1050°C to 5000Å thick SiO_2 and then an array of circular windows 20 mils in diameter was etched through the oxide. PtSi was produced within the windows, as well as on Si blanks by first backsputter cleaning the Si surface and then sputtering 450Å of Pt followed by *in situ* sintering at 700°C for 10 min. The unreacted Pt outside the windows was etched away with hot aqua regia.

Thin films of W were deposited on the above samples in an oil-free vacuum station using a Varian 6 kW e-gun (4). The source material consisted of MRC Marzgrade tungsten slugs and the background pressure during evaporation was kept at or below $\sim 3 \times 10^{-7}$ Torr. The thickness was monitored using a quartz crystal rate monitor. Deposition rates were typically at 300 Å/min, and the thickness of W deposits varied from 2500 to 3500Å. In addition to e-gun evaporation, some W-films were also deposited by low-voltage rf-diode sputtering (5). The deposition of Ti, V, Cr, Ni, and NiCr films, 1000-2000Å thick, was accomplished with filament evaporation in a conventional diffusion-pumped bell-jar system. Molybdenum was evaporated using an e-gun in a separate vacuum station from that used for W evaporation. The β-Ta (1000Å thick) was produced by d-c sputtering.

Following the metalization, the samples were annealed at various temperatures ranging from 700° to 900°C for ½ to 1 hr periods in a vacuum better than 2×10^{-6} Torr. The metallurgical interactions following the high-temperature anneal were studied using optical microscopy, x-ray diffraction [with a glancing angle wide-film Debye Scherrer camera (6)], sheet resistance measurements, and Talystep step-height measurements across the windows.

Results

Figures 1(a) through (d) show the effect of a 900°C, 1-hr vacuum anneal on the microstructure and topography of various contact windows on oxidized silicon wafers. Figures 1(a) and (b) show PtSi (900Å) in the contact windows before and after the 900°C thermal treatment. In the latter state, the PtSi has assumed a rough surface; this process, which is always accompanied by grain growth, was recently shown to involve partial agglomeration of the PtSi film (3). Figure 1(c) shows the microstructure in the as-deposited state of a PtSi contact sample coated with 3000Å of W. Upon annealing this sample at 900°C (1 hr), it may be seen from Fig. 1(d) that the tungsten within the PtSi contact windows undergoes a profuse reaction. The reaction product, which was subsequently identified as WSi_2, has a very rough texture. Judging from the Talystep trace, there appears to be an unusual increase in the volume of the material within the windows as a result of WSi_2 formation. In particular, there is a "pile-up" of WSi_2 at the edge of the windows. It was possible to etch away the unreacted W (over SiO_2) outside the windows using a ferricyanide-ethylene diamine etch, leaving sharply delineated WSi_2 over the PtSi dots. No evidence was observed of any appreciable lateral diffusion of either Pt or Si (as WSi_2); this is attributed to the relatively large thickness of the SiO_2 walls.

With a view to identifying the reaction product observed in Fig. 1(d), approximately 3500Å of W was e-gun evaporated on a 1¼ in. Si blank previously coated with 1400Å of sintered PtSi. After annealing this sample at 900°C for 1 hr in vacuum, its x-ray diffraction pattern showed a large number of strong lines which were identified as being due to WSi_2. In addition, several lines from the underlying PtSi which possessed a preferred (020) orientation parallel to the substrate were present. Positive phase identification was made by comparing the observed x-ray diffraction lines and their intensities along with those calculated for WSi_2 ($MoSi_2$, C11b type) and PtSi (FeP, B31 type). For computing the diffraction patterns of these compounds, the atomic positional parameters compiled

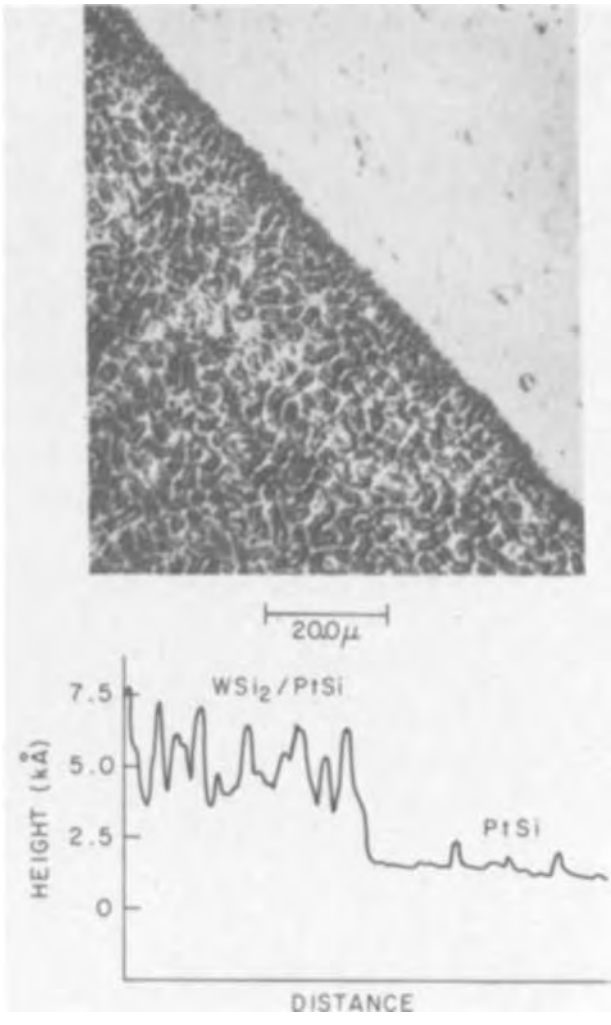

Fig. 2. Microstructure and topography of an annealed (900°C, 1 hr) sample of PtSi on Si partially coated with W (dark area).

by Pearson (7), and the program written by Yvon, Jeitschko, and Parthe (8) were used. There is a satisfactory agreement between the observed and calculated x-ray patterns for WSi_2. Almost complete (> 90%) WSi_2 formation was also observed in the case of W/PtSi/Si samples annealed for 1 hr at 850°, 800°, and 750°C, but not at 700°C. Heating the PtSi films in air at 500°C for 3 hr, or at 800°C in vacuum for 1 hr, prior to W deposition, did not affect the rate of WSi_2 formation upon subsequent annealing.

Figure 2 shows the microstructure of the annealed (900°C, 1 hr, vacuum) W/PtSi/Si sample which has reacted to form WSi_2 as well as a Talystep scan across WSi_2 to PtSi which had been shielded during the W deposition. The average step height of 3750Å is approximately the same as the thickness of W (approximately 3500Å) originally deposited on the PtSi/Si blank. This would suggest that in the W/PtSi/Si blank, the WSi_2 formation upon annealing is due to diffusion of Si through PtSi. Accordingly, both the WSi_2/Pt interface and the PtSi/Si interface sink down into Si. The sheet resistance of the annealed WSi_2/PtSi/Si combination was measured as 0.51 ohm/□. Assuming 3500Å of W in the unannealed W/PtSi/Si sample to give rise to 8750Å WSi_2 and taking into account the contribution of 1400Å of annealed PtSi ($\rho = 40$ μohm-cm), we estimate the resistivity of WSi_2 film to be ~54.5 μohm-cm. The WSi_2 film over PtSi has a matte surface, and unlike W which can be readily anodized (in, *e.g.*, aqueous citric acid solution) WSi_2 does not form anodic films to any appreciable extent, nor can it be oxidized upon heating in air up to 900°C (15 min). Its adhesion to PtSi, judging from the scotch tape peel test, is considered as being good.

The observation [Fig. 1(d)] that the growth of WSi_2 over PtSi largely occurs outward from Si would suggest the possibility of lateral spread of WSi_2 if the SiO_2 thickness at the contact windows were small enough. This was confirmed in an experiment with a charge-coupled device structure where the oxide thickness was approximately 2000Å. Figure 3(a) shows that the formation of WSi_2 (at 900°C, 1 hr, vacuum anneal) from 3000Å of W over PtSi in the contact windows results in a considerable "spill-over" of the WSi_2. Figure 3(b) shows the effect of an identical heat-treat-

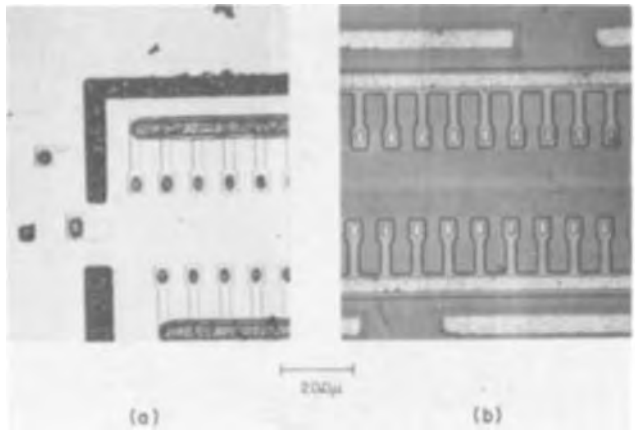

Fig. 3. Effect of a 900°C, 1-hr anneal on a CCD test structure containing (a) PtSi in the contact windows and metalized with W and (b) PtSi in the contact windows but no W overlay.

ment on the PtSi contact pads without W metalization over them. In this case, except for a coarsening effect, the PtSi contact areas remain well-defined.

The lateral spread as well as the spiky morphology of WSi_2 over PtSi may result in shorts both at the level of the W metalization and at levels above it, if WSi_2 penetrates an overlying dielectric film. With a view to prevent or retard such WSi_2 formation, the possibility of a barrier metal between PtSi and W was investigated. Inasmuch as the barrier metals themselves should possess good adhesion to the PtSi contacts, the present investigation was limited to Ti, V, Cr, Ni, NiCr, Mo, and β-Ta (1000-2000Å of each).

In the case of Si/PtSi/M type of systems V, Cr, and Ta reacted to form their disilicides which have the hexagonal $CrSi_2$ type of crystal structure. Upon annealing Ni-film on PtSi on Si, it was found that a quasi-binary (Ni,Pt) Si alloy had formed. This alloy has the same crystal structure as PtSi, but its lattice constants were 3-5% smaller than that of PtSi. Nichrome behaved similarly in that Ni was incorporated into the quasi-binary silicide (Ni,Pt) Si. In addition, a small quantity of fcc Ni(Cr) was also detected. The diffraction pattern of annealed Si/PtSi/Ti sample could not be associated with any of the previously reported silicides (7) of Ti. In the case of thin-film systems of type Si/PtSi/M/W, annealing in the range 800°-900°C always resulted in the formation of WSi_2 in addition to the previously mentioned silicides of the metal M. Chromium was found to be somewhat exceptional in this regard; in the case of Si/PtSi/Cr/W films, only localized formation of WSi_2 was observed in the optical microscope. The x-ray diffraction pattern contained reflections from both WSi_2 and W, with approximately equal intensities. The retarding effect of Cr may be due to its ability to form a passivating oxide layer on its surface.

Discussion

The present results clearly show that PtSi thin-films offer little resistance to high-temperature migration of Si across them into W and other refractory metalizations. This migration does not appear to be related to the phenomenon of agglomeration which was observed in PtSi thin-films at 900°C (3). We have observed profuse WSi_2 formation in Si/PtSi/W films at temperatures (750°-800°C) at which no agglomeration of PtSi thin films takes place. It appears, however, almost certain that PtSi provides an unpassivated (oxide-free) interface between W and PtSi/Si and that PtSi also provides rapid diffusion paths for Si atoms thereby permitting rapid W-Si interaction. This view is supported by results of $^4He^+$ ion Rutherford backscattering experiments which indicate that the surface of PtSi stays remarkably free of excess Si or oxygen even after annealing in air up to 600°C (9).

The crystallographic data on WSi_2 suggest that strong W-Si bonds may be present in this intermetallic: (*i*) In the WSi_2 structure (C11b, $MoSi_2$ type), shown in Fig. 4, each W atom is surrounded by a shell of 10 near-neighbors all of which are Si atoms. There is, thus, a larger number of W-Si bonds in WSi_2 (10 *vs.* 6.7) than that expected on the basis of simple alloy composition considerations. (*ii*) The volume of WSi_2 unit cell (80.6 Å^3, 6 atoms per unit cell) represents a contraction of 27% over the volumes of the component W (15.8 Å^3/atom) and Si (20 Å^3/atom) atoms. In a discussion of $MoSi_2$-type structures, Laves (10) pointed out that if both A-A and A-B contacts are assumed to be present, the geometry of C11b structure would require an ideal radius ratio R_A/R_B of unity. A tendency to meet such geometrical requirements is generally present in the case of most intermetallics. This may result in considerable adjustments in the volumes of the component atoms. In particular, Si has been known to undergo large volume contractions of up to 48%, and an associated decrease in the covalent nature

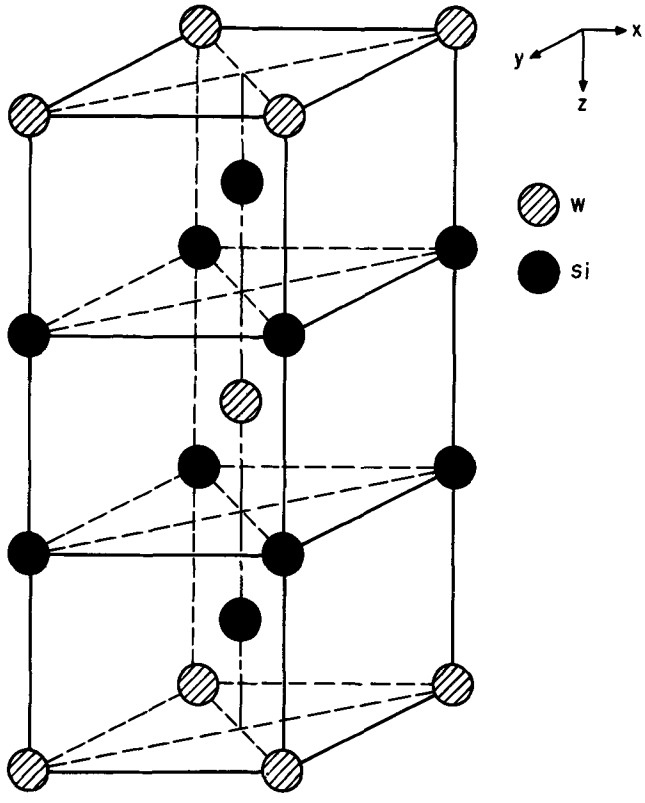

Fig. 4. Atomic arrangement in the tetragonal unit cell of WSi_2

of its bonds (11). A contraction of the order of 33% in the volume of Si atoms would be needed in order to satisfy the geometrical requirements of WSi_2 structure.

The increase in the metallic character of Si bonds which accompanies WSi_2 formation (and contraction of Si atoms) is perhaps partly responsible for the relatively low electrical resistivity of WSi_2, a compound rich in a semimetal. The presently observed increase in the volume of metalization upon WSi_2 formation correlates with the large volume (40.3Å^3) of WSi_2 per W atom which is greater than the atomic volume of elemental W by a factor of 2.5.

It is of interest to comment briefly on the possible diffusion processes leading to WSi_2 formation in W/PtSi/Si structures. Since PtSi stays untransformed during the heat-treatment of W/PtSi/Si films, it effectively acts as a marker. Thus, if W were to diffuse across PtSi into the Si, the PtSi layer would move up and its x-ray reflections would get stronger as WSi_2 formation proceeds. On the other hand, if Si were diffusing across PtSi, the PtSi layer would move down into the Si. The latter appears to be the case in the present experiments in which "PtSi-reflections" definitely did not increase in intensity upon W-silicide formation.

There are several possible ways in which Si may diffuse through PtSi into an overlying metal film. Among the simpler modes, we may cite migration of Si atoms along the grain boundaries of PtSi or, along the two sets of chains of Si atoms which are present in the crystal structure of PtSi (3). Searcy *et al.* (12) have estimated the thermodynamic bond energies of various transition metal-silicon (M-Si) bonds. According to their data, the M-Si bond energies (in electron volts/atom) for the metals studied in the present work increase in the order

Cr (4.81) → Ni (4.98) → Pt (5.38) → V (5.41)

→ Ti (5.45) → Mo(6.10) → Ta (6.75) → W (6.92)

It is significant that Cr forms one of the weakest bonds with Si whereas most of the other transition metals

studied form bonds with Si that are stronger than the Pt-Si bond. Interestingly, Cr was the only metal among the various metals tested that offered some promise as a barrier to WSi_2 formation in thin-film systems of type W/M/PtSi/Si. The fact that the bond energy for the W-Si bond is much larger than that for the Pt-Si bond raises the possibility of a reactive W/PtSi interface. A recent kinetic study (13) of WSi_2 formation in the system W/PtSi/Si indicated that the simple diffusion model [*e.g.*, square root of time dependence observed earlier in the W-Si system (14)] is not applicable to the present case. The thermal activation energy is unusually high at ~4.4 eV/mole. It was suggested that the W/PtSi interface may very well be a reactive one especially during the nucleation stage of WSi_2 formation. Such a complex, but thermodynamically possible nucleation process would then involve the creation of W-Si bonds at the expense of Pt-Si bonds at the W/PtSi interface and the nearly simultaneous restoration of the Pt-Si bonds by the out-diffusing Si atoms. The net effect is again the migration of Si atoms through PtSi into the W-film.

Migration of Si atoms through PtSi would also explain why there was little change in the average thickness of W metalization over PtSi/Si blanks even after WSi_2 formation (Fig. 2). However, when W is present over PtSi in the contact windows, the constraint at the SiO_2 walls may cause considerable buckling of the WSi_2. The "spill-over" of WSi_2 is probably due to an enhanced diffusion of Si at the SiO_2/W interface which is present along the windows. The spiky morphology of WSi_2 suggests that fingers of WSi_2/PtSi may protrude into Si, thereby providing additional channels for easy diffusion of Si.

Conclusions

(*i*) W on PtSi on Si reacts to form WSi_2 at temperatures above 750°C (1-hr anneals). Si is the diffusing species and PtSi provides an unpassivated interface between W and PtSi/Si. (*ii*) WSi_2 is a metallic conductor with a resistivity of approximately 54 μohm-cm. However, excessive WSi_2 formation in contact windows is undesirable because WSi_2 possesses a rough texture and it can extend outside the contact windows. (*iii*) Various transition metal silicides are also formed upon annealing (at 800°-900°C) other refractory metalization M on PtSi on Si, where M is Ti, V, Cr, Ta, Mo, Ni, and NiCr. (*iv*) Upon high-temperature annealing of thin-film systems of type W/M/PtSi/Si, WSi_2 is formed in all cases except that of Cr where about 50% of W stays untransformed at 900°C (1-hr anneal).

Technical Notes

Symmetry of Luminescing $(WO_4)^{-2}$ Groups in $CaWO_4$

R. J. R. S. B. Bhalla*

Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey 07003

Calcium tungstate represents an important class of self-activated luminescent materials (1). It has also been used as host material for rare earth activated lasers (2). Polarized emission of some rare earth activated $CaWO_4$ single crystals has been studied by photoluminescence and valuable information obtained about the symmetry of the activator sites (2). However, no information is available about the symmetry of the fluorescing $(WO_4)^{-2}$ groups in the self-activated $CaWO_4$ or any other tungstate phosphor. Polarized emission from appropriately oriented single crystals can be used to determine the symmetry of fluorescing $(WO_4)^{-2}$ groups in $CaWO_4$.

In the present communication, results of a cathodoluminescence study on the single crystals of $CaWO_4$ are reported. Polarization of the emission is observed and interpreted for the first time. Complete cathodoluminescence analyses including the emission spectrum, polarization of emission, and the rise and decay characteristics, were carried out using an electron microprobe analyzer, suitably modified for such studies

(3-5). This arrangement allows measurements to be made on very small single crystals (of the order of 0.001 and up to 1 cm).

Samples were prepared as polished thin sections so as to facilitate orientation determination under a polarizing light microscope. Selected single crystal chips were crushed and set in Lakeside 70 by melting the thermoplastic in an oven at 90°C. Finally, the sample surface was polished successively with 6, 3, 1, and ¼μ diamond pastes and coated with a thin layer of carbon (200-400Å) by vacuum evaporation to provide a conducting path for the electrons. This method of preparation yielded grains with many different crystallographic orientations.

The cathodoluminescence in the electron microprobe was observed through the light microscope (magnification 280X) which enabled observations to be made on the electron beam side of the sample surface. This is an advantage over the conventional cathodoluminescence apparatus when intrinsic anisotropy of the emission is to be examined. In the conventional cathode ray tube type of arrangement, the emitted radiation is examined on the opposite side of the screen; therefore, the radiation has to travel through the crystal thickness before reaching the detector. Such measurements may simply reflect the basic symmetry of the crystal rather than site symmetry of the luminescence centers.

Cathodoluminescence spectra were obtained using an interference-type spectrometer described by Greer and White (6). $CaWO_4$ emitted a characteristic bright-blue luminescence, and the emission spectrum consisted of a single broad and fairly symmetric band with a peak around 4400Å, in agreement with the published literature (7). The most important observation, however, was that the emission was found to be polarized. The grains oriented such that the c-axis was in the crystal plane, showed maximum polarization, while the grains oriented with the c-axis perpendicular to the crystal plane showed no polarization. Intermediate orientations showed intermediate degrees of polarization. The electric vector of the emitted luminescence was in a direction along the c-axis. The degree of polarization, measured as $p = \frac{(I' - I'')}{(I' + I'')}$, where I' and I'' are maximum and minimum intensities observed as the analyzer is rotated around its axis, was found to be 0.3. Spectra of emission were also examined in the two polarization directions; however, no significant change in the position or the shape of the band was found. The rise and decay traces of the luminescence were also obtained by pulsing the electron beam (4, 5). No detailed analysis was carried out but no differences were found in the decay times, measured through the monochromator at different wavelengths of the emission band (4200–6400Å). For the crystals oriented such that the c-axis was in the surface, the rise and decay times were measured with the analyzer parallel and perpendicular to the c-axis; however, no significant differences were found. Typical decay time at 25 keV potential and 50 $\mu A/cm^2$ current density (absorbed electrons), measured as the time required for the luminescence intensity to decay to $1/e$ of the maximum intensity, was of the order of 20 μsec. It may be pointed out here that cathodoluminescence rise and decay times can be dependent upon the primary beam energy and the current density, this dependence is more pronounced for the single crystals in comparison with the powders (4, 8). In the present study, no attempt was made to investigate the primary beam energy and current density dependence of the rise and decay characteristics.

Relatively little theoretical work has been done on the problem of luminescence in pure (unactivated) crystals such as $CaWO_4$. Recently Walter and Butler (9) carried out semiempirical LCAO-MO (linear combination of atomic orbitals-molecular orbital) calculations on the $(WO_4)^{-2}$ and isoelectronic $(VO_4)^{-3}$ complexes, assuming them to have tetrahedral symmetry, and explained the photoluminescence and excitation spectra of $CaWO_4$ and YVO_4 powders. In this communication an attempt is made to explain the polarization of emission considering the energy level scheme as calculated by Walter and Butler (9). The selection rules were calculated considering the effect of various lower symmetries on the emitting level of $(WO_4)^{-2}$ complex.

According to Walter and Butler (9) the emission transition is $2e \rightarrow t_1$. The configuration of the ground state would be $(t_1)^6$ and the first excited state would have the configuration $(t_1)^5$ $(2e)$. When the effect of electrostatic repulsion of the electrons is also taken into account the configuration $(t_1)^6$ $(2e)$ yields multiplets $^1T_1$, $^1T_2$, $^3T_1$, and $^3T_2$, whereas the configuration $(t_1)^6$ results in a singlet term $^1A_1$. Symmetry considerations show that for perfect T_d symmetry the only electric dipole allowed transition to the ground level would be from the levels with T_2 symmetry. The transitions from T_1 levels are forbidden. However, any lowering of symmetry would split the triply degenerate T_1 levels and the transition could then become allowed. Walter and Butler assign $^3T_1$ as the lowest lying excited state level. Since the ground state is a singlet, a transition from the triplet state is allowed only to the extent that there is spin-orbit coupling. The $(WO_4)^{-2}$ tetrahedron in the $CaWO_4$ is slightly distorted and has D_{2d} symmetry (10), being slightly contracted along the z-axis. The lowering of the symmetry has no effect on the ground state level, A_1, but the excited state level, T_1, would split up into two levels with the symmetries E and A_2, respectively. The selection rules under D_{2d} symmetry are given in Table I. Only the transition $E \rightarrow A_1$ is allowed in a direction perpendicular to the z-axis (c-axis of $CaWO_4$). Thus if the symmetry of emitting $(WO_4)^{-2}$ groups is the same as that obtained by crystallographic considerations then the crystals oriented such that the c-axis in the surface should show polarization with the electric vector of the emitted radiation in a direction perpendicular to the c-axis. This is, however, contrary to the experimental observation where it was found that the major electric vector of the partially polarized emission is in a direction along the c-axis. This means that the symmetry of the emitting $(WO_4)^{-2}$ groups is not the same as that deduced from the crystallographic considerations. Various theoretically possible symmetries which a tetrahedral molecule can assume are D_{2d}, C_{3v}, S_4, D_2, C_{2v}, C_3, C_2, and C_s. The triply degenerate level T_1 would split into either two or three levels under the influence of the lower symmetries, and the polarization under the reduced symmetry can be calculated using group theoretical arguments. These considerations show that polarization can be explained satisfactorily if the pseudo-symmetry of the molecule is taken as C_s. Complete selection rules for various possible symmetries are given elsewhere (4, 11). Under the field of symmetry C_s, the level T_1 would split up into three levels. Two of these levels would have a A'' symmetry and the third A'. The two transitions from the A'' levels, $A'' \rightarrow A'$, are allowed in the z direction (c-crystallographic axis) and the transition $A' \rightarrow A'$ is allowed in the (x,y) direction (perpendicular to the c-axis). Thus a partial polarization of the emitted radiation with the major electric vector along the c-axis would be expected as observed.

Table I. Electric-dipole selection rules under the D_{2d} symmetry for the emission transition $T_1 \rightarrow A_1$ (tetrahedral).

Transition	Polarization of emitted radiation	
	(x,y)	z
$E \rightarrow A_1$	Allowed	Forbidden
$A_2 \rightarrow A_1$	Forbidden	Forbidden

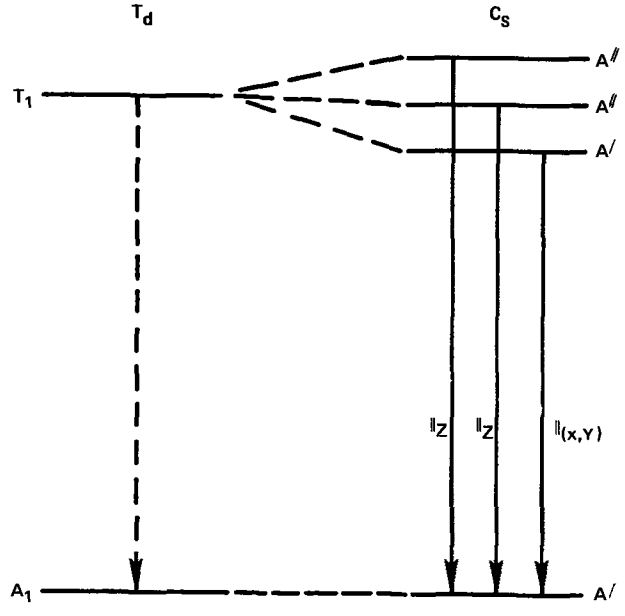

Fig. 1. Selection rules under the reduced symmetry. The T_d transition $T_1 \rightarrow A_1$ is forbidden, however, under the reduced symmetry C_s, the level T_1 splits into three levels, two with the symmetry A'' and one A'. The transitions $A'' \rightarrow A'$ are allowed along the c-axis, and the transition $A' \rightarrow A'$ is allowed perpendicular to the c-axis.

The energy level diagram and the polarization under C_s symmetry is shown in Fig. 1. Under C_s symmetry the calculated value of polarization, p, is 0.33 (assuming equal transition probability from each level). This compares fairly well with the observed value of 0.3.

It may be pointed out here that only electric dipole type transitions were considered to explain the observed polarization. Also, if the first excited level is $^3T_1$, the transitions to the ground state ($^1A_1$) are allowed only to the extent that there is spin-orbit coupling. Walter and Butler (9) place $^3T_1$ as the lowest excited state level immediately followed by a $^1T_1$ level. The selection rules remain unchanged irrespective of whether the lowest lying excited level is $^3T_1$ or $^1T_1$.

It is not clear at present what causes this reduction of the symmetry of the luminescing $(WO_4)^{2-}$ groups from D_{2d} to C_s. It must be remembered that the symmetry of the bulk of the $(WO_4)^{2-}$ groups is the same as determined by the crystallographic consideration, and it is only the symmetry of luminescing groups which deviates from that determined by the crystal structure analysis. The luminescing $(WO_4)^{2-}$ groups with C_s symmetry can be expected to be present in the crystals in only trace activator quantities to avoid concentration quenching.

It may be speculated that because of the degenerate nature of the first excited state level T_1 the symmetry is spontaneously lowered because of the Jahn-Teller effect. However if such were the case then it is not clear why this happens only to the fraction of the groups which are responsible for the luminescence emission. Another possibility is that the equilibrium lattice defects produced during the high temperature synthesis are located in such a way that they cause the neighboring $(WO_4)^{2-}$ groups to deform to the C_s symmetry and these deformed groups then act as luminescence centers.

A Simplification of Kämper's Striation Etch for Silicon

K. R. Mayer

Siemens AG, B GE 1, Munich 46, Germany

Kämper (1) proposed a method for revealing striations in dislocation-free silicon crystals working on a wide resistivity range of 0.001 up to 3000 ohm-cm. Previous methods, such as Vieweg-Gutberlet's (2) simple CrO_3/HF etch, are suitable for silicon of relatively low resistivity ($\rho < 1$ ohm-cm) only.

Kämper's method essentially consists of chemical polishing, two pretreatment procedures ("passivation," "activation"), and of the striation etching itself (see Table II) under illumination of the sample. Reaction time is about 15-20 min. Finally, the coating formed during the etching is removed by KOH.

Kämper's method has been criticized because it is complicated and difficult to be performed (3). As an alternative, it was observed that striations can be revealed in silicon of high resistivity (up to 1500 ohm-cm) by a simple CrO_3/HF etch after annealing the sample (3, 4) (annealing temperature $T = 1000°$-$1250°C$). It must be taken into account, however, that annealing

Key words: etching, silicon, striations.

might result in a change of material properties thus leading to a loss of both sharpness and fine structure of the chemically etched striations.

Therefore we tried to simplify Kämper's method. Our essential results are as follows (see also Table II). First, in order to obtain spotless surfaces, the wafer must be kept under liquid throughout the entire procedure. This is to prevent the wafer's surface from being exposed to air. In addition the chemical polishing step has to be stopped by HNO_3 (65%), not by water. In this way the formation of an adverse coating can be avoided [Archer, (5)]. Under these conditions Kämper's pretreatment steps 2 and 3 are not necessary.

Our striation etch consists of HF (48%), $NaNO_2$ (200-1000 mg/100 ml HF, depending on the sample resistivity), and a few drops of a usual acid wetting agent. The dangerous addition of acetic anhydride (which is proposed by Kämper to lower the surface tension) to the HF giving a strongly exothermic reaction can thus be avoided.

When HNO_3 is used as an oxidant, it must be taken into account that the reaction with silicon starts very slowly. This can lead to an uneven etch attack on the surface. Therefore we used $NaNO_2$ instead of HNO_3. $NaNO_2$ decomposes immediately in the acid solution to yield various nitrogen oxides [*e.g.*, NO_2, N_2O_4, HNO_2, see (6)] which give a faster reaction with silicon.

The illumination of the sample is effectuated by a 100W lamp. At least for silicon of very high resistivity ($\rho > 100$ ohm-cm) it is favorable to use the infrared part of radiation only by inserting a suitable filter ($\lambda > 650$ nm, as usually applied in *IR* photography). We found that illumination with shorter wavelengths often gives more hazy surfaces. The reason for this has not been well understood as yet.

The following procedure is proposed. Use thoroughly cleaned Teflon beakers and a particular sample holder (Fig. 1). The surface of the wafer must be lapped (grain size, 20 μm or less).

Polish the clean, lapped wafer chemically in a mixture of HNO_3 (65%), HF (40%), and acetic acid (100%) (8:5:5 parts by volume) for 10 min. Take 5 ml of etchant for each cm² of area to be etched. Stop by adding the same quantity of HNO_3 (65%). Immerse the sample together with the holder into water and thereafter into acetic acid. Make sure that the wafer remains entirely covered by the liquid. With chemically-mechanically polished wafers we often obtained bad results.

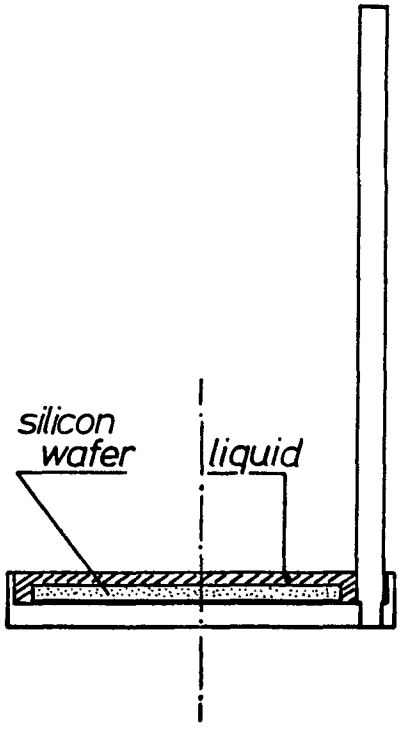

Fig. 1. Teflon sample holder

Table I.

Resistivity (ohm-cm)	Type	$NaNO_2$ (mg/100 ml HF)
<50	n	200
50-200	n	400
>200	n	1000
1-1000	p	1000

Add 2-5 drops of a slightly acid wetting agent [e.g., "Mirasol" (trade name of TETENAL, Photowerk, Hamburg, Germany), pH = 4-5].

Prepare about 5 ml striation etchant per cm² of area to be etched by dissolving the necessary amount of $NaNO_2$ in HF (48%) as given in Table I.

Switch on illumination. The sample together with the sample holder is taken out of the acetic acid. Let the acetic acid run off in such a way that a thin acid film remains on the wafer in order to protect the surface against contact with air. Immerse the sample together with the holder into the striation etch. Shake carefully. A completely uniform and colored coating develops. Etching is finished after 15-20 min. During the etching the solution may become opaque which does not affect the surface quality.

Immerse the sample into water. Finally dissolve the coating in a 10% KOH-solution (1-2 min). Rinse with water.

With wafers cut perpendicular to the growth axis it may be of some advantage to leave the colored coating on the surface in order to improve the visibility of the striation pattern and to get satisfactory photographs. The coating stays stable for several days. Obviously, the visibility of the striation pattern on cross-sectioned wafers also depends on the curvature of the striations with respect to a plane parallel to the growth axis (Fig. 2).

The experiments were mainly carried out with as grown n-type silicon crystals (phosphorus doped). Even with highly boron doped p-type silicon the striations do not appear as sharp as in n-type silicon. This is likely to be caused by a smaller periodic variation of the dopant concentration (the segregation coefficient of boron is nearly unity).

The described method can be applied to both floating-zone and crucible-grown silicon.

Table II gives a comparison of Kämper's original method with our simplified striation etching.

Figure 3 shows striation patterns of crystals of high resistivity (n- and p-type, respectively) as revealed by the simplified striation etching. There is little knowledge about the reaction mechanism of the striation etching. Undoubtedly, the etch rate only depends on the oxidation rate because the etchant contains a strong excess of HF (6).

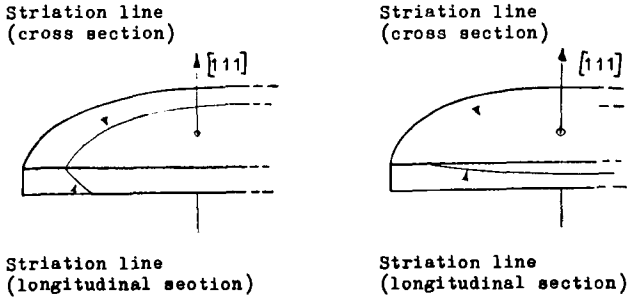

Fig. 2. Visibility of striations on a cross-sectioned wafer depending on the curvature of the striations on a longitudinal section (schematic). (a, left) Strong curvature (sharp striation line on the cross section) and (b, right) weak curvature (blurred striation line).

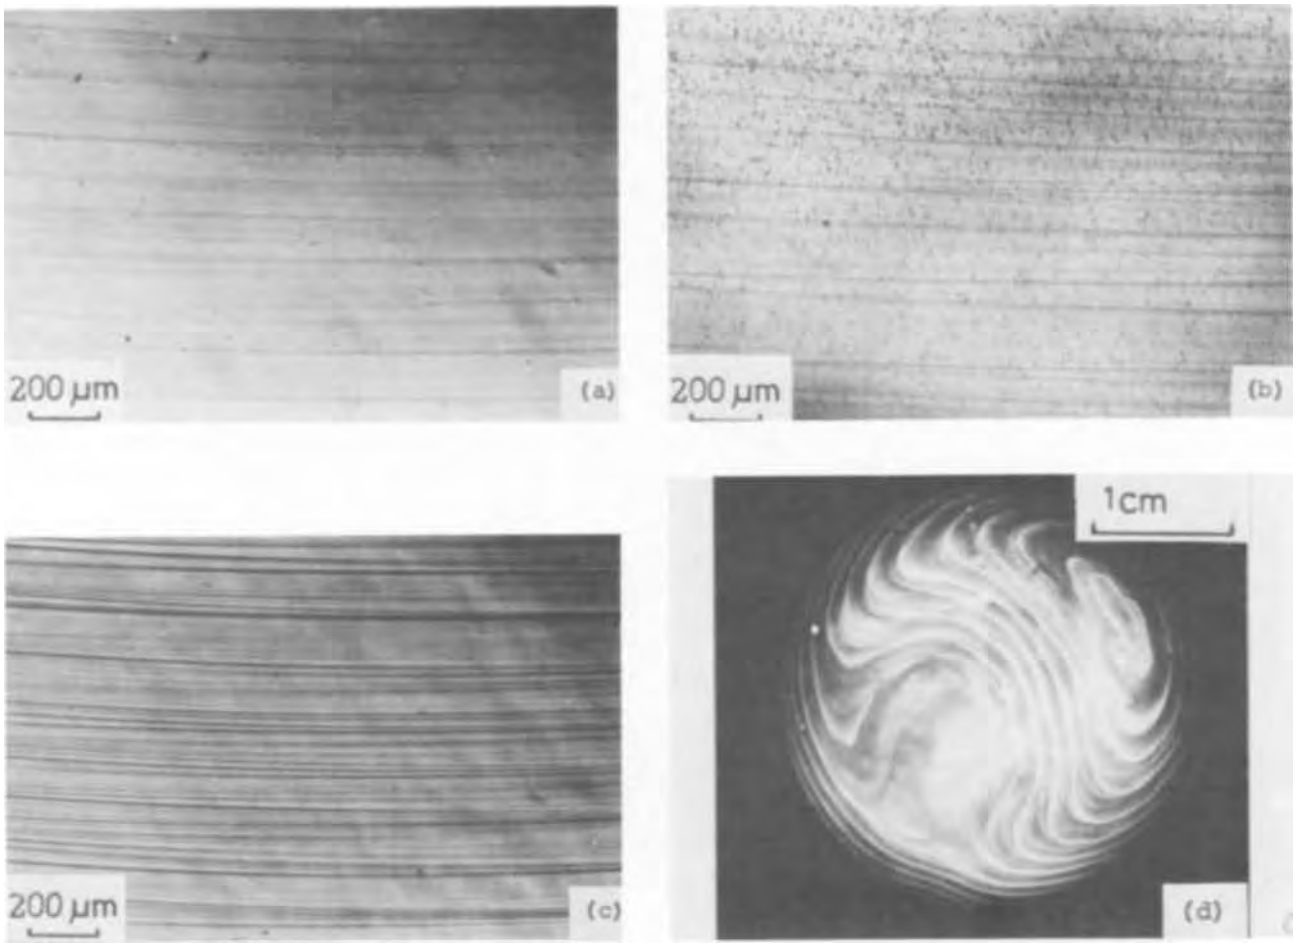

Fig. 3. Striations revealed by the simplified etch. (a) 1000 ohm-cm, n-doped; (b) 500 ohm-cm, p-doped; (c) 5 ohm-cm, n-doped; (a-c) are longitudinal sections; and (d) 30 ohm-cm, n-doped, cross section.

The oxidation itself can schematically be represented by an electron transition process from silicon to the oxidant depending on the electron density in the conduction band of the crystal. Therefore, a local periodic variation of the electron density (which is thought to be essentially caused by a variation of the dopant concentration) results in a periodically varying etch attack thus giving the striated pattern.

As to the necessary illumination of the sample during the etching, it seems that the average electron density of high-resistivity silicon (*i.e.*, $\rho > 1$ ohm-cm) must be increased in order to obtain a satisfactory reaction. This, however, leads to a decrease of the relative variation of the electron density in comparison with the original, not illuminated sample. With samples of lower resistivity the illumination is not always necessary.

On the other hand, some—as yet unknown—recombination centers may be present, the concentration of which varying in a similar way as the dopant concentration does. This would result in a periodic variation of the electron density generated by illumination. It is not clear whether or not this effect plays an important role.

Additionally, in the presence of relatively high concentrations of nondoping impurities (*e.g.*, oxygen or carbon), a completely different reaction mechanism may become predominant. As an example, striations caused by fluctuations of a high carbon concentration can simply be revealed by the common Sirtl etch (7).

Table II.

Steps	After Kämper	Simplified
1	Chemical polishing	Chemical polishing
2	Passivation (HNO_3/acetic acid)	—
3	Activation (KOH)	—
4	Striation etching (HF, acetic anhydride, HNO_3, $NiSO_4$)	Striation etching (HF, $NaNO_2$, wetting agent)
5	Final treatment (KOH)	Final treatment (KOH)

Vapor Phase Epitaxial Growth of GaN on GaAs, GaP, Si, and Sapphire Substrates from $GaBr_3$ and NH_3

Yasuo Morimoto, Kosuke Uchiho, and Shintaro Ushio

Research Laboratory, OKI Electric Industry Company, Ltd., 550-5, Higashi-asakawa, Hachioji, Tokyo 192, Japan

GaN is a III-V compound with wurzite-type crystal structure to which serious attention is now paid because of the potentiality for the application to optoelectronic devices. Various methods for the preparation of GaN crystals have been investigated (1). Recently application of the reaction between $GaBr_3$ and NH_3 has been proposed (2), which involves the reaction below

$$GaBr_3 + NH_3 \rightarrow GaN + 3HBr \quad [1]$$

Beside the above reaction, there should be a reaction described as

$$HBr + NH_3 \rightarrow NH_4Br \quad [2]$$

because NH_4Br was found to be included in GaN films grown on GaAs substrates as mentioned in the section below. This reaction [1] proceeds at fairly low temperature below 600°C, probably due to the weak binding force between Ga and Br (2), and so the growth of GaN is possible at low temperature. Since only Si and SiC were used as substrates in Ref. (2), the growth behavior of GaN was investigated in detail using substrates other than Si such as GaAs, GaP, and sapphire. The substrate surfaces used were (111) for GaAs, GaP, and Si, and (0001) for sapphire. The reactor arrangement and the typical temperature distribution in the reactor are shown in Fig. 1. The source $GaBr_3$ which presents as a complex $GaBr_3 \cdot 4NH_3$ (2) absorbing NH_3 is carried by NH_3 to the reaction zone and GaN is formed. The source ($GaBr_3 \cdot 4NH_3$) temperature and the flow rate of the carrier gas (NH_3) were kept constant at 240°C and at 1 liter/min, respectively. In this note growth behavior of GaN on GaAs, GaP, Si, and sapphire substrates are investigated in detail as a function of the growth temperature. And the quality of GaN films prepared is examined by x-ray diffraction and microphotographic observation. Preliminary measurements are also made on electrical properties of GaN films and on the changes of it due to the annealing.

Key words: GaN, heteroepitaxy.

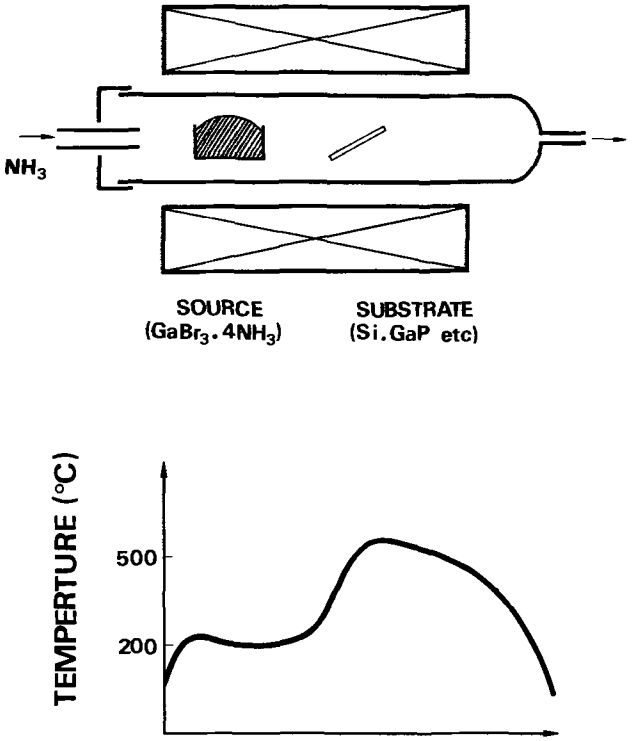

Fig. 1. Reactor arrangement for the vapor phase epitaxial growth of GaN. The typical temperature distribution in the reactor is also represented.

Results and Discussions

Yellow powder of GaN was deposited on the quartz reaction tube between 400° and 600°C. Below 400°C no deposition occurred, and above 600°C, black films were obtained which is due to the formation of Ga metal. From x-ray diffraction it was found that these deposits were GaN crystal with lattice constant of $a = 3.186$Å and $c = 5.178$Å.

The general tendency of the epitaxial growth of GaN on a substrate was described by four characteristic temperatures, T_1, T_2, T_3, and T_4. No deposition occurred below T_1 and black films were obtained above T_4. The films grew but the surface was gray and rough between T_1 and T_4. Yellow and transparent GaN films were formed between T_2 and T_4. The films obtained in the higher temperature side ($T_3 \sim T_4$) completely fell off from the substrates after the growth run or fell off by weak thermal or mechanical stimulus. The GaN films grown in the lower temperature region ($T_2 \sim T_3$) were adherent. This can be attributed to the difference of thermal dilation coefficient between GaN and substrates that the temperature range ($T_2 \sim T_4$) is separated into two parts, $T_2 \sim T_3$ and $T_3 \sim T_4$. Different values of T_1, T_2, T_3, and T_4 were obtained for different substrates. These values and also the scheme of the general tendency of the growth behavior are given in Table I. The temperature range, $T_2 \sim T_3$, is assigned to be the most suitable growth condition. The temperature gradient at the substrates did not act as an important factor in the range, $T_2 \sim T_3$, since GaN films were formed similarly in up- and down-temperature gradient regions.

Films of 3 to 6 μm in thickness were obtained in the growth run of 6 hr.

The quality of GaN films deposited on each substrate between T_2 and T_3 are discussed below.

1. GaAs substrate specification: Te-doped N-type, $n = 1.5 \times 10^{18}$ cm^{-3}; (111) A and B plane. The surface of the films deposited was very rough, on which many cracks were observed even with a naked eye. And the films were of very poor adhesion. This may be due to the large mismatch of lattice constants between GaN and GaAs (about 25%). Typical x-ray diffraction pattern is given in Fig. 2. The most intense line (0002) and weak line ($10\bar{1}1$) of powder pattern of GaN were observed, which indicates the GaN on GaAs substrates to be polycrystalline though the growing plane was oriented to (0001). An interesting fact was that very intense reflections from NH_4Br were observed. NH_4Br may be produced by reaction [2]. The inclusion of NH_4Br to GaN epitaxial layer was not observed by x-ray diffraction for other substrates, however, there can be a possibility of NH_4Br included in semiconductor grade of NH_4Br into GaN layer grown on GaP, Si or semiconductor grade sapphire substrates.

Table I. The growth behavior of GaN and the values of T_1, T_2, T_3, and T_4

Temperature	T_1	T_2	T_3	T_4
Form of the deposit	No deposit	Gray deposit with rough surface	Yellow, transparent and adherent deposit	Yellow and transparent but nonadherent deposit	Black deposit

	Temperature (°C)			
Substrate	T_1	T_2	T_3	T_4
GaAs	400	450	470	600
GaP	400	450	550	600
Si	400	430	540	600
Sapphire	380	420	570	650

2. GaP substrate specification: Undoped N-type, $n = 10^{16}$ cm^{-3}; (111) A and B plane. Although cracks were not observed with a naked eye, the film surface was fairly rough by the microphotographic observation. X-ray diffraction showed the deposit to be single crystalline, however very weak reflection from (1011) was observed, indicating the presence of a small amount of polycrystal and so the nonuniform growth of GaN crystals.

3. Si substrate specification: Sb-doped N-type, $n = 10^{19}$ cm^{-3}, $\rho = 0.01$ ohm-cm; P-doped N-type, $n = 10^{15}$ cm^{-3}, $\rho = 18$ ohm-cm; B-doped N-type, $n = 10^{19}$ cm^{-3}, $\rho = 0.01$ ohm-cm; B-doped N-type, $n = 10^{15}$ cm^{-3}, $\rho = 30$ ohm-cm; (111) plane. The GaN films deposited similarly on Si substrates irrespective of the conduction type (N- or P-type) or the carrier concentration of the substrates. The microphotograph of the film surface is shown in Fig. 3. Though there are many defects, the surface was very smooth compared with that of GaN grown on GaAs or GaP substrates. The conduction type of the substrates was found to have a remarkable effect on the adhesion property of the films to substrates, that is, the films were not adherent on P-type Si, while fairly adherent on N-type Si. On the other hand, the carrier concentration had little effect on the adhesion property of the films. The intense and weak reflection line from (0002) and (0004), respectively, were only observed by x-ray diffraction, which shows a uniform growth of single crystalline GaN over the substrates.

4. Sapphire substrate specification: (0001) plane. Sapphire was found to be the best substrate among all the substrates mentioned above, on which GaN single crystal films with mirror-like surface were readily formed. Any defects could not be observed on the surface even by the microphotographic observation, the formation of which could not be avoided on the surface of GaN films grown on GaP or Si substrates as shown in Fig. 3. A satisfactory adhesion to sapphire was also achieved.

Preliminary measurements on the electrical properties of GaN were also done which were performed mainly on GaN films grown on sapphire substrates because of the good quality of the films. The ohmic

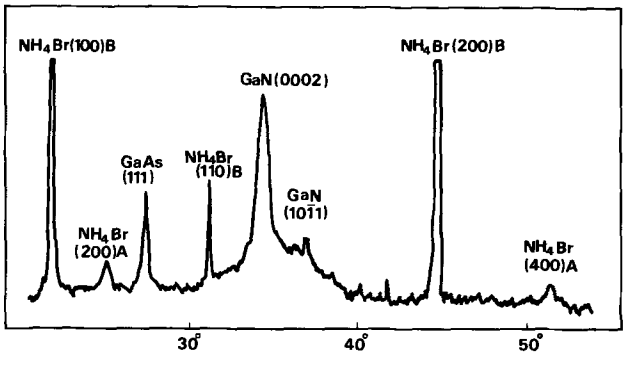

Fig. 2. Typical x-ray diffraction pattern from GaN films deposited on GaAs substrates. The most intense line for powder specimen is (10$\bar{1}$1) which is observed weakly. The line A and B show peaks from NH_4Br of high and low temperature phase, respectively. The reflections from GaAs are thought to arise from substrates, GaAs where GaAs is bare for cracks of GaN films.

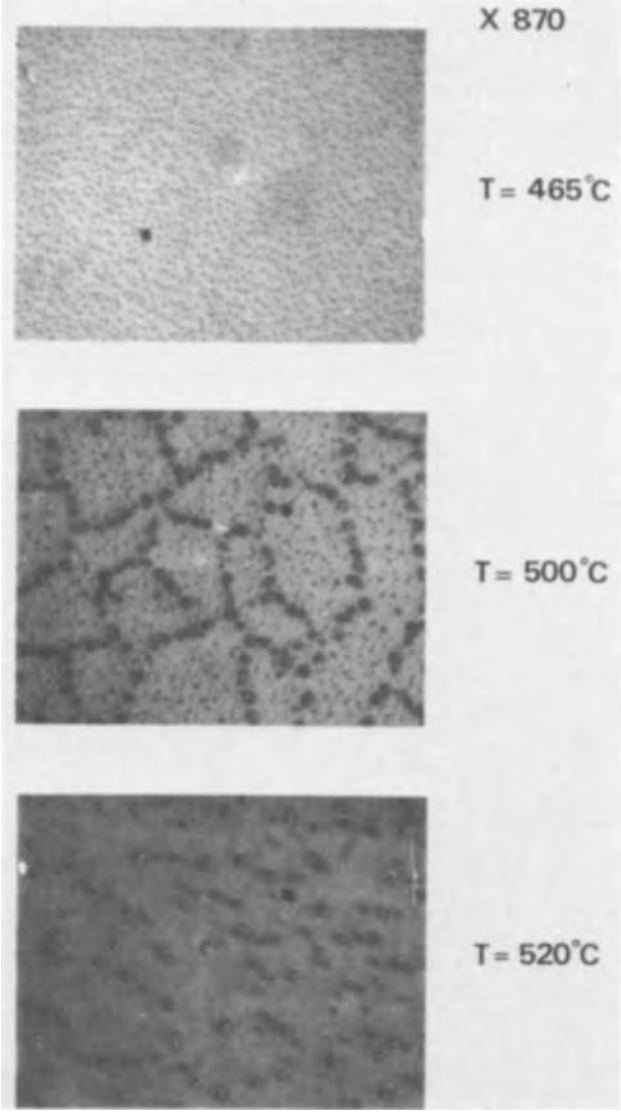

Fig. 3. The microphotograph of the GaN film surface grown on Si substrates. The temperatures shown indicate the growth temperature. The defects observed in this figure could not be recognized with a naked eye. The magnification of the microscope was ×870.

contact was achieved with Al or In by evaporation. The alloying of In to GaN was unsuccessful below 550°C. Above 550°C the films fell off from the substrates and seemed to decompose thermally because the color of the films changed into black. The atmosphere during this heat-treatment was nitrogen. Thus the alloying of In was not at all successful. The current *vs.* voltage characteristics of as-grown GaN crystals was similar to Fig. 6 in Ref. (2). Ohmic characteristics were observed in the small current region. Resistivity measured at room temperature by van der Pauw's method was of the order of 10^4 to 10^6 ohm-cm. The space charge limited current was observed in the large current region. Resistivity decreased two or three orders of magnitude when GaN films were annealed at above 400°C for 6 hr in vacuum or nitrogen atmosphere. This can be attributed to the generation of nitrogen vacancies formed by the thermal decomposition of GaN though clear evidence of it is not obtained. The temperature dependence of the resistivity of annealed GaN is given in Fig. 4. Since Hall effect could not be detected (high carrier concentration ?) the type of conduction was not determined clearly. However both as-grown and annealed GaN (both undoped) were thought to be N-type because ohmic character appeared for In-GaN-Si(N-type)-Au structure, on the other hand rectification behavior appeared for In-GaN-Si(P-type)-Au structure where forward direction appeared when In electrode was biased negative.

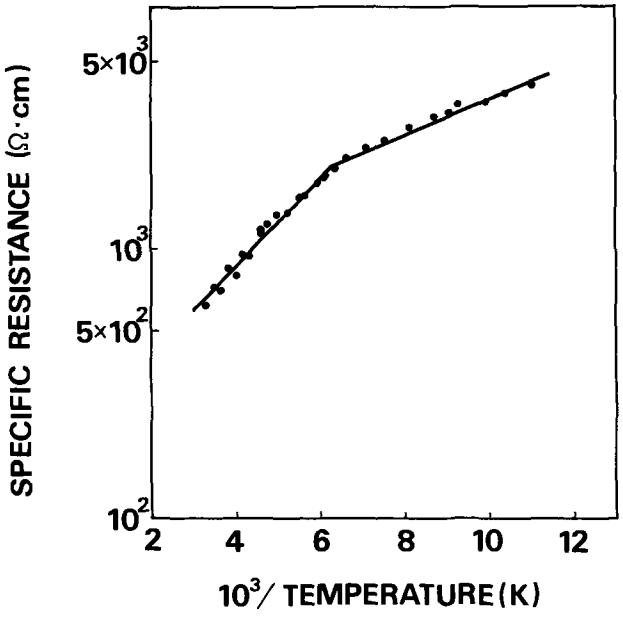

Fig. 4. Temperature dependence of resistivity of GaN annealed at about 500°C in vacuum for 6 hr. This Arrhenius plot gives two activation energies of 31 and 13 meV for high and low temperature region between 77° and 300°K.

Graphical Technique to Determine the Density of Surface States at the Si-SiO_2 Interface of MOS Devices Using the Quasistatic C-V Method

R. Van Overstraeten, G. Declerck, and G. Broux

Fysika en Elektronica van de Halfgeleiders, Departement Elektrotechniek, Katholieke Universiteit Leuven, B-3030 Heverlee, Belgium

The low-frequency C-V technique of Berglund (1) is a well-known technique to study surface states at the silicon-silicon dioxide interface. Problems arising at the low measurement frequencies are avoided by using the quasistatic C-V method of Kuhn (2) and Castagné (3). The current response of the MOS capacitor on a linear voltage ramp is measured with an operational amplifier to plot the C-V curve directly.

The relation between the surface potential ϕ_s and the gate voltage V_g is calculated with the Berglund integration

$$\phi_s(V_g) = \int_{V_{G1}}^{V_G} \left(1 - \frac{C_{LF}}{C_{ox}}\right) dV_g + \Delta_B \qquad [1]$$

In this formula C_{LF} is the experimental low-frequency MOS capacitance; C_{ox} is the oxide capacitance, found in strong accumulation; and Δ_B is the integration constant of Berglund. From expression [1] it can be seen that Δ_B is the surface potential at V_{G1}. As explained by Kuhn (2), Δ_B is obtained by fitting theoretical and experimental $C_{LF} - \phi_s$ curves in accumulation and strong inversion and by taking V_{G1} in accumulation where ϕ_s is well known.

The surface-state capacitance C_{ss} is derived from the experimental low-frequency MOS capacitance by

$$q N_{ss} = C_{ss} = \frac{C_{LF}}{1 - \dfrac{C_{LF}}{C_{ox}}} - C_{si} \qquad [2]$$

N_{ss} is the density of surface states in cm^{-2} eV^{-1} and C_{si} is the semiconductor capacitance which can be calculated as soon as the $\phi_s - V_G$ relation is determined. In practice the $N_{ss} - \phi_s$ curve is calculated using a computer. The inputs of the computer program are the measured value of the impurity doping, the oxide thickness, and the plotted C-V curve. The Berglund

Key words: method, density of surface states.

integration is performed according to Eq. [1] and N_{ss} *vs.* ϕ_s is calculated according to Eq. [2].

Accuracy of the Low-Frequency C-V Method

Before coming to the new graphical technique it is necessary to discuss the accuracy obtainable with the low-frequency method.

Influence of measuring inaccuracies.—As this effect has already been discussed in detail by Kuhn (2) only a numerical example will be given. The experimental data are: $N_D = 1.45 \times 10^{15}$ cm^{-3}; $C_{LF} = 1.17 \times 10^{-8}$F cm^{-2} at the minimum of the C-V curve ($\phi_s = -500$ mV); $d_{ox} = 1345$Å; and $C_{ox} = 2.50 \times 10^{-8}$F cm^{-2}. C_{si} calculated at $\phi_s = -500$ mV is 1.62×10^{-8}F cm^{-2}. Equation [2] gives

$$qN_{ss} = C_{ss} = 22.1 \times 10^{-9} - 16.2 \times 10^{-9}$$

$$= 5.9 \times 10^{-9}\text{F cm}^{-2}$$

or $N_{ss} = 3.7 \times 10^{10}$ cm^{-2} eV^{-1}. This N_{ss} value can still easily be detected whereas a density of 1.0×10^{10} cm^{-2} eV^{-1} would lead to

$$qN_{ss} = C_{ss} = 17.8 \times 10^{-9} - 16.2 \times 10^{-9}$$

$$= 1.6 \times 10^{-9}\text{F cm}^{-2}$$

From this last example it may be seen that $C_{LF} \cdot (1 - C_{LF}/C_{ox})^{-1}$ and C_{si} are of the same order of magnitude and that the difference C_{ss} is one order of magnitude smaller. A small error on these two terms thus gives a larger error on C_{ss}.

In general it may be stated that the measuring errors of C_{ox} and C_{LF} are of the order of a few per cent, as is the error of the theoretical value of C_{si} because of the uncertainties of the impurity concentration and of the integration constant Δ_B (Eq. [1]).

For a surface-state density of 1.0×10^9 cm^{-2} eV^{-1} the two right hand terms of Eq. [2] are two orders of magnitude larger than C_{ss}. Due to the measuring errors, the differences C_{ss} is totally inaccurate.

It may thus be concluded that it is very difficult to determine the density N_{ss} with an accuracy better than 1.0×10^{10} cm^{-2} eV^{-1}. The accuracy is best at the minimum of the low-frequency C-V curve as the two terms in Eq. [2] become smallest at that point. This conclusion will be used to set up the graphical technique.

Influence of the inaccuracies of Δ_B on the $N_{ss} - \phi_s$ curve.—Figure 1 shows the computer results for N_{ss} *vs.* ϕ_s for several Δ_B values. From this figure it may be derived that:

(*i*) Inaccuracies in the integration constant Δ_B strongly affect the N_{ss} curve in accumulation and strong inversion. The surface-state density is almost independent of Δ_B at a surface potential ϕ_s near −500 mV. This potential lies in the range where the low-frequency capacitance reaches the minimum value of the C-V curve.

(*ii*) Figure 1 also presents the N_{ss} values found on the same MOS structure by means of the conductance technique of Nicollian-Goetzberger (4, 5). The agreement between these results and those found at −500 mV by the quasistatic technique is quite good.

Influence of the oxide charge fluctuations on the $N_{ss} - \phi_s$ curve.—Figure 2 (5) shows the apparent surface-state density N^*_{ss} caused by surface potential fluctuations (3). The parameter to describe the surface potential fluctuations is the standard deviation σ_q of the oxide charge distribution. The results of Fig. 2 are obtained by theoretical calculations based on experimental values of the standard deviation σ_s of the surface potential fluctuations. As a complete discussion is given in Ref. (5), one only has to remark here that: (*i*) small deviations of the integration constant Δ_B clearly affect the $N^*_{ss} - \phi_s$ curve in accumulation and strong inversion; (*ii*) at midgap the influence of the oxide charge fluctuations is smaller than 1.0×10^{10} cm^{-2} eV^{-1}; and (*iii*) a peak density can be found at $\phi_s = 2\phi_F$.

Summary.—From the previous discussion it may be concluded that the low-frequency C-V method allows an accurate determination only at a bias corresponding to the minimum of the C-V curve. Even at that point it is difficult to determine N_{ss} within an accuracy better than 1.0×10^{10} cm^{-2} eV^{-1}.

Our graphical technique is based on the measurement of the low-frequency minimum capacitance. It is no limitation that N_{ss} will be determined only at one ϕ_s value, since it has been shown earlier (5) that N_{ss} is nearly constant in depletion and weak inversion.

Graphical Technique

For quality control purposes Fogels and Salama (6) already suggested a similar method to obtain an approximate surface-state density near midgap. However it is possible to base an easier graphical technique for Eq. [2] by rewriting the equation as

$$\frac{qN_{ss}}{C_{ox}} = \frac{\left(\frac{C_{LF}}{C_{ox}}\right)_{min}}{1 - \left(\frac{C_{LF}}{C_{ox}}\right)_{min}} - \left(\frac{C_{si}}{C_{ox}}\right)_{min} \qquad [3]$$

In this formula $(C_{LF}/C_{ox})_{min}$ is the experimental low-frequency minimum capacitance ratio, and $(C_{si}/C_{ox})_{min}$

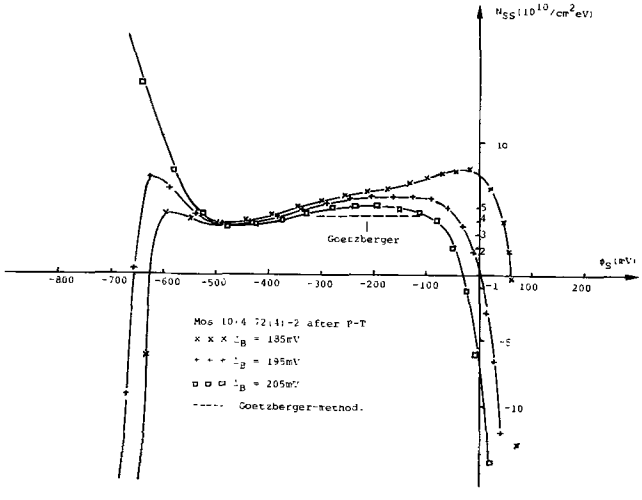

Fig. 1. Experimental results of the Berglund-Kuhn technique. The doping concentration $N_D = 1.45 \times 10^{15}$ cm^{-3} and the oxide thickness is 1345Å. The influence of different Δ_B values is shown. A comparison is made with the Goetzberger method.

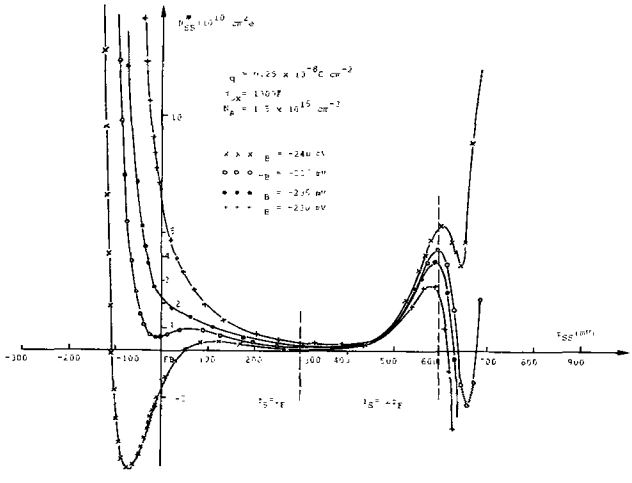

Fig. 2. Apparent surface-states density N^*_{ss} caused by surface potential fluctuations. The standard deviation σ_Q of the oxide charge fluctuation is 2.5×10^{-9} coulomb cm^{-2}.

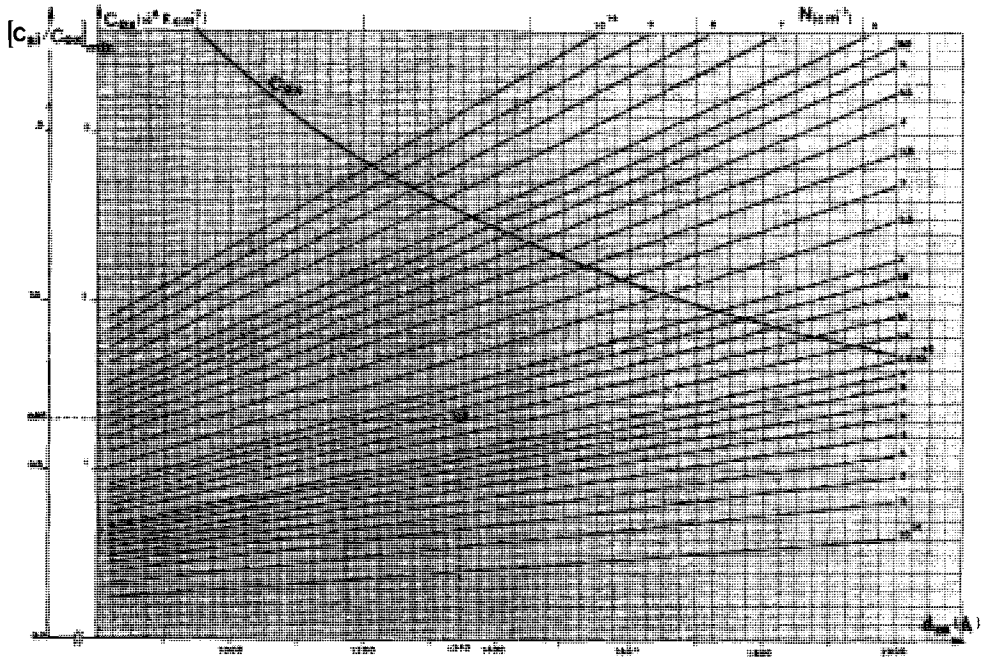

Fig. 3. $(C_{si}/C_{ox})_{min}$ is found as a function of measured N and d_{ox} values. The oxide capacitance C_{ox} is also presented.

is the theoretical low-frequency semiconductor capacitance, divided by the oxide capacitance. $(C_{si}/C_{ox})_{min}$ is calculated from the oxide capacitance and the doping concentration. A good value for the concentration can be found by measuring the minimum of the high-frequency C-V curve.

The graphical technique is presented in Fig. 3 and 4. Figure 3 shows $(C_{si}/C_{ox})_{min}$ as a function of the measured N and d_{ox} values. The oxide capacitance C_{ox} is also shown. Figure 4 shows qN_{ss}/C_{ox} as a function of $(C_{si}/C_{ox})_{min}$ for several values of $(C_{LF}/C_{ox})_{min}$ (Eq. [3]).

The technique is illustrated with the same example as given in Fig. 1. The experimental data are: $N_D = 1.45 \times 10^{15}$ cm^{-3}; $(C_{LF}/C_{ox})_{min} = 0.47$; $d_{ox} = 1345$Å;

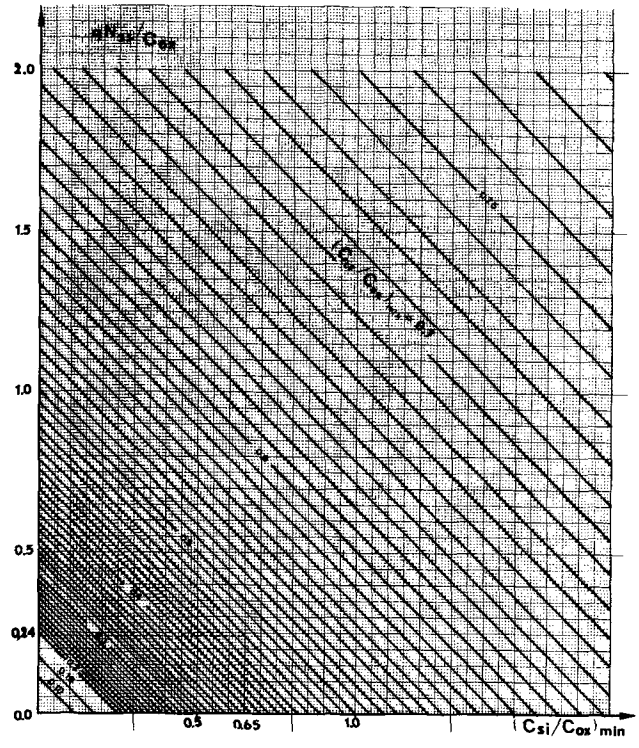

Fig. 4. Determination of qN_{ss}/C_{ox} as a function of experimental $(C_{LF}/C_{ox})_{min}$ and of the $(C_{si}/C_{ox})_{min}$ found in Fig. 3.

and $C_{ox} = 2.50 \times 10^{-8}$F cm^{-2} ($C_{ox} = \epsilon_{ox}/d_{ox}$ with $\epsilon_{ox} = 3.38 \times 10^{-13}$ F/cm).

From Fig. 3 the theoretical $(C_{si}/C_{ox})_{min}$ can be determined using the measured values of N_D and d_{ox}, giving for our numerical example $(C_{si}/C_{ox})_{min} = 0.65$.

Then Fig. 4 directly leads to $qN_{ss}/C_{ox} = 0.24$ as $(C_{si}/C_{ox})_{min}$ and $(C_{LF}/C_{ox})_{min}$ are known. Finally the density N_{ss} of surface states is found as 3.8×10^{10} cm^{-2} eV^{-1}, in very good agreement with the results of Fig. 1 at $\phi_s = -500$ mV.

Conclusion

A fast graphical technique is presented to evaluate the quality of MOS samples and to obtain an accurate value for the surface-state density at the minimum of the low-frequency C-V curves. Figures 3 and 4 can be extended to thicker oxide layers or to other substrate dopings when necessary. As for the normal low-frequency C-V method, the accuracy of this graphical technique is limited by measurement errors in the C-V characteristic and by errors on the substrate doping and on the oxide thickness. An accuracy of 1.0×10^{10} cm^{-2} eV^{-1} can be achieved.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 119, No. 7, 8, and 11; July, August, and November 1972; Vol. 120, No. 4 and 6; April and June 1973.

On the Mechanism of Low-Temperature Oxidation (23°-450°C) of Polycrystalline Nickel

M. J. Graham and M. Cohen (pp. 879-882, Vol. 119, No. 7)

P. J. Zimmer:[1] Regarding the saturation of the wall of the system with oxygen to minimize the subsequent absorption of oxygen during the oxidation of the metal in the paper under discussion, it would seem that this has no effect on the final result, because, in step (*iii*) of the above-mentioned paper, the subsequent reduction of the sample with hydrogen would remove the oxygen absorbed, if not by reaction to form H_2O, then by replacement, leaving the walls in the same state as if the oxygen were not used.

M. J. Graham and M. Cohen: The walls of the metal UHV system remain saturated with oxygen following the hydrogen reduction procedure [step (*iii*) in the paper under discussion], because only the specimen and the quartz tube are at the reduction temperature of 600°C. The rest of the system is at room temperature and oxygen is not removed from these cold walls which constitute the major internal surface area. Thus, the blank adsorption correction in a subsequent oxidation experiment is minimized when the walls are presaturated.

A Limitation of the Pulsed Capacitance Technique of Measuring Impurity Profiles

A. R. LeBlanc, D. D. Kleppinger, and J. P. Walsh (pp. 1068-1071, Vol. 119, No. 8)

J. Olenski:[2] Messrs. LeBlanc, Kleppinger, and Walsh have given in the paper under discussion the expression for an apparent impurity concentration obtained from real capacitance-voltage characteristics of an MOS structure

$$N(W) = \frac{-C^3}{q\epsilon_s\left(\frac{C_o}{C_o+C_s}\right)^2\frac{\beta\epsilon_s}{L_D F^2}\frac{\left\{F\left(e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}e^{\beta\psi_s}\right)-\frac{1}{2F}\left[1-e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}(e^{\beta\psi_s}-1)\right]^2\right\}}{1+\frac{\epsilon_s}{L_D C_o F}\left[1-e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}(e^{\beta\psi_s}-1)\right]}} \quad [1]$$

This can be transformed into

$$N(W) = p_{po}\frac{\left[1-e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}(e^{\beta\psi_s}-1)\right]^3}{\left[1-e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}(e^{\beta\psi_s}-1)\right]^2-2F^2\left(e^{-\beta\psi_s}+\frac{n_{po}}{p_{po}}e^{\beta\psi_s}\right)} \quad [2]$$

or in another form

$$N(W) = p_{po}\frac{\left(\frac{dB}{du_s}\right)^3}{\left(\frac{dB}{du_s}\right)^2-2B\frac{d^2B}{du_s^2}} \quad [3]$$

where $B = F^2$ and $u_s = \beta\psi_s$.

We can assume for small surface potentials $\beta\psi_s$ that a charge of minority carriers in a surface charge layer is negligible as compared to a charge of majority carriers and ionized impurity atoms. It means in our considerations that

$$e^{-\beta\psi_s} >> \frac{n_{po}}{p_{po}}e^{\beta\psi_s} \quad [4]$$

Then we can omit all components multiplied by $\frac{n_{po}}{p_{po}}$ and Eq. [2] simplifies to

$$N(W) \cong p_{po}\frac{(1-e^{-\beta\psi_s})^3}{[1-e^{-\beta\psi_s}]^2-2e^{-\beta\psi_s}(e^{-\beta\psi_s}+\beta\psi_s-1)} = p_{po}\frac{(1-e^{-\beta\psi_s})^3}{1-e^{-\beta\psi_s}(e^{-\beta\psi_s}+2\beta\psi_s)} \quad [5]$$

As can be seen from Eq. [5] the apparent impurity concentration normalized to the real acceptor concentration N_A given by

$$\frac{N(W)}{N_A} \cong \frac{(1-e^{-\beta\psi_s})^3}{1-e^{-\beta\psi_s}(e^{-\beta\psi_s}+2\beta\psi_s)} \quad [6]$$

depends on temperature and not on acceptor concentration. The dependence on concentration is important only when condition [4] is not valid. But for typical silicon substrates and epitaxial layers the maximum depth calculated from surface potential defined by that condition is beyond the region where the apparent concentration increase is observable. Assuming that $e^{-\beta\psi_s} = 100\frac{n_{po}}{p_{po}}e^{\beta\psi_s}$, $\beta = 38.7V^{-1}$, and $N_A = 2.10^{15}$ cm^{-3}, we obtain the surface potential value $\psi_{se} = 0.245V$ while $\frac{N(\psi_{se})-N_A}{N_A} = 0.1\%$ as calculated from Eq. [6]. This difference becomes smaller when N_A is increased. Thus the curves $N(W) = f(\psi_s)$ presented in the paper under discussion for different impurity concentrations can be transformed into one plot $\frac{N(W)}{N_A}$ which does not depend on N_A. That plot is shown in Fig. 1. On the other hand we can, *a priori*, neglect the charge of minority carriers when the

[1] Chemistry Department, Villanova University, Villanova, Pennsylvania 19085.
[2] Institute of Electron Technology, Warsaw, Poland.

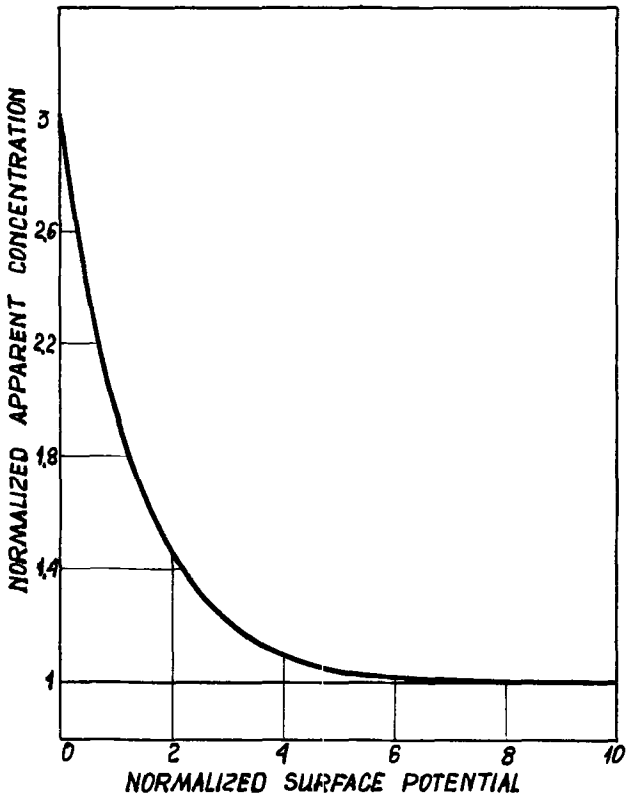

Fig. 1. Apparent impurity concentration normalized to real concentration N_A vs. normalized surface potential $u_s = \beta\psi_s$ calculated from Eq. [6].

structure is pulse biased from accumulation in the inversion direction. The minority carrier concentration for deep depletion is established by a d-c bias and does not vary when the pulse is short enough. Then we can always use Eq. [6] instead of Eq. [2].

Oxidation State of Anodic Tantalum Oxide after Heat-Treatment. I. Galvanostatic Method as Applied after Heating in Vacuum

Gerhart P. Klein (pp. 1551-1560, Vol. 119, No. 11)

E. Günzel:[3] Recently we carried out similar experiments to those of Klein in the paper under discussion with vacuum annealed anodic Ta_2O_5-films. Our specimens were powder pellets sintered at 2000°C and 10^{-5} Torr. The charge of the pellets was $CV_A = 1100$ μF·V (V_A = anodizing voltage), and they were anodized with a current density of 20 mA/pellet at 60°C in various electrolyte solutions. Heat-treatment conditions were 450°C, 10^{-5} Torr for 10 min. Reanodization was performed with 0.5 mA/pellet in the anodizing solution. Figure 1 shows the loss of oxygen as number of electrons/cm^3 *vs.* reanodization voltage. With this configuration the curves in the paper under discussion can be compared directly with our curves.

Pure stoichiometric Ta_2O_5-films are obtained by anodization in aqueous solutions of chromic acid. This was found by radiotracer experiments.[4] After heat-treatment the distribution of the defect concentration in these films exhibits nearly a uniform gradient independent of the electrolyte concentration (0.05 and 2M, curve A). One must conclude that deviations from the shape of curve A are caused by the incorporation of foreign ions. In oxide films containing phosphorous there is a maximum of deficiency concentration at $V/V_A = 0.4 \ldots 0.5$ (curves B-D) which was also found by the author in the paper under discussion for

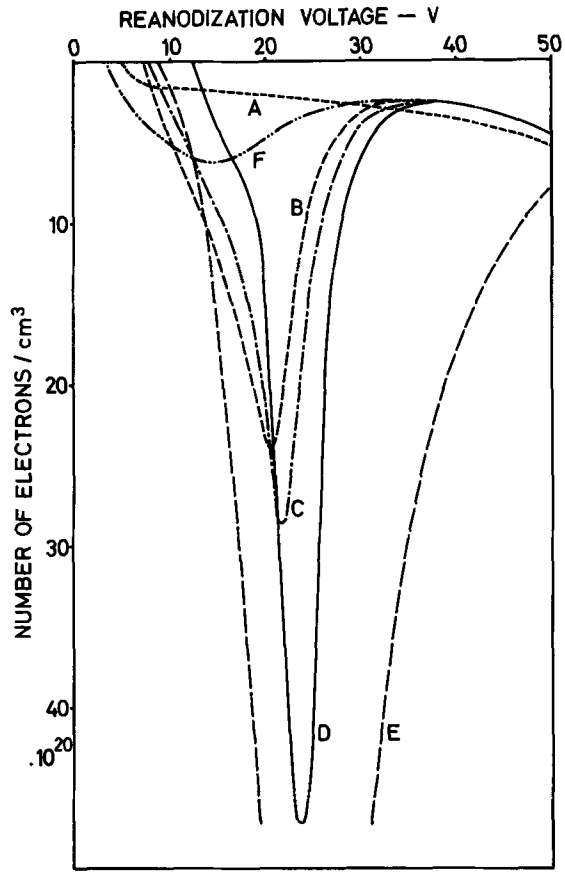

Fig. 1. Oxygen loss vs. reanodization voltage. Anodization voltage, 50V. Curve A, 0.05 and 2M chromic acid electrolyte; curve B, 0.002M phosphoric acid electrolyte; curve C, 0.1M phosphoric acid electrolyte; curve D, 5.0M phosphoric acid electrolyte; curve E, 5.0M sulfuric acid electrolyte; curve F, 0.2M citric acid electrolyte.

short times of heating. This maximum becomes sharper with increasing electrolyte concentration.

During anodization in sulfuric acid solutions there will be an incorporation of sulfur which markedly depends on the acid concentration (compare works of Footnotes 5 and 6). In contrast to dilute solutions (0.1M) we found a considerable effect with concentrated solutions (curve E: 5M). This curve suggests that sulfur is incorporated not only in the outward part of the oxide layer (like phosphorous) but in the entire oxide.

Curve F was obtained for an oxide film which was formed in 0.2M citric acid, *i.e.*, that even components of organic electrolytes can be incorporated into oxide films on tantalum and that this foreign matter can influence the oxygen distribution after heat-treatment.

It is demonstrated by such experiments that the maximum amount of oxygen loss after vacuum heat-treatment, and the oxygen diffusion, are increased by the presence of certain foreign ions. This result is in apparent contradiction to former investigations[7,8] in which anodic Ta oxide layers were heat-treated in air. It was found that in this case the oxygen diffusion is hindered by incorporated phosphorous. It can be assumed, however, that during heat-treatment in air at least the oxygen atoms in the outer part of the layer diffuse via interstitial sites whereas during heat-treatment *in vacuo* diffusion via vacancies takes place. Both kinds of diffusion can be affected by incorporated foreign ions in different ways.

Electrically Active Stacking Faults in Silicon

K. V. Ravi, C. J. Varker, and C. E. Volk
(pp. 533-541, Vol. 120, No. 4)

H. F. Mataré:[9] The electronic effects of process-induced defects (stacking faults) in silicon are of major importance to the device manufacturer. The authors of the paper under discussion are to be commended for their careful study of fundamental features of these defects, using modern tools.

They clearly demonstrate the two distinct regions around a defect zone, the reverse and forward biased regions, and the resulting contrast due to enhanced carrier generation within the depleted area. Similar SEB pictures on grown-in defects under lateral fields have been published before.[10]

Precipitates like SiO_2 and B, which are supposed to be present near the stacking faults, cannot however account for the differences in their electrical behavior as the independence of junction reverse current from the number of faults shows, and as the noncorrelation of fault length and reverse leakage and the correlation of fault length and "threshold-voltage" show. These properties of the stacking faults can be understood when one applies the known electronic model of defect line charges. The authors' opinion in the paper under discussion that impurity decoration will alter and perturb the behavior of dislocations or faults is correct but insulator inclusions (like SiO_2) in particular, will not eliminate the strong electronic effects of the non-closed lattice (dangling bonds). With the assumption that one sees here the SEM replica (EBIC mode) of the npn- or pnp-dislocation junctions, one can explain that:

(*i*) Space charge reversal occurs at transition from the self-biasing mode ($VR = OV$) to a biased mode.[10]

(*ii*) Current enhancement occurs due to a hook effect at the npnp-structures.

(*iii*) Longer faults have a higher transfer resistance and are less lossy for the main junction, as their bond overlap is incomplete.

(*iv*) Dislocation orientation is crucial with respect to the effect on the external junction field. Strongest effects on leakage current should be expected when the electric field vector is parallel to the Burgers vector of the partial dislocation, as in this case the dislocation shunts the external field.

The above conclusions are in line with the degenerate, high conductivity of dislocation cores and numerous scanning electron-beam studies on dislocations in silicon and germanium-mono- and bicrystals, subjected to lateral surface fields.[11]

K. V. Ravi, C. J. Varker, and C. E. Volk: We would like to thank Dr. Mataré for his comments on our paper.

A good agreement between theory and experiment is the fond hope of all investigators. However, most experiments have to contend with numerous uncontrolled or uncontrollable parameters which generally preclude an exact or, often, even an approximate verification of an idealized theory. We believe the case of crystallographic defects in semiconductors and their electrical ramifications is a good example of the situation wherein the theoretically expected behavior of the defects have not been verified by experiment. It is flattering that Dr. Mataré believes that our work has perhaps bridged this gap between theory and experiment. However, we believe that this is not the case.

A detailed atomistic model of structural defects cannot be derived from the electron-beam induced current (EBIC) display alone. A thorough analysis using transmission electron microscopy and detailed electrical measurements are also required.

The correct interpretation of contrast effects using the EBIC mode is of utmost importance and considerable effort has been expended by us to prevent misinterpretation of these effects. A detailed analysis of the I-V characteristics of a given diode always preceeds the EBIC analysis. This permits a direct correlation between the EBIC technique and the resulting I-V characteristics of the diode.

The zone of contrast surrounding the decorated stacking fault results directly from minority carrier recombination in a low lifetime region surrounding the stacking fault. When this zone extends into the space charge region, as in the case of electrically active stacking faults, the generation zone is easily observed with the EBIC technique.

The concentration of minority carriers in the space charge region of p-n junctions can be altered between a depletion of minority carriers when the reverse voltage is greater than kT/q to an excess of minority carriers when the forward voltage is greater than kT/q. Consequently, when the applied voltage V is in the range $-100 \text{ meV} < V < +100 \text{ meV}$ the magnitude of the recombination contrast can be enhanced or suppressed by altering the voltage across the p-n junction. However, the resulting display includes the effects of the video amplifier and the coupling circuit between the device and the amplifier chain. In our technique, a-c coupling is used to prevent the reverse current instabilities associated with high leakage junctions under voltage bias from degrading the quality of the display during the scan. When these factors are considered, the observed contrast effects can be understood in more conventional terms.

With regard to the mechanism(s) of recombination and generation of charge carriers at the stacking fault it seems to us that an analysis based upon the so-called "defect line charge" model of dislocations ignores the obvious perturbations resulting from impurity precipitation at the defects. Indeed if Fig. 5 and 8 of the paper under discussion are compared there is a direct correlation between the fault length and reverse leakage. The fault length in turn is related to the degree of decoration of the fault. As has been shown, boron is very likely to be a major constituent of the precipitates at the faults and it has also been determined subsequently that fast diffusing metallic impurities are also involved in the precipitates.[12] Consequently, the theoretically expected electronic effects of dangling bonds will be overshadowed by the effects of precipitates, their strain fields, and by a local increased concentration of impurities in solid solution around the faults. To make the assumption that "one sees the SEM replica of the npn- or pnp-dislocation junctions" is not valid and is not supported by any evidence. Regarding the four points raised by Dr. Mataré the following rebuttals are deemed to be in order:

(*i*) EBIC signals do not exhibit a polarity reversal under biased conditions as suggested in the above discussion. The pseudo-contrast reversal at low voltages results directly from the differentiating effect of capacitive coupling.

(*ii*) Current enhancement coincides with a voltage-power law relationship in the I-V characteristics of the diode.[12] There is no experimental evidence for a hook transistor effect, but considerable experimental evidence exists that an impurity atmosphere and/or strain field surrounds the fault which can introduce a generation-recombination zone around the fault.

(*iii*) The relationship between fault length and threshold voltage can be explained in terms of the position of the stacking fault and the associated pre-

cipitates with respect to the depletion region of the p-n junction.

(iv) Dislocation orientation is perhaps important if one considers a "clean" undecorated dislocation. Since the fault and the bounding dislocation are profusely decorated the more important factor is the strain/impurity atmosphere surrounding the fault. It has been found that both the strain field as well as the g-r zone surrounding the defect are roughly symmetrical with respect to the defect.

The Kinetics of Thin Oxide Film Formation on Iron Using Proton-Impact-Excited X-Ray Analysis

P. B. Needham, Jr., H. W. Leavenworth, Jr., and T. J. Driscoll
(pp. 778-783 Vol. 120, No. 6)

B. Chattopadhyay:[13] The authors in the paper under discussion have discussed the oxidation kinetics in terms of Uhlig's theory for logarithmic oxidation[14] which has been criticized[15-17] for neglecting the effect of surface-state charge. We[16,17] have modified Uhlig's model for p-type oxide formation by using Bardeen's concept on the rectifier theory of the metal/semiconductor junction.[18] This modified theory has been justified by estimating successfully certain critical parameters from the oxidation data of metals,[17] such as copper,[14] nickel,[19] and cobalt.[20] We would like to apply the theory to the present case of iron.

Our theory[16,17] applies to the oxide containing a uniform density space charge layer, *i.e.*, the so-called first stage of oxidation.[14] The energy drop due to surface-state charge, eV_s is estimated to be 2.34 eV, using the work function of iron as 4.7 eV[21] and the activation energy of oxidation as 3.58 kcal (0.155 eV)/mole. The surface-state charge density, n_s, is next estimated to be $6 \times 10^{14}/cm^2$ using the dielectric constant of ferrous oxide[22] as 14. This value of n_s, which is higher than $10^{13}/cm^2$, indicates the ineffectiveness of the metal property on the double layer[18] (of surface-state charge and space charge). The space charge density, on the other hand, is calculated as $7.5 \times 10^{19}/cm^3$ which is a reasonable figure for the density of trapping centers in the oxide.[16,17] Results at the highest temperature, namely 350°C, are used for present calculations. The energy increase due to space charge, eV_p, is finally estimated as 0.146 eV (using the maximum thickness in the first stage of oxidation, *viz.* 50Å). The results obviously show that $eV_s >> eV_p$, and thus indicate the importance and predominant contribution of surface-state charge over the space charge to the potential across the oxide. Therefore, it would be perhaps more justifiable to adopt the modified[16,17] rather than the original theory[14] to explain the direct logarithmic oxidation kinetics.

P. B. Needham, Jr., H. W. Leavenworth, Jr., and T. J. Driscoll: In the paper under discussion our experimental oxidation results were discussed in terms of Uhlig's theory of logarithmic oxidation for two reasons: (i) Uhlig's theory[14] predicts kinetics involving a transition to a higher logarithmic rate constant at some oxide thickness and (ii) the oxide thicknesses where we found such a transition to occur agreed well with values predicted using our experimental parameters (rate constants, time constants, and activation energy) with equations based on Uhlig's theory.[23] In the paper being discussed we stated that this agreement may have been fortuitous since there were unanswered questions concerning the effects of initial surface impurities (particularly sulfur), the stoichiometry of the oxide films, and the crystallographic orientation of the large substrate grains. Considering Fromhold's criticism[15,24] of Uhlig's theory because of Uhlig's use of boundary conditions which result in nonconservation of electrical charge during oxide film growth, it is welcome to find a proposed[17] alternate mechanism which might provide results similar to Uhlig's (which offer the best apparent interpretation of much experimental data, including the dependence of oxidation rate on the substrate crystal orientation, lattice transformation, and Curie temperature) without violating the conservation of electrical charge. We feel that the introduction of surface states at the metal-oxide interface seems reasonable and that such states could be important in describing oxidation data where electronic transfer is the rate-limiting step. However, there are, we feel, two problem areas in Chattopadhyay's development of the surface-state charge model[17] and the equations with which he has calculated (or estimated) the values of eV_s and eV_p using our experimental results.

(i) Chattopadhyay has stated[17] that the "negative space charge will induce a surface-state charge of opposite sign on the localized electronic states associated with the surface lying in the forbidden energy region between the conduction and valence bands of the semiconducting oxide." This seems to indicate that the positive surface charge which Chattopadhyay introduces must be equal in magnitude to the space charge in the semiconductor (Fe_3O_4) during oxide growth. Since the trapped charge in the space charge region initially increases with increasing oxide thickness, the concentration of charged surface states, n_s, and the resulting potential, V_s, must also increase (at least initially) with increasing oxide thickness, y. Chattopadhyay, however, has made the surface state potential V_s independent of the oxide film thickness y. The closest case to a thickness-dependent surface charge in the literature is Fromhold's[24] consideration of positive charge at the metal-oxide interface (located on the metal, and not on the oxide as in Chattopadhyay's case) which compensates negative charge trapped in the space charge region. He guarantees over-all charge neutrality by including it as a boundary condition to Poisson's equation, and obtains logarithmic oxidation kinetics for the case where the oxide thickness is much larger than the maximum electron tunneling distance in the oxide. Fromhold finds a much smaller effect on the transfer of electrons into oxide from charge in the interfacial and space charge regions due to, among other reasons, the necessity of reducing the positive charge at the metal-oxide interface (compared to Uhlig's) to guarantee over-all charge neutrality. In Chattopadhyay's model, however, it is not clear exactly what kind of charge balance is implied by the boundary conditions.

(ii) To obtain logarithmic rate law oxidation kinetics of the form $y = K_0 \ln (1 + t/\beta)$,[17] Chattopadhyay has used, in addition to the before-mentioned surface-state potential, V_s, a space charge potential V_p derived using Poisson's equation in which, we feel, an incorrect approximation was used in the final equation describing the potential V_p at the metal-oxide interface due to the space charge layer

$$V_p = 4\pi n_v e [\gamma y + (1/2)y^2]/\epsilon$$

Here $n_v e$ is the space charge density, γ is an interfacial layer in the semiconductor equivalent to the average length of the individual surface dipole (about 3Å), y is the oxide thickness beyond γ, and ϵ is the dielectric

constant of the oxide. He has dropped the term containing y^2 as an approximation for thin films. This would seem to us to neglect the scale of the constant γ, the thickness of the dipole layer region (*i.e.*, the surface-state charge region). At oxide thicknesses greater than $y = 6$Å, this deleted term will be larger than the γy term, and with the term y^2 in the exponential of the growth rate equation, $dy/dt = A \exp(-py^2 - \alpha y)$, where A, p, and α contain various constants, a direct-logarithmic rate law will not be obtained.

Errata

In the paper "The General Problem of Rediffusion in Semiconductor Devices" by Malcolm Fullenwider which appeared on pp. 1134-1135 in the August 1973 JOURNAL, Vol. 120, No. 8, the argument of the third term on the right-hand side of Eq. [3] should be:

$$\frac{(2n+1)L+x}{2(Dt)^{1/2}}$$

so that Eq. [3] reads:

$$C(x,t) = C_o - C_o \sum_{n=0}^{\infty} (-1)^n \operatorname{erfc} \frac{(2n+1)L+x}{2(Dt)^{1/2}} - C_o \sum_{n=0}^{\infty} (-1)^n \operatorname{erfc} \frac{(2n+1)L+x}{2(Dt)^{1/2}} \quad [3]$$

The purpose of this communication is to present a corrected version of Fig. 3 which appeared in the paper "The Electrolytic Behavior of CaF_2 Crystals under Reducing Conditions," by J. W. Hinze and J. W. Patterson which appeared on pp. 96-99 in the January 1973 JOURNAL, Vol. 120, No. 1. The corrected version, shown below, differs from the original only in that emf *vs.* temperature line "predicted from Wagner's analysis" (1) is shifted upwards, significantly closer to the observed data for the cell $Ca|CaF_2|Th, ThF_4$ and to the emf *vs.* temperature line "predicted from thermodynamic data." The error was detected as the result of a private communication on the matter from C. Wagner (March 9, 1973).

The main conclusion that "... the usefulness of CaF_2 as a solid electrolyte extends down to its stability limit ..." remains unaffected; however, the original version of Fig. 3 constitutes a misrepresentation of Wagner's analysis because the line so predicted should not have been that far removed from the overlying thermodynamic emf line.

The source of this excessive discrepancy was traced to the inconsistent use of ΔG^o_f data for CaF_2 by Hinze and Patterson in their paper. Whereas the thermodynamic emf line was calculated on the basis of JANAF data (2) for CaF_2 formation, the other line was calculated from equivalent emf data given by Hamer *et al.* (3). The corrected figure shown in this erratum uses the JANAF values for both lines and thus brings them closer together.

OCTOBER 1973

Energy Options[1]

Arthur M. Bueche

General Electric Research and Development Center, Schenectady, New York 12301

Under the heading of "energy options," as you might guess, it is my intention this morning to discuss some of the technical options available as we seek solutions to the "energy crisis."

The "energy crisis," of course, is a phrase that came into public prominence only during the past year. It presently runs a mere second among current items of interest to the daily press, the weekly news magazines, and other news media, but, in time, we can expect it to be back in "the number one spot." And this is appropriate because the "energy crisis" is a very real one, deserving the full attention of all of us.

Among the technical options, I will spend a little extra time this morning on one of particular interest to electrochemists, the so-called "hydrogen economy," although it is apparent as one reviews the list of other energy options that electrochemical technology of one kind or another is involved in nearly all of them.

However, we should also remember that when one speaks of "energy options," there are those who look well beyond just technology. Indeed, some people even try to claim that the energy crisis is not really a technical problem at all. Depending on how you look at it, it is a geopolitical problem, involving massive shifts in the world's balance of power based on ownership of oil reserves. Or it is a strictly domestic political problem, dependent on decisions with regard to natural gas prices, depletion allowances, and off-shore drilling regulations. Or it is strictly an economic problem, meaning that consumers are finally going to have to start paying a fair price for the incredible energy bargains they have been getting in the past. Or it is an environmental problem, which is really just a communications problem, educating people to understand the trade-offs required in matching their needs and desires for energy with their ecological hopes and dreams. Or it is a sociological and psychological problem, where the actual habits and wishes of people must be changed in the direction of using less energy; meaning, as a result, that their lives will be less easy, less pleasant, and less productive.

On the other hand, in spite of all of these alternatives, the energy crisis may just have to be a technological problem.

I say this because it has been proved over and over again in the past that it is easier to invent something new than it is to change people's habits; that it is easier to get a new technical idea than it is to alter the attitudes of different countries and cultures toward each other; that it is easier to do research than it is to improve the ability of people (even in the same family) to communicate with each other; that getting patents and putting them to use is easier to accomplish than upsetting the built-in political and economic status quo. For all these reasons, in the long run, the most likely, only source of workable answers to the energy crisis can realistically be expected to come from new technology.

[1] The Electrochemical Society Lecture delivered at the Chicago, Illinois, Meeting of the Society, May 14, 1973.

Let me qualify what I mean when I say "in the long run." Certainly, we are now exploiting many of the benefits of recent and current research and development to alleviate the energy crisis: nuclear plants of improved effectiveness are going on line; combined-cycle steam and gas generating stations are on the market and will very soon be in operation; more sophisticated and integrated systems-control methods are being introduced to improve the reliability of electric power. And there are other examples. These things are helping alleviate the present problems, although admittedly not rapidly enough or on a large enough scale, to provide the major solutions we must eventually have. That is what I mean about "in the long run," because it is an inescapable fact that many of the technological advances that can, hopefully, make additional major contributions to the solution of the energy crisis are several years, and in some cases, several decades, in the future.

To put this whole matter in perspective, let us take a quick look at where our present energy comes from, where it is used, and where some experts believe changes in these patterns will occur during the next 15 or so years.

Figure 1 shows the sources of our energy at the beginning of this decade. Oil, at 42%, is, of course, the area of greatest present concern, especially with its potential effect on the U.S. balance of payments and the resultant possible impact on the balance of power between nations. Natural gas supplies are being rapidly depleted. The greatest challenges to the technologists are in the areas of coal, where our reserves are extremely bountiful, and in nuclear energy, where the potential for electric power is so great. Water (hydro) is not considered a major new source of energy; we have pretty much already put to use our best opportunities for hydro-plants in the United States.

Who uses all this energy? Figure 2 shows the percentages. Surprisingly, the electric utility industry is not the overwhelming user of energy that many people have been led to believe. Rationing of electric energy

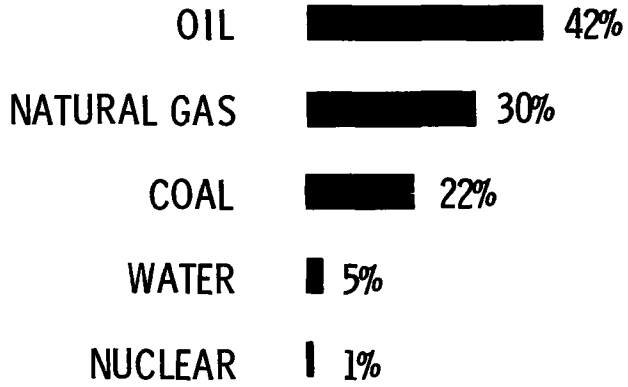

Fig. 1. Sources, energy use, 1970

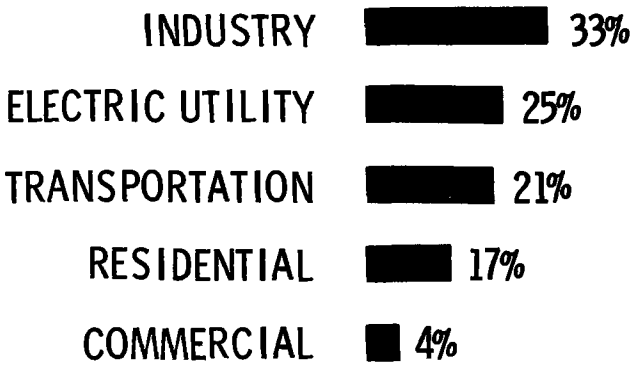

Fig. 2. Markets, energy use, 1970

seems self-defeating in view of its relative advantages, cleanliness, and efficiencies.

Indeed, all the most respected analysts of future trends (see Fig. 3) insist that the electric utility industry will have to grow substantially during the next 15 years, from about 25% of the total to some 37%. This is a tremendous challenge to R&D people in the electrical industry to make sure that this necessary increase in their services is accomplished with optimum effectiveness. Actually, in terms of per capita consumption, the changes in energy use during the next 15 years will be more in terms of the "type" of energy used rather than the "total."

Now let us look at the electric utility industry itself (Fig. 4). In 1970, nearly one half of its fuel was coal. Oil, surprisingly, was only 11% (although it has since increased because of ecological pressures), which means that changes in national and international oil policies would have rather less over-all effect on the utility industry than on other segments of our economy and society. Or conversely, rationing electricity would probably result in only minor savings of oil.

The future prognostications here are another great challenge to those performing R and D for the electrical business (Fig. 5). Because of the question marks related to the future of natural gas and oil supplies, and the generally accepted fact of rather limited op-

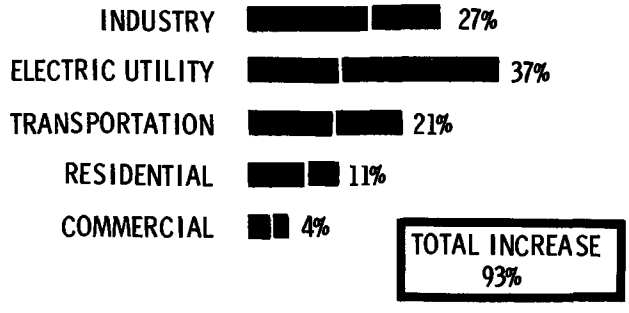

Fig. 3. Markets, energy use, 1970-1985

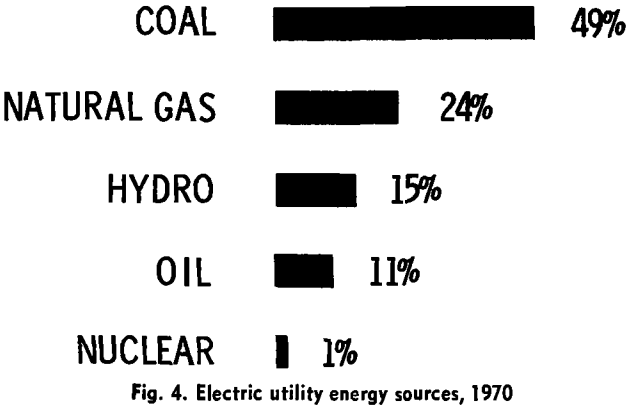

Fig. 4. Electric utility energy sources, 1970

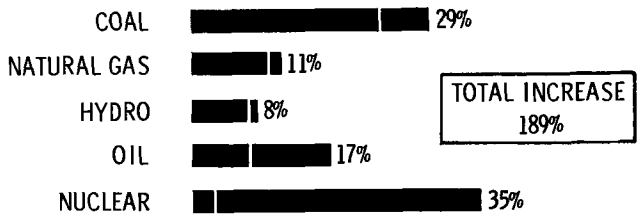

Fig. 5. Electric utility energy sources, 1970-1985

portunities for more hydro-power, we must do our utmost to find ways to increase the anticipated use of coal. This can be done by finding better ways to mine it, clean it, and, most likely, gasify it. At the same time, we might well turn our creative attention to the apparently vast reserves of shale oil. Similarly, we are challenged to make sure the estimated increase in nuclear power meets, and hopefully exceeds, the estimates of the experts who prepared these prognostications.

All of these challenges, all of these long-term responsibilities for finding real solutions to the energy crisis, put a substantial burden on the technologist.

Actually, potential technological solutions to the energy crisis fall into rather simple sounding options:

(*i*) Find new kinds of fuel, new basic energy sources, not now being used, such as fusion power and solar energy.

(*ii*) Find enlarged sources of present fuels; improve ways to locate and secure oil, gas, and uranium.

(*iii*) Improve on presently available fuels to produce cleaner oil and gas; especially cleaner coal, perhaps by gasifying it and scrubbing it in the process; and learn more effective means of enriching uranium.

(*iv*) Improve energy conversion techniques for higher efficiency, less waste, less left-over heat, and fewer environmental side effects.

(*v*) Improve transmission and power delivery systems for efficiency, safety, and environmental reasons, perhaps even going to the "hydrogen economy" that I have mentioned.

(*vi*) Improve the efficiency of the "end-use" of our available energy; *i.e.*, better engines, more efficient lamps and appliances, better insulation to reduce energy requirements for both heat and air conditioning, more effective use of waste heat now being thrown away, and so on.

Let me try to describe some of the electric industry technology that is being, and will be, conducted in a search for solutions in one or more of these six areas.

Actually, electric power research and development in the United States is in a state of rapid growth and considerable ferment. This situation arises because of the "energy crisis" we have discussed and from the additional fact that, as I have just listed, there are such vast technological options and opportunities for finding solutions.

Let us look briefly at the present national commitment to electric power R&D (Fig. 6). Federal Government funding now totals about $280 million per year, with 90% of this coming from the Atomic Energy Commission (AEC). However, it can be anticipated that an increasing share of the Federal Government's R&D support in this area will come from sources other than the AEC.

The electrical manufacturers are the second largest factor in electric power R&D. The utility industry itself has traditionally had relatively low direct R&D expenditures; instead they have relied heavily on the manufacturers to do the R&D, who then recover their R&D costs through the prices of their products.

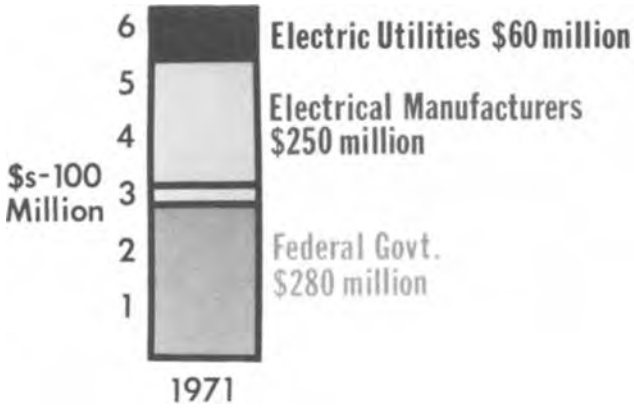

Fig. 6. Electric power R&D funding, 1971

This whole situation has the potential for explosive change, although actual change to date has not been radical.

Here is how we believe the situation will develop over the next five years (Fig. 7). The Federal Government, whose electric power R&D expenditures have been rising at 15-20% annually, will still remain the dominant factor. The electrical manufacturers will remain a strong number two.

Based on initiatives presently under way, the electric utilities are aiming to become a much more significant factor in R&D. Their share of the national total will likely increase from something under 10% in 1971 to over 20%, as shown here.

Now, I should hedge this prediction by reminding you that I referred to "utility industry initiatives presently under way." The prediction could be completely changed, however, if some proposed legislation is passed and implemented. For example, Senator Jackson has introduced a bill that would establish a $2 billion per year federal program in energy R&D. No one is sure who would provide and spend what under this proposal, but it would surely send the totals "right off the chart" (Fig. 8).

Well, I count myself among the world's staunchest advocates of increased R&D in this area, but I must admit to having some misgivings about how we could suddenly find the good people, the facilities, the potentially workable ideas, and the intelligent management needed to make proper and effective use of such vast amounts of money. In spite of some claims to the contrary, the job of solving the energy crisis is not really directly comparable to putting a man on the moon.

We in the manufacturing part of the electrical business readily recognize the more immediate, short-range

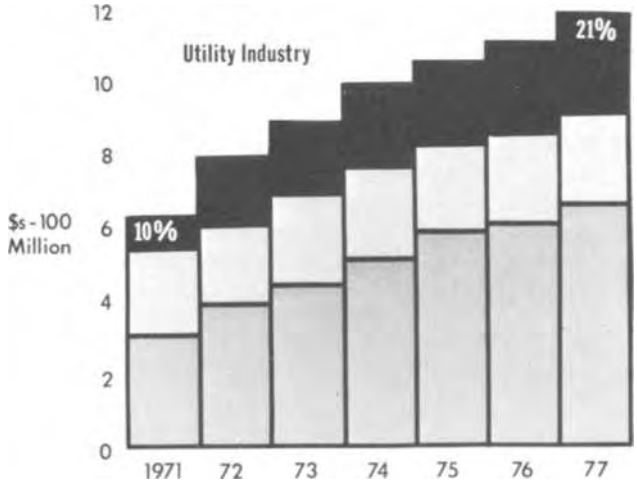

Fig. 7. Electric power R and D funding, 1971-1977

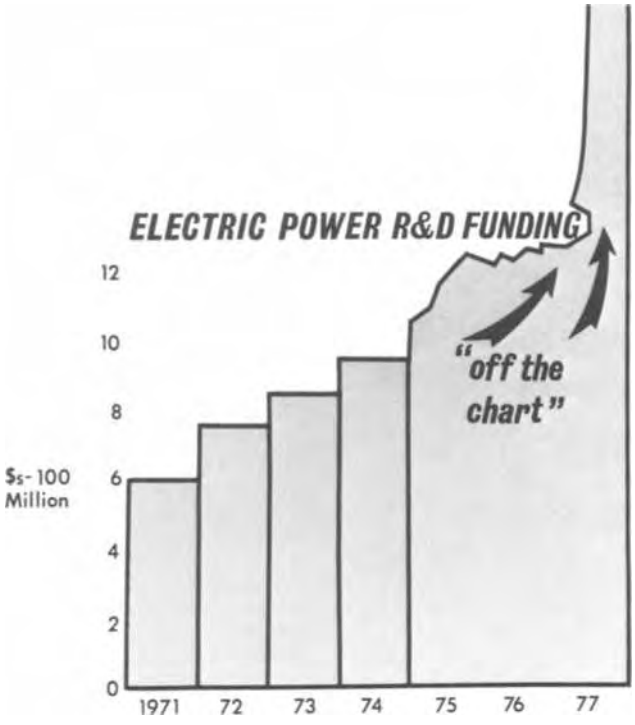

Fig. 8. Electric power R&D funding proposed for 1971-1977

problems we should be solving: improving generation efficiency through combination steam and gas cycles and by developing turbines that will operate at higher temperatures; assuring the life of nuclear fuel and the reliability of nuclear plants; exploring new methods for transmitting larger blocks of power over longer distances; trying to find answers to the ever-increasing problems of power-plant siting (a particular concern for the electric utility industry itself); continuing the constant search for higher reliability throughout the entire electric power systems of our country.

These, and many other areas I will not take time to mention, are some of the short-range challenges for the manufacturers and to the new cooperative R&D efforts of the electric utility industry. At the same time, we have some very exciting long-range options.

So let me conclude by spending a few minutes examining some of the more "far-out" energy technologies that have been touted as "the" answer that will solve our energy, economic, political, and environmental problems in one fell swoop, if only "those crazy scientists who could so easily put a man on the moon would just buckle down and put their minds to it."

There are more than a dozen such future hopes—*e.g.*, fusion, MHD, solar power, cryogenic transmission, the hydrogen economy, and so on—that have received enough public attention to convince many people that they are nearer, and easier, and cheaper, and cleaner, and safer than the facts, as we now know them, warrant.

But it remains that some of these are very real hopes for helping solve future energy crises before the end of this millenium.

Let me review several areas in which we in General Electric are deeply involved, from an R&D standpoint, and give you some candid views about their prospects.

First, in the basic area of energy sources—that is, fuel—the (perhaps) ultimate source for this planet is controlled thermonuclear fusion.

Hydrogen fusion, of course, is essentially the process of getting energy from the same source as the sun, from the joining of lightweight atoms. It is the hydrogen-bomb reaction—controlled.

Starting some 16 years ago, and for nearly a decade, General Electric was in the unique position of investing several million dollars of its own money to support fully its own research program on Controlled Nuclear Fusion. We knew from the beginning that it was a long shot, and it turned out that our first effort was premature.

We explored all the best ideas that we, or anyone else, had at the time and finally concluded, a half dozen years ago, that practical fusion power was just too far in the future to justify a continued commercial investment, at least until a better idea came along.

Now, in the past year or so, a new idea has come along: laser-ignited fusion. So we are involved again in fusion research. Along with EXXON, Northeast Utilities, the Empire State Electric Energy Research Corporation, and the New York State Atomic and Space Development Agency, we will be investing substantial sums of money over the next 3 years, plus the talents of some of our top scientists, in the laser-ignited fusion program being led at the University of Rochester in New York by Professor Moshe Lubin.

The most optimistic of realistic guesses about fusion is that it will not be ready for a major role in the energy picture until at least the turn of the century, by which time the evolution of other technologies and factors may vastly affect its economic viability. There are those who believe that fusion's ultimate role will be providing, from isolated locations, nuclear fuel for more conventional nuclear generating plants. Meanwhile, it is too big an idea basically to ignore. So, we are not ignoring it. But we believe it should be approached as an area of research, not as a large-scale development effort at this point in time.

Another obvious area for fuel research is to make better use of our most abundant fossil fuel: coal. At Schenectady we are substantially enlarging our R&D program in coal gasification. We have unique ideas that may make it possible to use even the dirtiest "caking" coals. Also, based on a tradition of research with membranes of various kinds, we have good ideas for taking the pollutants out of gasified coal before it is burned, which has obvious advantages over today's method in which one tries to take the SO_2 and other crud out of stack gases after combustion.

Coal gasification is not a long shot like fusion, for example. But making the process attractive enough to offset the economic, ecological, and social problems of expanding the coal mining industry will take substantial time. However, a commercial gasification process is available right now; and we have recently announced a joint program in this area with Lurgi, a German engineering firm with long experience in coal gasification.

I will mention four unique approaches to energy conversion in which we are currently making R&D investments.

Our investment in magnetohydrodynamics (MHD) is being made in the hope that we can get generating efficiencies of above 50%. (This, of course, is also the aim of our work on combined cycles and other approaches to more conventional power generation.)

The basic concept of MHD is that a very hot ionized gas, a plasma at temperatures in the range of 3100°-4900°F, replaces the metal conductor that moves through a magnetic field to create a current in a conventional generator. In past years, we invested heavily in this tempting idea and built some large test equipment. But the purely technical problems of gas conductivity and noncorroding electrode materials were formidable. More recently, people in our space business have made progress in developing a closed-cycle MHD system, as contrasted with the more frequently promoted open-cycle method, which shows sufficient scientific promise to justify continuing investigations.

The superconducting generator is another "long-term" prospect on my list. Our people, and others, have already demonstrated that superconductivity offers the possibility of decreasing by a factor of nearly three the size of generators for a given rating.

Another idea for improved energy conversion efficiency is the so-called "potassium topping" cycle. We recently proposed to the Office of Coal Research a program in which potassium (or cesium) would be used instead of boiling water in a coal-fired furnace boiler. In the potassium vapor turbine, the potassium would leave the boiler at a temperature of up to 1500°F, drive a turbo-generator, and then the potassium vapor leaving the topping-turbine would condense on the outside of condenser tubes, producing boiling water inside the tubes at 1050°F to run a conventional power plant. Addition of the "potassium topping" cycle offers the potential of total plant efficiencies in the range of 50-60%.

In the past years, General Electric has invested very heavily in fuel cell research.

Our invention of the ion-exchange fuel cell led to the first actual "practical application" of a fuel cell: the Gemini spacecraft unit that provided reliable onboard electricity without exceeding extremely stringent weight limits.

Currently, we are concentrating on fuel cells for the space shuttle and for some specialty marine applications. Fuel cells can be reliable, environmentally attractive power plants, but we believe that problems of cost of materials and their availability, of life, and of specialized fuel requirements are such that they must be regarded as still in the research phase.

We are also making substantial long-range investments in energy handling with regard to storage and delivery.

Three specific items might be mentioned briefly.

(*i*) One of our calculated-risk investments is in new types of batteries that may be useful for bulk energy storage as a possible substitute, perhaps underground, for the pumped hydro-plants that are frequent targets of the environmentalists. Success here might well influence our decision making with regard to the trade-off between base load and peaking capability of our power generation methods and will influence the development of system interties.

(*ii*) We are now in the second phase of an Edison Electric Institute (and Government) supported R&D program on cryogenic cable; *i.e.*, taking advantage of the vastly improved conductivity of metals at liquid nitrogen temperatures. Our first 40 ft test cable performed very well; the current phase is one of scale-up and refinement. But the day is still some years off before all of Chicago can be supplied with power through a few underground, supercold cables.

(*iii*) High voltage d-c power equipment is already a reality. The big "future" here, I believe, is that we have barely begun to tap the potential for using new solid-state technology for power conditioning on a very large scale.

For example, we can expect to see solid-state devices replacing a wide variety of electromechanical ones in applications such as voltage regulators and similar equipment that must stand up to many, many switchings. Solid-state science can profoundly affect the power delivery industry just as surely as it has already revolutionized the communications and information handling industries. For example, it can give us new options for transmitting large blocks of power through d-c interties, which will result in still more stable and versatile power systems.

Well, all of the long-range items I have mentioned so far are ones in which we are performing "at the bench" R&D programs, many of them on a very substantial scale. Perhaps I should also mention one intriguing area where we have carried out extensive techno-economic studies and have more recently begun experimental research.

This is in the area loosely referred to as the "hydrogen economy." The interest in hydrogen stems from

three major facts. First, hydrogen can be burned in a completely compatible manner from an ecological viewpoint.

Now, it is well known that if you burn hydrogen directly in air, you reach very high flame temperatures that not only cause basic problems with the materials in the combustor, but also produce a disturbing quantity of oxides of nitrogen.

However, if you dilute the combustion with steam you can reach manageable temperatures of 3000°F. We have already operated gas turbine stages 200°F above that, so we know that this is possible. At 3000°F there is a theoretical Carnot efficiency above 80% and a practical efficiency above 50%, an attractive prospect, and oxides of nitrogen can be kept well within reasonable bounds. (Of course, another possible alternative is to recover the oxygen as well as the hydrogen from any process based on the thermal decomposition of water, which I shall discuss in a moment, and delivering them side-by-side. The recombining combustion process then can become completely "clean," or, shall we say, as clean as water can be.)

Second, hydrogen affords much flexibility in designing utility systems. We can envision distributed generation (gas turbine and even perhaps fuel cell plants of about 100 MW) near the load.

Third, and most significant, hydrogen can be inexpensive to transmit. Overhead electric transmission costs 6-18 cents per million BTU per 100 miles; underground transmission may cost 5-10 times as much. By contrast, hydrogen gas may be transported by pipeline for less than 2 cents per million BTU per 100 miles.

Of course, hydrogen is more expensive than other fuels. However, as the cost of other fuels rises, and we will all be noticing this in our home heating and gasoline bills in the days ahead, hydrogen becomes, on a percentage basis, less of a premium fuel. Right now most hydrogen is produced by natural gas reforming; before we run out of natural gas, we must consider making hydrogen from our abundant coal resources. Our own scientists recently have devised a method to achieve this, using the cracking of steam with molten tin and the reduction of the tin oxide with coal.

Even more attractive is the possibility of producing hydrogen and oxygen using only heat and water. Of course, to do this directly requires temperatures above 5000°F, and it would be extremely difficult to separate the gases. However, using a series of chemical reactions, it should be possible to devise processes that operate at 1000°F, or lower, which might ultimately be attainable from a high temperature nuclear reactor. Our people in Schenectady have devised a series of such processes, and since the first was conceived during Hurricane Agnes in 1972, we have given the subsequent ideas girls' names. "Beulah" is a copper-magnesium-chlorine process. "Catherine" is a very intriguing lady I will tell you about at some later time.

We have, of course, also looked at straight electrochemical production of hydrogen. Even though we have devised a highly efficient cell (above 80% efficiency at 100 A/ft^2) using ion exchange membrane electrolytes, we do not presently see how to make hydrogen electrolytically for less than $3 per million BTU, and there is a speculative chance of making it thermochemically for about half of that cost. Whether the latter is any bargain will depend tremendously on the future availability, and thus price, of conventional fuels.

We believe hydrogen could be distributed and used safely although some public education will be required. I can assure you that we are working hard in this area, but at the same time, don't hold your breath. We need several more years of research before we can make any meaningful judgment on the ultimate value of this technology.

During our discussion period I will be glad to give you our viewpoint about a variety of other energy sources, conversion, and distribution schemes in which we are not, not now at least, investing much if any effort. I refer to such things as thermionic converters, thermoelectricity, solar energy, outer space solar energy collectors with microwave transmission to earth, geothermal power, and so on.

Geothermal power, at the most optimistic, I believe, could provide only a very small percentage of our total power needs, and that only in limited geographical areas. In any case, the mention of geothermal power reminds me of a TV network broadcast I heard a few weeks ago in which the commentator's concluding comment had an interesting message for all of us.

This TV newscast included a couple of minutes explaining the idea of geothermal power. With background views of Yellowstone Park geysers and hot springs, the possibility of using heat from the bowels of the earth to run turbine generators was outlined. Then the announcer finished, "The enviromentalists don't see geothermal power as a threat yet because they don't think there's much hope it will work." Well, one man's hope is another man's threat.

But there is something in what the TV man said. In looking at these long-term solutions for future energy crises, it is easy for we technologists to be concerned only with the fantastic basic technical problems confronting us—trying to show they will work!

But let us not forget:

(*i*) If fusion succeeds, there will be all sorts of worries about centralization of huge energy sources.

(*ii*) MHD temperatures mean more oxides of nitrogen, and, along with topping cycle possibilities, elements like potassium could easily be added to the vocabulary of ecologically dirty words.

(*iii*) Unless new metals for fuel cells can be found, their broad use could be a big drain on our balance of payments.

(*iv*) We have already heard about the "Hindenburg syndrome" which might slow down acceptance of the "hydrogen-economy."

(*v*) Solar energy would require terribly wasteful use of land, and I hesitate to even ponder the environmentalists' response to those microwave beams bringing power from outer space.

(*vi*) Some of the best new high-density batteries are based on (heaven forbid!) sodium and sulfur.

(*vii*) Coal gasification does not necessarily do away with either the hazards of deep mining or the problems of strip mining.

Now, some of these "negative-scare" items I have just listed are secondary technological problems which we must not overlook. Others are economical and political matters. Through them all runs an undercurrent of a need I mentioned earlier, the need to help people continue to understand that the high energy society they demand will itself inevitably demand certain trade-offs.

But you will recall that I started this morning with the basic thesis that, in the long run, it is easier to generate new technology than it is to change the habits, *mores*, prejudices, and desires of people and their long-established institutions.

So, we technologists will have to take responsibility for solving some of those secondary as well as the basic technical barriers as these new ideas for solving the energy crisis come along.

All things considered, I think technology has been remarkably responsive to the needs and wants of the people in the past. I am confident that creative technical people will keep coming along at an ever-increasing rate and that they will, indeed, help give us the kind of world we want for ourselves and our children in the future.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

NOVEMBER 1973

Humphry Davy, Innovator in Electrochemistry

Samuel Ruben*

Ruben Laboratories, New Rochelle, New York 10801

The early developments of the sciences, particularly electrochemistry, in England were initiated by self-motivated men with imaginative minds and an inherent sense of direction. They engaged in self-motivated experimental work to fulfill their bold dreams and complemented this by practical applications of their scientific results. A natural driving curiosity was a distinctive characteristic of the personalities of these men. In order to make their efforts more fruitful, they required means of disseminating their accumulated knowledge; they found these means in lectures, discussions, and publications, such as the ones provided by the Royal Institution.

The Royal Institution of London enjoys a special place in the history of science. Its role in the scientific community seems to reflect the personality of Count Rumford, its adventurous founder. He was endowed with a creative mind and a desire to combine scientific discoveries and advances with the dissemination of this new knowledge for purposes of improving the arts and industries.

Humphry Davy and his successor, Michael Faraday, were two outstanding and dedicated individuals who had the ability to educate themselves to the highest levels in the sciences. The Royal Institution provided both men with the opportunity to fulfill their dreams; each made major contributions to the development of chemistry and electrochemistry.

Humphry Davy was born in Penzance, Cornwall, on December 17, 1778, the eldest child of a middle-class family. He was endowed with a quick, imaginative mind and the ability to learn rapidly from books. These books served not only as a means of instruction, but also as a source of inspiration to him.

He attended a local grammar school where, among other subjects, he was taught Latin and Greek. At fourteen years of age he was enrolled in a better school at Truro where he acquired a knowledge of the classics. Being somewhat of a romanticist, he retained this knowledge and in the many lectures which he gave he frequently delighted his audiences by quoting related passages from the Greek philosophers. These illuminated his lectures and made them more than briefs on science and, thus helped to establish his reputation as a fascinating lecturer and natural philosopher.

After Truro, Davy spent a year applying his imaginative mind to literary fields, particularly poetry. He also engaged in fishing and hunting, activities for which he retained a love, which accompanied an appreciation for the beauty of nature throughout his life. His ability for composing poetry in later years received encouragement from Coleridge and Southey, and some of his poems were even published in Southey's "Annual Anthology" of 1799 and 1800. At this time he had only a speculative interest in the sciences.

When his father died, the family was left with an estate diminished by unwise investments. This situation made it imperative that he acquire a training so that he could assist in the support of the family. He decided that he would like to follow the medical profession. Therefore, on February 10, 1795, he applied for an apprenticeship with Dr. J. Borlaise, a surgeon and apothecary, and was accepted. He enjoyed his duties as an assistant to Dr. Borlaise and planned to meet the requirements for practicing medicine by completing his apprenticeship and the necessary studies and by taking the examinations given by Edinburgh University. He kept an excellent record of his experiences with Borlaise, including personal thoughts relative to his work. During his two years of experience with Borlaise, he became interested in the chemistry of blood and the problems involving the chemistry of respiration. He would later make some original contributions in these areas.

At this stage of his life he was fortunate to meet people who recognized and encouraged his creative thinking, assisting him in the process of self-education and encouraging his interest in the science of chemistry. He had become a good friend of Gregory Watt, a son of the famous inventor, James Watt, who had been educated in the sciences at Glasgow and who admired Davy's keen mind. Watt introduced him to Davies Giddy, a member of the Royal Society, who had a profound influence on the course of Davy's intellectual life. Besides encouraging his creative thinking, Giddy allowed Davy full use of his excellent library, a privilege which was of inestimable value as a motivating factor. In later years, he helped him by introducing his work to his friends, Dr. Beddoes and Count Rumford. Giddy changed his name to Gilbert in 1808 and was known by this name in the various offices he occupied in the Royal Society.

By 1797 Davy's interests were principally in the study and understanding of the growing science of chemistry. He was fortunate to become interested in it at a time when it was no longer under the influence of the phlogiston theory. Work of men in various countries of Europe had changed thinking from the qualitative phlogiston theory with its variable unknown "phlogiston" element to a quantitative scientific approach based on measurable changes in weights and volume. This approach was stressed particularly by Lavoisier, the father of modern chemistry, whose measurements with a chemical balance became the true arbiters for determining chemical compositions, reactions, and analyses. The greatest motivating force in 1797 which excited Davy's interest in the study of chemistry was Lavoisier's *Traité Élémentaire de Chimie*, which gave him a comprehensive picture of the science of chemistry as it was then understood. It contributed to his involvement in a vigorous study of chemistry and experimental work. Lavoisier had the subject of compounds arranged under a system of nomenclature which indicated their compositions, and to some extent, their derivations. While studying Lavoisier's book, Davy made and collected apparatus to learn the facts of chemistry through practical experience derived from experimental work. There were

* Electrochemical Society Active Member.
Key words: Davy, self-motivation, Royal Institution of London.

some items in the book which he could not logically accept and he began gathering the information required to disprove them. Ten years later he was able to prove the fallacy of Lavoisier's description of muriatic acid as "oxymuriatic" acid. He published a paper in which he proved that oxygen was not the essential component of muriatic acid, but that the acid was essentially composed of an aqueous solution of a compound of hydrogen and an element which he identified as chlorine.

One man who assisted Davy by helping him develop a better understanding of the rudiments of science and laboratory equipment was Robert Dunkin. Dunkin was an instrument maker who was as well versed in mathematics, electricity, and magnetism as anyone of his time. He constructed a number of instruments and demonstrated their operations to Davy, thus teaching him some of the rudiments of laboratory science. Davy's highly imaginative, although still undisciplined mind caused him to express unproven, speculative thoughts as facts in these early stages of his self-education and experimental work. However, bitter experience taught him how readily one could stray from the truth and his critical faculties eventually developed, enabling him to engage in meaningful research and to make outstanding contributions to the growing science of chemistry.

Davy quickly recognized the importance of publishing one's work. Each paper published was like the rung of a ladder—a step toward recognition by one's peers. A faulty rung not based on proven results would cause a halt in progress until it was replaced by one which could withstand the tests of scientific criticism.

Davy's two-year apprenticeship to Borlaise had inspired an interest in the chemistry of physiology, and particularly in the chemistry of respiration in a wide range of living organisms. As a consequence of his studies in these areas, he was able to prove that the carbon cycle operated in the sea as well as on land. He was fascinated by a book written in 1795 by Dr. Mitchell entitled "Remarks on the Gaseous Oxyde of Azote and Its Effects," and in 1798, became critical of Dr. Mitchell's statement that nitrous oxide gas was an agency for spreading contagious diseases, producing ill effects when it was breathed in or came in contact with the skin. Davy set up a simple assembly of apparatus necessary to produce nitrous oxide. He then tested the effects of the nitrous oxide gas on animals by having them breathe it or by allowing skin contact. He found that the animals experienced no ill effects. He experimented with it on himself and found some very interesting results unrelated to the statements published in Dr. Mitchell's book.

Since he needed larger quantities of nitrous oxide gas to continue his research on its physiological effects, he wrote to Dr. Beddoes at Bristol about his experiments. Dr. Beddoes knew of Davy through their mutual friend, Davies Giddy, and on October 2, 1798, he offered Davy the position of chemical assistant at the Medical Pneumatic Institute. This institute, founded by Dr. Beddoes, was dedicated to the study and application of the therapeutic value of various gases. Davy was asked to complete an account of his initial work on nitrous oxide and this was published in 1799. A year later he published an intensive study on the effects of nitrous oxide gas on humans in a separate volume entitled "Researches, Chemical and Philosophical, Chiefly Concerning Nitrous Oxide." He reported pleasurable effects upon breathing the gas and found it was nontoxic. Also, he found that it had an analgesic effect in small quantities, relieving him of a toothache which returned when the gas was discontinued. He discovered that it had an anesthetic action when taken in large quantities. Thus began the history of what in dental practice has been referred to as "laughing gas." Davy found that some of the gas was absorbed in the bloodstream, but that it did not combine chemically with the blood and could be freely eliminated without having a toxic effect. Further studies of the physiological effects of other gases, such as nitric oxide and a mixture of carbon monoxide and hydrogen, nearly proved fatal to him. In his work on gases he had determined the residual capacity of the lung. The publication of his work in 1800 created great interest and was a true rung in his ladder toward professional recognition and fame.

In January 1800, he learned of a great discovery: chemically produced electricity. This discovery would play an important part in his rise to fame since it helped to make possible his notable contributions to electrochemistry. He recognized the importance of Alessandro Volta's announcement of the electric pile which had been described in a communication to the Royal Society. Volta's electric pile, composed of dissimilar metals separated by an absorbent spacer saturated with an aqueous conductive solution, for the first time made possible the generation of a continuous flow of electric current. Before this time experiments with electricity were limited to intermittent discharges of short duration provided by an electrostatic generator and stored in a "Leyden jar." Now, electrical effects could be studied with a continuous controllable flow of current which was more readily measurable with regard to intensity and quantity. Utilizing the electricity from voltaic cells, Davy duplicated the work of Nicolson and Carlyle who had reported the fact that when an electric current was passed through water, hydrogen and oxygen were liberated at their respective poles. Cavendish had demonstrated that the gases liberated and combined to form water when subjected to an electric spark.

Davy was evidently acquainted with the higher capacity cell of Cruickshank, who had changed the structure of the voltaic cell by inserting large plates of zinc and copper alternatingly in a resin-lined, grooved wooden box. After assembly of the plates in their respective grooves, Cruickshank added a conductive aqueous solution in the space between them. With these larger plates, he obtained a sufficiently strong current to decompose several compounds electrolytically in solution, and he electrodeposited several metals. Davy believed there was much to be learned about the fundamentals of voltaic generation of electric currents. He duplicated the higher capacity cell of Cruickshank and became involved in a study of the controlling chemical factors. When he constructed a voltaic cell using zinc and silver electrode elements separated by a porous spacer containing muriatic acid, he obtained greater electrical force than with electrodes separated by spacers impregnated with saline solutions. He reported that cells having spacers containing nitrous acid were also capable of increased electric output. With this work he proved that the generation of electric current was dependent upon the oxidation of its zinc element and that the total force generated included the result of the chemical activity of the solution in contact with the positive electrode. He investigated many other compositions of solutions in contact with dissimilar metal electrodes and related their composition to voltaic cell characteristics. In his work on various active solutions, he made dual-electrolyte cells with the more highly oxidizing electrolyte in contact with the positive electrode. Davy found that carbon derived from charcoal could be combined with zinc to form a spaced couple which would generate an electric current. This finding was not considered to be of great importance because Volta had experimented with graphite electrodes, but years later in the development of commercial electric batteries such as the LeClanché cell and its progeny, the dry cell, carbon became the electrode material for contacting the negative reactant or depolarizer such as manganese dioxide.

In September 1800, his first paper on galvanism was published in Nicolson's Journal. A second paper followed three weeks later. In 1801 Count Rumford, who was acquainted with Davy's work on galvanism, invited him for an interview. This led to a recommendation to the Board of Managers of the Royal Institution

that Davy be appointed assistant lecturer in chemistry. On February 16, 1801, the Board concurred, adding other duties such as assistant editor of the Journal of the Institution.

Davy continued his work on galvanism after his employment at the Royal Institution, and six weeks later gave his first lecture on this subject. This lecture, on April 25, 1801, was attended by Count Rumford, Sir Joseph Banks, and other distinguished philosophers. It was a brilliant success and was reported in the *Philosophical Magazine*. Five months later he was promoted to lecturer in chemistry.

In January 1802, his unique personality was expressed when he gave his first course in chemistry. His highly imaginative mind aided him in expressing his ideas concerning chemistry and relating chemistry to all the sciences. His audience was fascinated by the breadth of his vision in relating chemistry to mineralogy, biology, zoology, physiology, and medicine. He philosophized on the opportunities presented to those engaged in the related disciplines by a better understanding of chemistry. These lectures indicated the thorough knowledge of the sciences he had acquired from the literature, through discussions, and by keen observations of his experimental work.

Count Rumford had originally intended that the Royal Institution orient its studies toward industrial problems and in order to increase its financial support, it began to do so. The important English industries, dyeing and tanning, felt a great need for better processes, and Davy was asked to cease his laboratory work on galvanism to study these needs. After two months of study and visits to tanneries, Davy returned to his laboratory to investigate new and old substances useful for tanning and a method of depilating skins with alkaline materials. His observations and comments on the processes of tanning were published in the *Journal of the Royal Institution*. The over-all results of his work were published as a tanner's guidebook which was used by the industry for many years. In 1805 he was awarded the Copley medal by the Royal Society for his work on the chemistry of tanning.

The success of Davy's lectures, largely due to his humanistic approach to the interpretation of the sciences, had a secondary effect of materially helping the Royal Institution in a period of financial stress. This was appreciated by the Board of Managers and on May 21, 1802, they conferred upon him the title of Professor of Chemistry. On November 17, 1803, he was elected Fellow of the Royal Society. The Board of Managers also extended his duties by requesting him to plan and give a course on agricultural chemistry to the members of the Agriculture Board. These lectures were based on the results of many experiments, discussions with farmers, and extensive study of the available literature on the subject of agricultural chemistry. In 1804 he was elected a Fellow Commoner of Jesus College, Cambridge. In 1805 he was asked to collect minerals in Cornwall, the lakes in Wales and in Ireland, and to study the geology of these regions. He made an analytical study of what he observed and cast it in a comprehensive report. Later, he gave a lecture on this subject. Continuous study and laboratory work accompanied by creative thinking helped establish his reputation as one of the outstanding philosophers of chemistry.

Davy was now allowed to resume his experimental work on the studies of galvanism. He showed that the relation of electricity to chemical affinity was basic to the understanding of electrochemical action. Using the electricity from voltaic cells, he was able to prove that one could change the material state of substances and their residual chemical properties. In his first Bakerian lecture of November 20, 1806, Davy predicted the value of electricity in discovering the true elements of materials. He proved this later by his isolation of metallic potassium and sodium from their hydroxide compounds.

One of his important contributions toward the establishment of the fundamentals of electrochemistry was his generalization on the study of migration of materials in solution caused by the application of an electrical current. He stated that,

> Hydrogen, the alkaline substances of metals and certain metallic oxides are attracted by negatively electrified metallic surfaces and repelled by positively electrified metallic surfaces and contrawise, oxygen and acid substances are attracted by positively electrified surfaces; and these attractive and repulsive forces are sufficiently energetic to destroy or suspend the usual operation of chemical affinity. It is very natural to suppose that these excellent and attractive energies are communicated from one particle to another particle of the same kind so as to establish a conducting chain in the liquid and that the locomotion takes place in consequence (3, 6).

Considering the state of the art at this period, Davy's explanation of chemical and electrical affinities was an instructive guide for work in the developing science of electrochemistry. His imaginative mind foresaw the industrial possibilities of using electricity to decompose neutral materials and, thus, to produce alkaline or acidic compounds on a large scale. His lecture, "On Some Chemical Agencies of Electricity," created much interest for it brought a new concept to the minds of chemists. In 1807, he was awarded the medal and prize from the French Institute for the best experimental work of the year on galvanism. Napoleon had established this medal when he was First Consul, and it was awarded to Davy despite the fact that England and France were at war.

Davy's work on the electrochemical decomposition of fixed alkalies led to his most famous discovery on October 6, 1807—the isolation of the metals, potassium and sodium. He accomplished this by the electrochemical decomposition of molten potash which produced metallic potassium for the first time. The same technique was later used to produce metallic sodium. He initially named the metals "potagen" and "sodagen," but later changed them to "potassium" and "sodium." He not only discovered these metals in a pure state, but also determined their physical and chemical properties. At a later time he applied the same methods to produce the alkaline-earth metals, but was not successful. This failure was due to the fact that hydroxide compounds of the alkaline-earth metals are not electrolytically conductive or fluid enough when heated. By using the method reported by Berzelius, namely, that of using a mercury electrode to form amalgams, he was able to produce some of the alkaline-earth metals. He also produced alkaline-earth metals and boron by reduction of their oxides with the alkali metals. His work verified Lavoisier's belief that oxygen was a component of the basic alkaline compounds, and his discoveries supported his own theories concerning the electrical nature of chemical affinity—a fundamental concept of electrochemistry.

He published two important books, "Elements of Chemical Philosophy" in 1812, and "Elements of Agricultural Chemistry," a year later. His "Elements of Chemical Philosophy," noted for its excellent presentation of contemporary chemical science included a sketch of the history of chemistry. Davy's wide reading enabled him to relate the work of the alchemists and the chemists of Lavoisier's period to the development of the science of chemistry. He stressed his thoughts on the laws governing chemical combinations and proportions by which elements combine. The imaginative thinking of Davy can be noted from the statements in the following paragraph,

> . . . whether matter consists of individual corpuscles or physical points endowed with attraction and repulsion, still the same conclusion may be formed concerning the powers by which they act and the quantities which they combine and these

> powers seem capable of being measured by their electrical relations and the quantities on which they act being expressed by numbers. The laws of crystallization of different proportions and the electrical polarities of bodies seem to be intimately related and completely illustrative of their connection and probably will constitute the mature age of chemistry (3, 6).

Many years later the prophetic meaning of these sentences was appreciated.

He returned to the laboratory to continue his experimental work and investigated the properties of a compound of nitrogen and chlorine discovered by Dulong in Paris which had aroused his interest. While performing experiments to determine the compound's characteristics, a vial exploded and wounded him by blasting small splinters of glass into his face. He concluded that the compound was nitrogen chloride and presented a paper on its properties to the Royal Society.

During Davy's last four lectures on chemistry at the Royal Institution, there was a young man in the audience who was enthralled with the lectures and wrote a meticulous set of notes. Michael Faraday had been invited to the lectures by Mr. Dance, a member of the Institution and an admirer of Faraday's keen mind and serious dedication to studies of the chemical sciences. Faraday sent Davy a plea for a position as a chemical assistant at the Royal Institution and included the notes he had made of Davy's lectures. Davy recognized the unique qualities of Faraday's mind, but was unable to employ him as his chemical assistant at that time. He promised to communicate with him if such an opportunity occurred. He did give him a few days work as his temporary secretary while his eyes were recovering from the effect of the nitrogen chloride explosion. Three months later Davy discharged his laboratory assistant for misconduct and recommended to the Board of Managers that Faraday be engaged as his chemical assistant. They concurred on March 1, 1813. This appointment proved to be of tremendous benefit both to the Royal Institution and to Faraday. The Royal Institution benefited from Faraday's skill in measurements, his patience, and his unerring intuition; Faraday benefited from a close association with the outstanding chemical philosopher, Humphry Davy.

Davy and Faraday had certain qualities and interests in common. Both had creative minds and were compulsive readers of scientific literature. They both educated themselves to be experts in their subjects. It has been written that of the many outstanding contributions Davy made to the Royal Institution and to science, his recognition of Faraday's abilities was one of his greatest.

Davy asked Faraday to accompany him as his assistant on a trip to the Continent in October, 1813, about six months after Faraday had become his chemical assistant. Lady Davy was to accompany them as well. There they would meet prominent scientists such as Ampère, Laplace, Gay-Lussac, Chevreul, Berthollet, Guyton de Morveau, Humboldt, De La Rive, and Volta for discussions and exchange of information. They would also study the volcanoes of France and Italy. They received passports and *laissez-faire* from France even though England and France were still at war. They carried portable chemical apparatus in their private coach which they used in demonstrating chemical experiments.

In November 1813, while in Paris, they met Clement and Desmorne who showed them a new elemental material considered to be a complex form of chlorine which had been discovered only two years before by M. Courtois, a salt peter manufacturer. This subject became a matter of investigation and Davy identified it as the element, iodine. In Genoa at the home of a chemist, the pair observed experiments with electric fish (torpedoes). In a paper given some years later, Davy reported his investigations showing that this new source of electricity was developed by nerves. In Florence they were delighted to see the first telescope built by Galileo who had used it for discovering the satellites of Jupiter. At the Accademia del Cimento they borrowed a large optical lens for producing an intense localized area of heat. With this lens they investigated the combustion of diamonds. In March 1814, they identified the combustion product as pure carbon dioxide and established the fact that diamonds were a crystalline form of pure carbon. While in Milan they had a visit from Alessandro Volta, the man who had discovered the means of generating a continuous flow of electric current by chemical reaction. Volta's great discovery was an important step for the significant developments in electrochemistry later made by both Davy and Faraday.

Shortly after his return from the trip to the Continent, Davy devoted study time to the problem that had plagued the coal mining industry: the recurrent explosions in coal mines caused by the ignition of coal gas and air. Many lives had been lost over the years in all countries by miners caught in these explosions which were ignited by their illuminating equipment. His studies on combustion and heat transmission through confined areas led to his invention in October 1815, of the mine safety lamp in which the flame was enclosed by copper gauze. This lamp could, therefore, be used in atmospheres containing explosive quantities of the coal gas without igniting them. It also gave a qualitative indication of the presence of explosive concentrations of combustible gas by increases in the intensity of the flame. A flame of decreased intensity was an indication that the oxygen content in the atmosphere was less than 18%. While records show that others had worked on a mine safety lamp, it was Davy's systematic experiments on utilizing the heat conductivity of surrounding wire gauze cylinders for the prevention of an ignition path from the flame of the wick to the external atmosphere that made his lamp the first effective and practical mine safety lamp.

Davy believed that the duty of men of science was to contribute their discoveries to the benefit of mankind. He refused to patent his lamp and dedicated its use to the mining industry. In October 1818, he received the Rumford gold and silver medals from the Royal Society for his development of the safety lamp. He was also presented a service of silver plates by the Newcastle mining industry. In his will he requested that these be used for the establishment of the annual Davy medal for outstanding discoveries in chemistry.

In 1818 Davy was named a baronet. He went again to Italy with a plan to devise a method of unrolling the papyri documents discovered at Herculeum. On November 30, 1820, he succeeded Sir Joseph Banks as President of the Royal Society, a position he held until 1827.

Davy became interested in electrical and related magnetic effects. He had been impressed by the announcement of Oersted's discovery of the magnetic properties of a conductor carrying a current. In investigating the magnetic effects surrounding an electrically heated platinum wire, he found these effects to be independent of the wire's temperature. He reported experiments in which steel needles placed transversely to conductors became magnetized. In basic observations on the conductivity of different metallic conductors, he showed that the melting point limited the quantity of electricity that could be transmitted through the conductor and that its conductivity was increased if cooled, and the converse occurred when it was heated.

In January, 1824, he invented a method for galvanic protection of the copper sheathing of the hulls of naval vessels by electrically connecting a mass of more oxidizable metals such as iron, tin, or zinc to it. This method which had worked in the laboratory, failed when tried in actual seawater. This was not because of incorrect reasoning, but because of the rapid overlaying accumulation of organic materials such as weeds

and barnacles which obscured the galvanic protective action. A century later this process of galvanic protection was to prove invaluable in the protection of oxidizable metal structures.

His last Bakerian lecture of October, 1824, on the relation of electrical and chemical changes, contained his last published thoughts on electrochemistry and earned him the Royal Society Medal. The minutes of the Board of Managers of the Royal Institution of February 4, 1825, include the following item:

> It appears that Sir Humphry Davy, having stated that he considered the talents and services of Mr. Faraday, assistant in the laboratory, entitled to some mark of approbation from the managers, and these sentiments met the cordial concurrence of the board; Resolved, that Mr. Faraday he appointed director of the laboratory.

Thus, Michael Faraday, the man whom Davy had served as mentor and whose career had taken on significance as Davy's laboratory assistant, now, twelve years later, became the director of the laboratory. That Faraday in the ensuing years fulfilled his sponsor's expectations was evidenced by his many discoveries. He was the first scientist to place electrochemistry on a quantitative basis and the first to generate an electric current flow in a conductor by induction from a magnetic field.

Davy was elected President of the Royal Society for the seventh time in 1826. But in that year he suffered a stroke and resigned from the Society. His health was failing rapidly and he decided to leave England and settle in Rome. In 1828, having to forego scientific work and field sports, he devoted his time to writing a book on fishing, "Salmonia," which he illustrated with his own drawings. Although partially paralyzed from several strokes, he spent his last month in Italy writing a series of dialogues which were posthumously published under the titles "Consolations in Travel" and "The Last Days of a Philosopher." He suffered another stroke and was soon joined in Rome by his wife and brother, John. His recovery was slow, and he insisted on moving to Geneva where he died during the night of his arrival, May 29, 1829, at the age of fifty.

In generalizing on the self-motivation of Sir Humphry Davy, a characteristic which helped to produce one of the outstanding scientists of his era, the following may be cited: his love and respect for books; his imaginative mind which gave expression to new concepts and translated them into reality; the inspiration and encouragement derived from people with whom he shared common interests; public interest; and, finally, the encouragement given by his peers to the establishment of electrochemistry as a science.

He was torn in spirit between two loves—creative science and poetic expression. His friend, Wordsworth, the renowned poet, commented on Davy's integration of the study of chemistry with aesthetic satisfaction in his "Lyrical Ballads" (1802) when in the preface he wrote:

> Poetry is the first and last of all knowledge—it is as immortal as the heart of man. If the labours of Men of Science should ever create any material revolution, direct or indirect, in our condition and in the impressions which we habitually receive, the poet will sleep then no more than at present, but he will be ready to follow the steps of the Man of Science. The remotest discoveries of the chemist, the botanist, the mineralogist will be a proper object of the poet's art upon which it can be employed (13).

Manuscript submitted Oct. 12, 1972; revised manuscript received May 22, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Chlorine—Caustic Soda

I. Production.—U.S. production of chlorine reached a record level of 9,800,000 tons in 1972, an increase of 6.3% over 1971, and 1% over 1970, the previous record year. Canadian production was 922,120 tons, up 7.3% from the preceding year (1).

Production rates increased significantly in the second half of 1972. U.S. operations rose from a low of 86.7% of capacity in January to 93.7% in November and 95% by the end of the year. In Canada, production rates increased from 82.8% of capacity in January to 97.5% of capacity in December.

During 1972, there were start-ups of new or expanded chlorine facilities at four locations and the

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.
The material presented herein has been gathered from many sources, as noted in the References, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

shutdown of operations at two others. Eighteen plants converted their cells to coated metal anodes. In Canada there was one expansion, one shutdown, and two conversions to metal anodes. Total U.S. capacity in 1972 was 28,600 tons/day, slightly lower than in 1971 due primarily to the closing of one major production plant. In Canada, capacity increased by just over 3% to 2,814 tons/day (1-4).

Supplies of caustic continued tight. Most major producers were eliminating discounts on both caustic and chlorine. Suppliers announced price increases on chlorine of $6/ton in May. Caustic prices were similarly increased by the major producers in September to $81/ton for standard grade (5-7, 10). A further increase of $7/ton in the price of chlorine was announced by major producers in November and December. All companies concerned point out that the chlorine price increases are aimed at cutting back discounts and do not lift the selling price over the current $75 list (13). With the probability of tight supplies of both caustic and chlorine continuing, there seems little possibility of price erosion from current levels (6).

Only marginal capacity increases in the chlor-alkali industry are expected during 1973. These will be due largely to modernization of existing facilities. The year for substantial capacity increases will be 1974 when several plants in the 800-1500 tons/day range will come on stream. All of these plants will use diaphragm cells. Most companies are steering clear of mercury cells, at least for the time being (1, 8, 9). The Chlorine Institute estimates that by the end of 1974, expansion now announced will boost U.S. chlorine capacity of 28,600 tons/day by more than 6500 tons; an increase of over 24% (1). In 1972, 72.4% of U.S. chlorine production was from diaphragm cells and 24.2% from mercury cells; miscellaneous production from all other sources accounted for 3.4% (3).

The turnaround in the chlorine industry is being helped by the booming demand for vinyl chloride. New chlorine plants are needed to keep pace with this demand to avoid chlorine shortages in the 1974-1975 period. PVC expansions at eight locations amounting to 1.4 billion lb/yr additional production have been announced. Vinyl is the biggest single consumer of chlorine, accounting for 17% of all U.S. chlorine consumption (10, 11).

Chlorinated solvent demand, which fell off during 1971, is expected to aid chlorine growth with a 5-6% increase in solvents output during the next five years (9).

Caustic is continuing in short supply because of the continuing heavy demand of the paper and glass industries and year end improvement in the aluminum industry. With soda ash also in short supply, caustic users will be unable to switch until producers are able to bring in new trona capacity. PPG postponed a scheduled shutdown of its Barberton, Ohio soda ash unit to aid the supply of caustic products (12).

Although chlorine plant operating rates are about 95% and could climb higher during 1973, chlorine producers are concerned over the future impact of new technology on their markets. The N.L. Industries magnesium plant at Rowley, Utah will produce by-product chlorine. Du Pont is building a 500 tons/day chlorine plant at Corpus Christi, Texas to recover chlorine from by-product hydrogen chloride via Kellogg's Kelchlor process. Mobay is using Uhde electrolytic cells to recover chlorine from by-product muriatic acid (9).

The energy crisis with the attendant threat of power shortages and the probability of higher power rates adds to the concern of electrolytic chlorine producers

PPG's announced 1,500 tons/day plant at Lake Charles, Louisiana has been postponed for about a year because power is not available despite a firm contract for natural gas (9).

The Chlorine Institute in its February, 1973 meeting took note of the stringent environmental and Occupational Safety and Health Act (OSHA) standards and their impact on chlorine plant design. One industry spokesman estimated that capital costs for a new chlorine plant could increase 2.5-4.5% to pay for additional facilities to comply with regulations governing safety and plant effluents (20).

II—Current Changes in Chlorine Operations (2-4, 14-17, 19, 23)

Company and location	Type of cell	Total expanded capacity tons/day	Completion date
A. Production Started			
Linden Chloride Products Linden, N. J.	Start-up of existing Krebs mercury cell plant	460	½ in 1972 ½ in 1974
Vicksburg Chemical Co. Vicksburg, Miss.	Start-up of existing nonelectrolytic potassium nitrate-chlorine plant	90	September 1972
Pennwalt Corp. Portland, Ore.	Diamond diaphragm Expansion and conversion of existing plant to DSA®	330	December 1972
Vulcan Materials Co. Wichita, Kans.	Hooker diaphragm converted to DSA®	275	1972
Stauffer Chemical Co. St. Gabriel, La.	Uhde mercury cells	520	1972
Mobay Chemical Co. Baytown, Texas	Uhde HCl cells	200	1972
Canadian Occidental Petroleum Ltd. North Vancouver, B.C.	Added Hooker HC-60 cells with DSA®	395	1972
Hooker Chemical Corp. Montague, Mich.	Hooker S-3 conversion to DSA®	220	1972
Pennwalt Corp. Wyandotte, Mich.	Diamond cells converted to DSA®	260	1972
Velsicol Chemical Corp. Memphis, Tenn.	Added 8 Hooker S-4 cells with DSA®	150	1972
BASF Wyandotte Geismar, La.	Diamond cells converted to DSA®	410	1972
BASF Wyandotte Geismar, La.	Hooker S-4 cells converted to DSA®	400	1972
B. Plant Shutdowns Scheduled			
AMAX Vicksburg, Miss.		90	
Dow Chemical of Canada, Ltd. Sarnia, Ontario	Mercury	700	1973
BASF Wyandotte Geismar, La.	Uhde mercury	150	December 1973
Olin Corp. Saltville, Va.	Mercury	300	March 1, 1972
Sobin Chlor-Alkali Inc. Niagara Falls, N. Y.	All chlorine production diaphragm cells	50	February 1, 1972
Stauffer Chemicals Co. Niagara Falls, N. Y.	All chlorine production diaphragm cells	175	December 31, 1972
Domtar Pulp & Kraft Paper Ltd. Cornwall, Ontario	Vorce cells		August 1972
Canadian Industries Ltd. Hamilton, Ontario	All chlorine production mercury cells		End of 1974
Hooker Chemical Corp. Niagara Falls, N. Y.	Vorce cells		1974
Pennwalt Corp. Portland, Ore.	Gibbs cells		1972
Dow Chemical of Canada Ltd. Thunder Bay, Ontario	Mercury cells		1973

III—New or Expanded Plants Planned or Under Construction (2-4, 23)

Plant and Location	Type of cell	Capacity	Completion date
Diamond-Shamrock Houston, Texas	Diamond diaphragm cells	1,200 tons/day	1974
Georgia-Pacific Plaquemine, La.	Hooker H-4 diaphragm cells	800 tons/day	Late 1974
Hooker Chemical Corp. Niagara Falls, N. Y.	Hooker H-4 diaphragm cells	1,000 tons/day	1973-1976 Modernization
Hooker Chemical Corp. Taft, La.	Hooker H-4 diaphragm cells	900 tons/day	1974
PPG Industries Lake Charles, La.	PPG-DeNora diaphragm cells	1,500 tons/day	Not announced
Canadian Industries Ltd. Becancour, Quebec	Diaphragm cells	390 tons/day	1974
Du Pont Corpus Christi, Texas	Kellogg process —nonelectrolytic	500 tons/day	1st Quarter 1974
Shell Chemical Co. Houston, Texas	Hooker S-4 converted to DSA®	Expand to 375 tons/day	1973
Olin Corp. Charleston, Tenn.	Mathieson mercury cells	Double capacity	1973
BASF Wyandotte Geismar, La.	Diamond diaphragm cells Hooker diaphragm cells converted to DSA®		1972-1973
American Magnesium Co. Snyder, Texas	Restart magnesium cells	20,000 tons/yr	1973
Dow Chemical Co. Freeport, Texas	Dow diaphragm cells		2nd Quarter 1974
Dow Chemical Co. Midland, Mich.	Dow diaphragm cells		1st Quarter 1973
Dow Chemical Co. Pittsburgh, Calif.	Dow diaphragm cells		Middle 1973
Dow Chemical of Canada Ltd. Sarnia, Ontario	Replacement of mercury cells with Dow diaphragm cells		Mid-1973
N.L. Industries Grantsville, Utah	BASF—magnesium cells	225 tons/day	1972
Dow Chemical Co. Dallasport Washington	Magnesium cells	50,000 tons/yr	Not announced
Diamond-Shamrock Deerpark, Texas	Addition and conversion of diamond cells to DSA®	810 tons/day	1st Quarter 1973
Hooker Chemical Corp. Taft, La.	Conversion of existing S-4 cells to DSA® Conversion of existing C-60 cells to DSA® With increased load	700 tons/day	1973

DSA® is a registered trademark of the Electronor Corporation.

IV. Developments.—A. Metal anodes.—The North American chlor-alkali industry has continued its program of converting chlor-alkali cells to coated titanium anodes. More than 30 cellrooms are now completely converted from graphite and an additional 12 plants have signed contracts and are in various stages of change over.

These metal anodes are producing more than 7000 tons of chlorine each day and with the additional contracted capacity, more than one-third of the total North American market will be producing chlorine from the titanium-based anodes.

The actual capacity of several plants has been expanded by either running at higher current density or adding additional cells to run on the same electrical circuit. The first plant to be completely converted to DSA® has been in operation for over 3 yr, while many cells have now completed 5 yr operation using these anodes.

In a number of ways the titanium based anodes have played their part in minimizing pollution, particularly in relation to the diaphragm-type cells. An interesting statistic is the fact that during 1972, 1 billion kWhr of electrical energy has been saved by using these anodes rather than graphite.

The development of the application of metal anodes in processes other than chlor-alkali continues. Chlorate, hypochlorite, and metalwinning cells are successfully operating with titanium based anodes (23).

Olin-Mathieson who in early 1972 announced a new titanium anode jointly developed with ICI's Imperial Metal Industries Limited (34), is continuing to convert their Augusta, Georgia mercury cell plant to the new metal anode system.

Chemnor, Panama City, Panama, has received what it considers to be the second basic U.S. patent on dimensionally stable anodes. It has been granted U.S. Pat. 3,711,385 on the use of a platinum group metal oxide in the coatings for metal anodes used in electrolytic chlorine production. Its first key U.S. Patent, 3,632,498, was issued January 4, 1972 (35).

B. New chlorine process developments.—Hooker Chemical Corporation announced that it will use a 150,000A diaphragm cell using metal anodes and designated as the H-4 in new Hooker plants located at Niagara Falls, New York and Taft, Louisiana (25). Hooker also reports that the cell has been licensed to a major chlorine producer (4).

Diamond-Shamrock is offering for licensing, a diaphragm cell equipped with metal anodes for operations up to 150,000A (21).

A number of U.S. companies have announced designs of sodium hypochlorite cells for on-site treating of municipal sewage; Pacific Engineering's Pepchlor unit using lead dioxide electrodes; also Diamond's Sanilec cell and Engelhard's Chloropac cell, both using noble metal or oxide coatings on titanium. A unit is also available from Ionics, Incorporated of Watertown, Massachusetts which features a TFE ion exchange membrane developed by du Pont. The membrane keeps hydrogen from mixing with chlorine during production of sodium hypochlorite from salt. Ionics, Incorporated which designed the system has installed a unit in a Boston waste treatment plant (26, 27).

Asahi Chemical Industry Company of Japan announced a chlorine cell based on a special ion exchange membrane that produces caustic of mercury cell grade without the danger of mercury pollution. Asahi states that the costs are no higher than for caustic produced by orthodox methods (28). A $1.7 million 4400 metric ton/yr chlorine-caustic pilot unit will be erected at Asahi's Nobeoka Works on Kyushu Island (29).

Kellogg announced that it plans to install its Kelchlor process for converting large quantities of by-product or waste hydrogen chloride into chlorine at a cost under $20/ton including investment. The process is a variation of the Deacon process using homogeneous catalysis (oxides of nitrogen). The process will be installed in a du Pont fluorocarbon plant at Corpus Christi, Texas (18, 22).

Two companies have methods for deriving chlorine directly from seawater using electrolysis methods. Kyushu Electric Power Company of Japan with Kyushu University developed the method to keep shellfish and other marine life off seawater cooled coastal plant converters and piping instead of using liquid chlorine (30).

Naikai Engyo Company of Okayama, Japan is using an Asahi Glass process for concentrating seawater by means of electrodialysis using membranes. Salt is recovered by crystallization. The process is said to require less labor and far less space than solar basins. The plant will produce 150,000 tons/yr of salt (33).

DeNora announced a similar electrolyzer equipped with metal anodes designed by DeNora. Using seawater as the raw material a final active chlorine concentration of 1-2 gal/liter can be obtained. The unit is expected to find applications in sewage treatment as well as control of organisms in seawater cooling systems (31).

The chemical division of PPG Industries announced the development of a system for purifying disphragm cell caustic. The system, which is available for licensing, will upgrade standard grade caustic for some

critical applications by removing small but unacceptable amounts of sodium chloride, sodium chlorate, and metal impurities. Purity and clarity of product is much higher than achievable with PPG's ammonia extraction (DH) process. The system has been in commercial use by PPG for three years (32).

C. Mercury cells.—The closing or conversion of mercury cell plants that began with the publicity given the health hazards associated with mercury continued into 1972. However, much of the alarm that buffeted the industry two years ago has subsided. Production statistics from the Chlorine Institute indicate that in 1972 four more plants in the U.S. and Canada either shut down or announced conversion to diaphragm cells. Only two mercury cell plants started up in 1972 and virtually all future expansion plans announced for the 1973-1975 period are with diaphragm cells (1-3).

A number of companies have made available equipment and processes for controlling mercury emissions. Several that were announced during 1972 are:

Union Carbide	Molecular sieve process (Purasiv System) for removing mercury from hydrogen (36)
Sobin Chemical	A process using sodium borohydrate for mercury reduction (37)
Showa Denka	A process for recovering mercury from hydrogen (38)
FMC	New patented mercury recovery process available for licensing (39)
Monsanto	Removal of mercury from hydrogen and air streams with Brinks mist eliminator (40)

U.S. consumption of mercury during 1972 was estimated at 52,000 flasks, slightly lower than 1971. Mercury used as make-up in the production of chlorine declined by about 10%. U.S. production in 1972 was 6300 flasks, the lowest since 1950. About 20 mines were active during the year compared to 55 in 1971. At year's end there were less than 6 producing mines (24). Producing states are California 81%, Idaho 3%, with small amounts from Alaska, Nevada, and Texas (24). The average New York price of mercury during 1972 was $218/flask compared to $295 in 1971 and $408 in 1970. The price continued its downward trend, hitting $145/flask in May. Beginning about midyear, prices were strengthened by news of a cutback in Canadian production and the withholding of mercury from North America by Italy and Spain and the conservative selling policy of the GSA for its surplus mercury. By year end the price had recovered to about $280/flask. Only 500 flasks were sold by the GSA during 1972 (24).

Imports of mercury during 1972 amounted to 30,000 flasks compared to 27,000 flasks in 1971. Imports were from Canada (43%) Mexico (20%) Algeria (12%); Peru, Spain, and Yugoslavia combined (19%) (24).

Other Alkalis and Electrolytic Processes

Caustic Potash.—Caustic potash production in 1972 was 176,950 tons, down 10% from the 198,192 tons produced in 1971. A total of 13 plants reported caustic potash production during 1971 (41).

Diamond-Shamrock Chemical Company announced completion of a dry caustic potash plant at Delaware City, Delaware. The company stated that this was the first new plant to come on stream in over 10 years. The facility will produce dry caustic potash in flake and crystal form (42).

Sobin shut down its 23,000 tons/yr caustic potash plant at Niagara Falls, New York in February 1972. However, the company will continue to manufacture caustic potash at Hooker Chemical's mercury cell plant at Niagara Falls under terms of an agreement between Hooker Chemical Corporation and Sobin announced last year. The Hooker facility has a 36,000 tons/yr capacity (3, 43).

In early November, Sobin Chemical announced elimination of discounts on caustic potash and potassium carbonate to take effect January 1, 1973. The current list price for 45% liquid caustic potash in bulk shipments is $4.25 per hundred weight and $7.00 per hundred weight for 50% liquid caustic potash from west coast terminals (44).

Soda Ash.—Total production of soda ash for the year was 7.46 million tons, an increase of 5% over 1971. Of this total 3.23 million tons were natural soda ash, an increase of over 12.5% over 1971, and 4.23 million tons of synthetic soda ash, about the same tonnage as for 1971 (45, 46). Trona Mines of Wyoming supplied the major portion of the natural soda ash with the remainder coming from dry lake beds in California (48). The synthetic production was comprised of 1,867,000 tons light ash and 1,960,000 tons dense ash (46).

Demand for soda ash was quite strong this year and is expected to carry through 1973. Production was suppressed somewhat by gas shortages and problems with salt suppliers (47).

Forty-seven per cent of the total sodium carbonate produced in the U.S. goes into manufacture of glass, 25% into manufacture of other chemicals, 7% into pulp and paper, 6% into alkali cleaners, 3% into water treatment, 6% exported, and 6% for others. A tight caustic soda market in 1972 helped sodium carbonate to maintain its glass market (47).

Year end soda ash prices were quoted at $2.475/100 lb for light and dense soda ash. Bulk soda ash in car lots at the works was quoted at $1.775/100 lb for the light and dense soda ash (48).

A number of expansions by natural soda ash producers are under way in the west.

Hooker Chemical Corporation's plant at Searles Lake, California is based on evaporation of saline brine and will produce 150,000 tons a year of soda ash and other related chemicals. Completion of the facility is expected late in 1973.

Stauffer Chemical Company completed its 500,000 ton expansion at its Green River, Wyoming plant to bring the company's over-all capacity at this site to 1,500,000 tons/yr (49).

Kerr-McGee Chemical Corporation intends to increase the capacity of its 150,000 tons/yr plant at Trona, California to 1,050,000 tons annually. Completion is expected in 1974 (50).

Allied Chemical is currently doubling its capacity at Green River, Wyoming to 1.1 million tons annually. The expanded facilities are scheduled for completion early in 1973. Recently Allied announced another expansion phase which when completed in 1974 will give the Green River, Wyoming plant a capacity of 2.2 million tons of soda ash per year (50).

FMC is reported to have made a 500,000 ton expansion at its Green River, Wyoming plant to bring the plant's capacity to 1,750,000 annual tons. Another expansion of 750,000 tons at this facility is planned for completion by 1975 (51).

PPG's planned shutdown of its 600,000 tons/yr synthetic soda ash plant at Barberton, Ohio slated for the end of 1972 is being delayed until the end of March, 1973. Operations are being maintained as long as possible to help prevent a critical shortage of soda ash while new capacity is coming on stream by western producers. Shutdown of this plant is forced by pollution problems (52).

A modification in the Solvay system producing soda ash with HCl instead of calcium chloride as a by-product was unveiled at a recent annual American Institute of Chemical Engineers meeting. The proposed modification substitutes the use of reactive magnesia in place of limestone to causterize ammonium chloride. The pollution-free method for production of the synthetic soda ash is not given much chance of success in the U.S. because of the current trend toward natural soda ash. However, in industrial countries lacking natural soda ash the process might find a market (53).

Sodium Chlorate.—Preliminary data from the U.S. Department of Commerce indicates that U.S. produc-

tion of sodium chlorate in 1972 was 182,500 tons, a decrease of about 6% from 1971 production of 193,752 tons (54).

Sodium chlorate production facilities in the U.S. and their 1972 listed capacities are as follows (55):

Company	Capacity (tons/yr)
Brunswick Chemical Co. Brunswick, Ga.	7,000
Georgia-Pacific Corp. Bellingham, Wash.	3,500
Hooker Chemical Corp. Columbus, Miss.	62,500
Hooker Chemical Corp. Niagara Falls, N. Y.	15,500
Huron Chemicals Co. Butler, Ala.	4,000
Huron Chemicals Co. Riegelwood, N. C.	7,000
Kerr-McGee Hamilton, Miss.	32,500
Kerr-McGee Henderson, Nev.	30,000
Pacific Engineering and Production Co. Henderson, Nev.	6,000
Penn-Olin Corp. Calvert City, Ky.	31,000
Pennwalt Corp. Portland, Ore.	16,500
PPG Industries, Inc. Lake Charles, La.	15,000
Total	230,500

Paper bleaching accounts for about 70% of the U.S. sodium chlorate consumption followed by the production of other chlorates at 16% and herbicides at 7% (55).

Sodium chlorate stocks which reached a historical high of over 20,000 tons at the close of 1971 were reduced during 1972 to about 7000 tons by year's end (55).

Hooker Chemical will start up its $5 million 45,000 ton/yr sodium chlorate plant at Taft, Louisiana at the end of the first quarter in 1973. The plant will use a new cell design embodying metal anodes with precious metal coatings supplied from England by Marston Excelsior Limited, an affiliate of Imperial Metal Associates. This plant was originally scheduled to come on-stream in the first quarter of 1972 but construction was held off because of the slowdown in the southern pulp and paper industry, the prime outlet for chlorate (56, 57).

Kerr-McGee has just completed incremental expansions of 10% at both its Hamilton, Mississippi and Henderson, Nevada production sites. Capacity of each plant is now 33,000 tons yearly (59).

Brunswick Chemical Company is considering an expansion that could add 1000 tons/yr capacity in 1973 (55).

During 1972, Electric Reduction Company of Canada, which supplies over 60% of that country's needs, announced expansion at both its North Vancouver and Buckingham, Quebec plants. The present capacity at North Vancouver is 45,000 tons per year. The 20% expansion planned for Buckingham will increase annual capacity of that site to about 35,000 tons (58).

Squamish Chemicals Limited, a subsidiary of GOW Enterprises, announced that a 12,000 tons/yr sodium chlorate plant had begun production at Squamish, B.C. Most of its output will be sold to the MacMillan, Bloedel Mill at Harmac, British Columbia and the Cariboo Pulp and Paper Mill at Quesnel, British Columbia (60).

A further market for sodium chlorate could develop if plans to use solid propellant boosters for the space shuttle program materializes. This program, scheduled for the 1980's may require up to 100 million lb/yr propellant. The propellant used will most likely be a synthetic rubber mixed with ammonium perchlorate (63).

The list price for pulp and paper grade sodium chlorate remained at $134.50/ton for most of the year. Late in 1972, as stocks were diminished, major producers announced price increases of $6/ton. This action eliminated discounts and raised the list price to $135/ton (61, 62).

Sodium.—Metallic sodium production in 1972 totaled 159,886 short tons, an increase of 4.5% from the 153,075 tons in 1971 (64). Behind this increase in sodium production was a strong domestic and export demand for lead antiknock compounds. U.S. production of lead antiknock compound was up by 8% in 1972. With crude oil supplies tight and refiners straining to squeeze all the gasoline they could out of the barrel, refiners were using all the antiknock compounds they could get to improve the octane rating of their product. U.S. exports also filled the gap caused by a strike at Octell, Limited, the United Kingdom's only antiknock producer.

However, with low lead and no lead regulations still very much a factor, decline in sodium production is expected to reoccur around late 1973 (65).

About 83% of the sodium goes into tetraethyl and tetramethyl lead manufacture, 4% metal reduction, and 13% miscellaneous (67).

Lockheed Missiles and Space Company has developed to the prototype stage, fuel cells that use alkali metals such as sodium and lithium. The company has an undisclosed way to control the reaction; it is being used not only in a straightforward "static power cell" but also a dynamic cell that directly converts the electrochemical energy to rotational shaft energy without the need for a conventional electric motor (66).

Prices for sodium remained fairly constant during the year. Regular fused material in drums was quoted as 26.5-27.5¢/lb and the 12 pound brick at 30¢/lb (68).

Aluminum.—The U.S. aluminum industry increased production of primary metal by 4% to about 4,075,000 short tons, according to the Bureau of Mines, U.S. Department of the Interior. The relatively small increase in production in 1972, despite the estimated 11% gain in consumption resulted in a nearly balanced supply-demand position at the close of the year, compared with a severe oversupply situation at the end of 1971 (69).

Although demand grew markedly during 1972, prices remained low. Major producers adjusted the price for primary metal to 25¢/lb in May. This was below current list prices, but 1¢/lb above market levels (70). Prices on a broad range of aluminum products were firming by years end. Discounts of 1.5-3¢/lb on commodity sheet and foil products were eliminated (71).

With inventories reduced, smelters which operated at 84% of rated capacity during 1971, gradually increased output to a 93% operating level by the end of 1972 (72).

Major producers announced restarting of pot lines to meet the growing demand. In early 1972, Alcoa restarted a 20,000 tons/yr capacity line at its Warrick, Indiana smelter (73). Later in the year, Reynolds restarted two 25,000 tons/yr lines at Troutdale, Oregon; Kaiser started a 40,000 tons/yr line at Ravenwood, West Virginia; and Alcoa a 30,000 tons/yr line at its Rockdale, Texas smelter (74, 75).

Reynolds also plans to have two additional pot lines with a capacity of 35,000 tons/yr in operation at its Listerhill reduction plant in Sheffield, Alabama (73).

Olin Corporation announced in late November, 1972 that it planned to dispose of its unprofitable aluminum business. This would include partial ownership along with Revere Copper and Brass of a primary aluminum reduction complex, as well as a sheet and plate mill, four extrusion plants, and an architectural aluminum products operation (76).

The aluminum market growth is expected to be ahead of the economy as a whole as well as ahead of the rest of the base metals list. The average growth rate for the 1969-1980 period is expected to be 4.8% compared to 4.0% for copper, 3.4% for iron and steel, and 3.8% for the GNP for the same period. Rapid growth for aluminum is expected in industries supplying machinery, computers, and related equipment, electrical machinery and equipment, metal containers, and transport equipment (77).

Alcoa announced a new electrolytic process for aluminum that will cut pollution and reduce power re-

quirements. It plans a 15,000 tons/yr prototype for the process which should be operating in 1975. The new process starts with alumina which is treated with chlorine to form aluminum chloride. The chloride is reduced electrolytically providing chlorine for recycle. The approach eliminates emissions of fluorides and could cut electrical power consumption by 30% (78, 79).

Another process, called the Toth process, announced by the Applied Aluminum Research Corporation (AARC) of New Orleans, begins with a chlorination step that can use many types of alumina including some low grade minerals. Impurities are separated by fractional condensation. Aluminum chloride is then reacted with manganese metal to produce aluminum metal and manganese chloride (80).

The reaction proceeds quickly and at moderate temperatures, as low as 500°F. By-product manganese chloride from this process is converted to the oxide and the chlorine recycled. The manganese oxide is reduced carbothermally. Operating costs of the Toth process could be 20-45% less than for the conventional Bayer-Hall process (80).

Both Reynolds Metals and Kaiser Aluminum are licensing a USSR developed technique for ingot casting. The ingots are free of the undesirable "skin" that must be trimmed off those produced conventionally. In the Soviet method, skin formation is forestalled because the casting molds use an electromagnetic field that prevents the aluminum from touching the mold walls (82).

Officials of the Georgia Department of Industry and Trade were trying to get funding to build a pilot plant that would produce 5 tons/day alumina from kaolin clay via a nitric acid extraction process. The alumina content of kaolin averages 35-39%. Georgia has a 5 billion ton deposit of kaolin in the middle of the state. Costs for extraction would be roughly the same as from bauxite. It would have the advantage of being a fully domestic raw material whereas much of the bauxite consumed in the U.S. is imported (81).

Alcoa, as a hedge against future shortages of bauxite, announced purchase of a large deposit of anorthosite, a rock composed almost entirely of feldspar from which alumina can be recovered (83).

Magnesium.—Magnesium production hit a record 125,000 tons in 1972 due to a substantial increase in the fourth quarter. Fourth quarter output was approximately 34,500 tons compared to 29,000 tons for the previous quarter and 31,101 tons for the final quarter of 1971. The total output for 1971 was 123,485 tons (84).

U.S. consumption of primary magnesium metal in 1972 was 105,000 tons leaving an excess of 20,000 tons (85). Based on ten-month figures, the U.S. was a net exporter; 15,454 tons exported to 4,108 tons imported (84).

In plant operations and proposals, American Magnesium Company expects to have its 20,000 tons/yr plant in Snyder, Texas back into operation around the end of 1973 and plans to eventually increase production to design capacity of 30,000 tons/yr (85).

In Utah, N.L. Industries' magnesium and chlorine plant at Rowley, on the Great Salt Lake, started limited production with some trial shipments of 5,000-10,000 pound lots. Their December price list quoted 36.5¢/lb for solid ingot (86).

The proposed Alcoa plant at Addy, Washington will apparently use the Frech Magnatherm Process to extract magnesium and silicon from dolomite limestone in the area, Alcoa having received license for its use from Pechiney Ugine Kuhlmann. Construction on the $50 million, 40,000 tons/yr, facility is slated to begin in April, 1973 with start-up proposed for March, 1975 (87, 88).

Elsewhere in magnesium, Dow Chemical Company, which produced most of the 125,000 tons output last year, upped its prices by 1¢/lb in January, 1973. The new prices are 99.8% pig, 38.25¢/lb; AZ91B die casting, 33.75¢/lb; notched ingot, 39¢/lb. Dow also increased prices of magnesium oxide by $10/ton bulk (89).

Battelle's Magnesium Research Center in Columbus, Ohio is investigating a method of fluxless melting and casting of magnesium. This involves using SF_6 gas as an oxidation inhibitor in concentrations of 9.1% instead of flux. They look for a savings in price of 4¢/lb as well as a decreased risk of air pollution, less by-product sludge, and other benefits (90).

In Detroit, enthusiasm was rising due to new casting methods, the Frech process, as well as the fluxless melting technique. The Frech process is a hot casting method used in Europe which allows for increased automation as well as greater production speed (91). The enthusiasm for magnesium is due to a desire for less weighty engine elements for new automobiles which have more components to meet safety requirements. American Magnesium is known to be evaluating one or more large (119,000A) electrolyzers of Russian design (85).

Manganese.—There was no actual production of manganese ore containing 35% or more manganese in the United States in 1972 according to the Bureau of Mines, U.S. Department of the Interior.

Production of manganiferous ore, in Minnesota and New Mexico, was at a reduced rate from that of the previous year. Imports of ferromanganese were at an appreciably higher rate than in 1971, with the Republic of South Africa and France the principal sources. General imports of manganese ore containing 35% or more manganese were expected to be down to 1,800,000 tons with Gabon and Brazil continuing to be the two largest suppliers.

Domestic consumption of manganese was again expected to decrease from that of the previous year; a figure of 2,050,000 short tons is indicated. Consumption of ferromanganese and silicomanganese appeared to be little changed from 1971. Problems of pollution control, power availability, and imports, continued to face the producers of manganese ferro alloys (92).

In March, the American Metal Market dropped its price quotation for manganese ore containing 46-48% manganese from 59-63¢ nominal to 58-61¢ nominal per long ton unit. The producer's price for standard high carbon ferromanganese having a minimum manganese content of 78% continued at $190/long ton, FOB producer plant. American Metal Market's quote for the 78% alloy was $178-$180/long ton. Standard electrolytic manganese metal remained priced at 33.25¢/lb FOB producer plant for shipments of 30,000 lb or more (92).

South Africa's Electrolytic Metals Corporation is planning to boost electrolytic manganese production from 12,000 to 17,500 tons/yr. The added tonnage will be available by July, 1973 since only increased cell and auxiliary capacity is needed (93).

Delta Manganese, a subsidiary of London based Delta Metal Company Limited, is in the process of building an electrolytic manganese metal plant at Nelspruit, Eastern Transvaal, Republic of South Africa. Plans call for production to start by 1974 with initial capacity of 16,000 tons/yr to be achieved within two years (92).

The world's first commercial pellet plant for manganese ore, that of Industria e Comercio de Minerios S.A. at Santana, Amapa Territory, Brazil produced its first pellets in May (92).

The General Services Administration continued to offer surplus metallurgical grade manganese ore for sale on a negotiated basis with deliveries limited to 30,000 tons/fiscal yr. The offers met with little response (92). Interest was shown in manganese catalysts for the control of automotive emissions, with indications of cost and technical advantages over platinum. Bell Laboratories reported on its work with rare earth oxides of manganese. In Japan, Mitsui Mining and Smelting Company was prepared to market a newly developed manganese catalyst afterburner (92).

The Ethyl Corporation announced a manganese-based fuel additive package for use with lead free gasoline. According to Ethyl, the additive would bridge the gap between leaded and unleaded gasolines and will not poison platinum catalysts used in automobile exhaust systems (95).

The use of manganese additives to gasoline to improve their octane rating and to fuel oil to reduce pollutants and smoke from stack gases and exhaust from turbines has been criticized because of the neurological effects associated with long-term inhalations of high concentrations. An industry spokesman pointed out that the increase of manganese in the air from fuel was extremely small and posed no health problems. Manganese in the air of all major cities has been under observation by the Environmental Protection Agency and the U.S. Public Health Service for a number of years. Concentration ranges up to 14 μg manganese/m^3 have been noted. However, the average is much lower and none of it comes from fuel use. Apparently there are no neurological effects below 5000 μg/m^3 (94).

Hughes Tool Company launched a giant barge for a project in the Pacific involving the deep sea mining of manganese nodules from the ocean floor at depths up to 12,000 feet (96).

Beryllium.—Domestic consumption of beryllium ore decreased somewhat in 1972 from that for 1971. Imports declined again in 1972 to 3900 tons, down 7.2% from the preceding year. At mid-year the government stockpiles contained 229 tons of beryllium metal and 7,387 tons of beryllium-copper master alloy, both unchanged from 1971. Stockpiles also contained 20,296 tons of beryl ore (11% beryllium oxide equivalent), 712 tons less than the 1971 figure. U.S. production, approximately equal to last year, was almost entirely from Brush-Wellman's Utah mine (97).

Of the total beryllium demand, two-thirds of the metal went to alloys which are coming into increased use in electrical components. Because of beryllium-copper's high strength, electrical conductivity, and fatigue resistance, the alloy is being sought for electrical connectors in areas which require high reliability such as business machines, aircraft, communications, etc. (98).

A beryllium-titanium combination was found to improve qualities which allows fabrication of turbine blades of better aerodynamic shape, capable of higher speeds with superior resistance to both fatigue and to foreign objects striking the blades (99).

In May, Brush-Wellman was awarded a $13.5 million contract by the Navy to supply beryllium components for the Poseidon missile program (100).

During 1972 the price of the pure metal remained constant at $30-35/STU though some price reductions were posted for selected beryllium copper products (101).

Chromium.—Mining of chromite ore in the United States ceased in 1961; however the United States in 1972 continued to be one of the world's largest consumers according to the Bureau of Mines, U.S. Department of the Interior. Domestic consumption of chromite increased about 5% compared with 1971. The refractory industry accounted for most of the increased usage (102).

Total consumption of chromite during 1972 was 1,138,000 tons, an increase of 4.2% over 1971's 1,092,967 ton consumption (103).

Imports of chromite were lower than domestic consumption, but shipments of chromite from government stockpiles, sold in prior years, helped to reduce drawdown of the consuming industries stocks. Imports of chromium alloys reached a new yearly record high in August and were expected to reach 140,000-150,000 tons for the year (102).

A total of 12,556 tons of chemical grade chromite and 13,620 tons of refractory grade chromite were sold under these programs (102).

Published prices of chromite in 1972 per long ton FOB cars Atlantic ports, were as follows: South African (Transvaal) 44% chromium oxide, no ratio $24-27; Turkish 48% chromium oxide, 3 to 1 chromium to iron ratio $55-56 and Russian, 48% chromium oxide, 4 to 1 ratio, $45-46.50/metric ton loading point. This compares with the 1971 published price of $55-56 on the same pricing basis (102).

Some chrome ore was brought into the U.S from Rhodesia after March. Importation was legalized by the Byrd Amendment to the Military Authorization Act of 1971 which lifted the embargo on Rhodesia chrome. Without Rhodesian chrome domestic producers would be largely dependent on the Soviet Union for their requirements. Russian chrome increased from $25/ton to over $70 at one point in 1971, since the economic sanctions against Rhodesia went into effect in 1966. With the lifting of the embargo, prices have declined to their present levels (104, 105, 107).

Although chromium finds its largest market in the metallurgical refractories and chemical industries, the use of chrome-plated plastics by the automotive industry is growing at a rapid rate. Techniques are now available and in commercial use for applying chrome plate onto a variety of plastic surfaces. At the present time about 90% of the plastic currently being plated is ABS. The big gainers in the trend to plated plastics are plastics and suppliers of processes for treatment and plating. The main losers are the zinc producers and the zinc die casters (106).

Chrome producers are also looking to a substantial new market for chrome alloys which is expected to develop as the automotive industry adopts antipollution devices in new model cars. This could account for a total annual consumption of 40,000 tons of contained chrome on all new model cars after 1974.

Titanium.—The general titanium metal picture in 1972 showed improvement over 1971. Sponge consumption and ingot production were 7.5 and 10% higher, respectively, consumption of scrap and ingot increased 27% and 14% respectively, and stocks of sponge were reduced 300 tons during the ten month period (108).

	Metal production (short tons)			Metal consumption (109)		
Type	1971	1972	% Change	1971	1972	% Change
Sponge				12,145	13,068	7.5
Ingot	18,387	20,267	10	17,058	19,498	14
Scrap				6,149	7,801	27

Estimated industry capacity is 85 million lb for ingot and 47 million lb for sponge (110). Titanium Metals Corporation of America (TMCA) and Reactive Metals Incorporated (RMI) Companies, having reduced their inventories, reopened their sponge producing plants in February and April respectively to meet current orders. On June 28, GSA announced contracts for these companies. Each firm will deliver 6.5 million lb of sponge over a 2 yr term. These purchases by GSA will bring the stockpile holding up to 67 million lb (108).

Negotiations with Oregon Metallurgical Corporation for similar sponge deliveries have not been concluded. Importation of titanium sponge mostly from Japan totaled 4,000 short tons, an increase of 45% from 1971. Exports of mill products were one million pounds, an increase of 25% over 1971 (110).

The following chart shows the shifting pattern for titanium mill products (111):

	1961	1971
Commercial aircraft		
Airframe	4%	15%
Engine	10%	31%
Military aircraft		
Airframe	26%	10%
Engine	37%	20%
Missiles and space	16%	7%
Helicopter and ordnance	2%	1%
Industrial	5%	16%

Three general applications for titanium have formed the basis for the most recent growth in the industrial

category; the expanding use of titanium as a substrate for anodes used in the production of chlorine and related products, use of cathode structures in metal electrowinning processes and the evolution of low-cost welded tube product for containing brine or chlorine solution during heating or cooling processes and also for power plant surface condensers (111).

Domestic prices for titanium sponge (99.3% purity) at $1.32/lb remained unchanged for the second year while the same grade Japanese and United Kingdom sponge remained at the 1970 level of 1.20 to 1.25 U.S. dollars per pound. The price of rutile pigment at year end was 26 to 27¢/lb.

The titanium pigment industry found itself in tight supply throughout most of 1972. Domestic consumption of titanium dioxide was 780,000 tons, up about 42,000 tons from 1971. This was met by domestic production which was virtually the same as last year at 680,000 tons with the difference coming from imports.

Du Pont is reported going totally to the chloride route to produce titanium dioxide. The sulfate process plant in Baltimore, Maryland was closed and its production switched to Edge Moor, Delaware where the chloride process is used. In addition, Du Pont is doubling the capacity at New Johnsonville, Tennessee to 228,000 tons. Kerr-McGee, which has a 37,000 ton unit at Hamilton, Mississippi, is expanding the rated capacity of that plant in excess of 46,000 tons after the first quarter of this year (112).

Rutile production was reported for the first time in the United States since 1967 with the start-up of Titanium Enterprises' mine located at Green Cove Spring, Clay County, Florida. Planned production rate for total heavy mineral concentrate is 140,000 tons annually.

Benilite Corporation of America has licensed its process for converting ilmenite to rutile to Taiwan Alkali Company; production is expected late in 1973.

For the first time reconstituted rutile made from ilmenite became a factor in the market; imports were mainly from Australia and Japan.

Du Pont concluded an agreement with Allied Minerals NZ for joint operations of the heavy sand deposit at Eneabba, Western Australia. A pilot plant facility is to be operated first to study the full-scale production feasibility (108).

Lithium.—Production and consumption of lithium compounds during 1972 was at a record high according to the Bureau of Mines, U.S. Department of the Interior. Lithium carbonate produced from brines in California and Nevada accounted for much of the increase.

As a result of trade sanctions, domestic imports from Southern Rhodesia were nil for the fourth consecutive year. Previously they were over 90% of domestic imports. Although domestic exports were strong, Russian exports continued to penetrate the foreign market (113).

Foote Mineral Company mined spodumene at Kings Mountain, North Carolina and recovered lithium carbonate from brines at Silver Peak, Nevada. Lithium carbonate was recovered from brines at Trona, California by American Potash and Chemical Corporation. Lithium Corporation of America mined and milled spodumene at Bessemer City, North Carolina. Great Salt Lake Minerals and Chemical Corporation formed by Lithium Corporation of America and Salzdetfurth A.G., West Germany, harvested salts from the Great Salt Lake in Utah.

Processors of lithium raw materials to lithium primary products were Foote Mineral Company, American Potash and Chemical Corporation, and Lithium Corporation of America. Production data are not available for publication (113).

Industrial domestic uses were in ceramics and glass, greases, welding and brazing fluxes, air-conditioning equipment, rubber and pharmaceuticals.

Important developing markets for lithium were the large-scale use of lithium carbonate by the aluminum industry and the increased use of lithium hypochlorite for bleaches and as a sanitizing agent for swimming pools (113).

Much of the new research in lithium has been directed towards the development of light weight, high energy batteries. The AEC is working on a lithium-sulfur battery to power an automobile. The battery can deliver more than 100 Whr/lb, or five times more than the power of lead-acid batteries (114). Foote Mineral continues to support an active development program on lithium batteries for military uses (115). Lockheed announced development of a light alkali metal battery fueled with water and either sodium or lithium. According to Lockheed the battery will produce 10-100 times more electricity than a lead-acid battery when compared on a pound for pound basis (116). Other companies reportedly working on primary lithium batteries for consumer use are GTE Laboratories, ESB Incorporated, and P. R. Mallory (114).

In another field of research, the National Institute of Mental Health reported that the daily use of lithium carbonate may be effective in preventing broad swings in mood in people who suffer from manic-depressive state (117).

The price of 99.9% pure lithium metal at year end was $8.18/lb in 1000 lb lots; lithium carbonate was 52.5¢/lb in carload lots (118).

Copper.—During 1972 copper production from U.S. mines started relatively low and fluctuated greatly during the year, from 130,000 tons in January to a high of 147,000 tons in March to a low of 115,000 in July. Total mine production of recoverable copper was 1.64 million tons, an increase of 9% over last year's figures. Smelter output from domestic ores increased by 12% over 1971, to a figure of 1.67 million tons. Refinery production from primary materials was estimated to increase 13%, to a record high of 1.8 million tons. Production of refined from secondary materials was 420,000 tons, 5% greater than in 1971 (119).

Consumption of copper during 1972 was up 7% over the 1971 figures, to 2.22 million tons. U.S. imports of unmanufactured copper totaled 415,618 tons, up 15% from 1971. U.S. exports of refined and scrap copper was 200,000 tons, down 3% from 1971. Fabricator stocks of copper in all forms trended erratically downward from 511,000 tons at the start of the year to 471,000 by the end of October.

Over-all prices in 1972 on the domestic scene decreased 0.6¢/lb for electrolytic wirebar copper to 51.44¢/lb, while on the LME wirebar copper was quoted at an average of 48.53¢/lb, an increase of 0.04¢/lb (119). Prices were highest in March, 53.75¢/lb, and lowest in November, 47.00¢/lb, for copper in the domestic outside merchant market (120).

In the areas of plant proposals and announcements, Anaconda Company has started construction of a $22 million plant at Anaconda, Montana which is expected to produce 36,000 tons/yr of copper. The method of production uses ammoniacal hydrometallurgy to convert sulfide ore to copper metal. The process utilizes only chemical and electrical techniques eliminating the roasting and smelting steps that cause fumes, dust, and sulfur dioxide pollution. In this process, devised by research personnel at the Anaconda Primary Metals Division, Tucson, Arizona, copper concentrates are leached with ammonia at low temperature and pressure. The copper is extracted from this using an organic solvent and then an acid electrolyte, and finally, the metal is recovered by electrowinning. The main advantages of the process are that the equipment and plant costs may be reduced to one-tenth and one-half, respectively, that of conventional plants with the added bonus of being pollution free (121).

Also in copper production in January of 1972, Phelps Dodge Corporation disclosed that it had discovered a mineral zone in the Northwestern area of the Cape Province of the Republic of South Africa. The mineral zone is reportedly rich in lead and copper with minor zinc and silver values. Results from test drillings and

assays place the copper content at 0.8% and lead at 1.5%. The deposit is estimated to be 130 ft thick and 3000 ft long (122).

In Pinto Valley, Arizona, Cities Service Company started site preparation work on a 40,000 tons/day mine and mill complex. Two and one-half years will be needed to bring the ore body into production including an open pit mine which is expected to produce 125 million lb/yr of recoverable copper and molybdenum. The ore will be processed at the Inspiration Consolidated Copper Company facilities located nearby (123).

American Smelting and Refining Company has plans for a new copper mine near Casa Grande, Arizona, and a plant at Tucson for chemically recovering the copper. The plant and mine should be ready for operation by 1974 (124).

Phelps Dodge anticipates a mid-1974 starting date for operations at its Metcalf copper mine near Morenci, Arizona. The mine is expected to produce 50,000 tons/yr of ore (124).

A new pollution-free process to produce copper, elemental sulfur, and high grade iron from copper concentrates is being studied for commercial feasibility at a plant built and operated by Cyprus Metallurgical Process Corporation near Tucson, Arizona (125).

In a move which angered Chile's President Salvador Allende, a French court issued an injunction blocking distribution of Chilean copper in France in October. The court action was requested by Kennecott Copper on the grounds that despite the nationalization of its El Teniente mine it still retains its rights to the copper from the mine. Kennecott officials said they were prepared to take action throughout Europe if the court case was lost in France (126).

Still occupying a place in the limelight is the environmental part of copper production. Stringent limits on sulfur dioxide emissions have been declared and must be met by 1975. Various methods are being tried to achieve these limits using scrubbing or concentrating techniques, hydrometallurgical processes, and other methods to keep the gases from polluting the atmosphere. No matter which method is used, however, it appears certain that to meet standards in time great amounts of money will be needed and this will, no doubt, influence the copper market greatly in years to come (127). Capital investment costs to meet pollution controls through 1976 are estimated to range from 300 to 690 million dollars. Depending upon costs and foreign competition, it was estimated that U.S. supplies may be reduced 3.5-14% and U.S. prices increased by as much as 8% (128).

Development of precious metal anodes in conventional solvent extraction electrowinning facilities will permit electrorefined quality copper to be produced and could in itself prove to be a major factor in determining an acceptable solution to the pollution control problem (129).

Nickel.—Data published by the U.S. Department of the Interior indicate that the level of activity in the domestic nickel industry in 1972 was changed little from that in 1971. Domestic mines produced approximately 17,000 tons of nickel from laterite ore, from which the processing plant recovered about 13,000 tons of nickel in ferro nickel. By-product plants recovered about 2500 tons of nickel in various forms. Primary nickel consumption was approximately 165,000 tons, up 18% from 1971 (130).

A worldwide surplus of nickel supply over demand continued for the second full year. However, depressed demand, which was partially responsible for the surplus was alleviated in the U.S. by increased industrial activity in the last three quarters of the year (130).

Congress authorized disposal of all the nickel held in the national stockpile. Reportedly it will be sold to the Treasury Department for use by the mint (130).

Increasing imports of ferro nickel for consumption in the U.S. marked a substantial change in the pattern of nickel usage. Imports of ferro nickel from Japan, the Dominican Republic, New Caledonia, and Greece were reported (130, 133).

With nickel inventories near record highs at the start of 1972 major producers such as International Nickel Company and Falconbridge Nickel Mines announced cutbacks in production of 30% and 5% respectively (131).

Amax Nickel Refining Company announced that the metal refinery at Port Nickel, Louisiana purchased from Freeport Minerals, would be expanded and reactivated. The plant, originally built to handle nickel and cobalt concentrates from Moa Bay, Cuba, will start up in early 1974 with a capacity of 80 million lb/yr of nickel. Initial feed will be 54,000 tons of nickel-copper matte from Bamangwato Concessions Limited (Africa) (132).

By the end of 1972 the nickel business appeared to be improving slowly. However, primary metal producers indicated it might be a year or more before consumption gets fairly close to capacity. There appears to be optimism in the outlook for more growth in nickel plating, automobiles, housing, and accessories for auto catalytic units and the coming Wankel engine (133).

A high-yield hydrometallurgical process for recovering nickel from laterite and sulfide ores has been developed by Republic Steel. A 92% recovery is claimed. The system can handle grades of ore over a wide range, including low-grade sulfide concentrates, and it does not emit sulfur oxide gases (134).

Prices for primary nickel increased by 20¢/lb to $1.53 on the first of September, 1972.

Zinc.—U.S. mine production of zinc continued its decline through 1972 to 491,000 tons, down 2% from 1971 (135). The number of states reporting mine production in 1972 dropped to 17, two less than 1971. Ten states showed decreases, seven registered increases, and no production changes were reported from Montana or Nevada (136).

Smelter production from ore declined 150,000 tons. The decline resulted from lower mine production and a drop in imports of zinc concentrates. General imports of zinc in concentrates decreased 24% below that of 1971 to approximately 260,000 tons which is less than half the tonnage received in 1970 before the smelter closures (137). U.S. zinc metal production decreased by 62,000 tons to 774,500 tons. Japan in 1972 became the world's largest producer of zinc metal with 883,500 tons (138).

Imports of zinc metal increased to 525,000 tons, a 64% increase over 1971. Canada accounted for over half of the 200,000 ton increase in imports for 1971 (136).

Authority was given in April to dispose of 515,200 tons of zinc from the national stockpile for domestic use. Of this quantity of zinc, 171,375 tons had been disposed of by November, 1972.

If this rate of disposal continues, the surplus of zinc in the stockpile will be used up in two more years instead of nine as originally planned (136).

U.S. consumption of zinc in 1972 is indicated below (139):

Bases: Recoverable zinc content	Tons 1971	Tons 1972	% Change
Zinc slab	1,254,059	1,428,632	+14.0
Ores	119,258	140,400	+18.0
Zinc base scrap Copper base scrap Al-Mg base scrap	277,272	300,000	+8.2
Totals	1,650,589	1,869,032	+13.2

Consumption of zinc in the United States rose 13% to slightly over 1.87 million tons for an all time high. Increases were recorded for all but one of the broad use categories for 1972 as compared with 1971; galvanizing up 6%, brass and bronze up 38%, zinc-base alloys up 15%, rolled zinc up 40% and zinc oxide up 21%. The decline of 8% for other uses included wet batteries, zinc dust, light metal alloys, and desilverizing lead (136).

The cost-price squeeze was a major factor in the closures of five mines and two electrolytic smelters. The closure of the two smelters accounted for a capacity reduction of 252,000 tons and removed Anaconda from the zinc business. Two horizontal retort plants are scheduled to close in December, 1973, reportedly because it is uneconomical to install required air-pollution control equipment (137). Industry wide an estimated 62 million dollars will be required for the zinc industry to meet the 1976 pollution control standards. This will accelerate the trend towards the demise of high-cost producers (140). However, on the positive side a new zinc-copper mine was brought into production early in October by Kerramerican Incorporated at Bluehill, Maine (136). Asarco is planning to expand its 108,000 tons/yr electrolytic plant at Corpus Christi and in addition is planning a new electrolytic plant to go into operation by 1975 at another location (141).

With regard to technological improvements, the jarosite process in use at Texas Gulf Incorporated's new 120,000 tons/yr electrolytic zinc plant near Timmins, Ontario is reported to increase over-all zinc yield from 88 to 93%. The 5% boost in production is obtained by preventing zinc losses as zinc ferrite in the leaching operation (142). A process in use at Bunker Hill's Kellogg, Idaho electrolytic zinc plant is purported to reduce the mercury content of acid obtained from ore roasting at the plant from 100 ppm to less than 1 ppm (143).

The price of domestic zinc (prime western) was frozen at 18¢/lb by the Cost of Living Council, but the price of foreign zinc for sale in the U.S. increased three times during the year and in December reached 19.5, 20.00, and 20.25¢/lb depending on the source, country, and company (137). A new grade of foreign zinc was introduced in December, continuous galvanizing zinc (CGG), and was priced at the 20.25¢/lb (144). A number of requests to the Cost of Living Council have been made to declare zinc an international commodity and free from price control but have been rejected. There is some feeling that reconsideration is being contemplated, and some favorable action may be forthcoming.

Electrical Energy

U.S. power generation.—The following tables summarize the production and consumption of electrical energy for the twelve-month period January through December, 1972.

Production of Electrical Energy (Billion-kWhr)

	1971*	1972* (157)	Change (157)
Production by electric utilities			
Coal fired plants	714.8	770.6	+7.8
Gas fired plants	375.9	375.7	0.0
Oil fired plants	218.2	272.5	+24.9
Nuclear plants	37.9	54.0	+42.5
Total fuel burning	1,347.6	1,472.8	+9.3
Hydroelectric	266.3	272.7	+2.4
Total	1,613.9	1.745.5	+8.2
Private industry, self-generated	103.5	106.1	+2.5
Total U.S. power consumption	1,717.5	1,851.6	+7.8

* Both 1971 and 1972 figures are preliminary.

Installed Generating Capacity (Million-kW)

	1971	1972 (157)
Public owned capacity		
Steam	42.8	46.6
Hydro	36.8	37.3
Nuclear	0.9	0.9
Total	80.5	84.8
Investor owned capacity		
Steam	260.0	281.1
Hydro	19.1	19.3
Nuclear	7.8	14.4
Total	286.9	314.8
Total electrical utility industry capacity*	367.4	399.6

* Not including privately owned capacity.

Fuel Consumption—Electric Utility (12 months ending Dec. 31, 1972)

	1971	1972 (157)	Change (157)
Coal—millions of tons	327.93	351.0	+7.0
Gas—billions of cu ft	3992.98	3978.7	−0.3
Oil—millions of barrels	396.24	493.9	+24.6
Coal and coal equivalent—millions of tons	618.16	646.3	+4.5

Sales to Ultimate Consumers (12 months ending Dec. 31, 1972) Total industry (billion kWhr)

	1971	1972	Change
Residential	479.1	511.4	+6.8
Commercial	333.7	361.8	+8.4
Industrial	592.7	639.5	+7.9
Other	60.9	64.9	+6.5
Total	1466.4	1577.7	+7.5

Studies by various private and government organizations indicate that the United States is facing an energy crisis which is likely to remain critical over the next ten to twenty years. After that it is felt that new technology should start making its presence felt in a big way (145, 146).

Total energy requirements are expected to increase from 74 quadrillion BTU's in 1972 to a range of 112 to 130 quadrillion BTU's by 1985. Consumption of primary energy by the electrical utility industry is expected to grow from 19 quadrillion BTU's in 1972 to 44 quadrillion BTU's in 1985. This represents an increase in share of the total energy from 25% in 1972 to 36% in 1985 (147).

It is anticipated that the bulk of electrical power produced in the 1970's will be from fossil plants; in the 1980's from light water nuclear plants; and by the end of the 1990's from fast breeder nuclear plants.

The cost of electricity to large industrial customers is expected to double in the next 30 years. The following projection has been made of the average industrial rate for electrical power in the Detroit Edison system (148):

Year	Cost
1940-1970	1.0 to 1.2¢/kWhr
1980	1.4¢/kWhr
2000	2.0¢/kWhr

Nuclear power.—Only 4% of our present electrical energy requirements are provided by nuclear power, up from 2.2% in 1971. The National Petroleum Council (NPC) projects 300,000 MW of installed nuclear capacity by 1985. This would supply 48% of the total requirement for electricity (149).

During 1972, the Atomic Energy Commission (AEC) issued full power operating licenses for 7 nuclear power reactors, partial-power licenses for 2 others and construction permits for an additional 8 units. New applications during the year for construction of 6 new units, brought the number of nuclear power plant facilities licensed for operation and construction, or under AEC review for construction to 116 at year end. The partial-power licenses and several voluntary restrictions on power-generating levels were brought about by a fuel rod densification problem that was discovered during the spring at the Ginna Nuclear Power Plant (150).

At the end of 1972, the status of nuclear power plants in the U.S. was as follows (151):

29 Operable plants	14,683 Mwe
55 Being built	47,775 Mwe
76 Ordered	80,000 Mwe
160	142,458 Mwe

Of the plants ordered, 43 totaling some 45,500 Mwe (1 Mwe = 1,000 kW) in capacity are not yet under AEC licensing review.

The average time now for processing a construction permit application has risen from 12 months (1968) to 22 months. A combination of technological and environmental problems has disrupted the nuclear power program. The schedule called for 65 nuclear generators to be placed in operation between 1970 and 1975, but 23 have been delayed for periods ranging from a few months to years. In general, the program is two to three years behind the original timetable (149, 150).

The annual growth of nuclear power since 1957, when the first commercial plant (Shippingport, Pennsylvania) went into operation has been (151):

Year	Nuclear units ordered	Installed capacity (Mwe)
1972	35	37,929
1971	20	19,921
1970	14	14,305
1969	7	7,203
1968	14	12,872
1967	30	25,427
1966	20	16,345
Thru 1965	20*	8,456
Total	160*	142,458

* Excludes 7 small prototype plants no longer in operation.

Demand for nuclear fuel.—The table below commutes the forecasted growth of nuclear power to the requirements for uranium:

Year	Generating capacity GWE	U_3O_8 requirements short tons
1972	12	9,200
1975	59	18,200
1980	150	37,000
1985	300	66,600

The AEC estimates that there are sufficient recoverable reserves available to be mined at costs under $10/lb in the U.S. to meet domestic U_3O_8 requirements through 1985. However, unless mine exploration and development drillings are increased and new ore processing mills built or present ones expanded, the AEC predicts a shortage of uranium concentrate by 1980 (152).

Facilities for enrichment to uranium 235 appear, after completion of current improvement and upgrading programs, sufficient to meet needs until the early 1980's. To meet enrichment needs of the early 1980's and beyond, the AEC is encouraging private industry to develop plans directed toward the construction and operation of new commercial uranium enriching facilities (151).

AEC has a pilot plant facility under construction at Oak Ridge, Tennessee to demonstrate the operation of a uranium isotope separation cascade using the gas centrifuge process. This facility will be used to better define the economics of the centrifuge process as compared to the gaseous diffusion process for meeting the increased separative work requirements for enrichment of uranium in the post-1980 period. The facility is expected to be in operation by mid-1976 (151).

Nuclear authorities have calculated that with the expected growth in nuclear power and using only light-water reactors, the low cost uranium resources will be used up in less than 30 years. The AEC is working towards providing a cure with the fast breeder reactor. The light-water reactors are only able to recover less than 2% of the energy potentially available in natural uranium. The fast breeder, on the other hand, is able to recover some 70% of the energy potentially available in natural uranium (153).

Russia is reported to have started up the world's first commercial-scale nuclear breeder reactor this year (154). The U.S. is committed to successfully demonstrate a commercial size plant by 1980 (151).

New developments.—Superconductive materials are now being employed in electrical generators. The key feature of the generator is the windings of niobium titanium wire. When refrigerated to cryogenic temperatures, these windings can carry about 50 times more electricity than conventional generator windings, producing a magnetic field three to four times greater than normal. Because of such performance, superconducting generators are expected to occupy 10-30% the volume of conventional generators and to lose much less energy through dissipation as heat. By the late 1970's, this type of generator is expected to be commercial for ships, aircrafts, and central power stations (155).

A British firm is studying a concept whereby high-temperature gas cooled nuclear reactors will heat gases to high temperature reducing levels for production of iron and furnish electricity for downstream steel-making operation (156).

A new type of battery now under development at the Argonne National Laboratories shows promise of economically storing electrical energy produced during nighttime hours for use during peak-load periods. Design calculations show the lithium/sulfur battery is potentially capable of storing 11,000 kWhr of electric energy in a unit weighing 5-8 tons. The design goal is a battery costing only $15/kWhr of storage capacity (150).

Research in thermonuclear power continues to build up but there has as yet been no demonstration of technological feasibility. Commercial application of this source of power is still predicted after the year 2000.

Manuscript received July 23, 1973. This report was presented at the Industrial Electrolytic Luncheon at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this report will appear in a Discussion Section to be published in the June 1974 JOURNAL.
