Morphology and Capacity of a Cadmium Electrode

Studies on a Simulated Pore

F. G. Will* and H. J. Hess

Research and Development Center, General Electric Company, Schenectady, New York 12301

ABSTRACT

Conditions in a single pore of a battery plate were simulated by using a cadmium chip of millimeter dimensions covered with an electrolyte film of micron thickness. *In situ* microscopy was applied to study changes in the electrode morphology during charge and discharge. Passivation and increases in particle sizes due to precipitation and electrodeposition of dissolved cadmium species were found to cause profound loss in electrode capacity on repeated charge and discharge.

Cadmium battery plates often exhibit a gradual decrease of their capacity when they are repeatedly charged and discharged (1). A certain part of the "lost" capacity may be regained by changing the conditions of charging and discharging. Another part of the capacity, however, is lost irreversibly. The phenomenon is more pronounced in sealed cells working with a minimum of electrolyte than in flooded, vented cells.

Studies of Cd battery plates with microscopy, x-ray diffraction, and electron microscopy techniques have shown that the decrease of the plate capacity is related, at least in part, to changes in the plate morphology (1-3). Migration of Cd species from the interior of the plate to its surface accompanied by an increase in the size of the particles has been demonstrated. This migration becomes more pronounced as the number of cycles and the rate of charging and discharging increases. Recently it was shown that the loss of capacity on cycling can be substantially reduced by adding certain metal oxides to the battery plate (4).

Numerous studies have dealt with the mechanism of the Cd electrode in bulk solutions of alkali. These studies have established the solubility of Cd as a function of electrolyte concentration and temperature (5-7). No full agreement exists with regard to the nature of the dissolved Cd species. Authors in the past have alternately proposed a dissolution-precipitation (8-14) and a solid-state transport mechanism for the Cd electrode (15-17). Recent results obtained with a ring-disk electrode seem to show that in concentrated alkaline solutions the discharge occurs solely by a dissolution-precipitation mechanism and that both mechanisms enter when charging the electrode (18). The proposed mechanism involves the formation of $Cd(OH)_3^-$ ions as an intermediate species in solution (18-19)

$$Cd + 3\,OH^- \rightleftarrows Cd(OH)_3^- + 2e^- \quad [1]$$

$$Cd(OH)_3^- \rightleftarrows Cd(OH)_2 + OH^- \quad [2]$$

The mechanism of the Cd electrode is complicated by the formation of passivating layers. Certain experimental evidence suggests the formation of CdO films as the cause for passivation (20-21). However, CdO has so far escaped positive identification. The mechanism is further complicated by the formation of several phases of $Cd(OH)_2$ (22-25).

The behavior of battery plates on cycling and the mechanism of Cd electrodes in bulk electrolytes have both been studied. However, a gap exists in our understanding of the effects of repeated charging and discharging on the morphology of smooth Cd electrodes in bulk electrolyte and the mechanisms occurring in porous Cd electrodes such as Cd battery plates. It is apparent that the mechanism of a smooth Cd electrode in bulk electrolyte may differ substantially from the mechanism occurring in the pores of a Cd battery plate. The nonuniform current distribution and changes in the electrolyte concentration in the pores during charging and discharging are expected to give rise to such differences in mechanism. For Cd electrodes covered with electrolyte films of 0.5-2 mm thickness, nonuniform current distribution and changes in the electrolyte concentration during charging and discharging have, in fact, been demonstrated to exist (26).

The present study is aimed at establishing the effect of repeated charging and discharging on the capacity and morphology of Cd electrodes in thin films of alkaline electrolyte. Conditions in a single pore of a battery plate were simulated by using a flat miniature Cd electrode covered with a thin film of electrolyte. Such an electrode may be considered as resulting from unwinding a hollow cylinder of inner diameter equaling the pore diameter (26). With the exception of the nonsignificant electrode width, all dimensions were chosen to approximate those encountered in actual battery plates. The counterelectrode was positioned side-by-side rather than opposite to the test electrode. This resulted in a highly nonuniform current distribution and minimization of electrolyte convection in vast contrast to the usual conditions in bulk electrolyte. The geometry permitted *in situ* microscopic examination of changes in the morphology during charging and discharging. Optical microscopy was supplemented by scanning electron microscopy to identify changes in the morphology during the initial cycles.

Experimental

Over-all arrangement.—The film electrolyte experiments were carried out in a cell positioned on the stage of a Leitz Ortholux microscope to allow examining changes in the electrode morphology during charge and discharge. The microscope stage was enclosed in a polyethylene bag, continually flushed with nitrogen, to reduce effects due to the diffusion of oxygen and carbon dioxide into the cell. The carbonate concentration accumulating in the cell during the maximum duration of an experiment was determined by analysis as 0.13 moles of K_2CO_3 per liter of 6*N* KOH.

Electronic instrumentation.—Experiments were carried out under conditions of controlled voltage or controlled current. In the former case, an electronic potentiostat was used to apply potentials with a precision of ±1 mV between the test electrode and the reference electrode. In the latter case, an automatic electronic cycling device was used to apply constant currents between test and counterelectrode. The voltage-time transients under conditions of constant charge and discharge currents were recorded on a Hewlett Packard strip chart recorder. The voltage limits during charge and discharge could be set to various arbitrary values.

Cell design.—The experiments were performed in a Lucite plastic cell of outer dimensions 3 × 3 cm × 0.6 cm thick. A cross section of the cell is shown in Fig. 1. The counterelectrode is contained in a well of dimensions 2 × 2 cm × 0.3 cm deep. It consists of a section of a nickel hydroxide battery plate. The reference electrode is a self-contained hydrogen electrode as described elsewhere (27). It communicates with the electrolyte in the well via a capillary with a 1 mm opening. The opening is located at a distance of 1-2 mm from the test electrode. The latter consists of a copper strip of 1 mm width, 10 mm length, and 0.13 mm thickness. A cadmium oxide layer of dimensions 1 × 1 mm and a few micron thickness is deposited on the end of the copper strip adjoining the well. Shell Epon 828 epoxy resin is used to cement the test electrode into the cell housing in such a way that its upper surface is flush with the top of the Lucite cell housing. A spacer of silicone rubber or polyethylene covers the entire rim of the cell housing except for the 1 × 1 mm layer of cadmium oxide on the copper strip. A glass cover consisting of a microscope slide with 0.25 mm thickness is placed upon the spacer. Thus the spacer thickness determines the thickness of the electrolyte film covering the test electrode.

Electrode preparation.—In all but a few cases, test electrodes were prepared by electrophoretically depositing a cadmium oxide-binder composition on the copper substrate strips. The copper strips were cut from large specimens of electropolished copper foil. The strips were then amalgamated to further reduce the evolution of hydrogen during cathodic experiments. The evolution of even small amounts of hydrogen interferes with the microscopic examinations due to entrapment of bubbles between the test electrode and the glass cover. Electrophoretic deposition resulted in cadmium oxide layers which were even and uniform down to thicknesses of a few microns.

Cadmium oxide-binder compositions were prepared by ball milling a mixture of 12 parts by weight cadmium oxide with 1 part polyvinylidene fluoride and 63 parts dimethyl acetamide (DMA). Thirty parts DMA and 0.3 parts $Cd(NO_3)_2 \times 4H_2O$ were added subsequently. Electrophoretic deposition of cadmium oxide was accomplished at room temperature in a cell containing a platinum anode and the copper substrate foil as the cathode. Typically the application of a voltage of 100V for 20 sec led to a cadmium oxide layer thickness of about 5μ. The porosity and the theoretical capacity of the cadmium oxide layers were calculated from experimental determinations of the film thickness and the weight. Porosities of 46-50% were calculated for cadmium oxide layers of 5-7μ thickness. The theoretical capacity referred to an area of 1 cm² and a thickness of 1μ was calculated as 0.55 A-sec/cm²/μ.

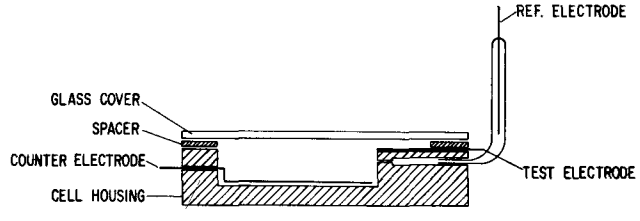

Fig. 1. Cross section of electrolytic cell

Experimental procedure.—After filling the self-contained hydrogen electrode with electrolyte and forming a sufficient amount of hydrogen in the glass capillary, the cell was placed on the microscope stage and the well filled with electrolyte while a reducing potential of −150 mV was applied between the test electrode and the hydrogen reference electrode. The spacer and the glass cover were then placed on the cell housing. With nitrogen flowing through the polyethylene bag, the residual current transient was recorded. When the residual current had decayed to only a few per cent of the cycling currents, typically after 1 hr, the cycling experiments were started. Experimental runs were terminated by using either of two procedures: (*i*) The KOH electrolyte was substantially diluted with distilled water with a constant potential applied, followed by rinsing with water and drying with nitrogen. (*ii*) The cell was disconnected from the electric circuit, the KOH solution immediately discarded, and the cell rinsed with distilled water and dried with nitrogen. No discernible differences in morphology between these two procedures could be detected in micrographs at magnifications up to 20,000X.

Results and Discussion

Effect of cycling on capacity and morphology of CdO films.—Changes in the capacity and morphology of cadmium oxide films during the initial ten cycles in 6*N* KOH were studied in detail, using scanning electron microscopy for increased resolution in addition to the *in situ* microscopic examination. After a given number of cycles, the electrode was removed from the cell, washed, dried, and kept in a dessicator until examined in the scanning electron microscope. A new experiment was always started with a freshly prepared cadmium oxide film. Uniform layers of cadmium oxide on copper strips with thicknesses between 4 and 8μ were prepared by electrophoretic deposition as outlined in the experimental section. The experiments were carried out with a constant electrolyte film thickness of 12.5μ. A variation of the film thickness between 12.5 and 500μ produced no significant changes in the experimental results (27) from those obtained with 12.5μ electrolyte films.

Figure 2 shows the capacity *vs.* the number of cycles for seven different electrodes from the first discharge to the eleventh charge. The first charge, resulting in the reduction of cadmium oxide to cadmium, is always accomplished at a constant potential of −150 mV. A determination of the amount of charge from an integration of the current-time transient is unfeasible because of the simultaneous reduction of oxygen and evolution of hydrogen immediately following the filling of the cell with KOH. Subsequent charges and discharges are performed with a constant current density of 1.4 mA/cm² to cutoff voltages of −200 and 300 mV, respectively. The first discharge results in capacities between 1.4 and 3.1 A-sec/cm². When correction is made for variations in the cadmium oxide film thickness, d_{CdO}, of these electrodes, the discrepancies between the initial capacity values per unit area, C_1/A,

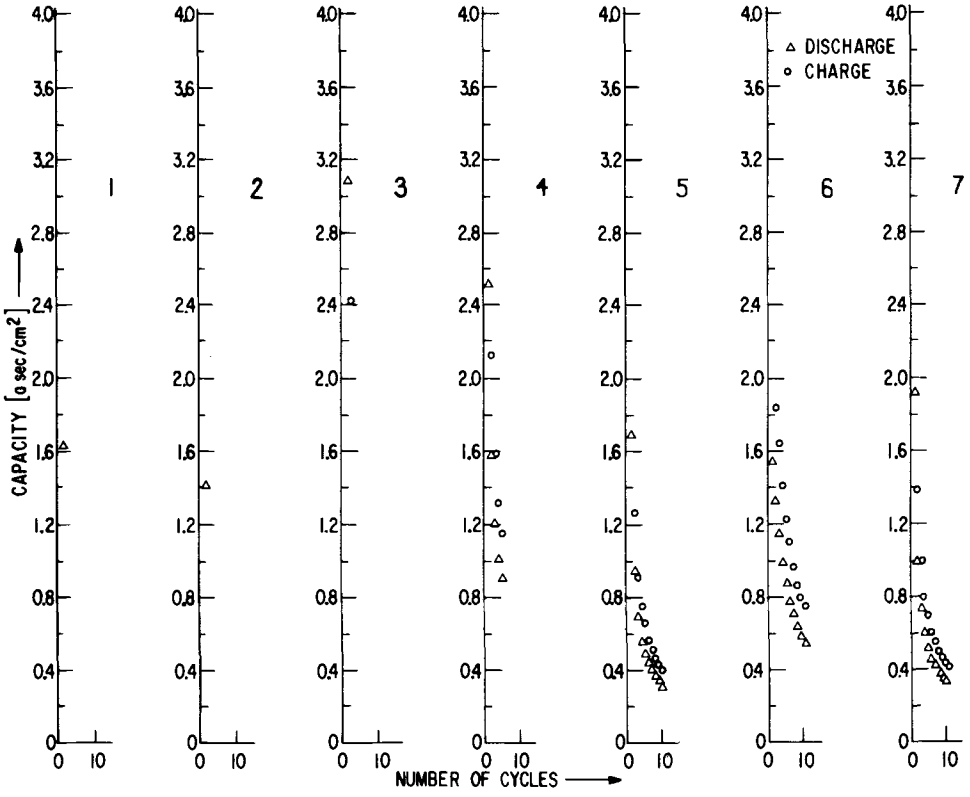

Fig. 2. Capacities of seven different CdO film electrodes *vs.* number of cycles, using a constant 6*N* KOH film thickness of 12.5μ, applying $\pm$1.5 μA/cm^2 between limits 300/—200 mV.

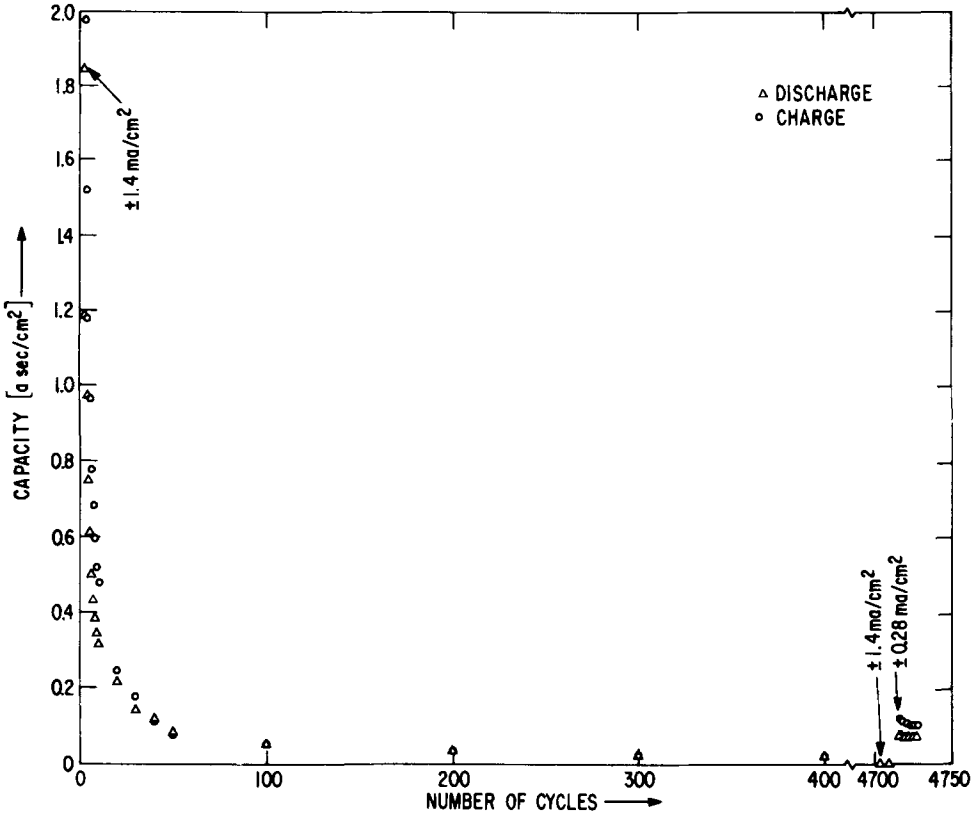

Fig. 3. Capacity of 6μ CdO film electrode (electrode 8) vs. number of cycles, using 12.5μ film of 6*N* KOH and voltage limits 300/—200 mV.

of the seven electrodes are much reduced. Table I presents a summary of the initial capacities per unit area, C_1/A, the capacities referred to 1μ cadmium oxide film thickness and 1 cm^2 area, C_1/Ad_{CdO}, and the ratios of subsequent discharge capacities to the initial capacities, C_n/C_1. The table also shows the ratios of the initial capacities to the theoretical values, C_1/C_{theor} and, in addition to the data obtained on electrodes 1-7 of Fig. 2, data obtained on an eighth electrode which was cycled more than 4000 times (see Fig. 3).

As evidenced by Fig. 2 and Table I, a drastic loss in capacity occurs during the first ten cycles. Typically the capacities decrease to one-third of the initial values within five cycles and to one-fifth within ten cycles. Loss of capacity continues on further cycling, but at a smaller rate, as shown in Fig. 3 for up to 4700 cycles. The shape of the charge and discharge curves remains approximately the same during the initial ten cycles. This is shown in Fig. 4 for the first and tenth cycles. The product of chart speed and time is plotted on the abscissa which is equivalent to the actual length of the curves on the recorder chart. The chart speed during the first cycle was 0.25 in./min as compared to 1 in./min for the tenth cycle. Hence the curves reflect

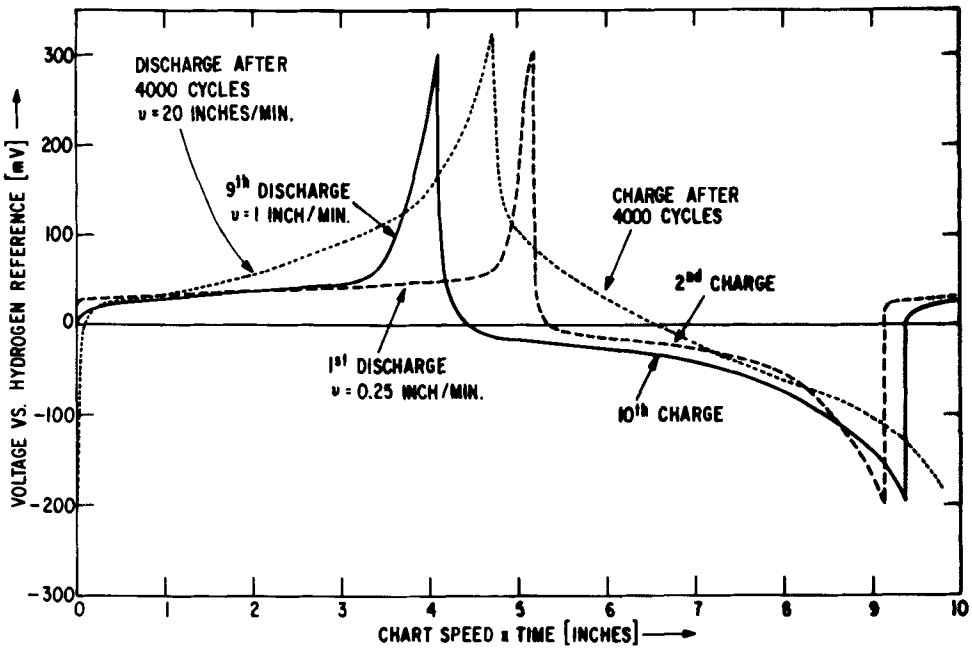

Fig. 4. Recorder traces of discharge and charge curves of electrode 8 after 1, 10, and 4000 cycles, applying ±1.4 mA/cm². Product of chart speed and time (identical to length on recorder chart) is plotted on abscissa.

the large loss of capacity during the first ten cycles as also evidenced by Fig. 3. While the discharge curves for the first and tenth cycles show a pronounced potential arrest near the $Cd/Cd(OH)_2$ equilibrium potential, such a potential arrest is virtually absent in the discharge curve after 4000 cycles, obtained at a chart speed of 20 in./min. The voltage rises continually during the entire discharge which means that higher overvoltages are required for oxidation and reduction of the electrode. This suggests the formation of passivating layers which were apparently not formed to any large extent during the first ten cycles. A different cause for the pronounced loss of capacity during the first ten cycles must therefore exist, and a careful study of the changes in morphology during the first ten cycles was undertaken.

Figure 5 shows an optical micrograph of a cadmium oxide layer in dry condition immediately after electrophoretic deposition, obtained in dark field at a magnification of 220X.[1] Figures 6 and 7 are scanning electron micrographs (SEM) of the same surface obtained at magnifications of 2000X and 10,000X. The layer is uniformly brown, and the SEM's show a large number of well-developed cubic particles of sizes 0.1-1μ. Many of these particles are covered with what appears to be the binder. Exposure of a cadmium oxide layer to a 6*N* KOH film for 10 min on open circuit turns the brown color of the deposit into a bright white color. This is shown in the optical micrograph in Fig. 8. Only a few brown particles remain at the surface after this exposure. The SEM's in Fig. 9 and 10 resolve the changes in the particle shapes caused by the exposure of the electrode to KOH. The formation of a large number of platelets, many of them with hexagonal shapes, is evident. The lateral dimensions lie in the range 3000 to 5000Å. Undoubtedly these particles are β-$Cd(OH)_2$ (25).

Figures 11-13 show the morphology of a surface which results when exposing a cadmium oxide film to

[1] Unless otherwise stated, the following photomicrographs were all obtained in dark field at a magnification of 220X.

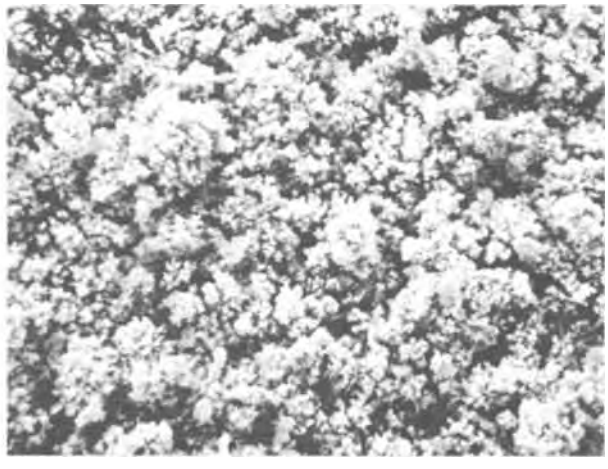

Fig. 12. SEM of same surface as Fig. 11 at 2000X

6*N* KOH with a reducing potential of −150 mV applied for 3 hr. After this reduction, the surface appears uniformly gray in the microscope (Fig. 11). A large number of small, highly reflecting particles are present, but their shapes cannot be resolved in the microscope. The SEM's in Fig. 12 and 13 show that the crystal habit has changed but the particle sizes have not (compare Fig. 6 and 7). The cubic particles in Fig. 7 are no longer visible in Fig. 13. Most of the cadmium particles in Fig. 13 have sizes between 2000 and 3000Å.

During the first discharge, which results in the formation of $Cd(OH)_2$, microscopic examination reveals the formation of dark areas on the surface which ultimately grow together. The distinct darkening of the surface is the only effect of discharge which can be observed in the microscope. Figure 14 shows the surface after complete discharge at a magnification of 220X.

The SEM's in Fig. 15 and 16 show that a large number of well-defined crystals, mostly of sizes 1-2μ, have been formed. The hexagonal shape of these crystals identifies them as β-$Cd(OH)_2$ (25). In addition, a few needle-like crystals, most likely γ-$Cd(OH)_2$ (25), and distinctly shaped particles with sizes one order of

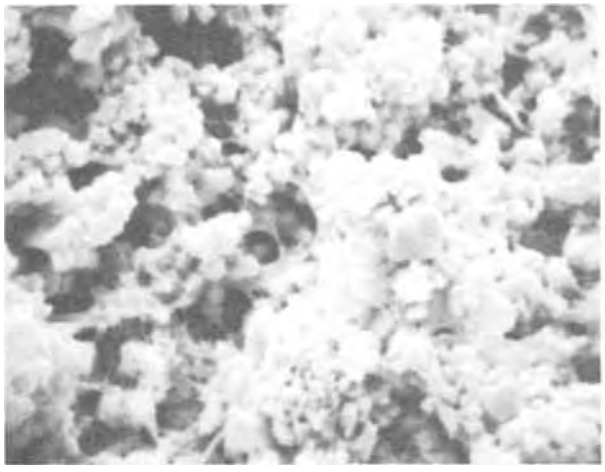

Fig. 13. SEM of same surface as Fig. 11 at 10,000X

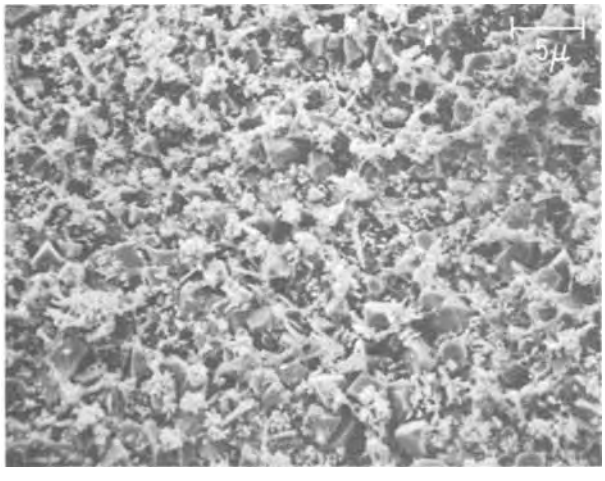

Fig. 15. SEM of electrode 1 at 2000X

magnitude smaller are visible. It is suggested that the crystals of β- and γ-$Cd(OH)_2$ are precipitated from the supersaturated electrolyte and that the small particles are $Cd(OH)_2$ formed by solid-state oxidation of the cadmium particles of identical size as in Fig. 13. The micrographs in Fig. 14-16 were obtained on electrode 1 of Fig. 2 which was removed from the cell on open circuit after discharge at constant current to 300 mV. Electrode 2 in Fig. 2 was removed from the cell after the first discharge, while a potential of 300 mV was being applied. The morphology of this electrode was found to be identical to that of electrode 1.

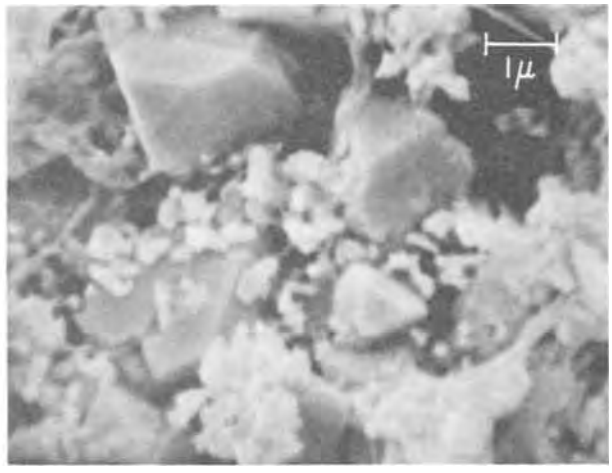

Fig. 16. SEM of electrode 1 at 10,000X

Electrode 3 was removed from the cell after the second charge while a potential of −150 mV was being applied. According to Fig. 2 the second charge leads to a capacity which is 20% smaller than that recovered on the first discharge. Simultaneously the microscope reveals a distinct brightening of the surface, and the particle size appears to have grown (Fig. 17). The SEM's in Fig. 18 and 19 show the formation of whisker-like crystals of lengths up to 10μ and widths up to 1μ. The formation of whisker-like crystals "on charge" has apparently never been described

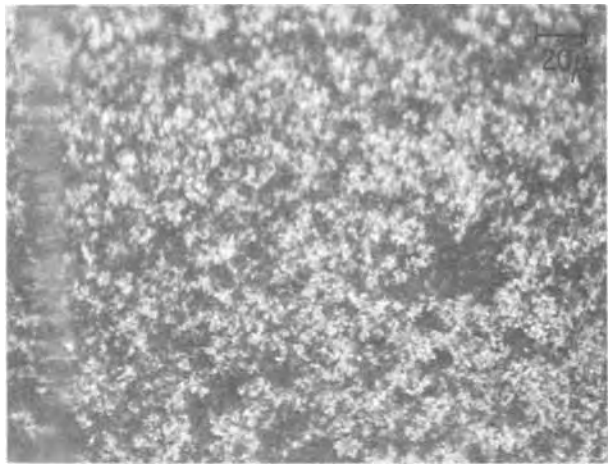

Fig. 17. Optical micrograph of electrode 3 after second charge to −200 mV.

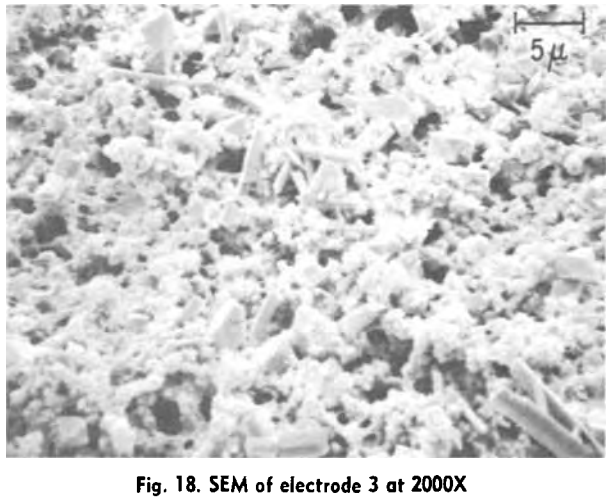

Fig. 18. SEM of electrode 3 at 2000X

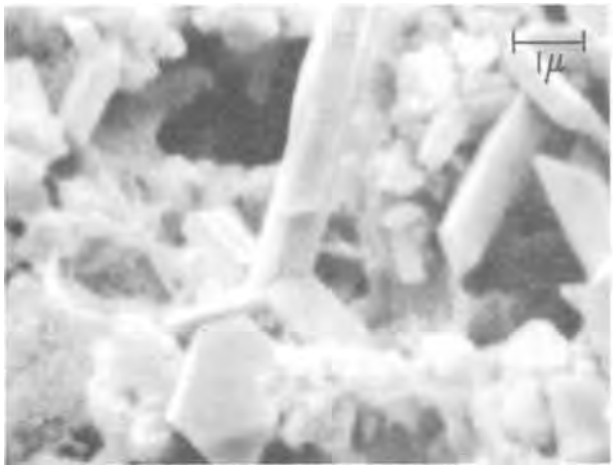

Fig. 19. SEM of electrode 3 at 10,000X

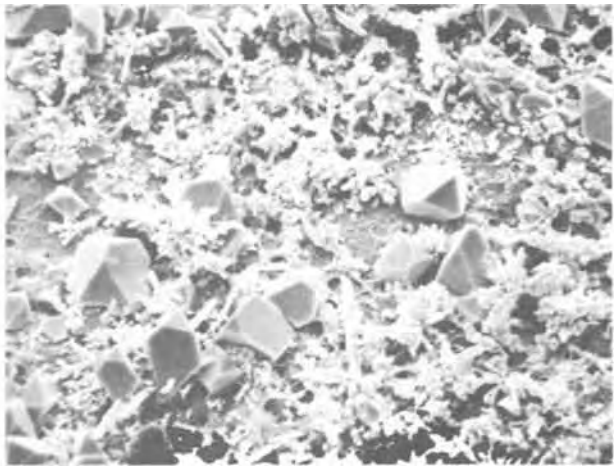

Fig. 21. SEM of electrode 4 at 2000X

before. The nature of these crystals was not identified in the present study. It is also evident from Fig. 18 and 19 that many of the hexagonal particles formed during the first discharge (compare Fig. 6) have remained unchanged during the charge. A great number of the small particles of sizes 2000 to 3000Å have also persisted.

Electrode 4 was removed on open circuit from the cell after completing the fifth discharge to 300 mV. Figure 2 shows that the capacity during five discharges has decreased to 36% of its original value. The photomicrograph in Fig. 20 reveals a coarsening of the surface compared to the appearance of the surface after the first discharge shown in Fig. 14. In the higher resolution of the scanning electron microscope a great number of hexagonal crystals of sizes 2-4μ are clearly visible (Fig. 21 and 22). Needle-like crystals can also be seen in these micrographs. Electrodes 5 and 6 were each cycled ten times. Electrode 5 was removed from the cell on open circuit, electrode 6 after keeping the electrode at 300 mV for 16 hr following the ten cycles. Further coarsening of the surface of electrode 6 is evident from Fig. 23 to 25. Figures 24 and 25 show that the number of well-crystallized particles of sizes 2-4μ have increased compared to Fig. 21 and 22. Extensive oxidation at 300 mV leads to a brownish appearance of the surface, as seen in the microscope, and to a disappearance of many crystals (Fig. 26). At the same time, an erosion of the remaining crystals is evident in Fig. 27 and 28 in that a distinct layer structure of the crystals has developed which was completely absent before the extensive oxidation at 300 mV (Fig. 25). No particular features in the SEM's can

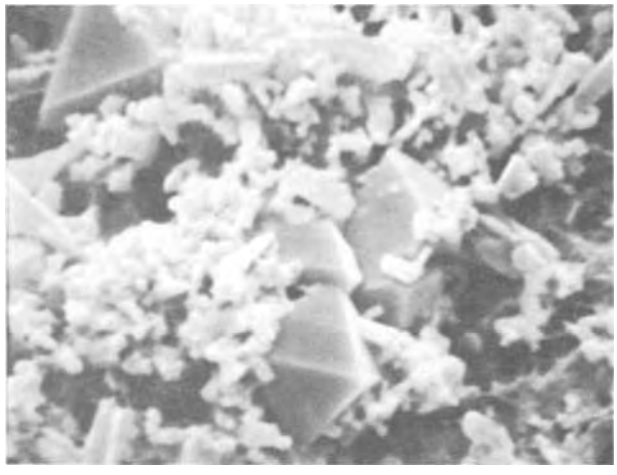

Fig. 22 SEM of electrode 4 at 10,000X

be associated with the brown color clearly observed in the microscope.

Figures 29-31 show the effects of extensive reduction of the electrode. Electrode 7 was kept at −150 mV for 16 hr after the 11th charge. The extensive charging leads to a considerable brightening of the surface (Fig. 29). As evidenced by the SEM's in Fig. 30 and 31, the large crystals formed during the ten preceding cycles (Fig. 16-28) have disappeared. The particles remaining on the surface have much less distinct shapes, and most of them have sizes between 2000 and

3000Å. In fact, the SEM in Fig. 31 looks very similar to that in Fig. 13 which was obtained after the first charge.

Electrode 8 was cycled more than 4000 times with current densities of 0.28 and 1.4 mA/cm^2. Figure 3 shows that the capacity on cycling decreases continually to values as low as 10 mA-sec/cm^2. The micrographs in Fig. 32-34 were obtained after more than 4000 cycles. In this case, the magnification of 220X is sufficient to resolve the shapes of a few very large particles (Fig. 32). The SEM's in Fig. 33 and 34 show the very large crystals which have formed in greater detail. Their sizes range up to 7μ. The hexagonal layer structure already seen in Fig. 27 is strikingly evident in Fig. 34. As in the case of extensive oxidation, the electrode turns brown on extensive cycling.

The initial capacities of electrodes 1 to 8 in Table I amount to between 50 and 70% of the theoretical values and are somewhat lower than the values obtained on pasted battery plates. This is most likely due to the much looser and more porous nature of the layer resulting from electrophoretic deposition as compared

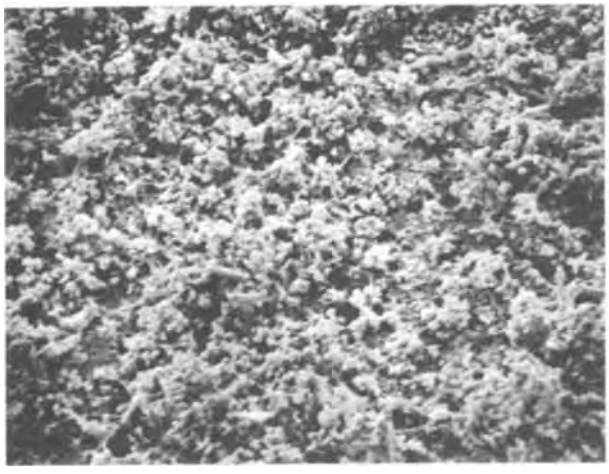

Fig. 30. SEM of electrode 7 at 2000X

to pasting. Loss of contact between the particles and the substrate is thus expected to be a larger problem than with pasted plates and would account for the relatively smaller initial capacities as well as for the more drastic loss of capacity during cycling. The less pronounced loss of capacity during cycling on pasted plates was actually demonstrated. Electrodes prepared by pasting cadmium oxide-binder mixtures of 63μ thickness on copper strips retained 88% of their initial capacity after ten cycles (27).

From the preceding detailed studies of the changes in the morphology during the first ten cycles, it is evident that the pronounced decrease of the capacity during these cycles (compare Fig. 2) is due to the observed formation of large $Cd(OH)_2$ crystals, probably caused by precipitation from the supersaturated KOH film during discharge. The supersaturation is favored by the consumption of hydroxyl ions in the discharge reaction. The lower *p*H, which is expected to result in the KOH film, causes the solubility of cadmium species to decrease. Once formed, many of the larger $Cd(OH)_2$ crystals do not appear to be reduced on continuous cycling (compare Fig. 18) and, hence, do not contribute to the capacity. During periods of extensive reduction, the large $Cd(OH)_2$ crystals seem to dissolve (Fig. 31), and dissolved cadmium species may then be electrodeposited on the test electrode. Dissolution of $Cd(OH)_2$ crystals is favored by the formation of hydroxyl ions during charging, due to the increased solubility of cadmium species at high *p*H. This process leads to a preliminary increase in the capacity up to factors of 3.

Effect of voltage on capacity.—The effect of the magnitude of the (anodic) discharge voltage on the charge capacity and the effect of the magnitude of the (cathodic) charge voltage on the discharge capacity was studied on an electrode with an electrophoretic cadmium oxide film of 3.5μ covered with a KOH film of 12.5μ thickness.

The procedure adopted was as follows: in determining the effect of anodic voltages on the charge capacity, a cathodic voltage of −200 mV was always applied for 20 min between each new measurement. A given

anodic voltage was then applied for 20 min and the capacity determined by applying a cathodic current density of -0.28 mA/cm^2 until a cutoff voltage of -200 mV was obtained. Conversely, the effect of cathodic voltages on the discharge capacity was determined by applying an anodic voltage of 300 mV for 20 min, then applying the cathodic voltage of interest for 20 min followed by applying an anodic current density of 0.28 mA/cm^2 until a cutoff voltage of 300 mV was obtained.

The results of these measurements are shown in Fig. 35. Above anodic voltages of 100 mV, the charge capacity increases linearly with the oxidizing voltage. In contrast, the discharge capacity for voltages more cathodic than -100 mV is independent of the magnitude of the reducing voltage.

The linear dependence of the charge capacity on the magnitude of the discharge voltage was observed previously when performing identical experiments in 0.1*N* KOH bulk electrolyte (27). This behavior had been explained in terms of the formation of passivating films during oxidation and the subsequent transport of ions through these films. In the present case, the original layer consists of individual cadmium oxide particles rather than a continuous cadmium film. Hence, after the first reduction to cadmium, it is appropriate to think in terms of the formation of passivating films around each individual particle. The question regarding the nature of these passivating films must be left open; they may consist of either $Cd(OH)_2$ or CdO. Since their thickness is found to be proportional to the amount of charge applied to the electrode, Fig. 35 signifies that the thickness of the film increases linearly with the voltage across the film. The deviation from the straight-line behavior at voltages between 0 and 100 mV is very likely caused by the increasing penetration of the electrolyte film by the electric field (26). The same phenomenon applies to the discharge capacity as a function of the reducing voltage. The independence of the discharge capacity on the reducing voltage between -100 and -300 mV implies that within the reduction time of 20 min, all reducible particles were in fact reduced with voltages as low as -100 mV while the large $Cd(OH)_2$ particles remain unreduced during short-term reductions. "Reducible" are considered the small particles (compare Fig. 18) in good contact with the substrate surface.

Mechanism for changes in capacity and morphology. —The results in this study are consistent with the following mechanism: on discharge, a solid-state and a dissolution-precipitation mechanism occur simultaneously, both contributing to the measured capacity and the latter leading to the formation of large crystals. The net reactions may be written as

$$Cd + 2\,OH^- \rightleftarrows Cd(OH)_2 + 2e^- \quad \text{(solid state)} \quad [3]$$

$$Cd + 3\,OH^- \rightleftarrows Cd(OH)_3^- + 2e^- \quad \text{(dissolution)} \quad [4a]$$

$$Cd(OH)_3^- \rightleftarrows Cd(OH)_2 + OH^- \quad \text{(precipitation)} \quad [4b]$$

Many of the precipitated particles have poor contact with the substrate. The particles oxidized via solid-state Reaction [3] become surrounded by a layer of cadmium hydroxide which hinders subsequent charge transfer and requires increasing overvoltages. This is evident from those parts of the discharge curves, where the voltage rises steeply with further discharge (compare curve after 4000 cycles in Fig. 4).

On charging, the rate and duration of charging is significant in determining the reaction mechanisms. On short and high-rate charges, the solid-state Reaction [3] (in reverse direction) dominates and explains the observed persistence of the large precipitated $Cd(OH)_2$ crystals. On prolonged and low-rate charges, Reaction [4b] leads to the observed dissolution of $Cd(OH)_2$ crystals. In this case, sufficient time is available for this slow process (18) to occur. The dissolution process is furthermore favored by the increase in pH during charging which raises the solubility of cadmiate ions. The dissolution is followed by the reverse of Reaction [4a] which leads to the electrodeposition of cadmium. In parallel to the dissolution-electrodeposition process, the solid-state reduction of many particles takes place, in particular the smaller ones which are in good contact with the substrate surface. As this process proceeds, the particles become surrounded with a conducting layer of cadmium which facilitates further reduction. This is very likely the reason why charging occurs with smaller overvoltages than discharging.

Cadmiate ions are expected to diffuse and, during discharge, to migrate toward the counterelectrode. Once they have left the small volume of the film electrolyte, very long charging times are required to electrodeposit them on the test electrode. The areas of the test electrode near the electrolyte well are preferred sites for deposition. The observed growth of tree-like structures during prolonged reduction is evidence for this mechanism.

Conclusions

For thin films of concentrated KOH under conditions of highly nonuniform current distribution, simulating

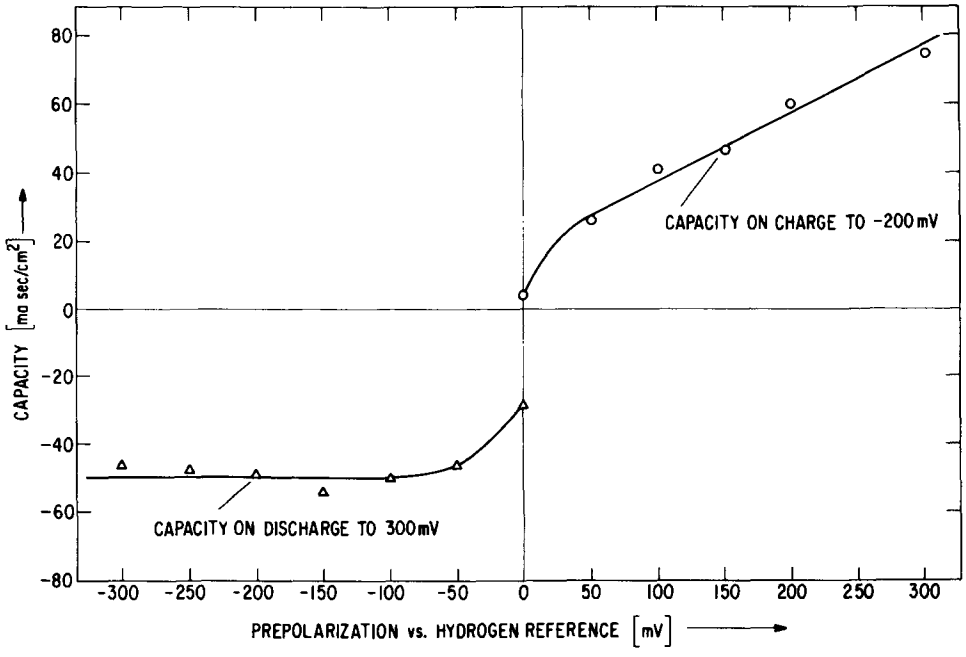

Fig. 35. Charge and discharge of 3.5μ CdO film electrode *vs.* prepolarization, using a 12.5μ film of 6*N* KOH and $\pm$0.28 mA/cm^2.

conditions in a single pore of a cadmium battery plate, we arrive at the following conclusions:

1. The first discharge leads to the recovery of typically 60% of the theoretical capacity, but the capacity decreases steeply during cycling, typically to 12% of the theoretical value in ten cycles. Discharge leads to the formation of large well-behaved crystals of β-$Cd(OH)_2$ and some γ-$Cd(OH)_2$ due to dissolution and subsequent precipitation of soluble cadmium species which is favored by the decreasing pH during discharge.

2. The large crystals do not contribute to the capacity on subsequent cycling and, hence, are responsible for the pronounced loss of capacity observed during the initial cycles.

3. The remaining capacity is due to the charge and discharge of particles of the original size via a solid-state transport mechanism.

4. The formation of passivating films, probably cadmium oxide, is suggested by the appearance of a brown film accompanied by a further decrease of the capacity on continued cycling.

5. Prolonged reduction leads to the dissolution of the $Cd(OH)_2$ crystals due to the increase in pH on charging. Electrodeposition of cadmium leads to increased capacity on subsequent discharge.

6. The method of preparing the electrode may have significant effects on the morphology and capacity. Pasted cadmium oxide electrodes display better coherence between particles than electrophoretic cadmium oxide electrodes and show considerably smaller loss of capacity on cycling.

Recent Results on Lead-Calcium Alloys as Grid Materials for Lead-Acid Batteries

G. W. Mao, J. G. Larson, and P. Rao

Gould Inc., Automotive Battery Division, Mendota Heights, Minnesota 55118

ABSTRACT

Pressure cast lead-calcium alloy positive grids for float applications can cause some unexpected service failures due to abnormal growth. Such failures have been interpreted as a result of irregular grain structure and weaker grain boundaries. Since lead-calcium is a precipitation hardening alloy, either heat-treatment or controlled solidification can yield favorable grain size and distribution of Pb_3Ca precipitates in the matrix. The present investigation shows that controlled solidification of pressure cast grids can produce physically sound grids which are corrosion and growth resistant. Differences between industrial and automotive SLI grids cast by gravity and pressure casting techniques are revealed. The effect of casting temperature on the microstructure and anodic corrosion characteristics of lead-calcium alloys ranging from 0.01 to 0.1% calcium content is also presented.

For many years the lead-acid battery industry has manufactured batteries using lead-antimony alloy grids; however, the presence of antimony leads to side reactions that are deleterious to battery performance. To avoid this problem, Bell Laboratories introduced lead-calcium alloy (1). Since then lead-calcium cells have been used exclusively in full-float service. A major drawback of lead-calcium is its unpredictable

Key words: lead-acid battery, lead-calcium grids, corrosion morphology, pressure cast grids.

grid growth behavior. Excessive grid growth occurs in certain plates while other plates within the same cell are practically unaffected. Also, lead-calcium is difficult to cast and weld.

Hardening of a lead-calcium grid does not take place immediately after casting, but occurs later due to aging. Limitations as to the other types of service in which lead-calcium grid battery can be used have not yet been established.

The uniqueness of lead-calcium for a grid alloy lies in its low rate of self-discharge and minimal stand loss. The calcium content of such alloys has always been maintained below 0.10%. Such grids are normally gravity cast, but there is a trend toward pressure casting these grids.

Howard and Willihnganz (2) reported that accelerated testing caused abnormal growth and preferential grain boundary corrosion of pressure cast positive lead-calcium grids with 0.07-0.08% calcium. They related these characteristics to the irregular grain structure and weaker grain boundaries of pressure cast positives.

Townsend (3) revealed that the tensile strength of 0.05-0.09% calcium-lead is sensitive to the cooling rate of the solidifying alloy, and increased with increasing cooling rates. This is a direct consequence of precipitation from a greater degree of supersaturation. In other words, casting conditions would definitely influence the over-all corrosion behavior of the alloy grid, since corrosion behavior is sensitive to precipitate distribution within the matrix.

Pressure casting is accepted in the industry to produce lead-calcium negative grids because negative grids are not subject to the same anodic environment as the positives. Pressure casting is favored because it is economically attractive and is amenable to precise quality control.

In 1967 a program was initiated to obtain acceptable pressure cast lead-calcium positive grids by controlling and optimizing various relevant casting parameters. Fundamental work on the lead-calcium system was simultaneously carried out to establish the influence of composition and casting conditions on over-all corrosion behavior of the alloys. This was necessary to understand and interpret the differences in corrosion and growth behavior of pressure cast and gravity cast grids. The effect of annealing lead-calcium grids has been reported previously (4, 5).

Experimental

Alloy rod corrosion.—Alloy rods 0.63 cm in diameter were gravity cast from a molten metal temperature of 750°F, into a mold maintained at 375° and 500°F respectively. Anodic corrosion of these rods, having various calcium content up to 0.09% was carried out at 2.8V constant potential in 1.115 sp gr H_2SO_4 at room temperature. The corrosion cells were 250 ml Pyrex beakers covered with closely fitted Plexiglas lids. The test rod was mounted in the center of the cover and positioned vertically in the electrolyte. This formed the anode. A pure lead sheet cathode was arranged concentrically 3 cm from the anode. The ratio of initial anode to cathode area was 1:17. Details of similar rod corrosion experiment were described elsewhere (6).

Optimized pressure casting.—A special pressure casting machine was built. With it, various processing variables relevant to the casting operation, such as mold temperature, molten metal temperature, rate and flow path of metal entry into the mold cavity were optimized to yield physically sound grids having relatively large grain size and proper precipitate distribution. For example, industrial battery grids were cast in a cast iron mold where the temperature of both mold halves was controlled. The molten metal entry into the mold was controlled so that it entered at a very low velocity with a minimum amount of turbulence. Vacuum was applied at the end of the mold cavity, directly opposite to the metal entry to minimize air entrapment in the solidifying grids.

Efforts to optimize pressure casting parameters was done only on industrial type grids.

Battery grid corrosion.—Grids having 0.06-0.07% calcium were cast by two different methods, *i.e.*, gravity and pressure casting. Two types of grids were chosen: an industrial type of rectangular design (25.72 cm × 28.41 cm × 0.635 cm) and an automotive SLI type (14.29 cm × 13.49 cm × 0.178 cm).

In addition, 300°-500°F annealing of pressure cast automotive and industrial grids was done. In the case of SLI automotive grids, both pasted and bare grid cells were used; while in industrial grids, only bare grid cells were used.

Corrosion and growth studies on the industrial positives were performed on bare three-plate cells in 1.210 sp gr H_2SO_4. A positive potential of 75 mV above the open circuit (1.185V) was maintained for 60 days at a temperature of 180°F (5). At the end of the test both microstructures and grid dimensional changes were recorded.

Corrosion studies in SLI unpasted grids were performed on 5 plate cells (2 positives/3 negatives) assembled in Plexiglas jars in 1.265 sp gr H_2SO_4 at room temperature. These were anodically corroded at 2.8V for 12 weeks. Similarly, 5 plate (2 positive/3 negative) pasted SLI cells were subjected to 2.6-2.8V constant voltage overcharge. These pasted cells had 25 A-hr capacity based on the 20 hour rate. Every week the cells were discharged at 44A which approximated a 50% depth of discharge. One week was counted as one cycle. The basic objective of these two tests was to accelerate the corrosion of both pasted and bare grids so that their corrosion resistance and growth characteristics could be established.

Experimental Results

Anodic corrosion.—Weight loss of alloy rods due to anodic corrosion at 2.8V constant potential for 60 days is plotted as a function of calcium content for two different casting mold temperatures in Fig. 1. The curve represents the basic trend from duplicated experiments. The weight loss here corresponds to the actual difference in weights of the alloy rods before and after corrosion following removal of all adherent corrosion products.

For the alloys cast in a 375°F mold, the weight loss goes through a minimum between 0.04 and 0.06% calcium. For alloys cast in a 500°F mold, however, the weight loss goes through an extended minima between 0.03 and 0.07% calcium.

The absolute values of corrosion weight loss are of little significance unless they are discussed in conjunction with corroded microstructures, indicating the morphology of corrosion attack. It is the nature of corrosion attack that determines grid growth characteristics and subsequently positive plate life. For this rea-

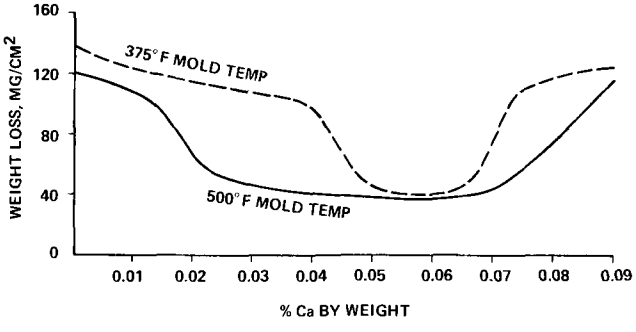

Fig. 1. Effect of casting temperature and calcium content on the anodic corrosion weight losses of gravity cast lead-calcium alloy rods.

son, a thorough evaluation of the microstructures of the various alloys was made.

Microstructures (Fig. 2) indicate that casting in lower temperature molds (375°F), favors the development of irregular grains and serrated grain boundaries for all various calcium alloys. The grain sizes become extremely fine as the calcium content increases beyond 0.06%. Whereas, casting similar alloys in a higher temperature mold (500°F) promotes the development of relatively large, uniform grains characterized by smooth boundaries, irrespective of the calcium content.

For alloys (Fig. 3) cast in a 375°F mold with less than 0.04% calcium, the corrosion penetration is basically intergranular, since the matrix precipitation is small, thus making high energy grain boundaries more vulnerable.

In alloys with 0.04-0.06% calcium, the volume fraction of precipitates is high and most of it is contained in the lead rich matrix and these matrix precipitates control the mode of corrosion. The switch in the mode

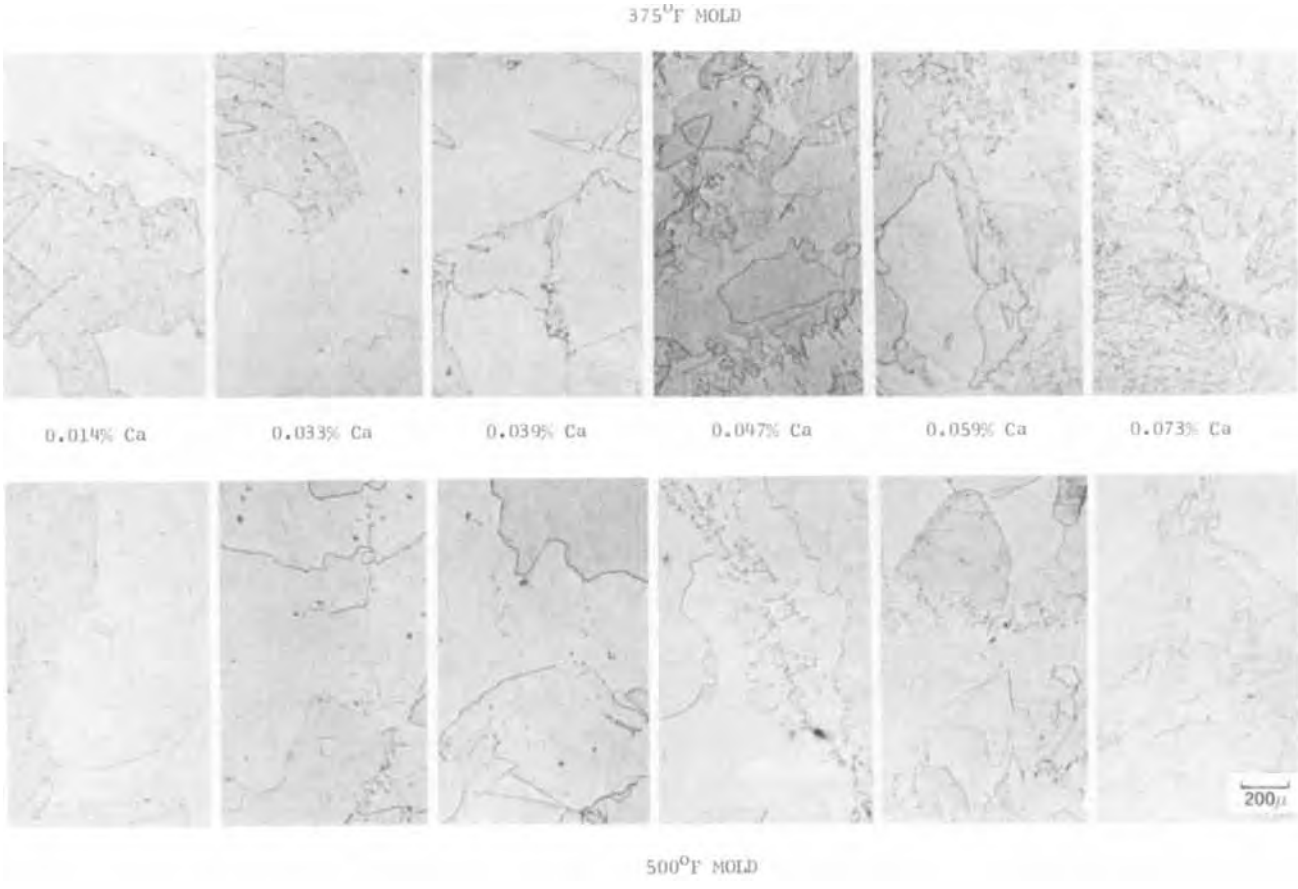

Fig. 2. Effect of casting temperature and calcium content on the microstructures of gravity cast lead-calcium alloy rods

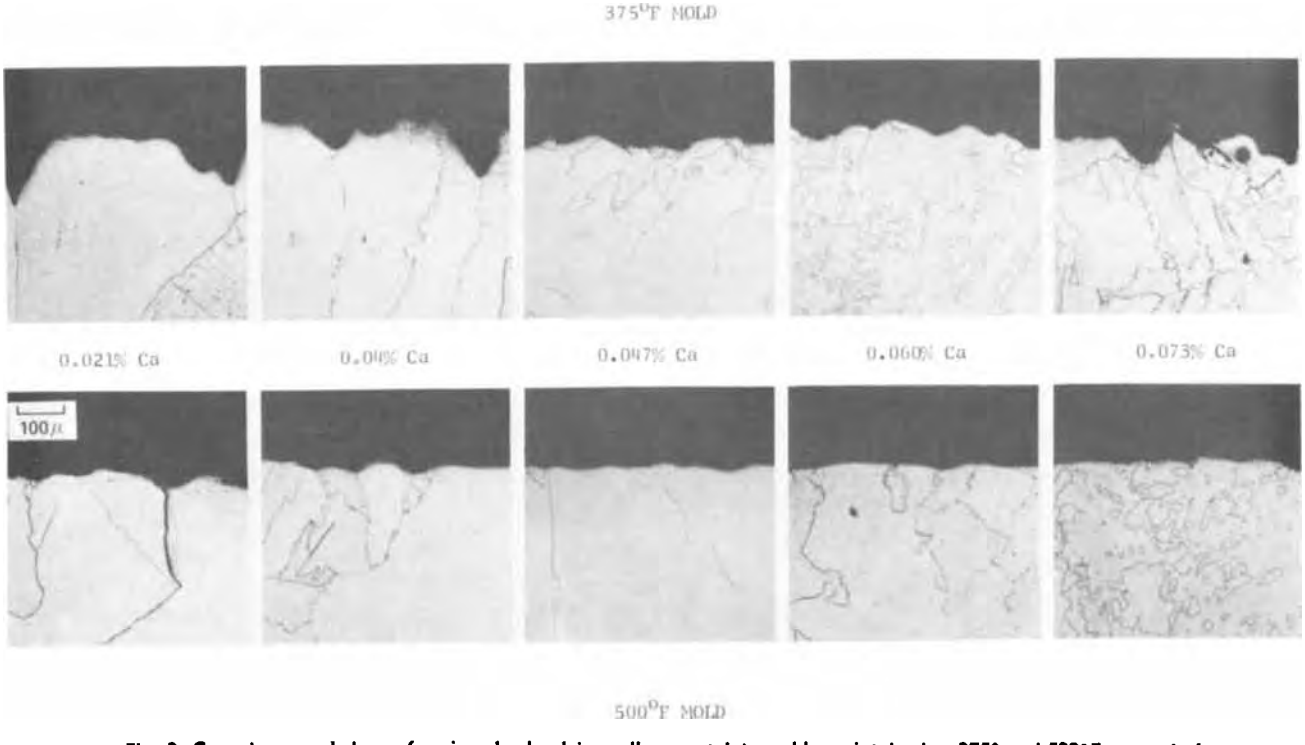

Fig. 3. Corrosion morphology of various lead-calcium alloys cast into molds maintained at 375° and 500°F respectively

of attack from intergranular to a matrix dominated corrosion as the calcium content increases beyond 0.04%, explains the observed minima in corrosion weight loss. However, fine but irregular grain size, together with extensive precipitation in alloys beyond 0.06% calcium combine to permit rapid consumption of grains, and this corrosion process accounts for the higher weight losses.

On the contrary, the range of calcium composition is much wider for alloys that exhibit stable corrosion properties when cast in a 500°F mold. In these alloys, the volume fraction of corrosion active precipitates, and their distribution, control the rates and the mode of corrosion, while the grain boundaries play a secondary role. The basic corrosion process in alloys exhibiting minimal weight losses are similar to the alloys cast in a 375°F mold. More significant than the absolute values of anodic corrosion weight losses, is that alloys cast in a 500°F mold have alloy structures that exhibit remarkable stability to corrosion and thereby deter any tendency for preferential attack as revealed by their corroded microstructures. This characteristic should definitely contribute to improved growth resistance and thereby increase the reliability of grids in float service.

This corrosion behavior has clearly established the necessity for controlling mold temperature while casting lead-calcium grids to obtain grids exhibiting stable corrosion behavior.

Industrial battery grid test.—The grid growth data arising out of accelerated corrosion testing at 180°F are shown in Fig. 4. Only the horizontal growth is compared. Pressure cast grids produced under optimized casting conditions grew at the same rate as the control gravity cast grid. Furthermore, when these pressure cast grids are annealed, the growth rate is slowed further. However, pressure cast grids cast without controlled process conditions show the highest growth rate. Although annealing did slow down the growth rate as shown in Fig. 4 and as shown by Cannone *et al.* (5), it was still slightly higher than the unannealed pressure cast grids produced under optimized conditions.

Macrographs of grid sections taken at various portions of the grid reveal that grids cast under optimized process conditions are physically sound and free of large interconnecting pores and voids (Fig. 5), while the grid cast under unregulated process conditions reveals large voids and a large degree of interconnecting pores (Fig. 6). Macrographs of grid sections taken from a gravity cast grid indicate that they are physically sound, and quite similar to the grid cast under optimized pressure casting conditions. It appears that

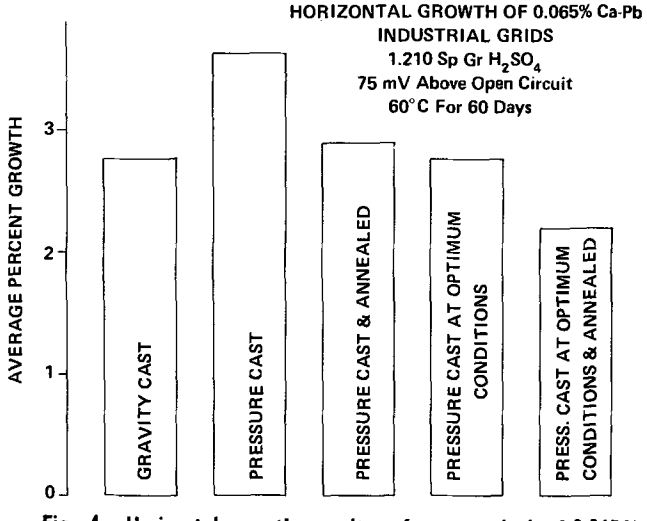

Fig. 4. Horizontal growth results of unpasted lead-0.065% calcium industrial grids. Accelerated growth test.

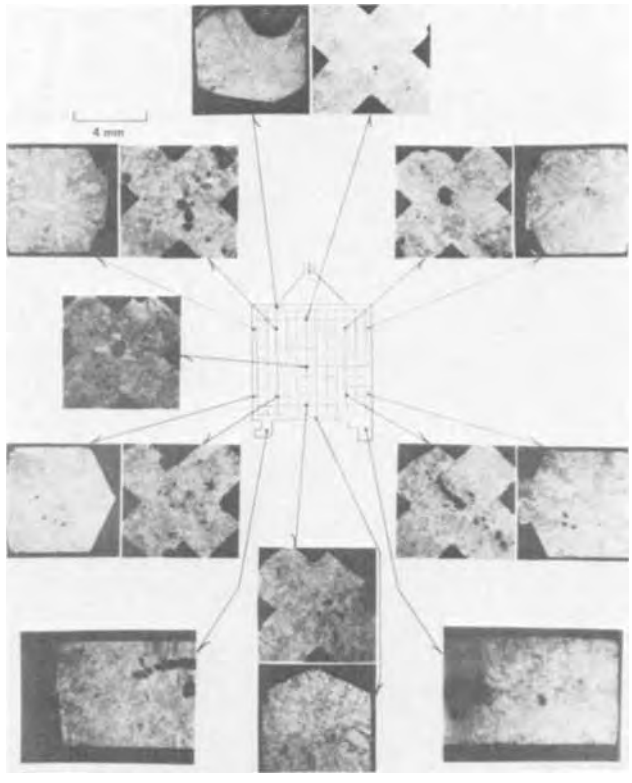

Fig. 5. Macrostructure of various sections of a pressure cast lead-0.065% calcium industrial grid, cast under regulated process conditions.

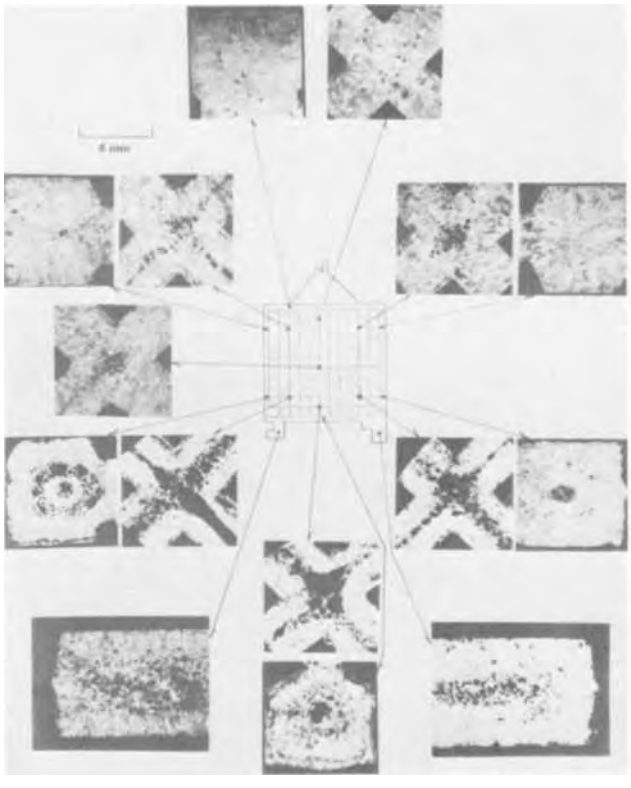

Fig. 6. Macrostructure of various sections of a pressure cast lead, 0.065% calcium industrial grid, cast under normal process conditions.

lack of physical soundness in these pressure cast grids would curtail the strength of grid members and is primarily responsible for their undesirable growth characteristics. Any differences in metallurgical structures arising from the pressure casting will have to play

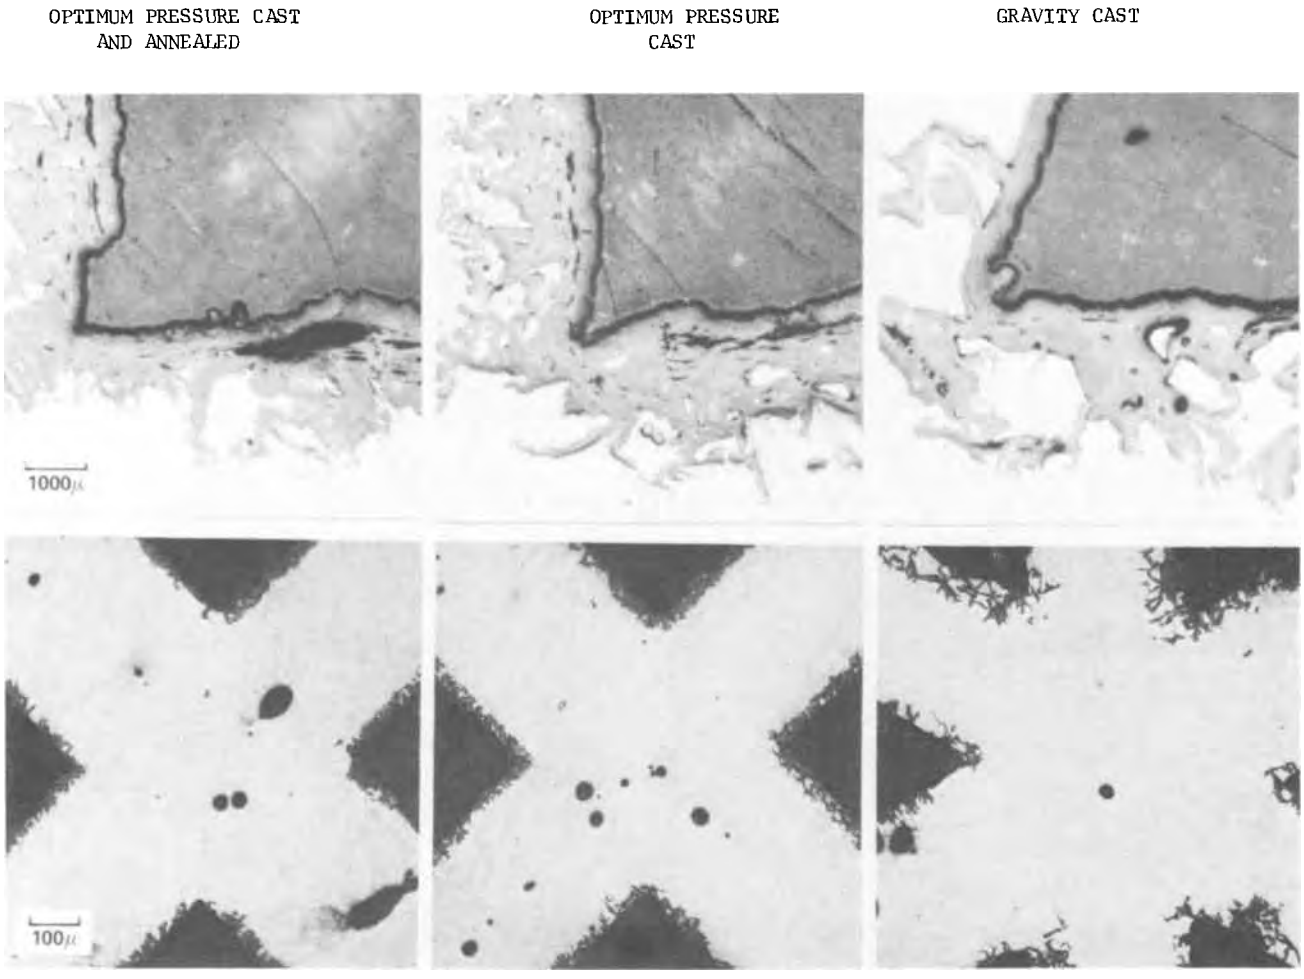

Fig. 7. Corrosion morphology of lead-0.065% calcium industrial grids. Accelerated growth test

a secondary role in its corrosion or its growth characteristics.

The corrosion morphology of these grids strikingly reflects their individual growth characteristics (Fig. 7). In the gravity cast grid, the preferential intergranular type attack is predominant. The grain boundary penetration suggests that since a major portion of the induced stresses are developed in the grain boundary, growth behavior will become unpredictable. Both annealed and unannealed pressure cast grids cast under optimized conditions reveal that the corrosive attack is less severe and more uniform.

Optimized pressure casting conditions are such that substantially faster cooling rates of the solidifying grid alloy, at a defined mold temperature, are achieved than in gravity cast methods, resulting in uniform precipitation of the corrosion active Pb_3Ca precipitates. This reduces the severity of grain boundary corrosion penetration and renders the matrix corrosion more uniform. Both of these factors contribute to slower growth rates.

When pressure cast grids free of internal defects are annealed, it is known that some degree of grain coarsening occurs followed by redistribution of precipitates within the matrix (3). The presence of active precipitates within the grains will favor matrix corrosion over localized grain boundary attack, since grain boundaries are left free of most of the active precipitates. Hence, annealed pressure cast grids exhibit relatively greater stability toward both corrosion and attendant growth.

Automotive battery grid test.—The five plate (25 A-hr) cells were initially put on a 2.6V constant voltage overcharge. But at this test regime, the capacities of the cells during weekly discharges were slowly declining. It was, therefore, decided to give them a 1.0A current boost charge at the seventh cycle. Following this, the cells were put on a 2.8V overcharge instead of 2.6V. The switch was made not only to minimize capacity losses but also to make the overcharge more severe and consequently accelerate grid growth. The weekly discharge capacity has been plotted as a per cent of the original 20 hr rated capacity in Fig. 8. The rapid decline in capacity during cycling of all the lead-calcium cells appears to be related to loss of active material due to shedding. However, all lead-calcium cells, irrespective of the method of grid casting, exhibit nearly identical behavior. The test was terminated after 16 cycles, since most of the cells exhibited steep rises in end-of-charge current values. Localized short circuiting was suspected in these cells and was confirmed

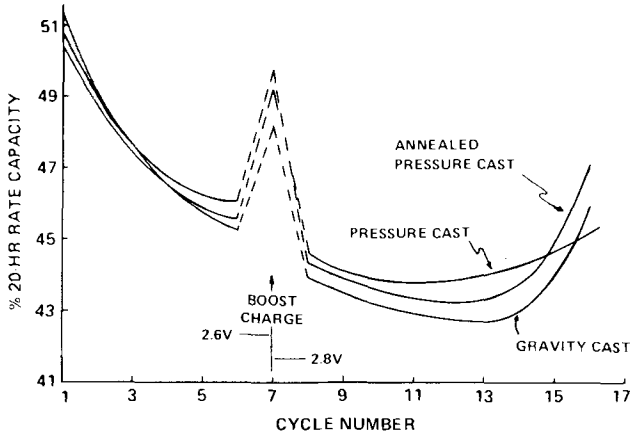

Fig. 8. Constant voltage overcharge performance of automotive lead-calcium cells.

upon examining the positive plates after disassembly of cells.

The unpasted cells consisting of five bare grids (2 positives/3 negatives) were anodically corroded at 2.8V in 1.265 sp gr acid for 12 weeks. This test was started at the middle of a pasted plate overcharge test to supplement the corrosion and growth data of pasted cells. Higher end-of-charge currents in pasted lead-calcium cells over those of similar but unpasted cells become evident (Fig. 9). The similarity in current variations both in pasted and bare grid cells, irrespective of the method of grid casting is to be noted.

The growth data of all the lead-calcium cells, both for pasted and bare grids, are presented in Fig. 10. Pasted and cycled grids show larger growth than their corresponding bare grid counterparts. This is expected on account of the inducement of higher stresses on the underlying grid structure by the active material. Gravity cast grids, both in pasted and bare grid condition show the least growth. Also, the gravity cast grids are characterized by relatively uniform growth. However, in pressure cast and annealed pressure cast grids, excessive growth seems to be occurring only in the lower half of the grid (area away from the casting gate). When cross-sections were examined, the lower part of the grid was having interconnecting pores and large voids. Lack of physical soundness in this region is primarily responsible for the abnormal growth—more so than any metallurgical structural differences arising out of the pressure casting operation. Actually, when these pressure cast grids are annealed, the growth is accelerated (Fig. 10) instead of slowed. Upon annealing, some interconnecting small pores agglomerate and thus create large voids. Since the automotive grid members are relatively thin sections to begin with, the presence of such large internal voids decreases the effective thickness of the grid members to withstand the destructive effects of corrosion and

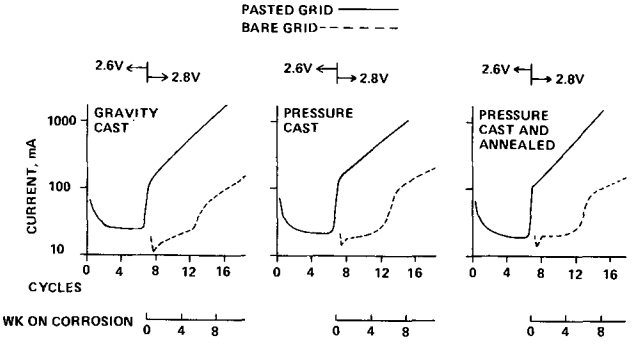

Fig. 9. Current variations during 2.8V constant voltage overcharge of pasted and unpasted lead-calcium cells.

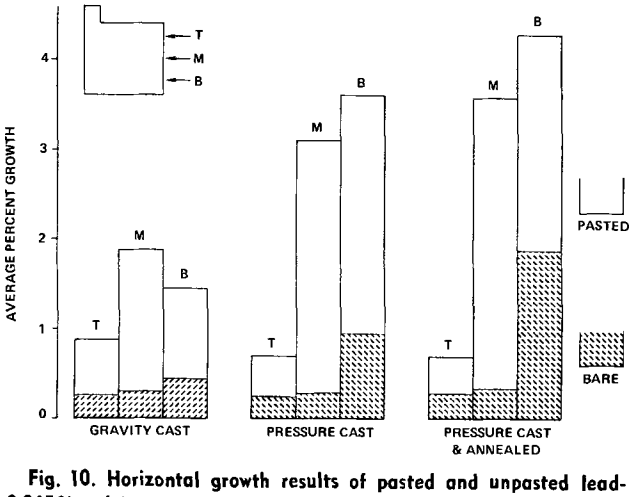

Fig. 10. Horizontal growth results of pasted and unpasted lead-0.065% calcium automotive SLI grids. 2.8V constant voltage overcharge test.

cycling, thereby seriously curtailing both corrosion and growth resistance.

In pressure cast grids, both metal turbulence in the mold cavity and rapid freezing appear to give rise to air entrapment, causing voids in the solidified grid. In the lower half of the grid area, grains are merely in intimate contact, resulting in a probable continuous fissure along the grain boundaries. During corrosion, the greater the volume of PbO_2 liberated in and adjacent to these defects, the greater the internal stress that will act as a wedge to force open the grains. This inevitably leads to expansion of the grid, thus its growth.

Now turning to metallurgical structures, it is seen that larger grains and smooth grain boundaries are characteristic of gravity cast grids while fine grains with serrated boundaries are characteristic of pressure cast grids (Fig. 11). If minimal growth of physically sound gravity cast grids is to be attributed to coarse grains, then it was thought that annealing to coarsen the grains would relieve some of the abnormal growth characteristics of pressure cast grids. Although 500°F annealing of pressure cast automotive grids led to extensive grain coarsening (Fig. 11), annealing did not contribute to any growth resistance in these grids—unlike the physically sound annealed pressure cast industrial grids.

Discussion

One of the earlier papers (2) on anodic corrosion of pressure cast grids relates the abnormal growth to preferential attack and grain boundary slip along solute impoverished zones, particularly adjacent to grain boundaries. It is our thinking that such impoverished zones or "precipitate free zones" do not occur in the lead-calcium alloys. Normally such zones occur in overaged alloys and are characterized by loss of ductility or complete embrittlement of the alloy.

Townsend (3) indicates that in all of the lead-calcium alloys studied, the strength normally increases with increased aging time. Neither we, nor Townsend detect any loss in ductility of aged lead-calcium alloys. Our observations are based on the fact that upon accelerated aging of pressure cast lead —0.06 calcium grids at 140°F for 4 months, no hardness losses were detected. From this it is apparent that changes in metallurgical structure of alloys arising out of aging are not contributing to grid growth.

On the other hand, it has been shown through fundamental corrosion studies on rods that alloy structures exhibiting great stability to preferential attack and growth could be produced by controlling the casting mold temperatures. Similar structural features in industrial battery grids are attained by pressure casting under optimized conditions. This accounts for slower growth rates and better corrosion resistance of the industrial pressure cast grids.

Pressure casting was not optimized during casting of automotive SLI grids, since these grids are short lived in contrast to industrial grids. Lack of physical soundness in pressure cast grids as the primary cause for excessive grid growth is better illustrated by the test results of automotive grids than thicker industrial grids, since here the beneficial effects of annealing are obscured by physical defects. However, structural changes resulting from annealing does contribute to growth resistance even in the presence of internal defects as demonstrated in the pressure cast industrial grids.

In conclusion this study has established that:

1. There is a good correlation between lead-calcium alloy structure and corrosion morphology.
2. Lack of physical soundness in certain regions of pressure cast grids is more responsible for excessive growth than any metallurgical structural differences arising out of pressure casting operation, and particularly as the grid thickness decreases.

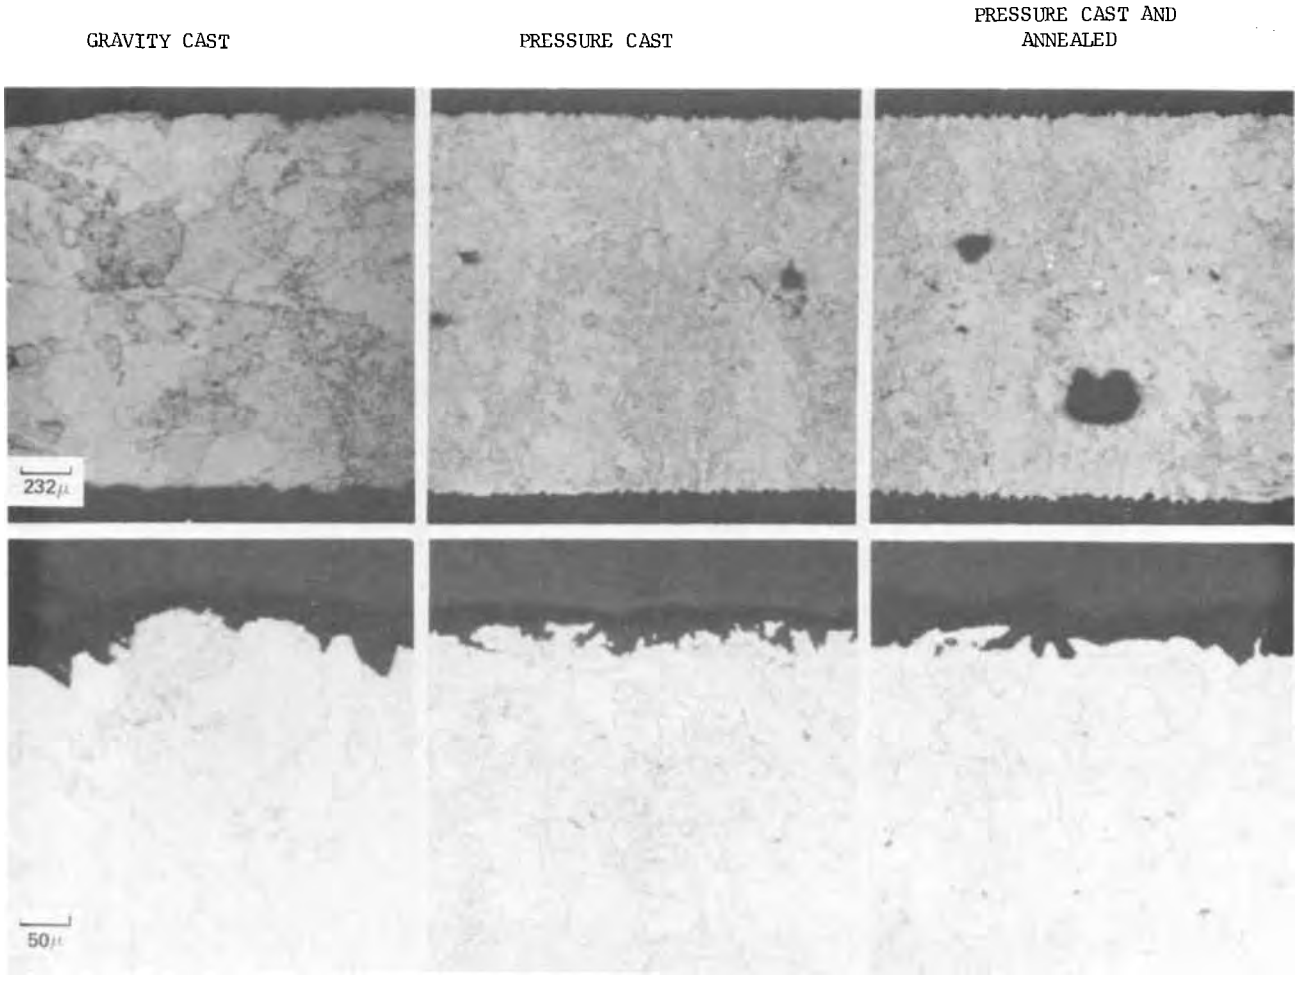

Fig. 11. Corrosion morphology of unposted lead-0.065% calcium automotive SLI grids. 2.8V constant voltage corrosion for 12 weeks

3. Casting conditions are more critical than a particular casting technique to yield acceptable lead —0.065% calcium alloy grids, since this particular step controls both the active precipitate distribution and grain size in the alloy. By casting in a mold held at a relatively higher temperature, lead-calcium alloys containing up to 0.07% calcium can be produced that are characterized by uniform and stable corrosion properties. Such alloys also exhibit good resistance to excessive growth in grids.

4. Under severe constant voltage conditions, even as high as 3.5%, grid growth in automotive SLI grids does not seriously impair either the overcharge life or capacity.

Electrochemical Behavior of Germanium in Fused LiCl-KCl Eutectic

Joseph M. Shafir and James A. Plambeck*

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

ABSTRACT

The electrode potentials of the Ge(II)/Ge(0) and Ge(IV)/Ge(II) redox couples in fused LiCl-KCl eutectic were found to be −0.792 and −0.665V *vs.* the standard molar platinum reference electrode (SMPE). A voltammetric study of Ge(II) showed that potentials more negative than −0.80V are sufficient for electrodeposition of germanium. Chronopotentiometric reduction of Ge(II) on gold followed the Sand equation and gave evidence of alloy formation. The cell Au-Ge (12 weight per cent Ge, l)/Ge(II) in LiCl-KCl/Ge(s) was studied, and the following parameters were determined for the alloy: $\Delta S°_f = 14.2$ eu, $\Delta G°_f = -1.24$ kcal/mole, $\Delta H°_f = +9.00$ kcal/mole. Optical and scanning electron metallographic studies were made of germanium deposited on a gold substrate.

Literature Review

Attempts to electrodeposit germanium have a long history. Winkler, who discovered the element, electrolyzed aqueous ammoniacal ammonium tartrate solutions of it (1). Further study of the aqueous electrochemical properties of germanium was instigated by the work of Tainton and Clayton (2) who found that small amounts of germanium had a very adverse effect on the electrodeposition of zinc. Several attempts to deposit germanium from aqueous media have since been made, such as those of Hall and Koenig (3) and of Schwarz, Heinrich, and Hollstein (4). A careful study by Fink and Dokras (5) concludes that in any aqueous medium only a thin initial flash of metallic germanium can be obtained. This is followed by hydrogen evolution since the hydrogen overpotential on germanium is low. It is thus necessary to employ nonaqueous media to electrodeposit massive germanium.

Organic baths have been used to electroplate germanium. Of these, the most popular appear to be ethylene glycol and propylene glycol. Fink and Dokras (5) produced thick adherent metal plates from solutions of GeI_4 in ethylene glycol. Solutions of $GeCl_4$ in propylene glycol were used by Szekely (6).

Fused salt media have been employed in the electrowinning of germanium from its oxide. Tressler and Dennis (7) formed metallic germanium by the electrolysis of GeO_2 in molten fluogermanate or cryolite baths. Fink and Dokras (5) employed a fused tetraborate bath to obtain the metal from GeO_2. Barbier-Andrieux (8) did an extensive study of the electrowinning of germanium from germanium dioxide in fused salts such as germanates, borates, silicates, borosilicates, phosphates, and fluorosilicates. Bockris, Diaz, and Green (9) have discussed the production of germanium dendrites by electrolysis of a $Na_2B_4O_7$-GeO_2 melt.

Experimental

Materials.—Reagent grade lithium chloride and potassium chloride (Fisher Scientific Ltd.) were purified as previously described (10). Germanium rod (99.99%) was obtained from A.D. MacKay Inc., New York. The graphite rods used as electrodes were obtained from Union Carbide Corporation, New York (spectroscopic electrodes SPK). Gold used in the thermodynamic study of gold-germanium alloy formation was obtained in bar form from Johnson Matthey and Mallory Ltd., Toronto.

Apparatus.—The apparatus used was similar to that previously described (10-12). The electrodes used for voltammetric scans were made of tungsten wire 5 mm long and 0.5 mm in diameter sealed in uranium glass. Potentials were measured with a Hewlett-Packard Model 3400A digital voltmeter. Voltammetric scans were made with a Metrohm-Polarecord 261 polarograph. Constant potential electrolyses were carried out with a Wenking Model 61RH potentiostat using gold electrodes.

Chronopotentiometric measurements employed a gold foil electrode approximately 0.4 cm^2 in area. The counterelectrode and reference electrode were respectively a carbon rod and a platinum(II)/platinum(0) couple in separate isolation compartments. The constant current was obtained from a Model 6525A d-c power supply (Hewlett-Packard) controlled by appropriate mercury-wetted relay switching circuitry. Traces were recorded on a Model 175A oscilloscope equipped with 1750B and 1781B plug-in units and a 196B camera (Hewlett-Packard), using ASA 3000 Polaroid film.

The gold-germanium alloy [eutectic composition, 12 w/o (weight per cent) germanium (13)] was prepared by placing appropriate amounts of gold and germanium in a quartz boat which had been cleaned by boiling in perchloric acid. The mixture was fused under a flow of argon (dried by passage over magnesium perchlorate) in a Lindberg-Hevi-Duty 54032A furnace in conjunction with a Lindberg-Hevi-Duty 59344 temperature controller. In the thermodynamic study, the alloy was held in a Pyrex cup which was attached to a glass rod. Electrolytic contact with the alloy was made with a tungsten wire sealed in uranium glass. The germanium bar used as a reference electrode was suspended from a platinum wire sealed in a Pyrex tube.

The topography of the germanium deposit on a gold substrate was studied using both optical and scanning electron microscopes: a Carl Zeiss Ultraphot(III) Metallograph, a photographic metallurgical microscope (Carl Zeiss Oberkochen, Wuertt., West Germany), and a Stereoscan S4 scanning electron microscope (Cambridge Scientific Instruments Ltd., Cambridge, England).

Procedure.—The procedure used for carrying out the coulometric oxidations and measurements under argon has been previously described (11, 12). The germanium rod was anodized to give solutions of germanium(II), which could be further oxidized to germanium(IV) at a carbon electrode after the germanium rod had been removed. Measurements of potential were made against a platinum(II)/platinum(0) reference electrode and all potentials given in this paper are with reference to the standard molar platinum electrode (SMPE) (14).

Key words: germanium, germanium-gold alloy, electrodeposition, fused chlorides.

In order to obtain reproducible voltammetric curves, it was found necessary to hold the tungsten microelectrode at positive (chlorine evolution) potential for a few moments before each scan. This was done in the bulk melt. Similar procedures were found necessary to obtain reproducible chronopotentiometric curves. The solutions of Ge(II) were prepared coulometrically. The gold electrode was anodized until all deposits of germanium were removed, *i.e.*, until chlorine evolution just began. It was necessary to carry out this procedure carefully and at low current density (<50 mA/cm^2) to avoid appreciable anodization of gold into solution. The electrode was then momentarily anodized at this potential, the current was shut off, and the compartment stirred by rotation of the flag. Cathodic chronopotentiometric curves were all run 30 sec after cessation of the anodic current.

In the thermodynamic study of gold-germanium alloy formation, which was a study of the cell: Au-Ge alloy/Ge(II) in LiCl-KCl/Ge, the previously prepared LiCl-KCl eutectic was fused and filtered in order to remove any magnesium present, as magnesium ribbon was used in melt preparation. A 0.2M solution of Ge(II) was prepared *in situ* by electrolytic anodization of germanium; the resulting solution was thoroughly stirred after cessation of Ge(II) generation. The solution temperature was monitored with a calibrated Chromel-Alumel thermocouple sheathed in a Pyrex tube. The germanium bar, alloy holder, and thermocouple were placed as close together as possible to minimize thermal gradients. Potential-time measurements were made every 2 hr after a new temperature setting had been made. The experiment was conducted under a static dry argon atmosphere. The thermocouple effect of the electrodes was determined in a separate experiment, and this potential was subtracted from the observed cell potential.

The cross-sectional sample used in the optical microscopic examination was prepared by imbedding a germanium-plated gold specimen edgewise in plastic. The sample was then polished, progressing from a coarse abrasive to a polishing lap using 0.05 μm Al_2O_3 (Linde B). The germanium-plated gold specimen was prepared by electrolytic reduction of solutions of Ge(II) at a constant potential of −0.86V. Germanium(II) solutions were prepared by coulometric oxidation of a germanium bar. Germanium plate thickness was determined with a filar micrometer eyepiece attached to a Tukon Tester (Wilson Mechanical Instrument Company, New York).

Results

Potentiometry.—A total of 27 concentration-potential data points were obtained from four separate coulometric oxidations of the germanium bar electrode at 450° ± 1°C. The concentration of Ge(II) ranged from 0.001 to 0.1M. A plot of electromotive force as a function of the logarithm of coulombs used was linear and had a slope of 0.075 ± 0.006 V/log unit, in agreement with the theoretical value of 0.072 V/log unit expected for a two-electron process at this temperature. The potentials became stable rapidly, usually within 5 min after cessation of the electrolysis and gentle stirring.

The standard potential was calculated in the usual manner (10) and is reported with respect to the appropriate standard platinum electrode on the molar, molal, and mole fraction scales in Table I. The conventions and standard states used in this table have been described elsewhere (14).

Further coulometric oxidation of the germanium(II) solutions at a carbon rod produced visible bubbles at the rod at polarization potentials significantly less than that of chlorine evolution, suggesting the formation of volatile $GeCl_4$ (bp, 84°C). Linear plots of electromotive force against logarithm of concentration ratio could not be obtained or had unreasonably low slopes,

Table I. Standard potentials of germanium couples

Couple	$E°_M$	$E°_M$	$E°_X$	Standard deviation
Ge(II)-Ge(0)	−0.792	−0.792	−0.792	0.008
Ge(IV)-Ge(II)*	−0.665	−0.681	−0.771	−0.002
Ge(IV)-Ge(0)†	−0.728	−0.736	−0.781	−0.008

* Based on a two-electron process.
† Calculated from experimental free energies.

as would be expected if $GeCl_4$ volatilized from the melt. Steady and rapid drifting of the observed potentials in the negative direction also support this interpretation. By taking values as rapidly as possible, this problem could be reduced but not avoided. Using eight points from two runs taken under the best possible conditions and assuming the two-electron oxidation, we calculate standard potentials of −0.664, −0.666, −0.664, −0.667V (Run 1) and −0.666, −0.667, −0.665, −0.663V (Run 2), these values being given in order of increasing generation. The average is −0.626V, standard deviation 0.022V. The systematic deviation is due to loss of $GeCl_4$.

Attempts to cathodize germanium metal into solution were not successful. The only reaction observed was lithium deposition on the germanium, at approximately the standard potential of the Li(I)/Li(0) couple (14).

Voltammetry.—A voltammetric scan of the electrolyte alone indicated a limiting anodic current at about +0.2V (chlorine evolution), a limiting cathodic current at −2.6V (lithium deposition), and a sharp cathodic peak at −0.56 ± 0.05V. This cathodic peak was not due to melt impurities but was highly sensitive to electrode treatment and history. Elimination of the prescan anodization reduced the peak to about 5% of its previous value. This peak is attributed to the reduction of adherent insoluble polymeric chloride films (15) formed when the tungsten microelectrode was anodized in the bulk melt.

Addition of germanium(II) to this melt (by anodization of a germanium rod) produced an additional cathodic wave whose half-wave potential was −0.76V, in reasonable agreement with the standard potential, −0.79V, of the germanium(II)/germanium(0) couple as shown in Fig. 1. The wave height increased with addition of germanium(II) but the relationship was not strictly linear. Curve A in Fig. 1 shows the latter stage in the reduction of the insoluble polymeric chlorides at potentials less than −0.74V, followed by Ge(II) reduction. Curve B represents a voltammetric

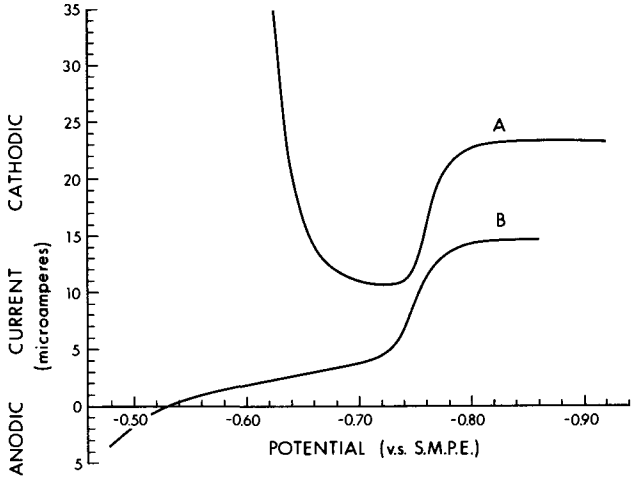

Fig. 1. Voltammetric scans of Ge(II) in fused LiCl-KCl eutectic at 450°C, using a tungsten microelectrode. Curve A was obtained with preanodization of tungsten microelectrode; curve B is a repeated scan, with no preanodization.

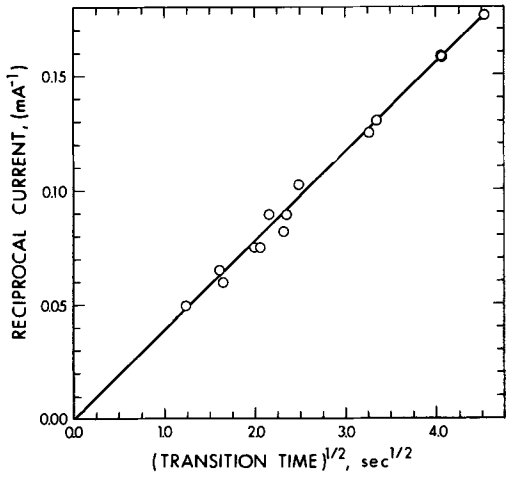

Fig. 4. Plot of reciprocal current vs $\tau^{1/2}$ for the first transition in the chronopotentiometric analysis. Concentration of Ge(II), 7.9 × 10^{-5} mole/cm^3; electrode geometric area 0.4 cm^2.

scan for which the tungsten microelectrode was not preanodized in the bulk melt. When the scan was first made toward more negative potentials, then reversed, an anodic process began to appear at about −0.75V, corresponding to the reoxidation of the deposited germanium (Fig. 2). This study indicates that constant-potential electrodeposition of germanium should be possible at potentials more negative than −0.8V.

Chronopotentiometry.—In order to attempt to observe the behavior of Ge(II) deposition in the melt under constant current electrolysis conditions, a chronopotentiometric study was carried out. Chronopotentiometric curves were run at current densities between 12 and 40 mA/cm^2. A typical curve is shown in Fig. 3. The transition region indicated as B was well-defined in all cases. The transition(s) at C and beyond were poorly defined at low current densities but became more distinct at current densities greater than 25 mA/cm^2. The length of the first transition was taken from the origin, A, to B, although an initial dip close to A was observed on all curves. We now believe that this initial dip is due to formation of surface Au-Ge alloy. The transition B is ascribed to the exhaustion of Ge(II) at the electrode surface in the usual manner. The Sand equation $i\tau^{1/2} = \frac{1}{2}\pi^{1/2} nFAD^{1/2}C$ is obeyed for this process as shown in Fig. 4, and from the data of Table II the diffusion coefficient of Ge(II) was calculated to be 2.2 × 10^{-5} cm^2/sec, in reasonable agreement with values for other divalent ions in this solvent (16).

Using low current densities, and careful observation of the electrode during chronopotentiometry, it was observed that the clean gold electrode took on a bright, mirror-like silver finish soon after cathodic current flow began. With continued electrolysis the finish continually dulled, until after the end of the first transition, B, when massive black deposits began forming. These deposits, unlike the initial finish, did not adhere to the electrode and could be knocked off by gentle stirring.

The data for the transitions observed is given in Table II. Measurement of $E_{\tau/4}$ data was difficult due to the fact that not all chlorine generated in the vicinity of the gold electrode could be removed. This led to varying initial values of potentials. To circumvent this problem, the "true" potential of this point was taken from the chronopotentiogram where the lowest current density was used to anodize the germanium from the gold electrode. All potentials were then measured from this point.

At low current densities (less than 17 mA/cm^2) no transition other than the first could be defined. At higher current densities, other transitions became noticeable, especially a well-defined second one. It has been shown by Berzins and Delahay (17) that the Sand equation for a second transition is given by

$$(\tau_1 + \tau_2)^{1/2} - \tau_1^{1/2} = \pi^{1/2} nFAD^{1/2}C/2i$$

A plot of $1/i$ *vs.* $(\tau_1 + \tau_2)^{1/2} - \tau_1^{1/2}$ was made for the second transition, but it was found that no linear relation existed, and hence the electrode process occurring was not diffusion-controlled. The formation of the black massive germanium deposit noted at the end of the first transition (B in Fig. 2) permits the nonlinearity of the plot $(\tau_1 + \tau_2)^{1/2} - \tau_1^{1/2}$ *vs.* $1/i$ to be ascribed to the rapidly changing electrode area upon

which the germanium was being deposited. Third transitions were noted at large current densities. These were ill-defined, again probably due to rapid electrode area changes.

Thermodynamics of gold-germanium alloy formation.—The gold-germanium phase diagram has been established (18) and shows simple eutectic formation at 12 w/o germanium. Using this alloy composition, the potential of the cell Au-Ge (12 w/o Ge,l)/Ge(II) in LiCl-KCl/Ge(s) was studied over the temperature range 400°-500°C. A preliminary study of the cell showed that Ge(II) is not stable in the LiCl-KCl melt over extended periods of time when a flow of argon is maintained above the cell assembly; germanium needles grew from the germanium bar and the interior of the upper, cool portion of the apparatus became coated with a white material, presumably $GeCl_4$. It was concluded that Ge(II) disproportionates to Ge(IV) and the metal, *i.e.* $2Ge(II) \rightleftarrows Ge(0) + Ge(IV)$, where Ge(IV) exists as germanium tetrachloride gas. From the standard potentials of the Ge(II)/Ge(0) and Ge(IV)/Ge(II) couples, the equilibrium constant for the disproportionation reaction is calculated to be 1.69×10^{-2} l mol^{-1}. Thus for a 0.02M solution of Ge(II), a concentration of Ge(IV) equal to 7.0×10^{-6}M is required to maintain equilibrium conditions; however, since Ge(IV) is volatile as $GeCl_4$, the disproportionation reaction is slowly forced to the right. To minimize this effect a static argon atmosphere over the cell was necessary; otherwise, the Ge(II) concentration was reduced to the point where reversible potentials were not obtained.

The temperature-potential measurements of the alloy cell are shown in Fig. 5. Data were taken by alternately raising and lowering the temperature; no hysteresis in the cell potential was observed. The cell potential at any given temperature was constant (within 0.1 mV over a 15-min interval). These facts, together with the observation that the equilibrium cell potential recovered its initial value after passage of small amounts of current in either direction through the cell, indicated that the system was reversible. The potential at both the Ge(s) and Au-Ge (12 w/o Ge, l) electrodes is dictated by the concentration of Ge(II) in solution, since the extent of the reaction $2Au + Ge(II) \rightarrow Ge + 2Au(I)$ is small as can be seen from the standard potential of the Au(I)/Au(0) couple, +0.205V (14).

The entropy of alloy formation can be determined from the slope of Fig. 5 and the relationship $\Delta S = n\mathbf{F}(dE/dT)$, where n is the charge on the Ge(II) ion, **F** is Faraday's constant, and dE/dt is the slope of the potential-temperature plot. The standard free energy of alloy formation is directly calculable from the open-circuit potential of the galvanic cell at 450°C ($E°$). The standard enthalpy of alloy formation, $\Delta H°$, is calculable from the free energy and entropy of alloy formation. For the alloy Au-Ge (12 w/o Ge), the following parameters were determined: $\Delta S°_f = 14.2 \pm 0.2$ eu ($dE/dT = 3.07(\pm 0.04) \times 10^{-4}$ V/K); $\Delta G°_f = -1.24 \pm 0.02$ kcal/mole; and $\Delta H°_f = 9.00 \pm 0.10$ kcal/mole. By considering the Nernst equations for the half-cells $Ge(II) + 2e^- \rightarrow Ge$ and $Ge(alloy) \rightarrow Ge(II) + 2e^-$, it can be shown that $E_{cell} = -2.303\ RT/2\mathbf{F} \log a_{Ge(alloy)}$, where $E_{cell} = 26.8 \pm 0.4$ mV (after correction for the thermocouple effect of +9.4 mV) at 723°K and $a_{Ge(alloy)}$ is the activity of germanium in the alloy, which was calculated to be 0.426 ± 0.010. Defining γ as the activity coefficient of germanium in the alloy and X as the mole fraction of germanium in the alloy, then $a_{Ge(alloy)} = \gamma X$ (where $X = 0.270$) gives a value of $\gamma = 1.57 \pm 0.03$. Table III gives a comparison of the thermodynamic properties measured in this work with those of other Au-group(IV) element alloys (19, 20). It should be noted that the interaction between gold and germanium is small as are the interactions between gold and tin and gold and lead. The dip shown at A in Fig. 3 corresponds to a shift of approximately 50 mV in potential. The open-circuit potential corresponding to the standard free energy of gold-germanium alloy formation was found to be 26.8 mV. The gold-germanium composition at A is not exactly known but the 50 mV potential shift at A strongly indicates gold-germanium alloy formation.

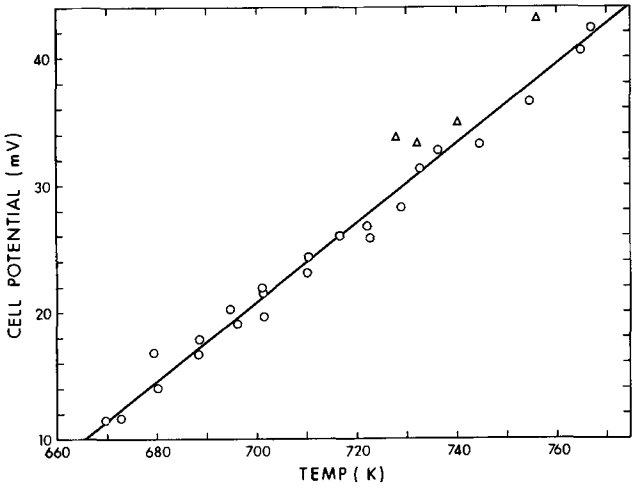

Fig. 5. Plot of potential vs. temperature for the cell Au-Ge (12 w/o Ge,l)/Ge(II) in LiCl-KCl/Ge(s). Nonequilibrium values taken in separate run indicated by triangles.

Using a current density of 50 mA/cm^2 for approximately 3 sec, Ge(II) was plated on to the gold electrode and this plate was then anodized. The $E_{\tau/4}$ for the anodic chronopotentiogram was −0.46V as compared to $E_{\tau/4}$ for the reduction chronopotentiogram which was of the order of −0.84V. The potential of the anodic chronopotentiogram did not rise sharply, *i.e.*, oxidation of germanium was extended over a large period of time. This behavior is also indicative of alloy formation.

Optical metallography of deposited germanium.—Figure 6 is a cross-sectional photomicrograph of germanium deposited onto a gold substrate as previously described. The gold substrate, originally 250 μm in width, was found to be 160 μm wide. The outer layers had a total width of 340 μm. The germanium layer is not pure germanium but is a gold-germanium eutectic as can be discerned by its structure (21) which resembles pearlite. In several regions the germanium had penetrated the gold band so that both outer layers were connected; these connections were blue-gray in color.

Table III. Thermodynamics of gold-metal eutectic alloys, 450°C

Metal	Eutectic composition, mole fraction metal	$\Delta G°_f$, kcal/mole	$\Delta S°$, eu	$\Delta H°_f$, kcal/mole	dE/dT, mV/deg	Activity, metal	Activity coefficient, metal

* Data extrapolated to 450°C.

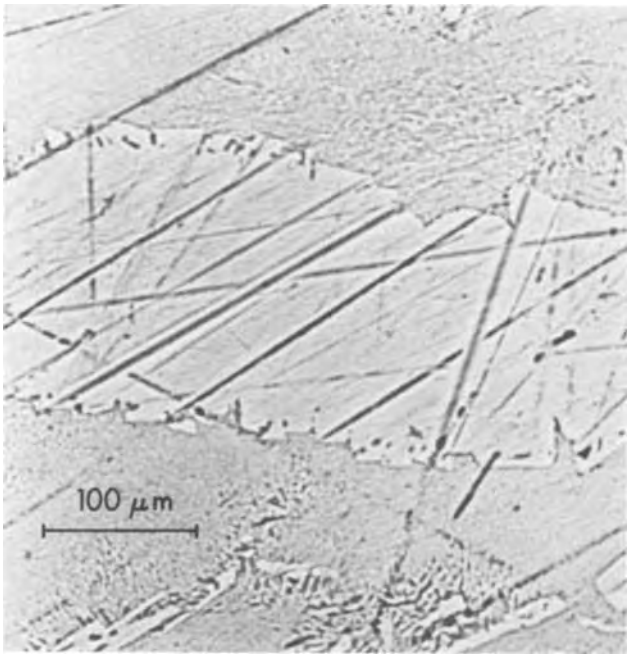

Fig. 6. Photomicrograph of cross section of Ge deposited on gold

Needle-like deposits of germanium were obtained in all experiments utilizing constant potential as the mode of electrodepositing germanium. The needles varied up to 1 cm in length and up to 200 μm in width, and grew from the gold-germanium interface into the solution.

Scanning electron microscopy of deposited germanium.—The samples were obtained either by allowing the sample to slowly cool in the eutectic as the eutectic froze, or by withdrawing the sample from the eutectic melt and cooling it to room temperature. Samples obtained with slow cooling were much smoother than those obtained on rapid cooling. Use of more reducing, *i.e.*, more negative potentials gave rise to rougher surfaces than use of a less reducing potential.

A photomicrograph of a sample obtained by constant-potential electroreduction of a solution of Ge(II) at −0.85V followed by rapid sample cooling showed surface cracks. These cracks produced by the rapid sample cooling were at least 3 μm deep and showed that the gold-germanium deposit was layered.

Conclusion

The oxidation states of germanium stable in the LiCl-KCl melt at 450°C are +2 and +4. The standard reduction potentials of both have been measured. Germanium metal can be electrodeposited from this melt, but the reduction process on gold is complicated by alloy formation. The thermodynamics of this alloy formation have been studied.

Intergranular Corrosion of a Ferritic Stainless Steel

R. P. Frankenthal*,[1] and H. W. Pickering*,[2]

United States Steel Corporation, Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

The chromium-depletion theory of intergranular corrosion has been confirmed for a ferritic stainless steel. The potential range over which intergranular attack occurs is limited by the passivation potential of the matrix and that of chromium-free iron. The concentration of chromium in the depleted zone is less than 5% at most grain boundaries and approaches 0% at a few. The width of the depleted zone is less than 1 μm. Under strongly oxidizing conditions another form of intergranular attack occurs in both the sensitized and nonsensitized conditions.

The intergranular corrosion of ferritic stainless steels has been explained by numerous models (1-4). Bäumel (4) suggested that the chromium-depletion theory, proposed by Strauss, Schottky, and Hinnüber (5) in 1930 and by Bain, Aborn, and Rutherford (6) in 1933 for austenitic stainless steels, is also valid for ferritic ones.[3] This theory holds that sensitization to intergranular attack is due to a chromium-depleted zone along the grain boundary resulting from the precipitation of chromium carbide at the boundary; if the chromium concentration of the depleted zone is less than that required to maintain passivity, *i.e. ca.* 13%, preferential dissolution of the depleted zone will occur.

Bond (8) has results for ferritic steels that are consistent with the chromium-depletion theory; but they do not prove it. Also, the extent of depletion, *i.e.*, the chromium concentration and the width of the zone, has yet to be determined for ferritic or austenitic stainless steels.

Cihal and Prazak (9) suggested for austenitic stainless steels, *e.g.*, Fe-18Cr-8Ni, that a chromium-depleted zone should behave electrochemically like an Fe-Ni alloy; the passivation potential of Fe-Cr-Ni alloys becomes more noble with decreasing chromium concentration. Thus the depleted zone should passivate only at potentials more noble than that required to passivate the matrix. Further, preferential attack of the depleted zone should be limited to a potential range between the passivation potential of the matrix (maximum possible chromium content) and the passivation potential of the chromium-free Fe-Ni alloy (minimum possible chromium content). Their (9) experimental evidence is *not* convincing, because much of the intergranular corrosion takes place at a potential at which the matrix is also dissolving, according to their anodic polarization curves. However, Schüller, Schwaab, and Schwenk (10) show that one form of intergranular attack is limited to this potential region.

In this paper the test of Cihal and Prazak (9) is applied to a sensitized ferritic stainless steel and extended to obtain quantitative data on the chromium content of the depleted zone. In addition, the width of the zone is determined by scanning electron microscopy.

Experimental

The principal alloy investigated was a vacuum-melted, hot-rolled[4] Fe-20Cr ferritic alloy with the following analysis in weight per cent (w/o): Cr-20.2; C-0.014; N-0.005; O-0.014; P-0.003; S-0.005; Si-0.014; Mn-<0.005; Ni-<0.03; Cu-<0.01; Mo-<0.01; Al-0.008; Ti < 0.01. Rectangular specimens were machined from a 1.5-cm thick hot-rolled slab. Some specimens were used without further heat-treatment; others were annealed at 1070°K for one week and quenched.

In addition to the above alloy, zone-refined iron and ferritic iron-chromium alloys, containing 4.8, 9.6, and 14 w/o chromium, were used for the determination of the effect of chromium content on the passivation potential. Each of these was hot-rolled, annealed at 1070°K for one week, and quenched.

Two electrolyte solutions were used: 0.5*M* H_2SO_4 (*p*H 0.3) and 0.5*M* NaCl, 0.05*M* H_2SO_4 (*p*H 1.1); they were deaerated with helium. The electrochemical cell and electrical circuit have been described previously (11).

All specimens were polished with an aqueous suspension of 0.3 μm particles of alumina prior to insertion into the cell. The initial applied potential, −0.5V (SHE), was sufficiently cathodic to reduce most of the air-formed oxide film (12). After film reduction the potential was switched to that under study. The current and the potential were monitored continuously. All potentials are reported relative to the standard hydrogen electrode (SHE). All experiments were performed at room temperature, 296°K.

Scanning electron micrographs were taken with a Cambridge Stereoscan microscope; to interpret properly the spatial relationship between the attacked grain boundary and the precipitate decorating the boundary, stereo pairs were obtained.

The Strauss test for susceptibility to intergranular corrosion was performed as follows: the specimen was immersed for two days in a boiling solution of 10% $CuSO_4 \cdot 5H_2O$, 10% H_2SO_4. After the specimen was removed from the solution, washed, and dried, it was lightly polished with an aqueous suspension of 0.05 μm particles of alumina to remove reduced copper and superficial surface attack; the specimen was then examined microscopically. A modified Huey Test (16) was also performed.

Results

During microscopic examination it was observed both for the hot-rolled and for the hot-rolled, annealed Fe-20Cr specimens that most of the grain boundaries were decorated with quasi-continuous sheets of a precipitate. The alloy was dissolved in bromine-methanol solution exposing the precipitate (Fig. 1). Conclusive identification was not possible. X-ray diffraction patterns of the precipitate extracted from hot-rolled specimens were identified as $(Cr,Fe)_7C_3$, while those from hot-rolled, annealed specimens were identified as $(Cr,Fe)_{23}C_6$; however, electron diffraction patterns could not be identified with either carbide.

Steady-state anodic polarization curves were measured for the various hot-rolled, annealed alloys and for annealed iron in the 0.5*M* H_2SO_4 solution. From the potential-current curves (Fig. 2) it is evident that the passivation potential is a strong function of the

[4] A 3-in. ingot is heated to 1500°K; six passes through rolls; reheated; four additional passes.

Key words: chromium, chromium-depletion, iron, passivity.

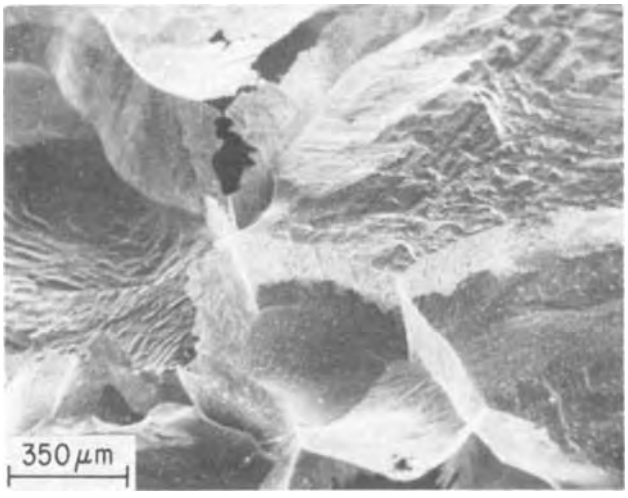

Fig. 1. Alloy has been dissolved in bromine-methanol solution exposing sheet-precipitates along grain boundaries. It can be seen that each side of a grain was bounded by one continuous sheet.

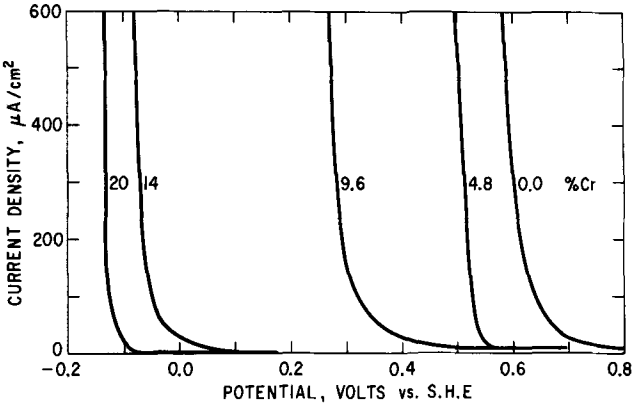

Fig. 2. Anodic polarization curves in the vicinity of the passivation potential for various Fe-Cr alloys in 0.5*M* H_2SO_4.

chromium content of the alloy. The Fe-20Cr alloy in the hot-rolled, annealed condition can be passivated also in the 0.5*M* NaCl, 0.05*M* H_2SO_4 solution, but iron and the Fe-4.8Cr and Fe-9.6Cr alloys cannot be passivated.

The Strauss test showed that the hot-rolled Fe-20 Cr alloy was sensitized, *i.e.*, grain boundary attack occurred, whereas the hot-rolled, annealed one was not. The other Fe-Cr alloys and the iron were not sensitized after annealing. The alloy in the hot-rolled and in the hot-rolled, annealed condition exhibited intergranular attack in the modified Huey Test.

The susceptibility to intergranular attack was also determined potentiostatically in both solutions for the Fe-20Cr alloy in the hot-rolled and in the hot-rolled, annealed conditions. The results are summarized in Table I. For the nonsusceptible specimens the steady-state current density in the potential region of passivity was always less than 1 $\mu A/cm^2$; for the susceptible specimens the current density never was less than about 10 $\mu A/cm^2$. For the latter grain boundary attack

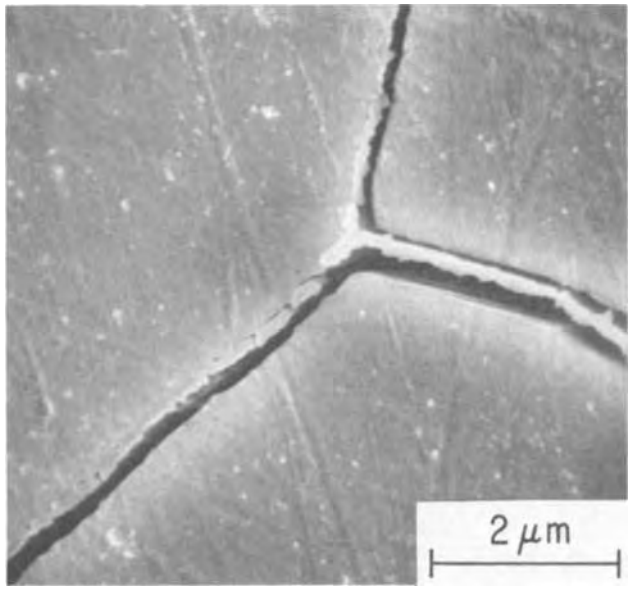

Fig. 3. Scanning electron micrograph of boundaries corroded in 0.5*M* H_2SO_4 at 0.48V. The sheet-precipitates are clearly visible.

could normally be observed in the optical microscope after less than 1 hr; no attack was observed on the former after 24 hr. It is clear that in these experiments the susceptible boundaries never became passivated.

A typical example of grain boundary attack in the H_2SO_4 solution is shown in Fig. 3. The sheet-precipitates are clearly visible; they are never attacked under these experimental conditions. The boundary between the corroded area and the matrix is always smooth, as observed at the specimen surface (Fig. 3). Specimens were held at potential for periods of time up to 24 hr. Measurements on many specimens and many boundaries indicate that the maximum width of the attacked zone is reached within 2 hr. At 0.48V the widest zone observed was 0.7 μm and the narrowest was 0.05 μm.

A typical example of corrosion in the chloride-based solution is shown in Fig. 4 and 5. The attack starts and propagates along grain boundaries; but it also spreads away from the boundaries, forming large pits. The sheet-precipitate is clearly visible in Fig. 5; it is never attacked under these experimental conditions.

Grain boundary attack at high potentials (>1.2V) was not investigated further, except to determine that the matrix and not the precipitate was dissolved.

Discussion

The results confirm the chromium-depletion theory of intergranular corrosion (5, 6), as applied to ferritic stainless steels. The maximum potential at which intergranular attack is observed in the H_2SO_4 solution lies below the passivation potential of iron (Table I, Fig. 2); if the maximum potential were higher than the passivation potential of iron, the chromium-depletion theory would not be applicable (9). Other theories (1-3, 7) are not consistent with these results, inasmuch as they cannot predict the decrease in intergranular attack with increasing potential from 0.48 to 0.58V and the absence of attack at potentials from 0.60 to 1.20V.

Table I. Susceptibility to intergranular corrosion

Electrolyte solution	Thermal history	Potential (V)	Results
0.5*M* H_2SO_4	Hot-rolled & annealed	$-0.05 \leqq E \leqq 1.20$	No intergranular attack
		$E \geqq 1.25$	Intergranular attack
	Hot-rolled	$E \leqq 0.48$	Intergranular attack
		$E = 0.52$	Some intergranular attack
		$E = 0.58$	A few boundaries attacked
		$0.60 \leqq E \leqq 1.20$	No intergranular attack
		$E \geqq 1.25$	Intergranular attack
0.5*M* NaCl, 0.05*M* H_2SO_4	Hot-rolled & annealed	$0.10 \leqq E \leqq 0.60$	No intergranular attack
		$E \geqq 1.00$	Intergranular attack
	Hot-rolled	$E > 0.00$	Intergranular attack

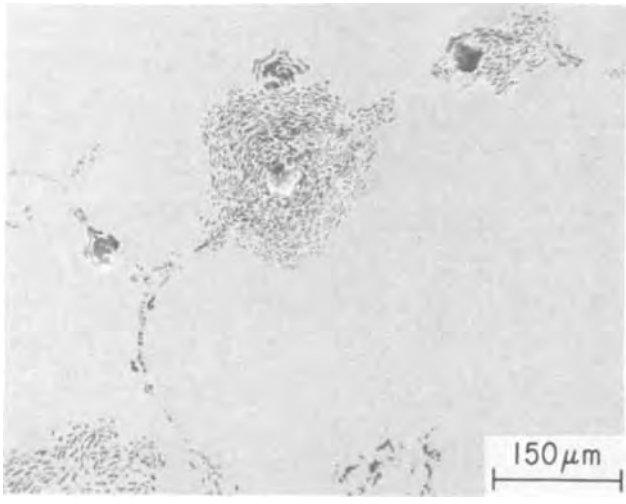

Fig. 4. Scanning electron micrograph showing grain boundary attack in solution containing 0.5M NaCl, 0.05M H_2SO_4. Attack starts at grain boundary but spreads away from the boundary at later stages in chloride-containing solutions.

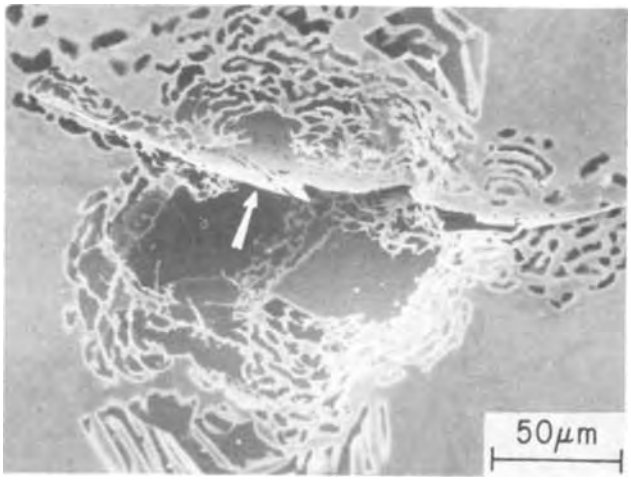

Fig. 5. Scanning electron micrograph showing grain boundary attack and subsequent pitting in solution containing 0.5M NaCl, 0.05M H_2SO_4. Sheet-precipitate (arrow) along grain boundary is clearly visible.

From the results in Table I and in Fig. 2 a lower limit for the chromium concentration of the depleted zone may be obtained. In the H_2SO_4 solution at 0.52V, a potential at which the passivity of the Fe-4.8 Cr alloy begins to decay, most of the grain boundaries were attacked; however, at 0.58V only a few boundaries were attacked and at 0.60V none was attacked. It is concluded that the minimum chromium concentration of the depleted zone is less than 5% for most boundaries; for at least a few boundaries the chromium content must be significantly less than 5% and perhaps approaches 0%. These concentrations represent the lower limit of the gradient from the boundary toward the matrix.

The results of the Strauss test are in agreement with the results of the potentiostatic experiments. The electrode potential of the specimens in the Strauss test is between 0.3 and 0.4V (13); in this potential range ferritic steels, or chromium-depleted zones, with chromium content less than approximately 10% will corrode (Fig. 2).

Since the maximum width (0.7 μm) of the attacked zone across a boundary did not change for corrosion periods from 2 to 24 hr, this width must correspond to that fraction of the depleted zone that dissolves at 0.48V. This width of 0.7 μm is in agreement with the fact that the depleted zone could not be detected by the electron microprobe, which has a beam width of 1 μm. The large variation in the width of the attacked zone, *i.e.*, from 0.05 to 0.7 μm, may indicate that the degree of chromium depletion varies considerably from boundary to boundary, a condition that could have arisen during solidification and cooling of the ingot and could be an effect of the orientation of the grains and of the precipitate.

In the chloride-based solution the grain boundaries of the sensitized alloy are attacked at all potentials, while those of the nonsensitized one are passive over much the same potential range as in H_2SO_4. This is also consistent with the chromium-depletion theory, inasmuch as Fe-20Cr, but not iron, Fe-4.8Cr, or Fe-9.6Cr can be passivated in the chloride-based solution.

The morphology of attack (Fig. 4 and 5) in the chloride-based solution is much different from that in H_2SO_4. This may be explained by the fact that although localized corrosion was initiated as a result of chromium depletion, it propagates in chloride solutions by another mechanism (14, 15) after the depleted zone has been dissolved.

At potentials of 1.25V and higher, intergranular corrosion was observed both in the sensitized and in the nonsensitized alloy, potentiostatically and in the modified Huey Test. This, of course, cannot be explained by the chromium-depletion theory. Aust, Armijo, and Westbrook (16) have suggested that in austenitic stainless steels this may be associated with continuous grain boundary paths either of second-phase or of solute-segregated regions. Their mechanism, however, is relevant only at very high potentials or under strongly oxidizing conditions, such as are rarely encountered in practical situations.

The quasi-continuous sheets of carbide, if indeed they are carbide, decorating grain boundaries (Fig. 1) apparently formed during solidification and cooling of the ingot, as evidenced by the dendritic structure of the sheets. Calculations show that there was sufficient carbon (0.014%) in this alloy with its large grain size (approximately 0.05 cm diameter) for these sheets to be carbide. In any event the sheets are Cr-rich, in view of neighboring Cr-depleted regions, the latter having been identified by the present experimental results.

Conclusions

The chromium-depletion theory of intergranular corrosion has been confirmed for a ferritic stainless steel. A sensitized steel corrodes intergranularly in a potential range limited by the passivation potential of the matrix (corresponding to maximum possible chromium content) and the passivation potential of iron (corresponding to minimum possible chromium content). From a comparison of the anodic polarization curves of Fe-Cr alloys of different chromium content with the potential range over which the extent of intergranular corrosion decreased to none, the minimum concentration of chromium in the depleted zone was established to be less than 5% and at some boundaries to approach 0%. The width of the depleted zone varied from 0.05 to 0.7 μm, as determined from scanning electron micrographs.

At sufficiently high potentials, above the range in which no intergranular corrosion is observed, both the sensitized and the nonsensitized steel exhibited intergranular attack. This attack cannot be due to chromium depletion adjacent to the grain boundary.

Acknowledgments

We thank C. E. Brickner and W. Gundaker for taking the scanning electron micrographs, A. Szirmae and L. Zwell for isolating and identifying the carbides, and S. Barnartt for helpful discussions.

Structure of Sodium Chloride Films Deposited onto a Leading Edge on Fused Silica

W. Robert Sinclair,* G. W. Kammlott, and R. A. Fastnacht

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Moving mask deposition can considerably affect the structure of evaporated NaCl films on fused silica giving larger grain sizes and enhanced orientation in the plane of the substrate. The dimensions of the mask slit, the substrate temperature, and the speed of the moving mask are important variables. The smaller the width of the slit in the mask the greater the degree of preferred orientation. An intermediate temperature (*ca.* 25°C) gives the largest grain size enhancement and the greatest degree of preferred orientation. The speed of the moving mask must be above the minimum value to achieve these effects. Having once formed an ordered film of small width one can expand the slit width and preserve the orientation.

There have been several studies of the effect on film structure of depositing through a moving mask onto a leading edge. Nowak (1) has reported the preparation of single-crystal films of silicon on amorphous silica at 1150°C by electron beam evaporation. The film was seeded on a bare spot of a silicon wafer and then led over a thermal oxide film while still maintaining the single-crystal arrangement. This maneuver was accomplished using a slotted mask. Unfortunately only the abstract of an oral presentation is available and it is difficult to assess this work especially with respect to experimental details. Another problem posed is the nature of the amorphous silica. This is a film grown from silicon and still attached to the silicon. Distler *et al.* (2) in various papers claim that such films can display a "memory" effect which reproduces the electrical potential at the silicon surface. Thus, if this effect were operative, the evaporated silicon would not have been deposited on a truly amorphous surface. It should be noted, however, that the findings of Distler and his various co-workers have been challenged by Chopra (3).

Braunstein (4) studied the deposition of silicon onto fused silica, single-crystal sapphire, or silicon using a mask system similar to the one indicated in Fig. 1. Braunstein was able to obtain single-crystal silicon on sapphire and on silicon at 1100°C. Films deposited onto fused silica at 1100°C were polycrystalline with very slight indications of preferred orientation. At room temperature, silicon deposited onto fused silica was amorphous whereas use of sapphire at room temperature led to single-crystal films. These films were prepared by vacuum evaporation using rf heating of a carbon crucible, by electron beam evaporation, and by chemical vapor deposition.

In later experiments Braunstein (5) obtained single-crystal films of silicon by evaporating silicon onto a fused silica substrate which had been preclad with gold film and was held at 800°-900°C during evaporation. This experiment was in effect a combination of the V. L. S. technique (6) as used by Nielsen (7) and Filbry and Nielsen (8) with the moving mask technique. Braunstein *et al.* (9) have also reported on this subject.

Clark and Alibozek (10) prepared single-crystal silicon areas by sputtering onto substrates held at 200°C. The substrates were mechanically polished silicon or thermally oxidized silicon (1μ thick). These authors showed that the moving mask substantially improved the orientation. They also sputtered through a moving mask but without the V-shaped fixed mask and obtained a highly oriented film.

These references represent the literature of which the authors are aware on the subject of structural effects resulting from film preparation by deposition through a moving mask system. The general idea of minimizing the number of nuclei by masking is intuitively appealing. The results of Clark and Alibozek

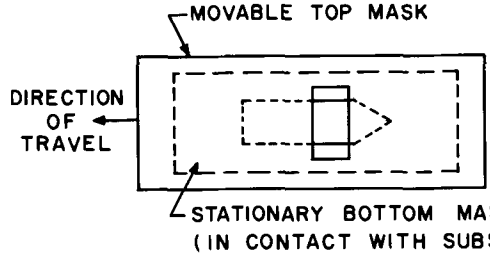

Fig. 1. Typical moving mask assembly used by Braunstein (4) featuring stationary bottom mask in contact with substrate and movable top mask.

Key words: sodium chloride films, moving mask deposition.

are, we feel, inconclusive in demonstrating the efficacy of moving masks per se in that possibilities of changing the film orientation by electric charge effects are also present (11, 12). The experiments of Braunstein and others where silicon was deposited onto a gold film are also open, we feel, to various interpretations. Here the possibility of thermal gradients caused by partially blocking radiation from the evaporation source must be considered.

Despite what we consider to be the inconclusive nature of previous experiments involved with the moving mask concept we have felt there is potential in the idea and that further study is warranted. Our objective in this paper is to present some initial results of a continuing study of the significant parameters involved in moving mask deposition. The ultimate aim of the work is to prepare single-crystal films on nonideal surfaces (*i.e.*, surfaces which are not single crystal and which do not satisfy the often stated requirements of close matching of lattice parameters between film and substrate). The system studied here is sodium chloride on fused silica. Sodium chloride was chosen because such films are easy to deposit and analyze; fused silica because it is in a sense ideally nonideal (*i.e.*, random structure with no grain boundaries) with no complicating features such as exsolution which occurs with some of the more complex glasses on heat-treatment. Because so many variables in thin film work are interrelated it is usually difficult to assess definitively the effects of changing a single parameter. The study presented here is aimed mainly at obtaining some information on the effects of varying substrate temperature and velocity, and varying mask dimensions and shapes.

Experimental Apparatus and Procedures

The apparatus used is depicted schematically in Fig. 2 and 3. Sodium chloride was evaporated downward from a baffled tantalum heater through a double mask system onto the fused silica substrate. In most of our experiments the top mask was fixed and the lower mask and substrate moved together. Keeping the position of the top mask fixed has the advantage of keeping the angle of deposition onto the substrate fixed. We have followed Nowak's (1) terminology and refer to this process as planar edge growth (PEG).

We have used a variety of sizes and shapes of lower masks in geometries similar to that shown in Fig. 1 where the lower mask is in contact with the substrate. We find that with either metal or mica masks the mask edge in contact with the glass substrate acts as a nucleating agent leading to much more random polycrystallinity than in experiments with a mask arrangement as shown in Fig. 3 where the lower mask is not in direct contact with the glass substrate. A straight slit was chosen over the flare type of Fig. 1 to simplify interpretation of the results. Usually, diffraction patterns were obtained only in the region near the end

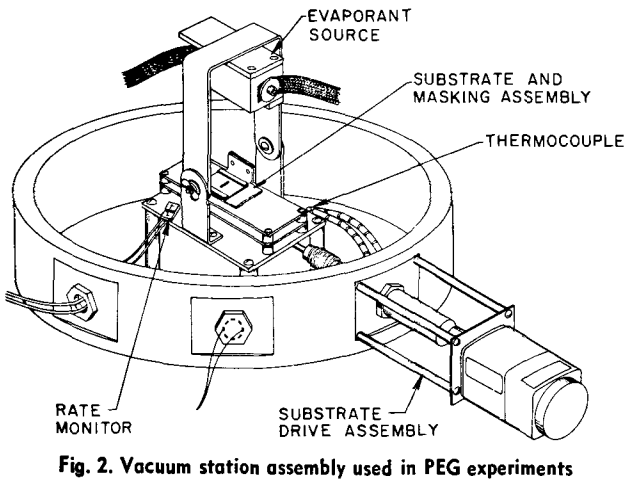

Fig. 2. Vacuum station assembly used in PEG experiments

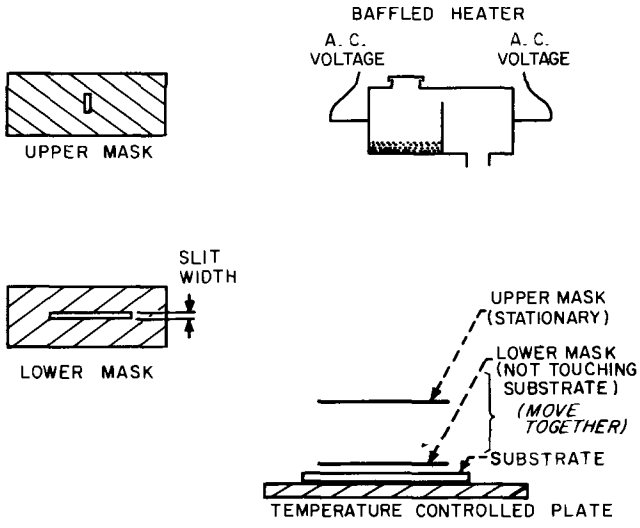

Fig. 3. Detailed drawing of moving mask assembly from Fig. 2 (side view) and diagram of masks usually employed. The slit width labeled on the bottom mask is the dimensional variable referred to in the body of this paper.

of the evaporated line. In other words, we present no information here of how quickly in the deposition process changes occur in the structure of the film but simply what the structure is at the end of the deposition.

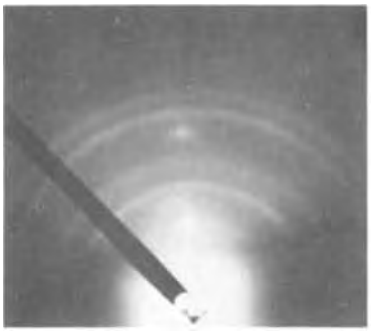
The sodium chloride used was from shattered Harshaw single crystals. The substrate was driven by means of a rotating screw powered by a motor outside the vacuum system and equipped with an adjustable gear train. Linear velocities were available in steps from 3.0 cm/min to 3.2×10^{-4} cm/min. The glass slide tested on a metal plate whose temperature could be controlled and measured using an attached thermocouple and associated circuitry. It is the temperature of this metal plate which is referred to herein as the substrate temperature. A conventional vacuum system with an oil diffusion pump was used. The pressure during evaporation was $0.5\text{-}2 \times 10^{-5}$ Torr. The deposition was monitored with a quartz crystal thickness gauge. The rate of deposition was controlled manually. During a run the substrate was moved only after the rate was fixed and stable. Little adjustment was required during a run.

At the conclusion of an experiment the slide was removed, sectioned, and inserted into the electron diffraction apparatus for structure determination by reflection electron diffraction (RED). In some cases the line broadening in these RED patterns was measured to enable estimation of the particle size using the Scherrer equation and the procedure outlined by Bartram (13). It is recognized, of course, that the RED technique samples only the outer surface region of the film and we must specifically assume that the changes in the structure of this outer surface region are symptomatic of similar changes in the bulk of the film.

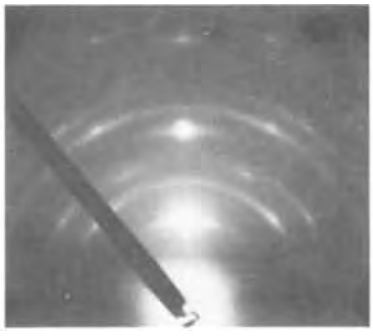
Results and Discussion

Sodium chloride deposited on glass at room temperature by usual evaporation techniques (*i.e.*, 90° evaporation with no masking) at a rate of 200 Å/min gives a RED pattern indicating no preferred orientation in the plane of the substrate as shown in Fig. 4a. This is in accord with results obtained by Schulz (14) some years ago. The results for substrate temperatures of −100° and +200°C are similar with respect to orientation differing only in the sharpness of the lines.

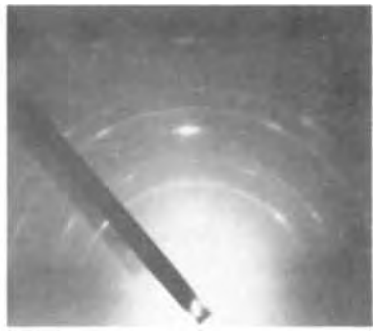
If now we deposit NaCl films at +200°, 25°, or −100°C using the masking arrangment of Fig. 3 we find that different results can be obtained depending



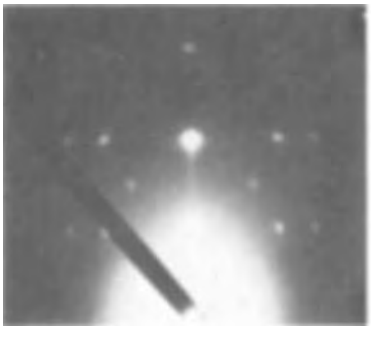
(a) 25°C substrate, no substrate movement.



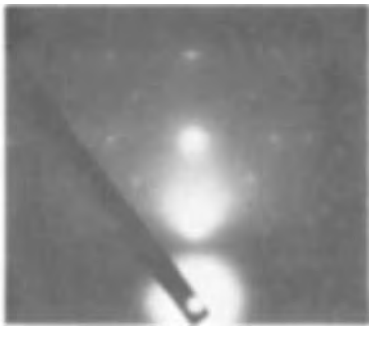
(b) 200°C substrate, 1.5 mm bottom mask slit width, 3 mm/min substrate speed.



(c) 25°C substrate, 1.5 mm bottom mask slit width, 3 mm/min substrate speed.



(d) 25°C substrate, 0.05 mm bottom mask slit width, 3 mm/min substrate speed.



(e) 25°C substrate, bottom mask as shown in Fig. 5, 3 mm/min substrate speed.

Fig. 4. RED patterns obtained from NaCl films prepared in various ways.

on experimental conditions. We shall consider first two variables, substrate temperature and the slit width of the bottom mask, keeping deposition rate (200 Å/min) and substrate velocity (3 mm/min) constant. Inspection of the RED pattern shown in Fig. 4b obtained from a film deposited at 200°C with a bottom mask slit width of 1.5 mm shows that PEG can indeed affect the orientation of the film in the plane of the substrate as judged by the breakdown of some of the RED semicircles in Fig. 4a into arcs. The degree of orientation of the films has been estimated by measuring the angular dispersion of selected reflections. To take a particular example, for the arc going through the point of the 620 reflection one finds angular dispersions of 180°, 20°, and 50° for −100°, 25°, and 200°C, respectively. This maximization of the orientation effect at an intermediate temperature appears to be generally true but is not always as dramatic as the chosen example. Comparison of Fig. 4b and 4c illustrates the effects obtained. Changes are also noted in the particle size as determined from the line broadening. In general, for a given substrate temperature the particle size is increased when the PEG procedure is used with the maximum enhancement achieved at the intermediate temperature, 25°C. For example, for a substrate velocity of 3 mm/min the particle size is *ca.* 40Å at −100°C, *ca.* 60Å at +200°C, and *ca.* 100Å (our upper limit of particle size determination by line broadening using 40 keV electrons) at 25°C. If the PEG procedure were not used the particle sizes would be 25Å or less depending on temperature.

The effect of the slit width of the bottom mask on film structure has been studied at −100°, 25°, and 200°C. In general the RED patterns indicate that orientation in the plane of the substrate is enhanced with decreasing slit width down to slit widths of 0.05 mm at least. At 0.05 mm slit width and a 25°C substrate temperature arcing of the higher order reflections has essentially been replaced by a spot pattern and the arcing of the low index planes is of very low intensity compared with the spot pattern as shown in Fig. 4d. Comparison of Fig. 4c and 4d shows the substantial increase in orientation resulting from decreasing the slit width from 1.5 to 0.05 mm.

In another group of experiments we have investigated the effect of substrate speed. Here temperature was fixed at 25°C, the deposition rate at 200 Å/min, and the slit width of the bottom mask at 1.5 mm. At a speed of 0.48 mm/min or less the film has a random structure in the plane of the substrate yielding RED patterns similar to Fig. 4a. At 3 mm/min an arced pattern is obtained as shown in Fig. 4c. At 30 mm/min some further enhancement of the orientation is obtained. Since the possibility exists that we were seeing here a film thickness effect rather than an effect due to the speed of mask movement, the dimensions of the upper mask opening were changed to increase the film thickness and likewise the substrate was stopped during deposition to allow film build-up on the area to be analyzed. From these experiments it was shown that the film thickness was not the important variable but rather the speed of the substrate during deposition. Schulz also (14) found the structure of NaCl films on glass to be independent of thickness in this thickness range (up to 2000Å) in his non-PEG experiments.

Finally, some experiments were done using a bottom mask as shown in Fig. 5. These differ from Braunstein's (Fig. 1) in that our bottom mask does not touch the substrate and we also have a long narrow section. The specific dimensions are given in the legend of Fig. 5. With NaCl, at least, this added narrow section is significant since without it no preferred orientation is obtained in a PEG experiment. Using the mask of Fig. 5, depositing NaCl onto fused silica at 25°C with a substrate velocity of 3 mm/min a spot pattern as shown in Fig. 4e is obtained which appears to be a mixture of only [020] and [011] oriented crystallites.

In order to correlate these experimental observations we have developed a simple qualitative picture of what processes are operating to give these results. We assume that at the advancing edge of the film

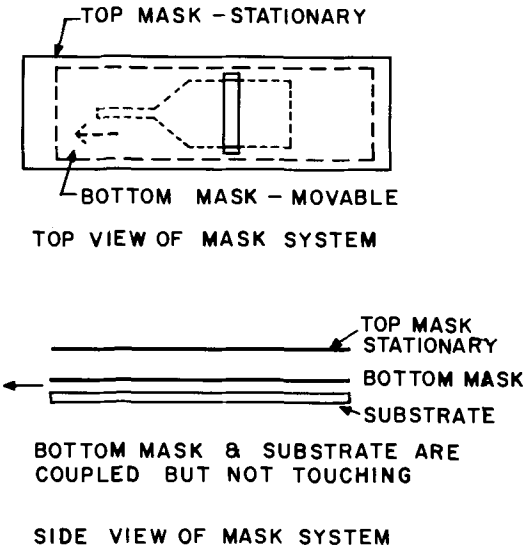


Fig. 5. Top view and side view of mask system used to allow flaring out of deposited film. The narrow neck is 1 mm wide x 10 mm long. The slot flares out at 45° to a final 12.5 mm wide slot.

there are adsorbed single molecules or groups of molecules (*e.g.*, dimers) which do not immediately attach firmly to the substrate but have mobility in the plane of the surface. Those which move away from the advancing film edge have the opportunity to merge with other wandering adgroups, to become firmly attached to the substrate and, to act as nuclei for crystal growth. The slower the advancing film proceeds the greater the opportunity to form randomly oriented nuclei. For a given rate of deposition there should also be mask speeds which would be so great that there would not be a leading edge as such but rather a collection of nucleating sites which would lead to polycrystallinity. This has not been observed as yet. With respect to the effects of temperature on structure noted previously and exemplified on Fig. 4b and 4c we would say that at −100°C there is very little mobility of the admolecules or possibility of reorientation. Therefore, a minimal effect on film structure occurs. Contrariwise, at 200°C we would say that the adgroup mobility is so great that nuclei can be formed in front of the leading edge. An intermediate temperature can be expected to be optimal.

None of this explains the mask width effects noted and we have no satisfying picture of what is happening here. For the moment we shall assume that we are observing a tyranny of large numbers. Certainly the crystallite size is quite small initially and by cutting the width from 1.5 to 0.1 mm we are reducing the number of crystallites competing for growth by a factor of 15 which may be significant.

The remarks of the preceding two paragraphs are admittedly vague and qualitative. This is, however, inevitable when such items as the molecular species being evaporated from this nonequilibrium source, the adgroup mobilities, and the critical size of a nucleus are unknown.

Finally, we would like to remark as to whether these results are in opposition to the general ideas of epitaxy wherein one expects to match substrate symmetry and bond lengths to the symmetry and bond lengths of the film. In our opinion these results do not contradict epitaxial theory. If one can assume that a glass surface is an approximation to an equipotential surface, then the only way that the glass surface can direct the adsorbed NaCl molecule is in a direction perpendicular to the surface. Therefore, by properly manipulating the experiment, we are allowing the sodium chloride to epitax on itself at the leading edge of the film.

Summary

1. Moving mask deposition can considerably affect the structure of evaporated NaCl films on fused silica giving larger grain sizes and enhanced orientation in the plane of the substrate.

2. The dimensions of the mask slit, the substrate temperature, and the speed of the moving mask are important variables. The smaller the width of the slit in the mask the greater the ordering. An intermediate temperature (*ca.* 25°C) gives the largest particle size enhancement and the greatest ordering. The speed of the moving mask must be above a minimum value to achieve these effects.

3. Having once formed an ordered film of small width one can expand the slit width and preserve the orientation.

On the Morphology of Zinc Electrodeposition from Alkaline Solutions

J. O'M. Bockris,*,[1] Z. Nagy,*,[2] and D. Drazic[3]

University of Pennsylvania, Electrochemistry Laboratory, Philadelphia, Pennsylvania 19104

ABSTRACT

The morphology of zinc electrodeposition was investigated from alkaline zincate solutions on single grains of known orientation in polycrystalline zinc electrodes under potentiostatic control. The effect of overpotential, solution composition, and substrate orientation were examined. The deposition morphology was observed with a scanning electron microscope. It was found possible to disrupt the deposition repeatedly for microscopic observation, and then continue deposition. At low overpotential (50 mV) epitaxial layer type growth was observed; the width of the macrosteps increased linearly with time. A theory explaining the linear step widening is proposed, which can also account for the observed effect of substrate orientation. At 100 mV, "boulders" were observed, not all of which were epitaxial with the substrate. They are suggested to be originated by nucleation. The boulder density per cm^2 is first sharply increasing, then slowly decreasing with time. A statistical calculation for this is given, based on the model that large boulders consume the smaller ones. With further deposition a small fraction (*ca.* 0.1%) of the boulders develop into dendrites, their number being limited by the available total current. Experiments were carried out to differentiate between overpotential and current control of morphology; overpotential was found to be the critical variable.

Electrodeposition reactions of metals form a special class of electrochemical reactions, since, in addition to the usual electron transfer processes and surface chemical reactions, the crystallization step has also to be taken into account in the treatment of the kinetics. Investigations of these reactions can be divided in two groups. To obtain knowledge concerning processes on the angstrom-level deposition, the change of surface due to formation of new crystals can be avoided with the use of pulse techniques, and the kinetics and mechanism of the reaction (under the surface conditions of the original substrate) can be investigated. On the micron level, on the other hand, it is just the changes of the surface (morphology) which is itself the subject of research. Recent reviews of both areas are available (1, 2).

The early mechanism of Erdey-Gruz and Volmer (3) consisting of repetitive nucleation and the subsequent spread of steps was not found consistent with the experimental facts. It required a minimum overpotential for deposition (not observed), and also failed to predict a Tafel type current-potential relationship. This difficulty was overcome by the application of Frank's theory of growth (4) to electrocrystallization, which introduced the screw dislocation as an inexhaustible, rotating growth step. This development, and the theory of bunching (5, 6) which explains the formation of macrosteps from atomic steps, were successful in explaining most of the observed epitaxial growth features such as layers, ridges, pyramids, spirals, truncated pyramids, and blocks (7-11). The macrosteps are usually bounded by low energy, high atomic density (low index) planes (12, 13). In spite of the general (but qualitative) success of the dislocation theory, other sources of growth steps should not be neglected. It has been shown (10) that microsteps caused by misorientation of the actual surface from perfect low-index crystal planes can be a major source of growth lines; and the nucleation mechanism has recently been shown to apply to dislocation free surfaces (14, 15), and is also expected to play a part in deposition at high overpotentials (16-17).

Nonepitaxial growth and development of preferred orientation (texture) is much less clearly understood. The two prevailing theories are the nucleation theory [*e.g.*, Ref. (18)] explaining texture by the appearance of nuclei having the smallest energy of formation, and the electrochemical theory (19) based on the different electrochemical growth rate and different electrosorption characteristics of the different crystal planes.

A number of investigations have been made on the morphology of zinc deposition from acidic zinc sulfate solutions. A detailed treatment of deposition habits on single crystals has been reported (20) and the texture of polycrystalline deposits has been examined (21-23). Deposition from alkaline solutions has been studied mainly with respect to dendritic growth (24-33) and only limited observations were made of nondendritic type deposits (24, 25, 30, 32), and texture (33). The degree of mechanistic understanding is small.

A better understanding of the zinc deposition morphology from alkaline solutions is desirable not only because of its relevance to fundamental electrochemistry but also because of the importance of the alkaline zinc/zinc oxide electrodes in high energy density storage batteries. Thus, zinc-air cells (34) are among the most promising electrochemical energy storers for electrical transportation but their development is hindered by a lack of understanding of the electrode processes involved. An angstrom level kinetics and mechanism study was recently reported (35). In the present work the morphological aspects of deposition are discussed.

Experimental

Electrodeposition was carried out onto large-grained zinc electrodes (with known crystallographic orientation of some selected grains) from alkaline zincate solutions, under potentiostatic control. The morphology of the deposit was investigated *in situ* with Nomarski optical microscopy, and after deposition by scanning electron microscopy.

Electrode preparation.—The electrodes were machined from 99.999% pure zinc, into 3 mm diam rods.

Key words: morphology, zinc, alkaline zincate solutions, layer growth, boulder, dendrites, substrate orientation effect, scanning electron microscopy.

Large grains were grown, after machining, with the following technique. The working surface of the electrode was mechanically polished (180-320-600 silicon carbide papers, followed by 1μ alumina on cloth). The electrode was heat-treated at 330°C for 20 hr under purified nitrogen atmosphere to allow recrystallization and grain-growth to proceed (36), followed by slow (8 hr) cooling. The electrode was finally electropolished in a solution containing 50 volume per cent (v/o) conc. orthophosphoric acid and 50 v/o ethylalcohol (37, 38). The electrode was held in a Teflon holder exposing only the surface to be polished and was positioned horizontally below a flat platinum counterelectrode. The potential was kept below that of gas evolution, which would hinder the polishing process. The polishing was occasionally interrupted and the surface examined for smoothness with a metallurgical microscope equipped with Nomarski interferometry attachment. Polishing times between 2 and 4 hr were usually sufficient to produce a smooth surface.

The grain structure of the electrode surface could be observed with the microscope in polarized light (39); an example is shown in Fig. 1. A large grain was selected on each electrode and its crystallographic orientation was determined by x-ray (Laue back reflection) method (the other areas of the surface were masked by lead foil). All experimental observations were carried out on these selected grains only. The orientation of the selected grain on each electrode used in this study is shown in stereographic projection in Fig. 2.

After this preparation the electrodes were stored in a desiccator. Just before electrodeposition the surface of the electrode was given a final treatment; it was a cathodic reduction, in the cell itself, in zincate free solution (cf. below). This treatment was previously found necessary to produce an oxide film-free surface, on which acceptably reproducible kinetic data could be obtained (35). The surface was characterized by chronopotentiometry (35). Each of the electrodes was used in more than one experiment; between the experiments the electrodes were always electropolished, and before each experiment the surface was reduced.

Solution preparation.—High purity potassium hydroxide-zincate solutions were used which were prepared via potassium and zinc amalgams. The details of the process are given elsewhere (35). Most of the experiments were carried out with solutions containing 2M KOH and 0.1M zincate, in some cases a zincate concentration of 0.02M was used. For the cathodic reduction of the electrodes a similarly prepared 0.1M KOH solution was used.

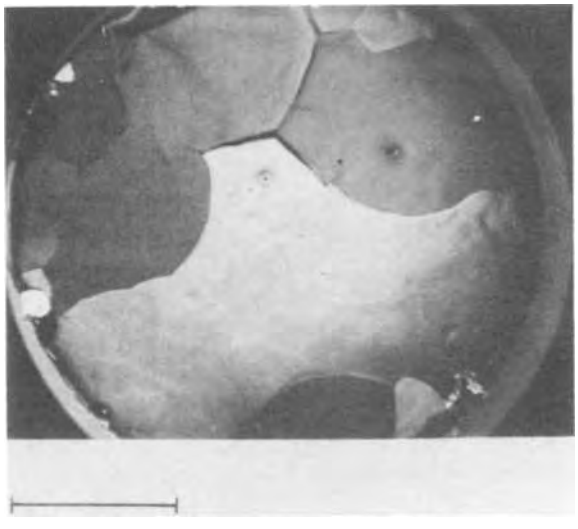

Fig. 1. Electrode No. 2 viewed in polarized light. The mask represents 1 mm.

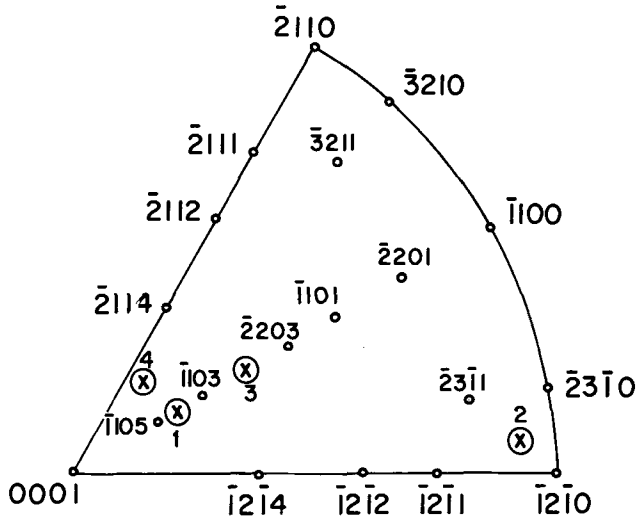

Fig. 2. Crystallographic orientation of selected grains on the electrodes, shown in stereographic projection.

The cell.—A cell was designed to allow *in situ* microscopic observation with short working distance (0.4 mm) objectives. The basic concept of the cell has been reported before (40), and a detailed description of the design is given elsewhere (41). A zinc sheet (7.5×10^{-3} cm thick) was used as a counterelectrode, it was positioned 22.5×10^{-3} cm above the working electrode. The reference electrode was a 1 mm diam zinc wire immersed in the test solution (the purity of all zinc used was at least five 9's). For the cathodic reduction treatment of the electrode an auxiliary platinum counterelectrode was used, placed in the cell outlet.

Deposition techniques.—General procedure.—The cell was assembled on the microscope stage (placing the observation hole of the counterelectrode over the grain to be examined) and was blown free of air by a stream of purified nitrogen. The 0.1M KOH solution was introduced under nitrogen pressure and the working electrode was galvanostatically reduced at a current density of 50 mA/cm^2 for 8 min. The cell was drained under nitrogen atmosphere, then flushed and filled with the test solution. Deposition was carried out potentiostatically (Wenking 61 TR) while the current was continuously recorded on a stripchart recorder. The overpotential was controlled at 50, or 100 mV, and in one experiment at 200 mV. All deposition was carried out at room temperature, from unstirred solutions. After the desired amount of charge was passed (in the range of 0.3-40 C/cm^2) the cell was flushed with distilled water and blown dry with nitrogen. The cell was disassembled and the electrode transferred to a nitrogen-filled desiccator where it was kept until the electron microscopic investigation.

Interrupted deposition.—In a number of tests the deposition was repeatedly interrupted for electron microscopic investigation, and then continued. The same procedure as given above was repeated in each case, including the reduction of the electrode before deposition. Between operations, the electrode was kept and transported in a nitrogen filled desiccator.

Deposition-dissolution-deposition series.—In some cases of the interrupted tests, an anodic dissolution of the deposit was substituted for a cathodic deposition step. The dissolution was carried out galvanostatically, at a current density below that of passivation. In the present test solutions 1.3 mA/cm^2 was found satisfactory.

Observation methods.—Optical in situ observation.—This method of observation of the deposition was carried out using a metallurgical microscope (Zetopan-M,

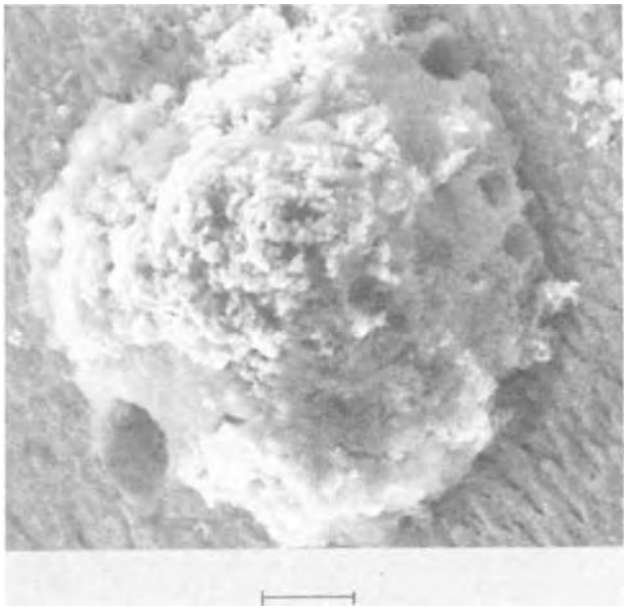

Fig. 3. SEM picture of deposition at 10 mV overpotential. The mark represents 5μ.

Reichart, Austria), equipped with Nomarski interferometry and contrast attachments (42, 43). Periodically pictures were taken of the surface with a Polaroid camera equipped with an electromagnetic shutter and automatic exposure control (Watson, England). The current efficiency of hydrogen evolution is very low in this system (35), and it did not interfere with optical observations.

Electron microscopy.—After the deposition, the electrode surface was investigated with a scanning electron microscope (JSM-U3, JEOLCO, Japan). Pictures were taken at two orientations of the electrode: (*i*) The electrode rod was aligned lengthwise with the optical axis of the electron microscope, or (*ii*) the "c" axis of the grain under investigation was aligned with the optical axis of the electron microscope. In the latter mode, the features of the deposit are expected to appear parallel with each other and be in hexagonal symmetry (120° angles) if the deposit is epitaxial with the substrate; in this case, the orientation of the features could also be determined. Occasionally, stereopair pictures were taken. The electron beam intensity was kept at the minimum value which still allowed good quality observation, to avoid contamination of the surface in the microscope.

Results

General description of the morphology of the deposits.—Detailed tests were carried out at 50, and 100 mV overpotentials, with an additional test at 200 mV; the general morphology of the deposits was different in each case. At 50 mV layers or ridges were found, while at 100 mV the deposit could be best described as consisting of "boulders." At 200 mV, dendritic growth was observed. (During some preliminary experiments mossy growth (27) was observed at 10 mV overpotential, as shown in Fig. 3.) The optical microscopy [with Nomarski interferometry and contrast attachments (42, 43)] did not prove fully successful in this investigation, for the following reasons. The large number of growth features ($\approx 10^7/cm^2$) caused the interferometric patterns to overlap, and the technique was not usable. The interference contrast technique allowed the continuous observation of the deposition *in situ*, but because the scale of the deposit features was close to 1μ, bordering the resolution and depth of focus of the optical system, only an over-all impression of the type of deposition could be obtained but details were not resolvable. The data presented in the following sections are based on electron microscopic observations.

Deposits at 50 mV overpotential from 0.1M zincate solution.—The deposition was of layer (or ridge) type on all electrodes, as shown in Fig. 4. Occasionally

boulders appeared on layers, some can be seen on Fig. 4a. At the grain boundaries, a smooth transition existed between the differently oriented layer structures (Fig. 4d). On photographs taken with the "c" axis of the grain aligned with the optical axis of the microscope (Fig. 5) the deposits always appeared as layer type, and were epitaxial with the substrate. The most prominent plane appearing was the (0001), bounded in each case by side surfaces of planes belonging to the $[\bar{1}\bar{1}20]$ zones. If the edges are perpendicular to the layers (*e.g.*, Fig. 6a,b) the bounding planes will be $[\bar{1}100]$. A drawing of the deposition, indicating the orientations, is shown in Fig. 7. Occasionally, the edges were more complex, as shown in Fig. 6c,d, and the orientations could not be determined from the present data; they were presumed to be low order pyramidal faces.

From interrupted deposition studies, a relation between the average layer width and the thickness of the deposit (expressed as C/cm^2) was found, and is shown in Fig. 8.

Deposits at 100 mV overpotential from 0.1M zincate solution.—At this overpotential, the deposit consisted of boulders. The first boulders were observed with the optical microscope after 10-15 sec of deposition, and they appeared in increasing numbers until the surface was completely covered, then their number decreased. The size of the boulders continually increased during the course of the deposition. A typical photograph series is shown in Fig. 9. They first appear to have the shape of a sphere, then turn into irregularly shaped boulders, and finally develop well-oriented crystalline faces during the deposition. At this latter stage, many of them have stepped sides (Fig. 10) and seem to consist of layers. Before they completely cover the surface of the electrode, occasionally a layer-type growth is visible beneath the boulders (Fig. 11, 15a). There is a tendency for the boulders to segregate at grain boundaries of the original substrate (Fig. 15). Photographs, taken with the "c" axis of the crystal aligned with the optical axis of the microscope (Fig. 12), reveal that not all of the boulders are epitaxial with the substrate (note the small misalignment of sides in the circles). The majority of them is epitaxial. These are comprised of layers, parallel to the (0001)

plane of the substrate, and are bound by side planes containing lines parallel to the <1̄1̄20> directions.

From the test series with interrupted deposition (*e.g.*, Fig. 9), the variation of average boulder density and size were determined as a function of deposition thickness (C/cm²), and are shown in Fig. 13 and 14. From these data, the charge needed for their formation can be estimated (assuming that the boulders are cubes), and compared to the actual charge density used in the deposition (Table I).

Effect of the crystallographic orientation of the substrate on the morphology of the deposit.—The orientation of the substrate had no effect on the qualitative character of the deposit. At 50 mV, layers were observed on all electrodes, and at 100 mV boulders appeared on every electrode. There were quantitative differences in the number and rate of growth of the features of the deposit. These are shown in Fig. 8, 13, and 14.

Redeposition of dissolved deposit.—The results of one such series (see above), with the depositions carried out at 100 mV overpotential, is shown in a photograph series in Fig. 15.

Deposition from 0.02M zincate solutions.—Limited number of tests were carried out, only to determine the type of deposit at each overpotential. Layers were found at 50, boulders at 100, and dendrites at 200 mV (Fig. 16).

Current-time behavior.—The current, at constant overpotential, was continuously recorded during depositions, a typical current trace is shown on Fig. 17. The average current densities, observed at different overpotentials in different solutions, are given in Table II. At the lower zincate concentration the current was under mass transport control, both at 50, and 100 mV overpotentials. At the higher zincate concentration the current was under mixed activation-mass transport control at 50 mV, and under mass transport control at 100 mV.

Discussion

Comparison of optical and electronoptical observation techniques.—Both techniques have been widely used in electrocrystallization studies (44). Transmission electron microscopy offers a better resolution, but at the price of arduous replication technique, which limits the observation to the end result of a deposition; further, the possibility of recrystallization between deposition and observation is always present. Light microscopy, especially coupled with modern interferometric methods (42, 43), has the advantage that it allows a continuous *in situ* observation of the deposition, its resolution is, however, limited to about 1μ horizontally, and to about 0.02μ vertically; for a structure like the stepped boulders (Fig. 10) where the width of the steps is less than 1μ, it is not applicable. The recent development of the scanning electron

microscope allows a compromise between the two methods. A resolution of 0.02μ is possible with direct observation of the surface. Laborious replication is not needed, and since the sample is not destroyed, the deposition can be continued after the microscopic investigation. Therefore, while *in situ* observation is not possible, the deposition can be repeatedly interrupted for observation. A number of questions remains to be answered, however:

(*i*) Does recrystallization take place significantly, after the current had been switched off (especially in the case of high exchange current density processes)?

(*ii*) Does the surface change (*e.g.*, by oxide film formation) in the time between removal from the cell and observation in the microscope?

(*iii*) What is the effect on continued deposition of the interruptions, and electron microscopic investigation?

There can be no generally valid answers to these questions. For the present work the following observations are relevant:

(*i*) At the end of one deposition the light microscope was focused on some clearly visible features at the highest magnification (780×) and the deposit was observed for 15 min after switching off the current. No changes were observed. Since in the actual experiments the cell was drained in less than 30 sec after

turning off the potentiostat, recrystallization problems are not expected. The corrosion of the zinc in the test solution is also known to be negligible (35).

(*ii*) The oxidation rate of zinc in dry air at room temperature has been reported (45) as 20×10^{-8} cm/48 hr. Since the electrodes were stored under dry nitrogen, and were exposed to air only for minutes between deposition and microscopic observation, the thin oxide film formed should not affect the observations. This film was then removed before further deposition by cathodic reduction in 0.1M KOH.

(*iii*) Two results obtained here are relevant to the third question. Deposition-dissolution-deposition series (such as shown in Fig. 15) allows the observation of specific boulders as they diminish and grow in size, indicating that they remain active in spite of the interruption and electron microscopic exposure. Furthermore, depositions carried out with numerous interruptions for observation, and ones carried out without any interruption, gave the same morphology at a given coulombs/cm^2 both qualitatively (type of deposition) and quantitatively (number and size of growth features).

Layer growth.—Crystallographic orientation of layers.—Layer growth is a common type of deposit, its appearance is explained by bunching of monoatomic steps into macrosteps (1, 2). This is applicable to the present case.

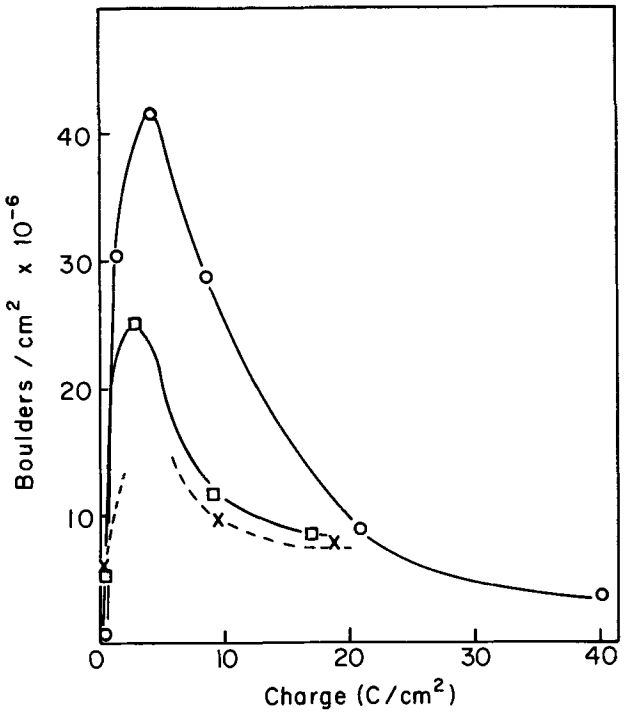

Fig. 13. Boulder density as function of charge. At 14 mA/cm^2, 1C is equivalent to 71 sec. x, electrode No. 1; ○, electrode No. 2; □, electrode No. 3.

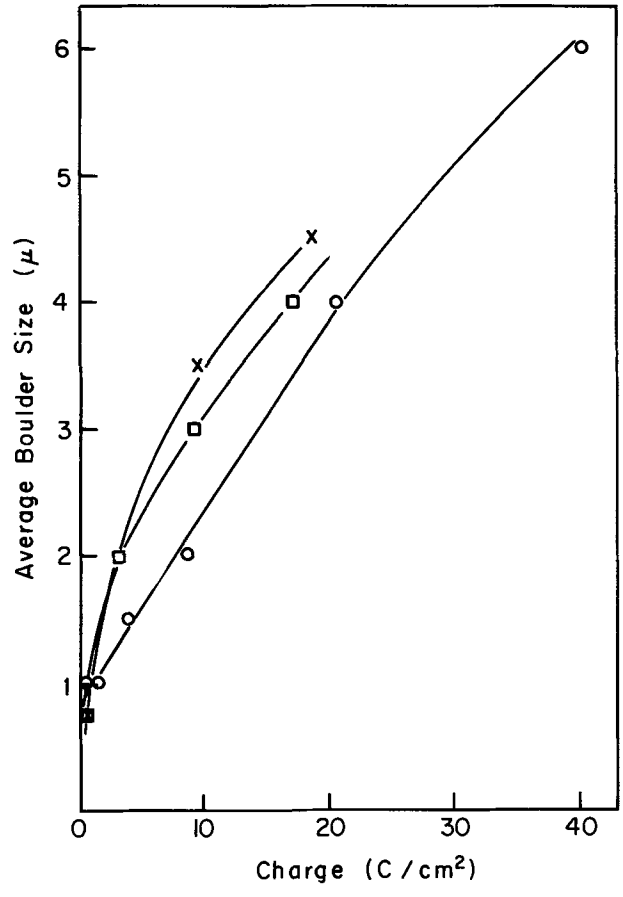

Fig. 14. Average boulder size as function of charge. At 14 mA/cm^2, 1C is equivalent to 71 sec. x. electrode No. 1; ○, electrode No. 2; □, electrode No. 3.

The crystallographic orientation of the layers was the same in all experiments. It should be noted here that the appearance of the layers is similar only when viewed along the <0001> direction, otherwise rather

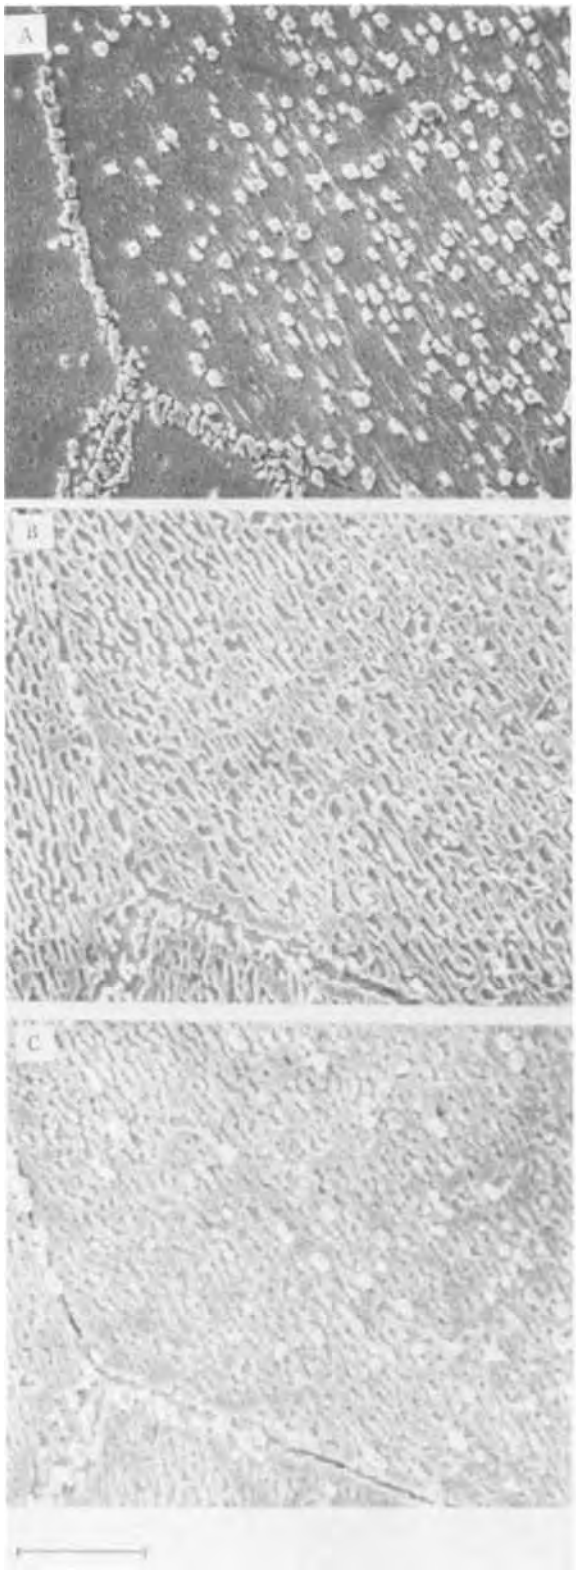

Fig. 15. SEM pictures from a deposition-dissolution-deposition experiment. The mark represents 16μ. A, after deposition of 1.2 C/cm^2; B, after dissolution of 0.3 C/cm^2; C, after further deposition of 1.4 C/cm^2.

different ("ridge" or "pencil" type) structures appear as illustrated in the triple grain boundary picture (Fig. 4d). This apparent difference, however, is due to the different orientation of the "c" axis of the grains and the epitaxial deposit with respect to the observation angle. The effect which can be created this way is illustrated in Fig. 6, which shows the same deposits viewed from different angles.

The appearance of the (0001), [$\bar{1}$100], and low order pyramidal planes is expected, based on Bravais's law of crystal growth (13, 46) and Stranski's calculation of equilibrium forms (12). A detailed study of zinc deposition morphology from acidic zinc sulfate solutions (20) has shown similar results. Deposition was carried out on a large number of single crystal faces and the resulting facets were analyzed by optical goniometry: the (0001) plane was the most prominent,

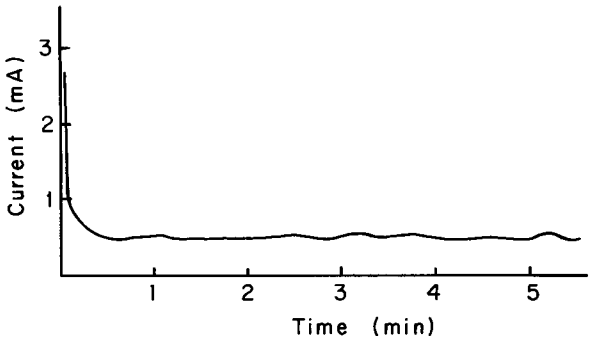

Fig. 17. An example of current-time behavior. Electrode No. 3. 50 mV.

with weaker reflections from the [10$\bar{1}$1] planes, other planes were found only in minor amounts. An analysis revealed that in each case, the most closely packed planes appeared. The appearance of the deposit was described as "layer," "ridge," or "pencil" type, depending on substrate orientation. On this basis, the appearance of hexagonal pyramids would be expected when the substrate is parallel to the basal (0001) plane, and these were indeed observed (24, 30, 32). The appearance of layers has also been reported for depositions from alkaline zincate solutions (24, 25) but their orientation has not been determined.

Mechanism of layer growth.—The sources of steps have been postulated as being dislocations (5). Recently, it has been shown (10) that in the case of copper deposition, on a (100) plane, the source was a slight misorientation of the examined surface from the crystal plane. The results of the present work offer the possibility of differentiating between these sources of steps. A higher index plane can be visualized as being formed of steps bounded by low index planes, and the two electrodes, on which detailed data were obtained on layer growth (Fig. 8), are in such orientation that both surfaces can be represented by steps bounded by (0001) and ($\bar{1}$100) planes only (these are the planes which were found predominant in layer growth), but their tilt with respect of the "c" axis is different. If the sources of steps are the microsteps due to the crystallographic orientation of the substrate, a theory based on this hypothesis should predict the observed differences in step growth (cf., Fig. 8).

The experimental data show a linear increase of step width with time (charge) but the rates are different for the two electrodes. For electrode 1, the rate is 2.2 μ/sec and for 3 it is 1.6 μ/sec. Such a linear widening of steps has been observed before (10), but no theoretical explanation is given in the literature. The following model of step widening is suggested.

Let us assume that at the start of the process the surface is comprised of "n" preliminary steps which are already multiatomic high, 20-30 $\times$ 10^{-8} cm or higher, as shown in Fig. 18. (This assumption will be discussed later.) Metal is being deposited to both surfaces of the steps and they are moving simultaneously outwards and laterally across the surface. Consider first the outward movement only, proceeding with an

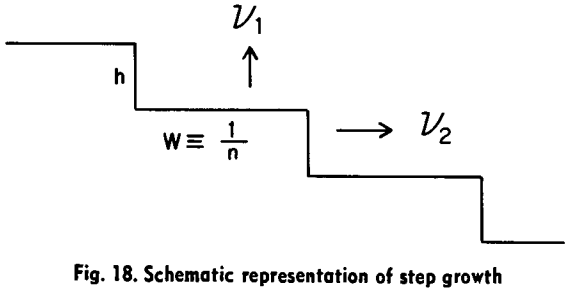

Fig. 18. Schematic representation of step growth

average rate of ν_1 (μ/sec). Step widening will occur if a fraction of the steps ($\rho_1 n$, where $\rho_1 < 1$) will move slower than the average speed ($\delta_1 \nu_1$, where $\delta_1 < 1$).[4] A slow step will be overtaken by a neighboring fast step when

$$\nu_1 t = h + \delta_1 \nu_1 t \qquad [1]$$

or at a time

$$t = \frac{h}{\nu_1(1 - \delta_1)} \qquad [2]$$

It is assumed that at this time the two steps will join and continue to move forwards as one step, thereby eliminating a step. Since there are $\rho_1 n$ such pairs, the rate of decrease of the number of steps can be written as

$$-\left[\frac{dn}{dt}\right]_1 \approx -\left[\frac{\Delta n}{\Delta t}\right]_1 = \frac{\rho_1 n\, \nu_1(1 - \delta_1)}{h} \qquad [3]$$

The total current flowing to the surface will be divided in two parts, one causing the outward, and one causing the lateral growth. Since the exchange current densities of the two growth planes are nearly equal (47) the rate of outward growth, at a total current density of i, can be expressed as

$$\nu_1 = a\, i \frac{w}{h + w} \qquad [4]$$

where a is a constant converting current density to linear growth velocity. Furthermore, the ratio of step width to step height will remain constant during the process, according to the model used[5]

$$\frac{w}{h} = C \qquad [5]$$

Combining [3], [4], and [5] gives the rate of disappearance of steps as

$$-\left[\frac{dn}{dt}\right]_1 = \rho_1(1 - \delta_1)\, a\, i \frac{C}{1/C + 1} n^2 \qquad [6]$$

An exactly analogous treatment can be made for the lateral motion, giving (using index 2 for this case)

$$-\left[\frac{dn}{dt}\right]_2 = \rho_2(1 - \delta_2)\, a\, i \frac{1}{C + 1} n^2 \qquad [7]$$

The total rate of step disappearance is then

$$-\frac{dn}{dt} = -\left\{\left[\frac{dn}{dt}\right]_1 + \left[\frac{dn}{dt}\right]_2\right\} \qquad [8]$$

Combining Eq. [6], [7], and [8] and solving the differential equation gives finally

$$\frac{1}{n} \equiv w = \left[\rho_1(1 - \delta_1)\, a\, i \frac{C}{1/C + 1} + \rho_2(1 - \delta_2)\, a\, i \frac{1}{C + 1}\right] t + w_o \qquad [9]$$

This is the sought relation between step width and time; in agreement with experimental data, the relation is linear. In order to compare the slopes of the lines, a further assumption has to be made. It is assumed that the nature of the processes taking place on the (0001) and ($\bar{1}$100) are similar (they are the first and third most closely packed planes) and therefore $\rho_1 \approx \rho_2$, and $\delta_1 \approx \delta_2$. Equation [9] can then be simplified

$$w = \{\rho(1 - \delta)\, a\, i\} \frac{C(C + 1) + (1/C + 1)}{(1/C + 1)(C + 1)} t + w_o \qquad [10]$$

In the expression for the slope, the parameters in the brackets are the same for electrodes 1 and 3, since

[4] A distribution of propagation rates could result, *e.g.*, from statistical fluctuation of impurity adsorption.

[5] The constancy of this ratio was experimentally observed for copper (10).

the growth faces are (0001) and ($\bar{1}$100) in each case, and the experiments were conducted under identical conditions. The difference in slopes therefore can arise only from the difference in the value of C. This can be obtained with the following argument. The primary steps are produced by the bunching of the monoatomic microsteps originally present on the surface. If one assumes that the microsteps are present due to the crystallographic orientation of the substrate (and not due to dislocations) the value of C is obtained as the cotangent of the angle of inclination of the surface to the "c" axis of the substrate (cf. Fig. 7). This angle is 29° for electrode 1, and 47° for electrode 3. Therefore, the theoretical ratio of the slopes of the lines of Fig. 8 can be calculated as 1.56 (ratio of electrode 1 to electrode 3). The experimental value is 1.35. The agreement is satisfactory, confirming the hypothesis that the origin of the microsteps is indeed the crystallographic orientation, rather than pairs of dislocations. That is, they are present on the surface because, as a high index plane, it consists of monoatomic steps of low index planes [cf. Ref. (1), Fig. 26].

The mechanism of the formation of the "primary" steps from the microsteps has not yet been treated. The kinematic theory is not applicable in the present case. Because of the high angle of inclination of the surface to the "c" axis, the width of the microsteps is only about 1-2 atomic length; the surface can be described rather as an atomically rough surface and not as one containing smooth terraces, as would be needed for the application of the kinematic theory. It is easy to show, however, that the bunching of the microsteps will be energetically favored. The edge energy per atom is always larger than the surface energy, and therefore, the coalescing of microsteps will decrease the total energy of the surface by decreasing the number of edges. It is possible that this occurs during the time the cell is filled with test solution, before the potentiostat is turned on, due to the high exchange current density of the electrode reaction (35).

Boulder growth.—Origin of boulders.—At the higher overpotential (100 mV), the main crystallographic feature of deposition is boulder growth [see also Ref. (25)]. Under the same conditions, dendrites were reported earlier (28, 29), but were observed only after a considerable "initiation time." The present work refers to surfaces formed at times shorter than the initiation time of the dendrites, and therefore dendrite growth was avoided (though occasionally some were observed).[6]

At low coulomb/cm^2 values, a duplex-type deposition was observed: a layer growth, similar to that observed at 50 mV, was partially covered by boulders (Fig. 11, 15a), with most of the deposited material going initially into layers and only about 10% contributing to boulder growth (Table I). At a later time (*ca.* 3 C/cm^2) the boulder growth takes completely over (Fig. 9, and Table I). The appearance of layers can be explained as in the above section. The boulders may be initiated by growth at screw dislocations, or by nucleation. Their appearance from either source could be expected because of the higher overpotentials (as compared with overpotentials associated with layer growth). With increased overpotential, the distance between the turns of a spiral decreases which leads to localized growth as compared to the wide overlapping spirals at low overpotentials, which leads to a uniform growth (1). At the high overpotentials the edge-energy will also be overcome and nucleation becomes a feasible process (1, 16-17). A numerical estimation of the minimum overpotential of nucleation can be made. Such a calculation was carried out earlier for silver (48). Since some of the parameters (equilibrium adion concentration, surface diffusivity of adions) needed for the calculation are not known for zinc, the results reported for silver will be used as a first approximation. It was shown that nucleation becomes possible at an overpotential of little above 100 mV at a step width of 7×10^{-5} cm [cf. Ref. (48), Fig. 8]. In the present experiments, the first boulders were observed after the passage of 0.1-0.2 C/cm^2. If one assumes tthat the step-width relations of Fig. 8 are applicable to 100 mV, and at such low charge, it can be estimated that boulders appeared on steps of 5×10^{-5} cm width, in reasonable agreement with the above theoretical prediction, indicating that nucleation is a possible explanation of boulder growth.

A distinction between the two mechanisms of boulder growth can be obtained from the crystallographic orientation of the boulders relative to the substrate. If growth originates from screw dislocations complete epitaxy is expected, while some deviation from epitaxy can arise if the boulders are nucleated. The preferred orientation of the nucleated boulders will be that of the substrate, since the epitaxial nucleation energy is less than that of the nonepitaxial, but the appearance of some nonepitaxial nuclei can occur. If, therefore, some of the boulders are found, upon determination of their orientation, to be nonepitaxial, this would show that nucleation mechanism was operative. This indeed was the case. The crystallographic orientation of the boulders can be determined from the present data after *ca.* 15 C/cm^2 charge has passed and well developed faces appear. A preferred orientation, epitaxial with the substrate, can be observed with numerous exceptions (Fig. 12). Note the misorientation of the edges of the boulders in the circles on Fig. 12, as compared to the other (epitaxial) boulders.

Nucleation can occur randomly on the surface or at specific sites (*e.g.*, impurities, dislocations). In the deposition-dissolution-deposition experiments (see above) it was attempted to dissolve and renucleate the boulders to differentiate between random and specific sites. No conclusive results were obtained. The preferred nucleation at grain boundaries (Fig. 15), however, indicates specific sites; both impurities and dislocations tend to segregate at grain boundaries. No data are available to allow selection between impurity and dislocation sites.

The change of boulder density with time.—The experimental data are presented on Fig. 13. The following model is suggested. The boulders are nucleated progressively with a constant rate of v(boulders/cm^{2}sec). The boulders are growing under linear diffusion control and therefore, the current into a particular boulder is proportional to its cross-sectional area (this is a good approximation once the surface is nearly covered by the boulders, cf. Table I). As a first approximation the boulders are taken as hemispheres with a radius of r. The current into a boulder is then, at i mA/cm^2 total current density: $r^2\pi i$. If a gives the volume of material deposited, in cm^3/sec, for each mA/cm^2, the change of volume of a boulder with time will be

$$\frac{dV}{dt} = i\,a\,r^2\pi \qquad [11]$$

The volume of a boulder is

$$V = \frac{2\pi}{3} r^3 \qquad [12]$$

and

$$dV = 2\pi\, r^2 dr \qquad [13]$$

Substituting into [11] gives

$$\frac{dr}{dt} = \frac{1}{2}\, i\, a \qquad [14]$$

and

$$r = \frac{1}{2}\, i\, at \qquad [15]$$

[6] At higher potentials dendrites were readily formed at short times (cf. Fig. 16c).

That is, the rate of increase of the radius of the boulder is independent of the size of the boulder, and a small one meeting a larger one will be consumed as shown in Fig. 19. The small boulder will be considered as consumed when the perimeter of the larger one reaches its midpoint. As a boulder is growing it will consume all other ones in its way which are younger than itself (these are continuously nucleating around it with a rate of v), until it reaches a larger one and will be itself consumed. The number of boulders the i^{th} boulder will consume in τ sec as a function of its age (τ) is

$$N'_i = \int_o^\tau v\,\tau\,2\pi r dr \qquad [16]$$

substituting r and dr from [14], and [15], and integrating gives

$$N'_i = \frac{\pi}{6}(i\,a)^2 v\tau^3 \qquad [17]$$

At time t there are boulders with ages ranging from 0 to t (being nucleated at a rate of v), so summarizing over-all boulders gives the number of consumed boulders (N'_{cons}) as a function of time

$$N'_{cons} = \int_o^t v\,N'_i(\tau)\,d\tau = \frac{\pi}{24}(i\,a\,v)^2 t^4 \qquad [18]$$

This expression, however, overestimates the number of boulders consumed because it assumes that all boulders continue to consume others up to time t, but once a boulder is consumed it ceases to consume others. Further, a boulder being at a specific point of the surface will be counted as consumed every time the perimeter of a larger boulder passes that point, but in reality it can be consumed only once.

Correction can be made using Avrami's statistical formula (49, 50), which has been used extensively in electrochemistry for the problem of film formation on electrodes (51). This formula was derived for a specific overlap problem, that of three-dimensionally growing nuclei in a solid-state phase transformation, but it is generally valid for overlap problems. In the phase transformation the volume fraction of the transformed material can be easily calculated knowing the rate of nucleation and the rate of growth of the nucleated grains, but only up to the point when the grains start to overlap. Avrami has shown that when overlap occurs the transformed volume fraction can be calculated as

$$\frac{V_{tr}}{V} = 1 - \exp\left(-\frac{V'_{tr}}{V}\right) \qquad [19]$$

when V_{tr} is the transformed volume, V is the total volume of the solid, and V'_{tr} is the calculated transformed volume neglecting overlap.

The present problem is analogous, and Eq. [19] can be rewritten as

$$\frac{N_{cons}}{N_n} = 1 - \exp\left(-\frac{N'_{cons}}{N_n}\right) \qquad [20]$$

where N_{cons} is the number of boulders consumed in time t, N'_{cons} is the calculated number of boulders consumed in time t, neglecting overlap, and N_n is the total number of boulders nucleated in time t given by

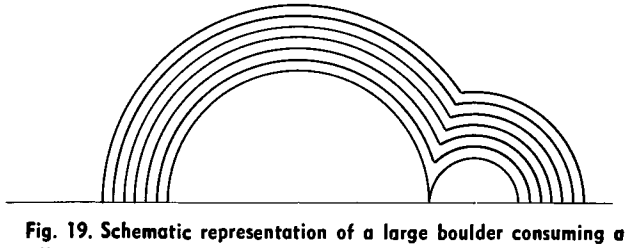

Fig. 19. Schematic representation of a large boulder consuming a smaller one.

$$N_n = v\,t \qquad [21]$$

The number of boulders remaining on the surface (N) will be obtained as

$$N = N_n - N_{cons} = N_n \exp\left(-\frac{N'_{cons}}{N_n}\right) \qquad [22]$$

And combining [22] with [18] and [21] gives the final results

$$N = vt \exp\left(-\frac{\pi}{24} i^2 a^2 v\,t^3\right) \qquad [23]$$

Equation [23] describes the curves of Fig. 13 with a reasonable agreement. It predicts a nearly linear rise, an exponential fall, and a maximum at 5 C/cm^2 (τ = 350 sec) and $N = 34 \times 10^6$ boulders/cm^2 (calculated with $v = 1.4 \times 10^5$ boulders cm^{-2} sec^{-1}, taken from the initial slope of the curves on Fig. 13). This agreement between observed and calculated number of boulders gives support to the suggested model consisting of continuous nucleation, and consumption of the smaller boulders by the larger ones.

Evolution of dendrites from boulders.—Previous work (28) on dendritic growth, carried out under similar experimental conditions, can be connected with the present results. Since deposition at longer times results in densities, the boulders can be assumed to be the dendrite precursors. On the basis of extrapolation of the curves of Fig. 13 to the dendrite initiation time [*ca.* 50 min (28)] one would expect the number of dendrites to be in the order of 10^6/cm^2. Experimentally only about 10^3/cm^2 were observed (28). The critical radius of curvature needed for dendrite growth has been shown for zinc (28) to cover a range of over two orders of magnitude, and therefore differences in the radius of curvature of boulder tips cannot account for this discrepancy. It is suggested here that, under the present experimental conditions, the number of dendrites is controlled by the total current. It has been estimated (28) that the growing dendrite tip draws 1.2 μA, and since the total current is 14 mA/cm^2 (still being controlled by linear diffusion since the height of the boulders is negligible compared to the diffusion layer thickness) the possible maximum number of dendrites is 1.2×10^4/cm^2. Furthermore, the tip current was found to be only a few per cent of the total (28), the rest flowing to the sides of the dendrites and to the substrate, therefore a dendrite density of 10^3/cm^2 is quite reasonable.

In summary: while there are a large number of precursors fulfilling the radius of curvature requirements, only a small fraction ($\approx$0.1%) will develop into dendrites, due to the limitations imposed by the total current. These will be the ones which, being nucleated first, are higher than average and so are able to draw current away from their neighbors.

Qualitatively, similar results were observed by Naybour (25) (though under different experimental conditions), *i.e.*, only a small fraction (less than 1%) of the original nuclei grew into dendrites.

The controlling factor: current or potential?—In theories of electrodeposition (1, 2) it is recognized that overpotential, rather than current density, is the controlling variable of morphology (though sometimes it is assumed that changes in current density cause morphological changes). Experimental indication is lacking, since the two variables change together according to the Butler-Volmer equation, and their effect is not at once separable. In the present work, a possibility arose to obtain experimental evidence by which the effects can be separated. Parts of the data were taken under (or near to) diffusion limiting conditions, where the potential could be increased without considerable coupled increase of the current. By lowering the zincate concentration, it was possible to reach a situation where currents at 50 and 100 mV overpotentials were

essentially the same (Table II). The morphology of the deposits obtained under this condition paralleled exactly that obtained at the high zincate concentration, where the current more than doubled with the increase of overpotential from 50 to 100 mV. The overpotential, not the current density, determined the nature of the deposit.

Acknowledgments

Useful discussions with Drs. A. Damjanovic, A. R. Despic, and G. Razumney are gratefully acknowledged. Our thanks are also due to Mr. R. White for his help and advice during the electronmicroscopic work. Financial assistance for this study was provided by the National Science Foundation under grant NSF-GK-16550; and the A.R.P.A. Program in Materials Science (University of Pennsylvania).

Manuscript submitted Dec. 20, 1971; revised manuscript received Aug. 4, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Measurement of Current and Potential Distribution at Rotating-Disk Electrodes

Barry Miller* **and Maria I. Bellavance**

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Current distribution at the rotating disk electrode has been experimentally evaluated by several techniques including single and double reference probe potential mapping, ring-disk electrode collection efficiency and resistive interaction, interrupter and steady-state resistance measurements, and automatic ohmic compensation methods. Mapping experiments are in quantitative agreement with the predictions of Newman's theory for this system and were further confirmed by resistance determinations and theoretically based correction methods. The implications of the data for various ring-disk and nonsteady-state experiments and also the utility of an approximate approach to estimating the degree of nonuniform current distribution are examined.

The uniform accessibility of the rotating disk electrode (RDE) to mass transfer (1) was implicitly assumed to produce a uniform current density until Newman (2) showed theoretically that there will generally not be a radially independent current distribution because of the solution ohmic potential drop. The shape of the current function *vs.* radial distance and the potential contours in solution depend on the relative interaction of solution ohmic drop, surface and concentration overpotentials across the disk for the given solution, electrode geometry, rotation speed, and electron transfer kinetics. We are concerned in this work with further experimental information on the current distribution at the RDE for testing the theory and its implications for various RDE and rotating ring-disk electrode (RRDE) applications.

Radial nonuniformity of RDE current has been most satisfactorily detected and compared to theory by direct measurement of the thickness distribution of an electrodeposited metal (3, 4). These experiments with copper deposition gave profiles substantiating Newman's theory.

The detection of nonuniform current distribution from reference probe potential or apparent ohmic resistance contours ideally requires measurements close to the RDE itself (2, 5). Angell *et al.* (6) have mapped isopotential contours with a reference electrode for several disk-insulating annular mantle geometries, describing the separation of isopotential lines as qualitatively in accord with Newman's predictions (2, 7). Resistance measurement through current interruption reflects only the value corresponding to a primary current distribution, regardless of that actually obtaining before interruption (8). McIntyre and Peck (9) found interrupter determined resistances independent of current, in support of Newman's conclusion (8).

A quantitative comparison of either interrupter values or potential mapping to theory has not been made at the RDE, to our knowledge. Nor has a test been made of the natural conclusion following from the above that only ohmic measurements made during current flow by appropriately located probes can detect the nature of the prevailing current distribution. Nanis and Kesselman (10) have calculated that the average resistance of the solution between disk and nonpolarizable counterelectrode would be 1.08 times higher for a uniform than a primary current distribution. They imply (10) that this would be detectable from interrupter comparisons of the current for "on" and "off" switching directions.

Albery and Ulstrup (11) suggested that radially increasing as opposed to uniform currents at the disk should be detectable through higher than theoretical collection efficiencies (12) at an RRDE. This expectation has been confirmed (4, 5, 13), although a quantitative interpretation has not yet been given. The comparison of current densities at ring and disk electrodes (sectioned electrodes), when they are independently held at the same potential, similarly affords a test of radial current uniformity (4, 14). Interactions of ring and disk through the ohmic drops from the prevailing currents have been generally disregarded. Ring potentials are shifted only by altering disk current; changes in disk potential without changing steady disk current, as is possible at a disk limiting current, have no effect on the ring potential (15). Potentiometric ring experiments (16) would be sensitive to resistive coupling of ring and disk through the solution and offer a new way to test the effect in the context of Newman's theory.

Several experiments are described in this work. Potential mapping with a single reference probe (6) has been repeated in a manner giving quantitative comparison to Newman's theory. Mapping technique has also been extended to a double probe configuration capable of further refining the detection of nonuniform current distribution. These experiments, in turn, have been correlated to measurements of RRDE collection efficiency. The determination of disk-ring ohmic interactions, comparison of interrupter and current flow resistance measurements, and automatic ohmic compensation techniques based on Newman's theory are also reported. Effects of varying electrode geometry and solution properties along with characterization of the Levich behavior of the electrodes employed are also considered.

The studies were carried out with the Hg_2^{++}/Hg couple in perchloric acid solution. The exchange current of this couple is sufficiently high (17) that concentration overpotential (η_c) becomes the only factor to counteract the primary distribution under all our conditions. Allowing for the reversible case not being the general one, we feel that examining the concentration overpotential-ohmic drop interaction provides a readily manageable and significant test of the theory of overpotential contributions to current uniformity at the disk.

Theoretical

Disk current distribution.—From the calculations of Newman (2), the shape of the full radial current distribution can be approximated [cf. Fig. 2 and 3 of Ref. (2)] if the ratio i/i_{av}[1] at the center of the disk ($r = 0$) is specified. This statement must be qualified to the extent that exceptions exist for which Newman found maxima or other effects in the radial current distribution. For example, such maxima appear in

* Electrochemical Society Active Member.

Key words: rotating disk electrode, current distribution, potential distribution, interrupter measurements, resistance compensation.

[1] Symbols are tabulated following the text.

some cases of Tafel kinetics at appreciable fractions of the limiting current (2).

The quantity $(i/i_{av})_{r=0}$ itself varies only within the limits of 0.5 (primary) to 1.0 (uniform). Albery and Hitchman (13, 18) have presented an approximation to the extended Newman theory by correlating a quantity ρ, the ratio of the ohmic to the dynamic charge transfer plus concentration overpotential resistances, to the Newman parameters J and $\beta\delta$ and thence to the $(i/i_{av})_{r=0}$ obtained from the complete theory (2). The mathematical difficulties of the latter are formidable and no less so for the reversible case. A suitable approximation is distinctly desirable. We have used the ρ method as well as extended computer calculations to obtain a theoretical $(i/i_{av})_{r=0}$ for our comparisons and discuss justifying evidence additional to that presented by Albery and Hitchman (13, 18). We require $(i/i_{av})_{r=0}$ because our experimental design has concentrated on measurements in the axial direction below the disk center where the potential profile is best defined spatially and least sensitive to electrode mantle effects.

We summarize first the parameters of Newman (7) necessary to describe the ohmic drop in solution for the primary current distribution. For the two probe directions experimentally examined here, the axial (z at $r = 0$) and the radial (r at $z = 0$), Newman's quantity ξ is given by z/r_o and $\sqrt{(r/r_o)^2 - 1}$, respectively. The solution of Laplace's equation (7) gives

$$\frac{\Phi}{\Phi_o} = 1 - \frac{2}{\pi}\tan^{-1}\xi \qquad [1]$$

The ohmic resistance of the solution (disk to counter-electrode at $\xi \to \infty$) is

$$R_\infty = \frac{1}{4r_o\kappa} \qquad [2]$$

We define $f = 2/\pi \tan^{-1}\xi = 1 - \Phi/\Phi_o$, a dimensionless probe position. In the case of a primary current distribution f is the fraction of the solution resistance R_∞ sensed from just outside the diffusion layer at the disk to a probe at ξ. The potential from the disk to a probe moved in the axial direction, E_z, will, in primary current theory, have intercepts at f equals 0 and 1 of 0 and IR_∞, respectively.

Apparent deviations of slope and intercept in an E_z-f plot when cell and electrode requirements are satisfied are then attributable to disk overpotentials and to the concurrent change in current distribution. However, even when the current distribution becomes uniform, the slope of the plot will be nearly indistinguishable from the primary case for $\xi > 1$ (beyond about one radius away in the z direction). In the case of Hg/Hg_2^{++} where $\eta_s \cong 0$, the extrapolation of the straight line portion of the E_z-f plot to $f=0$ will give an intercept approximating the concentration overpotential calculated with the average current flowing through the disk.

When two probes ($f_2 > f_1$) with fixed separation are used, the potential ΔE between them in the primary case is given by $(f_2 - f_1)IR_\infty$. If the distance between the probes is greater than r_o, the probe at f_2 should detect little or no deviation from a primary current distribution as a function of z. The potential ΔE for varying Δf may then be translated to an f_1 coordinate by using the quantity $\Delta E + (1 - f_2)IR_\infty$ which represents the ohmic drop between f_1 and a second probe at ∞.

Using subscripts a and c for anodic and cathodic disk current, respectively, the quantity $\Delta E_{a,o}/IR_\infty$, where $\Delta E_{a,o}$ is the value of $\Delta E_a + (1 - f_2)IR_\infty$ extrapolated to $f_1 = 0$, gives a direct measure of the relative increase in resistance equivalent to the $\Phi_o 4\kappa r_o/I$ ordinate in Newman's (2) Fig. 5. This factor ranges from 1.000. (primary) to $4/\pi = 1.273$ in the uniform case, corresponding to the change of $(i/i_{av})_{r=0}$ from 0.500 to 1.000 The cathodic tests were made at the limiting current, where the current distribution should be uniform. Consequently, a second test of the same relative increase is given by a direct comparison of $\Delta E_{c,o}/IR_\infty$ with the value $4/\pi$.

The abscissa of Newman's Fig. 5 is $(i/i_{av})_{r=0}$, and it is here that we have applied the approximate method (13, 18), instead of specifying N, δ, and J and solving the necessary set of simultaneous differential equations. The parameter ρ may be calculated from the ratio of R_∞ to the slope of the IR-free current-potential curve at the specified total current. In the general case, we may differentiate the exponential i-η_s relation, using the form of Newman (Ref. (2), Eq. [27])

$$i = i_o\left(\frac{C_o}{C_\infty}\right)^\gamma\left[\exp\left\{\frac{\alpha n\mathbf{F}}{RT}\eta_s\right\} - \exp\left\{\frac{-\beta n\mathbf{F}}{RT}\eta_s\right\}\right] \qquad [3]$$

A comparison to a full scale calculation can be taken from the $(i/i_{av})_{r=0}$ points of the three radial distribution curves calculated by Marathe and Newman (3) for copper deposition. In this cathodic Tafel case, Eq. [3] can be rewritten as

$$i = -i_o\left(\frac{i_L - i}{i_L}\right)^\gamma\left[\exp\left\{-\frac{\beta n\mathbf{F}}{RT}\eta_s\right\}\right] \qquad [4]$$

and differentiated after solution for η_s to yield

$$\left(\frac{\partial\eta_s}{\partial i}\right) = -\frac{RT}{\beta n\mathbf{F}}\left(\frac{1}{i} + \frac{\gamma}{i_L - i}\right) \qquad [5]$$

Using (3) $\beta = 0.25$, $r_o = 0.25$ cm, $i_L = -65$ mA/cm^2 and respective i_{av} values of 0.194, 0.495, and 0.69 times i_L, we obtain $1/A(\partial\eta_s/\partial i) = 22.84$, 11.48, and 11.3 ohms. R_∞ is given as 19.6 ohms, yielding ρ values of 0.86, 1.71, and 1.74. From a plot of ρ *vs.* $(i/i_{av})_{r=0}$ constructed from the tabulation of Albery and Hitchman (13, 18), we read $(i/i_{av})_{r=0}$ values of 0.875, 0.80, and 0.795 which compare quite exactly to the respective intercepts (3) from the detailed theory of 0.878, 0.802, and 0.793.[2]

The apparent success of the ρ approach in reproducing these values is clear. It is also of interest that the entire radial distribution curves of the two nearly equal $(i/i_{av})_{r=0}$ and ρ values are close to superimposable. However, we have also calculated cases related to the three curves just considered with conditions deliberately shifted to be similar to those earlier referred to from Newman (2) in which calculations show maxima in radial current distribution (and much lower currents at the edge of the disk than one would expect from the ρ value). The calculated cases here involved manipulating some of the parameters (β, N, J) four different ways to keep a given ρ of 4.6 constant with $i_{av}/i_L = 0.9$. The predicted identity of $(i/i_{av})_{r=0}$ from the four calculations with constant ρ was found to show an average deviation of less than 2% from that derived from the ρ value although each radial current curve had a maximum. The magnitude of the deviation depends on the calculational details but seems small enough to suggest that the estimate from ρ remains very good in spite of such further effects (here produced when the surface concentration approaches zero within the disk radius) that modify the full radial curve.

Following through with the ρ calculations applicable to the mercury system, we feel that experimental confirmation substantiates both the general theory and the approximate approach in the limits tested.

For the Hg/Hg_2^{++} case where $\eta_s \cong 0$, only differentiation of the η_c-i curve following from

$$\eta_c = \frac{RT}{2\mathbf{F}}\ln\frac{C_o}{C_\infty} \qquad [6]$$

[2] In the calculation of ρ, t_+ for copper, required by the Newman theory and not specified in Ref. (3), was ignored by us as being accounted for experimentally in i_L and i_{av}. Complete computer calculations following Newman show a change of only 10^{-3} in $(i/i_{av})_{r=0}$ for a t_+ range of 0-0.15.

is necessary. This sequence gives for both anodic and cathodic cases

$$\eta_c = \frac{RT}{2F} \ln\left(\frac{i_L - i}{i_L}\right) \quad [7]$$

and

$$\frac{1}{A}\left(\frac{\partial \eta_c}{\partial i}\right) = \frac{RT}{2FA}\left(\frac{1}{i - i_L}\right) \quad [8]$$

Inspection of Eq. [8] indicates that, for a given i_a, the most uniform situation of current distribution occurs for $i_L = 0$, *i.e.*, anodization into a metal-free solution usually considered when applying the RDE and RRDE to corrosion studies. Naturally, in the anodic case, R_a must still be minimized to keep ρ near zero and $(i/i_{av})_{r=0}$ near 1.

Ring-disk electrode.—Collection efficiency.—If the ring is set to collect Hg_2^{++} by reduction at the limiting current in a Hg_2^{++} containing solution, then for the three conditions of zero, cathodic (−), and anodic (+) current at the disk, i_r will be given by the following

I	i_r
−	$i_{rL} - N_c I$
0	i_{rL}
+	$i_{rL} + N_a I$

In the first case, the disk current, when cathodic and limiting, is expected to be radially uniform and N_c equal to N_t. If the anodic current distribution is also uniform then $N_a = N_c = N_t$; otherwise $N_a > N_c$.

Ring-disk potentials.—Albery, Bruckenstein, and Napp (16) showed that for a ring and disk of metal M, anodization of the disk to M^{+n} while $i_r = 0$ produces a potential between ring and disk

$$E_R^D = \frac{RT}{nF} \ln \frac{N_t}{\beta_t^{2/3}} \quad [9]$$

The expression was confirmed (16) for various I and ω values where ohmic drops were negligible.

Experimental

Apparatus and materials.—The galvanostat-potentiostat (19) and motor control-$\omega^{1/2}$ scanning and modulation circuitry (20) have been described earlier. Potentiometric measurements between disk, ring, and references in appropriate pairs have been made with follower amplifiers or high impedance-floating input digital voltmeter. Interrupter measurements were made with a summing point electronic switch (Burr-Brown 9859) at the control amplifier of the galvanostat configuration (19). Switch resistance was taken into account for current level. A Wavetek 114 function generator was used to turn the switch on and off and simultaneously provide a trigger pulse for a storage oscilloscope (Tektronix 564 with 3A3 and 3B4 plug-ins). The circuitry for the isosurface concentration voltammetry (ISCVA) experiments has been described (20).

The RRDE construction (19) was of gold, amalgamated with mercury before use. The six other electrodes employed were gold disks which were similarly mercury wetted and spun at high speed to remove excess mercury. The configurations of the electrodes are given schematically in Fig. 1 and in detail in Table I. *R* is a cylindrical RRDE of dimensions identical to those used extensively in this laboratory. The other configurations vary from *A*1, a relatively small cylindrical shape, through various mantle designs which conform better to the requirements of hydrodynamic theory (21).[3]

[3] Angell *et al.*, have shown that isopotential contours above the plane of the disk are those expected from electrode geometry. Our maps have concentrated on the axis below the center of the disk where it is expected mantle effects would be the least and where it has been our practice [in the regular cell pictured in Ref. (22)] to place the conventional Luggin capillary. By also obtaining the limiting current behavior of all our electrodes, we have compared both current (Levich) and potential ideality of these reference placements.

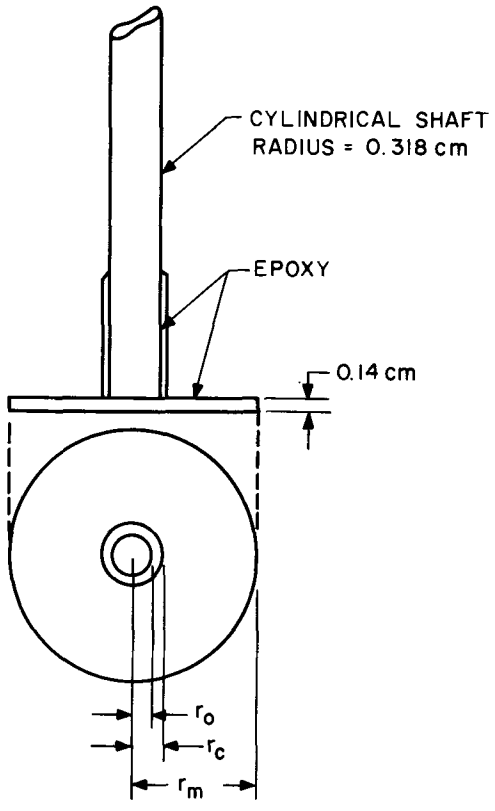

Fig. 1. Electrode configurations

To approach the theoretical requirements of a counterelectrode at infinity with practical dimensions, we employed the arrangement shown in Fig. 2 with a cell based on a three neck, round bottom 1 liter flask and 1 liter cell volumes. The counterelectrode (Hg pool), contacted by a Pt wire, had a minimum surface area of 28 cm^2. The reference probes were gold wires insulated for the last several cm with epoxy and terminating in an amalgamated 0.05 cm tip. Only the nearly planar mercury surface of the wire was exposed. The single probe could either be the upper part of that pictured or a separate single tip electrode.[4] Some experiments, particularly for RRDE measurements, were carried out in the cylindrical J-cell (22) of approximately 250 ml capacity normally used in this laboratory.

Interference with fluid flow by our reference probes is not detectable in limiting current measurements at different probe locations, though these data might not be sensitive to very local effects. Typical values of the diffusion layer thickness are 10^{-3} cm in these

[4] The treatment of Barnartt (23, 24) indicates a minimum distance of 2 × 0.05 = 0.1 cm to which an open end Luggin capillary of 0.05 cm diameter can be brought without affecting the field appreciably under current flow to a large disk ($r_o >> 0.05$ cm). In general, our measurements were begun at about this distance with the metal probes. The double probe (ΔE) experiments, because of the 1.11 cm probe separation, have an additional insensitivity to such shielding effects. Our cumulative experience suggests that shielding was a negligible factor.

Table I. Geometric parameters of electrodes

Electrode	r_o (cm)	r_c (cm)	r_m (cm)
A1	0.148	0.317	—
A2	0.148	—	1.265
B1	0.318	0.377	—
B2	0.318	—	1.252
B3	0.318	—	0.796
C	0.635	—	1.289
R	0.239 ($r_1 = 0.263$, $r_2 = 0.324$)	0.414	—

Note: r_c refers to the insulated cylindrical shaft extending all the way down to the plane of the disk; r_m refers to a case in which the insulated shaft radius << r_m.

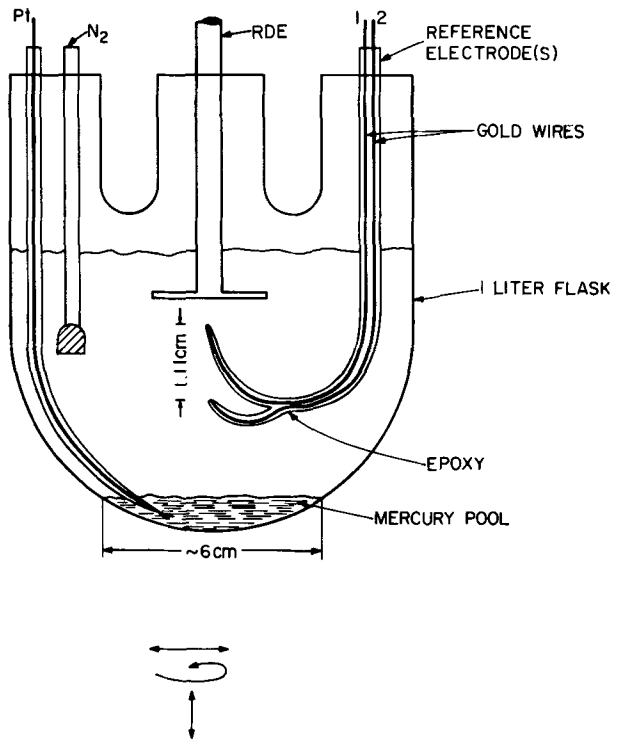

Fig. 2. Cell arrangement. Cell motions in micrometer mount as indicated at bottom.

experiments. Generally, potential comparisons using equal currents of opposite sign which stressed extrapolation of data to the disk surface showed no systematic perturbations attributable to proximity effects on either field or flow.

The cell was mounted in a clamp that was movable by screw adjustments in the three modes indicated in Fig. 2. The disk plane was fixed throughout the experiment, and the reference probes were rigidly set into one neck of the cell. To avoid magnification errors from the round cell walls, the reference probe tip was brought to the disk surface to establish $z = 0.0000$ cm and thereby viewed identically for all z. Cathetometers of 0.0001 cm resolution were employed. Radial mapping in the $z = 0$ plane was not attempted at less than the outer epoxy radius of an electrode to avoid $z > 0$ errors. Full mapping tests were only practical in the z direction. Effects on resistance due to changes in the disk-pool separation during z change were minimal and neglected.

Solutions were prepared from triply distilled water and reagent-grade perchloric acid and mercurous nitrate. All experiments employed an $[H^+]/[Hg_2^{++}]$ ratio required for a supporting electrolyte case, and the presence of nitrate was of no influence. Mercurous solutions were analyzed volumetrically with sodium chloride to a potentiometric end point. Electrodes were polished to a 0.3μ Linde A finish before amalgamation.

Conductivity was measured on a Beckman RC-19 bridge (±0.25%) in a cell of constant 100.6 cm^{-1}. All measurements were made at ambient temperature (23° ± 2°C), with care that conductivity data were taken as near to cell temperature as possible. Potentials were read on digital voltmeters of ≤0.1% full scale accuracy (Hewlett-Packard 3430A and Heath EU-805). Limiting currents were also read digitally.

Automatic ohmic compensation methods to be described were carried out with the analog circuitry shown in Fig. 3. At upper left is the scheme for feedback with a single reference probe. At lower left is the equivalent mode for the double probe potential difference as feedback. Point A is the common connection for either method to the analog correction circuit at right.

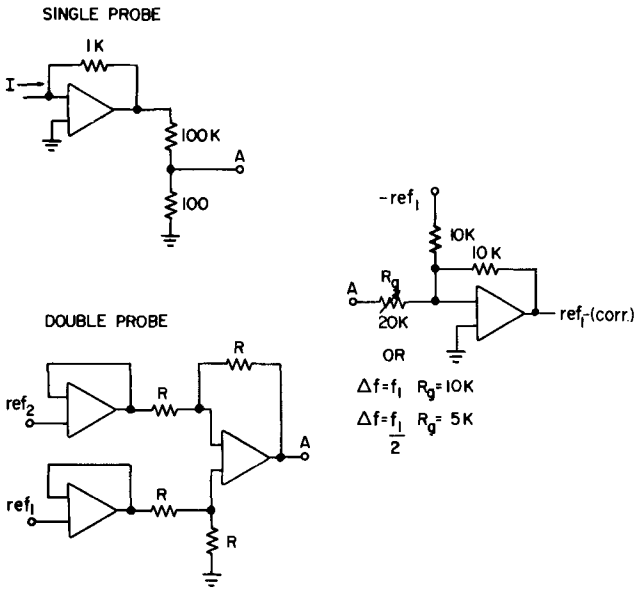

Fig. 3. Automatic ohmic compensation circuitry

Results and Discussion

Levich constant.—Limiting current characterization of the electrodes is shown in Fig. 4 and Table II. Electrodes are grouped in the figure by common disk radius (4 values). Over the speed range to 2500 rpm there is differentiation among mantle designs within a group only at the low end. (At higher speeds than 2500 rpm significant turbulence and air entrapment begin to distort the results, starting with the larger mantles). The ordinate is normalized to unity within each set to show per cent changes readily, but inspection of Table II also reveals that the absolute values of the $i_L/\omega^{1/2}C_\infty$ factor are given to a precision of 1% (standard deviation) including slight differences arising from 1M and 0.2M $HClO_4$ electrolytes.

These data confirm other discussion (25) of the relative insensitivity of the RDE to hydrodynamic ideality of design in the limiting current measurement. For the purposes of this paper we exclude effects on comparative current distribution that might be attributed to such variation. The data are also of practical significance for application of the ISCVA technique

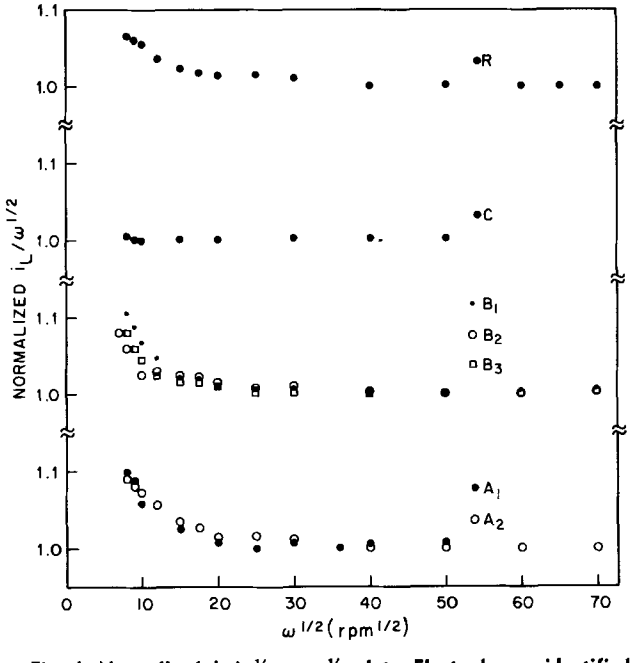

Fig. 4. Normalized $i_L/\omega^{1/2}$ vs. $\omega^{1/2}$ plots. Electrodes as identified in Table I.

Table II. Limiting disk current behavior

Electrode	A, cm²	$I/\omega^{1/2}$, mA-rpm$^{-1/2}$	$10^{-3}\, i_L/\omega^{1/2}\, C_\infty$, mA-cm-rpm$^{-1/2}$-mole^{-1}	Solution
A1	0.0688	0.0140	35.4	I
A2	0.0688	0.0138	34.9	II
B1	0.3177	0.0634	34.8	I
B2	0.3177	0.0630	34.5	II
B3	0.3177	0.0628	34.4	II
C	1.267	1.005	34.5	III
R	0.179	0.0352	34.3	I
I	1M $HClO_4$, 5.74 mM Hg_2^{+2}			
II	0.2M $HClO_4$, 5.74 mM Hg_2^{+2}			
III	1M $HClO_4$, 22.96 mM Hg_2^{+2}			

From these data, the average value of $D_{H_{g_2}}$ +2 in 1M $HClO_4$ at 23° ± 2°C with ν = 0.00863 cm²/sec is 8.2 × 10^{-6} cm²/sec.

(26) in which a constant surface concentration through control of the $I/\omega^{1/2}$ ratio at varying I is assumed. The lowest values of $\omega^{1/2}$ and therefore of current at which this constancy holds correspond to the minimum potential perturbation from equilibrium accessible for the fixed surface concentrations.

Single probe mapping.—Three typical E_z-f plots obtained for varying solution conditions, current direction, ρ parameter, and electrodes are shown in Fig. 5. The data points are well described by theoretical lines drawn between intercepts η_c and $\eta_c + IR_\infty$ calculated from [7] and [2]. The dimensions of the three electrodes restrict the data at low f values. The ρ parameters of 0.57 (*A2*), 1.3 (*B1*), and 4.0 (*B3*) suggest them all to have varyingly nonuniform current distributions. Figure 5 indicates that ohmic compensation with fIR_∞ determined by means of an axial probe at position f and known conductivity ought to give good extrapolation to the values of overpotential at the

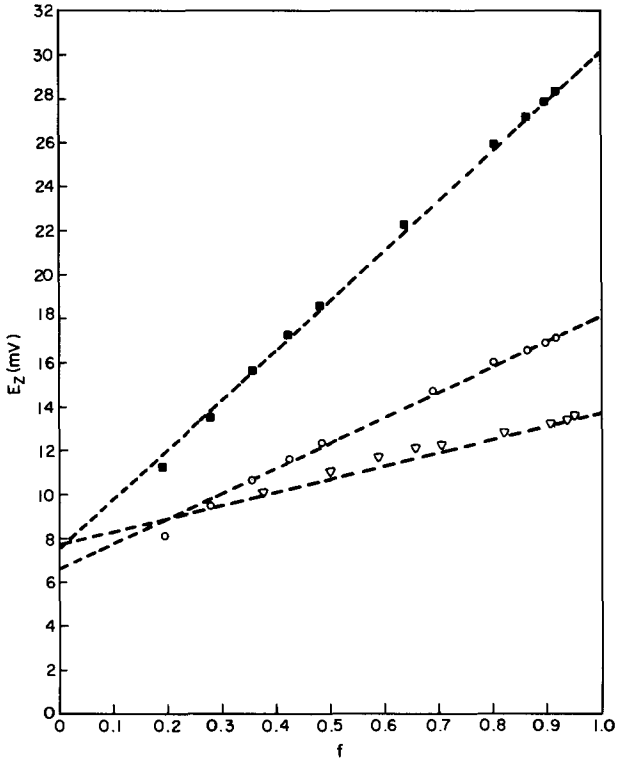

Fig. 5. Single probe potential E_z vs. f.

		I, mA	ρ
▽	*A2*,	−0.25 mA	0.57
○	*B1*,	−1.00 mA	1.3
■	*B3*,	+2.00 mA	4.0

All runs with 0.2M $HClO_4$, 5.74 mM Hg_2^{+2} solution. κ = 0.0692 mhos-cm^{-1}, ω = 1600 rpm. Dashed lines are drawn with slopes of measured IR_∞.

surface calculated assuming the average current across the electrode in spite of the predicted nonuniformity. Further quantitative indication of the actual $(i/i_{av})_{r=0}$ values from probes at low f is not evident with experiments of the limited accuracy of Fig. 5.

Assuming a generally accurate η_c calculation, we have plotted various data including a sample of every one of the electrodes in the form of an f_{exp} *vs.* f correlation in Fig. 6. The estimate of R_z/R_∞ or f_{exp} is calculated from $1 - (E_\infty - E_z)/IR_\infty$ where $E_\infty = IR_\infty + \eta_c$ and η_c is obtained with [7], implicitly assuming $i = i_{av}$ at $r = 0$. The range of parameters covered in Fig. 6 is shown in Table III. The straight line is $f_{exp} = f$. We can conclude from both Fig. 5 and 6 that the agreement between f_{exp} and the geometric f based on z and ξ provides confirmation for all electrode geometries tested of the Newman resistance theory (7) for the RDE.

Measurements in the r direction at $z = 0$ for all the electrodes generally support the conclusions from Fig. 5 and 6. The calculated sum of $\eta_c + fIR_\infty$ is always reproduced within a few mV except for certain cases with the cylindrical designs *A1*, *B1*, and *R*, where the measured values tend to be lower. This conforms to expectation with the reduced insulating region around the disk (6). Also, with the limited range of radial f values accessible due to the mantle starting point, we restrict further quantitative presentation to the axial direction. However, it may also be pointed out that some axial and radial mapping was carried out in the J-cell and, even with the more restricted dimensions involved, the slopes and extrapolations followed very closely the conclusions of the above measurements in the more ideal cell. This holds true also for the automatic compensation techniques to be described.

Double probe potential difference.—In the single probe studies summarized in Fig. 6, a 1-mV error ranges from 2-16% of IR_∞. With the additional η_c uncertainty, it is difficult to achieve resolution sufficient to define the region close to the electrode where changes due to nonuniformity may be detected. The double probe method is, in principle, free of the non-ohmic potentials and contains only the further assumption, now documented in Fig. 5 and 6, that the potential between the second probe at f_2 and ∞ may be calculated from $(1 - f_2)IR_\infty$. The most suitable electrode for detailed study was *C*, with the largest radius, approachable to f_1 of < 0.1 at two probe tip diameters. We thus report only such data for this electrode except for supplementary results from *R* in ring-disk experiments.

Six runs yielding $\Delta E + (1 - f_2)IR_\infty$ *vs.* f_1 plots are shown in Fig. 7, with ρ variation obtained for the single solution through $\omega^{1/2}$ control of i_L. The IR_∞ intercept is obtained with [2] and Ai_L values. The pair of ΔE values shown was taken at each position before the cell was moved. Data were taken for increasing z at least until the decreasing ΔE_c and ΔE_a values were within 0.1 mV. (Further increase of ξ gave ΔE decreasing to essentially zero in accordance with theory.) The plots can be compared directly to the theoretical curve in Fig. 1 of Smyrl and Newman (5).

Extrapolation of the experimental $\Delta E + (1 - f_2)IR_\infty$ to $f_1 = 0$ yielded the necessary $\Delta E_{a,o}$ and $\Delta E_{c,o}$ to

calculate $\Delta E_{a,o}/IR_\infty$ and $\Delta E_{c,o}/IR_\infty$. The intercepts and calculations from Fig. 7 are collected in Table IV along with the ρ_a factors obtained through [2] and [8] and the corresponding $(i/i_{av})_{r=0}$. The six values each of $\Delta E_{c,o}/IR_\infty$ and $\Delta E_{a,o}/IR_\infty$ are used for the ordinates of Fig. 8 points, where the solid line is the theoretical one of Newman's (2) Fig. 5. For each anodic point are plotted two values of $(i/i_{av})_{r=0}$ calculated, respectively, from ρ_a and from a computer program using the extended Newman theory. (The cathodic points all have $(i/i_{av})_{r=0}$ of unity.) The data are in good consonance with the predictions of the theory. The agreement is considered to affirm both the Newman theory and the approximate Albery-Hitchman calculation for the disk center.

Two experiments similar to the above but with ΔE_a and ΔE_c measured as a function of I up to $\pm|Ai_L|$ for two fixed z values are plotted in Fig. 9. Both $\dfrac{\Delta E_c}{\Delta E_a}$ and $\dfrac{\Delta E_c + (1 - f_2)IR_\infty}{\Delta E_a + (1 - f_2)IR_\infty}$ are given in the ordinate *vs.* I/Ai_L. Also shown as abscissa is the ratio $(i_a/i_c)_{r=0}$ corresponding to each point, from ρ calculations as previously. ρ_a at $I = -Ai_L$ is 10.8, giving $(i_a/i_{av})_{r=0} = 0.60$. The ρ_a and ρ_c values become equal as $I \to 0$. The correspondence between the double probe potential ratios and the change in the $(i_a/i_c)_{r=0}$ ratio clearly shows how the shifts in current distribution with current level (δ in the Newman theory) may be detected in this manner. The values of the $\Delta E + (1 - f_2)IR_\infty$ ratios, 1.148 and 1.097, at the fixed f_1 of 0.243 and 0.448, respectively, follow reasonably the predicted 1.194 ratio at $f_1 = 0$ for $(i_a/i_{av})_{r=0} = 0.60$.

Automatic IR compensation.—Compensation of resistance between the reference probe and disk, assuming the primary current ξ-R_∞ relation, was carried out automatically in two ways with the circuitry of Fig. 3. With a single probe, a cathetometer measurement of z was used to calculate R_z/R_∞ from ξ and then R_z was determined when R_∞ was gained from a conductivity measurement and [2]. The appropriate fraction of current follower output equivalent to a continuous correction IR_z was then fed back and subtracted from the reference potential. The 1K resistor current follower output is divided by 1000, giving a 1 ohm correction modified by the gain of the analog stage, which here can correct for R_z of 0.5 to more than 100 ohms.

The second technique utilized the double probe with known separation and a cathetometer-derived f_1 and thus f_2. ΔE between the probes senses a fraction of IR_∞ equal to Δf. Two convenient analog correction conditions are to set the distance from the disk for $f_1 = \Delta f$ or $f_1 = 2\Delta f$, whence either ΔE or $2\Delta E$ is the correction required for the nearer probe as disk reference. R_∞ determination is not required with double probes.

Both techniques were successfully applied and double probe resistance compensation with the ISCVA technique (20, 26) is shown in Fig. 10, with both linear-time $\omega^{1/2}$ scanning and square wave modulation. In these methods, $I/\omega^{1/2}$ is held constant while I is varied, and the measured E_z is plotted *vs.* I (or *vs.* time, taking data in the steady-state region, for constant $\Delta I/\omega^{1/2}$ under modulation). The $(\partial E_z/\partial I)_c$ or $(\Delta E_z/\Delta I)_c$ outputs corresponding to scan or square

wave control are the sum of IR_z and the desired electron transfer resistance, which for the Hg/Hg_2^{++} electrode under the experimental C (5.74 mMC_∞ + 11.4 mM from $I/\omega^{1/2}$) is < 0.02 ohm. This being negligible in comparison to the ohmic resistance to be compensated, about 1.4 ohm, the desired result is an experimental slope or modulation of near zero.

In Fig. 10, traces A and C are the uncompensated slope and $\Delta E/\Delta I$ outputs (measured at 1.42 and 1.35 ohm, respectively) for a setting of $\Delta f = f_1/2$ at the probes. [R_∞ = 2.46 ohms, $2\Delta f$ = 0.586, and $2\Delta f R_\infty$ = 1.44 ohms]. Correction of E_{z1} by $2\Delta E$ (R_g = 5k) gives traces B and D which exhibit the desired compensation. Equivalent results not shown here were obtained by the single probe method.

Ring-disk electrode studies.—Potentiometric measurements.—The mercury disk of R was anodized at various currents into mercury-free 0.2M $HClO_4$, and the potential between ring and disk was measured. The theoretical (IR-free) value (16) of the potential E_R^D from [9] with N_t = 0.366 and $\beta_t^{2/3}$ = 1.108[5] is 14.17 mV. The measured E_R^D up to an I of 5 mA (28 mA/cm²) is given in Fig. 11. Least squares analysis of the line gives an intercept at I = 0 of 14.03 ± 0.05 mV, in satisfactory agreement with theory, and a slope of 6.46 ± 0.02 ohms. Since R_∞ is 14.85 ohms from [2], the indicated values of f and ξ corresponding to the ring as probe are 6.46/14.85 and 0.78, respectively. The radial distance equivalent to this ξ is $\sqrt{[(0.78)^2 + 1]^2 r_0^2}$ = 0.302 cm. The ring radii are 0.263 and 0.324 cm, bracketing this distance.

For the seven points shown in Fig. 11, the ρ values increase with current from 0.11 (nearly uniform current) to 5.8 [$(i/i_{av})_{r=0}$ = 0.67]. In spite of the change in current distribution, a constant ohmic correction factor seems applicable to this experiment. Equation [9] was shown to hold (16) for the Ag/Ag^+ couple independent of I and $\omega^{1/2}$ in 0.1M $HClO_4$, where ohmic drop effects on E_R^D were negligible (I ≤ 30 μA). In the present case, with $\omega^{1/2}$ scanned over wide limits (20-90 $rpm^{1/2}$) at current levels common to Fig. 11, the E_R^D values were constant at each I to ±0.5 mV. The difference between experiment and [9] is still the ohmic drop. No difference in current distribution is expected in the mercury-free solution as a function of $\omega^{1/2}$ since $i_L \cong 0$ at all speeds.

[5] The calculated value (12) of N_t from the gold dimensions is 0.350 and the value consistently found in practice is 0.366 ± 1%. Effects of outward motion of r_0 and r_2 due to the rotating mercury film of less than 2% would account for the difference. This effect tends to cancel in $\beta_t^{2/3}$ where 1.108 was measured and 1.106 calculated.

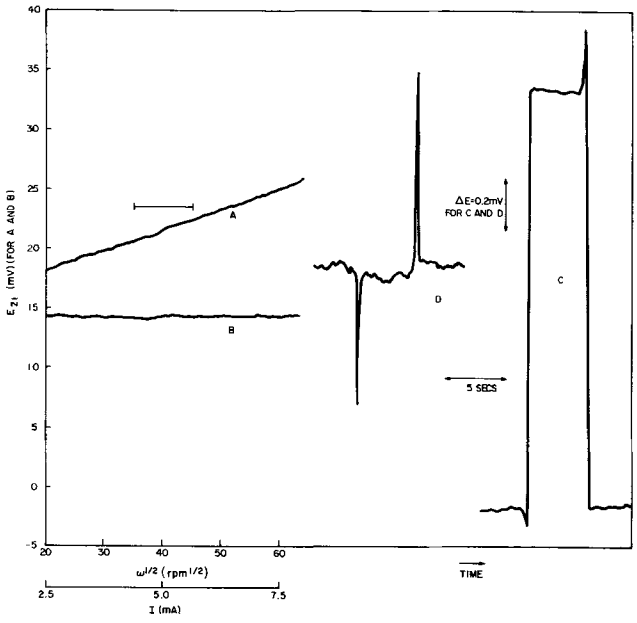

Fig. 10. ISCVA E_{z1} potentials with B2, 1M $HClO_4$ — 5.74 mM Hg_2^{++}, $I/\omega^{1/2} = 0.125$ mA-rpm$^{-1/2}$, $zI = 0.413$ cm, $f_1 = 2\Delta f = 0.586$. Traces A and B vs. I, C and D vs. time. A: uncompensated scan; B: as A, except compensated as in text; C: uncompensated square wave modulation of $\omega^{1/2}$ or I amplitude indicated by horizontal marker above A($\Delta\omega = 45.2 - 35.2$ rpm$^{1/2}$); D: as C, except compensated as in text.

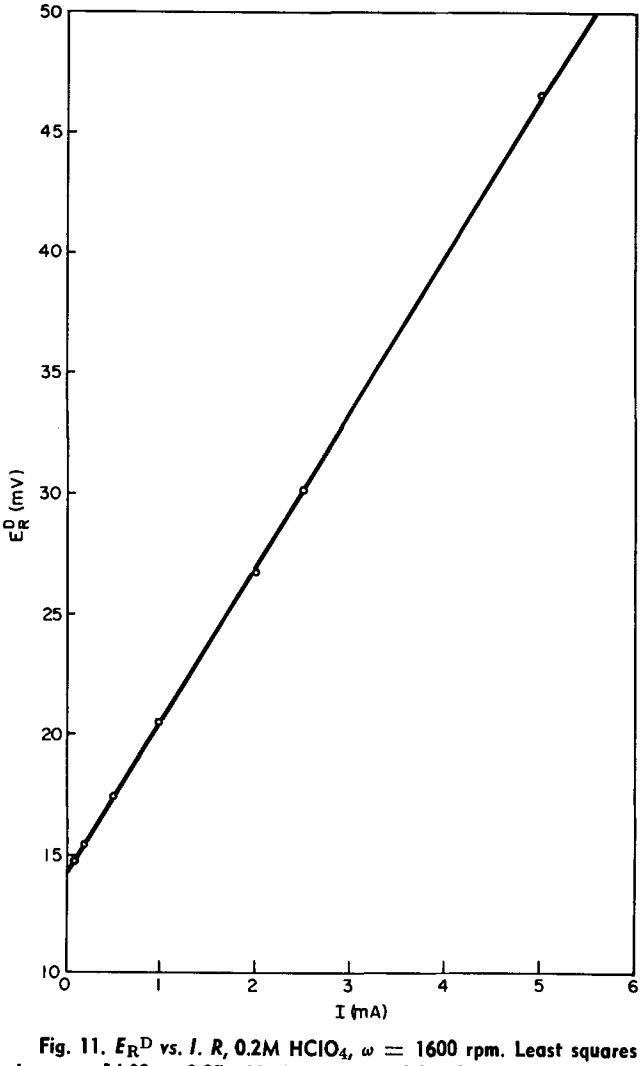

Fig. 11. $E_R{}^D$ vs. I. R, 0.2M $HClO_4$, $\omega = 1600$ rpm. Least squares intercept 14.03 ± 0.05 mV, slope 6.46 ± 0.02 ohm.

With the same system, the potential $E_R{}^{ref}$ was measured over three decades of disk current and therefore of Hg_2^{++} surface concentration. In this one experiment, the probe was a fine-tip Luggin capillary with a saturated calomel reference since the solution was initially mercury-free. The results are the data points (a) in Fig. 12. The reference probe was at an axial ξ of 2, and thus for $R_\infty = 14.85$ ohms, an R_z of 10.5 ohms. In conjunction with the disk-ring resistance from Fig. 11 of 6.50 ohms, this indicates an ohmic drop between ring and reference due to disk current of (10.5-6.5)I. Applying such a correction to 12(a) gives the set of points 12(b). An automatic correction to $E_R{}^{ref}$ is suggested by making R_z equal to the slope of Fig. 11, *i.e.*, $\xi = 0.80$, $z = 0.191$. The best correspondence to a 2.303 $RT/2F$ slope for the upper two decades of disk current was experimentally found at $z = 0.182$ cm. Two sets of data obtained for $E_R{}^{ref}$ for that reference position are shown as (c) in Fig. 12. The line is a theoretical 29.5 mV/decade I plot. Deviations at the lowest currents are mostly due to accumulation of small amounts of Hg_2^{++} in solution from repeated runs.

Reverse effects to those considered above, namely of ring current on $E_D{}^{ref}$, may be readily investigated since the flow pattern is such as not to cause an alteration in the surface concentrations (and Nernst potentials) at the disk by ring processes. $E_D{}^{ref}$ was measured with the axial probe far removed ($f \to 1.0$) and as a function of anodic and cathodic ring current up to 5 mA in Fig. 13. The ring limiting current in the 22.96 mM Hg_2^{++}-1M $HClO_4$ solution was −6.07 mA. The slopes are 1.48 ohm (anodic) and 1.09 ohm (cathodic) in a solution giving $R_\infty = 3.37$ ohms.

The difference in slopes possibly arises from the changing current distributions in cathodic and anodic directions at the ring. Since the ring is not uniformly accessible and tends to infinite current density at the inner edge, overpotential effects will cause a shift of current toward the outer edge. From [8] it is seen that a cathodic current is more effective in contributing polarization resistance than an equal magnitude anodic current. Effects in this direction at the ring make $E_D{}^{ref}$ larger in the anodic case where the current should be relatively higher near the disk-probe axis than for equal cathodic current.

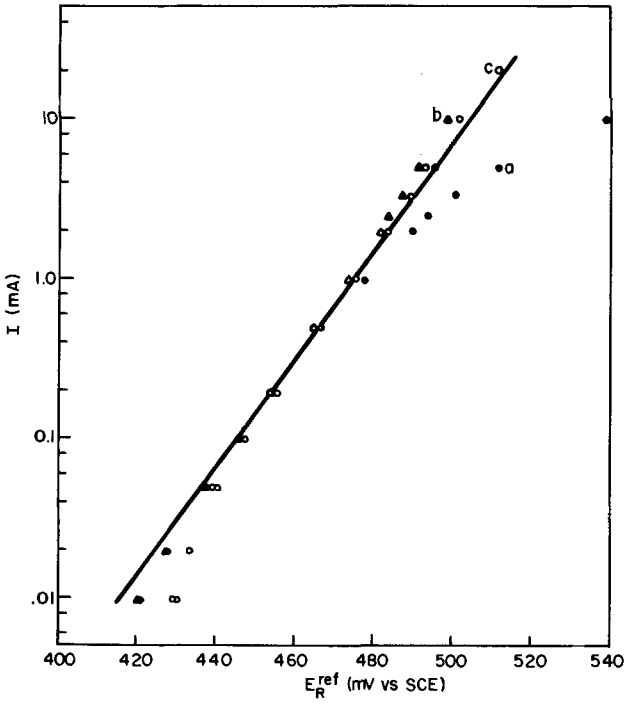

Fig. 12. $E_R{}^{ref}$ vs. log I. R, 0.2M $HClO_4$, saturated calomel reference (ring is positive). $\omega = 1600$ rpm. (a), ● z = 0.478 cm; (b), ▲ a corrected for 4.0 I volt drop; (c), ○ z = 0.182 cm.

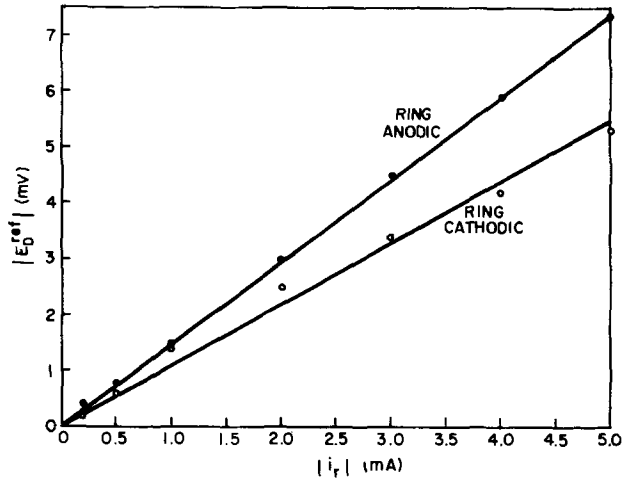

Fig. 13. $|E_D^{ref}|$ vs. $|i_r|$. R, 1M $HClO_4$ — 22.96 mM Hg_2^{+2}, ω = 1600 rpm, z large ($f \rightarrow 1.0$). ●, anodic i_r — least square slope $1.47_5 \pm 0.02$ ohm; ○, cathodic i_r — least square slope 1.09 ± 0.05 ohm.

Coordinated mapping and collection efficiency studies.—Studies were made with electrode R of $\Delta E + (1 - f_2)IR_\infty$ *vs.* f plots and of the values obtained for collection efficiencies N_c and N_a at the same anodic and cathodic currents, $\pm A|i_L|$. The results are summarized in Table V. The value of $(i/i_{av})_{r=0}$ for the anodic case is calculated from ρ and from the three experimental intercepts following the procedure of Fig. 7, except that the extrapolation of the straight portion of the plots was used for IR_∞. The conditions were selected for a high ρ_a and thus a rather nonuniform anodic current. The ratio $N_a/N_c = 1.066$ reflects the higher concentration gradient at the disk edge as sensed in collection efficiency by this particular ring geometry. N_a/N_t determinations for R in mercury-free perchloric acid solutions of various concentrations, as previously done for silver (4), shows a trend with the ρ parameter of about the same level as shown with the current reversal experiment. A combination of these approaches offers a quantitative means to test the relation between disk current distribution, altered systematically, and the resulting collection properties. In the absence of a complete theory, the apparent correlations will not be pursued further here.

Interrupter experiments.—The double probe configuration offers a nearly ideal way to study the transient buildup and decay of the ohmic resistance drop with fast interrupter methods since the changes are not obscured by other sources of potential variation at the disk electrode itself. The total change of ΔE is between zero and the corresponding steady-state values, $I(R_{z2} - R_{z1})$. The latter is what was measured in the double probe mapping experiments and the difference in resistance will be called ΔR here. We wish to compare ΔR to the instantaneous interrupter values for current make and break, $\Delta R'_{on}$ and $\Delta R'_{off}$ (anodic and cathodic), to compare the $\Delta R'$ to the primary distribution prediction of Newman, and to observe the time constant for the change $\Delta R' \leftrightarrow \Delta R$. The previous technique of using $\pm A|i_L|$ to select variable anodic current distribution and a uniform steady-state cathodic current was applied with electronic switching in make and break directions.

The scope pictures have been exactly traced and are shown, for clarity, as the composites for I "on" (Fig. 14) and I "off" (Fig. 15). The four values of $\Delta R'$ determined from the instantaneous change are listed in Table VI. They are within the scope reading error of each other and the theoretical value of 6.7 ohms for the primary resistance R_∞ times $2/\pi$ ($\tan^{-1} \xi_2 - \tan^{-1} \xi_1$), confirming Newman's predictions quantitatively. The steady-state values, ΔR, from the scope pictures compare well to DVM data taken in conjunction and reflect the prevailing current distribution in the manner earlier discussed. For this case $\rho_a = 8.6$ which gives a $(i_a/i_{av})_{r=0}$ of 0.62.

The time constant, τ, of the current decay after the instantaneous drop of the cathodic current in Fig. 15 (time to $1/e$ decrease) is about 120 μsec. The predicted

	Interrupt				Steady state	
	+ on	+ off	− on	− off	− I	+ I
Ohms, ref. to disk	6.4	6.4	6.5	6.6	8.8 8.7	7.2 (Scope) 7.0 (DVM)
Δf R_∞, ohms	6.7	6.7	6.7	6.7		
Ohms, cell	11.3	11.3	11.5	11.3		

(8)[6] $\iota \cong r_o C_p/4\kappa$, $C_p \cong 28$ μf/cm^2 is reasonable for the ideally polarized surface (limiting current) in 0.1M $HClO_4$.

Also shown in Table VI are the results of interrupter measurements between disk and mercury pool. The four resistances obtained are identical within experimental error. The average value, 11.3_5 ohms, is an experimental measure of R_∞ which, from [2], is 11.0_4 ohms. This is satisfactory confirmation of the geometric assumptions about the cell. However, the suggestion (10) that interrupter data will demonstrate the increased average resistance for uniform current appears incorrect; only the primary R_∞ value will be measured, as follows from Newman (8). The value for uniform current, 1.08 R_∞ (10), is not extractable from the transient data after interruption either, since the polarization and charging processes at the electrodes obscure it.

Interrupter measurements give the correct uncompensated ohmic drop sensed by the reference when current I is flowing in the experimentally limiting case of a steady-state primary current distribution or where the design of cell and electrodes is such that this is coincident with the uniform case. Techniques were employed in this paper which gave good apparent automatic compensation at a RDE in situations where the current distribution was nonuniform. In such cases the interpretation of the resistance corrected potential in terms of electrode processes is not unambiguous. Unfortunately, in the rotating disk system it is not always possible to avoid ohmic drop related nonuniformities even with analytically sized disks and fairly conductive solutions. In the light of the utility of the ρ parameter, which is further documented in this paper, the diagram of Albery and Hitchman (13, 18) correlating the κ, r_o, and $\partial\eta/\partial i$ requirements to keep $\rho \leq 0.1$ (uniform current) deserves special attention, particularly considering the calculational difficulties of employing the full Newman theory (2) in a convenient manner.

Summary

Potential and resistance measurements with well-defined probes have further quantitatively substantiated the Newman theory for current and potential distribution at the RDE. Comparisons of interrupter and steady-state resistance measurements have indicated that transient behavor of the current distribution during the acquisition of the steady state is both a possibly significant experimental factor and another way to detect the nature of the steady-state distribution. For both mapping and resistance methods, the double probe technique is particularly effective. Successful automatic compensation of resistance based on the feedback from precisely located probes through Newman's model is demonstrated, simultaneously corroborating the theory. Observation of nonuniformity of current by potential measurements has been correlated to increases in collection efficiency in a RRDE. The approximate treatment of Newman's theory through the ρ parameter method of Albery and Hitchman is shown throughout this work to be a significant and valid simplification.

[6] A reviewer has informed us of a recent addition of the factor of about 4 to the original equation. The comparison of the limiting current of a fast reaction and ideal polarization is recognized as possibly doubtful.

Electrocatalysis of Oxygen Reduction by Sodium Tungsten Bronze

I. Surface Characteristics of a Bronze Electrode

J. McHardy*,[1] and J. O'M. Bockris*,[2]

Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

When a metallic crystal of the nonstoichiometric compound sodium tungsten bronze, Na_xWO_3, was used as an oxygen electrode in acidic solution, sodium was lost from the crystal by anodic dissolution, leaving a thin semiconducting layer on the surface. The composition change in the surface layer corresponded to a decrease in x from ~0.7 to ~0.25 for a crystal free of intentional impurities, and from ~0.7 to ~0.05 for a crystal containing traces of platinum. The difference may result from more rapid hole injection in the latter case, associated with the enhanced rate of oxygen reduction observed. The response of the bronze electrode to light revealed a bandgap of ~2 eV and a flatband potential of 0.5-0.6V *vs.* RHE for the semiconducting layer, both apparently independent of platinum content. Donor concentrations in the surface layer determined from $1/C^2$ vs. E (Mott-Schottky) plots were in good agreement with sodium concentrations determined by ion probe mass spectroscopy.

Sodium tungsten bronze, Na_xWO_3, is a nonstoichiometric compound with x a continuous variable from 0 to 1. The compound comprises a WO_3 matrix containing interstitial sodium ions and an equivalent number of quasi-free electrons (1). When x exceeds 0.25, the electrons occupy a conduction band and bestow metallic conductivity on the compound (2). As x increases from 0 to 1, the crystal structure passes through a series of transformations, each representing an increase in symmetry (3). Cubic symmetry in the form of a defect perovskite structure is normally restricted to the composition range $0.4 < x < 1$ but has been extended to considerably lower x values by chemically removing sodium from a crystal initially in the normal cubic composition range (4).

Metallic crystals of sodium tungsten bronze prepared by electrolyzing a molten mixture of Na_2WO_4 and WO_3 were reported to exhibit electrocatalysis for oxygen reduction comparable with platinum (5), but subsequent work demonstrated that the high catalytic activity required the presence of about 100 ppm platinum in the crystals (6). In the course of experiments designed to elucidate the role of platinum in electrocatalysis by Na_xWO_3, it became apparent that the surface of a bronze electrode behaves more like a semiconductor than a metal, and this paper describes an investigation of its semiconducting behavior.

Experimental

Preparation of bronze electrodes.—Tungstic oxide obtained from K&K Laboratories was of 99.5% purity. Baker Analyzed sodium tungstate dihydrate was dried for a minimum of 24 hr at 120°C before use.

On the basis of preliminary work, alumina was selected as the crucible material and McDanel ACN high-purity alumina crucibles were used throughout. At first, 40 ml crucibles were used but later on 100 ml crucibles were adopted. The crucible was placed inside a quartz cell which was surmounted by a Pyrex cap and an O-ring seal as described previously (7). Gold wire electrodes (1 mm diameter, 99.99% pure) were sheathed in McDanel high-purity alumina tubes and mounted vertically through the cap of the cell by means of Beckman Teflon tube fittings. Spectroscopic analysis revealed no contamination of the bronze crystals by gold. The cell was heated in a vertical tube furnace (Electro-Applications Inc. No. 620) and the melt temperature maintained at 800° ± 3°C with a Barber Coleman Model 427P Control Unit and a Chromel-Alumel thermocouple in a closed alumina sheath.

Sodium tungstate and tungstic oxide were weighed directly into an alumina crucible which was immediately lowered into the quartz cell. The reagents were fused and allowed at least 4 hr to equilibrate.

A slightly tapered seed crystal about 1.5 × 1.5 × 5 mm cut from a previous crystal with a diamond wheel (Micro-Mech. Inc. Precision Wafering Machine Model WMSA 810) was attached to a gold wire by beating out the tip of the wire into a foil and wrapping it around the wider end of the seed. The seed and a counterelectrode of coiled gold wire were lowered into the melt and allowed a few seconds to warm up.

The constant current employed to grow a crystal was generated by a Dressen Barnes Model 3-150L d-c power supply in series with a Clarostat decade power resistance box. The seed crystal was initially driven anodically at about 10 mA cm^{-2} to clean the surface. The current was then reversed and increased periodically to maintain a cathodic current density of about 5 mA cm^{-2} on the crystal.

The value of x in the bronze crystal increases with the ratio of $[Na^+]$ to $[WO_3]$ in the melt, but the relationship is not a simple one (8). In most cases, the melt composition was 42 m/o (mole per cent) Na_2WO_4: 58 m/o WO_3 and yielded crystals with a sodium content corresponding to $x \sim 0.7$. Electrolysis was continued for about two days and yielded a crystal with (100) faces (cubic morphology) approaching 1 cm on an edge.

Platinum and other impurity elements were introduced into a crystal during its growth by continuous codeposition, a small concentration of the impurity being maintained in the melt by anodic dissolution of the appropriate element. In the case of platinum, for example, the anodic current was divided between the inert (gold) electrode and a 1 cm^2 platinum electrode. The crystal was grown at a fixed total current of 15 mA with a certain fraction of that current passing through the platinum anode. The platinum content of the crystal increased with the fraction of the current passed by the platinum anode, up to a maximum of ~400 ppm at $i_{Pt} = 8$ mA. Attempts to exceed this concentration resulted in a spongy platinum deposit that stifled further crystal growth.

Upon removal from the melt, crystals were allowed to cool in air and were then cleaned of solidified melt with boiling water. Crystals were mounted in Teflon as described previously (9).

Analysis.—Sodium concentrations were determined by measuring the lattice parameter, a, and applying the equation (in angstroms) (10)

$$a = 0.0819x + 3.7846 \quad [1]$$

The lattice parameter of a crystal was measured by the x-ray powder diffraction method using a Phillips Spectrometer and CuKα radiation.

Platinum concentrations were determined by spark emission spectroscopy. Analytical standards were prepared by heating the calculated weight of chloroplatinic acid with a mixture of $3Na_2WO_4$:$2WO_3$:W in nitrogen at 900°C for 2 hr. The ratio of the three reagents was chosen empirically to yield a bronze of x-value close to 0.7 by the reaction (11)

$$\left(\frac{x}{2}\right) Na_2WO_4 + \left(\frac{3-2x}{3}\right) WO_3 + \left(\frac{x}{6}\right) W = Na_xWO_3 \quad [2]$$

The technique had a precision of ±25% and a lower detection limit for Pt of 50 ppm. Other, more precise techniques such as x-ray fluorescence, atomic absorption, and activation analysis suffered from interference by tungsten or sodium.

Optical experiments.—Crystals mounted in Teflon were given a metallographic polish. No special polishing procedure was required until the final stage, when 1μ diamond paste was used instead of alumina. The polishing materials were removed from a crystal by washing it successively in boiling 30% H_2O_2 and boiling conductivity water. The specimen was then mounted in the Teflon assembly (Fluorocarbon Inc. Union Elbow Reducer) shown in Fig. 1.

The test solution was 0.1N $HClO_4$ prepared from reagent grade 70% perchloric acid and conductivity water. The Vycor cell which featured a quartz 50 mm optical window appears in Fig. 2. The reference electrode was the Pd/H electrode, prepared by the method of Fleischmann and Hiddleston (12). Potentials quoted here have been corrected to the scale of a reversible hydrogen reference electrode in the same solution.

A freshly polished specimen was conditioned prior to test by cycling it 20 times between 0.5 and 2.0V at 50 mV sec^{-1}. This procedure was found sufficient to stabilize the current *vs.* potential trace during a sweep. All experiments were performed at room temperature (25° ± 2°C).

The light sources were a series of high-intensity Osram arc lamps operated from a Spectroline Model

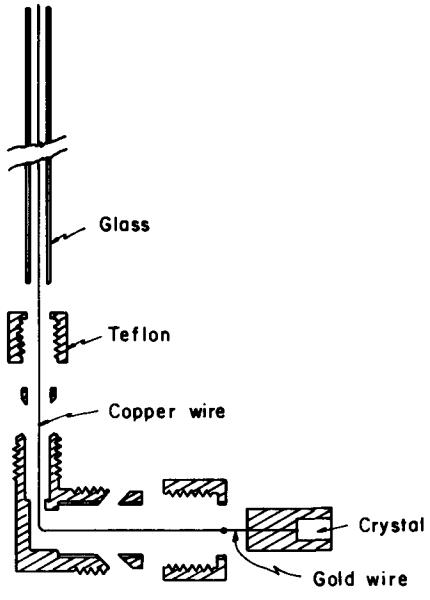

Fig. 1. Teflon and glass crystal mount for optical experiments

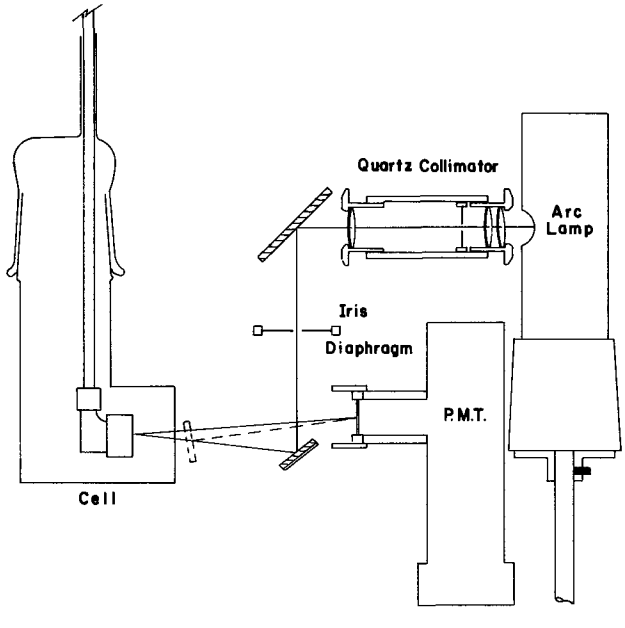

Fig. 2. Apparatus for reflectance spectroscopy

1500 power supply. Each arc lamp put out essentially the line spectrum of a single gaseous element. Monochromatic light was achieved by filtering out all but one line of the spectrum with Spectroline glass filters. The intensity of an arc lamp tended to drift gradually with time, and it was necessary to measure the intensity every few minutes during each experiment. An RCA 1P-21 photomultiplier tube (p.m.t.) in a Schoeffel D-500 housing was used to measure light intensities. The tube was operated at an anode voltage of 500V in conjunction with a Schoeffel Model M-400 photometer. Both the electrochemical experiments and the measurements of light intensity were performed on an optical bench. Preliminary tests showed that for distances greater than about 3 cm a lamp could be treated as a point source of light.

A potassium ferrioxalate chemical actinometer (13) was employed to calibrate the response of the p.m.t. to the two mercury lines at 245 and 365 nm, respectively. The response at other wavelengths was then obtained from the published curve of relative spectral response for this type of p.m.t. (14).

Reflectance spectra were obtained with the arrangement shown in Fig. 2. The weakness of typical reflected intensities necessitated the performance of this part of the work in a dark box. The collimated beam of monochromatic light was reflected into the p.m.t. either by the bronze electrode or by a front surface mirror which was mounted on a hinge so that it could be swung into position in front of the cell window.

Using a triangular voltage sweep generator as the reference input to the potentiostat, the potential of the test electrode was swept at 50 mV sec^{-1} between -1.5 and $+2.0$V. The potential was also applied to the X input of an XY recorder. The intensity of the beam reflected from the electrode surface was measured with the p.m.t. and photometer. A d-c voltage from 0 to 5V put out by the photometer in proportion to the meter reading was applied to the Y input of the XY recorder. The reflected intensity was normalized by comparison with the intensity reflected from the front surface mirror. Absorption by the quartz window and the $HClO_4$ solution was negligible. Potentials were controlled by a Tacussel PIT 20-2 potentiostat and monitored with a Data Technology 350 digital voltmeter. In order to measure the current, the p.d. across a resistor in series with the counterelectrode was fed into a potentiometric electrometer. The output from the null meter of the electrometer was recorded on a 10-in. strip chart recorder to provide a continuous record of the current. A capacitance box in parallel with the measuring resistor could be adjusted from 0 to 200 μf to damp out unwanted oscillations in the recorder trace.

Photocurrents were measured under steady-state potentiostatic conditions. In many cases, the photocurrent was smaller than the dark (background) current and the following procedure was developed to measure it. The voltage signal from the current-measuring resistor was backed off by the potentiometer dials of the electrometer so that the null meter could be set on a more sensitive range (typically corresponding to 10^{-7}A) for a full scale deflection. The recorder could thus register small variations in a relatively large current. The limit of what could be achieved in this way was governed by "a-c noise." To some extent, the a-c noise could be damped out by a suitable choice of capacitance in parallel with the measuring resistor, but RC combinations with time constants larger than 20 sec required too long to register the photocurrent. In practice, the smallest photocurrent that could be accurately measured was about 1% of the dark current.

Capacitance measurements.—Crystals were prepared, polished, mounted in a Fluorocarbon Inc. straight union reducer (9), and stabilized as above. The test solution was 0.1*N* $HClO_4$ prepared from ultrapure acid and triple-distilled water. The solution was prepared and pre-electrolyzed in a closed glass system that included the test cell (15). Prepurified nitrogen was passed through copper turnings heated to 400°C and two columns of molecular sieves (Linde 13X) before being admitted to the test solution.

Differential capacitance was measured as a function of potential by means of galvanostatic charging curves, using the circuit shown in Fig. 3.

Charging curves were obtained by first connecting both the galvanostat and the potentiostat to the cell and then rapidly (10^{-9} sec) opening the circuit between the potentiostat and the counterelectrode by means of the mercury switch. The change in potential produced by the galvanostatic step function (typically 20 mA cm^{-2}) was recorded on a storage oscilloscope. Capacitance was calculated from the initial portion of the trace (<10 μsec) using the equation

$$C = \frac{i}{\frac{dV}{dt}} \qquad [3]$$

The oscilloscope was triggered by the output of the potentiostat which rapidly went into saturation upon disconnection from the cell. Charging curves were obtained every 100 mV, starting from 2.00V and going down.

Ion probe mass spectroscopy.—Specimens for analysis were prepared from unmounted crystals in the following way. Each crystal was metallographically polished on one face, cleaned in isopropanol vapor, rinsed in conductivity water, and suspended in 25 ml of 0.1*N* $HClO_4$ solution so that only the polished face was immersed. The stabilizing procedure described above was applied to each crystal in a fresh sample of solution. The samples of solution were subsequently analyzed for sodium by atomic absorption spectroscopy on a Perkin Elmer Model 300 spectrometer. After stabilizing, a crystal was cut down to yield a polished specimen about 0.7 cm square by 0.25 cm thick. Finally, each specimen was cleaned in isopropanol vapor and rinsed in boiling conductivity water.

Analysis was performed on the CAMECA Ion Analyzer (16). The instrument has the following capabilities: (*i*) mass spectroscopic analysis of an area only a few microns in diameter; (*ii*) the creation of ion images with an optical magnification of 350X; (*iii*) the determination of concentration profiles with depth

of any selected element with a resolution of 50-100Å. Techniques (*i*) and (*ii*) were applied to the study of platinum distribution and that work is covered in Part II of the paper (6). Only the application of technique (*iii*) to the study of sodium distribution is described here.

The mass spectrometer provided a chart of relative intensity (of Na^+ ions in the secondary beam) *vs.* time, corresponding to the sodium concentration of the surface as material was continuously sputtered away. The intensity was calibrated by assuming that the steady value, normally reached within a few seconds, corresponded to the bulk sodium concentration determined from x-ray diffraction data. The penetration was calibrated from the depth of the crater at the end of a "burn" which was measured by Nomarski polarization interferometry (17).

Results

Optical experiments.—Photocurrents were always anodic and depended on wavelength and intensity of the incident light and on electrode potential. The currents did not depend on the history of an electrode or whether the solution was saturated with oxygen or nitrogen.

In all cases, the photocurrents increased in direct proportion to the inverse square of the optical path length (corrected for the refractive index of the solution) between the lamp and the electrode. A typical example appears in Fig. 4. Since the lamp behaved like a point source, the photocurrent was thus a linear function of light intensity. The slope of the line in Fig. 4 corresponds to a quantum yield (ϕ) equal to 1.3% or 0.013 electrons per incident photon.

Typical plots of ϕ *vs.* light frequency at constant electrode potential appear for crystals with and without platinum, respectively, in Fig. 5. Curves drawn through the three points of such curves all extrapolated to $\phi = 0$ at a frequency of $5 \cdot 10^{14}$ sec^{-1}, corresponding to a photon energy of about 2.0 eV.

The variation of ϕ with electrode potential is shown for crystals with and without platinum, respectively, in Fig. 6. The form of the curve was essentially the same in each case, but the value of ϕ at any given potential was lower for the crystal containing platinum.

Results of the reflectance experiments are illustrated by the absorbance *vs.* potential curve in Fig. 7. The curves were similar for all specimens and all frequencies, the absorbance showing no variation except

tial was changing, an observation suggesting that the color changes result from a solid-state process.

In order to determine what processes were responsible for the photocurrent, the following experiment was performed. Using conditions that favored a large photocurrent illumination was continued for 7.5 hr. Every 2.5 hr a 50-ml sample of the test solution was removed and replaced by 50 ml of the stock solution. The sample was subsequently analyzed for sodium by atomic absorption and for tungsten as the thiocyanate complex by spectrophotometry (19). Results of the experiment expressed as average currents are given in Table I. They show that sodium dissolution accounts for ~30% of the photocurrent at 2.05V.

Capacitance measurements.—At potentials above 1.0V, the differential capacitance of a bronze electrode obeyed the Mott-Schottky equation (20) which may be written (making the usual assumption that the entire Galvani p.d. acts across the space charge region)

$$\frac{1}{C^2} = \frac{8\pi}{eN_D\epsilon}[(E - E_{fb}) - kT/e] \qquad [4]$$

where e is the electronic charge, N_D the donor concentration, ϵ the dielectric constant, and E_{fb} the flatband potential. The slope of a $1/C^2$ *vs.* E plot thus yields the donor concentration, and the intercept yields the flatband potential. Representative plots of $1/C^2$ *vs.* E (Mott-Schottky plots) for crystals with and without platinum, respectively, appear in Fig. 8. A computer least-squares fit of the experimental points from 2.0 through 1.2V was used to determine the slope and intercept of each Mott-Schottky plot, and the results for five crystals appear in Table II.

No data were available on the dielectric constant of Na_xWO_3, so a value for WO_3, derived by Kir'iashkina *et al.* (21), was used. They measured dielectric permittivities of compressed powders as a function of density and obtained a mean value for the ratio of ϵ to ρ (the

Table II. Donor concentrations calculated from Mott-Schottky plots

Pt content in ppm	Donor concentration, N_D, in cm⁻³	Equivalent x-value
0	2.5×10^{21}	0.14
70	2.3×10^{21}	0.13
120	2.9×10^{21}	0.16
290	1.2×10^{21}	0.06
390	0.8×10^{21}	0.04

density in gram-centimeter⁻³) of 6.93. The density of WO_3 with the cubic bronze structure (estimated by substituting $x = 0$ in Eq. [1]) is 7.2 g-cm⁻³ and hence ϵ is about 50. The presence of sodium undoubtedly alters ϵ, but since the surface layer is so depleted in sodium, the error is probably not serious.

At potentials below 1.0V the differential capacitance of a bronze electrode rose rapidly with decreasing potential, reaching values of several hundred μf-cm⁻² which were too large to permit accurate measurement.

Ion probe mass spectroscopy.—Typical results of sodium concentration *vs.* depth for crystals with and without platinum, respectively, are reproduced in Fig. 9. There was a sodium-depleted surface in both cases but the depleted layer was thinner and much lower in sodium for crystals containing platinum. The initial peak results from chemical enhancement of the sodium emission by adsorbed oxygen (22). The peak height was used to estimate relative sodium concentrations where they were too low to read off the chart. Data calculated from the concentration profiles and the sodium analyses of test solutions are summarized in Table III. The two sets of data agree in general to within half an order of magnitude.

Discussion

Sodium distribution.—Both ion probe analysis of a crystal and atomic adsorption analysis of the solution it was tested in demonstrated that sodium was lost from the surface. The variation of sodium concentration with depth approximated to a step function, where the rising part of the step had a slope dx/dl of about 10^6 cm⁻¹ (Fig. 9). For a platinum-free crystal of $Na_{0.7}WO_3$ the composition of the surface layer after a stabilization treatment corresponded to $x \simeq 0.25$ and its depth was between 500 and 2000Å. For a crystal of the same bulk sodium content but containing platinum, the surface layer had an x value of about 0.05 and a depth between 200 and 400Å.

* Two areas were examined on one crystal.

A sodium ion that moves out from the bulk of the crystal to the bulk of the solution must pass through three distinct regions: (*i*) the metal/semiconductor interphase in the crystal, (*ii*) the semiconductor region, and (*iii*) the semiconductor/solution interphase. The passage through each region will have its own rate constant, k_1, k_2, k_3, respectively, and the relative magnitude of the three constants will govern the qualitative form of the sodium concentration profile; some of the possibilities are sketched in Fig. 10. The type of reasoning employed in constructing these hypothetical profiles was as follows. Consider the case $k_3 > k_1,k_2$: this means that passage of sodium through regions (*i*) and (*ii*) is difficult, but that anodic dissolution of sodium out of the surface is easy. Concentration gradients will therefore build up across regions (*i*) and (*ii*) but the concentration of sodium just inside the surface will be vanishingly small.

Comparison of Fig. 9 and 10 reveals that the surface of a Pt-free crystal is characterized by the relation $k_2 > k_1,k_3$, while the surface of a crystal containing Pt is characterized by the relation $k_1 < k_2,k_3$. In both cases, k_1 is small and k_2 is large. The major difference is in the rate constant for the electrochemical step, k_3, and a possible explanation in terms of hole injection is proposed in the next section.

Formation of a semiconducting layer.—Hole injection, i.e., the removal of electrons from the valence band of a semiconductor, is tantamount to the breaking of molecular bonds, and frequently results in oxidative decomposition of the semiconductor (23). In the case of compound semiconductors, decomposition occurs by anodic dissolution of the most electronegative element, *e.g.*, holes generated in a zinc oxide electrode by illumination cause decomposition by the reaction

$$ZnO + 2h^+ \rightarrow Zn^{2+} + \tfrac{1}{2} O_2 \qquad [5]$$

In this example, the holes are created by exciting electrons from the valence band into the conduction band of the semiconductor, but holes may be generated in the dark if highly oxidizing species are present on the semiconductor surface. For example, •OH radicals formed on the surface of gallium phosphide during the reduction of H_2O_2 can be further reduced by reaction with electrons from the valence band (24).

Sodium tungsten bronze is metallic for x values down to 0.25 (2) and no shortage of "holes" exists to limit the initial rate of sodium dissolution. Below $x = 0.25$, however, the material is an n-type semiconductor (4), and holes are scarce. Immersion of metallic Na_xWO_3 in acidic solution will therefore result in a loss of sodium by a corrosion mechanism until x in the surface reaches 0.25

$$Na_xWO_3 \rightarrow Na_{0.25}WO_3 + (x - 0.25)Na^+ + (x - 0.25)e^- \qquad [6]$$

$$H^+ + e^- \rightarrow \tfrac{1}{2} H_2 \qquad [7]$$

Thereafter, further sodium loss from the bronze will be limited by solid-state diffusion. If now a supply of holes is provided, x can fall below 0.25 as sodium is lost by the reaction

$$\frac{1}{x} Na_xWO_3 + h^+ \rightarrow Na^+ + \frac{1}{x} WO_3 \qquad [8]$$

The source of holes may be the excitation of valence electrons into the conduction band by illumination (vide infra), or possibly the reduction of highly oxidizing species on the electrode surface. Such species could be formed as reaction intermediates in the reduction of oxygen to water. Hole injection will then be more rapid into a crystal containing platinum than into one free of platinum because oxygen reduction proceeds thousands of times faster when platinum is present (6). Consequently, the sodium concentration in the surface should fall to lower values for a crystal containing platinum than for one free of platinum.

Properties of the semiconducting layer.—A minimum photon energy of 2 eV was required to produce a

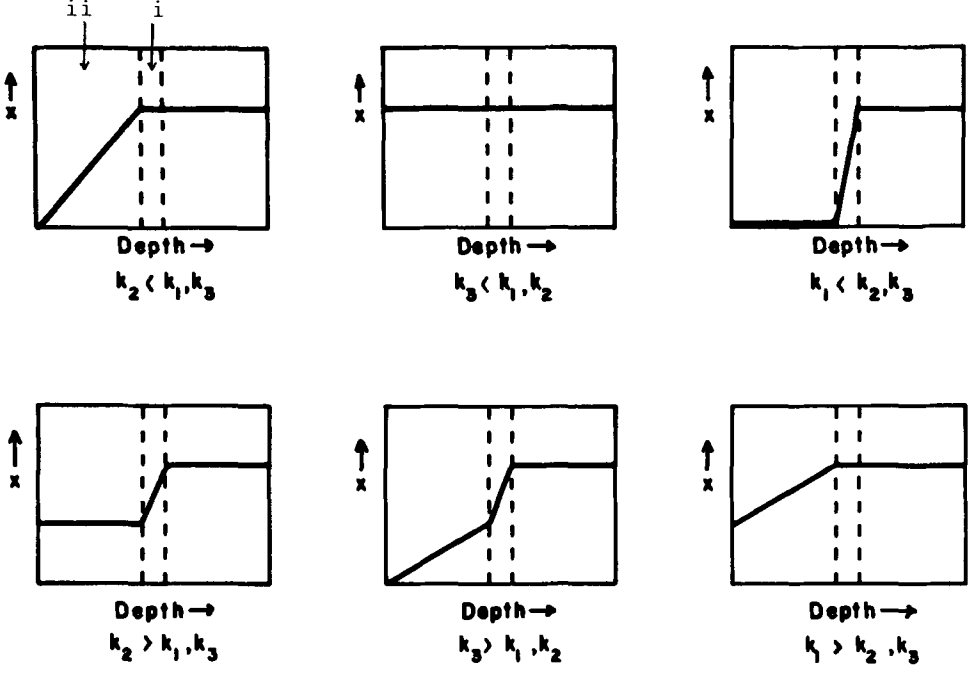

Fig. 10. Hypothetical sodium concentration profiles for various relative diffusion and dissolution rate constants. The ordinate represents x in Na_xWO_3.

photocurrent in a crystal irrespective of platinum content, and this energy threshold undoubtedly corresponded to the bandgap of the semiconductor. By comparison, the bandgap of WO_3, also an n-type semiconductor, is about 2.7 eV (25).

The form of ϕ-E curves (Fig. 6) is qualitatively consistent with the following regime:

(*i*) Electron-hole pairs excited by the incident light are drawn apart by the electrostatic field in the semiconductor.

(*ii*) The electrostatic field will depend on the term $(E - E_{fb})$ where E_{fb} is the flatband potential. When $E = E_{fb}$ the field is zero and recombination is very rapid. Above E_{fb} the concentration of holes in the surface will increase exponentially with $(E - E_{fb})$.

(*iii*) Holes at the surface will participate in electrode reactions at a rate proportional to their concentration. The photocurrent will thus be zero at the flatband potential and then increase exponentially with potential until it approaches the rate at which holes are generated. Thereafter a limiting current will be observed.

The photocurrent on a crystal containing Pt was several times smaller than that on a Pt-free crystal. The difference correlates well with the effect of platinum in lowering the sodium concentration in the surface, and confirms that the photoreaction is sodium dissolution according to Eq. [8]. Above the reversible OER (oxygen evolution reaction) potential, however, the possibility of oxygen evolution by hole capture must be considered

$$2H_2O + 4h^+ \rightarrow O_2 + 4H^+ \qquad [9]$$

The distribution of the photocurrent between reactions [8] and [9] may be estimated for the case of a crystal at 2.05V from the data in Table I. Since sodium dissolution accounted for 30% of the total photocurrent, oxygen evolution by hole capture apparently contributed ~70%. In Fig. 6, ϕ increases threefold between 1.23 and 2.00V. It follows that the photocurrent due to sodium dissolution at 2.05V is equal to the total photocurrent at 1.23V (where Reaction [9] can make no contribution) and therefore that the sodium dissolution rate is independent of potential in this range. Tungsten probably enters the acidic solution as colloidal WO_3 formed when sodium concentrations in the surface drop below the level needed to stabilize the cubic lattice (4) and the structure collapses.

By analogy with Dewald's results on zinc oxide (26), the Mott-Schottky behavior of electrode capacitances at anodic potentials characterizes the bronze surface as a wide bandgap n-type semiconductor, but Mott-Schottky behavior has not previously been reported on such heavily doped material. In spite of this fact, the Mott-Schottky results (Table II) are in reasonable agreement with the results of ion probe analysis (Table III), confirming both the absolute magnitude of the surface x-values and the tendency for x to decrease as platinum is introduced.[3]

The electrode potential at which photocurrents ceased to be manifest on bronze electrodes provides an estimate of the flatband potential E_{fb} of 0.5-0.6V. By contrast, Mott-Schottky plots give E_{fb} as 0.8-0.9V; the discrepancy is discussed below.

Surface redox reactions.—(*i*) *High potentials.*—Discontinuities in Mott-Schottky plots at 1-1.2V (Fig. 8) suggest that a sharp decrease in donor concentration occurs as the potential is raised. This is the reverse of the normal effect, *e.g.*, for WO_3 (27), in which certain donor levels are activated only at high potentials. Furthermore, results to be presented in Part II (6) indicate that the surface of the bronze electrode undergoes a reversible oxidation reaction close to the oxygen electrode potential. The value of E_{fb} obtained by extrapolating Mott-Schottky plots from potentials above 1.2V thus pertains to the "oxidized" bronze surface. The fact that E_{fb} from Mott-Schottky data exceeds E_{fb} from optical data supports the idea of a lower donor concentration at the higher potentials (28).

The reversibility of the surface reaction and its close correspondence with the OER betoken a mechanism in which oxygen atoms in excess of the normal stoichiometry enter and leave the lattice

$$H_2O + nNa_xWO_3 \rightleftarrows 2H^+ + 2e^- + nNa_xWO_{(3+1/n)} \qquad [10]$$

The excess oxygen present at high potentials would lower the apparent donor concentration. Ingold and DeVries (29) found that sodium tungsten bronze can exist with O:W ratios that range from 3 to 3.5, thus the value of n in Eq. [10] could be as low as 2, in which case the reaction would involve one electron transfer per unit cell, or approximately 10^{-4} coulombs cm^{-2} per monolayer of Na_xWO_3.

(*ii*) *Intermediate potentials.*—Unlike the C-E curve of the zinc oxide electrode (30) which levels off at the capacitance of the Helmholtz double layer, the bronze capacitance continued to rise with decreasing potential, reaching several hundred $\mu f\text{-}cm^{-2}$. Such large values signify the presence of a pseudocapacitance, arising from a faradaic adsorption equilibrium. The coverage by adsorbed species, θ, is a function of potential, and since each value of θ corresponds to the accumulation of a certain charge, the variation of θ with potential gives rise to a pseudocapacitance.

Bockris and Kita (31) showed that large capacitances observed on iron electrodes during galvanostatic transients could be explained in terms of the quasi-equilibrium

$$H^+ + e^- \rightleftarrows H_{ads} \qquad [11]$$

Although proton discharge according to Reaction [11] is unlikely to occur at potentials high enough to account for the large capacitances observed, a reaction involving surface polytungstate groups could produce the same effect, *e.g.*

$$\begin{array}{c} | \\ -W-O^- \\ | \end{array} + H^+ \rightleftarrows \begin{array}{c} | \\ -W-OH \\ | \end{array} \qquad [12]$$

Analogous reactions have been advanced to explain the pH dependence of the flatband potential of germanium electrodes (32).

(*iii*) *Low potentials.*—Standard equilibrium potentials according to Pourbaix (33) for redox reactions in the W-O-H system are listed in Table IV. Since all the redox potentials lie close to 0.0V, the color changes undergone by the bronze surface in this region might result from one of these reactions. A further possible reaction, postulated in a similar system by Hobbs and Tseung (34), involves the formation of hydrogen tungsten bronze

$$xH^+ + xe^- + WO_3 \rightleftarrows H_xWO_3 \qquad [13]$$

but Armstrong *et al.* (35) claim that no hydrogen enters the lattice unless the potential is below −0.2V. Both the complex shape of the reflectance *vs.* potential curve (Fig. 7) and the visual detection of several discrete color changes (15, 18) indicate that more than one redox reaction may occur. The color change close

Table IV. Standard equilibrium potentials for the W-O-H system in acid solution (33)

Reaction	E^0 *vs.* NHE in volts at 25°C
$W + 2H_2O \rightarrow WO_2 + 4H^+ + 4e^-$	−0.119-0.059 pH
$2WO_2 + H_2O \rightarrow W_2O_5 + 2H^+ + 2e^-$	−0.031-0.059 pH
$W_2O_5 + H_2O \rightarrow 2WO_3 + 2H^+ + 2e^-$	−0.029-0.059 pH
$W + 3H_2O \rightarrow WO_3 + 6H^+ + 6e$	−0.090-0.059 pH

[3] The surprising success of the Mott-Schottky equation in describing the behavior of highly doped semiconductors may reflect the "exhaustion" of the surface by mobile carriers at potentials where the equation applies.

to 0.0V may result from a reaction such as

$$W^{6+} + e^- \rightleftarrows W^{5+} \quad [14]$$

and color changes at lower potentials may involve hydrogen. The hysteresis in the reflectance curve could mark the latter reaction as being relatively slow.

(iv) Implications for the OER.—The precise identity of each redox reaction undergone by the surface of a bronze electrode between −1.0 and +2.0V *vs.* RHE has not been established, but there are at least three processes involved. At oxygen evolution potentials the surface layer enters a highly oxidized state, perhaps analogous to the pertungstate ion, $W_2O_7^=$. Between the reversible potentials of the OER and the HER, surface groups react with protons in solution, and at lower potentials one or more reactions cause color changes. Unsuccessful attempts elsewhere to detect activity for oxygen reduction by nonsteady-state techniques undoubtedly failed because the OER was masked by reactions involving the substrate. No such difficulties arise under steady-state conditions.

Electrocatalysis of Oxygen Reduction by Sodium Tungsten Bronze

II. The Influence of Traces of Platinum

J. O'M. Bockris*,[1] and J. McHardy*,[2]

Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The rate of oxygen reduction at a given potential on a sodium tungsten bronze crystal increased by up to four orders of magnitude as platinum was introduced into the crystal and at the maximum platinum concentration achieved (~400 ppm), the rate approached that on metallic platinum. The rate of oxygen reduction increased in proportion to the cube of platinum concentration, C_{Pt}, while the rate of oxygen evolution increased linearly with C_{Pt}. Ion probe mass spectroscopy indicated that the platinum was incorporated preferentially at impurity particles in the bronze but the macroscopic average platinum concentration in a crystal varied little with depth. Assuming that the platinum in a crystal was present in metallic form, its specific activity for oxygen reduction was over 10^3 times that of bulk platinum. The results are consistent with a model in which "spillover" of adsorbed intermediates from platinum to the bronze gives rise to an enhanced rate of oxygen reduction on the platinum.

The work of Sepa *et al.* (1) indicated that crystals of the nonstoichiometric compound sodium tungsten bronze Na_xWO_3 (where x can take any value between 0 and 1) catalyzed the electrochemical reduction of oxygen to water almost as well as platinum which is the best catalyst known for that reaction in acid solution. The finding held the promise of significant progress for both the theory and application of electrocatalysis, and stimulated considerable interest (2). Subsequent work (3) demonstrated that the high catalytic activity observed by Sepa required traces of platinum in the crystals, and this paper describes an investigation of the effect.

Experimental

The distribution of platinum in a crystal was examined by ion probe mass spectroscopy (4). Test solutions were prepared from triple-distilled water and ultrapure acids. Either sulfuric or perchloric acid was used and except for mechanistic work on pH dependence the solution strength was close to 0.1*N*. The purification of gases, the pre-electrolysis of solutions, and the preparation and analysis of bronze electrodes have all been described previously (4). The experiments were performed in a standard three-compartment glass cell (5) thermostated at 25° ± 0.1°C by means of a water jacket. The solution was saturated with oxygen for all tests. Electrochemical measurements were made under steady-state galvanostatic conditions, using the battery and resistor circuit described by Genshaw (6).

The bronze electrode, having been suspended above the solution during pre-electrolysis, was lowered into the solution. An anodic current was applied such that the potential rose to about 2V and when the potential became steady (less than 1 mV min^{-1} drift), its value was recorded. The current was reduced in steps to zero, the steady-state potential being noted each time. A cathodic current of 1 mA cm^{-2} was then applied and a decreasing sequence followed in the same way as for anodic currents. Except where noted, the same results were obtained if currents were started at zero and increased, but steady state at each point generally took longer to reach. Even with the more rapid procedure, the low current points on the cathodic line sometimes required a period of hours to reach steady state.

For a number of electrodes the effects of varying pH and oxygen partial pressure were studied. The pH was varied by starting with strong sulfuric acid in the solution reservoir and successively diluting it with more and more distilled water. The exact pH value was determined after each test by titration against standard KOH solution.

Baker Company calibration mixtures containing 10 and 1% of oxygen, respectively (balance nitrogen), were used to study the effect of oxygen partial pressure on electrode kinetics.

Results

Ion probe analysis.—The polished surface of a crystal seen under low power magnification manifested numerous irregular regions[3] a few microns across which were of lighter color than the matrix. The mass spectrum obtained on a light-colored region in a crystal containing 165 ppm Pt is compared with that of the matrix in Table I. Small differences in intensity for a given ion (*e.g.*, Fe^+) are probably not significant, but the inclusion particle was clearly richer in the elements Al and Pt. In the absence of internal standards, no estimate of relative concentrations of different

[3] As a rough estimate, the regions occupied a total of about 1% of the surface area.

Table I. Major peaks (arbitrary units) in the mass spectra of two regions on a crystal of Na_xWO_3 containing 165 ppm of platinum

Mass No.	Ion	Relative intensity Matrix	Inclusion
16	O^+	4.7	1.5

elements is possible, because the intensity of a given peak also depends on such factors as volatility and stability of the ionic species. The quantitative mass spectroscopic analysis of a typical crystal (kindly obtained for us by B. C. Gerstein at Iowa State University) given in Table II shows that the most predominant impurity was aluminum. This impurity undoubtedly originated from the alumina crucible in which crystals were grown, and it is likely that the main component of an inclusion particle was alumina.

Two series of ion images produced by the CAMECA Ion Analyzer are reproduced in Fig. 1. The Pt images which were very weak, almost invariably coincided with Al images. A rare exception is illustrated in Fig. 1a by the Pt image in the center of the photograph. Instead of coinciding with an Al image, it is associated with a bright spot in the W image. The site is probably one where a drop of the Na_2WO_4/WO_3 melt was occluded during crystal growth and then subsequently exposed by polishing. Dark spots in the Na and W images occurred wherever Al images were observed.

Results of the ion probe work thus provide strong evidence that the incorporation of platinum in a crystal occurred preferentially (if not exclusively) at inclusion particles.

[a] i_L = diffusion limited current (estimated). Abnormally low values on crystals containing Pt suggest that only a small fraction of the surface activity catalyzes oxygen reduction.
[b] See Fig. 5.

Electrode kinetics.—No differences were observed whether a crystal was tested "as grown" (suspended in the test solution by the gold wire upon which it was grown) or after mounting in Teflon, grinding, and polishing it (7). The effects of platinum and other impurities on OER (oxygen electrode reaction) kinetics are summarized in Table III. The addition of 390 ppm of platinum improved activity for O_2 reduction by almost four orders of magnitude. The values of log i at $E = 0.9$V and $E = 1.9$V were selected as the criteria for catalytic activity to avoid the long extrapolations of the Tafel regions required in estimating i_0. The catalytic activities for oxygen reduction (0.9V) and oxygen evolution (1.9V) are plotted against log C_{Pt} in Fig. 2; the straight lines drawn through the data points correspond to the empirical equations

$$i_{0.9} \propto (C_{Pt})^3 \quad [1]$$

and

$$i_{1.9} \propto C_{Pt} \quad [2]$$

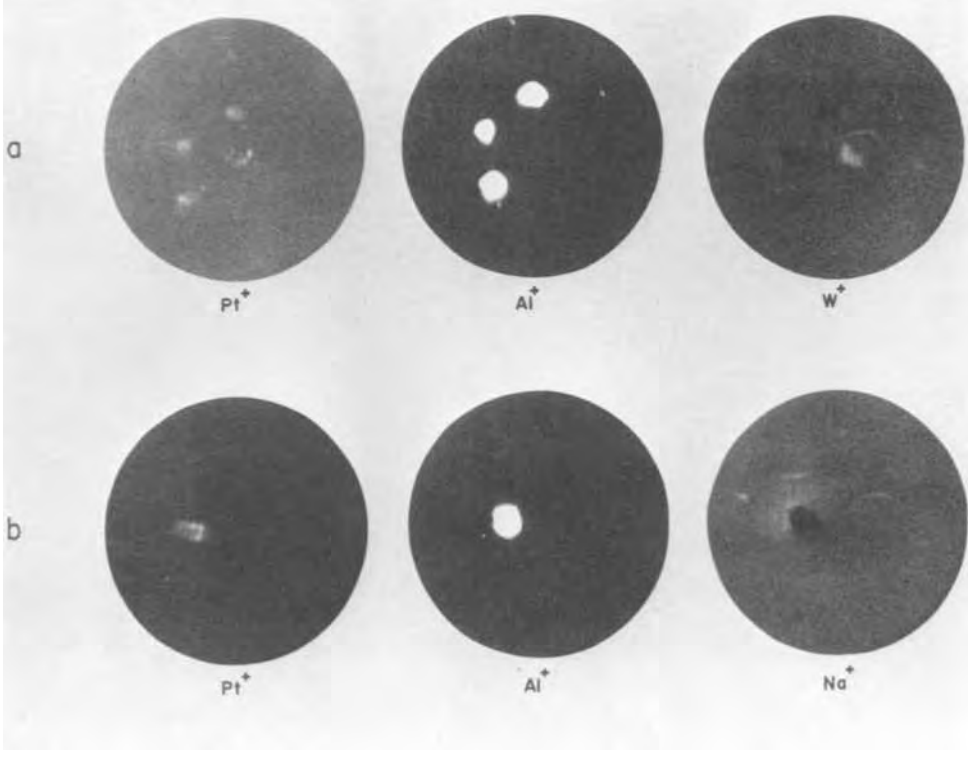

Fig. 1. Ion images of regions 175μ in diameter on two crystals of sodium tungsten bronze. (a) Average Pt content 290 ppm. (b) Average Pt content 390 ppm.

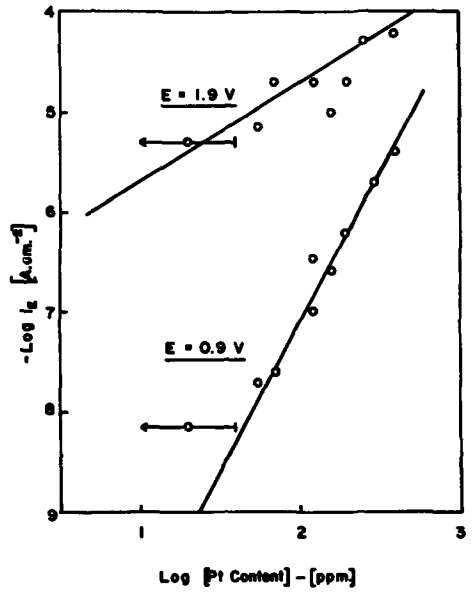

Fig. 2. Log-log plots of catalytic activity vs. Pt concentration for oxygen evolution (1.9V) and oxygen reduction (0.9V), respectively.

Very similar results were obtained when comparisons were made at other potentials.

Of the several impurities tested, only the noble metals improved the catalytic activity of sodium tungsten bronze, and among the noble metals, platinum had the largest effect. From the limited data obtained, the order of merit among the noble metals in this context appeared to follow the relative activities of the pure metals.

Attention is drawn to the column of Table III in which approximate values of diffusion limiting current are compared. The limiting current on a crystal containing platinum is only about 1% of that anticipated for a homogeneous electrode, *e.g.*, solid platinum.

Kinetic parameters with respect to potential, oxygen partial pressure, and *p*H are summarized in Table IV. The anodic reaction order with respect to *p*H is questionable because the anodic Tafel slope tended to increase as the strength of the sulfuric acid decreased. Subsequent work was performed in perchloric acid in case this tendency might reflect a participation of $SO_4^=$ ions in the OER (8), but the Tafel slopes still increased with decreasing acid strength, and the reaction order remained obscure.

In successive tests, the catalytic activity of a crystal for oxygen reduction increased slightly and then leveled off. When the usual anodic treatment was omitted, the initial cathodic performance was extremely poor. Typical cathodic curves showing the difference between initial and final activities appear in Fig. 3. In parallel with the improvement in cathodic activity, the form of the anodic line changed with time as shown in Fig. 4. A departure from linearity occurred at about 10^{-5} A-cm^{-2} on a fresh crystal whereas no such depolarization was observed above 10^{-7} A-cm^{-2}

Table IV. Kinetic parameters for the oxygen electrode reaction on sodium tungsten bronze

Bronze	$\left(\frac{\partial E}{\partial \ln i}\right)_{pH,p_{O_2}}$		$\left(\frac{\partial \log i}{\partial pH}\right)_{E,p_{O_2}}$		$\left(\frac{\partial \log i}{\partial \log p_{O_2}}\right)_{E,pH}$

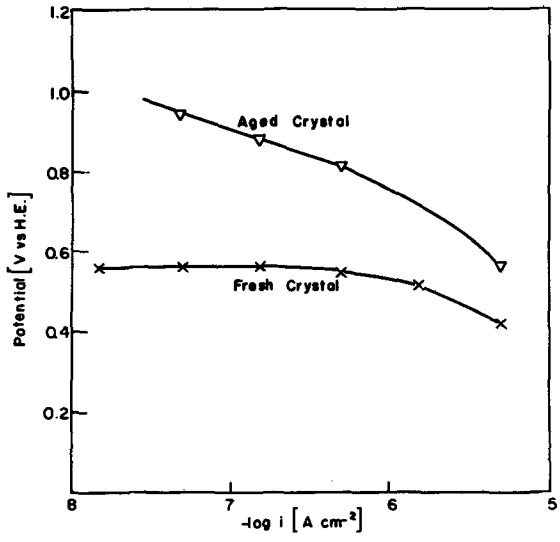

Fig. 3. Effect of aging on cathodic *E*-log *i* behavior

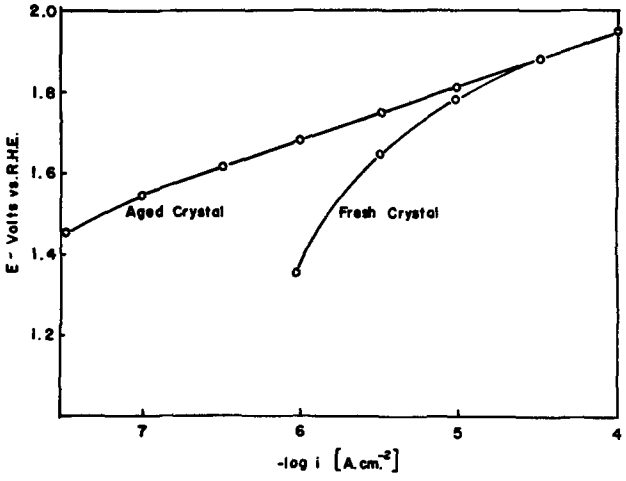

Fig. 4. Effect of aging on anodic *E*-log *i* behavior

on a well-aged crystal. These results fully support the view expressed in Part I (4) that the "aging" of a crystal actually involves anodic dissolution of sodium from the surface. The dissolution rate rapidly diminishes and apparently levels off at about 10^{-7} A-cm^{-2}. The anodic depolarization is unlikely to reflect the oxidation of impurities because no such depolarization was observed on a Pt electrode (Fig. 5).

A phenomenon observed on platinum-free crystals after anodic treatment is illustrated in Fig. 6. When

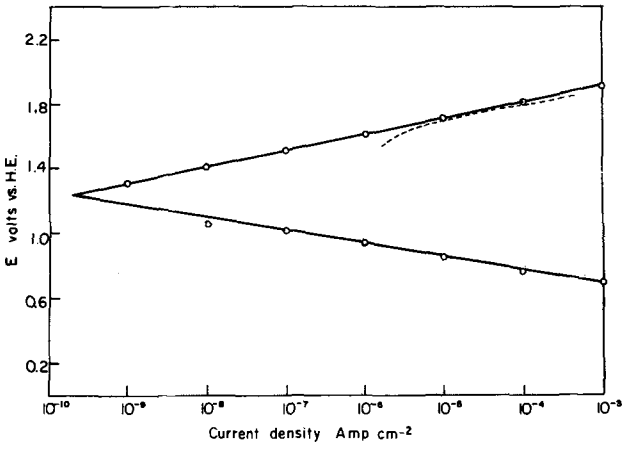

Fig. 5. *E*-log *i* curves for the OER on platinum before (- - - -) and after (———) pre-electrolysis.

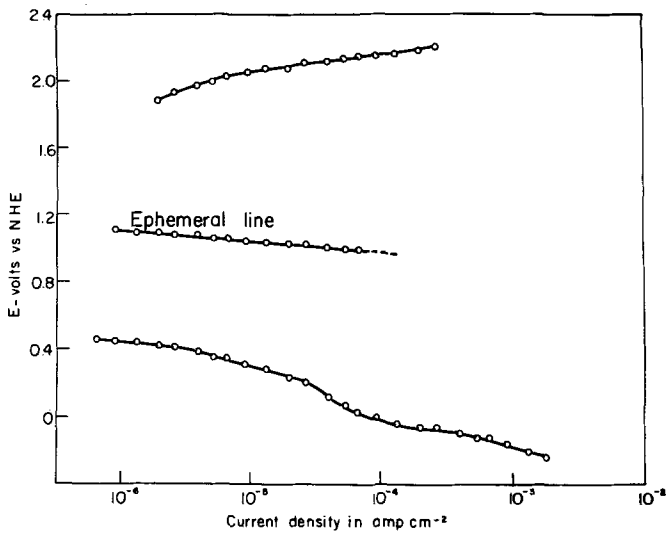

Fig. 6. *E*-log *i* behavior for a crystal free of platinum showing the ephemeral cathodic line obtained after anodic treatment.

the cathodic curve was plotted by starting from zero current and working up, an ephemeral Tafel line that resembled a high i_0 oxygen reduction line was obtained. A finite quantity of electricity, q, was associated with the ephemeral process, and q increased approximately linearly with anodic pretreatment potential as shown in Fig. 7. When a cathodic charge equal to q had passed, the potential at a given current density dropped to a point on the normal cathodic line, and the ephemeral behavior could be reproduced only after further anodic treatment. The reversible oxidation of the bronze surface involved in the ephemeral behavior was discussed in Part I (4). The fact that an ephemeral cathodic line was not observed on crystals containing platinum probably indicates that the cathodic process was too rapid to permit detection by the steady-state techniques employed in this investigation.

Discussion

Mechanism of the oxygen electrode reaction.—The anodic and cathodic parameters in Table IV are not consistent with a single mechanism (7), but they do permit two important deductions. First, the mechanism for each reaction (O_2 evolution and reduction, respectively) is unaltered by the addition of platinum to a crystal. Second, the only type of mechanism for O_2 reduction that can give a Tafel slope of $-2RT/F$ and unit partial pressure dependence is one where the first electron transfer step is rate determining. The evident involvement of hydrogen ions in the rds, albeit a complex one, suggests then that the rds may be the one widely postulated for other electrodes in acid solution (9)

$$O_2 + H^+ + e^- \rightarrow \text{(adsorbed intermediates)} \quad [3]$$

Platinum distribution.—On a macroscopic scale, the distribution of platinum was essentially uniform as evidenced by the fact that mechanical removal of the original surface by grinding and polishing did not alter the catalytic activity (7). On a microscopic scale, however, ion probe analysis revealed that most of the platinum (at least in a crystal of relatively high Pt content) was associated with alumina inclusion particles.

It is not immediately obvious why the platinum in a crystal should concentrate at an inclusion particle. There is no reason, for example, why platinum electrodeposited on the bronze surface should migrate toward alumina, but a qualitative and speculative explanation is possible in terms of colloid chemistry. A colloidal alumina particle, eroded by the melt from the crucible, is likely to acquire a negative charge by the equilibrium

$$Al_2O_3 + WO_4^= \rightleftarrows Al_2O_4^= + WO_3 \quad [4]$$

hence attracting cations to its surface. Platinum ions will be prone to accumulate on the surface because of their (presumably) +4 charge. Colloid particles which settle out onto the growing crystal will be discharged, and the platinum associated with the colloid will be reduced to the metal. The concentration of platinum in the crystal will thus depend on the concentration both of platinum ions and of colloid particles in the melt. Qualitative confirmation of this prediction was obtained recently (10): a bronze crystal grown in a platinum crucible was found to become more active after alumina powder was added to the melt.

Models for the effect of platinum on catalytic activity.—Electronic models.—As a working hypothesis during the experimental phase of the project, the influence of platinum on the catalytic activity of sodium tungsten bronze was attributed to an effect of platinum on electronic levels in the semiconducting surface of the bronze (3). Attempts to construct specific models, however, met with limited success (11). In particular, platinum had no effect on the bandgap or the flatband potential of the semiconducting surface layer (4), a fact that conflicted sharply with the basic requirements of such models. Further evidence against an electronic role for the platinum was the observation that the donor concentration in the surface layer agreed closely with the concentration of sodium (4).

The failure of electronic models, and the results of ion probe analysis, both point to a model in which platinum metal, in some special state, is the active catalyst.

Platinum-centered models.—The first problem facing a platinum-centered model is to explain the remarkable amplification in specific activity of the platinum over that of the bulk metal. If the rate of oxygen reduction on a crystal containing 0.039% Pt were referred to 0.039% of the surface area,[4] the apparent activity would be over 10^3 times that of oxide-free bulk platinum ((Table III).

A trivial model which postulates gross inhomogeneity of the platinum distribution such that the

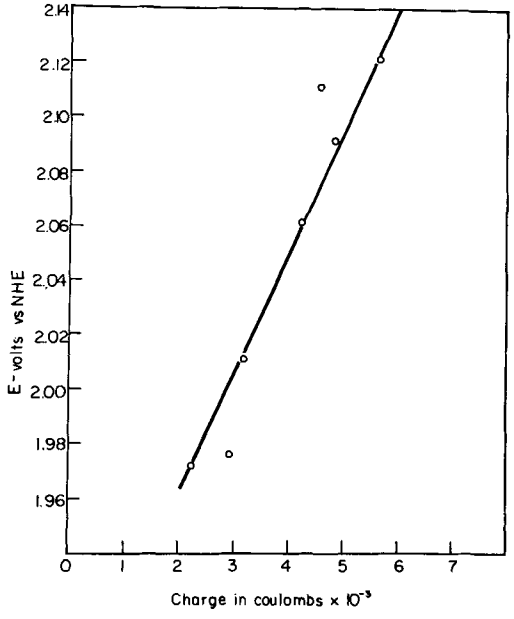

Fig. 7. Charge associated with the ephemeral line as a function of anodic treatment potential.

[4] For a microscopically uniform distribution, a bulk Pt concentration of 0.039 w/o (weight per cent) would correspond to an area concentration of about 0.02% of the surface.

surface of a crystal is enriched in platinum can be discarded on several counts: no change in activity was observed when the original surface was removed by grinding and polishing, and a large area of platinum on the surface is inconsistent with both the distribution observed by ion probe analysis and the low limiting currents for oxygen reduction (Table III).

The next simplest type of model is one that attributes the amplification in catalytic activity to geometrical or crystallographic effects. As no information is available on the size or shape of the platinum particles, the amplification could reflect either a large effective surface area of the platinum resulting from microscopic roughness (or porosity) of the inclusions, or an intrinsic superiority in activity of the platinum particles, resulting perhaps from the predominance of certain crystal faces. This type of model fits most of the experimental observations, but cannot be reconciled with Eq. [1]; the discrepancy will be brought out below.

Synergistic models.—Two models may be proposed in which the enhanced catalysis arises from synergism between the platinum and the matrix; the models are known as "adlineation" and "spillover," respectively. The thesis of adlineation, first advanced in 1928 by Schwab and Pietsch (12), is that the active sites in a two-phase catalyst are the linear boundaries between the phases. An electrochemical example of adlineation appears in the work of Fleischmann *et al.* (13) in which the rate of hydrogen evolution was found to be 10^7 times greater around the edge of a ruthenium film on mercury than on top of the film.

Spillover is a term coined by Boudart (14) to denote surface diffusion of reaction intermediates from a catalyst to its "support." In the present context, adsorbed intermediates produced by Reaction [3] would diffuse from the platinum to the bronze and there undergo further electrochemical reduction to water.

Comparison of prediction from the models with experiment.—If catalysis were due simply to platinum metal, both anodic and cathodic activities should increase linearly with the effective area of platinum. Assuming first that the diameter of the platinum particles remained constant, the number of particles and hence the total area would increase linearly with concentration. At the other extreme, were the number of particles to remain constant, the area would vary as the concentration to the 2/3 power. In the general case, where both the number and size of the particles changed, the area would vary with $(C_{Pt})^u$ where $2/3 \leq u \leq 1$ (15). The simple, platinum-centered type of model can thus account satisfactorily for the dependence of anodic activity on C_{Pt}, but not for the cathodic dependence.

Following the same type of argument as above, the adlineation model would predict a dependence for both anodic and cathodic activities on $(C_{Pt})^v$ where $1/3 \leq v \leq 1$, and is no more able to account for the observed cathodic dependence than was the simpler model. Since the spillover model involves factors other than geometry, it is not subject to the same limitations as the previous models and can be reconciled (vide infra) with a dependence of the activity on $(C_{Pt})^w$ where $w > 1$.

Development of the spillover model.—Enhanced catalytic activity by spillover normally requires that the rds be a reaction involving two adsorbed species. One of the species adsorbs directly onto the support while the other is generated by a reaction on the catalyst and spills over onto the support. The oxygen reduction reaction does not fulfill this requirement, but there is a way in which spillover could affect the rds on platinum (Eq. [3]). At potentials between 0.8 and 1.0V, the adsorption of oxygen species on platinum is governed by the Temkin isotherm (16), whereby the adsorption energy decreases linearly with the fractional coverage, θ. In view of the fact that activation energy for an adsorption step decreases approximately linearly with increasing adsorption energy (17), the rate of Reaction [3] should depend strongly on θ. Spillover of adsorbed species from the platinum to the bronze will result in a lower value of θ on the Pt, and hence an increased velocity of the rds.

Using the data of Wroblowa *et al.* (18) an estimate can be made of the possible increase in rate at a given potential arising from a decrease in θ. The variation of adsorption energy, $-\Delta H_{ads}$, with θ is described by the relation

$$-\Delta H_{ads} = 12(1 - \theta)\,\text{kcal mole}^{-1} \qquad [5]$$

and at 0.9V, θ is about 0.5 (referred to a saturation coverage on Pt of 110 μC-cm^{-2}). If spillover reduces θ to almost zero, the adsorption energy would increase by 6 kcal mole^{-1}. Assuming a Brϕnsted factor of 0.5, the activation energy would thus decrease by 3 kcal mole^{-1}, and the reaction rate would increase by about 150 times.

The spillover model alone cannot therefore explain the observed amplification ($>10^3$) in the catalytic activity of platinum for oxygen reduction, and a combination of spillover with some other model is indicated. Before going on to discuss this possibility, however, it is convenient to consider the catalysis of oxygen evolution.

At potentials above 0.95V, the surface of a platinum electrode is covered with an oxide film (19), and spillover will have relatively little effect on the total coverage by oxygen species, or on reaction rates. A graph of per cent Pt activity *vs.* per cent Pt concentration from the anodic data in Table II is plotted in Fig. 8. Although the data show considerable spread, the graph is essentially linear, as predicted by Eq. [2], and has a slope (activity/concentration) of about 160. The linear dependence indicates that the surface area of platinum particles also increases linearly with concentration. Such a dependence can be obtained only if the diameter of the particles remains constant, and their number increases in direct proportion to concentration (15). The slope is a measure of the amplification in catalytic activity of platinum for oxygen evolution. The amplification may reflect either geometric or crystallographic factors, but the available data do

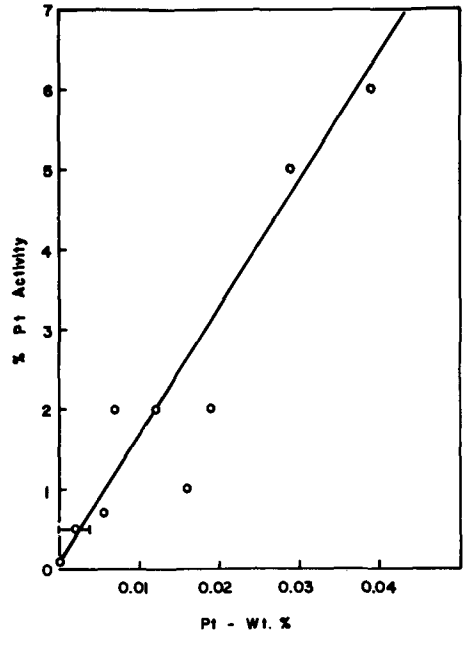

Fig. 8. Linear plot of catalytic activity for oxygen evolution at 1.9V (as a percentage of that for pure platinum) *vs.* Pt concentration.

not distinguish between these possibilities. Whatever the origin of the amplification, it seems reasonable to assume that it will also apply to oxygen reduction. Phenomenologically, the enhanced activity may be discussed in terms of an "effective" area of platinum on the surface of a bronze crystal.

From Fig. 8 the effective platinum surface area for a crystal containing 0.039% (390 ppm) platinum is is about 6% of the total area. The maximum rate of oxygen reduction on the crystal predicted from the spillover model is therefore (6/100) × 150, or about nine times that on an equal area of solid platinum. In point of fact, the cathodic activity of the crystal was somewhat less than that of oxide-free platinum: 4 μA-cm^{-2} at 0.9V compared with about 10 μA-cm^{-2} for platinum under equivalent conditions (9). The difference between predicted and observed activity could result from: (*i*) a decrease in θ that was less than 0.5, or (*ii*) inability of some of the platinum particles to participate in the process of spillover.

If one assumes that the difference arises from (*ii*), it becomes possible to rationalize the observed dependence of cathodic activity on platinum concentration. Consider an inclusion particle as a flat region with a circular boundary, Fig. 9. Since there is no evidence in the literature that oxygen species can spill over from platinum to alumina, only those platinum particles lying in a continuous path to the edge of the inclusion are likely to lose adsorbed oxygen to the bronze surface. All the "active" platinum will thus be located in an annular zone around the edge of the inclusion. If the radius of the inclusion is r, and the average width of the active zone is z, then the fractional area of the platinum particles involved in spillover will be about $2\pi rz/\pi r^2$ or $2z/r$. The area of active platinum, Δ^*, per unit area of crystal will thus be given by

$$\Delta^* = \frac{2z}{r}\Delta \qquad [6]$$

where Δ is the total fraction of the surface occupied by platinum. Now Δ varies linearly with the number of platinum particles and hence with C_{Pt}, but z is a more complex function of these quantities. The width of the active zone depends on the probability that several platinum particles will be in contact with each other. For example, a dependence on $(C_{Pt})^2$ would arise if z were governed by the probability of two particles being in contact. The activity of a crystal, being proportional to the product of Δ and z, would then vary as $(C_{Pt})^3$, as observed in Eq. [1].

A final piece of evidence supporting the spillover model is the finding that anodic dissolution of sodium

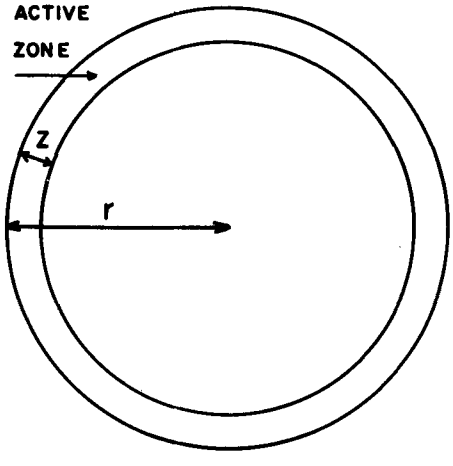

Fig. 9. Schematic diagram of an inclusion particle

out of the surface is enhanced if a crystal contains platinum (4). More rapid hole injection during oxygen reduction was invoked in Part I (4) to explain the effect, and that is precisely what is likely to occur during reduction of the reactive species which spill over from the platinum to the bronze.

Acknowledgments

This work was supported throughout by the United States Army Mobility Equipment R&D Center, Ft. Belvoir, Virginia, which also undertook the spectrographic analysis of our samples. We particularly wish to thank Drs. J. R. Huff and H. C. Egghart of Ft. Belvoir for their sustained interest and help. We are indebted to virtually everybody associated with the Electrochemistry Laboratory over the past five years for stimulating discussions (many relevant to this work), but contributions deserving special note were made by the following: Drs. A. Damjanovic, A. R. Despic, R. A. Fredlein, B. Lovrecek, and K. L. Mittal.

Electrochemical Generation and Measurement of Sulfide Ion in Molten LiCl-KCl Eutectic

C. H. Liu,[1] A. J. Zielen, and D. M. Gruen

Chemistry Division, Argonne National Laboratory, Argonne, Illinois 60439

ABSTRACT

An electrode composed of the eutectic mixture of nickel sulfide (NiS) and nickel (1:1 mole ratio) has been shown to be useful for coulometrically generating sulfide ion (S^{-2}) in molten lithium chloride-potassium chloride eutectic. A shiny nickel electrode coated with nickel sulfide functions reversibly as an electrode of the second kind for sulfide ion. With this indicator electrode, the solubility product of nickel sulfide in the temperature range 375°-475°C has been determined, and the heat of reaction for the solubility equilibrium $NiS(s) \rightleftarrows Ni(II) + S^{-2}$ has been calculated. The solubility behavior of lithium sulfide in the same temperature range has also been investigated.

There is considerable current interest in the solution chemistry of sulfide ion in molten salt solvents. Thus, the interaction of elemental sulfur with S^{-2} in melts has been the subject of several recent studies (1-3). A variety of species such as S_x^{-2}, S_2^-, and S_3^- have been proposed to account for results of electrochemical and spectroscopic studies of the equilibria involved in the reactions. A key requirement to making further progress in studying the solution chemistry of this system is the development of a method for the preparation of molten salt solutions containing known initial concentrations of S^{-2}. Due to the hygroscopic and corrosive nature of alkali sulfides and the difficulty in their preparation in pure form, the addition of such salts to the melts is neither a satisfactory nor a convenient solution to this problem. In numerous studies, coulometric generation of the chemical species of interest has been shown to be a highly useful technique in molten salts. Bodewig and Plambeck (3) generated S^{-2} by cathodizing a sulfur pool in contact with LiCl-KCl eutectic using a graphite electrode. If a solution of S^{-2} in the absence of sulfur is desired, the electrolytic reduction of a slightly soluble metal sulfide would appear to be a more convenient method.

Furthermore, for measuring the sulfide activity *in situ*, a sulfide indicator electrode is of considerable value. Bodewig and Plambeck reported that the liquid sulfur-sulfide couple showed Nernst behavior for a two-electron process in molten lithium chloride-potassium chloride eutectic and that polysulfides were formed (3). Thompson and Flengas measured the potential of the cell, $Ag/Ag_2S/AgCl/graphite/S(vapor)$, over the temperature range 490°-860°C and observed Nernst behavior (4). The emf of the cell, $Ag(s)/AgI(s)/Ag_2S(s)/S(l)/graphite$, was used to calculate the free energy of formation of silver sulfide by Kiukkola and Wagner (5) and by Reinhold (6). From an experimental point of view, we felt that a metal sulfide-metal electrode system acting as an electrode of the second kind for sulfide would have certain advantages over the other electrode systems described in the literature. Laitinen and Bhatia found that several metal oxide-metal systems showed reversible behavior as electrodes of the second kind toward dissolved oxide in the lithium chloride-potassium chloride eutectic melt at 450°C (7). However, the metal oxides are too soluble for these systems to be generally useful as oxide indicator electrodes.

In the present work, pure NiS and NiS containing an excess of the metal, have been tested as electrode materials for the coulometric generation of S^{-2} in molten lithium chloride-potassium chloride eutectic. Known amounts of S^{-2} can be added coulometrically using the NiS-Ni electrode as a generating electrode. The nickel sulfide-nickel system has been found to be a satisfactory indicator electrode for S^{-2} in this solvent. With the aid of this electrode system, the solubility behavior of nickel sulfide and lithium sulfide over the temperature range 375°-475°C have been studied.

Experimental

Solvent.—The eutectic mixture consisting of 40.9 m/o (mole per cent) potassium chloride and 59.1 m/o lithium chloride was obtained from Anderson Physics Laboratories, Urbana, Illinois. In the preparation of the eutectic, analytical reagents were mixed in the appropriate proportions, vacuum desiccated, melted under dry hydrogen chloride, purged of the hydrogen chloride by repeated flushing with dry argon followed by evacuation, treated with molten lithium which was deposited from the melt on a porous tungsten electrode, filtered through a quartz fritted filter, and sealed under argon.

Apparatus.—Furnace and temperature control.—A massive stainless steel core with a 2¼ in. opening at the top was heated by four 500W Firerod heaters (Watlow Electric Manufacturing Company, St. Louis), two of which were controlled by a Wheelco Capacitrol temperature controller. The core and insulating materials were enclosed in a stainless steel case with cooling furnished by running water through ¼ in. copper tubing welded to the case. By appropriate selection of Variac settings, the melt temperature could be controlled to within 1°C. The furnace was mounted on a sliding base with counterweights so that it could be easily lowered for observation of the electrolytic cell.

Electrolytic cell.—The cell consisted of an outer quartz or Pyrex jacket approximately 14 in. long and 2 in. OD with a 55/30 male joint at the top. Six thermometer adapters (Ace Glass, Inc., Vineland, New Jersey) were sealed to the top of a 55/50 female joint. A vacuum stopcock with Teflon plug sealed to the side of the joint served as an outlet for the argon flow. During an experiment, the male and female joints were sealed with black wax. A flow of dry argon was maintained through an inlet tube provided with a Teflon plug vacuum stopcock. This tube also served as the connection to the vacuum line. All electrodes, a thermocouple tube for monitoring the melt temperature, and the argon inlet were introduced through the thermometer adapters. Tightening nylon bushings against O-rings provided vacuum-tight seals. At the end of an experi-

[1] On sabbatical leave from the Department of Chemistry, Arizona State University, Tempe, Arizona 85281.

Key words: electrochemistry, sulfide ion, molten salts, NiS-Ni electrode.

ment, the cell was opened by melting the wax seal. The LiCl-KCl eutectic was contained in a large quartz beaker. Inserted in the quartz beaker were several smaller compartments consisitng either of quartz tubes with fritted disks, or of beryllia (National Beryllia Corporation, Haskell, New Jersey), thoria or magnesia crucibles (Norton Company, Worcester, Massachusetts). The compartments were heated to 450°C for a few hours, cooled, and kept in a dry N_2 atmosphere. The compartments were weighed before the experiment and with the melt contents after the experiment. In some cases, the melt contents were also determined by argentometric titration of the chloride present (8). Determination of the amount of melt present in each compartment by weighing agrees to 1-2% with determination by argentometric titration provided that the compartment has been washed free of the melt on the outside and redried at 250°C before weighing. The volume of melt present at various temperatures was calculated from the weights determined and the densities of the melt at these temperatures (9).

Electrodes.—Nickel sulfide-nickel eutectic electrodes were made as follows. Sulfur distilled twice from cp reagent under a stream of dry argon, and analytical reagent nickel shot were mixed in a 1:2 g-atom ratio in a quartz reaction tube, evacuated, vented to approximately 200 mm Hg of argon, and sealed. The nickel shot was placed in the middle portion of the tube, which was then horizontally clamped and heated with a Meeker burner. The sulfur was driven with a hand torch back and forth over the heated nickel until the brown vapor completely disappeared. A silvery melt, which is the eutectic mixture of nickel sulfide and nickel with a melting point of 637°C (10), was obtained and was left in a furnace at approximately 750°C for several hours with occasional shaking to insure complete reaction and thorough mixing. After cooling, the silvery product was removed from the reaction tube and cast into rods of about 4 mm OD in quartz tubes after evacuation and venting to argon atmosphere. The rods were then cut into 2 in. lengths and a small hole was drilled ultrasonically at one end. A nickel or platinum wire was then tied securely to each rod through the hole and served as the electrical contact. Before use, each electrode was polished with fine emery paper, washed with detergent, rinsed thoroughly with distilled water, acetone, and trichloroethylene, and vacuum dried. Pure NiS electrodes were made similarly by reacting 1:1 g-atom value of the elements at a temperature of 1000°C.

The platinum and nickel electrodes were made from high purity (at least 99.99%) metal foils or wires in coil form. Analytical reagent copper foils and wires were sometimes used as the auxiliary electrodes.

The reference electrode (8) consisted of a platinum coil immersed in an ~0.01*M*, solution of coulometrically generated Pt(II). For the purpose of correlating results from different experiments, measured potentials were extrapolated to values *vs.* a 1*M* Pt(II)-Pt electrode by the application of the Nernst equation.

Procedures.—The electrolytic cell was assembled in a glove box under dry nitrogen and then placed in the furnace. A rapid flow of argon was maintained while the cell top and the jacket were sealed together with sealing wax and the electrodes were introduced. The system was then evacuated to a pressure of 2-5μ Hg and heated to 400°C. After the melt levels in the compartments had equalized, the system was vented to argon and kept under argon flow. A Pt(II)-Pt reference electrode was then prepared by anodization at a constant current with coulometric measurement of the amount of electricity passed (8). A copper or nickel electrode in a separate compartment served as the auxiliary electrode in all electrolyses.

Two procedures were used to measure the sulfide concentration dependence of the nickel sulfide-nickel electrode potential. A nickel sulfide-nickel eutectic electrode and a shiny nickel electrode were placed in the same compartment. The "eutectic" electrode was cathodized to generate a known amount of S^{-2} and the shiny nickel was anodized slightly to provide some nickel sulfide on the surface. The potential at the nickel electrode was then measured against the Pt(II)-Pt reference. More S^{-2} was generated successively, and the potential was measured after each addition. The solubility of NiS in the melt was negligibly small compared to the analytical concentrations of S^{-2} in these measurements. It turned out that the solubility of Li_2S was relatively low in the eutectic salt melt and equilibration after each period of generation of S^{-2} was quite slow at the higher sulfide concentrations. A better procedure was to generate a large quantity of S^{-2}, let the solution equilibrate for 20-30 min, and measure the final stable potential. Nickel(II) was then coulometrically generated at the nickel electrode (or the eutectic electrode) to precipitate NiS, and the potential was measured after each period of generation. Equilibrium was reached very rapidly at points around the equivalence point of the titration. The current efficiency of the electrode reaction, $NiS + 2e^- \rightleftarrows Ni^0 + S^{-2}$, was checked in three ways. First, the eutectic generating electrodes were weighed before and after the passage of measured amounts of electricity. The weight losses, due to dissolution of S^{-2}, were then compared to the equivalents of electricity passed to determine the n value. Second, melt in the sulfide-containing compartment was dissolved in 0.1*M* NaOH-1*M* NH_3 under nitrogen and titrated argentometrically (11). Third, the S^{-2} generated was potentiometrically titrated *in situ* with Ni(II) coulometrically generated at a nickel electrode; the reverse titration of known amounts of Ni(II) with S^{-2} coulometrically generated at the eutectic electrode was also performed.

To determine the solubility of Li_2S in the eutectic melt in the temperature range 375°-475°C, a large excess of sulfide was generated at the eutectic generating electrode at 500°C. After two or three hours, with occasional stirring by hand using the electrode, the temperature was lowered to 475°C. After allowing 30 min for initial equilibration, the potential at the Ni indicator electrode was measured at 30-min intervals until no shift was observed in three successive measurements. The temperature was then lowered in 25° steps and the potential measurements were repeated. A stable potential was usually reached after 1½ hr of equilibration. Essentially the same potentials were observed when the temperature was raised although a much longer period was required for equilibration. The solubility of Li_2S was then easily calculated from the standard potential of the NiS-Ni electrode system determined at each temperature.

Results and Discussion

The suitability of several materials as containers for S^{-2} in the melt was investigated. Etching of quartz and Pyrex glass in contact with S^{-2} occurred quickly. In the case of thoria crucibles, there was evidence of release of O^{-2} from the container as a result of replacement by S^{-2}. Beryllia and magnesia crucibles were both satisfactory, showing no evidence of attack by S^{-2} over a period of 72 hr. Most of the experimental results reported here were obtained in magnesia crucibles.

Although S^{-2} could be generated by cathodization of the pure NiS electrode the results are not as satisfactory as those obtained with the eutectic electrode.

In the coulometric generation of S^{-2} at the eutectic electrode the electrochemical reaction, $NiS + 2e^- \rightleftarrows Ni^0(s) + S^{-2}$, takes place in the potential range −1.5 to 1.6V *vs.* the 0.01*M* Pt(II) reference electrode. In this potential range the residual current density of the melt at a shiny platinum electrode amounts to 0.05 mA/cm^2 (cathodic). This residual current level, typical

of properly purified melts, must be taken into consideration to account for the amount of S^{-2} generated to an accuracy of better than 1% (12). The *in situ* titration of S^{-2} with coulometrically generated Ni(II) gives very large potential breaks at the equivalence point. Titrations were performed at 25° intervals between 375° and 475°C. Figure 1 represents the titration curves at 375° and 475°C. These titrations and the reverse titration of Ni(II) with coulometrically generated S^{-2} yielded analytical results within 1% of values calculated theoretically. In four replicate determinations of the weight losses of the eutectic electrodes after the passage of measured quantities of electricity in the generation of S^{-2}, n values of 1.86, 1.82, 1.96, and 1.89 were obtained for a theoretical two-electron process. The slightly lower experimental n value is consistent with the expectation that a small amount of the Ni produced would fall off the electrode in the washing process before weighing. Argentometric analysis in ammoniacal solution (11) of the S^{-2} produced yielded a recovery of 96.7% of the theoretical amount. These results show that the reduction of NiS is a two-electron proces yielding S^{-2} and that the current efficiency for the process is essentially 100%.

The potential of the electrode of the second kind, Ni/NiS/S^{-2}, is given by the Nernst equation

$$E = E^\circ_{\text{NiS-Ni}} - \frac{RT}{2F} \ln a_{S^{-2}} \qquad [1]$$

where E is the potential in volts, $E^\circ_{\text{NiS-Ni}}$ is the standard potential, $a_{S^{-2}}$ is the activity of S^{-2}, and R, T, and F have their conventional signficance. Previous reports (8) as well as the present work indicate that activity may be conveniently replaced by concentration for dilute solutions in molten salt solvents. Molarity is used to express concentration in this work. The standard state for a soluble species is unit molarity. For a pure solid, the standard state is defined as its physical state at the operating temperature under 1 atm of pressure and taken as unity. The standard potential of the Pt(II)-Pt system is arbitrarily assigned the value 0.000V and serves as the reference point. $E_{\text{NiS-Ni}}$ is related to $E_{\text{Ni(II)-Ni}}$, the standard potential of the Ni(II)-Ni system through the solubility product of NiS, K_{sp}

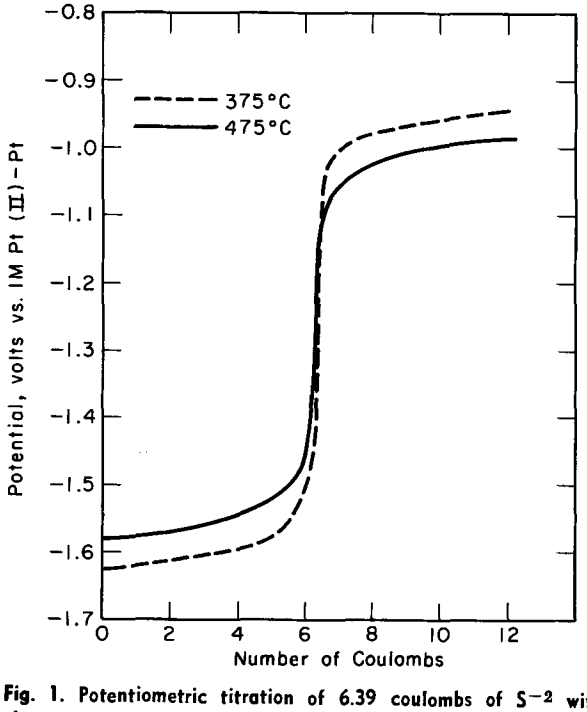

Fig. 1. Potentiometric titration of 6.39 coulombs of S^{-2} with coulometrically generated Ni(II). The weight of eutectic in the compartment was 14.65g.

Table I. Solubility products of NiS at various temperatures

Temperature, °C	$E^\circ_{\text{Ni(II)-Ni}}$, V	$E^\circ_{\text{NiS-Ni}}$, V	pK_{sp}
375	−0.786	−1.783	15.50
400	−0.790	−1.777	14.78
425	−0.794	−1.773	14.12
450	−0.797	−1.768	13.54
475	−0.801	−1.764	12.96

$$E^\circ_{\text{NiS-Ni}} = E^\circ_{\text{Ni(II)-Ni}} + \frac{RT}{2F} \ln K_{sp} \qquad [2]$$

Points on the titration curves in Fig. 1 before the equivalence point can be used to calculate $E^\circ_{\text{NiS-Ni}}$ by extrapolating the S^{-2} concentration to 1M. $E^\circ_{\text{Ni(II)-Ni}}$ can be obtained by extrapolating the Ni^{+2} concentrations to 1M at points on these curves beyond the equivalence point. Similar values of $E^\circ_{\text{NiS-Ni}}$ and $E^\circ_{\text{Ni(II)-Ni}}$ were also obtained in other experiments where Ni^{+2} and S^{-2} were coulometrically generated in separate compartments. In measurements involving Ni(II), both shiny and NiS-coated Ni electrodes were used. These measurements were made in the temperature range 375°-475° in 25° steps and K_{sp} values were calculated from the data with the aid of Eq. [2]. Table I lists the results. The E° value of $E^\circ_{\text{Ni(II)-Ni}}$ obtained at 450° agrees well with that reported previously by Laitinen and Liu (8).

It was found that Eq. [1] was obeyed by the NiS-Ni electrode at the temperatures investigated. Figure 2 presents the results at 450°C from five entirely independent sets of measurements (different symbols) using five different batches of melt. Within each experiment, the theoretical Nernst slope was very well obeyed for measurements at different concentrations. Somewhat larger deviations in $E^\circ_{\text{NiS-Ni}}$ and $E^\circ_{\text{Ni(II)-Ni}}$ were observed from experiment to experiment. The E°'s listed in Table I were obtained by extrapolating all measurements to 1M solutions by applying the theoretical Nernst slope and averaging the results. This procedure was chosen rather than a least squares analysis of all the results from different experiments at each temperature since Nernst behavior was observed for each experiment. The range of $E^\circ_{\text{NiS-Ni}}$ at 450° for 17 measurements in the concentration range 0.0013-0.012M was 9 mV with a standard deviation of 3 mV. For concentrations less than 0.001M positive deviations were observed. $E^\circ_{\text{Ni(II)-Ni}}$ showed a range of 7 mV for 17 measurements, in the concentration range 0.0035-0.067M with a standard deviation of 2 mV at 450°C.

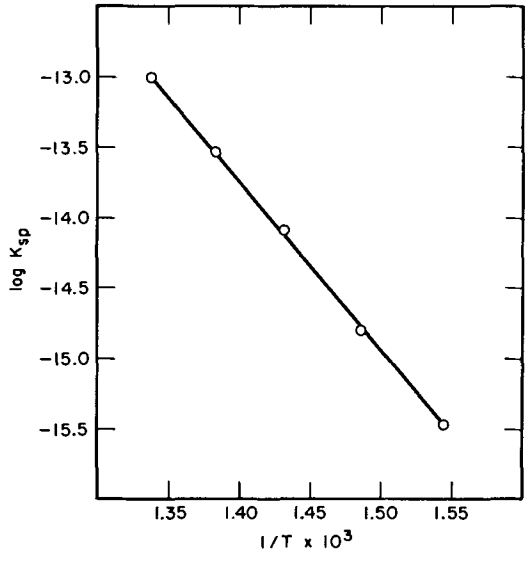

Fig. 2. Temperature dependence of the solubility product of NiS.

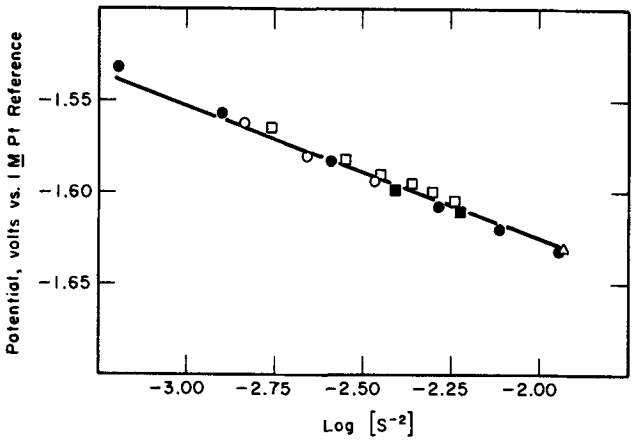

Fig. 3. Nernst plot for the NiS-Ni electrode

Positive deviations occurred below $5 \times 10^{-4}M$. Comparable results were obtained at the other temperatures. The pK_{sp}'s listed in Table I were measured with considerably more precision than the $E°$'s since the difference between $E°_{NiS\text{-}Ni}$ and $E°_{Ni(II)\text{-}Ni}$ from the same experiment was involved in the calculation. The range of pK_{sp} was 0.05 units from the same potential measurements to determine the $E°$'s.

A plot of log K_{sp} *vs.* $1/T$ yields a straight line and is shown in Fig. 3. The heat of reaction for the equilibrium $NiS \rightleftarrows Ni^{+2} + S^{-2}$ can be calculated with the aid of the van't Hoff equation. A value of 55.9 kcal was obtained.

Table II lists the solubility of Li_2S at various temperatures. The solubility was determined by direct potentiometry with the NiS-Ni indicator electrode. The temperature dependence of the solubility is shown in Fig. 4. Considering that deviations of 3-4 mV in the potential measurements have been observed, these results are probably accurate to ±10% which is about the limit of direct potentiometry in molten salts. The solubilities listed in Table II are much lower than the concentration levels examined by Bodewig and Plambeck in their electrochemical investigation of the sulfur-sulfide system (3). Obviously, the interaction of S with S^{-2} increases the solubility immensely. These interactions are, as mentioned previously, very complex and warrant further studies.

Transference Number of $NaClO_4$ in Dimethyl Sulfoxide and Dimethyl Sulfite

Alphonzo G. Nelson and Douglas N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The transference number of Na ions in $NaClO_4$ solutions in dimethyl sulfoxide varied from 0.310 at 0.499M to 0.357 at 0.0750M using the moving boundary method. The transference number of hydrated Cu ions in the following solution varied from 0.280 at 0.223M to 0.326 at 0.0343M. The transference number of Na ions in $NaClO_4$ solutions in dimethyl sulfite was 0.18 at 0.151M. All measurements were at 32°C.

The moving boundary method has been used to measure the transference numbers of $NaClO_4$· and $Cu(ClO_4)_2 \cdot 6H_2O$ in dimethyl sulfoxide and $NaClO_4$ in dimethyl sulfite. The hydrated copper ion was used in the following solution because it formed a stable boundary and made the boundary visible. Attempts to form a stable boundary using $LiClO_4$ in the leading solution were not successful, multiple boundaries being formed.

Use of hydrated copper perchlorate in the following solution required some minor changes in the equations previously presented by Bearman (1) and by Milios and Newman (2). The changes are necessary because the anode chamber is a two-salt system, hydrated and nonhydrated cupric perchlorate, rather than a single-salt as treated in previous analyses. The hydrated cupric perchlorate is the only salt initially in the anode chamber. However, as electrolysis proceeds, it is nonhydrated copper which is produced. A schematic representation showing the various solutions and boundaries is presented in Fig. 1. A third, probably indistinct, boundary will form between the original anolyte solution and the solution being produced at the anode as electrolysis proceeds.

The equation of continuity is valid for any species in the solution

$$\frac{\partial c_i}{\partial t} = \frac{-\partial (c_i v_i)}{\partial x} \qquad [1]$$

The current can be expressed in terms of the fluxes as

$$i = \mathbf{F} \sum_i z_i c_i v_i \qquad [2]$$

The equation of electroneutrality is

$$\sum_i z_i c_i = 0 \qquad [3]$$

Finally, a modified form of the Stefan-Maxwell equation is used to relate diffusive fluxes to chemical potential driving forces

$$c_i \frac{\partial \mu_i}{\partial x} = RT \sum_j \frac{c_i c_j}{c_T D_{ij}} (v_j - v_i) \qquad [4]$$

The definitions of the symbols used are given at end of the paper.

The above equations are solved for the leading solution and following solution in a manner similar to Milios and Newman (2) yielding the equation

$$t_1^o = \frac{\mathbf{F} z_3}{i} \frac{c_3}{c_o} \Bigg|_{x=-\infty} [c_o(v_o - v_b)]_{x=-\infty} \qquad [5]$$

$$t_2^o = \frac{\mathbf{F} z_3}{i} \frac{c_3}{c_o} \Bigg|_{x=\infty} [c_o(v_o - v_b)]_{x=\infty} \qquad [6]$$

or

$$\frac{t_1^o}{t_2^o} = \frac{[c_3/c_o]_{x=-\infty}}{[c_3/c_o]_{x=\infty}} \qquad [7]$$

Equation [7] is the Kohlrausch regulating function. Equation [6] is not used directly. In the above formulation, the notation, $x = -\infty$ refers to a position above the boundary, far enough away from the boundary so that only salt solution A (the leading solution) is present and far enough away from the electrode that $\partial \mu_{13}/\partial x = 0$. Likewise, $x = \infty$ refers to a position far enough below the boundary that μ_{23} is constant with only salt solution B present but still within the Kohlrausch regulated concentration region (see Fig. 1). t_1^o and t_2^o are transference numbers of cations 1 and 2 in leading and following solution, respectively, relative to the solvent, as pointed out by Milios and Newman (2).

In order to calculate the solvent velocity, a material balance is made in the anolyte chamber for a volume between an arbitrary control plane called the solvent plane, x, moving with the solvent velocity, v_o, and the solid electrode interface (see Fig. 1). The rate of change of the volume bounded by the solvent plane and closed electrode, V_o, is

$$\frac{dV_o}{dt} = \frac{d}{dt} \int_{V_o} dV = -v_o A - \frac{IM_e}{z_m \mathbf{F} \rho_e} \qquad [8]$$

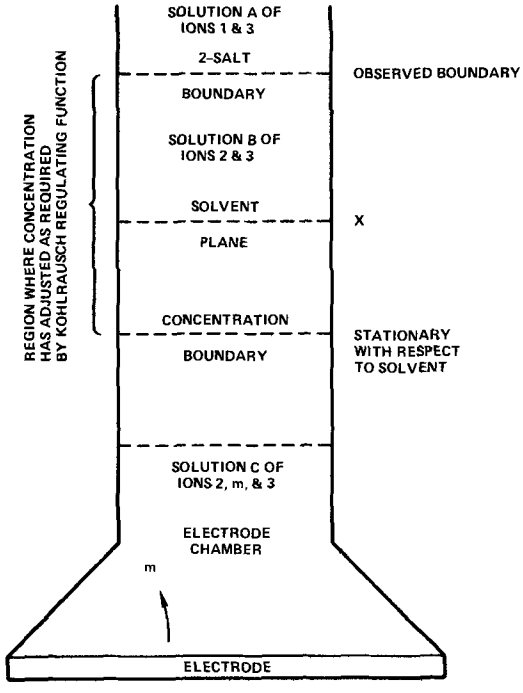

Fig. 1. Closed electrode with electrode material different from positive ionic species originally in solution.

* Electrochemical Society Active Member.

Key words: transference numbers, sodium ions, copper ions, dimethyl sulfoxide, dimethyl sulfite.

where A is the cross-sectional area, I is the total current passing through the electrode (negative for anode), M_e is the atomic weight of the metal anode, ρ_e is the density of the metal electrode. A material balance on the solvent gives

$$\frac{d}{dt}\int_{V_o} c_o dV = 0 \qquad [9]$$

Due to the dissolution of the electrode which produces a species not originally present in the following solution, two different positive ions are present in the following solution, the original one being designated by 2 and the metal ion being designated by m. Material balances on both of these ions yield the following

$$\frac{d}{dt}\int_{V_o} c_2 dV = \frac{It_2^o}{z_2 F} \qquad [10]$$

$$\frac{d}{dt}\int_{V_o} c_m dV = \frac{-I}{z_m F} \qquad [11]$$

It is assumed in this analysis that the boundary of the mixed solution of ion 2 and m never reaches the solvent plane. This assumption is justified in the present study because the distance between the anode and the concentration boundary is relatively large compared to the two-salt boundary movement. Otherwise, Eq. [11] would need to be replaced by the equation

$$\frac{d}{dt}\int_{V_o} c_m dV = \frac{It_m^o}{z_m F} - \frac{I}{z_m F} \qquad [12]$$

Since the solution in the anode chamber is a mixture of two salts, one can assume the density of the two-salt region below the solvent plane is linearly related to the concentration of both salts present.[1]

$$\rho_C = \rho_o + B_B c_{23} + B_m c_{m3} \qquad [13]$$

Here c_{23} is the concentration of the salt composed of ions 2 and 3, and c_{m3} is the concentration of the new salt formed by the metal dissolution, *i.e.*, of ions m and 3.

The exact expression for the density in this region is

$$\rho_C = M_B c_{23} + M_m c_{m3} + M_o c_o \qquad [14]$$

Therefore

$$c_o = c_o^o + b_B c_{23} + b_m c_{m3} \qquad [15]$$

where

$$c_o^o = \rho_o / M_o$$

$$b_B = (B_B - M_B)/M_o$$

$$b_m = (B_m - M_m)/M_o$$

Since $c_{23} = c_2/\nu_2$, and $c_{m3} = c_m/\nu_m$, Eq. [15] becomes

$$c_o = c_o^o + \frac{b_B c_2}{\nu_2} + \frac{b_m c_m}{\nu_m} \qquad [16]$$

Equation [9] then becomes

$$c_o^o \frac{d}{dt}\int_{V_o} dV + \frac{b_B}{\nu_2}\frac{d}{dt}\int_{V_o} c_2 dV + \frac{b_m}{\nu_m}\frac{d}{dt}\int_{V_o} c_m dV = 0 \qquad [17]$$

Substitution of Eq. [8], [10], and [11] with rearrangement yields

$$v_o = \frac{-i}{F}\left[\frac{M_e}{z_m \rho_e} - \frac{b_B t_2^o}{c_o^o \nu_2 z_2} + \frac{b_m}{c_o^o \nu_m z_m}\right] \qquad [18]$$

The expression for v_o, when substituted into Eq. [5] and [6], yields a set of equations which, when solved, give the expression

$$t_2^o = \frac{-c_o^o z_3 c_3}{c_o}\Bigg|_{x=\infty}\left[\frac{Fv_b}{i} + \frac{M_e}{\rho_e z_m} + \frac{b_m}{c_o^o \nu_m z_m}\right] \qquad [19]$$

and by means of the Kohlrausch relation

$$t_1^o = \frac{-c_o^o z_3 c_3}{c_o}\Bigg|_{x=-\infty}\left[\frac{Fv_b}{i} + \frac{M_e}{\rho_e z_m} + \frac{b_m}{c_o^o \nu_m z_m}\right] \qquad [20]$$

These equations are the final expressions needed for the calculation of the transference number from experimental data. When they are compared to the Milios and Newman (2) results, the two sets are seen to differ only in the last term which, in this case, represents the influence of the metal ion produced in the anode chamber being different than the following cation.

Experimental Equipment and Procedures

Solutions.—The solutions used in the present study were prepared from either dimethyl sulfoxide or dimethyl sulfite. The dimethyl sulfoxide was supplied by Crown Zellerbach Company, and the dimethyl sulfite was supplied by Aldrich Chemical Company. Due to the very hygroscopic nature of dimethyl sulfoxide, the water content of as-received dimethyl sulfoxide is on the order of 1076 ppm (3). Two other impurities also present insignificant quantities are dimethyl sulfide (DMS) and dimethyl sulfone ($DMSO_2$) (4). The as-received dimethyl sulfite was also found by Karl Fischer analysis to have a water content of 200 ppm. NMR analysis of the dimethyl sulfite indicated the presence of two major impurities each representing about 0.5% of the total weight, neither of which have been identified (5). The purification of solutions was accomplished by first placing the as-received dimethyl sulfoxide or sulfite in a flask containing Linde 4A molecular sieves. The flask was shaken approximately 3 hr, after which the contents were allowed to stand overnight. The resulting liquid was then centrifuged for 2 hr to remove the last traces of molecular sieve, and then transferred to a distillation column. Dimethyl sulfoxide was distilled at approximately 33 mm Hg pressure and 40°C. The dimethyl sulfite was distilled at 45 mm Hg pressure and 52°C. Karl Fischer titration of the product distillate indicated that the water content had been reduced to 30 ppm for dimethyl sulfoxide and 70 ppm for dimethyl sulfite. NMR analysis run on distilled DMSO indicated that no detectable organic impurities were present. NMR tests on distilled DMSU showed the disappearance of one of the peaks; the other peaks remained unchanged.

The three solutes used in this study were anhydrous purified $NaClO_4$ (City Chemical Corporation), anhydrous $LiClO_4$ (G. F. Smith Chemical Company, purity 97.4%), and reagent grade $Cu(ClO_4)_2 \cdot 6H_2O$ (Aldrich Chemical Company, purity 97-99%). The $NaClO_4$ was recrystallized three times by Yao (3). The salt was dried in vacuum at 70°C for three days; $LiClO_4$ was used as received. A Karl Fischer analysis run on the $LiClO_4$ indicates that approximately 1.74 molecules of water are present for every 10 molecules of salt. The $Cu(ClO_4)_2 \cdot 6H_2O$ was used as received.

Leading and indicator solutions were prepared by weight on a double pan balance (Volmer & Sons, Inc., New Rochelle, New York) inside of an argon filled Dri-Lab inert atmosphere glove box (Vacuum Atmosphere Corporation, Hollywood, California). The Dri-Lab was equipped with a unit through which the argon atmosphere could be continually recirculated for removal of oxygen and water. A Ni-Train unit consisting primarily of a titanium furnace was also provided with the Dri-Lab for the removal of nitrogen. These argon purifying units are capable of maintaining impurity levels between 1 and 5 ppm.

[1] For the copper perchlorate system studied it was found that $\rho_o = 1.093$ g/cm³, $B_B = 0.197$, $B_m = 0.2$ for ρ in grams per cubic centimeter and c_{23} and c_{m3} in mole/liter.

Electrodes.—"Baker Analyzed" copper wire 0.02 in. in diameter (J. T. Baker Chemical Company, purity 99.9%) was the anode. The vertical anode consisted of 24 strands of copper wire looped tightly together. Triple distilled mercury served as the cathode for the $NaClO_4$-$Cu(ClO_4)_2 \cdot 6H_2O$ tests. Contact was made to the mercury by a platinum wire sealed in soft glass.

Apparatus.—Boundaries were formed using a Tiselius cell (Perkin Elmer) with metal support stand and side electrode chambers. The channels of the cell were 0.2 cm thick, 1.5 cm deep, and 7 cm in length. A detailed description of the channel is given elsewhere (6).

In the present study, the boundary was followed by means of a cathetometer (Central Scientific Company), of accuracy ±0.5 mm located outside of the Dri-Lab. The bluish hue of the following cupric solution made it possible to observe directly the boundary formed between the two solutions. The boundary formed was visible down to about 0.03 molar in $Cu(ClO_4)_2 \cdot 6H_2O$, below which visual loss of the boundary occurred along the channel. Timing of the boundary was accomplished by means of antimagnetic stopwatches (Clark Stopwatch Company), of accuracy 0.005 min.

Velocity measurements recorded through a particular cell section are directly converted to volume displacements by multiplication of the cross-sectional area of the channel. The area was found by calibration of the cell with double-distilled water to be 0.3057 ± 0.0055 cm^2.

A Heath Kit regulated power supply (Model number IP-32) in series with a high impedance decade resistance box General Radio Company, was set so that the current remained constant to within ±0.05 mA regardless of the boundary position up the channel. The current readings were read on an ammeter (Simpson Electric Company).

The glass cell parts, electrode chambers, and syringes were cleaned in warm potassium hydroxide followed by dilute chromic acid. Finally, parts were rinsed with distilled water followed by acetone. The electrode chambers and syringes were stored in a vacuum oven at 375°C. The quartz cell was stored in a drawer.

Preparation for a run.—After assembly of the cell in its support stand in air, the apparatus was transferred into the Dri-Lab. Temperature control to ±1°C was accomplished by means of a Full Kontrol heater (Precision Scientific Company), and a temperature regulator (The Chemical Rubber Company, West Germany). These instruments were connected to a control relay box (Precision Scientific Company), mounted outside the Dri-Lab.

The apparatus was filled with solution by first filling the bottom section of the Tiselius cell with the copper perchlorate following solution just up to the flanged joint. A syringe reserved for the copper solution was used. The bottom cell section was then displaced relative to the mid-section so that the bottom was completely full of the following solution. The solution in the left channel was removed by the same syringe reserved for the copper solution. Next, the right side was filled up to the point where the liquid level was even with the right side opening of the top portion of the cell. The anode chamber was then filled until the level in the top cell portion was to the top. A Teflon plug was then inserted into the top carefully so no gas spaces were created. The plug had previously been coated liberally with Dow Corning Silicone grease. After the plug had been inserted, the anode chamber was filled up to the top and the chamber closed off by means of the Teflon stopcock located at the top of the chamber.

The cathode was prepared by inserting the platinum wire into the cathode chamber and then filling the chamber with triple distilled mercury up to the point where the platinum wire was completely submerged. Finally, the chamber and the left channel of the cell were filled with leading solution.

After the apparatus was connected to the electrical circuit, possible solution leakage from channel to channel through the sliding joints was checked. Problems with this type of leakage at the bottom portion during filling of the anode section necessitated this check. If a current was observed, the system was taken apart and the flanged joints recoated with Dow Corning vacuum seal grease and the procedure was started over.

After the leakage test, the potential was switched off and the bottom section of the cell carefully aligned with the middle section forming the sheared boundary. The boundary was given approximately 2 min for stabilization after which the cell was switched into series with the power source.

Operating procedure.—Average boundary velocities were recorded over 10-20 min intervals as the boundary progressed up the channel. When the boundary velocity had reached a constant value, four measurements were taken from which transference numbers were to be calculated. When the boundary had moved up through the top cell flange, the cell circuit was opened and the middle portion of the cell closed off by manipulation of the top and bottom cell sections. This procedure left a column of adjusted following solution closed off from which a sample could be drawn by syringe for later analysis by atomic absorption.

Results

$Na(ClO_4)$ in DMSO.—Stable boundaries were observed with sodium perchlorate as the leading solution and copper perchlorate hexahydrate as indicator and following solution. The data indicated a general trend of high boundary velocities near the starting point with decreasing boundary velocities with progression up the channel until a stable velocity was reached. Figure 2 shows the variation for a typical run. The initial high boundary velocity could have been due to the structure of the channel at the joint or could have been due to initial adjustment of the following solution concentration.

In calculating the transference number of the leading cation, Eq. [20] was used. The calculation of the transference number of the following solution was accomplished by Eq. [19]. The calculated transference numbers are given in Table I.

$NaClO_4$ in DMSU.—The results of a single run made on a 0.1508M solution of $Na(ClO_4)$ in dimethyl sulfite are also given in Table I. The transference number is given without correction for the solvent velocity due to unavailability of density data. The value is substantially lower than sodium ion transference numbers obtained in dimethyl sulfoxide. This suggests that a larger solvation sheath exists around the sodium ion in dimethyl sulfite than in dimethyl sulfoxide.

Error analysis—The per cent uncertainty in the calculated transference numbers, for the leading solution, can be attributed to the per cent uncertainty in the measured quantities v_b, I, c_3/c_o, and A. If the error in the boundary velocity, v_b, and cross-sectional area, A, is taken to be the mean deviation of these quantities, the uncertainty in the current, I, taken as the least count of the ammeter, and the uncertainty in the concentration ratio, c_3/c_o, taken to be the uncertainty in the weight of the salt, the total or maximum uncertainty in the transference number can be related to that of the separate quantities as follows

$$\frac{\text{Uncertainty } (t)}{t_{\text{avg}}} = \frac{\text{Uncertainty } (v_b)}{v_{b\ \text{avg}}} + \frac{\text{Uncertainty } (I)}{I_{\text{avg}}} + \frac{\text{Uncertainty } (w)}{w_{\text{avg}}} + \frac{\text{Uncertainty } (A)}{A_{\text{avg}}}$$

The left-hand side is the maximum per cent error of the calculated transference number. Summation of the contributions from each of the right-hand terms gives a maximum uncertainty of 0.7%. A comparison of the calculated per cent errors and the per cent deviation using various readings during a single run of the transference numbers shows that the observed variations are essentially the same as the errors estimated from uncertainties in the individual measured quantities. A more detailed error analysis is given elsewhere (4).

The main contribution to the error in the calculated transference number of the following solution arises from the uncertainty in the measured concentration of the salts. The uncertainty in the measurement of the following solution concentration arises because the actual syringe sample taken from the solution beneath the boundary may have been diluted by the leading solution left at the inner spaces of the flanged joints. Also, in several tests a sample of the following solution was drawn by sticking the syringe through a layer of leading solution. This method was used when the boundary was not run completely up the channel so that a sample of leading solution could also be taken.

Discussion

Della Monica *et al.* (7) have recently published transference number data for $AgClO_4$ in DMSO based on Hittorf cell measurements. They calculated the limiting equivalent conductance for perchlorate ions using two extrapolation techniques. Yao and Bennion (3) extrapolated equivalent conductance data to infinite dilution for $NaClO_4$ in DMSO and determined the limiting equivalent conductance for perchlorate ions based on the assumption that triisoamylbutylammonium ions and tetraphenylboride ions have equal limiting equivalent conductances.

The transference number data determined in this paper have been extrapolated to infinite dilution using the procedure suggested by Longsworth (8)

$$t_+{}^{o\prime} = \frac{t_+{}^o \Lambda'' \beta \sqrt{c}}{\Lambda'' + 2\beta\sqrt{c}} = t_+{}^\infty + bc$$

$$\Lambda'' = \Lambda_o - (\alpha\Lambda_o + 2\beta)\sqrt{c}$$

Using the DMSO properties reported by Yao and Bennion (3) give $\alpha = 0.5041$ and $\beta = 17.55$. The results are shown graphically in Fig. 3. The concentrations used are rather high for such extrapolations. The mean deviation is 0.9%. The limiting equivalent conductance for the perchlorate ion was found using the limiting equivalent conductance reported by Yao and Bennion (3) at 25°C. In this calculation it was assumed the transference number is independent of temperature between 32° and 25°C. Examination of transference number temperature variations as reported by Yao and Bennion (3) indicates that this assumption probably produces an error of about 0.5%. Since this error is less than the extrapolation error, no correction was made.

A comparison of the three determinations of the limiting ionic equivalent conductance for perchlorate ions in DMSO at 25°C is shown in Table II. It appears as if the procedure used by Yao and Bennion (3) gives a slightly high value for $\lambda_-{}^o$. However, the errors in

Overpotential Behavior at Pt Cathodes in Stabilized Zirconia Solid Electrolyte Fuel Cells

F. A. Kroger*

Department of Materials Science, University of Southern California, University Park, Los Angeles, California 90007

Etsell and Flengas (1) showed that application of voltages between 0.5 and 2V to cells of the type Pt (porous), Ar + O_2|ZrO_2 − CaO|Pt, O_2 at 700° and 1100°C with the left-hand electrode negative, led to saturated currents. The current was proportional to the oxygen pressure in the argon-oxygen mixture. The authors explained this by assuming that the current was limited by the diffusion of O_2 in the gas phase in the pores of the Pt electrode. For average size pores, this mechanism can be rate limiting only with O_2-inert gas mixtures. With pure O_2, diffusion is replaced by viscous flow, *i.e.*, a wind, which may constitute a limiting step only if the pores have submicron diameters (2); in pure O_2 overpotential was in fact not observed (1).

Experiments by Kleitz (3) and Yanagida *et al.* (4) on similar cells with inert gas-oxygen mixtures with 0.21 atm $\geq p_{O_2} \geq 10^{-4}$ atm at temperatures between 520° and 800°C show a limiting current $\propto p_{O_2}^{1/2}$, believed to be determined by diffusion of oxygen atoms through the platinum near the triple phase boundaries (4); experiments with nonporous foil electrodes at

* Electrochemical Society Active Member.
Key words: fuel cell, solid electrolyte, overpotential, limiting current, Pt cathode, oxygen diffusion.

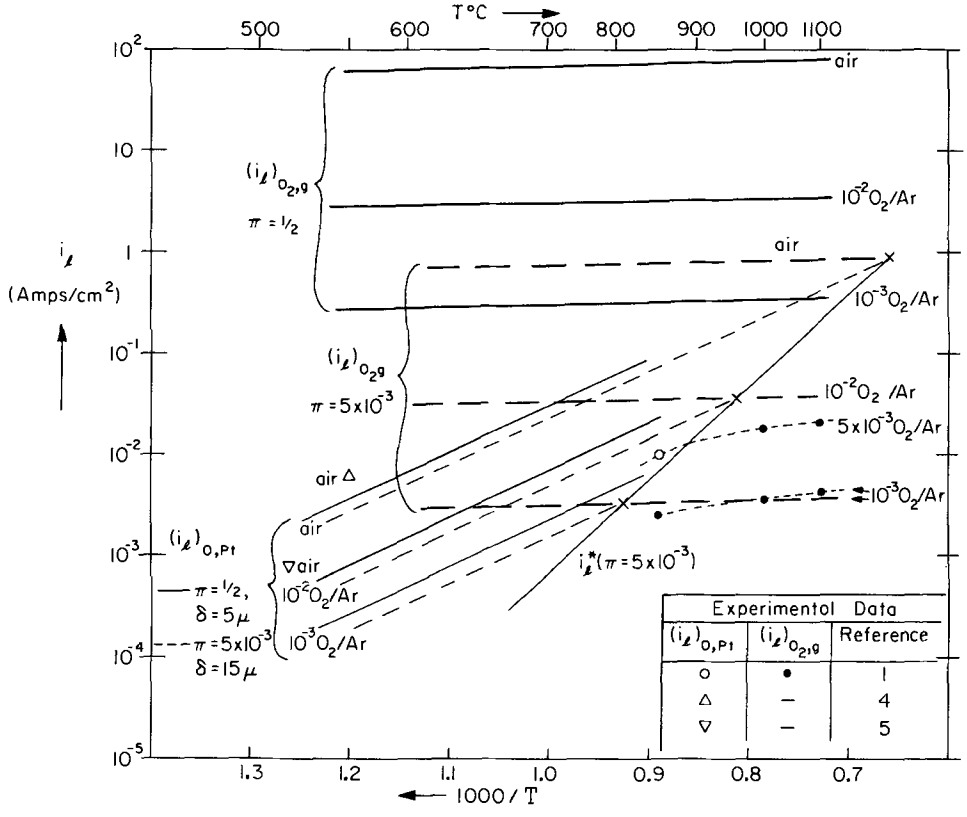

Fig. 1. Comparison of experimental values for the limiting current density with values calculated from Eq. [1] and [2] for three values of pO_2 and two different porosities.

temperatures between 520° and 685°C support this model (5). This mechanism is not limited to O_2-inert gas mixtures, as witnessed by the S-shape of the O_2 curve in Fig. 5 of Brook *et al.* (5).

All authors report rapidly increasing currents at higher voltages, related directly or indirectly to electronic conduction promoted by the increased polarization. As we shall see, the differences in the results at low voltages do not represent a discrepancy, but are due to a change in mechanism with changes in temperature, oxygen pressure, and porosity. Figure 1 shows values as a function of temperature for the current as limited by diffusion of O in Pt and as limited by gas-phase diffusion of O_2, each for various oxygen pressures and for two different porosities. In each case the limits shown in Fig. 1 were calculated from the expressions for the limiting current as given in Ref. (2) and (4)

$$(i_l)_{O_2(g)} = 4\,\mathbf{F}\,c\,D_{O_2(g)}(\pi/tl)\ln(1-x)^{-1}\ \mathrm{A/cm^{-2}} \quad [1]$$

$$(i_l)_{O(Pt)} = 2\,\mathbf{F}\,D_{O(Pt)}\,K\,pO_2^{1/2}\,\Omega/\delta\ \mathrm{A/cm^{-2}} \quad [2]$$

Equation [1] (List of Symbols is at end of note) holds for conditions under which composition changes in the gas outside the porous layer are prevented. If this is not the case, [1] still is valid, but with l and π replaced by $l' = l + \lambda$, and $\bar{\pi}$, respectively, λ being the thickness of the gas layer in which depletion of oxygen has occurred, and $\bar{\pi}$ an effective, average porosity. $\bar{\pi}$ can be estimated as follows. The removal of the oxygen at the pore entrance sets up concentration gradients in the gas outside the pore near the pore entrance. The equiconcentration planes will be approximately spherical close to the pore end, but will become planar at the distance λ from the pore end (Fig. 2a). In a rough treatment we can approximate the flow pattern by one with flat isoconcentration planes inside a cone with 90° top angle with the top at the pore end (Fig. 2b). The particle current of oxygen J_{O_2} through the gas in front of one pore is

$$J_{O_2} = -\frac{1}{RT} D_{O_2} A_x \frac{dpO_2, x}{dx}$$

with A_x the area of a section through the cone at x. If r is the pore radius

$$A_x = \pi^* \{(x + r)^2 - r^2\} = \pi^* x(x + 2r)$$

π^* indicating pi. Under stationary conditions this current is constant, independent of x. Then the oxygen pressure gradient over the gas layer with thickness λ is

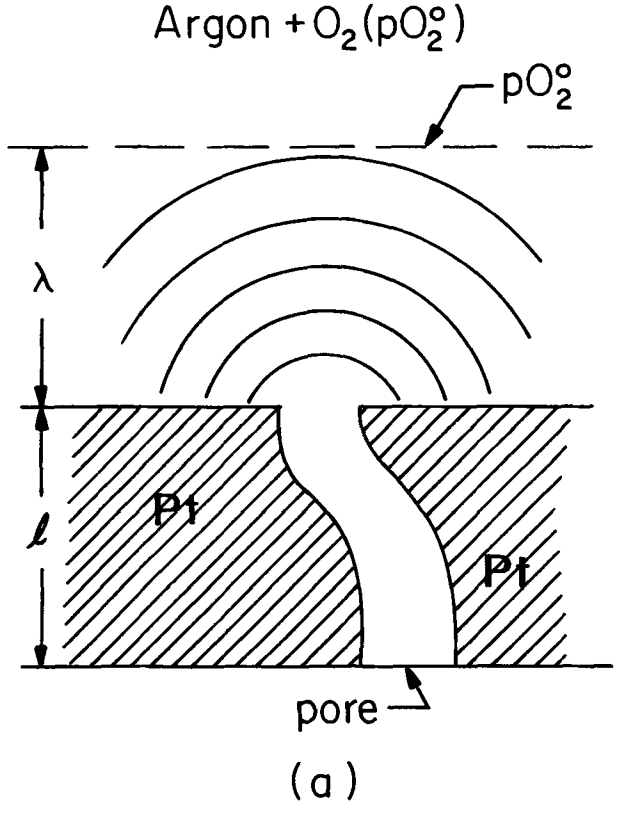

Fig. 2a. A pore in the porous platinum layer and equiconcentration lines for O_2 in the gas outside, near the pore (schematical).

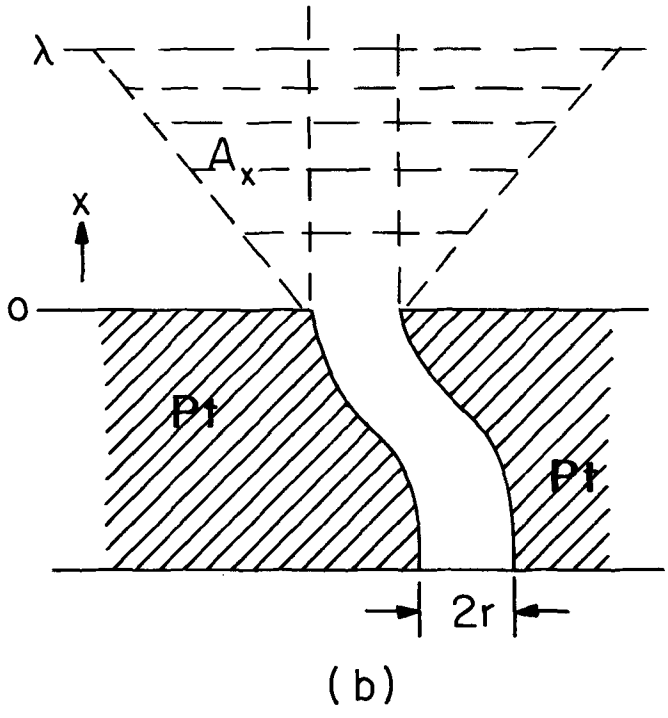

Fig. 2b. Approximate flat isoconcentration lines inside an inverted cone on top of the pore.

$$(\Delta pO_2)_\lambda = -J_{O_2}\frac{RT}{\pi^* D_{O_2}}\int_0^{-1}\frac{dx}{x(x+2r)}$$

Using the tabulated solution for the integral

$$(\Delta pO_2)_\lambda = J_{O_2}\frac{RT}{\pi^* D_{O_2}}\times\frac{1}{2r}\ln\frac{2r+x}{x}\Bigg|_0^\lambda =$$

$$-J_{O_2}\frac{RT}{\pi^* D_{O_2}}\times\frac{1}{2r}\left\{\ln\frac{2r\lambda}{(2r+\lambda)}-1\right\} \qquad [3]$$

The same J_{O_2} can be formulated in terms of a diffusion with a linear gradient through a cylindrical channel with an effective cross section A_e

$$J_{O_2} = -\frac{1}{RT}D_{O_2}A_e\frac{(\Delta pO_2)_\lambda}{\lambda} \qquad [4]$$

For N pores per cm^2 $= \pi/\pi^* r^2$, the effective porosity of the gas layer with thickness λ is $\pi' = NA_e$. Substitution of A_e using [4], and elimination of J_{O_2} with [3], remembering that $\pi = \pi^* r^2 N$

$$\pi'/\pi = 2\lambda/r\left\{\ln\frac{2r\lambda}{2r+\lambda}-1\right\} \qquad [5]$$

The effective average porosity of the combination of the gas layer and the Pt layer, $\bar{\pi}$ is found from

$$(\lambda + tl)/\bar{\pi} = (\lambda/\pi') + (tl/\pi) \qquad [6]$$

The gas layer will only be current limiting in cells in which the Pt layer is very thin.

In constructing Fig. 1, we have used Eq. [1] and [2] with $t \approx 1.5$, $l \approx 100\mu$, $\pi = 5 \times 10^{-3}$, and $\delta = 5$ and 15μ (note that π and δ are related). $D^T{}_{O_2(g)} \propto T^n$ is calculated from $D^{293}{}_{O_2N_2} = 0.22$ cm^2/sec, $D^{293}{}_{O_2,Ar} = 0.20$ cm^2/sec, using for n the average values for the corresponding self-diffusion exponents (6); typical values of n are between 1.66 and 1.81.

In O_2-Ar mixtures D_{O_2} varies from 1.16 cm^2 sec^{-1} at 500°C to 2.55 cm^2 sec^{-1} at 1000°C; for O_2-N_2 the corresponding variation is from 1.19 to 2.56 cm^2 sec^{-1}. According to Ref. (5), $D_{O(Pt,Rh)}K = 2.2 \times 10^{-16}$ exp ($-$ 0.94 eV/kT) g-atom cm^{-1} sec^{-1} atm$^{-1/2}$. The values for pure Pt may be 10 × larger. Recent measurements of $D_{O_2(Pt)}$ and the solubility of O in Pt (7) lead to a completely different expression $D_{O(Pt)}K = (2.4 \pm 0.67)\ 10^{10}$ exp ($-$ 8.45 ± 2.55) ev/kT g-atom cm^{-1} sec^{-1} atm$^{-1/2}$ which gives values for D_OK at 500°C that are 10^{18}-10^{51} smaller than the ones calculated from the expression from Ref. (5) [which are in turn smaller than values reported by Hoare (8)]. We have used the data from Ref. (5). It is obvious that our conclusions would be largely in error should one of the other sets of data prove to be the correct one.

As seen in Fig. 1, the experimental values for i_l in air as determined in Ref. (4, 5) fall close to the curve calculated from [2] for a highly porous layer using reasonable values of the parameters. Since the values of DK used were taken from experiments on nonporous films, the agreement lends support to the assumed model.

The data of Ref. (1) on the other hand, can be represented by [1] with $l \approx 100\mu$ only if we assume a low porosity, $\pi \approx 5 \times 10^{-3}$ with $t = 1.5$, or $\pi = 5 \times 10^{-2}$ with $t = 15$; the observed temperature dependence is, however, slightly larger than the theoretical one. Since Etsell and Flengas describe their Pt layer as a porous one, it seems *a priori*, unlikely that the porosity was so small. We then have to consider the possibility of a larger effective thickness corresponding to depletion of the gas mixture outside the Pt layer. The combination $l' = 1$ mm, $\bar{\pi} = 0.1$, corresponds to $\pi = 2 \times 10^{-2}$; only the combination $\bar{\pi} = 0.5$ and l' as large as 1 cm gives $\pi = 0.2$. Thus it seems that we have to accept a low value for π with probably depletion restricted mainly to the pores.

The difference in the temperature dependence and oxygen pressure dependence contained in [1] and [2] leads to a change in mechanism with a change in temperature and/or pO_2, the change occurring at a pressure $pO_2{}^*$ at a current density $i_l{}^*$ determined by the condition

$(i_l)_{O_2(g)} = (i_l)_{O,Pt} = i_l{}^*$. For $x = pO_2 << 1$, ln $(1 - x) \approx x$ and

$$pO_2{}^* = D_{O(Pt)}K\,\Omega\,tl/2c\,D_{O_2(g)}\pi\delta \qquad [3]$$

$$i_l{}^* = \mathbf{F}\,D^2{}_{O(Pt)}K^2\,\Omega^2\,tl/D_{O_2(g)}\,\delta^2\,\pi c \qquad [4]$$

$i_l{}^* \cdots 1/T$ as drawn in Fig. 1 for $\pi \approx 5 \times 10^{-3}$, separates the field at the right where gas diffusion is rate limiting from the field at the left where diffusion in Pt is rate limiting. The boundary, observable only at low pO_2 and/or low porosity is indicated in the 850°C data of Ref. (1) by a transition from a dependence $\propto pO_2{}^n$ with $n = 1$ at $pO_2 = 10^{-3}$ atm to $n < 1$ at $pO_2 = 5 \times 10^{-3}$ atm. Further work on cathodes for which the structure is better known is necessary to test the various models on variations in other parameters.

Electrochemical Properties of $RbAg_4I_5$ Solid Electrolyte

III. Chargeable Cells

Bruno Scrosati*

Laboratorio di Chimica Fisica ed Elettrochimica, Università di Roma, Rome, Italy

The organic semiconductors commonly known as "charge transfer complexes" (CTC) (1), possess a number of intrinsic properties which make them a very promising class of materials to use as halogen electrodes in solid-state cells. A CTC may be defined (1) as a system involving two components, one acting as electron donor (typically polycyclic aromatic compounds) and the other acting as electron acceptor (typically halogens). The most interesting property of the CTC is that their resistivity remains very low for a wide range of halogen composition (2). This circumstance promises their functioning as halogen electrodes in solid-state batteries. Furthermore, due to their low resistivity, the CTC may be used as electrodes without addition of inert components to assure good electronic conductivity, as is the case of the so far most used cathodes in solid-state cells. This results in immediate specific energy advantages.

In a previous work (3), it has been shown that the CTC, in addition to the above-mentioned advantages, also behave as reversible electrodes in solid-state cells. In particular it has been shown that the iodine-perylene (I_2-P) complex behaves as a reversible electrode in the $RbAg_4I_5$ solid electrolyte cell

$$Ag/RbAg_4I_5/I_2\text{-}P \qquad [1]$$

This reversibility was tested both by micropolarization curves and by the successful charge of the cell

$$Ag/RbAg_4I_5/AgI,P \qquad [2]$$

which is the fully discharged version of cell [1]. The charge process of cell [2] in fact leads to the formation of the I_2-P complex at the positive and the deposition of silver at the negative. The charge-discharge efficiency of cell [2] is very satisfactory, about 70%, as shown in Fig. 1. This is an interesting result since cell [2] may be stored for any desired length of time and activated just before use. The shelf life of this "reserve type" solid-state cell should be therefore very long (3).

The satisfactory behavior of cell [2] suggested further study to improve its technological properties. The results of this study are reported in this work.

Experimental

The electrolyte was prepared in the usual way (4). The positive electrode mixture was formed by mixing silver-iodide and perylene in such a proportion to originate, after a complete AgI to I_2 conversion, an I_2-P complex of 2/3 molar ratio. To reduce interfacial effects (3), to 1 part of this mixture, 3 parts of electrolyte were then added. The cell components were pressed into a single pellet with the following procedure. First a certain amount of powdered zinc (or, alternatively graphite) was slighty pressed in a stainless-steel dye. Then the plunger was raised up and on the top of the zinc pellet was added a moderate amount of electrolyte and pressed at higher pressure. Then the plunger was raised up again and a small amount (typically 0.07g) of the positive electrode mixture was added. The pressure was then raised to about 3000 kg/cm^2 to obtain the final pellet where the electrode materials were uniformly and intimately in contact with the electrolyte. The pellet obtained in this way had a diameter of 1.26 cm and average thickness and weight of 0.2 cm and 0.8g, respectively. The cell was finally assembled into a Teflon container with gold-plated terminals.

The polarization studies were performed by using a silver wire as reference electrode. This was inserted into the electrolyte by heating the wire in order to melt the electrolyte locally. Standard equipment was used to determine current-voltage curves and to register the charge-discharge cycles.

Results and Discussion

Since cell [2] is assembled in the discharge state, it is not strictly necessary to use silver as the negative. Any other material on which silver may deposit a charge can be used as alternative. If this material is inexpensive, as for instance zinc or graphite, the over-all cost of the cell would be reduced. In fact the silver utilized in the discharge would be that obtained from the conversion of silver iodide during charge.

To test this, the cell

$$Zn/RbAg_4I_5/AgI,P \qquad [3]$$

has been assembled. Cell [3] was submitted to 18 hr charge at 0.05 mA. The following discharge, at 0.1 mA,

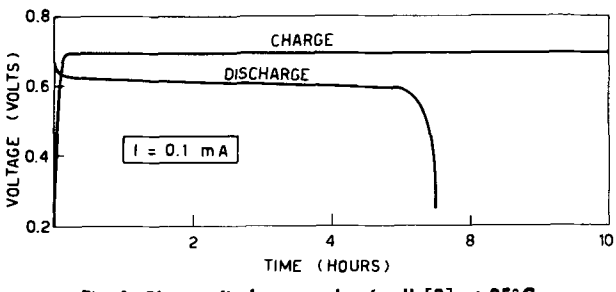

Fig. 1. Charge-discharge cycle of cell [2] at 25°C

* Electrochemical Society Active Member.
Key words: solid electrolyte, chargeable cells.

was satisfactory, giving a utilization (at 0.3V cut off) higher than 50% and being very flat in shape. This cycle is shown in Fig. 2A. In Fig. 2B is shown another cycle realized by charging a cell similar to [3] at 0.1 mA and discharging it at 0.2 mA. This cycle also was satisfactory, giving an efficiency of 53%. These results indicate that cell [3] also is chargeable with a reasonably good discharge efficiency. Figure 3 is a photograph of the positive side of a cell similar to cell [3] charged with a rectangular current collector up to 70% of its complete charge. The black color of the I_2-P complex (3) is evident over the clear color of the original AgI,P mixture. This is a further indication of the chargeability of cell [3].

Figure 4 shows current-voltage curves of the AgI,P electrode used in cell [3] (curve A) and of an electrode similar to the previous one but without AgI in it. In the latter (curve B) appreciable current, obviously due to electrolyte decomposition, flows at potentials ranging from 0.8 to 0.9V. One may therefore exclude electrolyte decomposition during charge of cell [3] if the charging voltage is maintained below 0.8V.

Cell [3] was submitted to continuous charge-discharge cycles which are shown in Fig. 5. Indications of cell deteriorations are evident even at the third cycle. The cell was disconnected and examination under the microscope showed deposition of silver in dendritic form on the negative electrode surface. Scrosati and Butherus (5) have shown that planar silver electrodes behave reversibly at low-current levels. When a considerable amount of charge is passed through the cell, however, one may obtain dendritic deposition of silver at the negative. It has been subsequently shown by Butherus (6) that irreversible degradation on cycling takes place when the cycle

regime involves a layer of silver thicker than 0.2μ. This undoubtedly represents the most serious limiting factor to the rechargeability of the $RbAg_4I_5$ cells which has to be limited to shallow cycling regimes only. Under these conditions in fact, Butherus has been able to cycle $RbAg_4I_5$ cells several thousand times (6).

Finally the charge-discharge curve of the cell

$$C/RbAg_4I_5/AgI,P \qquad [4]$$

where zinc has been substituted by graphite as the silver electrode support, is shown in Fig. 6. The charge

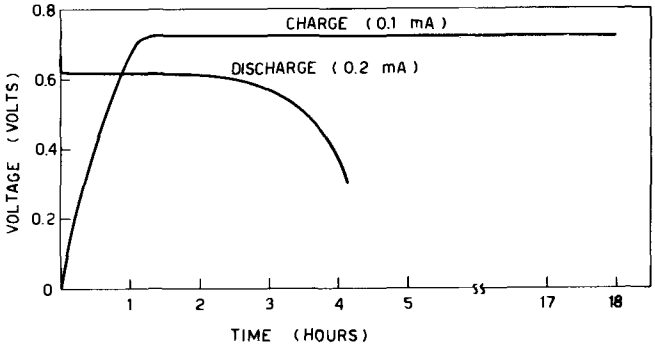

Fig. 6. Charge-discharge cycle of cell [4] at 25°C

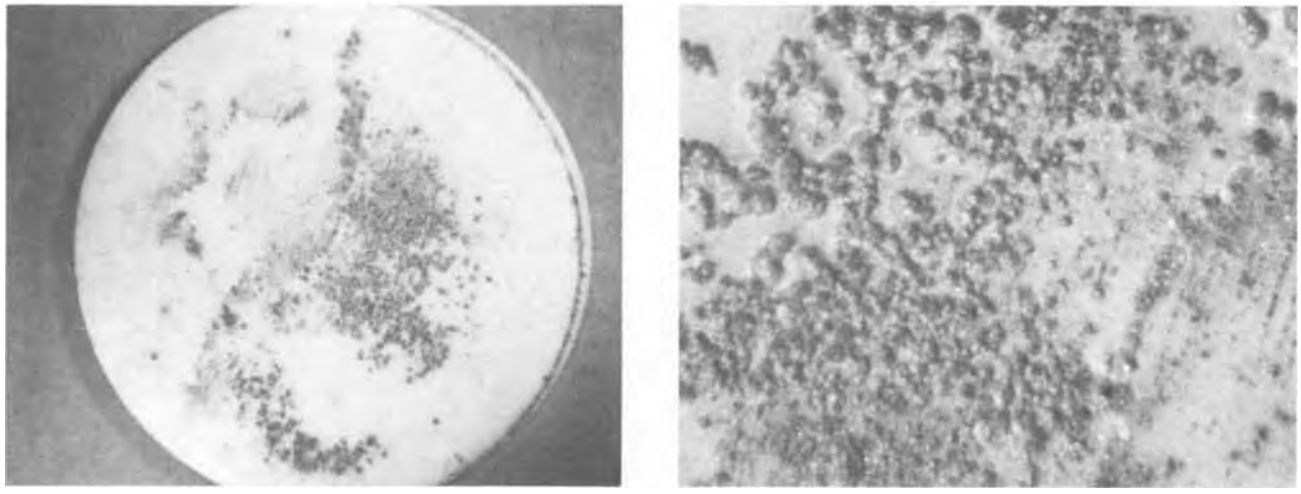

Fig. 7. Microphotographs (6X left and 25X right) of the negative side of a charged cell [4]

voltage rose slowly to a rather high stable value, *i.e.*, 0.72V, and the subsequent discharge gave a utilization of about 40%. A cell similar to [4] was disconnected after charge and microphotographs of its negative side are shown in Fig. 7. Deposition of silver in dendritic form is particularly evident here.

Conclusions

The main purpose of this work is to show that cells having the structure [3] or [4] may be successfully used as "reserve type," reduced-cost solid-state cells. The results of Fig. 2 and 5 indicate that this is indeed the case. Therefore the shelf life of these cells should be very long as might not be the case of primary $RbAg_4I_5$ iodine cells because of the well-known iodine diffusion through the polycrystalline electrolyte (7, 8). It does not seem to be possible, however, to obtain many deep cycles with cells [3] and [4] because of the tendency of silver to deposit in dendritic form, a process which results in a lack of contact points at the electrode-electrolyte surface and, ultimately, in an increase of cell internal resistance. This was also found by Raleigh in his studies on electrodeposition of silver from solid AgBr on various electrodes (9). In fact he reported that Ag electrodeposition onto Pt involves smooth buildup of monolayers while nucleated deposition occurs on graphite, resulting in dendritic growth.

Acknowledgments

The author would like to thank Dr. A. D. Butherus of Bell Telephone Laboratories for his helpful discussions on this study. This work was partially sponsored by the Consiglio Nazionale delle Ricerche (C.N.R.).

Continuous Flow Dielectrophoresis

R. H. Kirchoff and A. Hamdi[1]

Department of Mechanical Engineering, University of Massachusetts, Amherst, Massachusetts 01002

Previous work (1, 2) has established the use of the dielectrophoretic force to separate a solute from its solvent and to perform filtration in a continuous manner. Particles of various materials suspended in liquid dielectrics have been separated in a cell of cylindrical geometry under the action of nonuniform fields (1). Transformer oil has been purified to a breakdown strength of 100 kV/mm in a continuous flow dielectrophoretic cell. Carbon particles of a few tens of Å have been removed (2). Further applications of the dielectrophoretic force may be found in Ref. (7).

In this work, the equation of motion of a particle in a continuous flow dielectrophoretic separator has been solved under certain assumptions. The results have been expressed in terms of dimensionless parameters in order to provide a design curve for such a filter. Based on previous experimental work, limits on the range of the operating parameters of the cell have been indicated.

[1] Present address: Moharem Bey, United Arab Republic.
Key words: dielectrophoresis, deposition.

Analysis

A continuous-flow cylindrically symmetric separator is shown in Fig. 1. The fluid suspension enters at the top with velocity $V_z(r)$; in the presence of the nonuniform field, particles with a dielectric constant greater than that of the fluid will be attracted to the central electrode. The dielectrophoretic force on a particle in a cell of this geometry is given as (3)

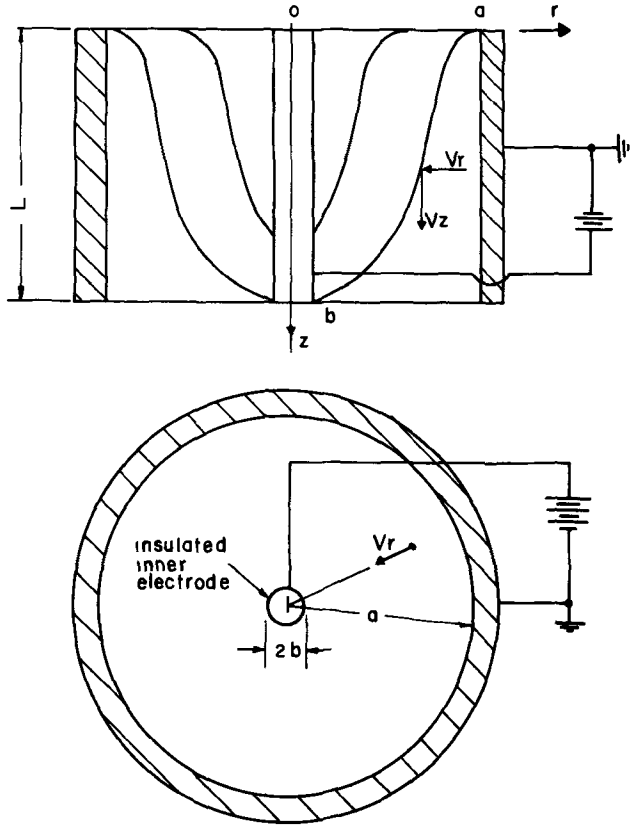

Fig. 1. Cylindrical separation cell

$$\bar{F}_e = -4\pi R^3 \epsilon_0 \frac{K_1(K_2 - K_1)}{(K_2 + 2K_1)} \frac{V_1^2}{r^3\left[\ln\left(\frac{b}{a}\right)\right]^2} \bar{r}_0 \quad [1]$$

where ϵ_0 is the permittivity of free space; r is the distance of the particle from the central axis; R is the radius of the particle; $K_{1,2}$ is the relative dielectric constant of the liquid and the particle, respectively; V_1 is the potential of the inner cylinder; $\bar{r}_0$ is the unit radius vector; and a,b outer and inner cylinder radii, respectively.

The equation of motion for a particle is written under the following assumptions: (*i*) the particle is assumed to be a point mass; (*ii*) the flow is laminar; (*iii*) the particles do not strongly interact; (*iv*) gravitational forces and electrostatic forces are neglected; (*v*) the resistance of a particle is given by Stokes law.

The equation of motion in the r direction may be written as

$$m\frac{dV_r}{dt} = F_e - F_d \quad [2]$$

where m is the particle mass and F_d is the Stokes drag law for a spherical particle $F_d = 6\pi\mu RV_r$. Combining Stokes law with Eq. [1] and [2]

$$\frac{mV_r^2}{6\pi\mu RV_r}\frac{dV_r}{dt} = \left[\frac{4\pi R^3\epsilon_0 V_1^2 K_1(K_2 - K_1)}{r^3\left(\ln\frac{b}{a}\right)^2 6\pi\mu RV_r(K_2 + 2K_1)} - 1\right] V_r^2 \quad [3]$$

Let $P_r = (mV_r^2)/(6\pi\mu RV_r)$ the ratio of the particle kinetic energy to the drag force in the r direction. When P_r is very small, the left side of Eq. [3] may be neglected which is equivalent to ignoring the Newtonian acceleration. This is justified when the inertia force on a particle is much less than the viscous drag force. P_r is a parameter having the dimension of length; it is equal to the distance the particle will travel before coming to rest when launched with velocity V_r into a stationary fluid. For the conditions of the separator in Ref. (1) P_r was found to be on the order of 10^{-13}m. Ignoring the acceleration term and rearranging the equation of motion in the r direction, the particle velocity may be written

$$V_r = 2R^2\epsilon_0 V_1^2 K_1(K_2 - K_1)/3\mu r^3\left(\ln\frac{b}{a}\right)^2(K_2 + 2K_1) \quad [4]$$

The equation of motion in the z direction is

$$m\frac{dV_z}{dt} = 6\pi\mu R(V_z - U) \quad [5]$$

where $U(r)$ is the mean fluid velocity in the annulus. Equation [5] may be rearranged as

$$\frac{mV_z^2}{6\pi\mu RV_z}\frac{dV_z}{dt} = (V_z - U)V_z$$

Let $P_z = mV_z^2/6\pi\mu RV_z$. When P_z is small, the Newtonian acceleration in the z direction may be neglected which implies that the particle velocity and the fluid velocity are identical in the z direction. For the conditions of the separation in Ref. (1) P_z was found to be on the order of 10^{-18}m. For laminar flow in an annulus (4) U is given as

$$U = \left(\frac{1}{4\mu}\right)\left(\frac{\Delta P}{\Delta z}\right)\left(b^2 - r^2 + (a^2 - b^2)\left(\ln\frac{r}{b}\right) \Big/ \ln\left(\frac{a}{b}\right)\right) \quad [6]$$

and the volume flow rate in the annulus is

$$W = \frac{8\pi}{\mu}\left(\frac{\Delta P}{\Delta z}\right)\left(a^4 - b^4 - (a^2 - b^2) \Big/ \left(\ln\frac{a}{b}\right)\right) \quad [7]$$

In the subsequent analysis Eq. [6] and [7] are used together to eliminate $(\Delta P/\Delta z)$.

The optimum length of the dielectrophoretic continuous flow filter is the minimum length for the separation of the axial flowing particle suspension. In Fig. 1 for a particle starting at (O,a) and ending at (L,b) the optimum length is the particle path projection L on the z axis. A similar particle starting at some radius $r < a$ will be collected in some length z less than the optimum length.

To find this optimum length, let $V_z = dz/dt$ and $V_r = -dr/dt$; eliminate the parameter t (time) and integrate along the particle path

$$-\int_o^L dz = K\int_a^b r^3 dr - M\int_a^b r^5 dr + N\int_a^b r^3 \ln(r/b)\,dr \quad [8]$$

K, M, N are constants. Performing the integration

$$L = A\left(A_1\left(\frac{b}{a}\right)^6 - \left(A_2\ln\left(\frac{b}{a}\right) + A_3\right)\left(\frac{b}{a}\right)^4 - A_4\right) \quad [9]$$

where

$$A = \frac{8d^4(\ln d)^3\mu W(K_2 + 2K_1)}{((d^4 - 1)\ln(d) - (d^2 - 1)^2 e_0 V_1^2 R^2 K_1(K_2 - K_1)\pi)}$$
$$A_1 = (d^2/16)b^2$$
$$A_2 = (3(d^2 - 1)/32\ln d)b^2$$
$$A_3 = ((12d^2\ln d - 3d^2 + 3)/(128\ln d))b^2$$
$$A_4 = ((3d^2 - 4d^2\ln d - 3)/(128\ln d))b^2$$
$$d = a/b$$

Substitute the constants A, A_1, A_2, A_3, A_4, and d into Eq. [10] and rearrange to get

$$\frac{LFe}{W_m} = F(d) \quad [10]$$

W_m is a form of mechanical work $W_m = (8/\pi)\mu W(b/R)^2$ having the dimensions of Newton-meters. And Fe is an electric force

$$Fe = \frac{K_1(K_2 - K_1)\epsilon_0 V_1^2}{(K_2 + 2K_1)}$$

having the dimension of Newton. $F(d)$ is a dimensionless shape factor.

$$F(d) = \frac{(\ln d)^2(4d^6 - 1)\ln d - 3(d^5 - d^4 - d^2 + 1)}{128\,((d^4 - 1)\ln d - 3(d^2 - 1)^2)}$$

L is the optimum filter length. Equation [10] is plotted in Fig. 2 which contains all the information necessary to select a filter of optimum length. The bottom line in Fig. 2 is for 100% particle collection. An analysis similar to the foregoing was used to predict the filter length necessary to collect x% of the incoming particles. These results are also indicated on Fig. 2.

By changing the limits of integration on Eq. [8] from O to Z and from a to r the particle path may be generated for 100% particle collection in length L. This particle path is shown in Fig. 3 together with the particle paths for less than 100% collection. Figure 3 is plotted for $d = 10$ only.

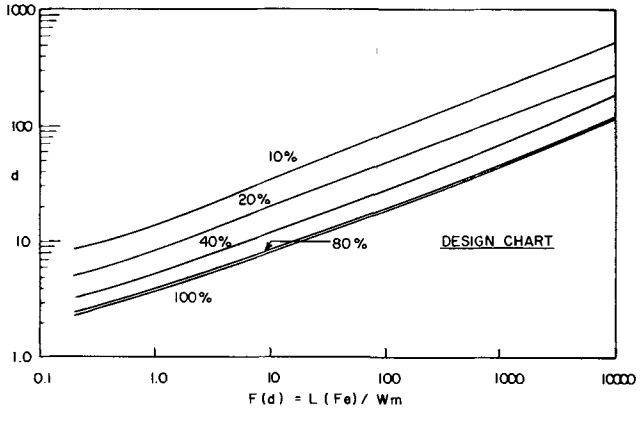

Fig. 2. Design chart

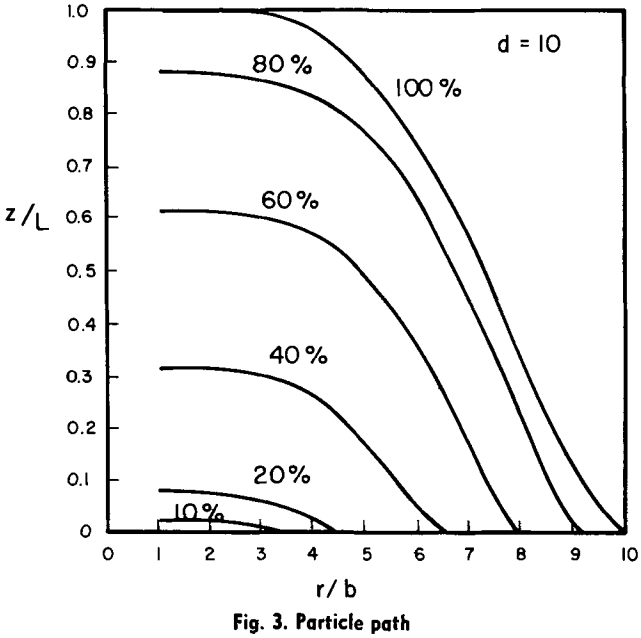

Fig. 3. Particle path

For the conditions of the experiment described in Ref. (1) in which almost 100% separation was observed, the curve of Fig. 2 predicts an optimum filter length from 3 to 12 cm depending on the applied voltage. The actual filter in Ref. (1) was estimated (5) to be about 19 cm in length. This reasonable agreement is taken as sufficient evidence that Eq. [10] can be used to design a continuous flow dielectrophoretic separation cell.

Limitations

There are a number of limitations reported in the literature (1, 2) which place some constraints on the parameters in Eq. [10].

In order to eliminate particle charging and subsequent electrostatic repulsion at the center electrode, that electrode should be coated with Teflon, plastic foam, or another suitable insulating material.

The field strength at the central electrode should be less than 2×10^6 V/m. Greater field strengths have the effect of drastically reduced collection at the central electrode. There is a minimum central electrode voltage of a few hundred volts below which no dielectrophoretic action takes place.

The period of the applied-voltage signal to the electrodes should be much less than the time constant ϵ/δ of the dielectric suspension in order to prevent the decay of free-charge density and the collapse of the nonuniform field in the separation cell.

There is a maximum residence time for which the fluid should remain in the separator. For residence time $t_r = L/V_z$ longer than this maximum, ionic charging of the fluid has been observed to take place with a subsequent decrease in particle collection (6). This time for ionic charging has been given in Ref. (6) as

$$t_s = \frac{\epsilon_0 \rho_1 \rho_2}{\rho_2 - \rho_1}(K_2 - K_1)$$

where ρ_1 and ρ_2 are the resistivities of the liquid and the particles, respectively. In order to avoid ionic charging $t_r < t_s$.

Conclusion

All the parameters involved in the design of a dielectrophoretic separator have been presented on a single dimensionless curve from which optimum filter parameters may be selected. Limitations on these parameters which have been observed in previous experiments have been included for completeness.

Predicting Current Efficiency of Industrial Aluminum Smelting Cells from Laboratory Measurements

W. E. Haupin*

Aluminum Company of America, Alcoa Research Laboratories, New Kensington, Pennsylvania 15068

Current efficiency tests are costly and difficult to control in industrial cells. On the other hand, current efficiency based on aluminum recovered from laboratory cells is always low. Cammarota and Schlain (1) demonstrated that meaningful current efficiencies can be obtained in laboratory-size cells by using boron nitride for the cell sides and cover, and by correcting for certain metal losses. At the end of each run they found it necessary to: (*i*) cool the cell quickly to avoid continuing losses, (*ii*) analyze the frozen electrolyte for reduced species, and (*iii*) machine away the outer surfaces of the graphite cathode and boron nitride walls and analyze each for reduced species. The aluminum equivalent of the reduced species found by analysis was then included along with the aluminum actually recovered to calculate current efficiency. Unfortunately, liberal use of boron nitride in cell construction made their cell expensive, and machining away part of the surface after each run limited its life.

Thonstad (2) gives an excellent summary of the various sources of current efficiency loss in an aluminum smelter. The corrections made by Cammarota and Schlain were both necessary and valid when one evaluates each loss as a function of cell size, age, and length of run.

Sources of Current Efficiency Loss

The principal current efficiency loss in an aluminum smelting cell results from CO_2 reoxidation of reduced metal species dissolved or suspended in the electrolyte. An activity of metal is maintained in the electrolyte by the following equilibria

$$Al + 3NaF \rightleftarrows AlF_3 + 3Na \quad [1]$$

$$2Al + AlF_3 \rightleftarrows 3AlF \quad [2]$$

NaF, AlF_3, AlF, and Na are present in the electrolyte at less than unit activity. Reduced species subsequently are reoxidized by CO_2 formed at the anode by the following, or similar, reactions

$$3AlF + 3CO_2 \rightarrow Al_2O_3 + 3CO + AlF_3 \quad [3]$$

$$6AlF + 3CO_2 \rightarrow 2Al_2O_3 + 3C + 2AlF_3 \quad [4]$$

$$6Na + 2AlF_3 + 3CO_2 \rightarrow Al_2O_3 + 6NaF + 3CO \quad [5]$$

$$12Na + 4AlF_3 + 3CO_2 \rightarrow 2Al_2O_3 + 12NaF + 3C \quad [6]$$

Although this reoxidation loss may be affected by cell design, it does not appear to be a function of cell size or age. Therefore no correction is required, provided the design factors (anode-cathode distance, gas-retention time, etc.) are adequately simulated.

Some investigators believe vaporization of reduced species from the electrolyte occurs only in laboratory tests. We believe it occurs also in industrial cells but these vapors are reoxidized by air and CO_2. The loss is mainly Na but includes a minor amount of AlF. It is measured by analyzing the condensed fume for reduced species without exposure to air. Its magnitude depends on bath composition, temperature, degree of electrolyte agitation, and gas velocity over the electrolyte. These factors can be measured and made equivalent to conditions present in industrial-cell operation. Velocity of gas leaving the anode at equivalent current densities is less in a small cell than in a large cell because of the increased ratio of area to perimeter. The purge gas, however, can be adjusted to compensate for the velocity difference. Since vaporization loss from an industrial cell is small, a fair degree of equivalence will be adequate.

Some of the metal produced is absorbed by the cell lining in the form of Na, Al_4C_3, and to a lesser extent, Al. This represents a major loss in laboratory cells due to the large surface-to-volume ratio and short period of electrolysis. In industrial cells the lining soon becomes saturated, and the loss through absorption becomes negligible over the major portion of the cell's life. Therefore, in small cells with short periods of operation, absorption loss must be measured and added to the production to make the results comparable to commercial production.

Sodium, Al_4C_3, AlF, and Al that dissolve or disperse in the molten electrolyte represent a considerable part of the total production in runs lasting only a few hours. In industrial operation, however, the metal held by the electrolyte is small compared to total production. Therefore, the Al equivalent of Al_4C_3 and reduced species in the electrolyte must be added to the actual Al produced to make small scale runs comparable to commercial production.

Regardless of how carefully the electrolyte is predried, it still contains moisture after melting. This water is electrolyzed to form H_2 and CO_2 and represents a loss of current efficiency in laboratory cells that would not be present in industrial cells after the first few days. Some loss by water may continue at a low level in industrial cells because a small amount of moisture may be added whenever Al_2O_3 is fed. Loss in current efficiency due to water is evaluated by analyzing the H_2 content of the cell gas and correcting it for H_2 evolved from hydrocarbons from the anode. With prebake anodes, the hydrocarbon correction is dependent on the anode baking temperature, and is usually minor. In the case of Soderberg anodes, it is more significant.

In summary, both electrolyte and cell lining quickly become saturated in the industrial cell and cease to trap additional metal. Therefore, it is valid to measure these losses in a laboratory cell and add their stoichiometric Al equivalent to the Al actually recovered. Further correction may be required for the loss caused by moisture. Other losses parallel industrial experience.

Alternate Cells

Boron nitride absorbs reduced species to a lesser extent than graphite but still has to be sacrificed and analyzed to obtain a correction factor. Therefore, less expensive graphite was used as an alternate since the only penalty was a larger correction. Table I, column 1, shows the results from electrolysis in a graphite container using the cell design illustrated in Fig. 1. In all runs the electrolyte was natural Greeland cryolite plus 6% reagent grade CaF_2, with Alcoa AlF_3 and smelting grade Al_2O_3 added to give the analysis shown in Table I. Use of a gas-collection hood over the anode and a purge gas reduced the residence time of gas produced by the cell, making observation of changes in gas flow and gas composition possible during the run. 	% Current efficiency		
Al_2O_3 consumed	84.1	86.1	92.0
a + c + d + e + f + h	84.8	85.9	94.0
100 − b − g	85.1	85.7	94.0

of CO and CO_2 flows to the metered argon flow were determined by gas chromatographic analysis. The gas was also passed through an absorption train similar to that described by Cammarota and Schlain (1), to check the chromatograph and to determine H_2. Argon flow was held proportional to current and, in the examples, equal to the Faraday equivalent for CO_2. Total A-hr were obtained with an electronic integrator.

Items a through f in Table I have been explained under the heading, Source of current efficiency loss. Item g, the aluminum equivalent of metal reoxidized by CO_2 expressed as a per cent of theoretical maximum aluminum production, was calculated

$$g = 50\,CO/(CO + CO_2)$$

where CO = gram mole of CO evolved, CO_2 = gram mole of CO_2 evolved.

Item h, aluminum equivalent of water electrolyzed or metal reoxidized by moisture expressed as a per cent of theoretical maximum aluminum production was calculated

$$h = 100\,W_{H_2}/0.01864I_h$$

where W_{H_2} = grams of H_2 evolved; I_h = ampere hours current passed; 0.01864 = Faraday equivalent of H_2.

Current efficiency by Al_2O_3 consumed expressed as a per cent of theoretical maximum was calculated

$$CE = 100(F_1W_1 - F_2W_2 + A)/0.6340I_h$$

where F_1 = fraction Al_2O_3 in electrolyte at start; F_2 = fraction Al_2O_3 in electrolyte at finish; W_1 = grams of electrolyte at start; W_2 = grams of electrolyte at finish; A = grams of Al_2O_3 added during run, if any; 0.6340 = Faraday equivalent of Al_2O_3.

The item a + c + d + e + f + h is the sum of aluminum recovered plus those losses in a small cell that would have been negligible in a large cell. The item 100 − b − g represents 100% current efficiency minus the two losses measured in a small cell that apply also to an industrial cell.

Although the correction for metal absorbed by the graphite lining was larger than that required by a cell made from BN, the corrected current efficiency was comparable to that obtained in boron nitride cells (1) and also agreed well with industrial practice for similar conditions. If a nonpermeable side lining were available, the lining correction would be eliminated. Since no nonmetallic, impermeable, molten fluoride-resistant material was known, Fe and Ni were tested as containers. Nickel was more resistant to CO_2 oxidation. The cell design for Ni is shown in Fig. 2. Frozen

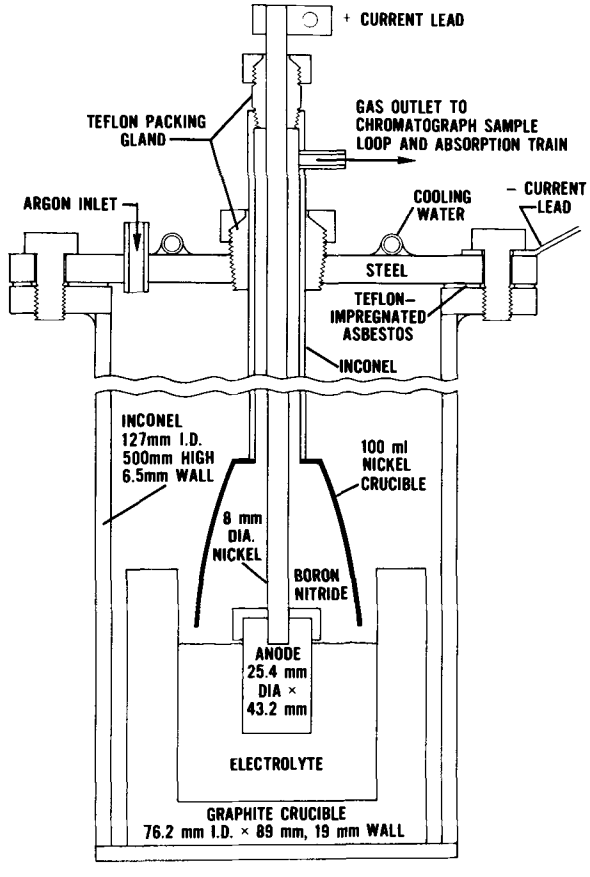

Fig. 1. Cell design for graphite

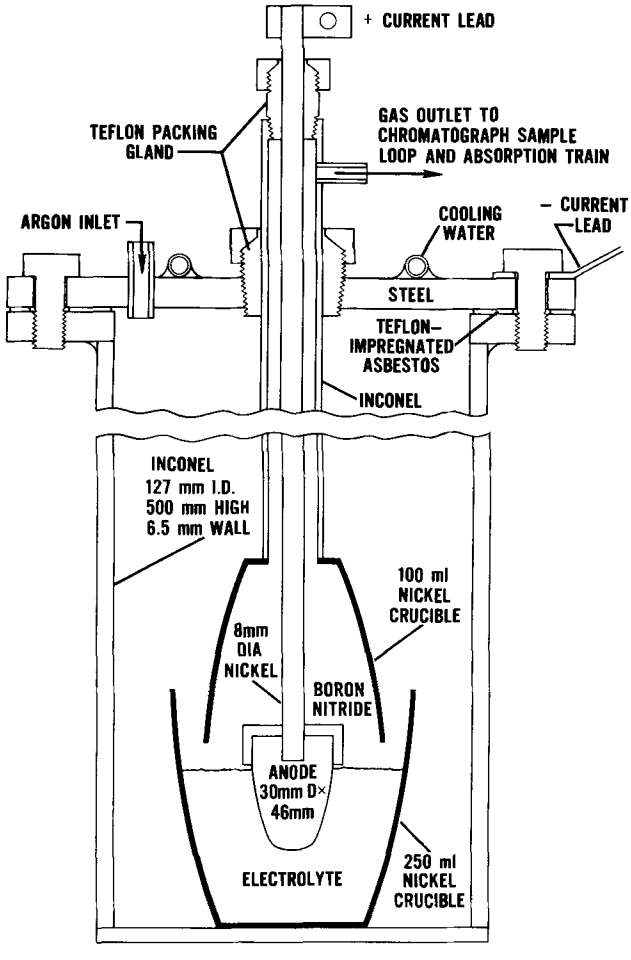

Fig. 2. Cell design for nickel

electrolyte was easily removed after the run by tapping the nickel crucible. Residual electrolyte was removed by immersing the crucible in molten NaCl until it was clean, then removing, cooling and washing it free of NaCl with water. Aluminum production was taken as the weight gain of the nickel crucible.

At first it was feared that this technique reduced the Al activity, and hence produced excessively high current efficiencies. Current efficiencies obtained, however, looked reasonable, and the counter electromotive force measured in this cell was comparable to that of cells with graphite linings, indicating similar Al activities. Cells of Ni, in fact, reached a stable counter electromotive force more quickly than cells of graphite, suggesting that a period of electrolysis was required to establish Na impregnation of the graphite surface before a coating of Al was obtained. It was concluded that Al diffused so slowly into Ni that during electrolysis Al remained on the surface at essentially unit activity. There must be some minimum C.D. below which this is not true, but the level is well below commercial levels. If electrolysis is continued too long, the melting point of the crucible will be lowered excessively by alloying, and it will perforate. This can be avoided by limiting electrolysis to 25 A/hr or less in a 250 ml crucible with a 0.7 mm wall. The results, using nickel crucibles, are shown in Table I, columns 2 and 3. It was still necessary to add the Al equivalent of the reduced species contained in the frozen electrolyte (measured by H_2 evolution) to obtain agreement with industrial current efficiencies. Agreement with industrial practice was better when correlation was based on cathode current density rather than anode current density. The most significant improvement of current efficiency resulted from lowering the NaF/AlF_3 ratio of the electrolyte which also lowers the liquidus temperature allowing a lower operating temperature.

It is believed that water removal by pre-electrolysis below the Al deposition potential, but above the H_2 deposition potential, would be an improvement in technique. Another possible improvement is to add a small measured quantity of Al at the start of electrolysis to quickly establish a metal pad, establish unit Al activity and, if pre-electrolysis is not employed, to remove moisture.

Hydrogen Evolution Reaction on Platinum in Liquid Ammonia

C. Lamarre* and A. K. Vijh*

Hydro-Quebec Institute of Research, Varennes, Province of Quebec, Canada

In our recent attempts to synthesize ethylamine by cathodic reduction of an aldimine in liquid ammonia by means of an hypothetical reaction

$$CH_3 - CH{=}NH + 2NH_4^+ + 2e \rightarrow CH_3 - CH_2 - NH_2 + 2NH_3$$

it was observed that the above reduction does not proceed in practice. The reduction of aldimine was attempted on platinum in solutions containing NH_4Cl dissolved in liquid ammonia. For obtaining the general background information on the system, potentiostatic and potentiodynamic polarization studies were conducted on platinum cathodes in (NH_4Cl in NH_3) solutions in several runs, before attempting the actual synthesis in ($CH_3 - CH{=}NH + NH_4Cl + NH_3$) solutions.

The data obtained in the (NH_4Cl in NH_3) solutions are reported here since they reveal some features of the hydrogen evolution reaction (h.e.r.) on platinum in liquid ammonia, a problem on which there is no previous information, it is believed, available in the literature. Since these studies were not conducted with the aim of examining the detailed mechanism of h.e.r., they are necessarily quite brief in nature.

Experimental

The experimental procedures have been described in detail in a recent publication in which anodic behavior of several materials in liquid ammonia (1) was examined. Smooth platinum cathodes were used. A variety of counterelectrodes was tried and the least corroding were found to be those fabricated from pyrolytic carbon. The electrode potentials in the following results refer to the hydrogen electrode in the same solution, *i.e.*, 1g NH_4Cl in 150 ml of liquid ammonia.

Results and Discussion

On cathodization of smooth platinum in (NH_4Cl in NH_3) solutions, hydrogen evolution is observed to occur. In Fig. 1, potentiostatic current-potential relationships, both in the ascending and descending directions of potential, for the h.e.r. are presented. The Tafel slope observed is *ca.* 140 mV and hence roughly equal to $2.3 \times 4\ RT/F$ since $2.3 \times 2\ RT/F$ in this system (−73°C) is 79 mV.

In the potentiodynamic profiles conducted over a wide range of potentials and at a number of sweep rates, no peaks are observed thus indicating that the electrode is not appreciably covered by adsorbed hydrogen during the h.e.r. A typical potentiodynamic profile is shown in Fig. 2.

The hydrogen evolution in this system would occur by means of the over-all reaction

$$2\,NH_4^+ + 2e \rightarrow 2\,NH_3 + H_2 \qquad [1]$$

which may be assumed to proceed via the following elementary steps

$$Pt + NH_4^+ + e \rightarrow Pt - H + NH_3 \qquad [2]$$

followed by

$$Pt - H + NH_4^+ + e \rightarrow Pt + H_2 + NH_3 \qquad [3]$$

or

$$Pt - H + Pt - H \rightarrow 2\,Pt + H_2 \qquad [4]$$

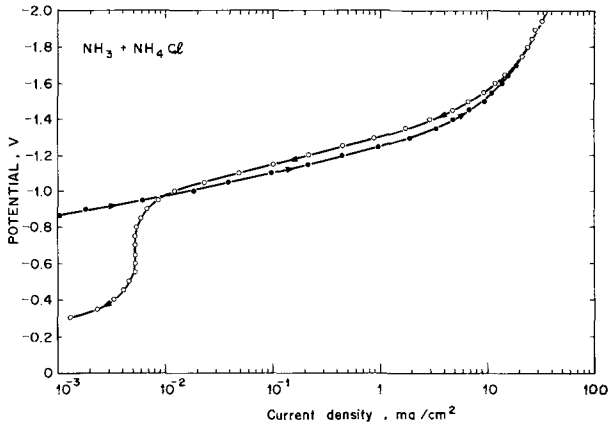

Fig. 1. Potentiostatic, steady-state (point-by-point) current-potential relationships for the electrolytic hydrogen evolution reaction on smooth platinum in (lg NH_4Cl in 150 ml of liquid ammonia). The Tafel slope, both in the ascending and descending direction of potential is *ca.* 140 mV, *i.e.*, 2.3 × 4 *RT/F* at the temperature of the experiments (−73°C).

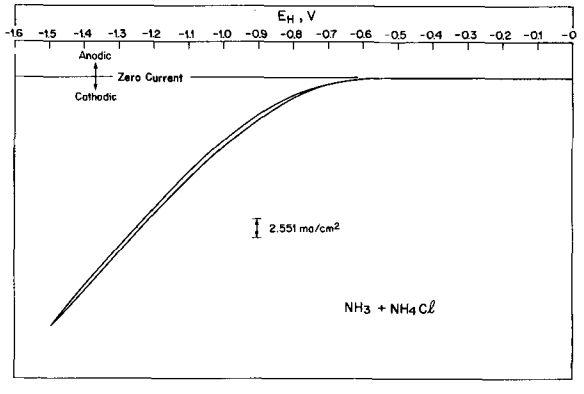

Fig. 2. A typical potentiodynamic profile on platinum in (lg NH_4Cl in 150 ml of liquid ammonia). Absence of any adsorption-desorption peaks may be noted. Sweep rate is 0.15 V sec^{-1}.

Since no electrode coverage is indicated in the potentiodynamic profiles (Fig. 2), the initial discharge step, *i.e.*, reaction [2] above may be deduced as the rate-determining step (rds) on the basis of general electrode-kinetic considerations (2-4). However, the Tafel slope consistent with this suggestion would normally be expected to have a value of 2.3 × 2 *RT/F*, as contrasted to the experimental slope of 2.3 × 4 *RT/F*. The experimentally observed Tafel slope has an anomalously high value in the sense that the usual theoretical procedures (2, 3) always give values equal to or lower than 2.3 × 2 *RT/F*, both under Langmuir and Temkin conditions of adsorption. Several explanations are available in the literature (2, 3) for rationalizing the values of Tafel slopes as high as 2.3 × 4 *RT/F* and some of them are: presence of a solid film on the electrode; potential-dependent adsorption of impurities, which appears unlikely in the present case (though not conclusively excluded) since elaborate care was taken (1) to minimize the presence of impurities in the present system; significant participation of proton tunneling (2, 5). In our case since the experiments were conducted at low temperatures (−73°C) it is possible that proton tunneling plays a significant role. The theoretically predicted Tafel slope for the initial discharge step occurring via a tunneling mechanism, as suggested here, has been derived by Conway (5) to be 2.3 × 4 *RT/F*, *i.e.*, close to the experimental value reported here.

The observed Tafel slope can also arise if filming of the electrode takes place, *e.g.*, by means of a reaction such as

$$Pt + NH_4^+ + e \rightarrow Pt—NH_4 \qquad [2a]$$

Such a filming process is indeed somewhat suggested by the hysteresis in the ascending and descending current-potential relationships in Fig. 1. Here, it is not implied that reaction [2a] is the only process by which filming can occur; in fact any conceivable process leading to a film (*e.g.*, chemisorbed radicals) will result in the enhancement of the 2.3 × 2 *RT/F* slope. For example, reaction [2a] could, at least hypothetically, be followed by a chemical step such as

$$Pt—NH_4 \rightarrow Pt—NH_2 + H_2 \qquad [5]$$

with the filming effect now arising from the chemisorbed $-NH_2$.

It is perhaps relevant to comment further on the significance of Fig. 2. For depicting the complete potentiodynamic profile, as in Fig. 2, over the potential region *ca.* 0.0 to −1.5V, it was necessary to employ low sensitivity on the current scale. In the actual experiments, however, the various regions of the profile were visually examined at high sensitivities in order not to miss any capacitative currents. One is thus quite safe in deducing the lack of appreciable electrode coverage by adsorbed hydrogen under steady-state electrolysis in the present system.

Conclusion

In the hydrogen evolution reaction on smooth platinum in liquid ammonia (at −73°C), a Tafel slope of ca. 2.3 × 4 *RT/F* is observed and an absence of appreciable electrode coverage by adsorbed hydrogen, as deduced from potentiodynamic profiles, is indicated. These results have been concluded to be consistent with a mechanism in which the h.e.r. proceeds with initial discharge step as the rds. The discharge occurs either via a proton tunneling mechanism or, alternatively, it proceeds onto a filmed electrode.

Acknowledgments

The authors thank Mr. R. Jacques for his skillful experimental assistance. Dr. G. Bélanger is thanked for some discussions. The authors are grateful to Dr. P. Lenfant for his interest and encouragement.

Dimensionless Correlation of Mass Transfer in Wire Electroplating Cells of Various Designs

Aladar Tvarusko*

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

A large portion of past fluid flow, heat, and mass-transfer studies in and around cylinders was made in simple geometries to facilitate the correlation of the results. Some of the technologically important systems, such as wire electroplating, are usually more complex and difficult to interpret. The purpose of this note is to correlate the diffusion-limited mass-transfer rates measured at a horizontal wire in cells of various designs in terms of dimensionless parameters.

The fluid flow in various wire electroplating cells with axial, normal, radial, or tangential fluid inlets and outlets has been described earlier with details of the cell designs (1). The limiting current densities, I_L, were also measured (2) in these cells as a function of volumetric flow rate, Q, during the reduction of ferricyanide ions in a large excess of supporting electrolyte at a stationary, horizontal, nickel-wire electrode. It was found that (*i*) the fluid velocity and its uniformity near the wire was greatly influenced by the cell design, (*ii*) log I_L increased linearly with log Q in all cells, and (*iii*) the rate of this increase and the magnitude of I_L were cell-design dependent in view of point (*i*).

The I_L values were measured in an alkaline solution of potassium ferro/ferricyanide which is well suited for the measurement of the diffusion-limited mass-transfer rates but not for wire electroplating. These results, however, can be generalized with the help of dimensionless groups containing several variables and thus applied to the electrodeposition of metals on wire. The various dimensionless numbers are very useful for the correlation of experimental data and development of functional relationships, and are widely used in fluid dynamics, heat, and mass-transfer studies.

The flow of fluids in geometrically similar systems is characterized by the Reynolds number, Re which is the ratio of inertia force to the viscous (friction) force. It is given by $\mathrm{Re} = UL^*/\nu$ where U is the average fluid velocity, L^* is a characteristic length of the system (*e.g.*, diameter or length of a body), and ν is the kinematic viscosity of the fluid. The average fluid velocity is given by $U = Q/S$, where S is the free cross-sectional area of the plating chamber normal to the dominant flow direction.

A cursory inspection of the various cells in Fig. 1 [see (1, 2) for details] indicates that the cells are geometrically not similar. This means that the frequently used equivalent dimension will give only a first approximation and the ultimate correlations will have to take into consideration several geometric factors.

The Schmidt number, Sc is widely used in problems of diffusion in flow systems and depends only on the properties of the medium. It is given by $\mathrm{Sc} = \nu/D$ where ν is the kinematic viscosity and D is the molecular diffusivity; Sc is large ($\sim 10^3$) for aqueous solutions.

The mass-transfer rate is characterized by Sherwood number, Sh. For a solution with an excess of supporting electrolyte it is given by $\mathrm{Sh} = I_L L^*/zFDC_o$ where L^* is a characteristic linear dimension, C_o is the bulk solution concentration, and the rest have their usual meanings. It is clear that the I_L values may be obtained from the Sherwood numbers for any concentration in the same or other solution.

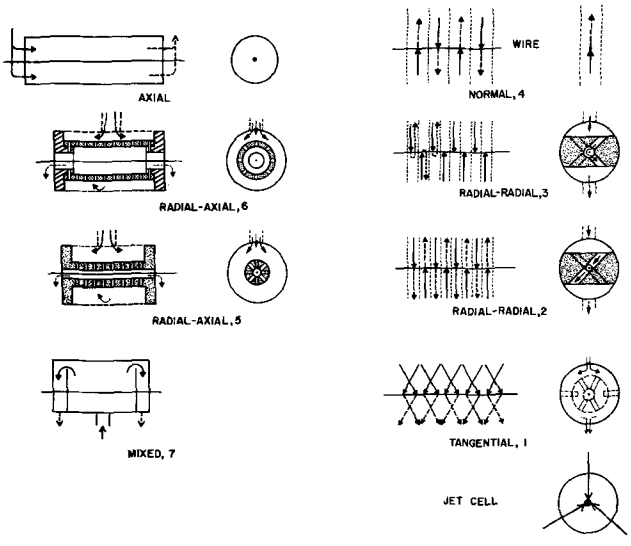

Fig. 1. Schematic illustrations of various cell designs

The diffusion coefficient of the ferricyanide ion, D, and the kinematic viscosity, ν, of the solution were calculated from the equations of Gordon *et al.* (Eq. [30] and Eq. [26], [27], respectively in (3)) to be $D = 6.19 \times 10^{-6}$ cm²/sec and $\nu = 0.0107$ cm²/sec which were used for all calculations. These values compare favorably with the values of Bazan and Arvia (4): $D = 6.84 \times 10^{-6}$ cm²/sec and $\nu = 0.0110$ cm²/sec.

Results and Discussions

The I_L values in simple tubular cells were found to decrease with increasing cell length, L (2). Dimensionless correlations for heat and mass transfer in circular tubes or annuli show that the Sh is a function of Re, Sc, and geometry (5, 6). According to Ross and Wragg (5), log Sh linearly depends on log ($\mathrm{Re} \cdot \mathrm{Sc} \cdot d_e/L$) and the slope of the line is influenced by the nature of the fluid flow and its intercept by the annulus radius ratio. This linear correlation can be clearly seen in Fig. 2 for the axial flow in tubular cells. The slope of the regression line should be either 0.33 for a fully developed laminar flow or 0.50 for a developing laminar flow (5). The slope of the experimental line, B, however, is 0.41 (Table I), which is equidistant from both values indicating the presence of a laminar flow in various stages of development. This is not surprising since the short

Key words: mass transfer, influence of fluid flow, cell design, wire electroplating, dimensionless correlation.

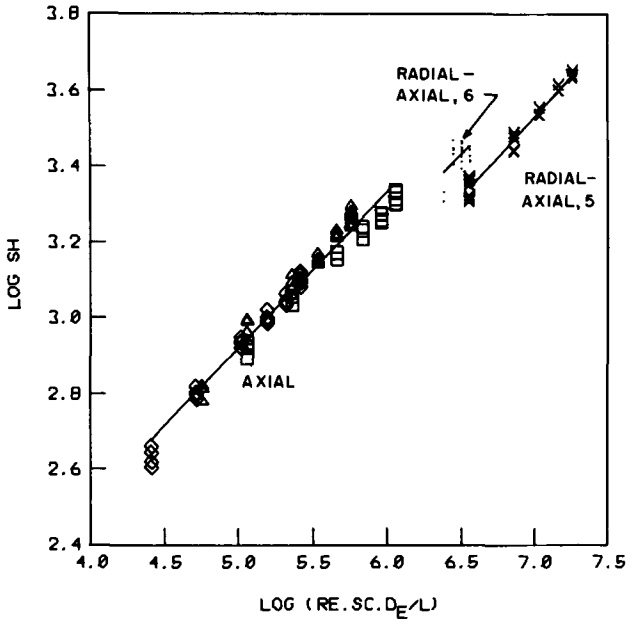

Fig. 2. Mass transfer in axial or predominantly axial-flow (radial inlets, axial outlets) regimes as a function of dimensionless groups containing the Reynolds and Schmidt numbers, the equivalent diameter and length of the tubular cell. The regression line constants are given in Table I.

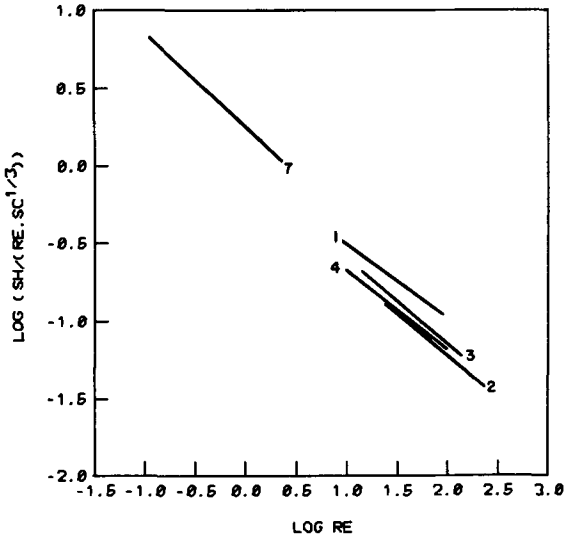

Fig. 3. Correlation of Chilton-Colburn j-factor for mass transfer in cells with normal, radial, or tangential flows. The regression line constants are given in Table I.

doughnut-shaped reservoirs at the fluid entrance and exit are not ideal hydrodynamic entry regions for either case.

In view of the absence of a well-defined flow condition in the tubular cells, the intercept is not expected to correspond to that predicted for either flow. The correlation of Ross and Wragg for a developed laminar flow (Eq. [9] in (5) in logarithmic form) predicts 0.554 for the intercept at our annulus radius ratio of 0.0131 and the experimentally obtained intercept is 0.861. This means that the experimental values are higher by a factor of approximately 2 than those predicted for a developed laminar flow.

A simple circular tube has a well-defined characteristic linear dimension, *e.g.*, length or diameter and the latter is usually preferred for the calculation of Re and Sh. The more complex conduits can be characterized by a number of linear dimensions but their use is cumbersome. Therefore, a simple characteristic linear dimension, the so-called equivalent diameter, d_e is preferred. The choice of the equivalent diameter is critical and must be characteristic for the system. In the case of annulus, d_e simple equals the difference of the outer and inner diameters and this was used in Fig. 2 for the axial flow correlation.

The plating chamber of an electrochemical cell with predominantly axial fluid flow can be considered as a closed conduit and its equivalent diameter can be easily obtained. It is 4 times the hydraulic radius which is the ratio of the cross-sectional area to the wetted perimeter of the plating chamber of constant cross section (7). If the cross section of the horizontal chamber (filled with fluid) is nonuniform, as in the case of the cells with radial inlets and axial outlets (Fig. 1), the volumetric hydraulic radius is used which is defined as the ratio of the volume of free space to the area of wetted surface (7). The results for two cells with radial-axial flow are also shown in Fig. 2 and were obtained using the following data: Line 5—d_e = 1.59 cm, L = 5.28 cm, S = 0.158 cm^2; Line 6—d_e = 1.49 cm, L = 5.26 cm, S = 0.633 cm^2. The correlation for all these axial flow cells is remarkable especially in view of the different designs and simple geometrical characterization.

The mass transfer in cells with dominantly axial flow was treated as that in a conduit of certain diameter and lengths (Fig. 2.) The mass-transfer data for cells with flow normal and radial to the wire surface are correlated separately owing to the nature of the fluid flow and are shown in Fig. 3. The diffusion-limited mass-transfer data are expressed as the Chilton-Colburn j-factor for mass transfer (6) which is the ratio of the Sh to Re · Sc$^{1/3}$ and is widely used in mass-transfer studies. The j-factor is independent of the characteristic length since it is present in both Sh and Re. The j-factor is correlated as a function of Re in which the wire diameter is the characteristic length. Figure 3 reveals that the correlation is remarkable for these cells of various designs.

A comparison of the present results with the available ionic mass-transfer data at large cylindrical electrodes in normal flow (8, 9) reveals that the B-values (Fig. 3, Table I) are similar to those published (−0.44 to −0.58). The coefficients of the exponential term (corresponding to the intercept values in Table I) are within the range of 0.557-0.920 which are similar to those in the literature [0.48 to 1.2 (8, 9)]. In view of the resemblance of the cell with a transverse flow in alternate directions (Line 4) to that used by Rao *et al.* (9), these two results will be compared. In order to account for the observed influence of the wire diameter, they (9) use $\sqrt{dL_E}$ for the characteristic length in Re, where d is the diameter and L_E the length of the electrode. The correlation obtained with this Re for the aforementioned cell is given by j = 1.493 Re$^{-0.51}$ which is comparable to their correlation j = 0.987 Re$^{-0.50}$.

In the case of the jet cell with three slots, the slope of the log I^*_L − log Q is near unity (2) and thus the j-factor − Re correlation would be of little use. The data can be advantageously represented by Sh/Sc$^{1/3}$ = 0.0127 Re$^{1.04}$ where Re is based on the wire diameter. It is interesting to note that Davies and Ting (10) studying the absorption of CO_2 into water jets found the mass-transfer rate to be proportional to Re$^{1.05}$ for turbulent jets exiting from "s" type nozzles with small length to orifice diameter ratio.

Table I shows the numerical values of the regression line intercepts and slopes and the results of the statistical analysis. The linear regression analysis of all data is statistically significant at greater than 99.9% with the exception of Line 6 (>99.0) which is presented for the sake of completeness. The coefficients of correlations are high with the exception of the aforementioned Line 6 and the jet cell with slots which was studied in a narrow range of fluid flows. The following can be said with 95% confidence: (*i*) The slopes are the same for cells with axial or predominantly axial

fluid flow (Fig. 2) and the intercepts are slightly different; (*ii*) For cells with nonaxial flow (Fig. 3) the regression line constants are different and depend on the pattern of the fluid flow. The three subgroups are indicated by the dashed lines. At higher confidence levels the differences would be significantly smaller; and (*iii*) The cell with fluid jets is distinctly different from the other cells in which the wire is surrounded by a large volume of solution.

Conclusion

Mass-transfer results obtained in wire electroplating cells were correlated and generalized with the help of appropriate dimensionless numbers. As a first approximation, the flow regimes in cells of various designs were characterized by Re number and a geometric factor and the correlations are significant. No single correlation has been obtained for the three cell groups of different flow regimes due to the simple representation of complex cell geometries and absence of hydrodynamically well defined fluid flows in the plating chambers. These results, however, can serve as the basis for scale-up and modeling of wire electroplating processes and be directly applied to small scale wire electroplating lines used, *e.g.*, for the electrodeposition of Ni-Fe alloys for magnetic plated wire memories.

SOLID-STATE SCIENCE AND TECHNOLOGY

JANUARY 1973

On the Formation of Surface States during Stress Aging of Thermal Si-SiO_2 Interfaces

A. Goetzberger,*,[1] A. D. Lopez, and R. J. Strain*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Under combined bias and temperature stress, the silicon-silicon dioxide interface is altered by the introduction of more surface states. This effect has been investigated in metal-oxide-semiconductor structures formed by a variety of oxidizing, annealing and metalizing procedures. In most cases, stress of 10^6 V/cm at 300°C caused a surface-state peak to appear in the lower half of the bandgap. The surface-state *vs.* energy curves vary with the oxidation conditions, but they are reproducible when sample preparation is reproduced. The influence of the following parameters was investigated: dry oxygen and steam oxidation, Cr-Au and Al contacts, e-gun and filament evaporation and post-metalization annealing. The surface-state density increases linearly with applied field, and it increases in proportion to the logarithm of time. The nature of the distribution also depends on the annealing procedures, and on the contact metal.

It is well known that fixed positive charge and fast surface states are created in Si-SiO_2 interfaces when negative bias is applied at elevated temperature to the gate electrode of an MOS capacitor (1-4). Deal *et al.* (1), in investigating the kinetics of this process, found that approximately equal amounts of surface charge and surface states are created. Arnold (5), using an IGFET conductance technique, discovered a sharp surface-state peak at 0.32 eV below midgap after negative bias had been applied to the sample at 250°C.

The purpose of the present work was to obtain more detailed information on the nature of stress induced surface states in oxides prepared in various ways. A rapid technique for evaluating surface-state distributions, the quasi-static C-V technique (6, 7) was utilized in these studies. In addition to the changes of surface-state densities, changes of flatband voltage upon aging were investigated.

Preparation of Samples

Metal oxide silicon samples were prepared by twelve different process sequences. Multiple samples were prepared in many cases, so that 23 samples were investigated in total. Most of the samples were made with <100> n-type silicon, although <111> and p-type samples were also tested.

The twelve processes are detailed in Table I. All of the oxides were grown to a thickness of 1000Å, and the first six (Roman I-VI) were prepared in horizontal tube furnaces using standardized, semiproduction conditions. This group includes both steam and dry oxides, and a variety of low-temperature anneals.

Table I. MOS sample preparation

	Oxidation		Anneal			Contact		Anneal		
	Atm	Temp (°C)	Atm	Time	Temp (°C)	Metal (Å)	Source	Atm	Time	Temp (°C)
I	O_2	1100	H_2	30	350	200 Cr / 3000 Au	Filament	—	—	—
II	O_2	1100	—	—	—	2000 Al	e-gun	H_2	30	350
III	O_2	1100	—	—	—	3000 Al	Filament	H_2	30	350
IV	Steam	950	—	—	—	2000 Al	e-gun	H_2	30	350
V	Steam	950	—	—	—	200 Cr / 3000 Au	Filament	—	—	—
VI	O_2	1100	—	—	—	200 Cr / 3000 Au	Filament	—	—	—
HE 1	O_2 (Cold-Wall)	1000	He (Cold-Wall)	30	1000	200 Cr / 3000 Au	Filament	H_2	30	350
HE 2	O_2 (Cold-Wall)	1000	He (Cold-Wall)	30	1000	2000 Al	e-gun	H_2	30	350
H_2-1	O_2 (Cold-Wall)	1000	H_2 (Cold-Wall)	30	1000	200 Cr / 3000 Au	Filament	H_2	30	350
H_2-2	O_2 (Cold-Wall)	1000	H_2 (Cold-Wall)	30	1000	2000 Al	e-gun	H_2	30	350
DI 1	$SiO_2 + Al_2O_3$ (see text)					200 Ti / 2000 Al		N_2	30	350
DI 2	$SiO_2 + Al_2O_3$		N_2	30	1100	200 Ti / 2000 Al		N_2	30	350

The four oxides identified by He and H_2 were grown under laboratory conditions, using a cold-wall system, with an rf heated silicon susceptor and a water-cooled quartz envelope. Perhaps more significantly, all these samples received a high-temperature anneal in either helium or hydrogen.

The final pair of samples (DI 1 and 2) were prepared at Bell Laboratories, Allentown, Pennsylvania. These samples had a two-layer dielectric, 1000Å of steam grown SiO_2 covered by 500Å of pyrolytic Al_2O_3. These films were produced according to the procedures described by Tung and Caffrey (9), and their electrical properties were described by Nigh (10). The two samples differ by the inclusion of a high-temperature inert gas anneal between the silicon oxidation and alumina deposition in the preparation of lot DI 2.

This diverse group of oxides was subjected to the experimental aging evaluations described in the next section.

Procedure for Stress Aging and Evaluation

Fundamentally, the experimental procedure consisted of two steps: accelerated aging of the MOS capacitors under combined electric and thermal stress, and evaluation of changes in interface properties.

Figure 1 shows the apparatus in which the temperature and bias stressing was done. The silicon slices with MOS capacitors were placed on the heated stage and bias was applied to the metalizations with wire probes. For most of the experiment, the standard stress-aging condition was 30 min at 300°C with −10V applied to the field-plate. Not visible in Fig. 1 is the stainless-steel cover which was used over the probe system; during the stressing, this cover was in place and the system was fed a steady flow of line nitrogen.

The evaluation of interface properties included shifts of flatband voltage and changes of the energy distribution of surface-state density. Surface-state density was extracted from plots of the high- and low-frequency C-V curves using a quasi-static (sweep rate between 50 and 100 mV/sec) low-frequency curve and a 1 MHz high-frequency curve on the same capacitor. According to Ref. (6) and (7) those two capacitance values can be used to obtain surface-state density N_{SS}

$$N_{SS} = \left[\frac{C_{LF}}{C_{ox} - C_{LF}} - \frac{C_{HF}}{C_{ox} - C_{HF}}\right] \frac{C_{ox}}{qA}$$

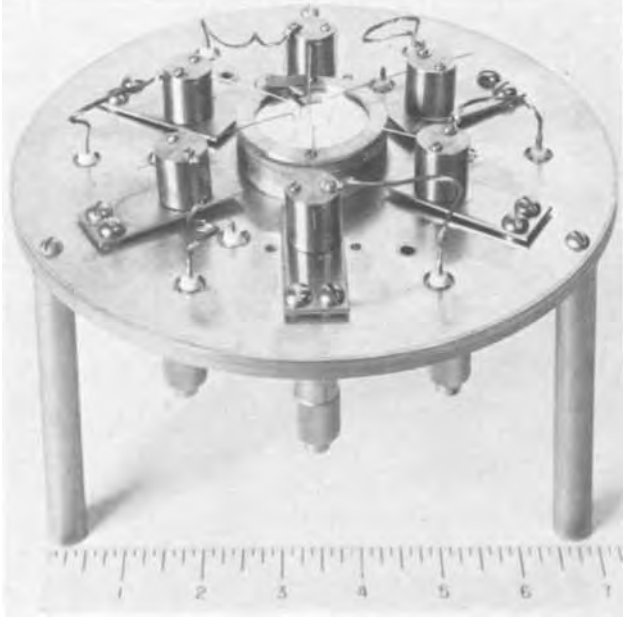

Fig. 1. A photograph of the stress-aging apparatus, with the cover removed to show the heater in the center, and probes mounted on magnets.

where C_{LF} = low frequency capacitance, C_{HF} = high frequency capacitance, C_{ox} = oxide capacitance, A = area of contact, and q = elementary charge. The validity of this equation is limited on one side of the energy gap by the onset of inversion and on the other side by the fact that surface states with short time constants contribute to the high-frequency capacitance. Figure 2 shows a typical group of high- and low-frequency curves, from which surface-state densities have been extracted.

In order to extend the range of the measurement and check consistency of results, stressing for most oxidation conditions was done on n-type as well as p-type samples. The results were in good agreement, as the next section will show.

Surface potential is obtained from the low-frequency curve by integration as described by Berglund (11). The undetermined additive constant was found in one of two ways: The integration was carried from accumulation to inversion and the total integrated surface potential was compared to the bandgap of 1.1 eV. Since the band edges are never quite reached, the total integrated surface potential was lower than 1.1V. The difference between the two was divided by two and added to the measured surface potential. This procedure assumes that the surface potential comes equally close to the band edges in the flat capacitance portions of accumulation and strong inversion. Good agreement was found between this method and another in which a point between flatband and inversion was selected on the high-frequency C-V curve and its surface potential obtained by comparison with the ideal curve. The flatband point per se is not too suitable for this adjustment because at this point some surface states may follow the applied high-frequency signal.

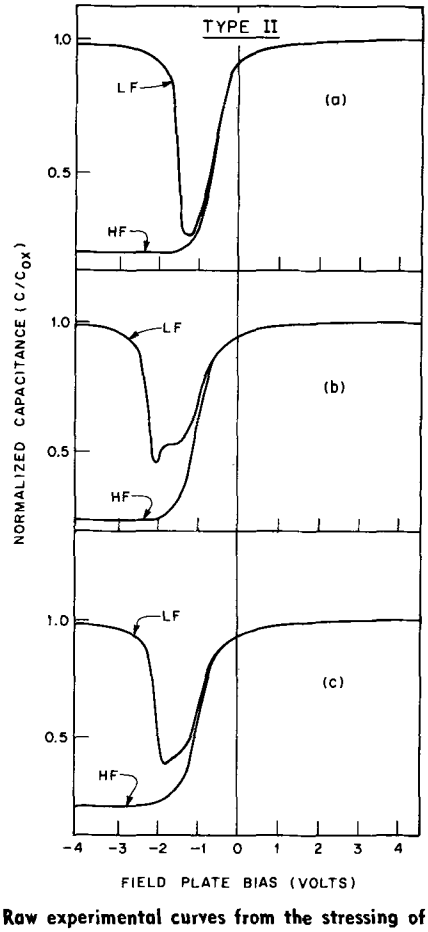

Fig. 2. Raw experimental curves from the stressing of the Type II oxides on n-silicon. The high-frequency curves (HF) are taken at 1 MHz, and the low-frequency curves are taken using the quasi-static technique.

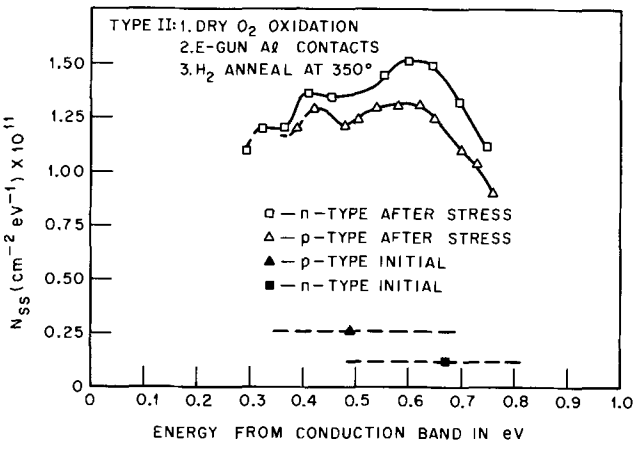

Fig. 3. Surface-state densities calculated from pairs of curves like those shown in Fig. 2. These results pertain to the type II oxide, which is grown dry, then contacted with e-beam evaporated Al, and annealed.

It was found that in the system used for aging the oxides, heat alone affected the oxides under certain conditions. This was particularly true of oxides I, V, and VI, which had Cr-Au contacts; as contacted all these samples had room temperature hysteresis and a relatively high surface-state density. These faults were eliminated by a very brief heating to 300°C in nitrogen. Consequently, all these samples were brought to a standardized initial condition by a short exposure to 300°C in the stressing chamber.

Summary of Results

The most marked feature of the stress aging is the development of a broad, but readily identifiable peak in surface-state density near midgap. This is illustrated by Fig. 3, which shows surface-state densities both before and after stressing for p- and n-type samples of the devices from group II. These curves were calculated from data like that shown in Fig. 2. These particular results show two distinct peaks; this is seen in certain other samples as well, but for the most part the aging will be characterized by the energy and amplitude of the higher peak. Examples of the more prevalent stress induced surface-state distribution, a single peak, are shown in Fig. 4. These distributions were observed after stressing the high-temperature annealed oxides.

Table II gives a summary of the test results on samples I-VI and the two DI samples, and Table III summarizes the tests on the samples prepared and annealed in the cold-wall system. These tables give brief

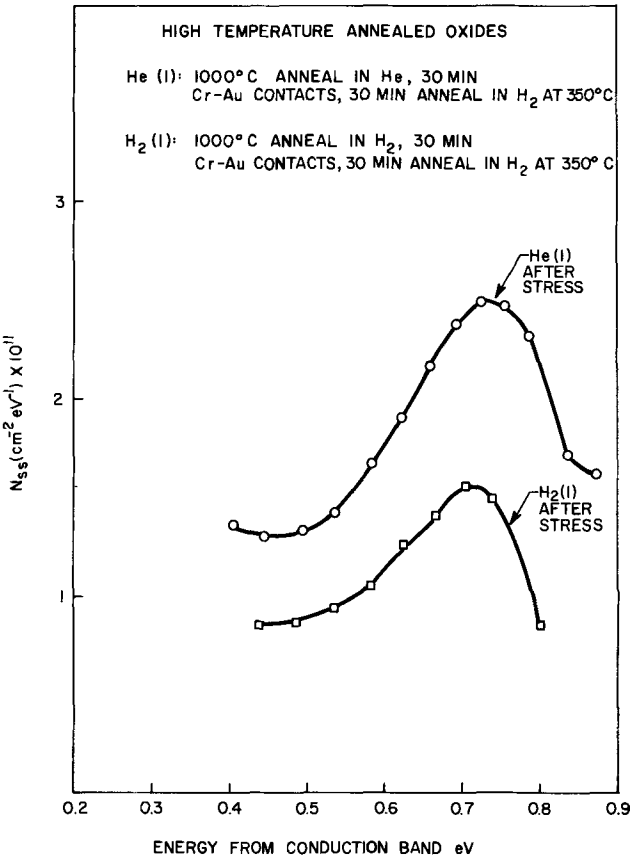

Fig. 4. Experimental surface-state distributions observed after stress aging dry, high-temperature annealed SiO_2. These oxides were annealed at 1000°C in either helium, sample He(1), or hydrogen, sample H_2(1). After contacting with CrAu they got a final anneal at 350° in hydrogen.

summaries of the processing, values for the surface-state densities and flatband voltages before and after stressing, and the apparent center energy of the largest induced surface-state peak. Two regularities are quite apparent when the surface-state data are scrutinized. The first has been observed frequently in the past; the largest increase in surface-state density is correlated with the largest initial density. Figure 5 illustrates this by a plot of final N_{SS} values against initial N_{SS} for all twenty-three test slices. Also shown is the (logarithmic) regression line for this data. The correlation is very good, and the slope is six times larger than the standard deviation about the regression line.

The second regularity is less expected. The energies of the peaks fall into distinct groups by metal. Figure 6 illustrates this by presenting the peak locations for all the samples. The energies fall into four groups with the following mean energies: 0.47, 0.57, 0.61, and 0.75 eV. These metal dependences may be related in some way to the contact dependent surface-state densities seen with very thin oxides (12).

Measurements were also made with positive bias, but the surface-state changes were much more modest with positive bias, although increases were observed. This experiment was made more complicated by the existence of positive ion contamination in many of the samples. The consequences of stress and ion drift were separated by lowering the temperature to 90°C and applying negative bias after positive bias stressing at 300°C. Because the ion trapping at the $Si-SiO_2$ interface is very weak (13), the ions could be swept away without affecting the stress results.

Shifts in flatband voltage were also measured, and these results appear in the last two columns of Table II. While these results are more susceptible to ion contamination, there are some fairly clear tendencies in the data. These are illustrated by the histograms of Fig. 7. Although they are superior in most other respects, the samples with electron beam evaporated aluminum contacts, show large and erratic shifts in flatband voltage. This can be attributed to latent damage (14) from the soft x-rays associated with electron impact on the target. Though the x-radiation effects appear to be totally removed by the low-temperature hydrogen anneal, the application of negative bias, temperature stress leads to a "slow trapping" type of instability. On the other hand, there seems to be no latent damage in those samples which were treated at high temperature after oxidation.

A correlation analysis has been done to ascertain the inter-relationship in this experiment between the surface-state creation and the flatband shift. The correlation is very slight, and statistically insignificant.

The surface-state generation has been examined more closely; the voltage and time dependence of surface state density were evaluated using type II oxides (dry thermal oxides with e-beam Al contacts). For the voltage dependence measurements the stressing conditions were 15 min at 300°C, initially unstressed dots receiving stress at various voltages. Typical surface-state distributions are shown in Fig. 8, where a sequence of peaks can be seen emerging near midgap. If the surface-state density in the highest peak is

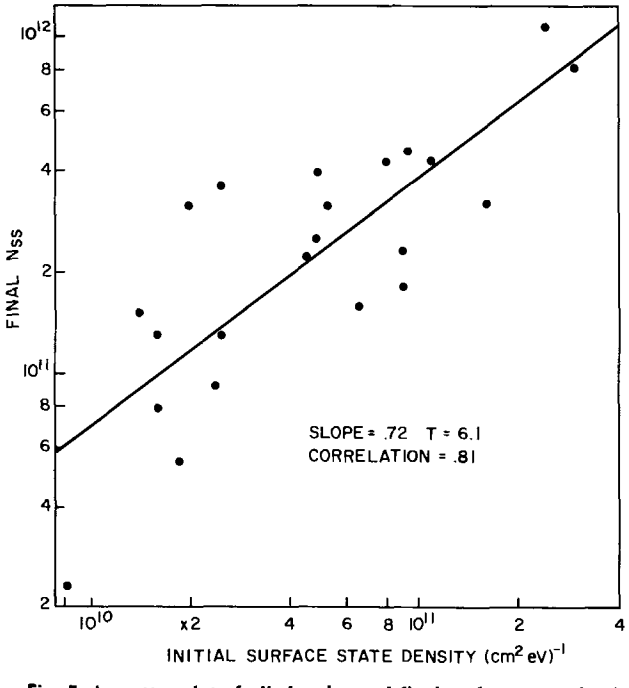

Fig. 5. A scatter plot of all the observed final surface-state densities as a function of the initial surface-state densities, showing the degree of correlation between initial and final values. The logarithmic slope of the best fit line is 0.72, *i.e.*, the rate of increase is slightly sublinear in the initial N_{SS}.

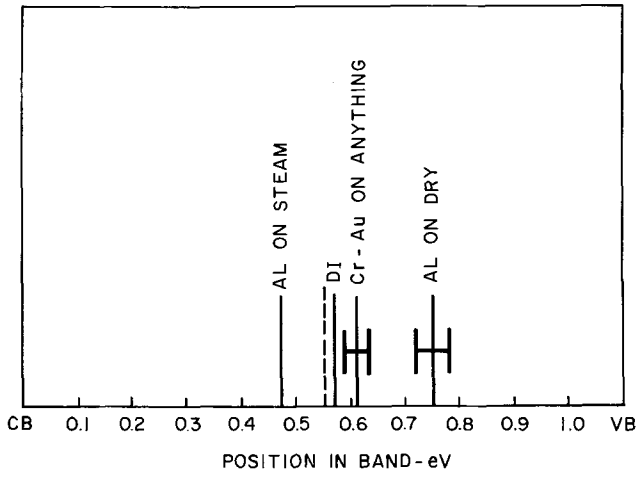

Fig. 6. A diagram showing how the stress induced surface-state peak locations are grouped in the bandgap, according to the processing, particularly metalization.

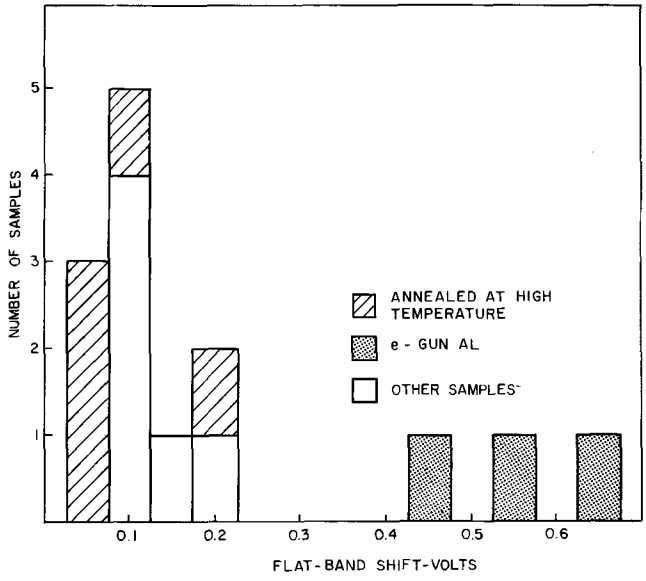

Fig. 7. A histogram showing the grouping of slow-trapping flatband shifts. Note the relative positions of high-temperature annealed oxides, and e-beam evaporated samples.

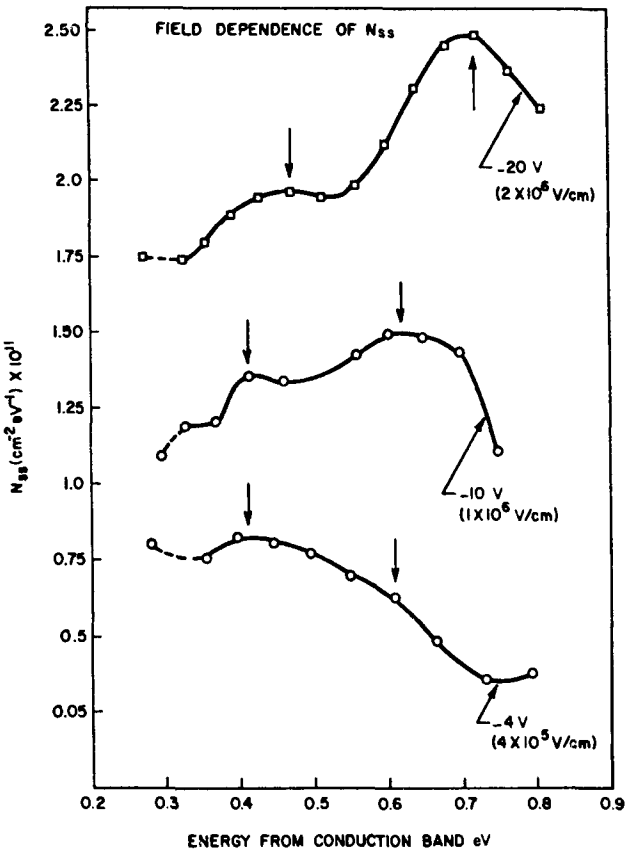

Fig. 8. Experimental surface-state distributions after 15 min of stressing of —4, —10, and —20V. The oxide in this case is the type II dry oxide.

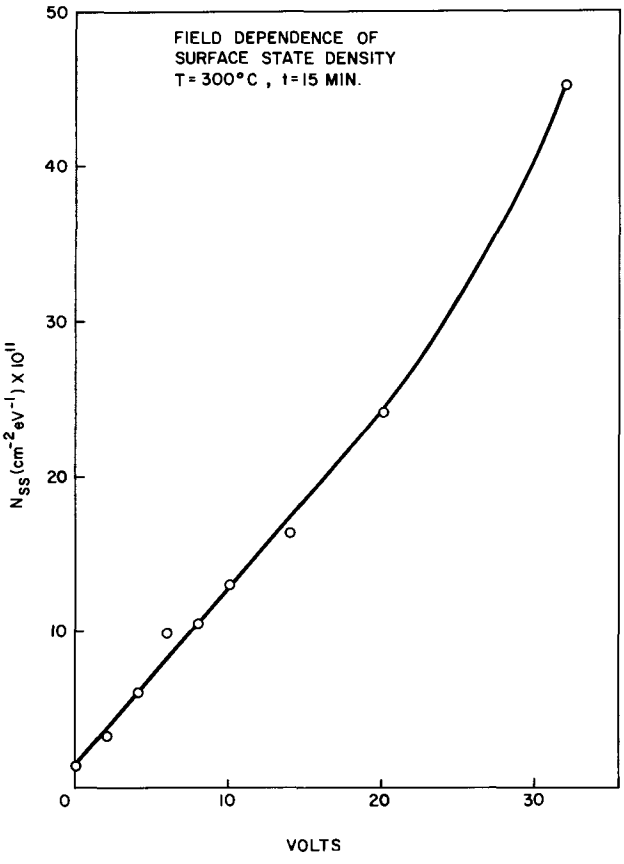

Fig. 9. A curve showing the essentially linear dependence of surface-state densities on stressing voltage. There does not appear to be a threshold for this effect.

plotted against voltage, a linear relationship emerges, as illustrated in Fig. 9.

Walden (15) has shown that the time evolution of charge crossing a barrier because of a high electric field frequently follows a log (t/t_0) law. Following this principle, the increase in surface-state density as a function of time has been plotted in Fig. 10 against the logarithm of time. The log behavior is strongly indicated at both 250° and 300°C. Since the reciprocal of the zero intercept time $(t_0)^{-1}$ carries the field and temperature dependence of the current transport, the intercept times for 250° and 300°C have been used to estimate the activation energy of the process of surface-state formation to be 1.4-1.5 eV.

Discussion of Results

Although a variety of results was obtained in the course of this experiment, the stress-aging behavior of MOS devices prepared in the same way was quite consistent. There are other effects, like disequilibrium during low frequency measurements (16) and gross nonuniformities (17, 18) which can give the appearance of surface-state peaks. These two possibilities can be ruled out; the first because the ramp measurements were made at a sufficiently slow sweep rate to assure equilibrium conditions, and the second because any nonuniformities would have to arise from random defects. Excellent sample-to-sample correlations of surface-state density profiles precluded any explanations based on random nonuniformities. Thus, the results and conclusions in the following paragraphs are all attributed to surface-state effects. The formation of surface states under stress also correlated very well with the initial surface-state density of the interface. During the course of the oxide preparation, several samples had high surface-state densities due to dry oxidation (19) or due to x-irradiation by the electron gun during electrode metalizations. Subsequent to these processes the samples were annealed in hydrogen

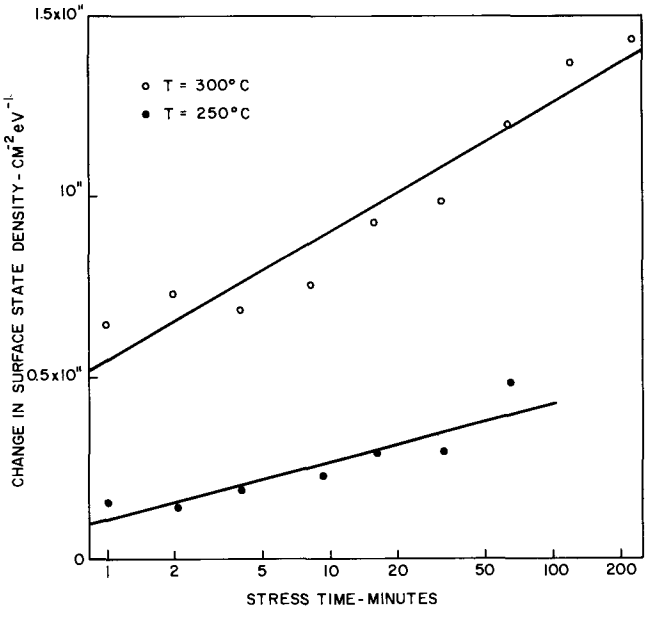

Fig. 10. The time development of surface states under stress at 10^6 V/cm at 250° and 300°C. A best fit log (time) line is shown for each set of points.

at 350°C; this process has been shown to be particularly effective in reducing surface-state densities when aluminum field plates are present (20). Deal *et al.* (21) have shown the annealing is associated with the diffusion of a contact activated species to the interface where it either compensates or annihilates the surface states. The results quoted in Table II indicate surface states are actually annihilated, because the most stable of the oxides I-VI is II, which received both dry oxidation and a large dose of soft x-rays. Had the surface

states created in these two processes merely been compensated, sample II would have been very unstable. It has not been established whether a longer anneal would have eliminated the flatband instability seen in this sample; it is likely that this is a result of residual radiation damage. This example serves to illustrate that the defects responsible for surface states are either chemically or structurally different from those leading to flatband shifts by slow trapping.

Surface-State Distributions

The surface-state distributions for the various types of oxides show distinct features which appear reproducibly in p- and n-type samples prepared in the same way. The structure in the curves and the strong dependence on the details of processing suggest complex processes at the interface. The following observations can be made by inspection of the curves: (*i*) All thermal oxides with one exception develop a surface-state density peak or at least a higher surface-state density in the lower half of the gap. (*ii*) The only exception is type IV which is a steam oxide with e-gun evaporated aluminum. (*iii*) The contact metal influences the position of the induced peak. (*iv*) The dry thermal oxide (type VI) is the only one showing an increase of the surface-state density without distortion of the distribution. (*v*) It can be observed that the p-type samples have a higher surface-state density than the n-type ones. This is in agreement with Ref. (1). (*vi*) <111> samples have the same surface-state distributions as <100> samples. Their flatband change is much more than for <100> as is well known (Table I), but the change of surface-state density is different only for the high quality type II oxide and not for type IV. (*vii*) Double-layer insulator films develop a peak of surface-state density at midgap. (*viii*) In high-temperature annealed oxides the type of contact has more influence than the annealing ambient.

Time Temperature and Field Dependence

The kinetics of surface-state growth during stress are similar to those of surface charge investigated previously. From Fig. 9 we recognized that the peak surface-state density increases linearly with field for fields below 2×10^6 V/cm. This linearity has also been observed for flatband voltage changes in Ref. (1) and (4). Just as in the case of flatband shift, there appears to be no threshold voltage for the effect.

From Fig. 8 it is obvious that the distribution during stressing does not stay the same. Two peaks of surface-state density are observed to emerge at different rates. One which is between 0.4 and 0.5 eV appears to be growing rapidly at lower fields. At higher fields it is outgrown by another peak between 0.6 and 0.8 eV. It should be noted that the same change of the density distribution can also be observed at constant field with increasing time. Therefore, it appears that the two peaks could be independent; one develops rapidly and saturates, and the other develops slowly and continues to high densities.

The energetic positions of the surface-state peaks of Fig. 8 are seen to move to higher energies. This is probably not related to intrinsic properties of surface states, but it arises from the superposition of two independent peaks of changing magnitude.

The logarithmic time dependence observed for the surface-state density increase is very much like that observed by Rossel *et al.* (22) for the field-induced change in threshold voltage in MOS transistors. The behavior was explained quantitatively on the basis of a model involving the tunneling of carriers from the silicon into the oxide. Walden's work has shown that $\log(t)$ charge dependence is common to many other charging processes; all that is required is that the particle current be strongly dependent on the interface field, and that the charged carriers become trapped near the interface, reducing the field. Possible means by which the trapped defects could form surface states include the charge model (23), and a chemical model, which requires an alteration of the chemical bond to form a defect capable of trapping electrons and holes (24).

It is unlikely that the formation of surface states is as simple as the trapping models cited above. If a trapped hole could be associated with each surface state, then a modest change in V_{FB} on n-type samples would be readily explained by the formation of donor-like states near midgap, because these would be neutral under flatband conditions. However, on p-type samples, donor-like states near midgap would be substantially ionized under flatband voltage. While on the average, ΔV_{FB} on the p-type samples is slightly larger than that on n-type, the increase is insufficient to justify an assumption of induced donor-like states; neutral states are more probable.

Evaluation of Oxide Quality

The two parameters most directly related to the quality and stability of an oxide are change of flatband voltage and surface-state density after stress. These two quantities have been combined in a single plot in Fig. 11. The surface-state density after a standard stress of 30 min at 300°C and 10V is plotted against change of flatband voltage due to stress. The best oxides are those closest to the origin. Estimated uncertainty of the points is indicated by circles. It is obvious that the most stable films are the double layer insulators. It is also interesting to note that all the points are in the upper left half of the graph. This means that it is possible to have increase of surface-state density and no change of flatband voltage, but that a change of flatband voltage is always accompanied by an increased surface-state density.

The high-temperature annealed oxides were not included in this graph because they were exclusively p-type, and it was observed that ionic contamination introduced during evaporation influenced their flatband voltages.

The question arises as to why the double layer insulators are so stable. A possible explanation lies in the fact that they were especially well annealed (25). The alumina deposition step involves annealing at 900°C in hydrogen. The importance of this step can be seen by comparing the DI 1 results (Table II) with the high-temperature hydrogen annealed oxide H_2-2 (Table III). Both behave very well during stress. An even better interface in sample DI-2 (Table II) is probably due to the 1100°C N_2 anneal which it received.

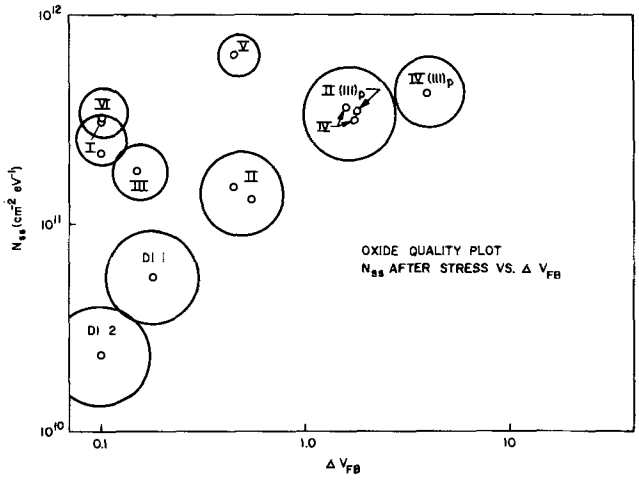

Fig. 11. This diagram summarizes "oxide quality." The oxides are plotted according to their poststress surface-state densities and flatband voltage shifts. The most stable oxides appear in the lower left corner, and the "worst" are diagonally opposite.

Conclusions

This investigation increases our knowledge about the formation of surface states in stressed interfaces. It was shown that the oxidation ambient, nature of metal contacts and postmetalization annealing are of importance for the stressing behavior. The exact physical model of the stress-induced surface states remains uncertain, although some correlation with charge transport across the interface region is likely. Simple charge trapping appears to be unlikely as an explanation for surface states, because the net apparent charge is too small.

The work reported here is strongly indicative both of the processing to use for stable oxides, and of the course of investigation to follow in order to elucidate the aging process.

Acknowledgments

The authors wish to thank M. Kuhn and J. R. Ligenza for valuable discussions and W. Powell for producing the high-temperature annealed oxide samples.

Manuscript submitted June 6, 1972; revised manuscript received Aug. 30, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Electrolytic Behavior of CaF_2 Crystals under Reducing Conditions

J. W. Hinze*,[1] and J. W. Patterson*

Department of Metallurgy and Engineering Research Institute, Iowa State University, Ames, Iowa 50010

ABSTRACT

Solid CaF_2 was studied from 550° to 800°C with fluorine chemical potentials ranging from Ni,NiF_2 to Ca,CaF_2 coexistence. Measurements of a-c conductivity and galvanic cell emf's lead to the conclusion that the ionic transference number for CaF_2 is essentially unity over the range of conditions studied and hence CaF_2 may be employed as a solid electrolyte therein.

Calcium fluoride has been used extensively (1-4) as the solid electrolyte in galvanic cells designed to determine the free energy of formation of various compounds. These measurements have been undertaken over wide ranges of fluorine activity and temperature without a very certain knowledge as to the limitations of CaF_2 as a solid electrolyte (5, 6). In this connection it is of interest to establish log P_{F_2} — $1/T$ ranges (7, 8) beyond which positive hole and/or excess electron conduction achieves a magnitude equal to or greater than about 1% of the total (ionic plus electronic) conductivity. On the basis of Wagner's theory (9-11) of mixed conduction, many experimental measurement schemes may be devised to shed light on this matter—chief among these are: a-c (total) conductivity determinations (11-13) (as a function of fluorine activity and temperature), open circuit emf measurements (14, 15) and d-c polarization measurements (13, 16-18). "Coulometric titration" variations of the polarization technique have also been developed more recently (19-21).

The need for such studies for CaF_2 has been pointed out previously (5, 6) but none have been reported to date. Wagner (22), however, has used color center migration data by Mollwo (23) in a theoretical analysis to provide an intentionally excessive estimate of the conditions wherein n-type conductivity becomes appreciable in CaF_2. The relationship of Wagner's analysis (22) to the present investigation is developed more fully below.

Previous conductivity *vs.* temperature studies on CaF_2 by Ure (24) and others (25, 26) are not very pertinent in the present context primarily because no efforts were made to establish a well-defined fluorine activity during the experiments. For the present purposes of deducing the electronic contribution to the total conductivity, it is necessary to not

Key words: solid electrolytes, calcium fluoride, electronic conductivity, ionic conductivity, ionic transference number, open-circuit emf, oxygen doping.

only fix the fluorine activity in each experiment, but also to fix it at different preselected values (at each temperature) so that the dependence of the total conductivity on fluorine partial pressure P_{F_2} and temperature can be determined. The question as to whether electronic contributions to the total conductivity are significant in CaF_2 has been left virtually unresolved by the previous conductivity studies. A recent study by Matzke (27) of the diffusivity of fluorine in CaF_2 indicates that the electrical conductivity of CaF_2 is due primarily to fluorine ions as Ure had concluded, but again no attempt was made to control the fluorine activity.

In addition to Wagner's analysis (22) previously reported open-circuit emf data provide the most direct evidence that the electrical conductivity of CaF_2 is predominantly ionic over wide ranges of temperature and fluorine partial pressure. Interestingly, the use of CaF_2 in many of these emf studies was justified on the basis of Ure's conductivity study.

The purpose of this paper is to present a-c conductivity and open-circuit emf data which indicate that the transference number for excess electron (n-type) carriers in CaF_2 is negligible even under the most reducing conditions.

Experimental Procedures and Apparatus

Fluorine activities were established by using metal, metal fluoride coexistence electrodes. Standard-free energy of formation data, $\Delta G°_f$, for the various fluorides were used to calculate the fluorine activity which is represented in terms of the effective partial pressure P_{F_2} of fluorine gas. Whenever possible, emf data were used in conjunction with calorimetric data of Rudzitis *et al.* (28) to establish the $\Delta G°_f$ values required. Markin's value (1) of -232.4 ± 0.6 kcal/mole for $\Delta G°_f(MgF_2)$ at 600°C was combined with $\Delta S°_f(MgF_2)$ deduced from standard emf *vs.* temperature plots by Hamer *et al.* (29) to give $\Delta G°_f(MgF_2)$ values over the temperature range from 500° to 850°C. This $\Delta G°_f(MgF_2)$ determination combined with emf measurements reported by Lofgren and McIver (2), Heus and Egan (3), and Rezukhina (4) served to establish $\Delta G°_f$ data for CoF_2, ThF_4, NiF_2, and YF_3 over the temperature range studied. The measurements of Heus and Egan (3) were made only at 600°C; thus, $\Delta S°_f$ values from Hamer *et al.* (29) were combined with these emf's to provide the desired $\Delta G°_f$ values. Experimental open-circuit emf data were not available for Mn,MnF_2 or Ca,CaF_2. Therefore, $\Delta G°_f$ data obtained from Hamer's compilation (29) were used to determine the P_{F_2} values for the Mn,MnF_2 electrode. Data from the JANAF table (30) for $\Delta G°_f(CaF_2)$ were used to determine the P_{F_2} values for Ca,CaF_2 coexistence.

Optical quality, high purity CaF_2 single crystal specimens were used in this study. The 1/8-in. thick specimens were purchased from the Harshaw Chemical Company as optically polished disks cut from a single crystal rod 3/4-in. in diameter with the [111] direction lying along the longitudinal axis of the rod.

The total conductivity of the CaF_2 single crystals was determined from measurements made on a number of symmetrical cells of the type

$$M,MF_n|CaF_2|M,MF_n \qquad \text{[Cell I]}$$

Both coexistence electrodes in this two-probe method are compacts fabricated from the same metal, metal fluoride mixture. The coexistence electrodes: Co,CoF_2; Ni,NiF_2; Mn,MnF_2; Th,ThF_4; Y,YF_3; and Ca,CaF_2 were employed in the a-c conductivity studies from 550° to 800°C. Open-circuit emf measurements were performed on nonsymmetric cells of the type

$$Ca|CaF_2|Th,ThF_4 \qquad \text{[Cell II]}$$

from 400° to 815°C. Encapsulation of the more volatile electrode constituents was achieved by means of graphite and stainless-steel cups pressed against the CaF_2 specimens.

All measurements were performed in purified helium atmospheres. The a-c conductivity measurements were made with the use of a Wayne Kerr transformer ratio arm bridge operated at 1592 Hz while open-circuit emf's were measured with a conventional potentiometer and a high-impedance null detector. The temperature was determined from the emf of a calibrated Pt-Pt 10% Rh thermocouple. Light spring pressure held the electrode|electrolyte|electrode sandwich in place in an alumina cell holder.

Results

The total conductivity *vs.* temperature dependences for the various coexistence electrodes are shown in Fig. 1. These data are replotted as log σ *vs.* log P_{F_2} isotherms in Fig. 2. For comparison, the log σ *vs.* log P_{F_2} isotherms predicted from Wagner's analysis (22) are shown as dashed lines in Fig. 2. The results of three open-circuit emf runs on cell II are shown on Fig. 3 along with the thermodynamic emf (sold line) predicted from $\Delta G°_f$ values for ThF_4 and CaF_2. Also shown on Fig. 3 are the open-circuit emf's (dashed lines) that would result from combining the same thermodynamic $\Delta G°_f$ data with Wagner's analysis (22). The disagreement with Wagner's estimate is not a serious matter primarily because that estimate was intentionally formulated to maximize the magnitude

of excess electron conduction in CaF_2 at low fluorine partial pressure.

Discussion

The log σ *vs.* log P_{F_2} data plotted in Fig. 2 do not indicate any rise such as would be expected from the onset of electronic conductivity at very low values of P_{F_2}. The 800°C isotherm remains flat all the way down to Ca,CaF_2 coexistence which is the stability limit of CaF_2. This is indicative of an ionic conductivity which is independent of P_{F_2} and is in accordance with theoretical predictions (22). This isotherm shows no evidence of the n-type conduction which could have occurred.

The gentle rise at the low P_{F_2} end of the lower temperature isotherms is interpreted to be an extrinsic effect and is not associated with the onset of excess electron conductivity. For example, the slope of the 550°C isotherm is only on the order of $-1/16$ and hence is quite removed from the value $-1/2$ which is to be associated with the onset of n-type electronic conduction. Also, the emf *vs.* temperature data of Fig. 3 do not exhibit any large decrease in emf at low temperature. Such a decrease would be expected if the observed conductivity rise were due to some form of electronic conduction. For these reasons the observed conductivity increase is believed to be ionic in nature and is thought to be a contamination effect.

Contamination by cations from the electrodes might appear to be a possible explanation; however, cation diffusivities in CaF_2 are known to be extremely low (24, 31-34), and this tends to rule out the cation contamination possibility. Rather, it is suspected that trace amounts of oxygen from the specimen environment are incorporated into the CaF_2 specimens, thereby augmenting the ionic conductivity. Conductivity and other effects due to oxygen incorporation into CaF_2 crystals have been observed and discussed by previous authors. (24, 35-37).

To supplement the foregoing evidence for the predominant ionic conductivity of CaF_2 under reducing conditions, the emf *vs.* temperature data of Fig. 3 are also offered. The solid line gives the emf that would be predicted for cell II if CaF_2 had an ionic transference number of unity (averaged over the fluorine activity range from Ca,CaF_2 coexistence to Th,ThF_4 coexistence). An uncertainty of ±51 mV in the thermodynamic emf line was obtained by simply adding the uncertainties in all the thermodynamic values used.[1] The measured emf values plotted in Fig. 3 are scattered more or less randomly about the predicted thermodynamic values and fall within the ±51 mV uncertainty band. Thus, within the uncertainty limits of existing thermodynamic data, it appears that the usefulness of undoped CaF_2 as a solid electrolyte extends down to its stability limit over the temperature range 400°-810°C.

Manuscript received June 22, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

[1] The uncertainty for $\Delta G°_f(CaF_2)$ was taken to be the uncertainty in $\Delta H°_f(CaF_2)$ at 298°K which according to the JANAF tables is ±1.5 kcal or ±33 mV. An uncertainty of ±5 mV was reported by Heus and Egan for the cell $Mg,MgF_2|CaF_2|Th,ThF_4$ at 600°C, and Markin gives the uncertainty for $\Delta G°_f(MgF_2)$ at 600°C to be ±0.6 kcal or ±13 mV.

LIST OF SYMBOLS

P_{F_2}	Fluorine partial pressure in atmospheres
$\Delta G°_f$	Standard free energy of formation in cal/mole
$\Delta H°_f$	Standard enthalpy of formation in cal/mole
$\Delta S°_f$	Standard entropy of formation in cal/mole-°K
R	Gas constant
T	Temperature in °K
σ_{ac}	Total conductivity of CaF_2 measured with an a-c bridge

Residues Remaining after RF Plasma Photoresist Removal

H. G. Hughes, W. L. Hunter,* and K. Ritchie

Motorola Inc., Semiconductor Products Division, Central Research Laboratories, Phoenix, Arizona 85008

ABSTRACT

A method of photoresist stripping in which oxygen plasma supplies the activation energy necessary for the rapid oxidation of the photoresist has gained widespread use. Oxygen plasma alone, however, does not remove inorganic impurities present in some resists. Recently obtained evidence indicates that interactions between these inorganic impurities and various substrates may result in modification of chemical properties and/or physical characteristics of the substrate surfaces from which the photoresist is removed.

RF oxygen plasma ashing is a method of photoresist removal in which rf energy converts oxygen to an active species which in turn oxidizes the photoresist to volatile products (1). An impediment to the use of oxygen plasma alone is present when photoresists contain inorganic impurities (2) such as tin compounds. This residue is an undesirable contaminant (Fig. 1). Observations suggest that the physical and/or chemical characteristics of the substrate may be altered by the foreign materials.

Results and Discussion

The residue in photoresist "A" was identified from spectrographic analyses as comprising mainly tin compounds. Residues remaining after ashing a 3000Å thick film of photoresist "A" are shown in Fig. 2 and 3. Adhesion of the residue to the SiO_2 substrate tends to increase with longer ash time, greater oxygen flow, and greater rf power. Figure 2 shows that the deposit could be removed by gentle scraping with a tweezer point. Another area of the same wafer is depicted in Fig. 3, following a twofold increase in ash time and rf power. Scraping similar to that used in Fig. 2 produced no observable movement of the residue indicating a marked increase in adhesion.

The adhesion of the residue was further demonstrated by its resistance to ultrasonic cleaning with various reagents (Table I). This seemed to indicate that the residual material was not organic (due to incomplete ashing) nor was it elemental tin. The residue could be removed slowly with hot 20% aqueous KOH and etched off readily with buffered HF, both of which also attack the SiO_2 surface. Hot sulfuric acid, which is used as a reagent in the morin test for tin and tin oxide (3), failed to strip the residue. The residual matter was also not held electrostatically since an ultrasonic aqueous sodium chloride bath did not dislodge the particles.

The form in which tin is present in photoresist "A" is not known with certainty. However, since stannic chloride is often used in the cyclization of natural rubber (4), and would be converted to tin oxide by oxy-

gen plasma, the effect of these compounds on thermal oxide was investigated.

A thermal oxide wafer was dipped in a 1% $SnCl_4 \cdot 5H_2O$-xylene solution. After oxygen plasma ashing for 30 min at 450W and 400 cc O_2/min, the wafer substrate appeared "cracked" in areas (Fig. 4). Although some of the residue could be mechanically dislodged, the "cracked" areas that appeared during ashing could not be removed by scraping with a tweezer point.

No apparent surface effect was noted with the SnO_2-xylene suspension dip. After ashing, most of the tin oxide residue could be wiped clean. However, isolated areas were found which were difficult to dislodge mechanically (Fig. 5). It appears, therefore, that should either of these compounds be present in a photoresist, the surface of the thermal oxide may become altered during oxygen plasma ashing.

Aluminum substrates were also investigated. After ashing, neither light microscopy (dark or light field) nor scanning electron microscopy (Fig. 6a and 6b) could detect any obvious residue or other surface distinction between initially photoresist-covered and bare areas of the same wafer. The presence of residual material was detected chemically, however. Aluminum deposited on silicon oxide was patterned with photoresist "A" and processed in the normal manner. No

etching was done prior to resist removal by oxygen plasma. After ashing, the "clean" wafer was placed in a potassium ferricyanide-potassium hydroxide aluminum etchant and a pattern formed even though no photoresist was present (Fig. 7). The residual contaminated areas appeared to etch more slowly. The grid step observed was estimated by Dektak measurement to be 100-200Å deep after 8 sec etch time. Upon further etching the pattern slowly disappeared. It was further noted that when powdered tin or tin oxide was mixed with powdered aluminum metal, the reaction rate of the metal with hydrochloric acid or aluminum etchant increased, whereas on the substrate the tin oxide seemed to form a protective layer on the aluminum oxide surface.

In all cases, photoresist "B" (essentially free of inorganics) was processed along with photoresist "A." No residual material nor detrimental effect was observed (Fig. 8 and 9). Aluminum processed with photoresist "B" followed by ashing did not show any preferential etching.

Conclusion

In conclusion, it is noted that the residual film left from oxygen plasma ashing of photoresist "A" is mainly inorganic material which may be adsorbed or bonded to the oxide surface in various degrees. With aluminum substrates, preferential etching can occur which was not observed on SiO_2 substrates. The contaminants can lead to undesirable effects in subsequent diffusions and passivation.

Impurity Striations in Czochralski Grown Al-Doped Si Single Crystals

B. K. Jindal, V. V. Karelin,[1] and W. A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Experimental and theoretical studies of interface shapes and striation structures were done on Al-doped Si single crystals. The interface shapes were observed to be complex, variable and with no evidence of a single central facet. Many of the characteristics of the striation structure are similar to those observed by Witt and Gatos, and some additional features are also described. Based on theoretical calculations of variation of Al concentration in the crystal as a function of variations of crystal growth rate, it is deduced that the likely mechanism of interface atomic attachment is by layer motion. Effects of thermal fluctuations and fluid flow are also considered.

Single crystals pulled from alloy melts by the Czochralski method generally exhibit impurity structures (1-7) which are related to fluctuations in the crystal-growth rate (1-5). The present paper deals with some experimental observations of impurity striations in Al-doped Si crystals, and a theoretical assessment of the impurity fluctuations in terms of assumed fluctuations in growth velocity. From these considerations, it seems most reasonable to conclude that the occurrence of the velocity fluctuations is directly related to erratic layer-flow behavior on the interface.

Experimental Procedure

Si single crystals containing 10^{16}-10^{18} Al atoms/cc were grown using a Czochralski-type apparatus from a melt containing 2.5×10^{-1}-2.5×10^{-2} weight per cent (w/o) Al (semiconductor grade Si and 99.999% pure Al). Using (100) seeds, all crystals were pulled at 5 cm/hr at a seed rotation rate of 14 rpm and a crucible rotation rate of -12 rpm (reverse direction). The grown crystals were cut in the middle along the growth axis to expose a (110) plane which was then polished with Linde B abrasive (particle-size, 0.05μ) and the final polish was always performed in a direction perpendicular to the striation direction. Next, the specimens were rinsed with distilled water and chemically polished using CP-4 (5 parts HNO_3, 3 parts CH_3COOH, and 3 parts HF). Etching utilized a CrO_3 solution mixed with HF (1 part 48% HF to 1 part 33% CrO_3 solution) that was prepared immediately prior to use.

Experimental Results

Macroscopic interface shapes.—Typical shapes of the crystal/liquid interface, as revealed by suddenly pulling the crystal out of the melt, are plotted in Fig. 1 and, as revealed by the striation patterns, are shown in Fig. 2. These different shapes are obtained as a result of the different temperature distributions in the furnace. Comparing these shapes with the theoretical work of Kobayashi and Arizumi (8), it is seen that the interface is not always uniformly concave or convex but can assume a complex configuration; the shape in Fig. 1(b) resembles more closely the temperature isotherms in the liquid phase as calculated by Kobayashi and Arizumi (8). The observation that the shape of the interface varies during the growth of a particular crystal leads one to conclude that the microscopic growth rate is not always the same over the entire crystal cross section. Also, a single macroscopic facet in the center is not observable; the absence of a macroscopic facet in Al-doped Si has also been reported by Mil'vidski and Berkova (9).

Striation structure.—The general striation pattern, without magnification, is shown in Fig. 2. Figures 3-5

[1] Present address: Moscow State University, Chemistry Department, Moscow, B-234, U.S.S.R.

show enlarged views of the particular areas marked in Fig. 2. From these figures it is seen that:

(*i*) There is no evidence of a single central facet and the striations appear as straight lines of varying lengths and not necessarily perfectly parallel to each other.

(*ii*) In going from the outer to the central part of the crystal, at a distance of about 2-3 mm from the edge, there is a rapid and discontinuous decrease in striation frequency (Fig. 3, 4). A discontinuity in the structure of both rotational and nonrotational striations has been observed in the growth of InSb crystals, which sometimes appears to be located at the boundary of the central facet with the off-facet region (5). In our case, a discontinuity in striation structure is observed even though there is no evidence of a single central facet.

(*iii*) The striations that extend from the outer into the central part are of variable length and intensity (Fig. 4, 5). Some striations lie entirely within the central part (see Fig. 6). These are also of variable length and intensity. In the central part, the striation frequency shows a slight decrease in going towards the crystal center and is variable along the vertical axis (Fig. 5). The intensity of any one striation is not constant over its entire length; for striations that lie entirely within the central part of the crystal, the intensity is high in the striation's central portion and decreases towards its ends (see Fig. 6).

(*iv*) In lightly doped crystals, the striations are quite difficult to observe. In these crystals, the striation frequency is larger when the crystal diameter is decreasing and smaller when the crystal diameter is increasing (Fig. 7).

Discussion

Since the striations are believed to be caused by a fluctuation in the crystal growth rate, to understand the details of the striation formation mechanisms, let us study the following aspects of the problem: (*i*) effect of crystal growth rate variation on solute incorporation; (*ii*) interfacial atomic attachment mechanisms operating under conditions of required growth rate variations; (*iii*) effect of thermal fluctuations on crystal growth rate; and (*iv*) consequences of fluid motion.

Solute redistribution.—Considering the liquid-solute profile illustrated in Fig. 8, we wish to calculate the variation of solute concentration in the solid associated with a fluctuation in freezing velocity. By this path, we shall determine the necessary velocity fluctuation consistent with the experimentally observed impurity

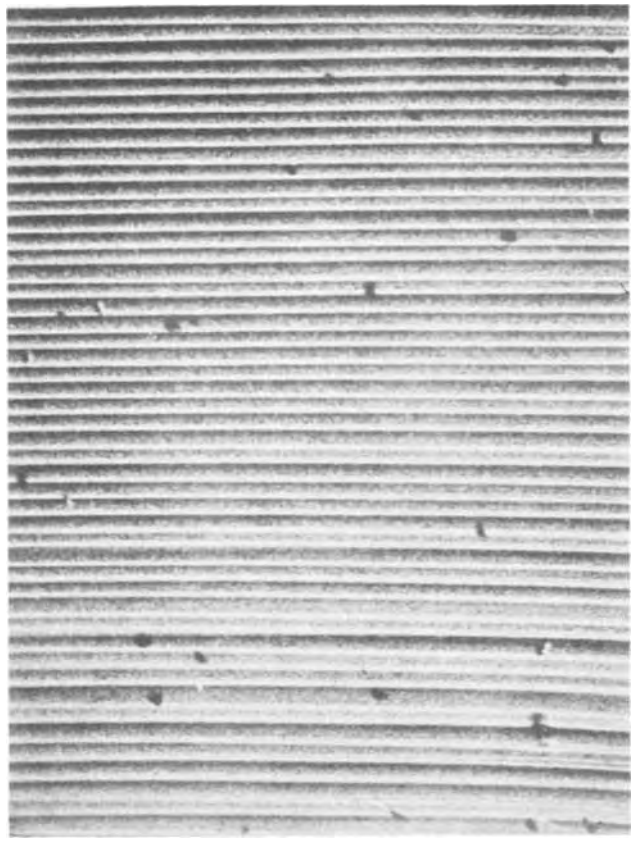

Fig. 3. Striation pattern in the outer regions of the crystal. Many striations end about 2 mm from the edge. Some striations extend deeper into the central part. (Magnification. 100×.)

fluctuation. Assuming the interface partition coefficient to be equal to the phase diagram partition coefficient k_0, the liquid concentration at the interface,

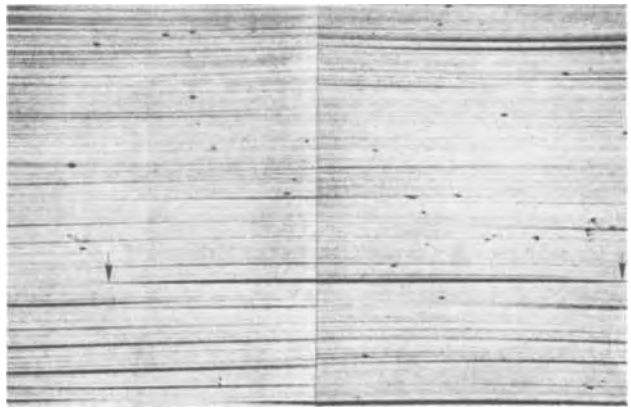

Fig. 6. The striation bounded by arrows lies entirely within the central part. (Distance between arrowheads ≈ 3 mm.)

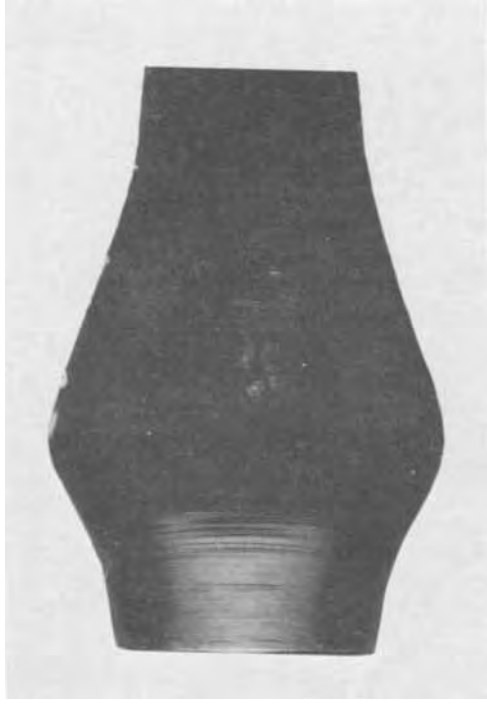

Fig. 7. Striation pattern in a lightly doped crystal. (No magnification.)

$C_L(0)$, is given by

$$C_L(0) = \frac{k}{k_0} C_L(\infty) \qquad [1]$$

where $C_L(\infty)$ is the bulk liquid concentration, and k is the effective solute distribution coefficient given by (10)

$$k = \frac{k_0}{k_0 + (1 - k_0)\, e^{-V\delta c/D}} \qquad [2]$$

where δc is the solute boundary layer thickness and D is the solute diffusion coefficient in the liquid.

We wish now to consider the change in $C_S(x)$ associated with a change in freezing velocity from V to V'. Since $k/k_0 \approx 1.1$, $\delta c \approx 10^{-2}$ cm (11), and the width of a striation is less than 10^{-3} cm in our experiments, for an approximate analysis we may choose $C_L(0) \approx C_L(\infty)$ and use the diffusion only initial transient approximation of Tiller *et al.* (12) to describe $C_S(\xi)$, where ξ is the distance measured from the beginning of the change to V'. In Fig. 9, $C_S(\xi)/C_L(\infty)$ is plotted *vs.* ξ for several values of V' ($V = 1.4 \times 10^{-3}$ cm/sec). Here, we note that a fluctuation of 5-10% in $C_S(\xi)/$

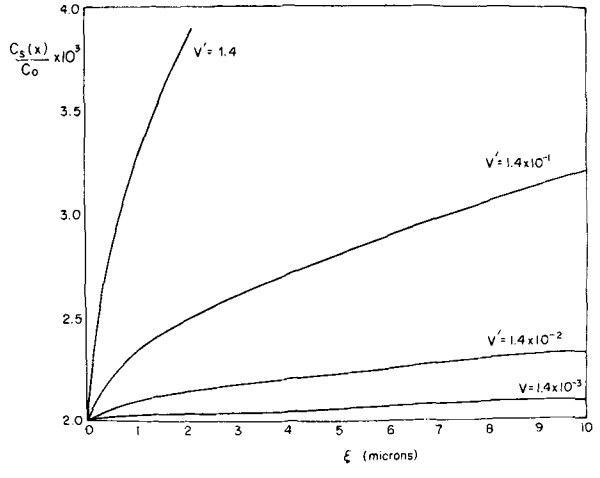

Fig. 9. Effect of variation of growth rate from V to V' on impurity incorporation in the crystal.

$C_L(\infty)$ over a distance of a few microns requires a velocity fluctuation $V'/V \lesssim 10^3$.

Interface attachment.—Since some of the striations are several millimeters in length, it is most likely that to obtain $V'/V \lesssim 10^3$, growth occurs by a layer-flow mechanism at these small driving forces rather than by a uniform attachment mechanism. Consider Fig. 10(a) in which the layers flow across the interface in a very regular way as the position of the freezing point isotherm changes due to steady pulling of the crystal. Suppose that, due to an adsorption event or a temperature fluctuation at the layer edge, the edge cannot continue to flow across the surface. We note that, as illustrated in Fig. 10(b), the layer height increases at e and a zone of supercooling grows at the face f over the region ee'. If, at some later time, the layer edge at e breaks away from its locking point, a multistep height layer will flow across the surface at greater than the average passage velocity. Initially, it will create a

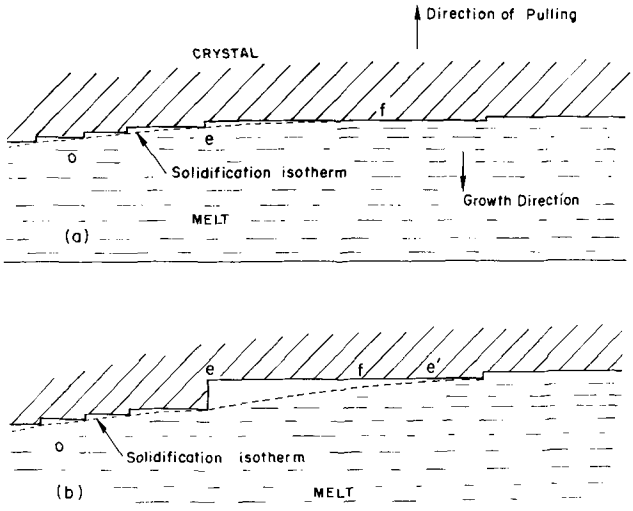

Fig. 10. Schematic representation of interface microstructure and solidification isotherm.

type of initial transient solute distribution which could be from less than a micron to millimeters in length depending on the step height and the passage velocity. It should eventually reach a type of steady-state build-up, and then, as the velocity slows down because of approach to the freezing point isotherm, the solute excess decreases to zero. This is consistent with the type of behavior observed in the present experiments.

Thermal fluctuations.—It is necessary to distinguish between those growth-rate fluctuations which are due to the passage of a thermal fluctuation from the bulk liquid to the interface, and those that are microscopic in nature and originate at the interface during the consumption of a local zone of undercooled liquid. With respect to the thermal fluctuations in the bulk liquid, let us consider a fluctuation of magnitude ΔT and frequency n Hz at a distance δT from the interface, where δT is the thickness of the thermal boundary layer. The temperature fluctuation ΔT_i at the interface due to the above fluctuation in the liquid is given by (13)

$$\Delta T_i = \Delta T \exp\left[\left(-\frac{\pi n}{\alpha_L}\right)^{1/2} \delta T\right] \qquad [3]$$

where α_L is the thermal diffusivity of the liquid. Letting $n = 1$ Hz, $\alpha_L \approx 10^{-1}$ cm^{-1}, $\delta T \approx 0.25$ cm, $\Delta T = 5$°C, we get $\Delta T_i \approx 1$°C. To see the effect of these thermal fluctuations on microscopic growth rate, let us recall that in the previous section the interface was depicted with many more layer edges per unit area in the peripheral section of the crystal than in the central section. Thus in the peripheral section, crystal growth is limited only by layer motion whereas in the central section the growth may have to wait the freeing of a pinned layer edge or the generation of a new one. Since the motion of a layer from an existing layer edge requires much less driving force than the generation of a new edge, therefore fluctuations of $\Delta T_i \approx 1$°C would cause variations of microscopic growth rate more often at the crystal periphery than at the crystal center.

For the case of a temperature fluctuation originating at the interface, if one considers the microscopic zone of a supercooled liquid, it is clear that a layer of solid $\sim 10\mu$ thick could readily form from a layer of liquid 10^{-1} cm thick which is supercooled by a few degrees. The latent heat of this layer of solid is essentially dumped into the remaining zone of liquid eliminating its supercooling. In this case, there is no thermal limitation on the rate at which this heat evolution can occur so that velocity fluctuations of several orders of magnitude could occur via this mechanism. Some of the mechanisms by which thermal fluctuations at the

interface can occur have been discussed by Morizane, Witt, and Gatos (1-5).

Hydrodynamics.—Cochran's (14) exact solution of the hydrodynamic equations for an infinite disk provide the following picture of the fluid motion. Far from the rotating disk, the fluid moves towards the disk, and in a thin layer immediately adjacent to its surface, the liquid acquires a rotating motion. The angular velocity of the fluid increases as the surface of the disk is approached until the angular velocity of the rotating disk is finally attained. In addition, the fluid also acquires a radial velocity under the influence of the centrifugal force. We may expect some divergence from the exact solution due to having a disk of finite radius and due to having a disk that is not flat.

When the diffusion problem was first formulated for the Cochran flow, it was assumed that the solute concentration is only a function of distance from the disk surface and not a function of radius r or the angle ϕ around the disk. However, the distribution of streamlines at a disk surface has been shown to exhibit a spiral pattern (15) such as illustrated in Fig. 11. These streamlines move across the surface, and for a flat untransforming disk, give a constant time-average momentum and solute distribution that is independent of r and ϕ. However, for a transforming interface, such as we have under consideration, we must consider that rotating spiral-shaped oscillations of the momentum and solute boundary layers occur to influence the local growth conditions. In addition, since the spiral arms of the solute distribution are more widely spaced as r increases, the concentration fluctuation that sweeps across the interface like a constitutional supercooling wave is largest at large r.

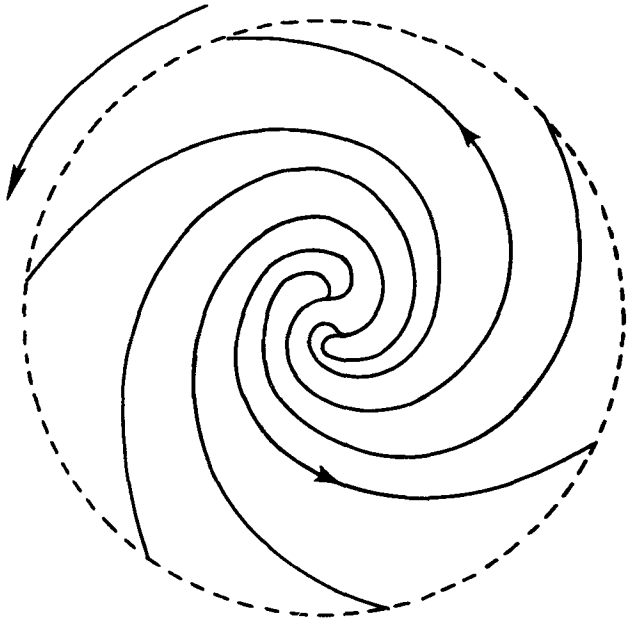

Fig. 11. Spiral streamlines at the surface of a rotating disk

Combining the above with the section on interface attachment, we can expect that the rotating concentration fluctuation acts somewhat like a trigger to release the adsorption-locked layer at point e of the interface (see Fig. 10). Thus, the amount of adsorption-induced undercooling needed before layer movement is stimulated decreases with increasing r so that the striation spacing should be less at larger r. Of course, some allowance must be made for interface shape effects.

The present model suggests that, at decreasing $C_L(\infty)$, the driving force for triggering the layer motion decreases, and if the absorption of a minor constituent is fixed, striations will still occur but will be erratically spaced because of the reduced trigger stimulus. If adsorption also decreases with $C_L(\infty)$, the entire striation effect should disappear. Of course, one should also expect to see some spiral solute patterns even without adsorption for such a postulated streamline pattern. Some of the results of Gatos and Witt (1-5) tend to support this expectation. In addition, for a pure melt, the fluctuations of the momentum-boundary layer will affect the temperature distribution slightly and will give rise to small but regular fluctuations of interface temperature.

Influence of AsH_3, PH_3, and B_2H_6 on the Growth Rate and Resistivity of Polycrystalline Silicon Films Deposited from a SiH_4-H_2 Mixture

F. C. Eversteyn and B. H. Put

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The deposition rate of polycrystalline silicon from a SiH_4-H_2 mixture is significantly influenced by the addition of AsH_3, PH_3, and B_2H_6. At a deposition temperature of 680°C AsH_3 causes a decrease by a factor of 7, PH_3 causes a decrease by a factor of 2.5, while a two times higher deposition rate is obtained with B_2H_6 addition. Out of these three dopant hydrides AsH_3 and PH_3 do not affect the activation energy of the deposition reaction compared to undoped growth (37 kcal/mole). The Arrhenius plot for the deposition of silicon from a B_2H_6-SiH_4 mixture shows two activation energies: 20 kcal/mole at T = 620°-900°C and 7 kcal/mole below 620°C. The experimentally found minimum values of the resistivity of doped polycrystalline silicon can be explained in terms of solid solubility and carrier mobility. At deposition temperatures below 700°C with and without addition of dopants the polycrystalline silicon surface is mirror-like. Significant differences have, however, been observed by electron microscopy. Compared to undoped growth boron was found to lower the etch rate of the polycrystalline silicon film markedly.

Increasing interest is being shown in the use of polycrystalline silicon in silicon device technology. The application of polycrystalline silicon films is compatible with silicon device processing where polycrystalline silicon is mainly used as gate material in MOS structures (1) (self-aligned gate).

Polycrystalline silicon can be deposited in different ways: by evaporating, by sputtering, and by chemical vapor deposition. Chemical vapor deposition is superior because it permits uniform deposition over oxide steps. To obtain a mirror-like surface, which enables very fine patterns to be etched in it, comparable with those in silicon oxide, the grain size of the polycrystalline silicon film should be as small as possible. DeLuca (2) has found that the grain size of the polycrystalline silicon film decreases with decreasing temperature. However, the deposition rate also decreases with decreasing temperature. At 650°-690°C an acceptable compromise between growth rate and grain size is realized. In this temperature region most polycrystalline silicon films suitable for high resolution I.C. processing are grown.

In the case where polycrystalline silicon is used as the gate material for MOS structures, it may be deposited undoped and subsequently doped by impurity diffusion. In the case where design considerations prohibit high-temperature processing after polycrystalline silicon deposition, doping by codeposition becomes necessary.

The present paper reports on the growth of doped polycrystalline silicon films by codeposition of silicon and either arsenic, phosphorus, and boron from the corresponding hydrides using hydrogen as a carrier gas. In particular the temperature dependence of the growth rate was studied. The effects of deposition temperature and dopant concentration on growth rate and resistivity are discussed.

Experimental

The polycrystalline silicon films were prepared in an uncooled vertical reactor. The substrates were positioned on a circular graphite susceptor coated with pyrographite. A pancake-shaped rf coil was placed on top of the flat-bottomed cylindrical silica bell jar. The distance between the rf coil and the susceptor was about 13 mm. Before deposition the susceptor was coated with silicon. During the deposition process the susceptor was rotated and the gases entered the reactor through a silica injection tube containing slits which were positioned 5 mm above the susceptor. The gas supply unit permitted the injection of any appropriate mixture of palladium-diffused hydrogen, hydrogen containing 5% SiH_4, hydrogen containing 200 ppm B_2H_6, hydrogen with 250 ppm PH_3, and hydrogen with 300 ppm AsH_3. The silane concentration in the reactor was kept below the value where homogeneous gas-phase decomposition occurred (3). The temperature of the silicon slices was measured with an Ircon 600 radiation thermometer corrected for emissivity of silicon and absorption of silica wall (emittance 63%).

The substrates were mechanically polished silicon slices partially covered with silicon oxide. Before each experiment the substrates were cleaned for 15 min in a boiling mixture of 2 parts H_2SO_4 (sp gr 1.84) and 1 part H_2O_2 (30%), rinsed in deionized water, and then spun dry.

The thickness of the polycrystalline silicon film deposited on silicon oxide was measured with a Taylor-Hobson Talysurf after the polycrystalline silicon on silicon oxide had been locally removed. This was done by masking and subsequent etching of the polycrystalline silicon in an etch mixture containing 1 part HF (49%) and 1 part CrO_3 solution (500g CrO_3 in 1000 ml water). At room temperature the etch rate of undoped polycrystalline silicon deposited in the temperature range of 590°-1050°C amounts to 2-5 μm/min, which markedly differs from the etch rate of silicon oxide in this etch mixture which is 0.18 μm/min. The thickness of the polycrystalline silicon film deposited on silicon was determined from the step height between the polycrystalline silicon deposited on silicon and the silicon substrate. For this purpose, near the oxide step present at the substrate surface, the polycrystalline silicon deposited on silicon oxide was locally removed followed by subsequent etching of the underlying silicon oxide with HF.

A big difference in etch rate between silicon oxide and polycrystalline silicon in the above-mentioned etch mixture has also been observed for polycrystalline silicon deposited in the presence of AsH_3 and PH_3. However, polycrystalline silicon films grown in the presence of B_2H_6 show a much lower etch rate of 0.2 μm/min in this etch mixture. For these layers the thickness was measured by beveling (4). The resistivity of the polycrystalline silicon films was determined by using the four-point probe technique.

Key words: polycrystalline silicon, doping, activation energy, thin films, silane.

Results

The growth rate of polycrystalline silicon from a SiH_4-H_2 mixture varies linearly with the SiH_4 concentration. This is also the case when dopants are added. Thereby the thickness increases linearly with deposition time and no induction period has been observed. No difference is found in the deposition rate of polycrystalline silicon on silicon and on silicon oxide. For all experiments the growth is expressed in microns per minute per percentage SiH_4 in the carrier gas, because the experiments have not all been carried out at the same SiH_4 concentration. This normalized value of the growth rate characterizes the deposition rate at a certain temperature since the growth rate varies linearly with the SiH_4 concentration.

The growth rate of undoped polycrystalline silicon at a deposition temperature of 680°C amounts to 0.1 μm/min % SiH_4. The resistivity of these layers is so high that it can be measured only on polycrystalline silicon films over 1.5 μm thick. Values over 500 ohm-cm are obtained. This value does not change on subsequent heat-treatment at 1150°C.

Effect of dopant addition.—When to the SiH_4-H_2 mixture one of the hydrides of As, P, or B is added, the growth rate/% SiH_4 varies as a function of the ratio of dopant atoms at silicon atoms in the gas phase as represented in Fig. 1-3, for a deposition temperature

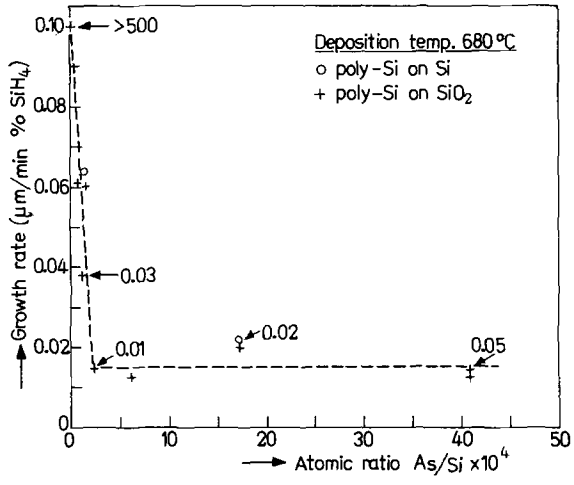

Fig. 1. Influence of addition of AsH_3 on the growth rate and resistivity of polycrystalline silicon deposited at 680°C. The numbers given in this figure represent the values of the resistivity in ohm-cm. $P_{SiH_4} = 0.36 \times 10^{-2}$ atm.

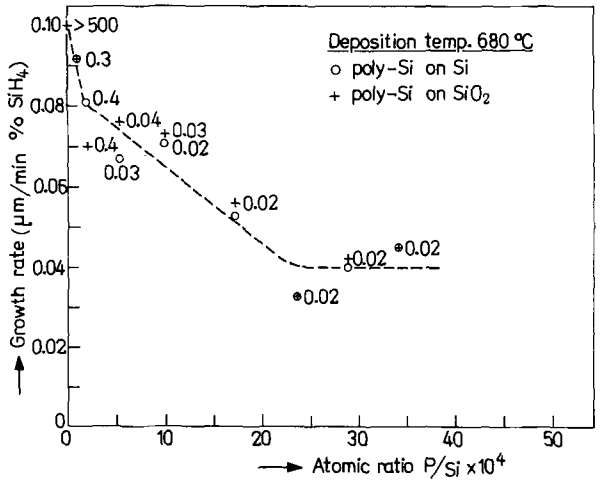

Fig. 2. Influence of PH_3 addition on the growth rate and resistivity of polycrystalline silicon layers deposited at 680°C. The numbers given in this figure represent the values of the resistivity in ohm-cm. $P_{SiH_4} = 0.36 \times 10^{-2}$ atm.

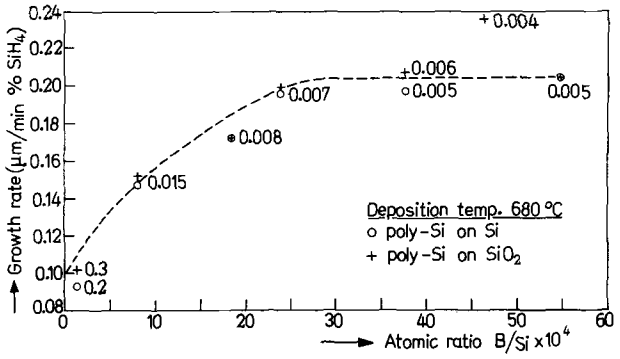

Fig. 3. Influence of B_2H_6 addition on the growth rate and resistivity of polycrystalline silicon layers deposited at 680°C. The numbers in this figure represent the values of the resistivity in ohm-cm. $P_{SiH_4} = 0.36 \times 10^{-2}$ atm.

of 680°C. It turns out that the observed decrease in growth rate compared to undoped growth is the most pronounced for AsH_3 (factor of 7) and less pronounced for PH_3 (factor of 2.5). For B_2H_6 an increase in growth rate by a factor of 2 is found.

The resistivity of the polycrystalline silicon films decreases with dopant addition in that region where dopant addition also influences the deposition rate and remains at a constant level where dopant addition does not influence the growth rate.

The surface quality of the polycrystalline silicon films is not influenced by the addition of dopants. Only at high B_2H_6 concentration ($B/Si > 35 \cdot 10^{-4}$) the surface becomes rough, probably due to the high deposition rate.

Influence of deposition temperature.—For these experiments the atomic ratio of dopant atoms to silicon atoms in the gas phase was chosen in the region where growth rate is practically independent of this value (see Fig. 1-3). Figure 4 gives the results of these experiments.

It appears that for undoped growth the deposition rate is not temperature dependent at temperatures over 830°C. When B_2H_6, PH_3, or AsH_3 are added to the gas stream the temperature at which temperature-dependent growth passes into temperature-independent growth increases. This is most striking for AsH_3. For undoped growth as well as for growth in the presence of AsH_3 and PH_3 the temperature-dependent growth can be described with an activation energy of 37 kcal/mole. For B_2H_6, however, the region of temperature-dependent growth can be divided into two parts: a region from 900°-620°C with an activation energy of

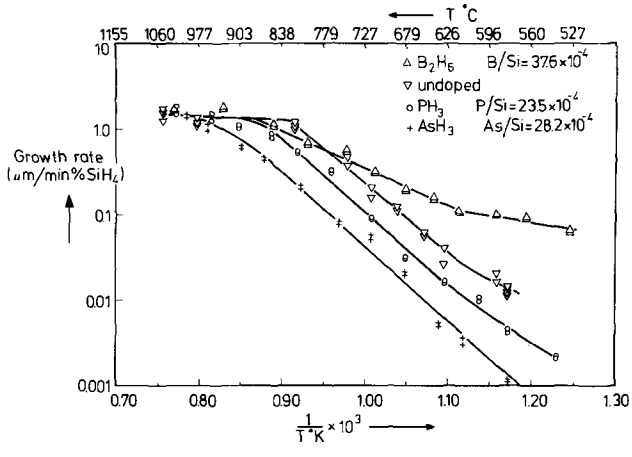

Fig. 4. Influence of deposition temperature on the growth rate of polycrystalline silicon films without and with additional doping of AsH_3, PH_3, and B_2H_6.

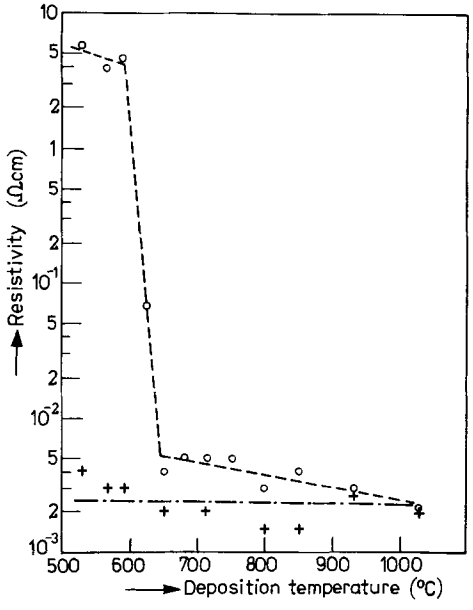

Fig. 5. Resistivity of polycrystalline silicon layers deposited from a SiH_4-H_2 mixture with the addition of B_2H_6 during growth before (O) and after (+) an additional heat-treatment for 30 min at 1150°C in H_2 as a function of deposition temperature. B/Si ratio in the gas phase: 37.6×10^{-4}.

20 kcal/mole and a region below 620°C with an activation energy of 7 kcal/mole. Although less pronounced a lower value of the activation energy below 620°C has also been observed for PH_3 and for undoped growth.

The resistivity of boron-doped polycrystalline silicon films as a function of deposition temperature is given in Fig. 5. The resistivity of as-grown polycrystalline silicon changes significantly at a deposition temperature of 620°C. Below 620°C a much higher value of the resistivity is obtained compared to deposition above 620°C. This difference, however, disappears after an additional heat-treatment for 30 min at 1150°C.

The surface quality of the layers changes with deposition temperature. Below 700°C a mirror-like surface is obtained with and without dopant addition when the deposition rate is kept below 0.07 μm/min. At deposition temperatures over 700°C the surface of the film gradually becomes rough, whether doped or not.

Discussion

In the experiments described in this paper all the substrates were treated before deposition in a boiling mixture of hydrogen peroxide and sulfuric acid followed by a rinsing treatment in deionized water which leaves an oxide film of about 15Å (5) on the silicon substrate. The hydrogen treatment in the reactor before deposition during the warming-up period does not result in an oxide-free silicon surface and a reaction between the oxide present on the silicon slice and the underlying silicon to produce the volatile SiO is not to be expected either (6). This means that no difference in the early stage of deposition on silicon and on silicon oxide should be expected because, in both cases, the silicon is covered with oxide. This was experimentally verified. It has been found by Kramer (7) that the presence of this thin oxide layer between mono- and polycrystalline silicon does not result in a higher contact resistance.

A great influence is observed on the growth rate when dopants (AsH_3, PH_3, B_2H_6) are added to the SiH_4-H_2 mixture from which the deposition of polycrystalline silicon is carried out as represented in Fig. 1-4

Without dopant addition as well as with the addition of AsH_3, the growth rate in the temperature-dependent region can be described with an activation energy of 37 kcal/mole as also has been found by Joyce and Bradley (8) for the growth of undoped silicon. If the deposition rate G is determined by reaction kinetics at the surface of a substrate then according to $G = A \exp(-E/RT)$ (9) the effect of AsH_3 on the deposition rate must be attributed to a decrease of A. The pre-exponential factor A represents the density of nucleation or growth sites and consequently, the effect of arsenic on the growth of polycrystalline silicon appears to be a blocking of the growth sites as also has been concluded by Farrow and Filby (10). A difference in growth mechanism can also be observed from electron micrographs. In Fig. 6 electron micrographs produced with the carbon-carbon replica technique are given for a polycrystalline silicon layer deposited without extra dopant addition and with the addition of AsH_3. Both layers have been deposited at the same deposition temperature and the layer thickness is, in both cases, nearly the same. A clear difference in surface texture is found. In the case of polycrystalline silicon layers deposited without dopant addition a smooth sur-

face is obtained which is not the case when the film is doped with arsenic. Here a faceted growth is observed which confirms the aforementioned blocking action of arsenic on the growth of polycrystalline silicon.

The influence of PH_3 is similar to that of AsH_3. However, the magnitude of the effect is less. While AsH_3 addition causes a decrease in the growth rate by a factor of 7 (see Fig. 1) the maximum effect observed with PH_3 is a decrease by a factor of 2.5 in the growth rate when the deposition temperature in both cases is 680°C (see Fig. 2). The electron micrograph also looks like the one obtained with AsH_3 as regards its surface roughness (see Fig. 6). Only the effect on surface roughness is less than in the case of AsH_3. It should be noted that although polycrystalline silicon layers doped with AsH_3 and PH_3 have a rather rough surface on electron micrographs, the surface looks mirror-like and visually cannot be distinguished from mechanically polished silicon slices.

The addition of B_2H_6 during deposition of polycrystalline silicon causes the opposite effect from that obtained with AsH_3 or PH_3. As given in Fig. 3 at a deposition temperature of 680°C, B_2H_6 addition to the gas stream increases the deposition rate by a factor of 2. By determining the growth rate as a function of deposition temperature, when B_2H_6 is added, we observe a decrease in activation energy compared to undoped growth or doping during growth with PH_3 and AsH_3. In the temperature region of about 620°-900°C the deposition rate of polycrystalline silicon grown in the presence of B_2H_6 can be described with an activation energy of 20 kcal/mole while a much lower value of 7 kcal/mole is found below 620°C.

The change in activation energy compared to undoped growth can be explained by a structural change of the polycrystalline silicon film due to the presence of boron. This is supported by the observation that polycrystalline silicon films deposited in the presence of B_2H_6 show a much lower etch rate (10 times) in a CrO_3-HF solution compared to undoped layers or layers deposited with AsH_3 or PH_3 addition. The experimental result that above and below 620°C another value of the activation energy is found, means that there should be also a change in film structure near this temperature.

The electron micrographs of polycrystalline silicon layers deposited in the presence of B_2H_6 at temperatures of 680° and 530°C are represented in Fig. 6. Compared to polycrystalline silicon deposited in the presence of PH_3 and AsH_3 it is significant that B_2H_6 addition during growth results in a smoother surface texture.

The resistivity of polycrystalline silicon deposited in the presence of AsH_3, PH_3, and B_2H_6 has been given in Fig. 1-3 and 5. It has been observed that at a certain deposition temperature there is a region in which the addition of more dopant in the gas phase gives no decrease in the resistivity of the deposited layer. From the solid solubility data and taking into account the lower value of the mobility in polycrystalline silicon the lowest value of the resistivity can be calculated. The results are given in Tables I and II for polycrystalline silicon deposited between 700° and 1000°C in the presence of PH_3 and B_2H_6. As can be seen from the results given in Table I and II the experimental value of the resistivity is close to the calculated value. This means that the minimum observed value of the resistivity of polycrystalline silicon layers deposited between 700° and 1000°C in the presence of PH_3 or B_2H_6 can be explained with the solid solubility data of P and B in polycrystalline silicon in accordance with the results of Cowher and Sedgwick (16). Below a deposition temperature of 620°C we observe in the case of B_2H_6 addition a sharp increase in resistivity (see Fig. 5). This can be ascribed to a sharp decrease in carrier mobility, as found by Ford (17), due to a change in film structure near this temperature. This effect disappears after an additional heat-treatment for 30 min at 1150°C probably due to a structural change of the polycrystalline silicon film.

Table I. Resistivity of polycrystalline silicon layers deposited from SiH_4 in the presence of B_2H_6

Deposition temp (°C)	Solid solubility (11) (cm^{-3})	μ mono-Si / μ poly-Si (12)	Expected value (ohm-cm)	Experimental value (ohm-cm)
1000	1.8×10^{20}	1.3	1×10^{-3}	1×10^{-3}-2×10^{-3}
900	1.1×10^{20}	1.3	2×10^{-3}	3×10^{-3}-4×10^{-3}
800	5×10^{19}	1.3	3×10^{-3}	3×10^{-3}-4×10^{-3}
700	1.8×10^{19}	1.3	8×10^{-3}	4×10^{-3}-5×10^{-3}

Deposition temp (°C)	Solid solubility (cm^{-3})	μ mono-Si / μ poly-Si (16)	Expected value (ohm-cm)	Experimental value (ohm-cm)
1000	10^{21} (13)	7	2×10^{-3}	3×10^{-3}
900	6×10^{20} (13)	7	2.2×10^{-3}	5×10^{-3}
850	4×10^{20} (14)	7	2.6×10^{-3}	5×10^{-3}
800	1.5×10^{20} (15)	7	4.2×10^{-3}	6×10^{-3}

For polycrystalline silicon layers doped during growth with AsH_3 the minimum value of the resistivity cannot be calculated since no data concerning the solid solubility of arsenic in silicon below 1000°C are available. However, postulating that also for arsenic-doped polycrystalline silicon the minimum value of the resistivity can be calculated from solid solubility and mobility, as is the case for B and P, the solid solubility of arsenic in silicon can be calculated from the values of the resistivity at different deposition temperatures. This results in solid solubility values of arsenic in silicon between 700° and 1000°C of 2-5 $\times 10^{19}$ cm^{-3}.

Conclusions

It is shown that at a deposition temperature of 680°C AsH_3 and PH_3 decrease the growth rate of polycrystalline silicon from a SiH_4-H_2 mixture markedly (for AsH_3 and PH_3 a factor of 7 and 2.5, respectively). Compared to undoped growth AsH_3 and PH_3 do not alter the activation energy of the deposition reaction and their effect on deposition rate is attributed to a blocking action of the growth sites. For B_2H_6 at a deposition temperature of 680°C an increase in growth rate by a factor of 2 is found. The activation energy of the decomposition reaction of SiH_4 is decreased by the addition of B_2H_6. This is explained in terms of a change in film structure due to the presence of boron. It thus seems that the polycrystalline silicon layers deposited in the presence of B_2H_6 have a denser structure compared to undoped growth or when grown in the presence of AsH_3 and PH_3.

The resistivity of the polycrystalline silicon films decreases with increasing addition of AsH_3, PH_3, or B_2H_6. The resistivity, however, reaches a minimum value which can be explained in the case of B_2H_6 and PH_3 by the solid solubility of B and P and the carrier mobility in polycrystalline silicon. The resistivity of polycrystalline silicon deposited in the presence of B_2H_6 increases markedly at temperatures below 620°C.

Arsenic Glass Source Diffusion in Si and SiO_2

M. Ghezzo* and D. M. Brown*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The diffusion properties of As in Si and SiO_2 using As_2O_3-SiO_2 chemical-vapor deposited glass-diffusion sources made from the oxidation of SiH_4 and AsH_3 are examined. Data on the glass-deposition rate, which decreases rapidly when the molar percentage of AsH_3 in the reactive mixture is greater than 10%, etch rates in buffered HF, and As diffusion data in O_2 and Ar ambients are presented. The As concentration where the glass becomes damaged during diffusion at 1100°C [7 mole per cent (m/o) As_2O_3 in Ar and 3 m/o As_2O_3 in O_2] is also examined.

Doped glass-diffusion sources deposited on heated Si substrates in the presence of O_2 and gaseous hydrides, SiH_4, B_2H_6, and PH_3 have been previously investigated and have been utilized for semiconductor-device manufacturing (1-6). However, most As diffusions until recently have been done using sealed-capsule diffusions with As-doped Si powders (7-9).

Surprisingly, As-doped glasses have not yet received much attention except as a component of the P_2O_5-As_2O_3-SiO_2 ternary glass system discussed by Kato *et al.* (10-11), and the GeO_2-SiO_2-As_2O_3 system utilized by Abe *et al.* (12). As_2O_3-SiO_2 glasses using $AsCl_3$ and SiH_4 (13), or $AsCl_3$ and organosilanes (14-17), have been studied, but very little work has been reported using As_2O_3-SiO_2 glass-diffusion sources formed from the oxidation of SiH_4 and AsH_3. This paper describes the results of such an investigation.

Experimental Techniques

The glasses were deposited on (100) p-type 1 ohm-cm Si wafers at 500°C using SiH_4 and AsH_3, each diluted to 1% in Ar and pure O_2. Argon was used as the buffer gas at a total flow rate of 3200 cc/min. The O_2 flow rate was fixed at 80 cc/min, the 1% SiH_4 at 380 cc/min, and the 1% AsH_3 was varied between 2 and 70 cc/min. The deposition system has been described previously by Brown and Kennicott (6). The thickness of the deposited glasses was 6000 ± 200Å. Both the thickness of these glasses and the thermal oxides used to study As diffusion through SiO_2 were measured ellipsometrically.

Deposition rate.—The glass-deposition rate of As doped SiO_2 *vs.* mole per cent AsH_3 in the reactants, and mole per cent As_2O_3 in the glass, is plotted in Fig. 1 for a substrate temperature of 500°C. The rapid decrease in deposition rate for the higher concentrations is presumably caused by the inhibition of silane pyrolysis by AsH_3 as discussed by Farrow and Filby (18). A more detailed study of this phenomenon as a function of substrate temperature is shown in Fig. 2 which shows the maximum allowable mole per cent AsH_3 curve for observable film deposition (growth rate ≧ 50 Å/min). This feature limits the practical

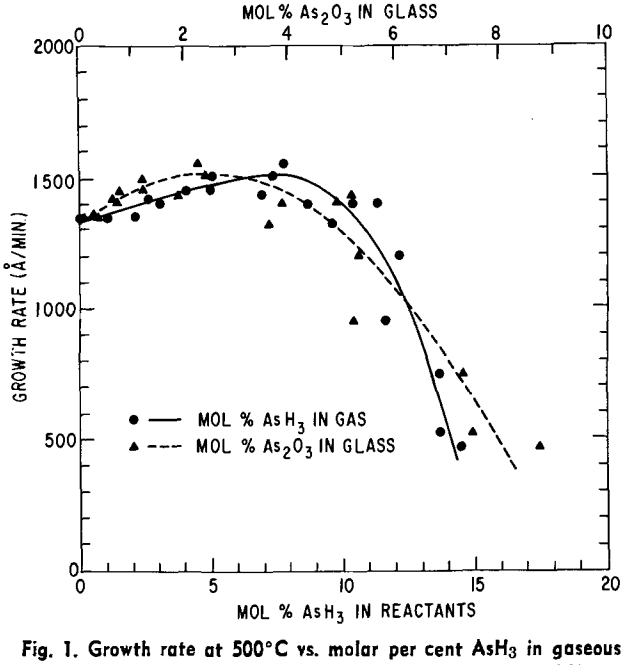

Fig. 1. Growth rate at 500°C vs. molar per cent AsH_3 in gaseous reactants and molar per cent As_2O_3 in glass. Flow rate of 1% argon-diluted mixture of SiH_4 is kept constant at 380 cc/min.

attainment of As_2O_3 concentration to about 10 mole per cent (m/o) using this system. Concentrations as high as 20 m/o have been attained using the $AsCl_3/SiH_4/O_2$ system (13).

As_2O_3 concentration.—An *IR* calibration curve for these glasses in terms of glass composition is plotted in Fig. 3. This curve given by Wong and Ghezzo (13) applies equally well to arsenosilicate glasses prepared from oxidation of silane and arsine as it was experimentally verified in some samples. Use of this curve allows a fast and accurate determination of the As_2O_3 concentration in glasses made from different mole per cent AsH_3 in the reactants by measuring the absorption-band peak ratio of the As-O 930 cm^{-1} vibration to the Si-O 1060 cm^{-1} vibration in the glasses as deposited. Besides, Fig. 3 provides experimental information on the correlation between the molar percentage of AsH_3 in the reactants and the molar percentage of As_2O_3 in the glass, appearing roughly

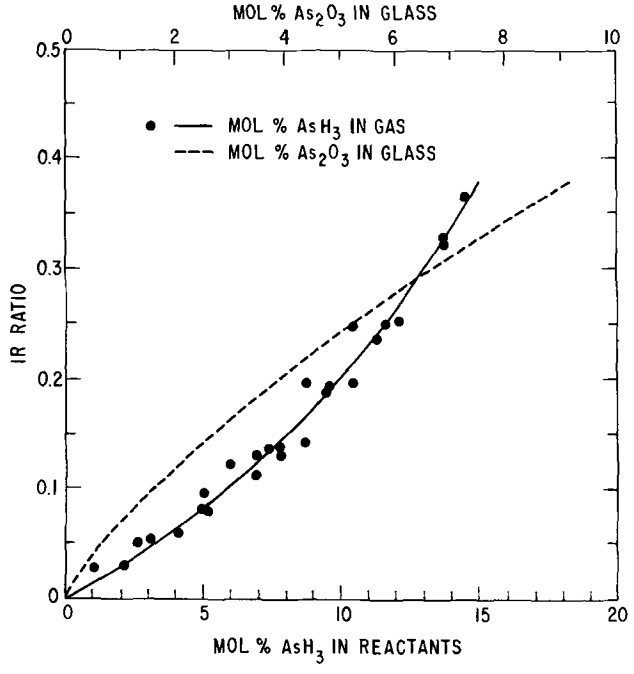

Fig. 3. Ratio of absorbance of the As-O band at 930 cm^{-1} to that of Si-O band at 1060 cm^{-1} of as-deposited arsenosilicate glasses (*IR* ratio) *vs.* molar per cent AsH_3 in gaseous reactants and molar per cent As_2O_3 in glass [after J. Wong and M. Ghezzo, Ref. (13)].

in a 2:1 ratio, as expected according to the molecular formula of these compounds and a complete oxidation of AsH_3 and SiH_4.

Etch rate.—The etch rate in buffered HF after glass densification at 1100°C in argon is plotted *vs.* As concentration in Fig. 4. A nearly two-fold increase in the dissolution rate with increasing As concentration up to 8 m/o As_2O_3 is observed. The rates are comparable to that of undoped SiO_2 and these glasses are therefore easily patterned using standard photoresist techniques.

Glass damage.—N-type glass-diffusion sources are much more susceptible to mechanical damage than the p-type borosilicate glasses for a number of reasons. The phosphosilicate and probably the arsenosilicate glass systems do not form a continuous range of solid solutions like the borosilicate system, as indicated from a comparison of their phase diagrams (19, 20). Hence there is a much greater tendency for phase separation and crystallization especially at high concentrations. These glasses also have a greater tendency to crack or detach from the Si substrate because of a greater degree of thermal mismatch with Si. This problem has been discussed by Arai and Terunuma (17) and studied by Wong (21). Some of these problems probably led to the use of the ternary glass systems used by Kato *et al.* (10) and Abe *et al.* (12).

Glass damage using the type of As glass prepared by the methods described above is observed for high concentrations of As_2O_3 after extensive heating at high temperatures. For instance, after diffusion in Ar the film which is a 7.3 m/o As_2O_3 glass shows clusters of irregular shape as shown in Fig. 5. As the concentration of As_2O_3 is reduced below 7 m/o the occurrence of these randomly scattered damaged regions is avoided completely. It is interesting to compare the nature of this damage and its threshold after heat-treatments at 1100°C in Ar with the damage in As glass films deposited with a different method. Wong and Ghezzo (13) who deposited films from an arsenic trichloride source found that damage starts at much lower concentrations (1 m/o As_2O_3) and appears as circular-interference fringes (Fig. 6) which are due to glass detachment from the substrate. Hence for As glasses the degree and nature of the damage depends on the glass-film preparation method.

The use of O_2 instead of Ar as the diffusion ambient changes the nature of the damage as shown in Fig. 7 where a 3.9 m/o As_2O_3 glass shows isolated crystalline clusters about 40μ in diameter which are at least five times larger than those in Fig. 5. Wherever damage in the glass occurs, associated damage in the underlying Si also occurs. The onset of damage is reduced for diffusion in O_2 at 1100°C to 3 m/o As_2O_3 while in Ar this limit is 7 m/o as stated above. The glass dam-

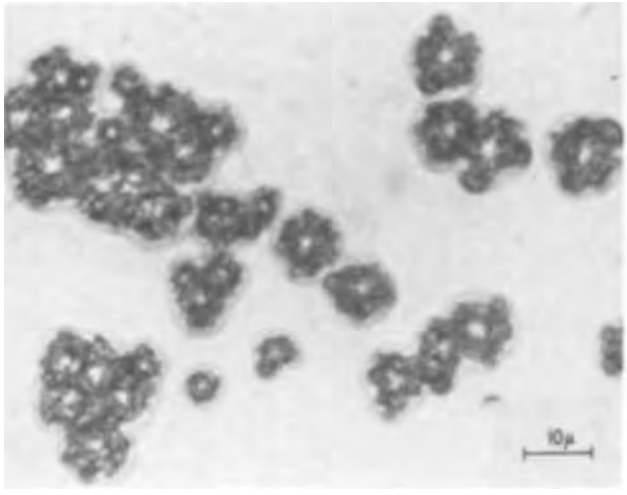

Fig. 5. Micrograph of arsenosilicate glass surface deposited from an arsine source on silicon after heat-treatment in argon at 1100°C for 5 hr. Damage appears in the form of clusters of irregular shape. Mole per cent As_2O_3 in the as-deposited glass is 7.3 (*IR* ratio = 0.32).

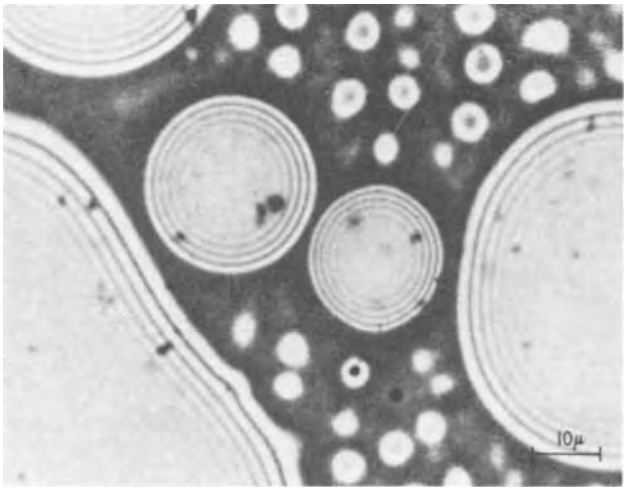

Fig. 6. Micrograph of arsenosilicate glass surface deposited from an arsenic trichloride source on silicon after heat-treatment in argon at 1000°C for 10 min [Ref. (21)]. Damage appears in the form of circular interference fringes due to lifting of the glass film on the substrate. Mole per cent As_2O_3 in the as-deposited glass is 3.6 (*IR* ratio = 0.19).

age region is noted on several of the diffusion data curves that follow.

Diffusion properties.—Arsenic diffusion from these glass sources in Si and through thin SiO_2 layers was done at 1100°C in Ar and O_2. These studies are presented in two groupings: (*i*) diffusion in Ar or O_2 without barrier oxides, and (*ii*) diffusion in Ar or O_2 through barrier oxides. Since As is a slow diffusant in Si, junction depths were about 1μ using a diffusion time of 5 hr at 1100°C. Diffusion through thermal SiO_2 and into bare Si was in most cases measured simultaneously by starting with thermally oxidized wafers, removing the oxide from half of the wafer's surface and then coating the entire wafer with doped glass. Glass damage occurring after diffusion was also monitored, and as discussed previously, generally no glass damage occurs for Ar or O_2 diffusions when the glass contains less than 7 or 3 m/o As_2O_3, respectively.

Diffusion in Si in Ar and O_2 ambients.—Sheet resistance, R_s, and junction depth, x_j, *vs.* mole per cent As_2O_3 in the glass for glass diffusions in Ar on bare Si are shown in Fig. 8. x_j shows essentially no variation with concentration which indicates that the diffusion constant is relatively invariant for the range of surface concentrations covered here (1 to 6 × 10^{19}/cc), as shown in Fig. 9, whose data were obtained from those of Fig. 8 assuming a complementary error-function concentration profile. This method of data reduction is approximate, because the complementary error function does not match the As diffusion profiles in Si (22, 23), but was used here because of the absence of another well-established model. The diffu-

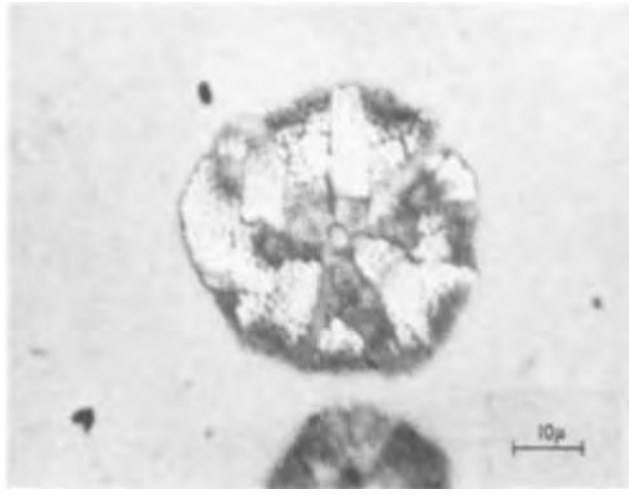

Fig. 7. Micrograph of arsenosilicate glass surface deposited from an arsine source on silicon after heat-treatment in oxygen at 1100°C for 5 hr. Damage appears in the form of individual crystalline clusters with a diameter of about 40μ. Mole per cent As_2O_3 in the as-deposited glass is 3.9 (*IR* ratio = 0.20).

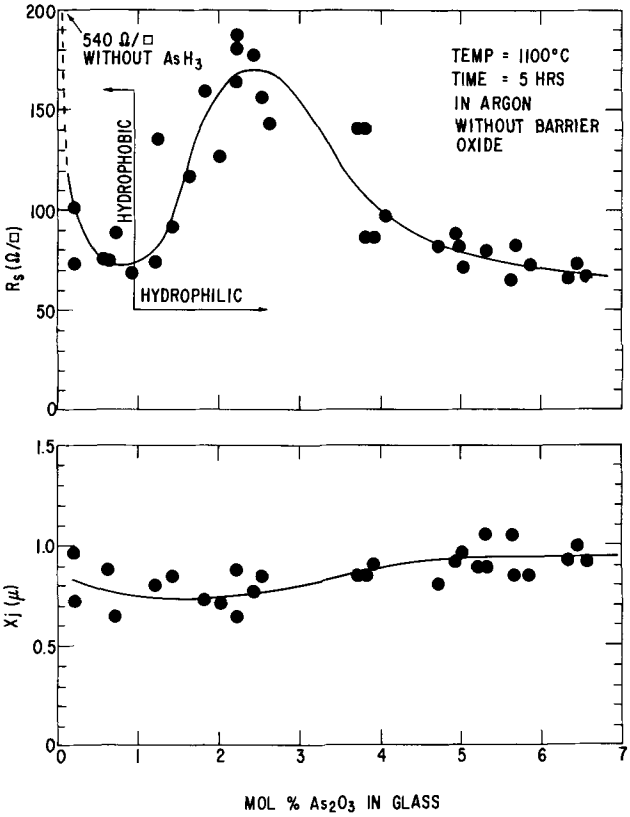

Fig. 8. Sheet resistance, R_s, and junction depth, x_j, of the diffused layers in Si *vs.* molar per cent As_2O_3 in the glass after diffusion in argon for 5 hr at 1100°C with the As-doped glass in contact with Si. After removal of all the glass in HF the silicon surface appears hydrophobic for As_2O_3 concentrations lower than 1 m/o and hydrophilic for higher concentrations.

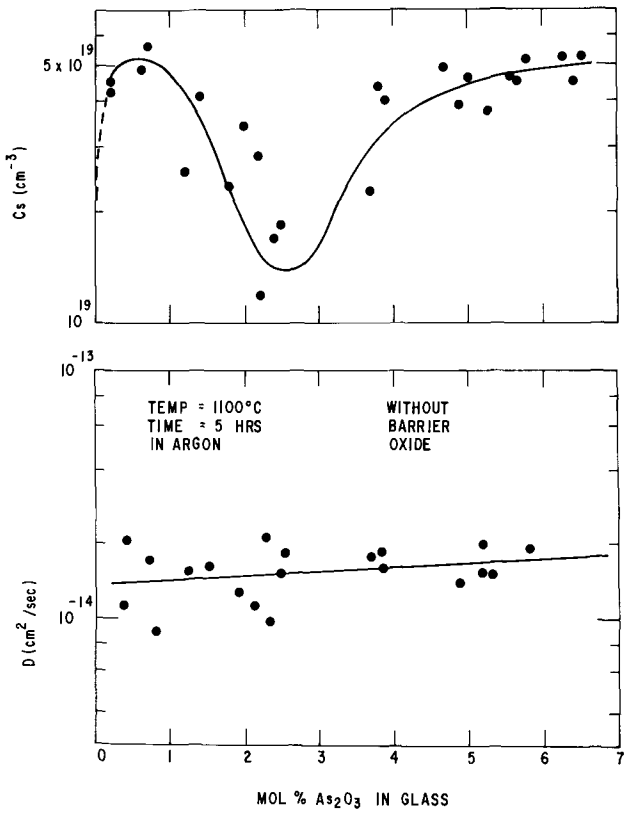

Fig. 9. Surface concentration, C_s, and diffusion coefficient, D, in Si at 1100°C in argon vs. molar per cent As_2O_3 in the glass as computed from the R_s and x_j data of Fig. 8 assuming a complementary error-function diffusion profile.

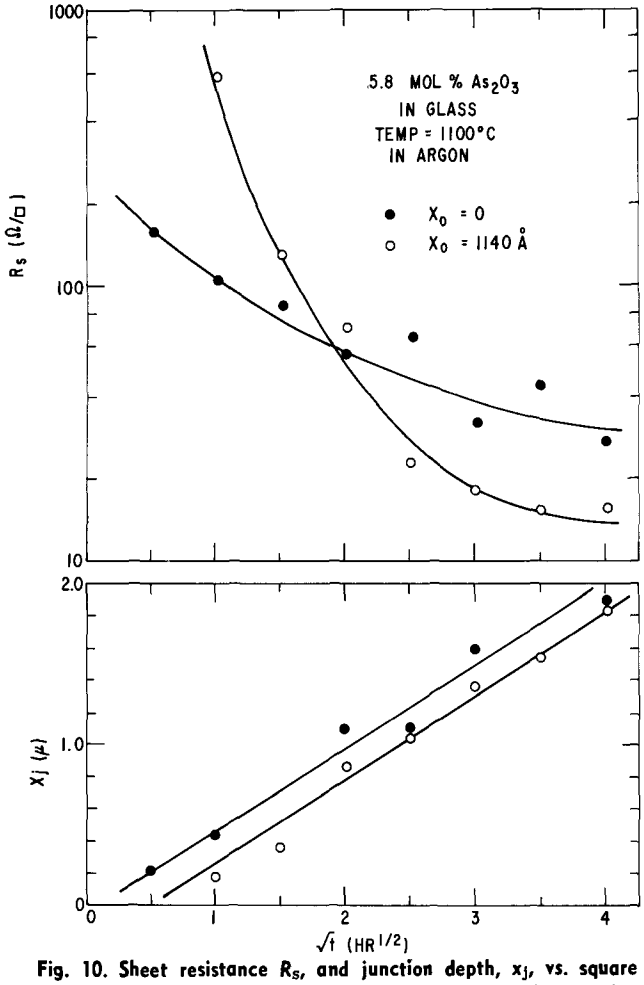

Fig. 10. Sheet resistance R_s, and junction depth, x_j, vs. square root of diffusion time after diffusion in argon at 1100°C from an As-doped glass of 5.8 m/o As_2O_3 in contact with Si ($x_o = 0$) or separated by a barrier thermal oxide of thickness $x_o = 1140$Å.

sion constant shown in Fig. 9 indicates values of 1.5 to 2.0 $\times 10^{-14}$ cm²/sec at 1100°C which are in good agreement with the data of Fuller and Ditzenberger (24) (2.7 $\times 10^{-14}$ cm²/sec), Armstrong (25) (2.0 $\times 10^{-14}$ cm²/sec), Raju *et al.* (26) (1.6 $\times 10^{-14}$ cm²/sec), and Masters and Fairfield (27) (2.4 $\times 10^{-14}$ cm²/sec).

The relative maximum in R_s for glass diffusion on bare Si which occurs for a 2.5 m/o As_2O_3 diffusion source is very surprising. This observation was reproduced several times by repeated experimentation, but we can offer no explanation for its occurrence. Another observation was made on these samples. After diffusion, the Si surface after glass removal in HF was hydrophobic in the region where the As_2O_3 concentration in the glass was <1 m/o but hydrophilic for greater concentrations. The hydrophilic nature of the surfaces that had been diffused using the higher concentrations of As_2O_3 in the glass suggests the presence of an insoluble surface layer. Since the surface concentrations obtained here (Fig. 9) are well below the solid-solubility limit (1.8 $\times 10^{21}$ cm^{-3}) (28) the presence of a second phase like that observed for solid solubility limited boron (29) or phosphorus (30) diffusions is unlikely. This surface layer might be free As, however, which would indicate that for diffusions in argon As is arriving at the Si-glass interface much faster than it can be absorbed by the Si.[1] The formation of an "arsenic-phase layer" was recently reported too by Parekh *et al.* (31) using arsenosilicate glass prepared by thermal decomposition and oxidation of TEOS (tetraethoxysilane) and $AsCl_3$. Plots of junction depth and sheet resistance *vs.* $t^{1/2}$ are given in Fig. 10.

Diffusions done in O_2 instead of Ar show slightly different characteristics. These data are shown in Fig. 11 and 12. Figure 11 gives x_j, R_s, C_s, and D *vs.* As_2O_3 concentration for a 5 hr 1100°C diffusion. In

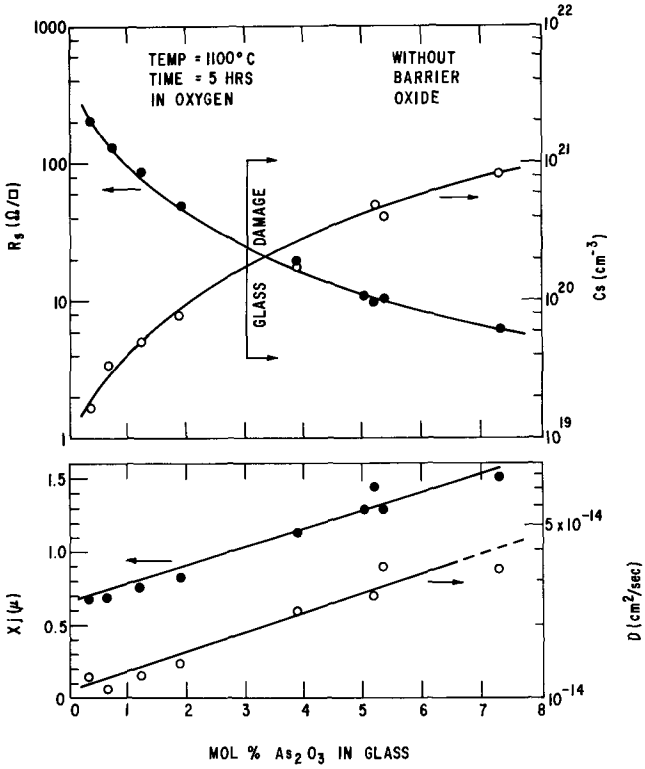

Fig. 11. Sheet resistance, R_s, junction depth, x_j, and computed values of surface concentration, C_s, and diffusion coefficient, D, vs. molar per cent As_2O_3 in the glass after diffusion in oxygen for 5 hr at 1100°C with the As-doped glass in contact with Si. Glass damage occurred for As_2O_3 concentrations higher than 3 m/o.

[1] This layer has also been observed during device fabrication and is not removed by buffered HF. However, it has been removed successfully by the use of ultrasonic cleaning. It should be noted however that the information in Fig 8 shows that this anomalous film can be avoided by using ≤ 1 m/o As_2O_3 glasses without lowering the sheet resistance.

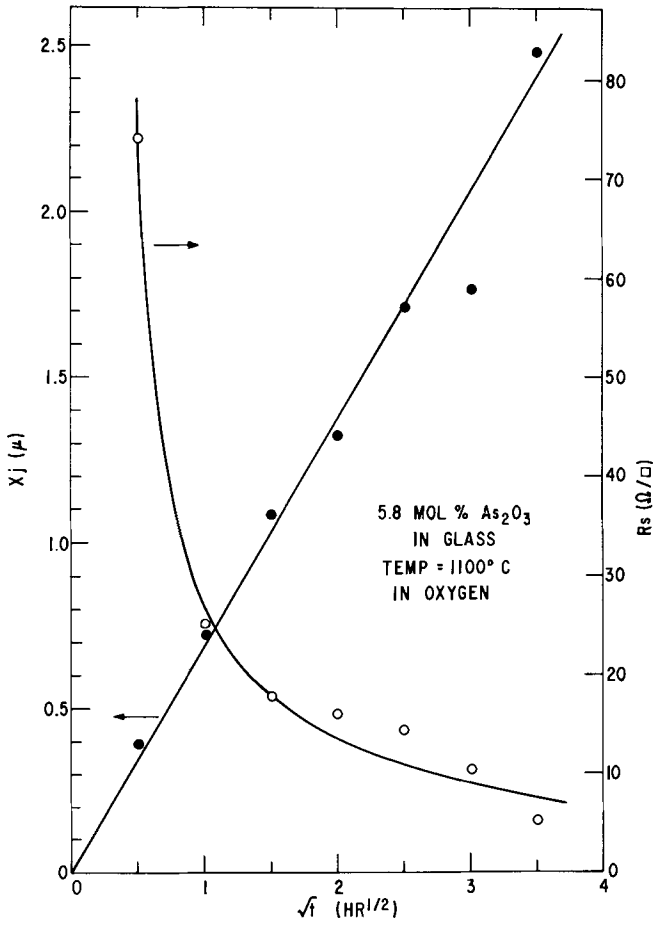

Fig. 12. Sheet resistance, R_s, and junction depth, x_j, vs. square root of diffusion time after diffusion in oxygen at 1100°C from an As-doped glass of 5.8 m/o As_2O_3 in contact with Si.

comparison with Fig. 8, the junction depth in Fig. 11 for low As_2O_3 concentrations is again about 0.7μ but increases to 1.5μ at 7 m/o As_2O_3. Normal monotonic changes in sheet resistance are also shown in Fig. 11 together with surface concentration and diffusion-constant data obtained assuming a complementary error function. An increase in the diffusion constant at 1100°C from 1.0×10^{-14} to 3.5×10^{-14} cm^2/sec in the 10^{19} to 10^{21}/cc surface-concentration range is observed. Finally, Fig. 12 gives the junction depth and sheet resistance *vs.* the square root of diffusion time using a 5.8 m/o glass source.

Diffusion in SiO_2.—Diffusivity of the As carrying species through SiO_2 was studied in the same manner as that used for As diffusions on unoxidized Si. A study of surface concentration *vs.* mole per cent As_2O_3 in the glass was carried out and separate experiments were utilized to determine the diffusivity in SiO_2 using the mathematical model of Sah *et al* (32). Here again an Ar or O_2 ambient was utilized.

Diffusion in SiO_2 in Ar ambient.—Figure 13 plots sheet resistance, surface concentration, and junction depth in the Si after diffusion through 1250Å of thermal SiO_2 *vs.* mole per cent As_2O_3 in the glass. Notice that in this instance the presence of the barrier oxide has removed the nonmonotonic changes in sheet resistance that are observed in Fig. 8. Notice also that the junction depth is only slightly decreased over those values observed in Fig. 8. This indicates that As is a relatively rapid diffuser in SiO_2 for these conditions. Similar behavior is observed in the plot of Fig. 10 where the sheet resistance and junction depth are plotted *vs.* the square root of time using data obtained from experiments utilizing a 5.8% glass and unoxidized and oxidized wafers. The penetration time for 1140Å

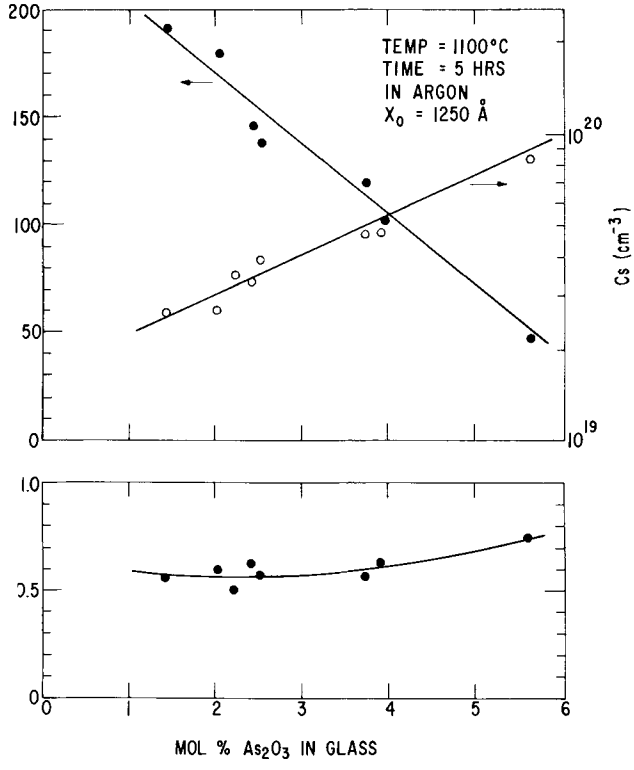

Fig. 13. Sheet resistance, R_s, junction depth, x_j, and computed surface concentration, C_s, vs. molar per cent As_2O_3 in the glass after diffusion in argon for 5 hr at 1100°C through a barrier thermal oxide layer of thickness x_o = 1250Å.

of oxide is only 0.25 hr at 1100°C. Experiments for various barrier oxide thicknesses, Fig. 14, also show the multiple behavior in R_s like that observed in Fig.

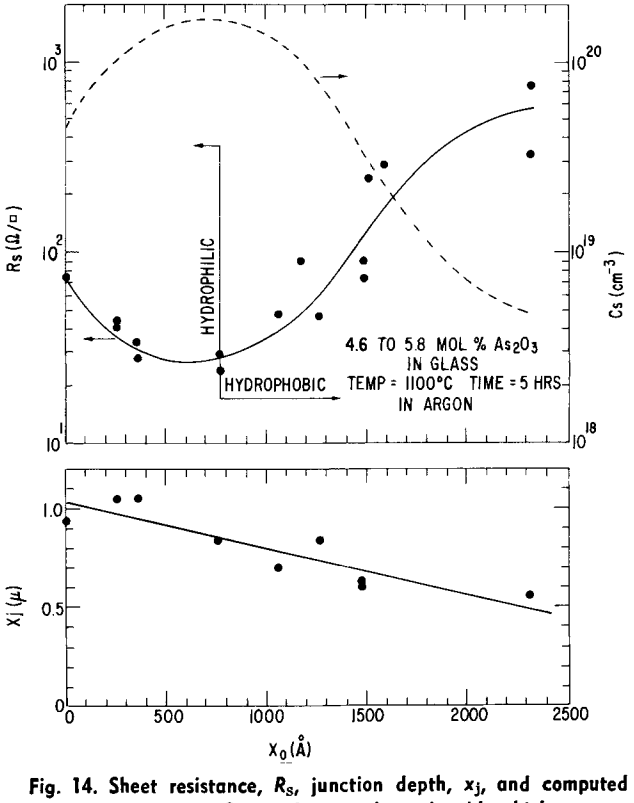

Fig. 14. Sheet resistance, R_s, junction depth, x_j, and computed surface concentration, C_s, vs. barrier thermal oxide thickness, x_o, after diffusion in argon for 5 hr at 1100°C from an As-doped glass of 4.6 to 5.8 m/o As_2O_3. After removal of all the glass in HF, the silicon surface appears hydrophilic for x_o smaller than 800Å and hydrophobic otherwise.

8 where the wafers were not oxidized. A hydrophobic-hydrophilic nature of the surfaces was also observed. Samples with less than 800Å of barrier oxide were found to have hydrophilic surfaces, whereas those above 800Å had hydrophobic surfaces after diffusion and after the glass was removed. This observation agrees with the transition that occurs with increasing As_2O_3 concentration shown in Fig. 8. The decrease of R_s with increasing oxide thickness in the 0-800Å oxide region is another surprising aspect of As glass diffusions. Teshima *et al.* (15) have observed the same phenomenon, and, in addition, recommend the use of barrier oxides to prevent the occurrence of Si surface damage during diffusion. The junction depth data in Fig. 14 were utilized to determine the diffusivity from Sah's (32) mathematical model in the same way that Brown and Kennicott (6) used similar data to determine the diffusivity of B in SiO_2. The diffusivity was determined to be 3.5×10^{-15} cm²/sec at 1100°C in Ar. As indicated in Fig. 13 there is an indication that there might be only a small concentration dependence for glasses containing up to 6 m/o As_2O_3.

Diffusion in SiO_2 in O_2 ambient.—Diffusivity data for As diffusion through barrier oxides when the diffusion is carried out in an O_2 ambient at 1100°C are shown in Fig. 15. These data give a diffusivity of 1.5×10^{-16} cm²/sec, which is smaller than that observed in Ar. This is reasonable since in Ar the diffusion species might be free As whereas in O_2 it most probably would be As_2O_3, since any reduction of As_2O_3 would be inhibited in O_2.

The fact that the glass layers were at least 6000Å thick did not preclude the build-up on Si and continuous doping of an additional 1000Å of glass during diffusion in an oxidizing ambient, with a consequent reduction in junction depth of the diffused layers due to increased thermal oxide masking thickness and movement of the SiO_2-Si boundary. Nevertheless, as the junction-depth reduction is the same for all the wafers, because they were diffused under the same conditions, the slope of x_j *vs.* x_o in Fig. 15 is

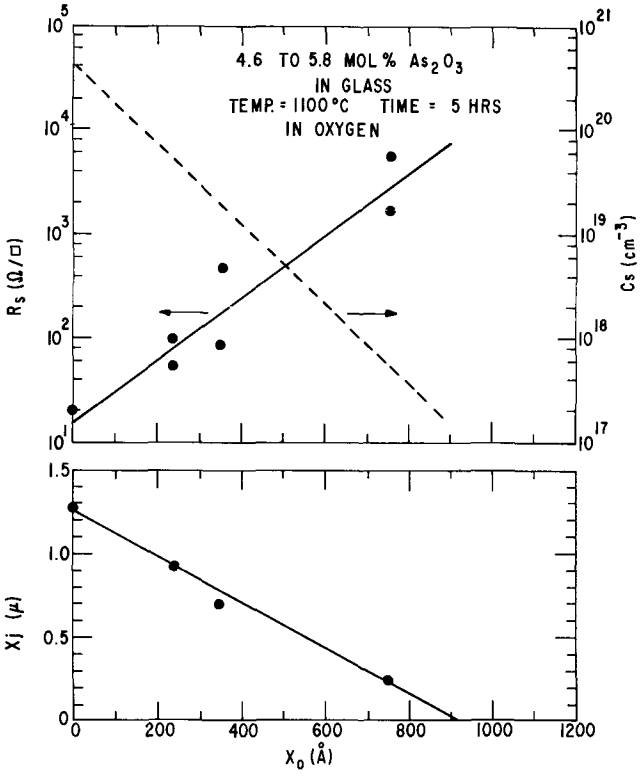

Fig. 15. Sheet resistance, R_s, junction depth, x_j, and computed surface concentration, C_s, *vs.* barrier thermal oxide thickness, x_o, after diffusion in oxygen for 5 hr at 1100°C from an As-doped glass of 4.6 to 5.8 m/o As_2O_3.

not affected by the oxide build-up and therefore this phenomenon can be neglected in the computation of the As diffusivity in SiO_2 in an O_2 ambient.

Summary and Conclusion

Arsenosilicate glass layers deposited at low temperatures (500°C) from Ar diluted mixtures of SiH_4, O_2, and AsH_3 have been investigated as As sources for As diffusion in Si and SiO_2. The film deposition rate decreased sharply for an AsH_3 concentration larger than 10% in the reactive mixture, limiting the molar percentage of As_2O_3 in the glass. Furthermore, as the deposition temperature changed, the highest AsH_3 concentration allowing film deposition changed accordingly in a monotonic relationship, dropping to only 1 m/o AsH_3 at 300°C. Etch rate of the densified films in buffered HF increased with As concentration in the glass becoming 1500 Å/min at 7 m/o As_2O_3, which is nearly twice the etch rate of pure SiO_2 (800 Å/min). Diffusion in Ar from glasses of different As_2O_3 concentrations gave anomalous results for the sheet resistivity of the diffused layers, which after an expected drop with increasing As concentration in the glass source increased again to a relative maximum corresponding to 2.5 m/o As_2O_3 before resuming the negative slope. This phenomenon did not occur in diffusions in an O_2 ambient. Arsenic concentration in the glass was found to be related to the onset of damage in the glass during heat-treatment, which for the diffusion conditions of 5 hr at 1100°C appeared at 7 m/o As_2O_3 in Ar, and at 3 m/o As_2O_3 in O_2. Besides, diffusion in O_2 enhanced the junction depth and the surface concentration of the diffused layers in comparison to similar Ar diffusions with an increase from 1.0 to 1.5μ for x_j, and from 5×10^{19} to 8×10^{20} cm^{-3} for C_s in glasses containing 7 m/o As_2O_3.

Diffusivities of As in SiO_2 were also investigated by means of diffusions at 1100°C in Ar and in O_2 ambients through thermal oxide barriers of different thickness. The results showed that the ambient is very important in determining the As diffusivity in SiO_2, because using the same glass-source composition the diffusivity in Ar was over one order of magnitude higher than in O_2 at 1100°C (3.5×10^{-15} cm²/sec in Ar *vs.* 1.5×10^{-16} cm²/sec in O_2 with a 5.8 m/o As_2O_3 glass source).

Impurity Atom Transfer during Epitaxial Deposition of Silicon

G. Skelly* and A. C. Adams*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

When epitaxial silicon is deposited on highly doped substrates, impurity atoms transfer from the substrate to the growing epitaxial film. This transfer, usually referred to as autodoping, may establish a lower limit on the dopant concentration in the epitaxial film and may prevent the formation of an abrupt doping profile. We have studied the transfer of arsenic during the deposition of epitaxial silicon by the pyrolysis of silane at a temperature of 1050°C. The amount of autodoping is determined from the flat portion of the doping profile and has been studied as a function of the substrate dopant concentration. The data are interpreted in terms of solid-state diffusion theory by assuming that during deposition the arsenic diffuses to the back of the substrate, evaporates from the back surface, transfers in the gas phase to the front surface, and then is incorporated into the film. Calculations indicate that 0.9% of the arsenic that evaporates from the back surface is deposited into the epitaxial film. Our results show that autodoping is linearly dependent on the substrate doping concentration and becomes significant when the arsenic concentration is greater than 2×10^{18} cm^{-3}. The autodoping can be reduced by a factor of about five by masking the back of the substrate with silicon oxide or by heating the substrate at a high temperature for a few minutes to allow the arsenic near the back surface to evaporate prior to deposition.

Many current silicon device structures require the deposition of lightly doped epitaxial layers over highly doped substrates or over highly doped diffused areas. In these structures, the transfer of dopant from the substrate to the growing epitaxial layer may be an important source of impurities in the epitaxial film. In some cases, this transfer of impurities may even establish a lower limit on the dopant concentration in the epitaxial film and may prevent the formation of an abrupt change in dopant concentration at the film-substrate interface. The dopant transfer that occurs when the epitaxial layer is formed by the hydrogen reduction of silicon tetrachloride or trichlorosilane has been reported (1-8). However, there is no detailed study of the dopant transfer when the layer is deposited by the pyrolysis of silane. In fact, it has been reported that for the silane process the transfer of dopant may not occur (9) or that the transfer can be eliminated by masking the back of the substrate with silicon oxide. (10). We have studied the transfer of dopant during the deposition of epitaxial silicon by the pyrolysis of silane for substrates doped with arsenic. The experimental results are presented and discussed in this paper.

The initial observation of a dopant transfer during epitaxial deposition from silicon tetrachloride was made by Basseches *et al.* (1) who suggested that the impurities were transferred from the back of the substrate wafer. Thomas, Kahng, and Manz (2, 3) reported that the dopant concentration in the epitaxial film decreased with distance from the interface. These authors proposed a model in which the dopant transfers from the substrate surface to the gas phase, mixes with the reactant gases, and is then incorporated into the growing film. A mathematical expression was derived which accounted for the observed impurity profiles. Grossman (4), who used the term "autodoping," derived an expression for the time dependence of the

* Electrochemical Society Active Member.
Key words: autodoping, diffusion, epitaxy, silane, silicon.

epitaxial reaction and suggested that impurities were released during a transient etching of the substrate at the beginning of the deposition. Grove *et al.* (5) studied epitaxial depositions on boron- and antimony-doped substrates, and Abe *et al.* (6) investigated autodoping in layers deposited on arsenic-doped samples. Both groups of authors concluded that the impurity profiles could be accounted for by solid-state diffusion of impurities from the substrate into the epitaxial film; autodoping effects were not required to explain the profile shape. In these previous investigations, the epitaxial layers were deposited by the hydrogen reduction of silicon tetrachloride at temperatures near 1200°C. Joyce, Weaver, and Maule (7) studied dopant transfer during the hydrogen reduction of trichlorosilane at similar temperatures using radiotracer techniques. They concluded that the proposed etch-back mechanism (2-4) was unlikely and that the impurities were transferred from the back of the substrate. They also found that autodoping was not important unless the doping level in the epitaxial layer was less than 5×10^{14} cm^{-3}. Recently, Shepherd (8) has presented a model of autodoping that assumes that impurities evaporate from the back of the substrate into the gas stream and then deposit in the epitaxial film. Gupta and Yee (10), who determined the experimental conditions necessary to obtain abrupt impurity profiles for silane-deposited epitaxial films, found that autodoping could be reduced by growing an oxide on the back of the substrate prior to the deposition.

Most previous workers have inferred the presence or absence of autodoping by comparing the shape of the doping profile with shapes calculated for thermal diffusion of impurities from the substrate into the epitaxial layer. Since it is very difficult to accurately measure and compare profile shapes, most previous studies have not given quantitative information concerning the magnitude of the autodoping effect. In addition, the dopant concentration in the substrate has not been systematically varied in many of the previous studies; consequently, there are few experimental data concerning the dopant transfer as a function of the impurity atom concentration in the substrate. In the work reported in this paper, autodoping is measured from the flat portion of the doping profile rather than from a comparison of profile shapes. In addition, autodoping has been studied for arsenic-doped substrates in which the dopant concentration ranges from 5×10^{14} to 4×10^{19} cm^{-3}.

Experimental

The epitaxial layers have been grown in a single-slice, water-cooled, vertical flow system which is induction heated using a high-purity graphite susceptor. The system has been previously described (11). The substrate, which is 3.1 cm in diameter, is mounted vertically so that the sample is approximately parallel to the gas flow. The epitaxial layers are formed by the pyrolysis of silane at an optical temperature of 1000°C. The actual temperature, obtained by correcting for emissivity and reflection from the quartz reactor walls, is estimated to be 1050°C (12). The silane concentration in the reaction chamber is 0.2%; the carrier gas is hydrogen which has been purified with a palladium diffuser. The gas flow through the reaction chamber is 2.13 l/min; the linear velocity is 1.80 cm/sec. The observed growth rate for these conditions is 0.35 μm/min. Thicknesses of the epitaxial films are typically 4-7 μm. Prior to the deposition, the substrates are cleaned by degreasing with organic solvents followed by a rinse in hydrofluoric acid. Final cleaning is performed in the reaction chamber by an *in situ* etch with 0.1% hydrogen chloride at an actual temperature of 1050°-1100°C. The etch rate is less than 0.02 μm/min. The epitaxial layers are deposited on the (111) or the (100) orientations; no differences between the two orientations have been observed.

Schottky diodes are formed on the epitaxial layers by evaporating gold to form circular dots which are 0.508 mm in diameter and 1000Å thick. The majority carrier concentration in the epitaxial film is determined from measurements on the Schottky diodes using the CIP technique (13, 14) with the modifications reported by Thibault (15). The validity of the Schottky diode and the CIP measurements has been established by also making planar and mesa diodes on some samples and by obtaining capacitance-voltage measurements on the different diodes. The agreement among the different diodes and the different measuring techniques is excellent. Majority carrier concentrations are converted to impurity atom concentrations using the equations reported by Kennedy *et al.* (16, 17).

Results

Typical profiles as measured by the CIP technique on Schottky diodes are shown in Fig. 1. These profiles show the measured majority carrier concentrations and have not been converted to impurity atom concentration (16, 17), thus the actual doping profiles are much sharper than the measured profiles shown in Fig. 1. Except for small changes in the deposition time, the epitaxial layers have been deposited under identical conditions for each sample; the only intentional variable is the substrate doping which is given for each curve. It should be noted that the doping concentration in the epitaxial film is nearly constant with distance from the surface except at the substrate-film interface. This implies that during growth, the dopant is introduced at a nearly constant rate. In these experiments, there is no intentional doping of the epitaxial layer; consequently, the steady-state doping level is a direct measure of the background doping level in the system during a particular experiment. The background impurity concentration is the sum of the impurities in the gases (the silane and the hydrogen) plus the impurities in the system (the gas line, the reactor walls, and the susceptor) plus the impurities from the substrate (the autodoping). Data such as that in Fig. 1 strongly suggest that the background doping level is often established by the im-

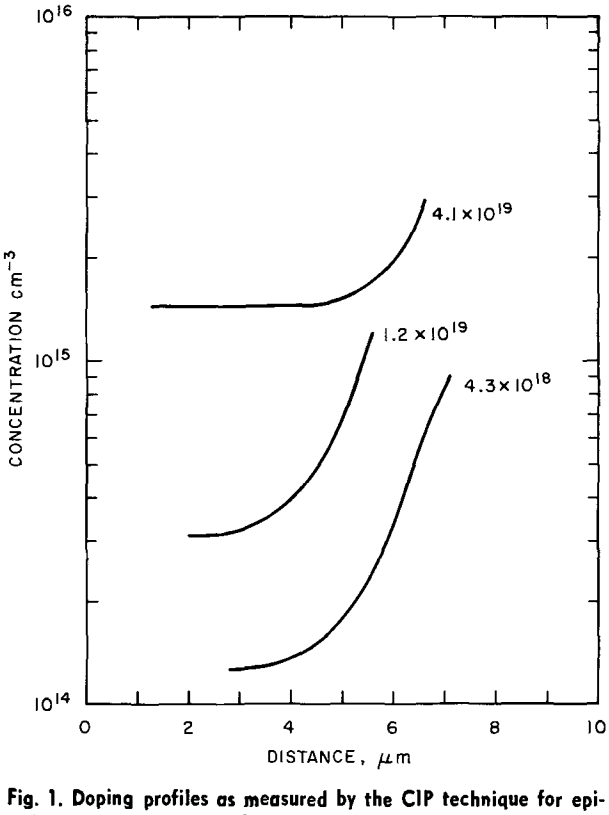

Fig. 1. Doping profiles as measured by the CIP technique for epitaxial layers deposited on three different arsenic-doped substrates.

purities from the substrate; the impurities from the other two sources are negligible. Before this conclusion can be accepted it is necessary to rule out the possibility of random fluctuations in the background doping level that might affect the results.

The absence of fluctuations has been established by correlating the epitaxial dopant concentration with changes in the substrate doping level. When the concentration of arsenic in the substrate is systematically increased or decreased, it is observed that the epitaxial dopant concentration also increases or decreases. When the substrate doping concentration is varied in a random manner, the epitaxial doping still correlates with the substrate doping. Results from such an experiment are shown in Fig. 2 which gives the concentration of dopant in the epitaxial layer for seven consecutive depositions in which the only variable is the arsenic concentration in the substrate (listed on the right in Fig. 2). When the arsenic concentration in the substrate is 5×10^{14}, 8×10^{18}, or 4×10^{19} cm^{-3}, the dopant concentration in the layer on the substrate is 6×10^{13} to 1×10^{14} cm^{-3}, 3×10^{14} cm^{-3}, or 1.5×10^{15} cm^{-3}, respectively. The reproducibility in the epitaxial dopant concentration rules out the possibility of random fluctuation in the background impurity concentration and shows that autodoping often establishes the background doping level.

In general we find that when lightly doped substrates are used and autodoping is not significant, the background doping varies from 5×10^{13} to 1×10^{14} cm^{-3}. This variation probably results from changes in the impurities released from the system since the same gases are used in all the experiments. This variation in the impurities from the system does not change any of our conclusions since the autodoping effects cause the epitaxial layers to be doped at concentrations much higher than this background doping.

The results from several experiments with arsenic-doped substrates are plotted in Fig. 3, which shows the epitaxial doping *vs.* the substrate doping. In each case the dopant concentration in the epitaxial film is measured from the flat portion of the doping profile. The substrate doping is obtained by four-point probe measurements using Irvin's curves to convert resistivity to impurity concentration (18); in some cases this has been checked by measuring the position of the plasma minimum in the infrared reflectance spectrum (19). Again the agreement is excellent. In the experiments shown in Fig. 3, the background doping level (shown

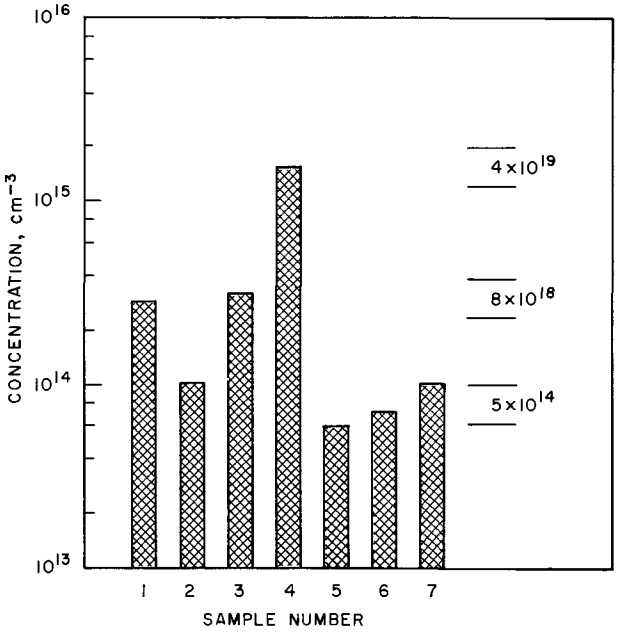

Fig. 2. Epitaxial dopant concentration for seven consecutive depositions on arsenic-doped substrates.

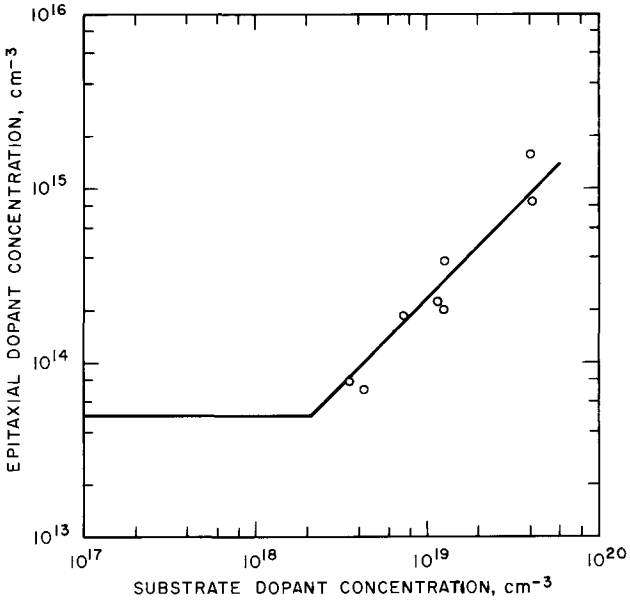

Fig. 3. Epitaxial dopant concentration for arsenic-doped substrates. The background doping level is 5×10^{13} cm^{-3}.

by the horizontal line) has been established to be 5×10^{13} cm^{-3} by depositing on substrates doped to 5×10^{14} cm^{-3}. The sloping line is drawn for the case in which the epitaxial doping is directly proportional to the substrate dopant concentration. The data are consistent with this model. It is clear from this figure that autodoping effects are not significant unless the arsenic concentration in the substrate is greater than 2×10^{18} cm^{-3}.

Several experiments have been performed in an effort to elucidate the autodoping mechanism and to determine if autodoping can be reduced or eliminated. In some experiments a heavily doped epitaxial layer, 3 μm thick, was deposited on a lightly doped substrate. The arsenic concentrations in the epitaxial layer and in the substrate were about 1×10^{19} cm^{-3} and 5×10^{14} cm^{-3}, respectively. The sample was cut in half and an "undoped" epitaxial layer was deposited on the front of one part and on the back of the other part, after the back surface had been polished smooth. When the epitaxial film was deposited on the heavily doped layer, the dopant concentration in the undoped layer was an order of magnitude less than when the undoped epitaxial film was deposited on the original substrate with the heavily doped region at the back. This shows that most of the dopant atoms that are transferred from the substrate to the growing epitaxial layer originate from the back of the substrate as originally suggested by Basseches *et al.* (1). Such a result is reasonable since the back of the substrate is in contact with the hot susceptor and is probably at a higher temperature than the front of the sample so that impurities evaporate from the back at a faster rate than from the front. This result indicates that autodoping will be reduced when the epitaxial layer is deposited over highly doped regions such as in buried layer structures. However, our data do not pertain to the possible lateral transfer of dopant, which may be the dominant mechanism in these structures (20).

The autodoping effect should be reduced or eliminated by masking the back of the substrate with a material which is impervious to the dopant. Epitaxial layers have been deposited on substrates with 15,000Å of steam oxide on the back. In this case the autodoping is reduced by a factor of about five but not eliminated. This agrees with previous reports in which similar results have been presented (7, 10). In these experiments, the arsenic must be transferred through the oxide. This transfer has been demonstrated by Joyce, Weaver, and Maule who measured the transfer of

radioactive arsenic from samples that were completely covered with a thick oxide (7).

The impurity atom distribution across the sample has been determined by measuring Schottky diodes on different parts of the same sample. The results show a slightly higher dopant concentration at the edge than at the center. This effect, which has been observed before (7, 8), has been used to argue that impurities are transferred from the back, over the edges, and toward the center of the sample (7). We have observed differences in dopant concentration between the center and the edge that are about the same as those reported by previous workers (7, 8). However, our differences are not consistent or reproducible; this may result from different gas flow patterns over different areas of the sample.

It is possible that autodoping results from the formation of volatile chlorides of the dopant atoms; the chlorine may come from residual hydrogen chloride that is not removed from the reaction chamber in the time between the vapor etch and the deposition. This possibility has been eliminated by performing experiments in which the epitaxial layers are deposited without the hydrogen chloride vapor etch. There are no significant changes in the doping level in the epitaxial film. This shows that volatile chlorides are not necessary for the transfer of impurities and implies that autodoping results entirely from thermal effects.

Discussion

The experimental data indicate that most of the autodoping originates when impurities are transferred from the back of the sample. This is reasonable since the front of the sample rapidly becomes covered by the growing epitaxial film and diffusion of impurities from the substrate to the front of this film does not normally occur. The condition required to prevent diffusion through the growing film is that the growth rate be much greater than the rate of diffusion, or

$$Gt >> (Dt)^{1/2}$$

where G is the deposition rate, t is the time, and D is the diffusion coefficient. If we consider a growth rate of 0.35 μm/min (5.83×10^{-7} cm/sec) and use the literature value for the diffusion coefficient of arsenic at 1050°C, 2×10^{-14} cm^2/sec (21), then the two terms are equal after a deposition time of 5.9×10^{-2} sec. After 5 sec of growth, Gt is nearly ten times greater than $(Dt)^{1/2}$, showing that for our deposition times the growth rate is much greater than the rate of diffusion and that diffusion through the growing film is negligible.

Our discussion of autodoping considers the case where impurities diffuse from the bulk to the back surface of the sample, evaporate from the back surface, transfer in the gas phase to the front of the sample, and deposit in the growing epitaxial layer. The presence of a gas phase transfer as opposed to surface diffusion has been established since autodoping effects are reported to be much greater in the direction of the gas flow (7, 20). If the rate limiting step in the autodoping process is the rate at which impurities diffuse out of the substrate, then the rate of impurity incorporation in the epitaxial film is proportional to the rate of out-diffusion from the sample and the autodoping effects can be described in terms of solid-state diffusion theory.

Smits and Miller (22) have studied the diffusion of impurities from silicon. They give the following expression for the case in which the impurity concentration in the gas phase is zero and the silicon is initially uniformly doped

$$N(y,z) = N_0 - N_0 \exp(-y^2)\{\exp(y^2)\operatorname{erfc}(y) - \exp[(y+z)^2]\operatorname{erfc}(y+z)\}$$

where

$$y = x/2(Dt)^{1/2}$$

and

$$z = (Dt)^{1/2}K/D$$

The initial impurity concentration in the silicon is N_0; N is the concentration at some time, t, and at some distance from the surface, x; D is the diffusion coefficient; and, K is a first-order rate constant for the evaporation of impurities from the silicon surface. Integrating this expression from $x = 0$ to ∞ and subtracting from the total number of impurity atoms initially present gives the number of impurity atoms which have diffused out of the silicon (22)

$$\overline{N}(t) = 2N_0(Dt)^{1/2}\{\pi^{-1/2} - [1 - \exp(z^2)\operatorname{erfc}(z)]/2z\}$$

Differentiating with respect to time gives the rate at which impurity atoms diffuse out of the substrate

$$R = \frac{d\overline{N}}{dt} = N_0K\exp(z^2)\operatorname{erfc}(z)$$

In the model we are considering, the amount of autodoping is proportional to the out-diffusion rate, R; the proportionality constant is the fraction of impurity atoms that transfer to the growing epitaxial layer. At long times ($z >> 1$), the rate of out-diffusion can be approximated by

$$R \approx N_0(D/\pi t)^{1/2}$$

Under these conditions, the rate of out-diffusion is limited by the rate at which impurities diffuse to the back surface. Our equation for the rate of out-diffusion has the same form as the equation given by Shepherd (8). The difference is in the pre-exponential factor. In our equation this factor is based on an experimentally measured rate constant. In Shepherd's equation, the pre-exponential factor is based on the activity coefficient of the dopant and a gaseous transfer coefficient. Our equations are derived for the case where the impurity concentration in the gas phase is zero. This should not be a serious limitation in a flow system where the gas is continuously removed.

A plot of the calculated rate of out-diffusion *vs.* time is shown in Fig. 4. The value of D (2×10^{-14} cm^2 sec^{-1})

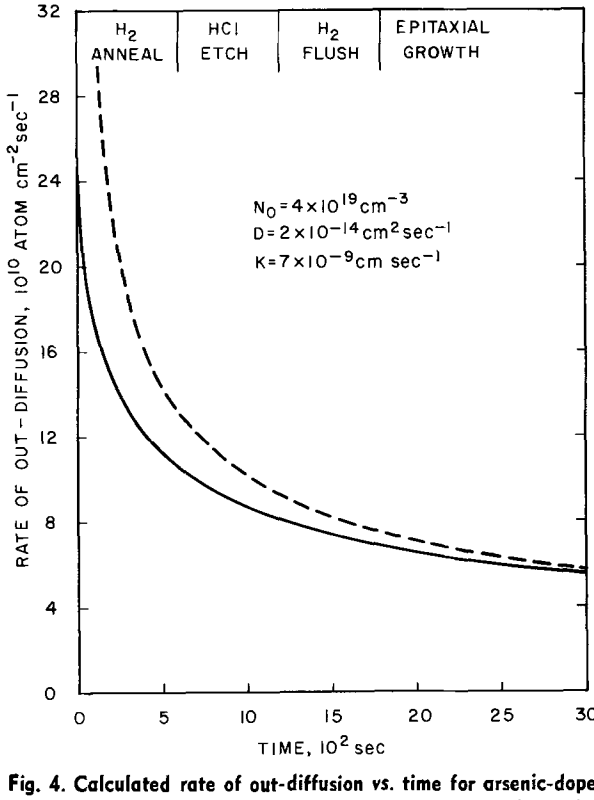

Fig. 4. Calculated rate of out-diffusion *vs.* time for arsenic-doped substrates and for a deposition temperature of 1050°C. The dashed line shows the diffusion-limited case.

has been taken from the data of Masters and Fairfield (21) for a temperature of 1050°C. The value of K (7×10^{-9} cm sec^{-1}) is the value reported by Abe *et al.* (6) at 1250°C corrected for the different temperature by assuming that K has the same temperature dependence as D, as suggested by Lehovec *et al.* (23). The dashed line in Fig. 4 shows the rate of out-diffusion for the diffusion-limited case, which is valid at long times; also shown are the time intervals for the different steps in the epitaxial process. The silicon removed during the hydrogen chloride etch has not been considered in calculating the rate of out-diffusion. Calculated curves for different values of D and K are shown in Fig. 5 and 6. Variations in D do not affect the initial rate; however, they cause a displacement of the curves at long times. This is reasonable since at long times the rate of out-diffusion becomes diffusion limited and is independent of K and proportional to the square root of D. Increasing the value of K only affects the initial part of the rate curve (Fig. 6) since the latter portion is diffusion limited and independent of K. Decreasing the value of K causes the rate of out-diffusion to decrease because the rate of out-diffusion is now limited by the rate of evaporation rather than the rate of diffusion to the surface.

Before discussing our data we briefly consider two additional aspects of this model. First, the fraction of impurity atoms transferred to the epitaxial layer can be determined by combining the measured impurity concentration in the film with the calculated number of impurity atoms that have diffused from the sample. Integration of the rate of out-diffusion between times of 1800 and 2400 sec gives 3.7×10^{13} atoms of arsenic that have diffused from 1 cm^2 of silicon with an initial arsenic concentration of 4×10^{19} cm^{-3} and at a temperature of 1050°C. The epitaxial doping concentration corresponding to this substrate doping is 9.4×10^{14} cm^{-3} (Fig. 3). Thus the number of arsenic atoms per square centimeter of an epitaxial film 3.5 μm thick (corresponding to a deposition rate of 0.35 μm/min and a 10 min deposition time) is 3.3×10^{11} atoms/cm^{-2}. Therefore, only 0.9% of the arsenic that diffuses out of the sample is incorporated in the epitaxial film. Shepherd found that 0.3% of the impurity atoms were transferred (8); however, he was working with much higher gas flows so the lower fraction is not unreasonable.

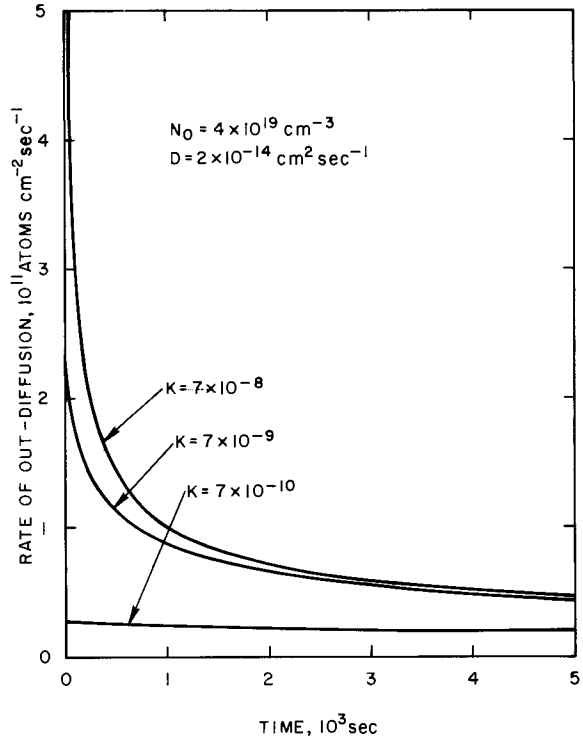

Fig. 6. Calculated rate of out-diffusion *vs.* time for different values of the evaporation rate constant.

The impurity profiles that result from thermal out-diffusion are shown in Fig. 7. It can be seen that the out-diffusion is confined to the region near the surface. Essentially all of the atoms that evaporate from the silicon come from within a few tenths of a micron of the surface. Although the surface concentration may become very low prior to the deposition, this evaporation of impurities from the substrate normally has only a slight effect on the shape of the final substrate-epitaxial film profile as shown by Abe *et al.* (6).

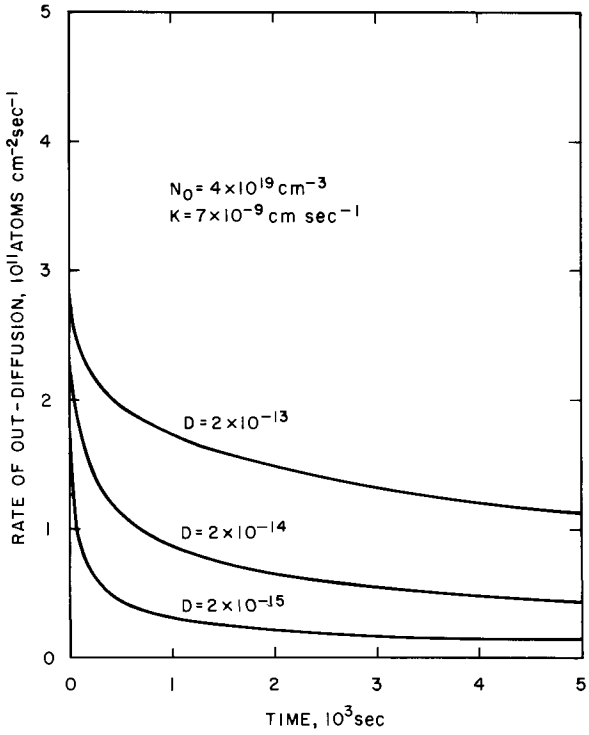

Fig. 5. Calculated rate of out-diffusion *vs.* time for different values of the diffusion coefficient.

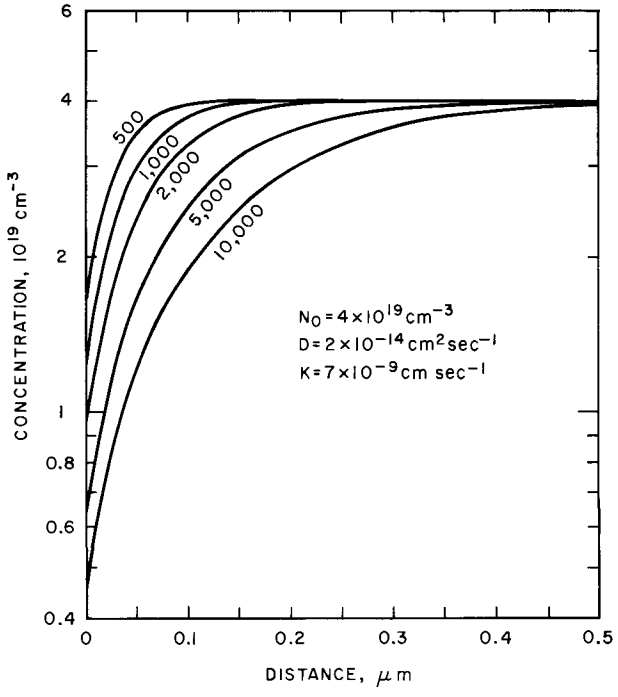

Fig. 7. Calculated substrate doping profiles resulting from evaporation of arsenic at 1050°C. The heating times in seconds are given for each curve.

In the model we are presenting, the rate of out-diffusion is directly proportional to the initial impurity concentration in the silicon substrate. Consequently, the dopant concentration in the epitaxial film should also be proportional to the substrate impurity concentration provided that the fraction of impurity atoms transferred to the epitaxial film is independent of the substrate doping level. Such a linear relationship between the dopant concentration in the epitaxial film and in the substrate is shown in Fig. 3. At very high substrate dopant concentrations, the autodoping may no longer be directly proportional to N_0 because the diffusion coefficient is concentration dependent (21). However, it is obvious that the experimental data approximate a linear relationship. When the substrate doping is less than about 2×10^{18} cm $^{-3}$, the number of arsenic atoms transferred is less than the background dopant concentration and autodoping effects are not observed. Basseches *et al.* (1) found a similar dependence of the epitaxial impurity concentration on the substrate dopant concentration; however, a quantitative relationship was not established.

The shape of the doping profile in regions which are not near the substrate-epitaxial interface is determined by changes in the rate of out-diffusion. From Fig. 4, it can be seen that for depositions between 1800 and 2400 sec, the change in the impurity concentration throughout the epitaxial layer is about 12%. However, part of this change is obscured by the high concentration of impurities that diffuse from the heavily doped substrate into the lightly doped epitaxial layer, and the region near the surface is not measured because of the built-in depletion layer of the Schottky diodes. Thus the total change in dopant concentration that can be observed should be about 5%. Such a small change is consistent with our measured profiles (Fig. 1) and explains the observation that the dopant concentration is nearly independent of thickness. Our model should also apply to the previous reports in the literature where flat doping profiles have been observed (5, 7, 10).

In some experiments we have eliminated the hydrogen chloride etch and the hydrogen flush from the epitaxial deposition procedure and have deposited immediately after a short hydrogen anneal. For these depositions, which typically occurred between times of 180 and 780 sec, the observed dopant concentrations decreased with distance from the interface by a factor of about two. This is consistent with the changes in the rate of out-diffusion as given in Fig. 4. The curves in Fig. 4 show that most of the arsenic escapes prior to the deposition. If we consider a 10-min deposition occurring between times of 1800 and 2400 sec, then only 18% of the arsenic atoms diffuse out of the substrate during the deposition. The remaining 82% diffuse out during the heat-treatments before the deposition and are swept out of the system. This is consistent with the data of Joyce, Weaver, and Maule (7) who found that most of the impurity atom transfer occurs prior to the deposition.

This particular model provides a quantitative explanation for the flat profiles and for the concentration dependence of the autodoping. We now briefly consider a qualitative extension of this model to explain some observations that have been reported in the literature. There are reports of doping profiles resulting from autodoping that are not flat (2, 3). This may result from evaporated impurities being absorbed on the susceptor or the reactor walls prior to deposition and being slowly desorbed during deposition, thus causing a net decrease in the gas phase impurity concentration during deposition. In our experiments we have attempted to minimize these effects by using a small susceptor and by cleaning and coating the susceptor prior to each deposition. Another explanation for the sloping profiles is the possibility of silicon slowly depositing on the back of the sample in addition to the more rapid deposition on the front. If this deposition occurs then the rate of out-diffusion will decrease with time more rapidly than shown in Fig. 4 and the doping profiles will not be flat. A slow deposition on the back of the substrate has recently been observed (24).

A possible method of reducing the autodoping is to heat the sample at high temperature prior to deposition and thus deplete the silicon near the back surface. We have calculated the rate of out-diffusion for substrates with an arsenic concentration of 4×10^{19} cm^{-3} which are heated at 1200°C for 20 min and then heated at 1050°C for 10 min immediately prior to deposition. For these conditions the calculated rate of out-diffusion at the start of the deposition is 1.0×10^{10} atoms/cm^{-2} sec^{-1} as compared to an out-diffusion rate of about 7×10^{10} atoms/cm^{-2} sec^{-1} when the predeposition heat-treatments are performed at 1050°C (Fig. 4). This high-temperature treatment may reduce the autodoping by a factor of seven; however, these calculations assume that D and K have the same temperature dependence and that the temperature changes are abrupt, so that any quantitative interpretation must be considered tentative.

Preliminary data indicate that antimony-doped substrates exhibit less autodoping than arsenic-doped samples. The decreased autodoping may result because the rate of evaporation is less for antimony than for arsenic, since the diffusion coefficients for arsenic and antimony are nearly the same (25). A lower limit for the rate of evaporation of antimony from silicon at 1050°C can be obtained from the data of Grove *et al.* (5), ($K > 1 \times 10^{-10}$ atoms/cm^{-2} sec^{-1}). For small values of K, the rate of out-diffusion can be approximated by N_0K, so that the out-diffusion rate is about 4×10^9 atoms/cm^{-2} sec^{-1} at the lower limit of K. This is an order of magnitude less than the rate for arsenic given in Fig. 4 and may explain the decreased autodoping for antimony-doped samples.

Acknowledgment

We wish to thank M. H. Hanes and L. R. Thibault for their help in making the CIP measurements; T. Misawa and R. A. Moline for making C-V measurements, and R. Lieberman for providing data on the hydrogen chloride etching of silicon.

Manuscript received May 24, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Effects of Heat-Treatment on Composition of CVD Films: The Case of Binary Arsenosilicate Glasses

J. Wong

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

By following the chemical composition and integrated intensity of the combined Si-O and As-O bands in the region 1400-800 cm^{-1} of the infrared as a function of thermal history of CVD (chemical vapor deposition) arsenosilicate films, it is found that structural changes and not composition variations are responsible for the observed shifts in band frequency and maximum absorbance in the resultant heat-treated films. This result indicates that loss of As_2O_3 to the ambient due to out-diffusion from low As_2O_3-content arsenosilicate-glass source (<1 mole per cent (m/o) As_2O_3) may be minimal, if not negligible, in the process of drive-in diffusion of arsenic into silicon at 1000°C and up.

Infrared absorption spectroscopy is a powerful technique for the characterization and structural evaluation of dielectric thin films on silicon (1-14). Aside from its usual ability to identify chemical entities present in the film, it is also capable of furnishing quantitatively chemical compositions of multicomponent films in a nondestructive manner. The latter application has been used to advantage recently to determine nondestructively the composition of as-deposited CVD (chemical vapor deposition) films of binary arsenosilicate (12) and borosilicate (13) in the range 0-20 mole per cent (m/o) As_2O_3 and 0-100 m/o B_2O_3, respectively.

A recent report (15) from this laboratory shows that heat-treatment in an inert argon atmosphere causes quite a marked variation in the vibrational spectra of binary arsenosilicate films vapor deposited on silicon from a one-liquid source SiH_4-$AsCl_3$-O_2-Ar system. The Si-O band at 1060 cm^{-1} shows a positive frequency shift to 1080 cm^{-1} accompanied by an increase in optical density (absorbance) of about 25-30%. The As-O band at 920 cm^{-1} shifts to 930 cm^{-1} and is accompanied by a decrease in optical density. Because of large differences in thermal and evaporation characteristics of the As_2O_3 and SiO_2 end components in this binary system, it is important to establish whether reduction in the As-O band intensity is due to evaporation loss of As_2O_3 to the ambient during heat-treatment at high temperatures, or structure changes within the glassy network without change in composition. The composition variation, or otherwise, of these films is relevant to the understanding of out-diffusion of arsenic species from the glass to the ambient in the process of drive-in diffusion of arsenic for the formation of N^+ diffused layers in silicon.

In an attempt to elucidate the correlation between changes in infrared band intensity and film composition and/or structural variation, the compositions of CVD arsenosilicate films before and after heat-treatment were followed by quantitative chemical analysis.

Key words: CVD films, arsenosilicate, infrared intensity, heat-treatment.

The integrated intensities of the Si-O and As-O vibrational bands in the range 1400-800 cm^{-1} were studied as a function of film thermal history. Spectral variations resulting from chemical treatment of the film in boiling water and conc HCl were also obtained for comparison.

Experimental

Binary arsenosilicate glass films were prepared on silicon wafers by a CVD technique using argon-diluted mixtures of SiH_4-$AsCl_3$-O_2 at 450°C. Details of the deposition procedure and composition determination of as-deposited films from the infrared spectra have been reported elsewhere (12, 15). A Sartorius microbalance sensitive to 20 μg was used to obtain film weights by difference. Film compositions were determined by an x-ray microprobe technique. This technique enables the same film to be analyzed before and after heat-treatment. Films were heat-treated at 800°C for 15 min in Ar (flowing at 1 ft^3 per hr^{-1}) using a conventional horizontal furnace. Infrared spectra were recorded with a Perkin-Elmer 457 double-beam recording spectrophotometer. Scan rates of 400 cm^{-1} per min and 200 cm^{-1} per min were used in the range 4000-2000 cm^{-1} and 2000-250 cm^{-1}, respectively. All spectra were taken at room temperature. The area under the Si-O and As-O vibrational bands in the frequency range 1400-800 cm^{-1} was measured with a calibrated OTT compensating polar planimeter.

Results and Discussion

In Fig. 1, the infrared spectra of a series of arsenosilicate films deposited on silicon wafers are plotted as linear absorbance *vs.* wave number in the range 1400-800 cm^{-1}. The dotted curves are those for the as-deposited films while the solid curves are those for the corresponding films heat-treated in Ar at 800°C for 15 min. It is evident in all cases that upon heat-treatment the Si-O band at 1060 cm^{-1} shows a positive frequency shift of ~20 cm^{-1} accompanied by an increase in absorbance at the band maximum. The As-O band at 920 cm^{-1} also shows a positive frequency

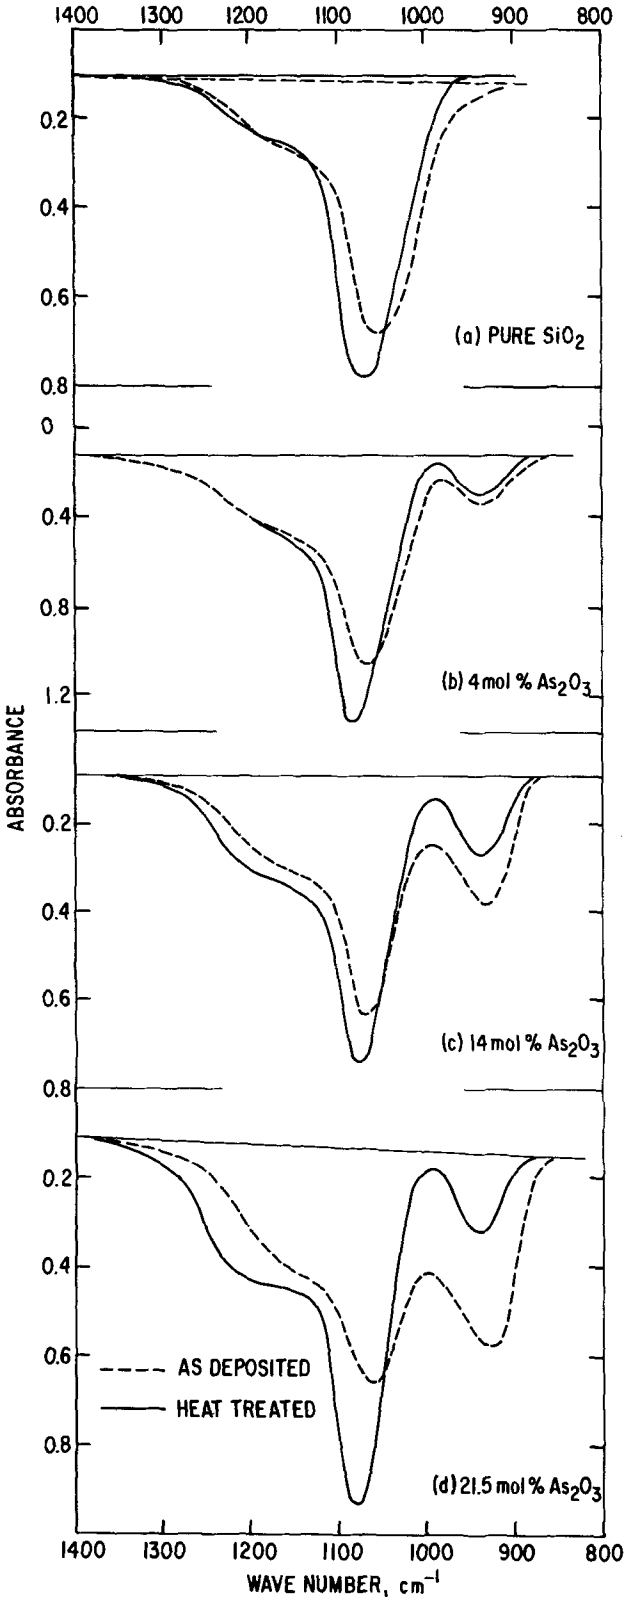

Fig. 1. Infrared spectra of a series of as-deposited and heat-treated arsenosilicate films in the region of the Si-O and As-O stretching vibrations. Heat-treatment: 800°C in Ar for 15 min. Thickness of as-deposited samples: (a) 0.52μ; (b) 0.82μ; (c) 0.70μ; and (d) 0.90μ.

shift of ~10 cm^{-1} but with a decrease in absorbance at the band maximum. Spectral variations of the Si-O band in a pure CVD SiO_2 (Fig. 1a) are similar to those in the binary films.

The total area (see Footnote b under Table I) under each of the absorption curves shown in Fig. 1 is given in Table I. In the binary films (samples 2-4 in

Table I

Sample	Mole per cent As_2O_3[a] (as-deposited)	Total area[b] under absorption bands in the range 1400-800 cm^{-1}: As-deposited	Heat-treated	Chemically treated	Microprobe analysis[e] As/Si atomic ratio: As-deposited	Heat-treated	Estimated error
1	pure SiO_2	73	73				
2	4	146	147		0.08_0	0.08_8	±0.005
3	14	94	94		0.33_4	0.35_1	±0.010
4	21.5	119	117	88[c]	0.56_8	0.53_9	±0.020
5	19.0	89		89[d]			

[a] Determined from the IR spectra of as-deposited films using a previously reported chemical calibration curve (12).

[b] Strictly speaking, the integrated intensity of a band is given by

$$\int_{\text{band}} \alpha(\bar{\nu})\,d\bar{\nu} = \int A(\bar{\nu}) \times \frac{1}{t}\,d\bar{\nu} = \frac{1}{t}\int A(\bar{\nu})\,d\bar{\nu}$$

where $\alpha(\bar{\nu})$ and $A(\bar{\nu})$ are the absorption coefficient and absorbance at frequency $\bar{\nu}$ respectively, and t is the film thickness. The integral $\int A(\bar{\nu})\,d\bar{\nu}$ therefore denotes the area under an absorption band when absorbance is plotted *vs.* wavenumber. Since we are interested primarily in the total absorption of the same film before and after heat-treatment, the term "total area" can be used interchangeably with integrated intensity because t is a common factor.

[c] Films exposed to conc HCl for 20 hr; or to boiling water for 3 min.

[d] Films exposed to 100% R.H. for 670 hr.

[e] High purity silicon and GaAs were used as standards for Si and As.

Table I) there is essentially no change in integrated intensity after heat-treating at 800°C in Ar for 15 min. This suggests that the total Si-O and As-O oscillators in each film remain invariant after heat-treatment and that there is no change in film composition due to volatilization loss of As_2O_3. Furthermore, a film of pyrolytic SiO_2 deposited at 450°C shows no change in integrated intensity (sample 1 in Table I) in the same spectral region after identical heat-treatments. This implies that the shift to higher frequency and narrowing of the half-width of the Si-O band at 1060 cm^{-1} in pyrolytic SiO_2 is merely a manifestation of structural changes in the silica network brought about by thermal annealing (1). Angular reorientation of the Si-O-Si centers (16) and/or further condensation of hydrogen-terminating Si-O chains (17) are possibilities of these structural changes. It is of interest to note that there is no further change in the SiO_2 spectrum upon heat-treatment beyond 800°C in the range 900°-1200°C.

The invariance of integrated intensity of the combined Si-O and As-O bands in the binary films and that of the Si-O band in pure pyrolytic SiO_2 in the range 1400-800 cm^{-1} before and after heat-treatment is informative. This seems to indicate that the observed As-O band in the spectra of as-deposited binary films has a substantial "borrowed" intensity from the Si-O band in the region below 1000 cm^{-1}. This borrowed intensity is reduced when the Si-O band narrows and shifts to higher frequency upon heat-treatment [see Fig. 1(a)]. The decrease in intensity of the As-O band in the heat-treated films appears therefore to be due to a reduction of this borrowed intensity and not to a reduction of As_2O_3 content in the film.

The above conclusion is substantiated by chemical analysis on the same films before and after heat-treatment at 800°C. In Table I, x-ray microprobe data on the same binary films used for the infrared study are given. Film compositions determined by this technique are expressed in terms of the atomic ratio of As/Si. It can be seen that, within instrumental error, there is no change in film composition after heat-treatment. Another series of arsenosilicate films containing 1.8-16.0 m/o As_2O_3 (as-deposited) showed no changes in film weight after heat-treatment for 15 min at 800°C in Ar (Table II).

For completeness, effects on film composition by chemical treatment in various environments have also

Table II. Weights of arsenosilicate films before and after heat-treatment at 800°C in Ar

Sample	Mole per cent As_2O_3 (as-deposited)	Film weight[a] (mg) As-deposited	Heat-treated
5	1.8	1.41	1.41
6	4.5	1.37	1.37
7	8.5	1.67	1.67
8	13.4	1.85	1.85
9	16.0	1.43	1.43

been studied. Variations in the infrared absorption in the range 1400-800 cm^{-1} are given in Fig. 2 for films containing about 20 m/o As_2O_3 (as-deposited). Each of these films was separately exposed to a controlled humidity (100% R.H.) at room temperature, treated in boiling water and in conc HCl. The spectral changes in these chemically treated films are qualitatively similar to those that occurred in the heat-treated films

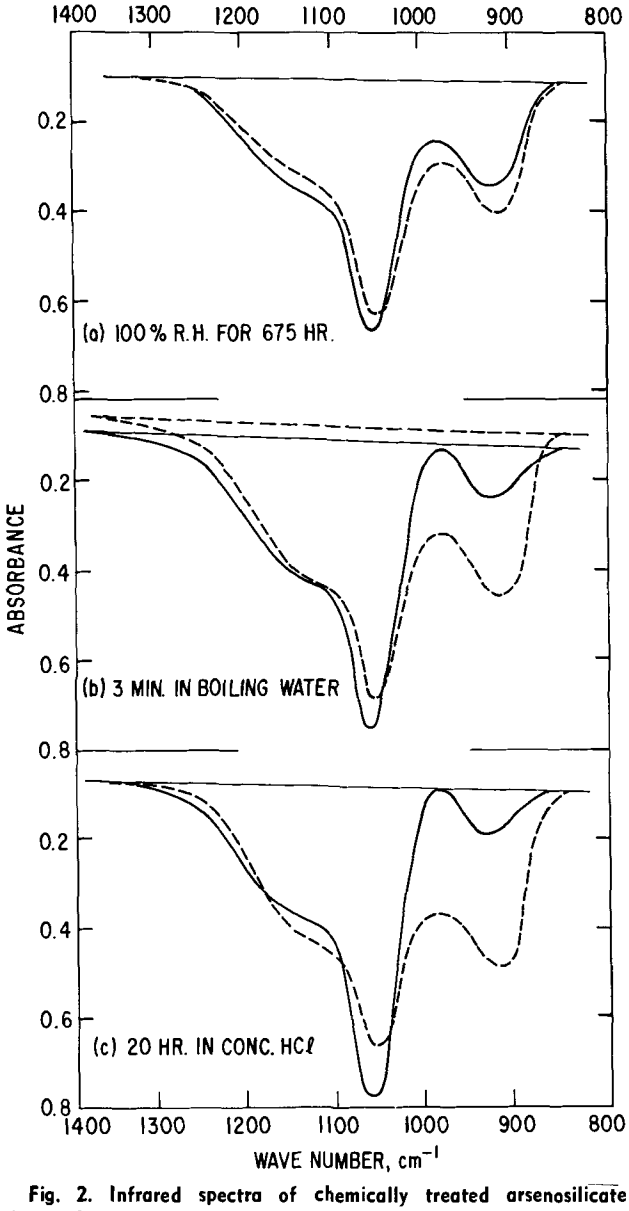

Fig. 2. Infrared spectra of chemically treated arsenosilicate films. The dotted curves represent spectra of the as-deposited films. Film composition (as-deposited): (a) 19 m/o As_2O_3; (b) and (c) 21.5 m/o As_2O_3.

shown in Fig 1. For films treated in boiling water and conc HCl, however, the total area under the combined Si-O and As-O bands decreases by about 25% (Table I) from the "as-deposited" values, showing that there is loss of As_2O_3 in the treated films. This is conceivable in light of the high solubility of As_2O_3 in both water and conc HCl, whereas pure SiO_2 is practically not etchable by either of these reagents. A film exposed to 100% R.H. at room temperature shows no change in integrated intensity implying that there is no leaching of film material by this treatment.

Conclusion

The combined data on infrared integrated intensity, chemical and gravimetric analyses indicate that there is no composition change due to volatilization loss of As_2O_3 at 800°C in Ar from CVD binary arsenosilicate glass films containing as much as 20 m/o As_2O_3. Loss of As_2O_3 to the ambient due to out-diffusion from low As_2O_3-content arsenosilicate glass source (<1 m/o As_2O_3) may be minimal, if not negligible, in the process of drive-in diffusion of arsenic into silicon at 1000°C and up (18). This is no doubt due to a lowering of the As_2O_3 activity (vapor pressure) in low As_2O_3-content mixtures.

Results from chemical treatments show that the combined integrated intensity of overlapping infrared absorption bands intrinsic of the material of interest is a good measure of composition conservation or otherwise in binary systems.

Acknowledgments

Thanks are due to M. Garfinkel for suggesting composition analysis of the films before and after heat-treatment. Useful discussions with J. W. Mitchell are deeply appreciated.

The Growth of Niobium on Perfect and Imperfect Sapphire

J. J. Cuomo* and J. Angilello

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Niobium prepared by rf sputtering has been found to nucleate and grow differently on the basal plane of low dislocation density (chemical vapor deposited) and high dislocation density (Czochralski-grown) sapphire (α-Al_2O_3) wafers. The low dislocation α-Al_2O_3 showed three different orientations related to each other by a threefold axis: (110) Nb//(0001) α-Al_2O_3 and [110] Nb//$\vec{a}_1$, $\vec{a}_2$, $\vec{a}_3$ α-Al_2O_3, while those films grown on more imperfect, high dislocation substrates, generally showed only one orientation: (111) Nb//(0001) α-Al_2O_3 and [110] Nb//[1120] α-Al_2O_3.

The orientation dependence of gold on air-contaminated and uncontaminated sodium chloride has been detailed by Matthews (1). Robbins and Rhodin (2) found a relationship between the maximum number of gold nuclei on MgO and the crystal from which the MgO was cleaved. It was concluded, that the number of gold nuclei depends on the difference in the number of point defects such as impurities in the MgO substrates. In both instances, a correlation between nucleation density and surface defects has been demonstrated. Matthews' work further shows the preference for one orientation to nucleate and another to grow, thus producing a change in orientation and/or crystallinity with nucleation density.

This work reports on the growth of niobium films by rf sputtering technique on the basal planes of "perfect" and "imperfect" sapphire/(α-Al_2O_3) having low and high dislocation densities, respectively. In order to improve the single crystalline quality of niobium on sapphire, CVD sapphire was chosen as a substrate due to its low dislocation density. However, we found the films grown on low dislocation substrates showed three different orientations related to each other by a threefold axis, while those films grown on more imperfect, high dislocation, substrates generally showed only one orientation.

Experimental Procedures

Low dislocation sapphire boules prepared by chemical vapor deposition were purchased from Lexington Laboratories, Lexington, Massachusetts. They were cut into 10 mil thick wafers and polished to a 1 μin. finish by Insaco Corporation, Quakertown, Pennsylvania. High dislocation sapphire wafers were cut and polished by Insaco Corporation from crystals prepared by the Czochralski growth technique. All samples prior to deposition were examined by the x-ray topographic techniques developed by Lang (3, 4) and Schwuttke (5). The orientation of the substrates used in this work were (0001). Niobium was deposited by rf sputtering using the following procedure. The chamber was pumped to 4×10^{-8} mm of Hg and the substrates were then heated to 450°C. Argon was introduced to 15×10^{-3} mm of Hg and the system was presputtered by sputtering niobium onto a shutter for 30 min. The substrates were exposed to the niobium atom flux at a power density of 7.4 W/cm². With the anode target grounded, the niobium accumulation rate was about 10 Å/sec. The substrates and film were examined after deposition by x-ray back-reflection Laue techniques and film orientations were confirmed by x-ray pole figure investigations. Both types of sapphire substrates were deposited on simultaneously; therefore, the conditions for growth were identical. The niobium films used during this investigation were of high quality as indicated by the high resistance ratios (6) and the bulk superconducting properties (7) shown.

* Electrochemical Society Active Member.

Key words: niobium, epitaxy, sapphire, sputtering, nucleation.

Results

Prior to niobium deposition, x-ray topographs were taken of the substrate. Figure 1a shows the topograph of low dislocation, perfect sapphire. The number of dislocation etch pits as revealed by polishing and etching techniques (9) is of the order of 50/cm². Figure 1b is an optical photograph of the pits in one of the highest density areas on the low dislocation wafer. The transmission x-ray topograph of the high

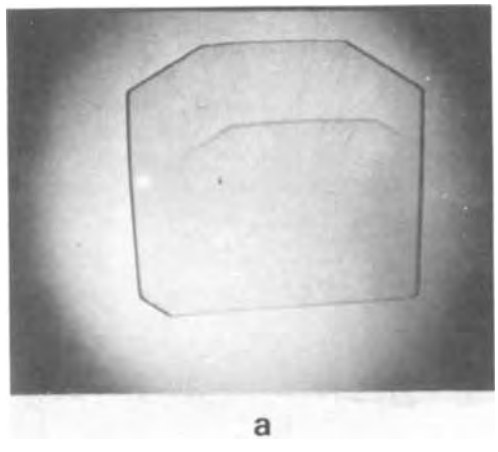

Fig. 1a. Transmission x-ray topograph of low dislocation CVD sapphire (0001). Approx. 4×.

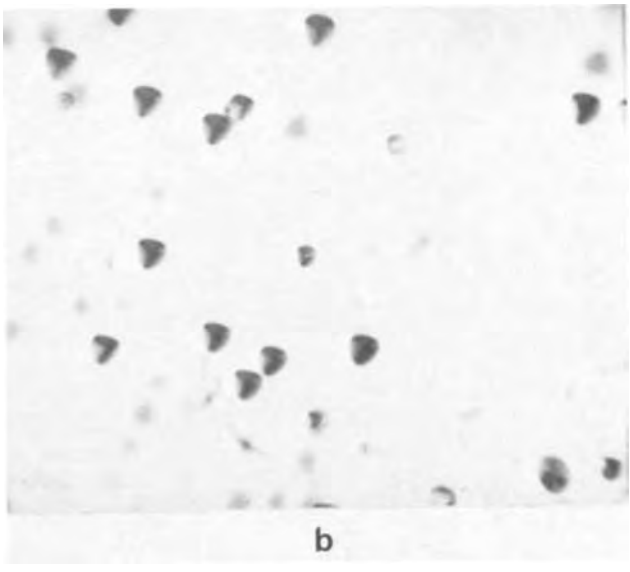

Fig. 1b. Dislocation etch pit pattern of the highest density area on low dislocation CVD sapphire (0001). 78×.

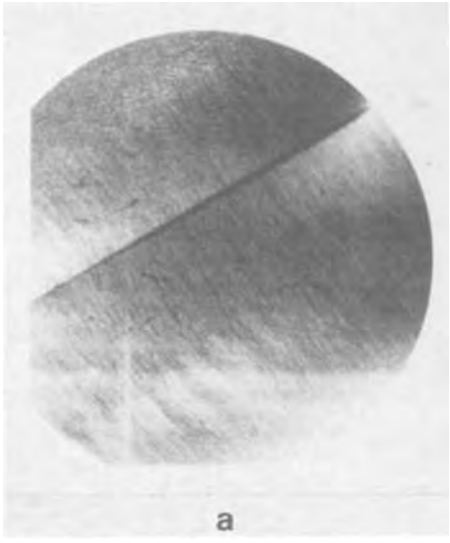

Fig. 2a. Transmission x-ray topograph of high dislocation density Czochralski sapphire (0001). Approx. 3×.

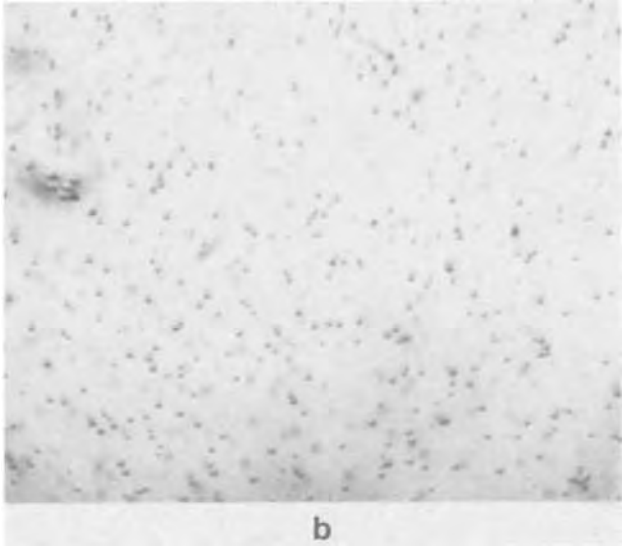

Fig. 2b. Dislocation etch pit pattern of high dislocation Czochralski sapphire (0001). 78×.

dislocation, imperfect sapphire is shown in Fig. 2a. The number of dislocations represented by this topograph, and the pit density shown in Fig. 2b, is of the order of 10^4-10^5/cm^2.

The results of an emission spectrographic analysis of chemical vapor deposited α-Al_2O_3 and Czochralski-grown α-Al_2O_3 are shown in Table I. The impurities found in both materials above the detectable limits were Si and Mg, which were similar for the two types of materials. Verneuil-grown sapphire was also examined and showed about 10 ppm Ti in addition to the other impurities. With the exception of the Ti content and some shallow angle grain boundaries, the Verneuil-grown sapphire showed substantially the same results as the Czochralski-grown sapphire.

Table I. Emission spectrographic analysis of CVD and Czochralski grown α-Al_2O_3

Impurities	CVD α-Al_2O_3 low dislocation, ppm	Czochralski α-Al_2O_3 high dislocation, ppm	Verneuil α-Al_2O_3 high dislocation, ppm
Si	3	3	3
Mg	0.3-1	0.3-1	0.3
Ti	N.D.*	N.D.	10-30

* Not detected.

Approximately 6000Å of niobium was desposited by rf sputtering on both CVD (low dislocation) and Czochralski (high dislocation) substrates. Figures 3a and 3b are x-ray back-reflection Laue photographs of low dislocation, perfect sapphire before and after niobium deposition, respectively. The orientation of the niobium is threefold heteroepitaxial, that is, (110) Nb // (0001) α-Al_2O_3 and [110] Nb // $\vec{a}_1$, $\vec{a}_2$, $\vec{a}_3$ α-Al_2O_3 giving rise to a highly textured polycrystalline film. A schematic depicting the orientation relationship of the niobium on (0001) of α-Al_2O_3 is shown in Fig. 3c. The 120° rotational symmetry of the (110) Nb on the (0001) plane of α-Al_2O_3 accounts for the threefold symmetry shown in the Laue photograph. A lattice overlay for a single set of spots is shown in Fig. 3d. The misfit is calculated to be 1.8% for the $[11\bar{2}0]$ direction.

Figures 4a and 4b are Laue patterns of high dislocation imperfect sapphire before (Fig. 4a) and after

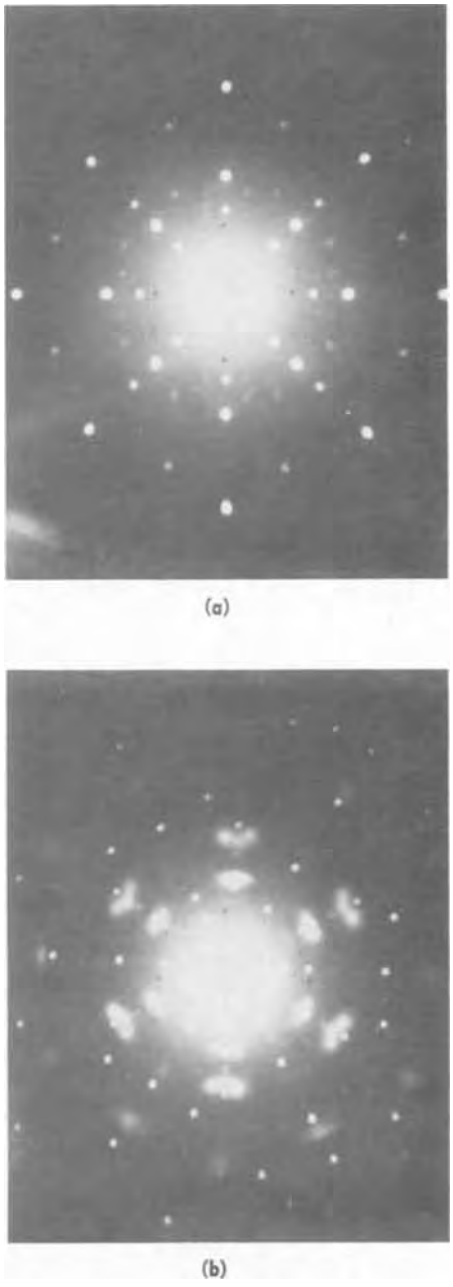

Fig. 3a and b. X-ray back-reflection Laue patterns of the low dislocation CVD sapphire (0001) before and after Nb deposition respectively.

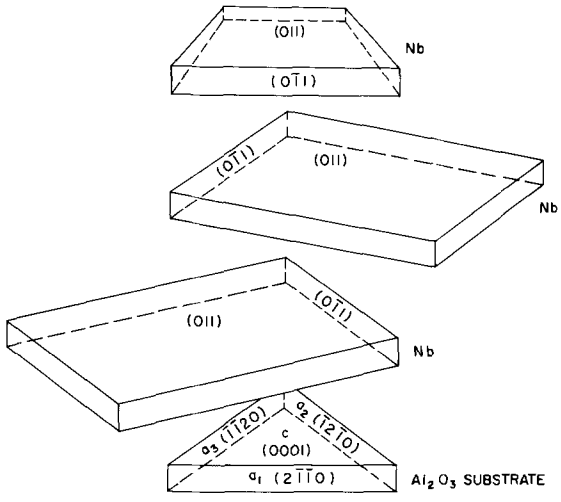

Fig. 3c. Schematic of the orientation of (110) Nb on (0001) α-Al_2O_3.

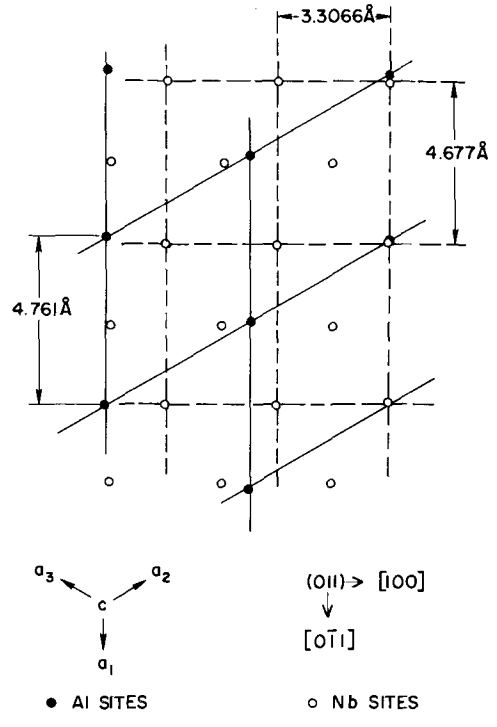

Fig. 3d. Lattice overlay of (110) Nb on (0001) α-Al_2O_3 for one of the orientations.

(Fig. 4b) the niobium deposition. In this case, the niobium is heteroepitaxial and single crystalline with the (111) Nb // (0001) α-Al_2O_3 and the [110] Nb // [11$\bar{2}$0] α-Al_2O_3. In some instances, small quantities of polycrystalline (110) Nb // (0001) α-Al_2O_3 was also found. Figure 4c schematically demonstrates the film substrate relationship and Fig. 4d is the lattice overlay of (111) Nb on (0001) α-Al_2O_3. The lattice misfit between Nb-Nb and Al-Al (8) is 1.8%, the same as in the previous case. It is interesting to note that in both cases the [110] direction of the Nb is parallel to the [11$\bar{2}$0] direction of the α-Al_2O_3 in the plane of the wafer.

Discussion

It is unknown at this time how defects contribute to the difference in nucleation and growth of niobium on the CVD and Czochralski sapphire. The difference in the number of emergence points of dislocations between the two materials would be insufficient to cause the difference in the nucleation and growth observed. Previous discussions (1) have shown that dislocation densities of the order of $10^5/cm^2$ are far below the nucleation density $10^{12}/cm^2$ needed to effect the preference for nucleation of a particular orientation. The result found is related to differences in the nucleation density between (111) and (110), to differences in surface defect concentration and type, and to interfacial surface energy difference between (111) and (110). Indeed, one must consider the orientation with the lowest interfacial surface energy since it will have the highest nucleation density (1).

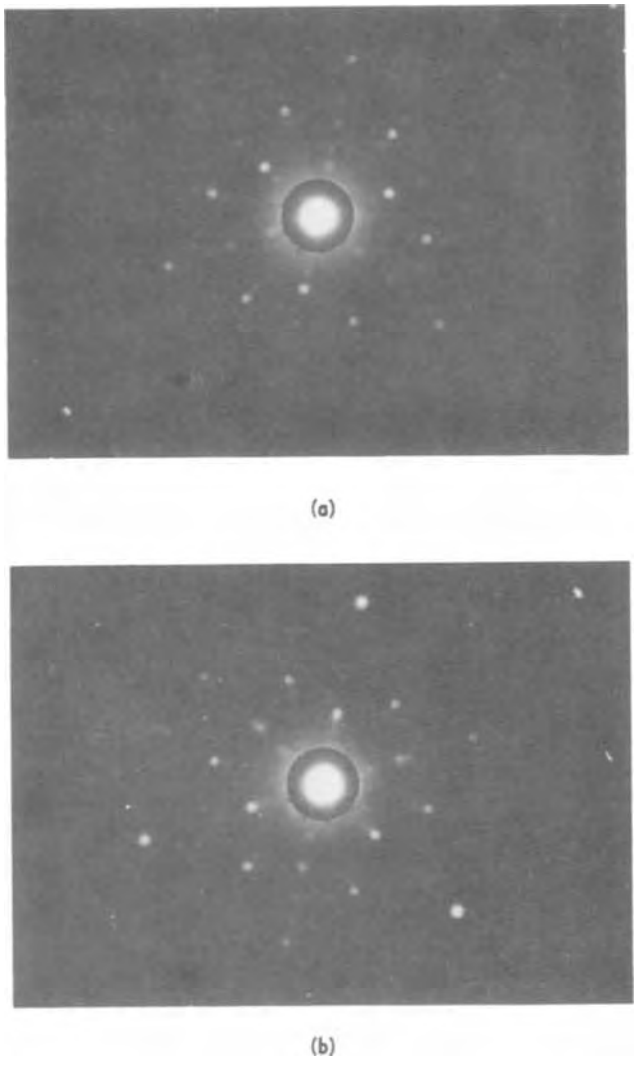

Fig. 4a and b. X-ray back-reflection Laue patterns of Czochralski sapphire (0001) before and after Nb deposition, respectively.

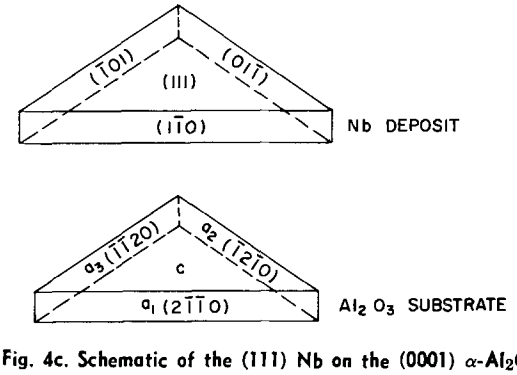

Fig. 4c. Schematic of the (111) Nb on the (0001) α-Al_2O_3

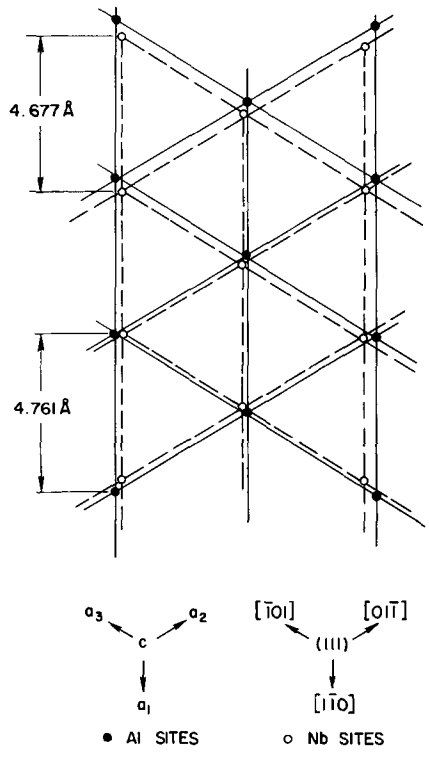

Fig. 4d. Lattice overlay of the (111) Nb on (0001) α-Al_2O_3

Further work is needed to distinguish among the various possibilities in particular studies during the initial stages of growth.

On the Anodic Sectioning of Vanadium

II. Studies on Anodic Sectioning

M. R. Arora* and Roger Kelly*

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Anodic sectioning can be accomplished with vanadium almost as readily as with Al, Mo, and W, the main problem being the instability of the anodic film. The basic technique consists of forming films in an electrolyte based on acetic acid (as was shown possible by Keil and Salomon) and then removing the films with aqueous KOH. The thickness calibrations were obtained separately for high and low sectioning voltages, the results for high voltages being as follows: total metal removed in units of $\mu g/cm^2$ equal to $5.5 + 0.64 \times$ volts (for voltages ≥ 4); thickness of oxide in units of $\mu g/cm^2$ equal to $2.0 + 1.14 \times$ volts (for voltages ≥ 7.5). Particular attention was paid to extending the calibrations to low sectioning voltages. In the case of the oxide thickness, the approach used can be regarded as an alternative to ellipsometry, being based on a three-step procedure in which a film is formed, 20 or 40-keV Kr^{85} ions are implanted, and the film is stripped with aqueous KOH. The fraction of the Kr^{85} activity which is transmitted can be shown, using amorphous stopping theory, to give direct information on the film thickness. The low-voltage calibrations were as follows: total metal removed in units of $\mu g/cm^2$ equal to $1.0 + 1.78 \times$ volts; thickness of oxide in units of $\mu g/cm^2$ equal to $-5.1 + 2.09 \times$ volts.

A major problem in the use of ion implantation is that a detailed knowledge of the depth distribution of the ions is required. For example, with implanted semiconductors the depth distribution directly determines the junction depth, peak impurity concentration, and the base width (1) and indirectly determines the depth of amorphization (2). A closely related problem is that of determining diffusion profiles under extreme conditions. For example, self-diffusion in the bcc metals Ti, U, V, and Zr is found to have two components (3) and there has therefore been recent interest in extending diffusion measurements with other bcc metals to the lowest possible temperatures (4). In other work there has been concern with near-surface diffusion anomalies which arise (it is assumed) due to Gibbs adsorption, *i.e.*, attraction or repulsion of solute atoms from the surface (5). In all cases, the thicknesses involved are extremely small (0-10,000Å) and sectioning can be difficult.

The most sensitive sectioning technique probably still remains that in which a thin, uniform layer of the specimen is converted electrochemically to an anodic oxide which is subsequently stripped. Layers with thicknesses as low as 15Å can be removed in this

* Electrochemical Society Active Member.

Key words: vanadium, anodization, thin films, depth distributions.

way (6); by contrast, backscattering techniques, which are often regarded as depth probes par excellence, have a resolving power of perhaps 100-200Å with the usual detectors used (7). The only problem with anodic sectioning is that it has been fully perfected for only two metals [(Al (8) and W(6)] and partly perfected for only a further five (Ag, Au, Cu, Nb, and Si). Thus in the latter cases the following faults can be cited:

Ag (9) and Cu (10):	current at fixed voltage remains constant.
Au (11):	current at fixed voltage remains constant and current efficiency is low (~2%).
Nb (12):	dissolution end point (in the sense of the present Fig. 3) is imperfect.
Si (13-15):	current efficiency is low (1-2%); thickness calibration depends on electrolyte.

We have therefore undertaken a continuing study to develop anodic-sectioning techniques for additional metals. A method suitable for Mo has already been described (16), while the present work is concerned with V. Nb and Ta will be discussed in Part III (17).

Actually, there is already a good precedent for anodizing V in view of the work of Keil and Salomon (18, 19) and Keil and Ludwig (20). These authors established what appears to be the only known electrolyte that will permit V to be anodized (see below). In addition, they described the basic electrochemical properties of V, including the facts that the anodization was close to 100% in efficiency, that the anodic current obeyed the expected exponential law, and that the film had a stoichiometry similar to VO_2. The principal contributions of the present work will be seen to lie in the treatment given to stripping and to thickness calibration, neither of which was treated previously (18-20).

Anodic Sectioning of Vanadium

Anodizing step.—The anodic sectioning of V is closely similar to that for Mo (16). Polycrystalline specimens, with dimensions of 15 x 20 x 0.1 mm and with a purity claimed to be 99.98%, were used. They were cleaned using a sequence of petroleum ether, dilute nitric acid, and distilled water and were then anodically sectioned at least 4 times at 50 volts. The electrolyte was the same as that used for Mo (16) and similar to that proposed by Keil and Salomon (19), namely glacial acetic acid such that each liter of solution contained 0.02 moles of $Na_2B_4O_7 \cdot 10H_2O$ and 1.0 mole of additional water. The electrolyte was not protected from air as in the previous work (18-20) and was therefore discarded after 8-10 anodizings or 2 hr, whichever came first. The cathode was either a Pt cylinder with an inside diameter of 2.5 cm or a 2.5 x 2.5 cm Pt square spaced 0.8 to 1.0 cm from the specimen, the choice depending on whether the experiment was concerned with both sides of the specimen (*e.g.*, a gravimetric calibration) or only one side (*e.g.*, a depth distribution). All anodizings were made at 25° ± 1°C with a power supply such that limits to both the current and voltage could be preset (Hewlett-Packard Model 6186B). Voltages refer to the total voltage from anode to cathode.

A crucial step in the anodizing (in those instances where a permanent film was desired) was that in which the specimens were dried in a jet of compressed air immediately after withdrawal from the electrolyte, for without such drying the films were unstable. The instability, as evidenced by changes in the interference colors, set in at about 60 sec, a result similar to that obtained previously with Mo (16). The instability is inherent to the oxides on V and Mo and not to the electrolyte, for films formed on Nb, Ta, or W in this electrolyte have the same high stability as films formed on these metals using aqueous ammonium pentaborate.

Effect of stirring.—Galvanostatic measurements with stirred and unstirred electrolytes showed that stirring affects the rate of film growth such as to lower the voltage-*vs.*-time curves (Fig. 1). Such an effect, which increases with increased stirring and decreased current density, has also been observed with Bi (21) and W (22) and has been explained in terms of the stirring preventing dissolved oxide from accumulating near the surface. All anodizings were therefore carried out in unstirred electrolytes.[1]

Effect of current density.—A second group of experiments was undertaken to explore the nature of the "anodizing end point," *i.e.*, the discontinuity in current which occurs when both current and voltage are preset and which is illustrated in Fig. 2. The object was to see if anodizing under these conditions, which are particularly controllable, was practical; in fact, anodizing with only the current preset [as with Ag (9), Au (11), Cu (10), and Si (13-15)] is not correct with V since, as a result of the low conductivity of the electrolyte, it leads to nonuniform film thicknesses. (The latter result followed by noting the interference colors during the course of an anodizing at 2.0 mA/cm² without voltage limitation.) The results (typical examples are included

[1] An effect of stirring as in Fig. 1 has been confirmed also for Mo. It is therefore important to note that the thickness calibrations of Ref. (16) were made without stirring.

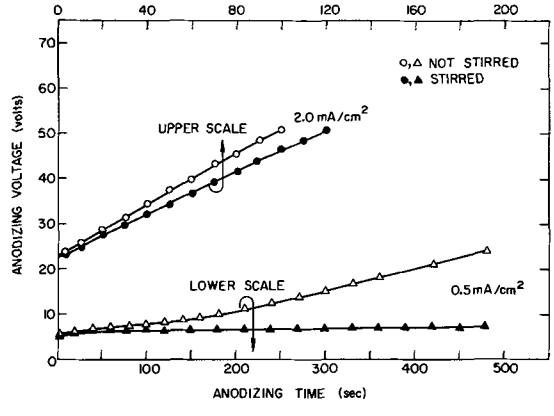

Fig. 1. Effect of stirring on anodization of V. The results show that stirring lowers the voltage-versus-time curves in an undesirable way. The cylindrical cathode was used.

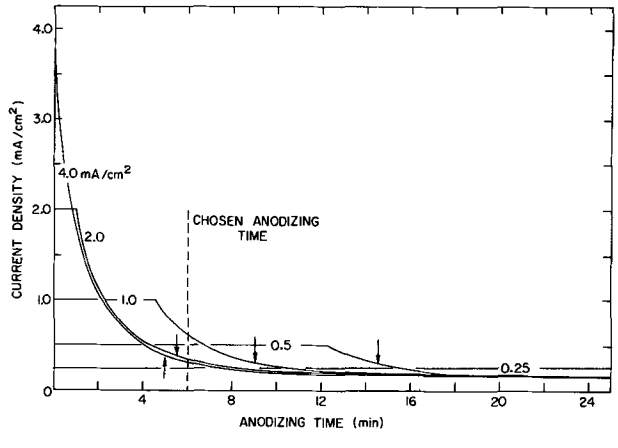

Fig. 2. Effect of initial current density on the anodizing end point. (*i.e.*, current discontinuity) and on the time for the interference colors to become uniform (marked with arrows). The results, which were obtained with a preset voltage of 50 volts, suggest that reproducible sectioning would be obtained with an initial current density of either 2.0 or 4.0 mA/cm² and a time of at least 6 min. The cylindrical cathode was used. The examples given are "typical" of a total of 14 curves.

in Fig. 2) confirmed that initial current densities of 4.0 and 2.0 mA/cm^2 gave excellent anodizing end points, with the value 2.0 mA/cm^2 being chosen for subsequent work.

The lack of an anodizing end point for 0.25 mA/cm^2, which is equivalent to a lack of voltage rise, will be recognized as being in agreement with previous work (19).

Effect of time.—Davies *et al.* (23) found with Si that there was a loss of Si to the electrolyte which was linear in the anodizing time, namely

$$\text{Loss} = 0.04 + 0.017t_{\text{min}}\ \mu\text{g/cm}^2$$

This effect is far more pronounced with V, as can be shown from a series of experiments in which films were formed with a preset current of 2.0 mA/cm^2 and a preset voltage of 50 volts, and were then measured gravimetrically

Anodizing time (min):	6	10	20	30	60
Total metal removed (μg/cm^2):	38.0	43.2	49.5	57.2	80.0
Thickness of oxide (μg/cm^2):	60.0	62.5	64.7	65.5	69.2

There is thus a continuing removal of metal during prolonged anodization at a fixed voltage whereas oxide formation is nearly independent of time. If the oxide thickness is re-expressed in units of μg/cm^2 of metal, an estimate of the metal loss during anodization is obtained

$$\text{Loss (if oxide is } VO_2) = -2 + 0.66t_{\text{min}}\ \mu\text{g/cm}^2$$
$$\text{Loss (if oxide is } V_2O_5) = 0 + 0.69t_{\text{min}}\ \mu\text{g/cm}^2$$

In a further group of experiments it was shown that an anodic film formed with 2.0 mA/cm^2 and 50 volts was uniform, as evidenced from the interference colors, starting at 5.5 min. Results for other initial current densities are marked with arrows in Fig. 2.

These experiments would suggest that a 6 min anodizing time is optimum, since it is short enough to minimize metal loss yet long enough to yield uniform films and to take advantage of the anodizing end point. In summary, the anodizing procedure proposed here thus involves a temperature of 25° ± 1°C, an anode-cathode spacing of 0.8-1.0 cm, conditions in which both current and voltage are preset, no stirring, an initial current density of 2.0 mA/cm^2, a total anodizing time of 6 min, and (when a permanent film is desired) the use of an air jet to dry the specimens. Relaxing any of these conditions will to some extent invalidate the thickness calibrations to be described below.

Stripping step.—Anodic films can be formed with perhaps 20 different elements but in only six cases (Ag, Al, Au, Cu, Mo, and W) is reliable stripping possible. This is because of the problem of the "dissolution end point," such that the reagent used to dissolve the film should not attack the underlying metal. To determine the nature of the dissolution end point with V, specimens were labeled with 30-keV Kr^{85} to a dose of 5 × 10^{15} ions/cm^2 and then anodized; the specimens were now alternately counted and exposed to 0.1% aqueous KOH (Fig. 3). It is seen that the films dissolve in ≤30 sec; the attack on the underlying V, by contrast, occurs at the negligible rate of 0.3 Å/min, as can be deduced by comparing curves as in Fig. 3 (but extended to 25 min) with an integral depth distribution as in Fig. 7, "dashed" (but for 30 keV).

Further experiments showed that also higher KOH concentrations could be used for stripping. For example, the rate of attack on the underlying V was still negligible (about 1.0 Å/min) using saturated KOH.

In a complementary series of experiments, specimens of V were first anodized to 12 volts and only then labeled with 40-keV Kr^{85} and exposed to 1% KOH. The

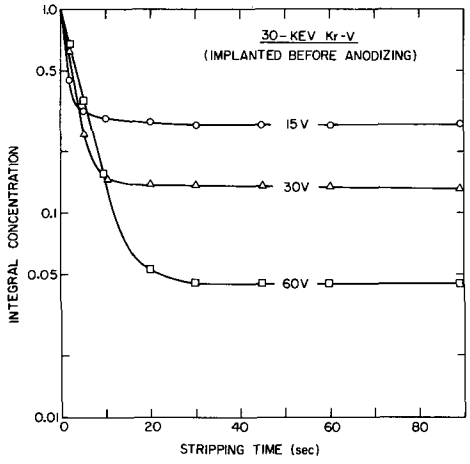

Fig. 3. Dissolution of anodic films on V in 0.1% KOH as inferred by the loss of activity. The activity was introduced prior to anodizing as 5x10^{15} ions/cm^2 of 30-keV Kr^{85}.

object was to determine the extent to which a transmission technique (24) could be used for obtaining depth distributions in the anodic film formed on V. The results (Fig. 4) showed that two problems arose, namely loss of film by sputtering and decreased solubility. They may be summarized as follows:

≤4 × 10^{14} ions/cm^2	sputtering loss unimportant	dissolution time ≤3 min
1 to 4 × 10^{15} ions/cm^2	sputtering loss of ~2 μg/cm^2 [2]	dissolution time ≤11 min
8 to 16 × 10^{15} ions/cm^2	sputtering loss of ~4 μg/cm^2 [2]	dissolution time ~21 min
3.2 × 10^{16} ions/cm^2	sputtering loss undeterminable	film insoluble

It was also shown that the use of saturated KOH gave little or no increase in the dissolution rate. Transmission experiments are thus practicable only for doses of ≤4 × 10^{14} ions/cm^2.

The marked sputtering loss found, which is untypical for an oxide (25), agrees with recent sputtering-coefficient measurements with anodized V (12), while the decreased solubility is undoubtedly related to the result that high-dose bombardment of V_2O_5 or VO_2 leads to preferential oxygen loss and eventual formation of crystalline V_2O_3 (26). Decreased solubilities following

[2] The sputtering loss was estimated by comparing Fig. 4 with a depth-distribution curve constructed using the oxide transmission data of Fig. 8.

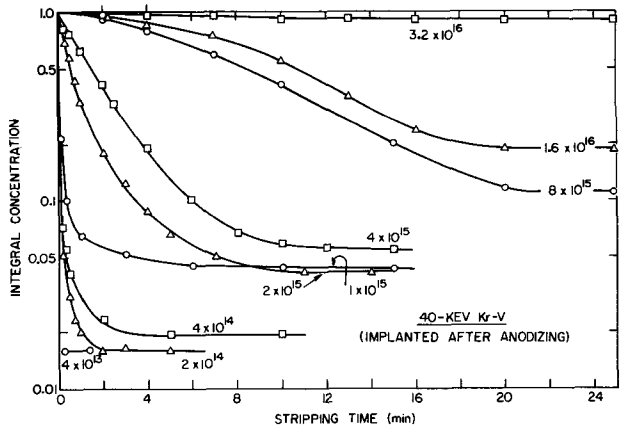

Fig. 4. Dissolution of 12-volt anodic films on V in 1% KOH as inferred by the loss of activity. The activity was introduced following anodization as various doses (indicated in units of ions/cm^2) of 40-keV Kr^{85}.

ion impact have also been confirmed for Nb_2O_5 (12, 17), Ta_2O_5 (17), and WO_3 (12).

Structure of the anodic oxide.—A limited amount of work on the structure of the anodic film formed on V was undertaken using the reflection electron diffraction attachment for a Philips EM-300 microscope. The film as formed was amorphous, and in this respect V thus resembles Al, Mo, Nb, Ta, and W. The amorphous structure was preserved to at least 370°C (10 min), while at 400°-425°C (10 min) crystallization went to completion. By way of comparison, the crystallization temperatures for anodic Nb_2O_5 and Ta_2O_5 are, respectively, 475° and 550°C (27). The temperatures found here for the anodic film on V will be noted to apply to films which were still attached to the metallic substrate and it is likely that, as with Nb and Ta (27), the free oxide would crystallize at perhaps 100°-150°C higher. The diffraction pattern of the crystallization product could be shown (17) to infer the stoichiometry V_6O_{13} (28), a result in quite satisfactory agreement with Keil and Salomon's (19) proposal of VO_2.

Thickness Calibrations

Gravimetric determinations.—The thicknesses of anodic films formed on V at ≥10 volts can, since there is a good dissolution end point (above), be easily determined using the conventional weight-loss method. The results are included in Fig. 5 and 6, and can in addition be represented as follows

Total metal removed (≥4 volts)

$$= 5.5 + 0.64 \times \text{volts } \mu g/cm^2 \text{ of metal} \quad [1]$$

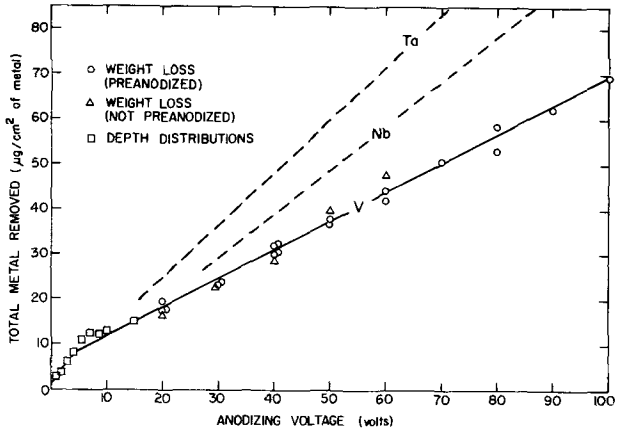

Fig. 5. Total V removed in an anodizing-stripping sequence under the standard conditions as summarized in text. Shown for comparison are the curves for Nb (25) and Ta (29) as deduced indirectly from measurements of oxide-film thickness.

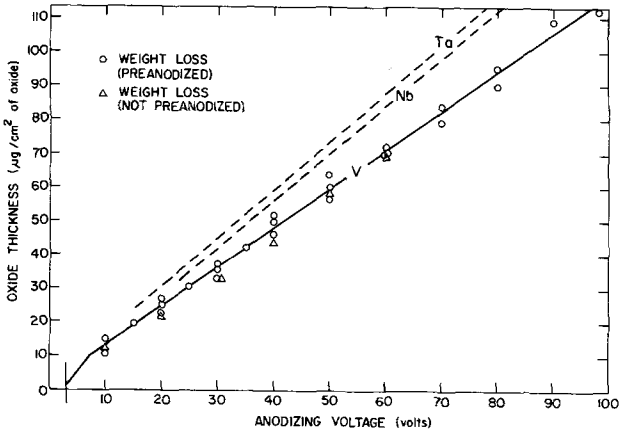

Fig. 6. Thickness of oxide film formed by anodizing (but not stripping) V under the standard conditions of text. Shown for comparison are the curves for Nb (25) and Ta (29). The present work does not establish the behavior between 0 and 3 volts.

Thickness of oxide (≥7.5 volts)

$$= 2.0 + 1.14 \times \text{volts } \mu g/cm^2 \text{ of oxide} \quad [2]$$

These relations are valid only to ~110 volts, as electrical breakdown occurred at higher voltages.

The corresponding curves for Nb (25) and Ta (29) have been included in Fig. 5 and 6 as they serve to emphasize the systematic behavior of the three group 5B metals. Note that the amounts of metal removed (Fig. 5) are, in the cases of Nb and Ta, based on the oxide-film thickness rather than on true anodic sectioning.

Metal-removal thicknesses from depth distributions.—An accurate knowledge of the metal-removal thicknesses for 1-15 volts is essential to a sectioning technique such as is being described here, yet it generally presents serious problems. We will therefore show how it is possible to estimate the metal-removal thicknesses for low voltages as a function of those for higher voltages. The method is related to that used for Mo (16) though with marked improvements.

As a first step, 39 specimens were bombarded with 20-keV Kr^{85} to a dose of 5×10^{15} ions/cm². With 3 specimens the residual activities were determined after repeated 3-volt sectionings. The result was a true depth-distribution curve (Fig. 7, dashed) with depth expressed in units of volts, the curve serving to show that there is no discontinuity in the depth distribution until ~9 volts. With the remaining 36 specimens the residual activities were determined after a single sectioning at various voltages. The resulting curve (Fig. 7, solid), when interpreted in the light of the true depth-distribution curve (Fig. 7, dashed), reveals the following three features about the thickness-voltage calibration: (*i*) the zero-voltage intercept is close to zero, (*ii*) the calibration is "well-behaved" starting at about 1 volt, and (*iii*) there is a discontinuity at 4 ± 0.5 volts.

To get further information, 26 specimens were bombarded under the same conditions as above and the residual activities were determined after repeated sectionings at 1-15 volts. Reference to Fig. 7 (solid) then enabled the metal-removal thicknesses to be expressed as a function of those for higher voltages, with detailed results as in Table I and an analytical expression as follows

Total metal removed ($1 \leq$ volts ≤ 4)

$$= 1.0 + 1.78 \times \text{volts } \mu g/cm^2 \text{ of metal} \quad [3]$$

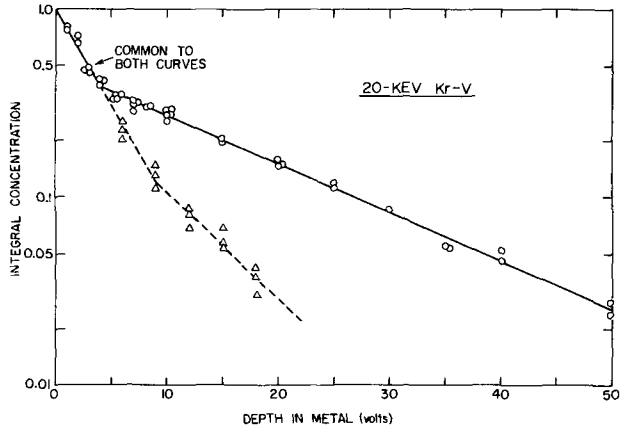

Fig. 7. Integral depth distributions in V for 20-keV Kr^{85} implanted to a dose of 5×10^{15} ions/cm². The depth scale is given in units of the sectioning voltage. Dashed: curve obtained after repeated 3-volt sectionings and which, except for the untypical depth scale, is a true depth distribution. Solid: curve obtained from a series of specimens, each sectioned once at a different voltage. Taken together, these curves demonstrate that there is a discontinuity at 4 ± 0.5 volts in the thickness-voltage calibration.

Table I. Metal-removal thicknesses for low anodizing voltages

Anodizing voltage	Number of sectionings	Residual activity	Thickness in terms of that for a single high-voltage sectioning*	Thickness in $\mu g/cm^2$ assuming the validity of Eq. [1]
1	7	0.139 ± 0.005	(1/7) ($x_{21.4}$)	2.7 ± 0.1
2	5	0.139 ± 0.001	(1/5) ($x_{21.4}$)	3.8 ± 0.0
3	4	0.079 ± 0.007	(1/4) ($x_{30.8}$)	6.3 ± 0.2
4	3	0.080 ± 0.012	(1/3) ($x_{30.6}$)	8.4 ± 0.5
5.5	2	0.108 ± 0.010	(1/2) ($x_{35.4}$)	10.9 ± 0.5
7	2	0.079 ± 0.004	(1/2) ($x_{30.8}$)	12.6 ± 0.3
8.5	2	0.083 ± 0.010	(1/2) ($x_{29.8}$)	12.3 ± 0.7
10	2	0.071 ± 0.002	(1/2) ($x_{32.6}$)	13.2 ± 0.1
15	2	0.048 ± 0.003	(1/2) ($x_{39.2}$)	15.3 ± 0.4

* The nomenclature "$x_{21.4}$" means "metal-removal thickness accomplished in a single sectioning at 21.4 volts."

Oxide-film thicknesses from depth distributions.—A related procedure, based on depth-distributions, has been used for estimating the thicknesses of anodic films formed at low voltages. It is in many respects an alternative to ellipsometry, which could in any case not be used with V due to lack of knowledge of the optical constants. Films were formed at 2-15 volts and the specimens were only then labeled with 20-keV or 40-keV Kr^{85} to a dose of about 1.5×10^{14} ions/cm^2 (higher doses, as shown above, cause a partial sputtering of the films). The Kr^{85} activity was now measured before and after dissolving the films in 1% KOH, with typical results for 40 keV as follows:

voltage:	3	6	9	12	15
fractional transmission of activity:	0.967 ±0.008	0.629 ±0.029	0.170 ±0.003	0.0353 ±0.0019	0.00380 ±0.00010

The basis of the thickness determination lies in recognizing that the fractional activity transmitted through an amorphous film of thickness x is given, according to amorphous stopping theory (30), by

$$C^{\text{int.}}(x) \approx \frac{1}{2}\,\text{erfc}\left[\frac{x - \langle x\rangle}{2^{1/2}(\langle \Delta x^2\rangle)^{1/2}}\right] f(x)$$

$$\equiv \frac{1}{2}\,\text{erfc}\,[A'x - B']$$

Here $C^{\text{int.}}(x)$ stands for integral concentration (*i.e.*, fractional transmission of activity), $\langle x\rangle$ is the mean projected ion range, $\langle \Delta x^2\rangle$ is the mean square projected ion straggling, and $f(x)$ is a factor [see Ref. (31) for its form] which has been here taken as unity. This means that, provided the relation for oxide thickness is of the type

$$x = A + B \cdot \text{volts} \qquad [4]$$

in any voltage interval, the fractional transmission measurements can be plotted to yield straight lines by using the relation

$$\text{erf}^{-1}[1 - 2C^{\text{int.}}(x)] = A'x - B'$$

$$= A' \cdot B \cdot \text{volts} + A' \cdot A - B'$$

where erf^{-1} stands for inverse error function. The results are shown in Fig. 8 and serve to establish (*i*) that the thickness-voltage relationship is "well-behaved" starting at about 3 volts, (*ii*) that there is a discontinuity at 7.5 ± 0.5 volts, and (*iii*) that the slopes are given by

$$\frac{\text{(slope for } \leq 7.5 \text{ volts)}}{\text{(slope for } \geq 7.5 \text{ volts)}} = 1.83 \pm 0.04$$

This along with Eq. (2) is sufficient information to allow the constants A and B in Eq. (4) to be determined at low voltages

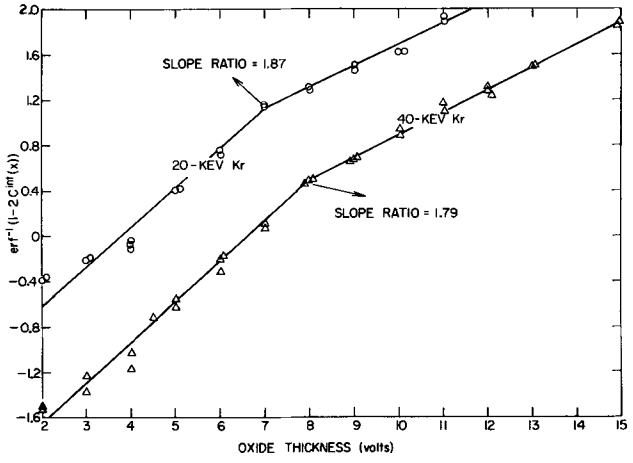

Fig. 8. The quantity $\text{erf}^{-1}\,[1 - 2C^{\text{int.}}(x)]$ vs. oxide thickness, with thickness expressed in units of the anodizing voltage. If the relation for oxide thickness is of the type $x = A + B \cdot$volts, then the slope of such a plot follows as being proportional to B. In the particular case there is evidently a discontinuity in B at 7.5 ± 0.5 volts such that B is larger by 1.83 ±0.04 below this voltage.

Thickness of oxide ($3 \leq$ volts ≤ 7.5)

$$= -5.1 + 2.09 \times \text{volts}\ \mu g/cm^2 \text{ of oxide} \qquad [5]$$

Effect of radiation damage on the calibrations.—All anodizings except those of the section on Metal-removal thicknesses from depth distributions were made with unbombarded specimens. To investigate whether bombardment causes a change in the anodic sectioning of V, 12 specimens were implanted with 10-keV Kr to various doses and were then anodized at 10 or 40 volts. After making suitable corrections for the weight of the implanted Kr, it was found that, to within an uncertainty of about 5%, there was no effect of radiation damage on the behavior of V (Table II).

Such a result is similar to that previously obtained for Mo (16) and Si (23), and is, in fact, probably rather general.

Reproducibility of the calibrations.—With a metal such as V, where anodic films are unstable and where such apparently trivial experimental details as stirring or electrode spacing affect the anodizing behavior, it might be expected that the calibrations would be unreliable. In fact, the experimental scatter was consistently small, having an average of 4% for Fig. 5, 5% for Fig. 6, and 4% for Table I (final column). By comparison, a 5% uncertainty has been claimed for Al (8) and 2% for W (6).

Discussion

The anodic sectioning of V proves to be a far simpler process than might be anticipated. The main problem is the instability of the anodic film, though this can be overcome provided a correct electrolyte is chosen [namely, similar to that of Keil and Salomon (19)] and provided the specimens are dried with an air jet (*i.e.*, in those instances where a permanent film is desired). Vanadium is then found to behave like Al (8), Mo (16), and W (6) in nearly every respect: (*i*) well-defined "anodizing end point," *i.e.*, a sharp discontinuity occurs in the current when both the current and voltage are preset; (*ii*) well-defined "dissolution end

Table II. Effect of radiation damage

Dose of 10-keV Kr (ions/cm^2)	Total metal removed in a 10-volt sectioning ($\mu g/cm^2$)	Total metal removed in a 40-volt sectioning ($\mu g/cm^2$)
zero	14.5 ± 0.1	32.5 ± 0.3
5×10^{15}	14.0 ± 0.1	33.8 ± 0.7
4×10^{16}	14.1 ± 0.1	32.7 ± 0.2
4×10^{17}	13.7 ± 0.3	35.0 ± 0.0

point," i.e., a sharp discontinuity occurs in the rate of dissolution of the specimen when the oxide-metal interface is reached; (*iii*) possibility of removing layers of metal as thin as 50Å, this being the approximate value for a 1-volt sectioning; (*iv*) possibility of using sectioning voltages up to ~110, thence of removing layers of metal with thicknesses up to 1300Å.

Considering the group 5B metals together (i.e., V, Nb, and Ta), perhaps the main similarities in anodizing behavior are that the anodic oxides are amorphous though crystallize in the region of 400°-550°C, and that the extents of metal removal or oxide formation for a given voltage vary systematically (Fig. 5 and 6). Rather different results are obtained with regard to stripping, as the dissolution end point following film formation with conventional electrolytes is of a poor quality with Nb and is virtually nonexistent with Ta (12, 17).

Electron-Microprobe Characterization of Vapor-Grown $InAs_{1-x}P_x$ Layers

James R. Buckmelter and John K. Kennedy

Air Force Cambridge Research Laboratories, Air Force Systems Command, L. G. Hanscom Field, Bedford, Massachusetts 01730

$InAs_{1-x}P_x$ alloys have a broad range of energy gaps which make them potential candidates for infrared detectors in the 0.94 to 3.6μ range (1). These alloys can be tailored to provide peak response at any discrete wavelength within the applicable range by choosing the proper As to P ratio, since the energy gap is a direct function of the composition. $InAs_{1-x}P_x$ alloys can be grown from the melt (2), by liquid phase epitaxy (3), or by vapor-phase deposition (4). Vapor-phase growth offers the advantage of closely controlled growth rates, high purity, orientation, and the ability to vary composition and doping with time. However, compositional analysis of vapor-grown films is difficult because of the generally thin layers, the different composition of the substrate, and the possibly graded layers.

A convenient technique for the analysis of layers as thin as 2500Å is electron-probe microanalysis at low accelerating potentials where the depth of penetration of the electron beam is low (5). The area to be analyzed can also be easily varied from a 1μ diameter spot to any arbitrary size; thus making it possible to focus on grain boundaries, particulates, or large areas. Homogeneity can be rapidly checked by moving various areas of the sample under the electron beam and noting any changes in characteristic x-ray intensity. Homogeneous and pure standards such as InAs, InP, GaAs, GaP, and others, are readily available and suffi-

Key words: microprobe, $InAs_{1-x}P_x$, epitaxy, vapor.

cient since correction procedures for intermediate compounds are reasonably well known (6, 7).

The electron microprobe was utilized to determine the As to P ratio of 24 ungraded $InAs_{1-x}P_x$ epitaxial layers. These layers were deposited on InAs substrates by a vapor-phase growth method similar to that described by Tietjen *et al.* (4). The epitaxial layers were approximately 10μ thick over a substrate area of approximately 1 cm^2. The analyses of these layers were based on the dead-time and background corrected x-ray intensities of the samples compared to standards of InAs or InP. These relative x-ray intensities or "k-ratios" were first calculated for various arbitrary compositions at an electron-beam potential of 10 keV and an x-ray takeoff angle of 52.5° by a computer program (MAGIC IV) (8) which performs all the necessary corrections. The k-ratios were then plotted as a function of composition as in Fig. 1. Several samples were checked for stoichiometry by measuring the k-ratios of all elements present, but once the samples were determined to be stoichiometric, the composition could be defined by measuring the k-ratio of only one element. The pKα line was used since the x-ray intensity of this line was sufficient for counting statistics, yet electron-beam penetration did not exceed 1μ at 10 keV. Those samples with greater than 25 mole per cent (m/o) As were also analyzed for As content. Each sample was analyzed at least twice by counting at 10 places for 40 sec each for every analysis. Background was determined on InAs for pKα and on InP for $AsL\alpha_1$ and this agreed with the background as determined by wavelength scans on InP and one of the alloys. Precision in the worst case for 3 analyses on one sample was 4% of the average measurement, but precision was usually better than 2% of the average measurement. The major limitation on precision was the microscopic surface texture of the material. The uneven surface nature of some samples, especially of the arsenic-rich compositions, made it difficult to focus the sample with the light optics for the crystal spectrometer, leading to a loss of precision (9).

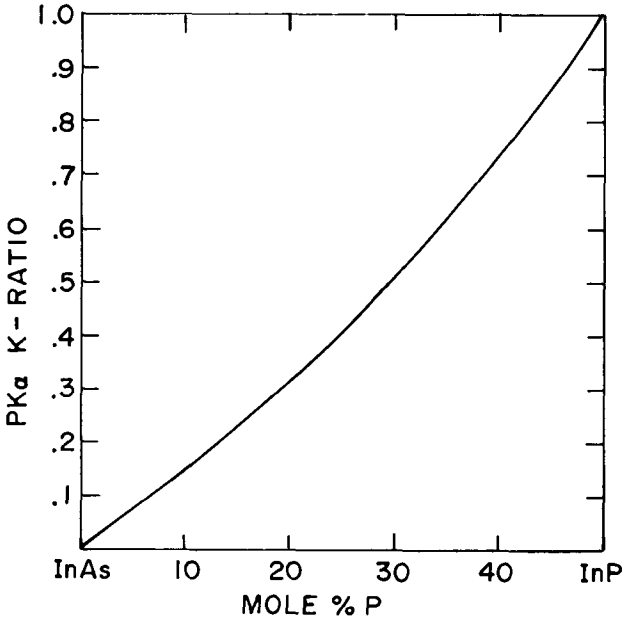

Fig. 1. pKα ratio vs. mole per cent phosphorus for $InAs_{1-x}P_x$ using InP as a standard at 10 keV.

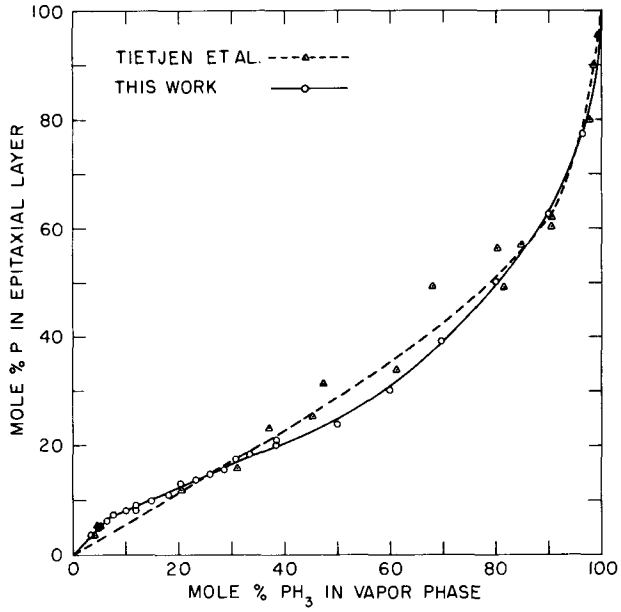

Fig. 2. Dependence of epitaxial phosphorous concentration on concentration of PH_3 in the AsH_3-PH_3 gas mixture.

Figure 2 is a plot of the m/o P measured by this technique *vs.* the m/o PH_3 in the vapor phase as calculated from the gas-flow rates. In this graph only the group V elements of the epitaxial layers and gas mixtures were taken into account for the calculation of mole percentages. Figure 2 agrees with the results reported by Tietjen *et al.*, (4) who used the more tedious destructive method of wet chemical analysis (10) to determine the composition of the epitaxial layers. Thus a direct physical, nondestructive, microprobe analysis technique can be applied to calibrate a vapor-phase growth system capable of producing any desired alloy of $InAs_{1-x}P_x$.

The Use of Metalorganics in the Preparation of Semiconductor Materials

V. The Formation of In-Group V Compounds and Alloys

H. M. Manasevit* and W. I. Simpson

Research and Technology Division, North American Rockwell Corporation, Anaheim, California 92803

The feasibility of using various metalorganic-hydride combinations in the preparation of III-V (1-5) and II-VI (6) compounds and alloys has previously been demonstrated in our laboratories. We now wish to report on the extension of the process to the formation of single-crystal films of the In-Group V compounds and alloys.

In 1960 Didchenko and co-workers (7) studied the reaction between trimethylindium (TMI) and PH_3 *in vacuo* and in solution and prepared InP powder by heating a yellow reaction product to 250°-270°C. Harrison and Tompkins in 1962 (8) reacted SbH_3 with TMI at low pressures (2 and 30 mm) and produced crystalline InSb by heating the orange product of their reaction in a sealed tube at 150°-160°C.

However, in our studies, which are directed toward the preparation of epitaxial thin films by chemical vapor deposition (CVD), the source of In was chosen to be triethylindium (TEI), which is a liquid at room temperature (mp −32°C; bp 144°C), rather than trimethylindium, which is a solid at room temperature (mp 88.4°C; bp 135.8°C).

The apparatus used in these studies is essentially similar to the single-temperature-zone vertical reactor apparatus previously described for producing other semiconductor compounds (2). However, because TEI and AsH_3 were found to react at room temperature to form a yellow liquid with low-vapor pressure, the reactor was redesigned to include a side tube near the top of the reactor in order to admit the Group V hydride into the reactor in lines separate from the TEI line. A center tube was also added to the reactor chamber in order to concentrate and direct the reactants toward the substrate. The center-tube configuration seemed to be beneficial for controlling InAs, InP, and $InAs_{1-x}P_x$ growth but optional for preparing $Ga_{1-x}In_xAs$ films. The presence of trimethylgallium (TMG) in the gaseous atmosphere seemed to enhance the uniformity of the deposit as compared with that obtained for pure InAs.

Most of the growth studies were devoted to the formation of InAs and $Ga_{1-x}In_xAs$ on Al_2O_3 and GaAs. Electrical data were obtained for films of these materials. Only a few experiments were performed in preparing the P-containing compounds; these studies were interrupted when the preliminary goal was achieved, *i.e.*, when the feasibility of epitaxy was demonstrated.

The epitaxial growth of the In-Group V compounds and alloys on commercially polished (0001) Al_2O_3 was found to be much more sensitive to the procedures used for substrate surface preparation than is the growth of GaAs on these substrates. The best growth seemed to be achieved on Al_2O_3 substrates which had been cleaned with organic solvents such as trichloroethylene and acetone.

The deposition procedure used most often involved growth in a H_2 atmosphere containing As and/or P produced by decomposing the appropriate hydride(s) (10% in H_2) at the hot pedestal prior to the introduction of TMG and/or TEI into the reactor.

In the preparation of InAs, typical flow rates were as follows; 10% AsH_3-in-H_2, 75-100 cm^3/min; H_2 carrier through the TEI bubbler (at room temperature), 1000 cm^3/min; total H_2 through the reactor, 10 liters/min. These conditions led to InAs growth at rates from 0.04-0.05 μm/min in the reactor with the center-tube configuration. In preparing the $Ga_{1-x}In_xAs$ alloys, the AsH_3-in-H_2 flows were typically 50-75 cm^3/min; the H_2 carrier for the TEI, 1000-1600 cm^3/min; the H_2 through the TMG bubbler (at 0°C), 2-3 cm^3/min; and the total H_2 flow through the reactor, 10 liters/min.

Following deposition, the epitaxial layers were routinely examined by optical microscopy, Laue back-reflection x-ray diffraction, and reflection-electron diffraction (RED). Selected films were analyzed electrically using a Hall-effect "bridge sample" photoetched in the epitaxial layer; inconsistent results were obtained using the van der Pauw (9) technique, perhaps because of inhomogeneities in the films. Optical data were obtained from transmittance scans usually made on polished surfaces with a Beckman DK-1A double-beam recording spectrophotometer. Electron-microprobe techniques were employed to determine the composition of the deposited films. Composition data were obtained by direct comparison of the excited characteristic x-rays of bulk GaAs and InAs with those of the deposited films.

Properties of InAs Films

The electrical properties of 0.5-1.1 μm thick InAs films formed on (0001) Al_2O_3 at 650°C and 700°C had measured resistivity values of 0.003-0.006 ohm-cm, carrier concentrations from 1.4 to 1.6 $\times$ 10^{17} cm^{-3}, and average mobilities from 6,700 to 11,200 cm^2/V-sec. Measurements at 77°K showed only small reductions in carrier concentration and slight increases in mobility, thus indicating relatively poor quality material in these thin films.

The Laue x-ray diffraction pattern reproduced in Fig. 1 was obtained from an InAs film grown directly on (0001) Al_2O_3; upon analysis the pattern was found to be that of (111) InAs growth on (0001) Al_2O_3.

InAs growth studies on the (111) "A" faces, (111) "B" faces, and (100) orientations of polished GaAs substrates and on 15-25 μm thick GaAs films grown on (0001) Al_2O_3 and (111)-oriented $MgAl_2O_4$ wafers indicated the growth rates to be essentially the same on these orientations, as measured on angle-lapped samples. The as-grown films were n-type. Qualitatively, the growths seemed better on (111) GaAs than on (100) GaAs. The surface structure of a (111)-oriented InAs film grown on a (111) GaAs film which had been grown on (0001) Al_2O_3 is shown in the photomicrograph of Fig. 2. Typical (111) crystallographic growth features dominate the surface.

Growth of $Ga_{1-x}In_xAs$ Films

Following the successful achievement of the growth of InAs on Al_2O_3 and on GaAs, studies were begun on producing the $Ga_{1-x}In_xAs$ alloy. All subsequent alloy growth experiments utilized premixing of trimethylgallium (TMG) and TEI to obtain a homogeneous gas mixture prior to mixing with AsH_3.

The electrical properties of some of the better films formed directly on (0001) Al_2O_3 substrates are recorded in Table I. Two different TMG and AsH_3 gas sources were used with the same TEI gas source. Those are reflected in the different carrier concentrations ob-

tained, $\sim 10^{16}$ cm^{-3} and $\sim 10^{17}$ cm^{-3}. The spread in mobilities probably is due to the fact that deposition and substrate-surface conditions were not optimized during this limited study.

The compositions given in Table I are based on electron-microprobe data. The bandgap energies are approximate values based on the location of the absorption edge obtained from optical transmittance curves; these bandgap energy determinations are uncorrected for film-thickness effects or other complications. There was relatively little variation in the composition of the alloy for films grown to various thicknesses on Al_2O_3 under nominally identical growth conditions. The uncorrected bandgap values also reflect the compositional change of the alloy film for the samples listed in the table.

The limited mobility data in Table I suggest 725°C to be a good temperature for growth directly on Al_2O_3, at least for the alloy with $E_g \sim 0.7$ eV. All of the films were grown in the reactor without a central tube. The preferred temperature for growth of the alloy films on Cr-doped (111)GaAs seemed also to be 725°C. An average mobility of 4500 cm^2/V-sec was obtained for an 11.7 μm-thick alloy film ($Eg = 0.68$ eV) at a carrier concentration of 7.6×10^{15} cm^{-3}. For reasons as yet unidentified, the mobilities of epitaxial $Ga_{1-x}In_xAs$ films grown on the "A" and "B" faces of (111)GaAs were lower than those for films formed on (0001)Al_2O_3.

A plot of the bandgap energy *vs.* film composition for the films recorded in Table I and other films grown using a reactor with a center tube is shown in Fig. 3. Values for the room-temperature bandgap energies of GaAs and of InAs are also shown on the graph. For comparison purposes, a dotted line representing a linear dependence of bandgap energy upon film composition between the two binary compounds is also shown. The experimental data obtained on these relatively few alloy films show some scatter and are seen to depart somewhat from the straight line drawn between the bandgap energies for the two pure compounds. They appear to fall along a smooth empirical curve such as has been drawn in the figure.

A similar concave-upward dependence of bandgap upon composition was also observed in the InAs-GaAs system by Abrahams *et al.* (10) using bulk materials, and by Antypas (11), and Wu and Pearson (12), who grew alloy films by liquid-phase epitaxy. Woolley *et al.* (13) obtained an essentially linear variation in energy gap in bulk alloys with composi-

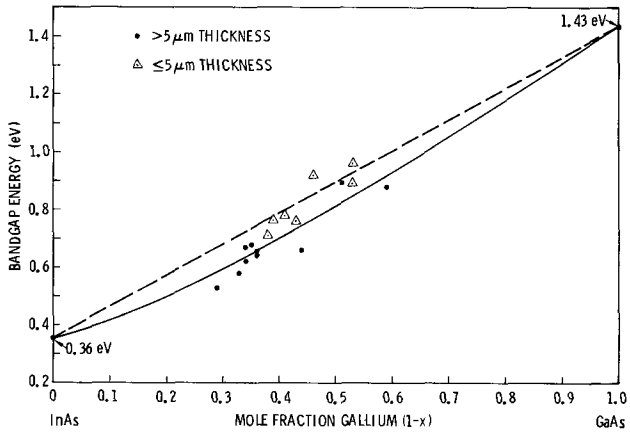

Fig. 3. Band gap energy vs. alloy composition for $Ga_{1-x}In_xAs$ heteroepitaxial films on (0001)Al_2O_3 substrates.

tions up to about 80 mole per cent (m/o) GaAs followed by a more rapid increase up to the gap characteristic of GaAs. Dzhakhutashvili and co-workers (14) determined that the dependence of the energy gap on composition becomes much more linear as the quality of the samples improves.

It has been found experimentally that the method used for establishing optical bandgap energies for $Ga_{1-x}In_xAs$ films, *i.e.*, graphically locating the room-temperature bandgap energy from optical data by selecting the zero-transmittance (maximum absorptance) intercept of the maximum-slope portion of the transmittance curve, is relatively accurate for films ≥ 5 μm in thickness. For thinner films larger intercept energy values result; for example, the bandgap energy for a ~17 μm film was 0.66 eV; a value of 0.77 eV was found when the film was thinned to ~2.5 μm. For this reason, the data points for films of thickness ≤ 5 μm were given reduced weight in establishing the smooth experimental curve drawn in Fig. 3.

Also, since TEI and AsH_3 react at room temperature but TMG and AsH_3 do not (at least no evidence for reaction has been observed during initial mixing), it is also plausible that the early stages of growth involve the formation of a layer of $Ga_{1-x}In_xAs$ of graded composition. Such a layer could result in the observed variation in uncorrected bandgap energies with film thickness.

Growth of InP and $InAs_{1-x}P_x$ Films

As previously indicated, the studies relating to InP and $InAs_{1-x}P_x$ growth have been very limited to date. InP growth was achieved on Al_2O_3 and GaAs by mixing vapors of TEI (H_2 flow was 1000 cm³/min through TEI) and PH_3 (typically 250 cm³/min of the 10% mixture) and decomposing their reaction product at 650°-660°C in a H_2 atmosphere containing excess PH_3. The film of InP on (0001)Al_2O_3 was rather dull appearing, with no distinguishing surface characteristics, but triangular crystallographic structures suggestive of (111) growth did develop on (111)GaAs substrates, and RED did confirm the films to be single crystal at the surface. It was found to be more difficult to control the InP growth on Al_2O_3 than that of InAs, presumably because of the greater instability of InP. The addition of arbitrary amounts of AsH_3 (5-12 cm³/min of the 10% mixture) to the gas stream led to the formation at 660°C of $InAs_{1-x}P_x$ films on Al_2O_3, GaAs, and InAs. Films with bandgaps of 0.5-0.9 eV were grown during this limited study.

Conclusion

The metalorganic-hydride method has been successfully extended to the formation of films of several of the In-Group V compound semiconductors and alloys. InAs, InP, $Ga_{1-x}In_xAs$, and $InAs_{1-x}P_x$ have been grown on insulating and semiconductor substrates using triethylindium, trimethylgallium, AsH_3, and PH_3 as the sources of In, Ga, As, and P, respectively. The versatility of this general process for film formation has again been demonstrated. Certainly further studies in this area are warranted and are in progress in our laboratories.

Vapor-Phase Deposition of Beta-Silicon Carbide on Silicon Substrates

K. Kuroiwa[1] and T. Sugano

Department of Electronic Engineering, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo, Japan 113

Silicon carbide is one of the semiconductors which have potential application for electron devices that can operate at high temperature and for blue light-emitting diodes. Cubic silicon carbide (β-SiC) crystals have been grown by precipitation from solutions (1-5), chemical vapor deposition (6-9), or by chemical conversion of Si (10-13). The growth of β-SiC by chemical vapor deposition onto Si substrates, or by chemical conversion of Si, can be done at temperatures lower than for the case of α-SiC by sublimation. They are suitable for obtaining SiC crystals with large areas because large Si wafers are commercially available. It is, however, difficult to obtain thick films of β-SiC by chemical conversion of Si.

This note reports our results of vapor-phase deposition of β-SiC by hydrogen reduction of $SiCl_4$ and CCl_4 onto the substrates which had been prepared by chemical conversion of Si.

Substrate Preparation

Substrates were prepared by chemical conversion to β-SiC of Si wafers with (111) orientation, and heated in a mixed gas of CH_4 or CCl_4 and Ar or H_2 at a temperature of 1300°C. β-SiC crystals, obtained by this method, up to around 1000Å thick do not have homogeneous structure. Near the surface of the crystal they have single crystalline structure, but near the interface between β-SiC and Si they have polycrystalline structure, attributable partly to the mismatch of lattice constants (β-SiC: 4.358Å, Si: 5.430Å), and partly to the growth of new β-SiC at the interface between the Si substrate and the previously grown β-SiC by diffusion of carbon through β-SiC layer to the interface (12).

On the β-SiC surface, a mesh-like pattern whose size is up to around 100μ is observed. This pattern seems to have resulted from the growth of β-SiC nuclei on the Si surface and becomes finer with increase of partial pressure of CH_4 or increase of ratio Ar/H_2 in the carrier gas. As the surface pattern becomes finer, the diffraction pattern of electrons reflected from the surface resembles more that of single crystals. This fact shows that the amount of disorder in β-SiC increases as the nuclei grow larger.

Apparatus and Deposition Technique

The substrate was placed upon a SiC-coated graphite pedestal which was heated by rf oscillator in water-cooled 64 mm ID quartz tube. Substrate temperature was measured with an optical pyrometer and corrected for the emissivity of the substrate and the absorption by the reaction tube.

Hydrogen was purified by passing it through a palladium diffuser. Desired mole ratio of tetrachloride gases to hydrogen was achieved by passing hydrogen separately through two saturators held at 0°C which contained $SiCl_4$ and CCl_4, respectively. The normal mole concentration of both $SiCl_4$ and CCl_4 to hydrogen was fixed to 0.1 mole per cent (m/o). The total hydrogen flow was 1-2 l/min. The deposition temperature was between 1300° and 1360°C. The deposition period was in the range of 1-48 hr.

Results

Deposition rate.—Figure 1 is a cleaved surface which is perpendicular to the direction of deposition. The thickness of the β-SiC layer of the substrate is negligibly thin as compared with that of the deposited layer. In Fig. 1 the interface between β-SiC and Si is clearly seen, so the thickness of the deposited layer can be seen directly under an optical microscope. But, the layer thickness cannot be determined accurately, firstly because the layer has a very rough surface, and secondly because the layer thickness takes different values from point to point within the same sample. Under the

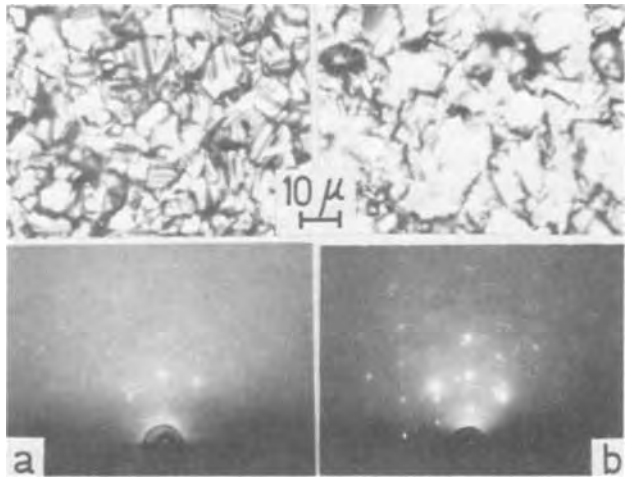

Fig. 3. Effect of preparation period of substrate; substrate orientation (111); preparation temperature 1325°C; CCl_4 concentration 0.2%; preparation period (a) 30 min, (b) 10 min.

Fig. 4. Deposition on silicon; substrate orientation (a) (111), (b) (110), and (c) (100).

condition of the deposition period of 48 hr, a layer up to about 40μ was deposited and the deposition rate was 0.4-1 μ/hr.

Effect of concentration of $SiCl_4$ and CCl_4.—As the concentration of $SiCl_4$ and CCl_4 in hydrogen increases from 0.1 to 0.5%, the polycrystalline character increases in the reflection electron-diffraction pattern of the deposited layer surface. Figure 2 shows the effect of the concentration. As far as electron-diffraction pattern is concerned, the crystalline state of many samples which were deposited under the condition of the concentration of 0.1% seems to be more ordered than that of the substrates.

Effect of preparation period of substrate.—β-SiC layers were deposited simultaneously on several substrates which were prepared under the same conditions except for the preparation period. Figure 3 is a part of the results. As the preparation period of the substrates decreases, grain size of the deposited layer grows larger, and spots in the electron-diffraction pattern grow sharper. β-SiC layers were deposited on the silicon substrate directly as a case of the limit of very short preparation period of the substrate, but this case did not always produce a satisfactory sample.

Deposition on silicon without β-SiC film on the surface.—Figure 4 shows the electron-diffraction patterns of the layers deposited on silicon substrates with (111), (110), and (100) orientations at the same time. The crystalline state of the layer on (100) surface is comparatively better. The deposition on the silicon substrate does not have good reproducibility, and the dependence on substrate orientation cannot be well-defined.

Effect of nucleus size of substrate.—To investigate correlation between the layer feature and the nucleus size of the substrate, β-SiC layers were deposited on two kinds of Si substrates, whose surfaces had been chemically converted to β-SiC. The first is a substrate having fine β-SiC nuclei with high density, and the second is a substrate having large β-SiC nuclei with low density. In Fig. 5, it is shown that the grain size of the deposited layer is in relation to the nucleus size of the substrate, that is, the grain size of the layer on the fine nuclei of the substrate is small, and that on the large nuclei of the substrate is large. But differences between the electron-diffraction patterns of two kinds of samples are not clearly seen.

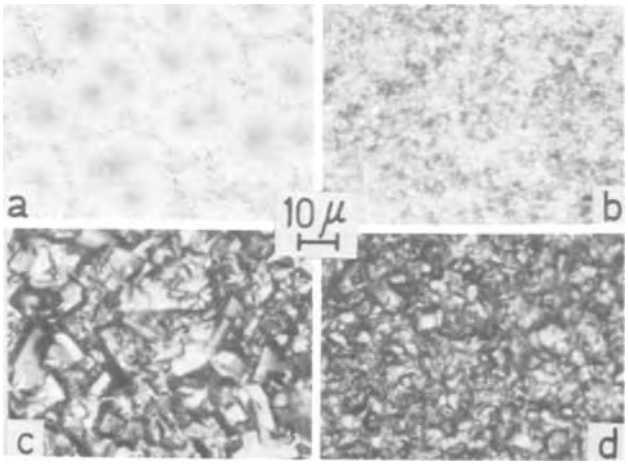

Fig. 5. Effect of nucleus size of substrate; deposition temperature 1320°C; deposition period 40 hr; concentration of $SiCl_4$ and CCl_4 0.1%; (c) deposited layer on (a), (d) deposited layer on (b).

As mentioned above, the electron-diffraction pattern of the deposited layer grows sharply with decrease of the preparation period of the substrate. In this case, if the preparation period of the substrate is very short, the β-SiC film does not cover the silicon surface completely, but nuclei of β-SiC grow like islands. An investigation of the deposited layer on such a substrate shows that the regions upon the nuclei of the substrate have a thicker β-SiC layer than the regions corresponding to the space between the nuclei or silicon surface.

Deposition at temperature of 1550°C.—Substrates were prepared by chemically converting surfaces of Si substrates to β-SiC and by depositing a β-SiC layer of several microns on them. Then the Si part of the substrates was etched off chemically and remaining β-SiC films were used as substrates in the deposition experiments at 1550°C. Oriented pattern of the 1550°C layer is clearly seen when the layer is deposited on the 1300°C substrate whose grain size is large and whose electron-diffraction pattern is sharp. A smooth surface, however, cannot be obtained by elevating the deposition temperature, if the surface of the β-SiC substrate is rough.

Discussion

The surface of the deposited layer is very rough, and the β-SiC layer deposits selectively upon SiC nuclei of the substrate, so that the grain size of the layer corresponds to the nucleus size of the substrate. These results indicate that on the nuclei of the substrate, β-SiC layers deposit selectively with a comparatively rapid deposition rate, but on the regions corresponding to the space between nuclei or silicon surface, β-SiC layers deposit with very low deposition rate, and that the deposited regions are hard to spread sideways. The amount of disorder in β-SiC increases as the nucleus grows large. Therefore, the crystalline state of the regions upon the nuclei of the substrate grows better with the decrease of the preparation period of the substrate. Judging from the electron-diffraction pattern, the crystalline state of grown layers seems to be more ordered than that of substrates. This fact means that well-crystallized regions are thickly deposited and these regions mainly contribute to the electron diffraction.

To obtain a smooth surface, it is necessary to speed up the deposition or to use substrates with uniform β-SiC layers. In order to speed up the deposition, it is necessary to raise the concentration of $SiCl_4$ and CCl_4, or to elevate the deposition temperature. But, if the concentration of $SiCl_4$ and CCl_4 is raised above 0.5%, only a polycrystalline layer is obtained, and the elevation of the deposition temperature above 1414°C melts silicon under the β-SiC substrate. So, it seems difficult to obtain a β-SiC layer of higher quality by this method and uniform SiC substrates must be used to obtain better results.

Wall Profiles Produced during Photoresist Masked Isotropic Etching

R. G. Brandes

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

and R. H. Dudley

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

Many processes for the definition of patterns in metal and dielectric thin films utilize photolithographic masks and chemical etching. When a second film is to be deposited over a previously etched film, the profile of the etched wall has a strong influence on the ability of the second film to conform (1). The purpose of this paper is to describe two simple idealized models of masked etching which predict the slope of an etched wall as a function of etching time and to present experimental results which test these models.

Most metal or dielectric films of interest in semiconductor or thin-film technologies are either polycrystalline or amorphous. Thus, if chemical composition and physical properties of the films are uniform, the attack by etchants should be isotropic. However, some effects such as limitations in mass transport, variations in mechanical agitation such as in spray etching, local variations in etchant properties with etch depth or time may impose directional nonuniformities in etch rate. Additionally, the adhesion of the particular photoresist used as a mask can influence its ability to protect the surface of the film. The following treatment, though idealized, is intended to provide a simplified base line from which common deviations from ideality such as compositional gradients can be considered.

Two conceptually simple models are considered for the development of wall profiles during isotropic overetching by the immersion technique. In one, the masking material continuously lifts from the film being etched as the etch front proceeds, exposing fresh surface, producing a moving center of curvature, and thus a constant radius of curvature of the etched wall. The second model assumes that the masking film remains intact, fixing the center of the isotropic etching front and producing an increasing radius of curvature. These two models are presented schematically in Fig. 1(a) and 1(b), respectively.

Movable center of curvature model.—Because of the fixed radius of curvature, the shape of the etched wall of the first model would not change with time and would have an average slope of 45° at all times after breakthrough of the etched film.

Key words: etching, masking, photolithography.

Fixed center of curvature model.—The fixed center of the curvature model is shown in Fig. 1(b). A film of thickness, h, is protected by a mask such as a layer of photoresist which contains an opening where etching is desired. Assuming that there is no enhancement or retardation of the etch rate at the mask-film interface and that the rate of etching of the film is completely isotropic, the etch front can be assumed to advance in two dimensions as a circle with center at O, located at

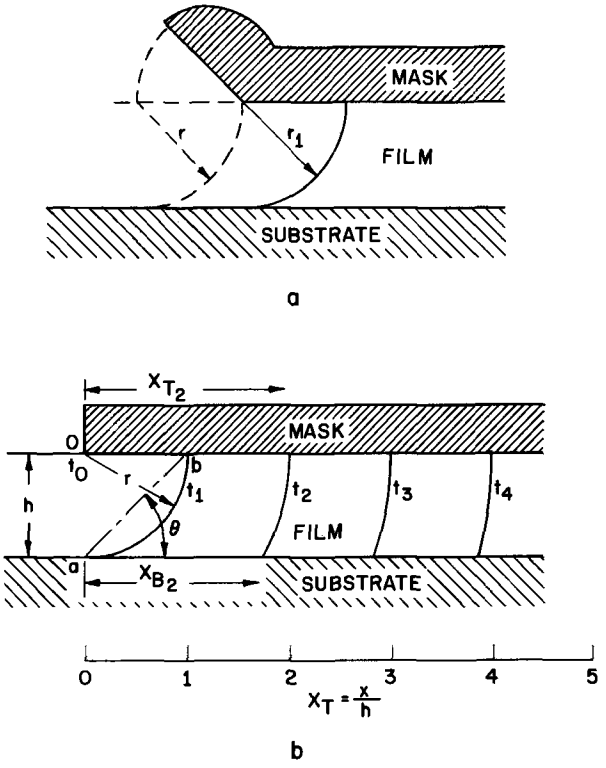

Fig. 1. (a) Schematic model of a wall profile for a movable center of curvature during overetching. (b) Schematic model of a wall profile for a fixed center of curvature during overetching.

Table I.

X_T	θ
1.0	45.0
1.5	69.1
2.0	75.0
3.0	80.3
4.0	82.8
5.0	84.2
6.0	85.2
7.0	85.9
8.0	86.4
9.0	86.8
10.0	87.1

the edge of the resist, and with radius r which is proportional to the time of exposure to the etch. At time t_0, no etching has occurred, and $r = 0$. At time t_1, at the instant of breakthrough, the distance of undercutting of the resist equals the film thickness or h and the average angle (θ) of slope from the horizontal is 45°. As the front advances further and the radius increases, it is evident from Fig. 1(b) that the slope becomes progressively steeper at t_2, t_3, etc.

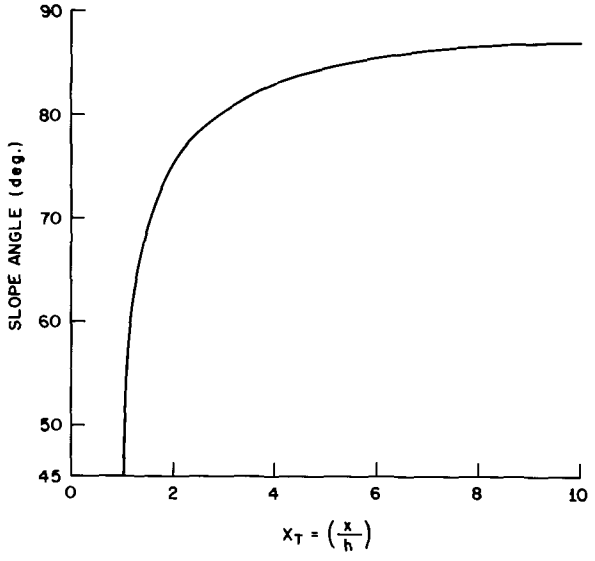

Fig. 2. Plot of $X_T = \left(\frac{x}{h}\right)$ vs. slope angle

Using O as the origin and letting r be the distance of advance of the etching front, the equation for the two dimensional etch front is that of a circle

$$x^2 + y^2 = r^2 \quad [1]$$

It is convenient to normalize all dimensions to the film thickness by dividing them by h, thus

$$X^2 + Y^2 = R^2 \quad [2]$$

where

$$X = \frac{x}{h}$$

$$Y = \frac{y}{h}$$

and

$$R = \frac{r}{h}$$

The points of interest are the intersections of the etch front with the two surfaces of the etched film a and b in Fig. 1(b). At the top surface $Y_T = O$ and $X_T = R$. At the bottom surface

$$Y_B = -1 \text{ and } X_B = (X_T^2 - 1)^{1/2} \quad [3]$$

also

$$\tan\theta = \frac{1}{X_T - X_B} \quad [4]$$

Table I contains the results of calculations of θ for X_T from 1 to 10. These data are plotted in Fig. 2.

Discussion of Fixed Center of Curvature Model

From Fig. 2 of the second idealized model, it is evident that although the slope at breakthrough is 45°, it steepens rapidly as it is etched for longer times. At 1.5 times breakthrough time, the angle approaches 70°; at double the breakthrough time, the angle is 75°. This implies that, in general, etch slopes will be steeper than 45° since nonuniformities in thickness and/or etch rate will necessitate excess etching time to assure complete etching over the entire substrate surface. Thus, the areas first to break through will be subjected to overetching in order to assure that other areas are cleared.

Experimental

A 1¼ in. diameter silicon slice with 6000Å of steam-grown oxide was coated with KMER (1:1) at 12,000

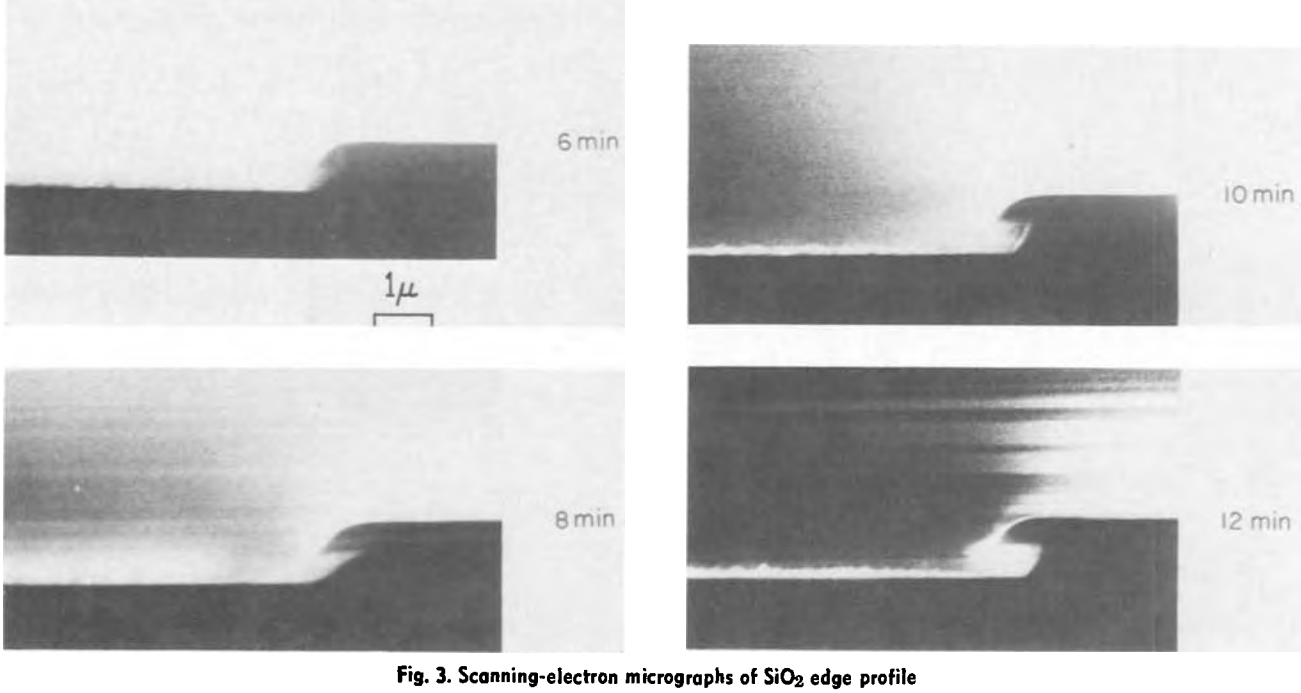

Fig. 3. Scanning-electron micrographs of SiO_2 edge profile

rpm providing a 5000Å resist coating. This resist was exposed to u.v. through an Ealing test array mask (Group II 10-100 cycles/mm patterns) and the image developed. The slice was then quartered. Each quarter was etched for a different length of time by immersion in a commercial buffered HF solution having an SiO_2 etch rate of 1000 Å/min. The etching times were 6, 8, 10, and 12 min; *i.e.*, up to a factor of 2 overetching.

Each quarter slice was then carefully scribed on the back side to break perpendicularly through the 10 cycle/mm bar pattern. These fragments were coated with 500Å of aluminum to avoid charging effects, and then scanned normal to the fracture surface in a Cambridge Stereoscan Electron Microscope following the technique described previously by Brandes and Curran (2).

Results and Conclusions

The etched-edge profiles viewed at 90° and at a magnification of 10,000 times for each of the etching times are presented in Fig. 3. It is evident that the resist did not lift during this experiment and that the edge profile steepened with overetching in qualitative agreement with the fixed center of curvature etching profile model of Fig. 1b. Thus, at least through a factor of 2 overetching, this mechanism is followed during thermal silicon dioxide etching. One may conclude that in etching contact windows, where a gentle edge gradient is desirable to permit uniform metalization, the etching should be carefully controlled to avoid overetching which produces steep walls.

Electron Microscopy of Electrolytically Etched Silicon Surfaces

M. J. Hill

Brown Boveri Research Center, CH-5401 Baden, Switzerland

During investigation of the conditions for jet-electrochemical thinning of silicon to prepare transmission-electron microscope (TEM) specimens, heavy etching of the surfaces was observed. Further studies revealed various types of etching when the specimens were examined in the TEM, and in view of the recent interest in electropolishing of n-type silicon (1, 2) and electroetching (3, 5) these etching results are presented here.

The etch figures take the form of holes or tunnels penetrating into the bulk silicon, the form and depth of the tunnels being dependent, among other parameters, on the resistivity ρ of the silicon and the voltage V applied across a simple electrolytic cell. On a much coarser scale electrolytic etching effects have previously been reported in Ge (4) and in Si (1, 3, 5) and also in GaP on the TEM scale (6).

Experimental

The simple electrolytic cell used here is shown in Fig. 1. The specimens were 3 mm diameter disks about 200 μm thick, suitable for the TEM specimen holder. Electroless nickel was deposited on the back surface of the disks and an Au wire bonded to the nickel. The specimens were mounted in the holder with "picein" so that the electrolyte reached only the chemically polished front surface. The cathode was a strip of platinum at a distance of 1 cm from the specimen, and a voltage of between 3 and 100V d.c. was applied across the cell for times of between ½ and 6 min. The electrolyte used throughout these experiments was 1 part 40% HF in 19 parts H_2O, and the silicon was always positively based. The starting material had a dislocation content of less than 3×10^4 cm^{-2} with (111) oriented surfaces, and was either n-type phosphorus-doped of resistivity between 0.1 and 100 ohm-cm or 10 ohm-cm p-type boron-doped. Prior to etching, the specimen surfaces were prepared by fine mechanical polishing followed by chemical polishing to remove at least 30 μm. Before mounting, the specimens were thoroughly cleaned in organic solvents followed by triply distilled water, and before etching they were soaked in the electrolyte for 10 min. During etching the current was usually unstable, and only the maximum and minimum values were recorded. The measured currents varied between 0.5 and 20 mA depending only slightly on voltage and resistivity. Further experiments have shown that there is a very large edge effect with increased etching and presumably increased C.D. within about 0.5 mm of the edge. The observations reported here are from areas within 0.5 mm of the centers of the disks, but it is clear that no value of C.D. can be assigned to the etching process.

After etching, the nickel film was removed and the disks were chemically thinned from the back side using a variation of the standard jet method (7). This gave areas of approximately 100 μm diameter, suitable for examination in the TEM.

Results

The form of the etch figures developed during the anodic etching depended on several parameters includ-

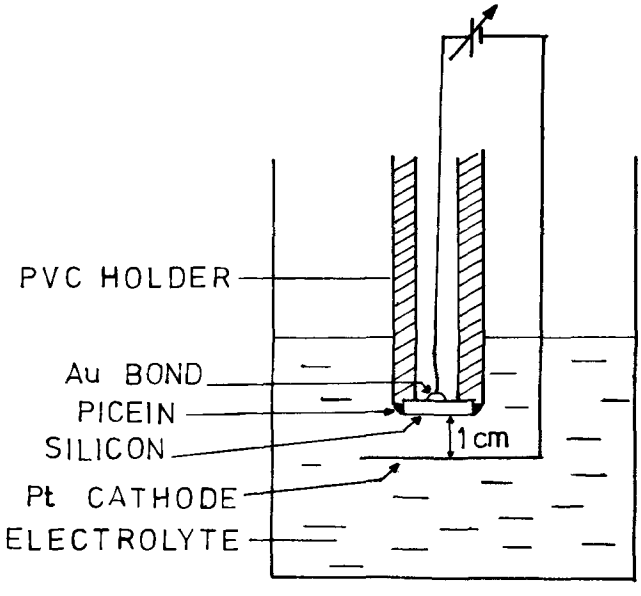

Fig. 1. Schematic of the electrolytic cell

Key words: anodic dissolution, etch channels, silicon, crystal oriented attack.

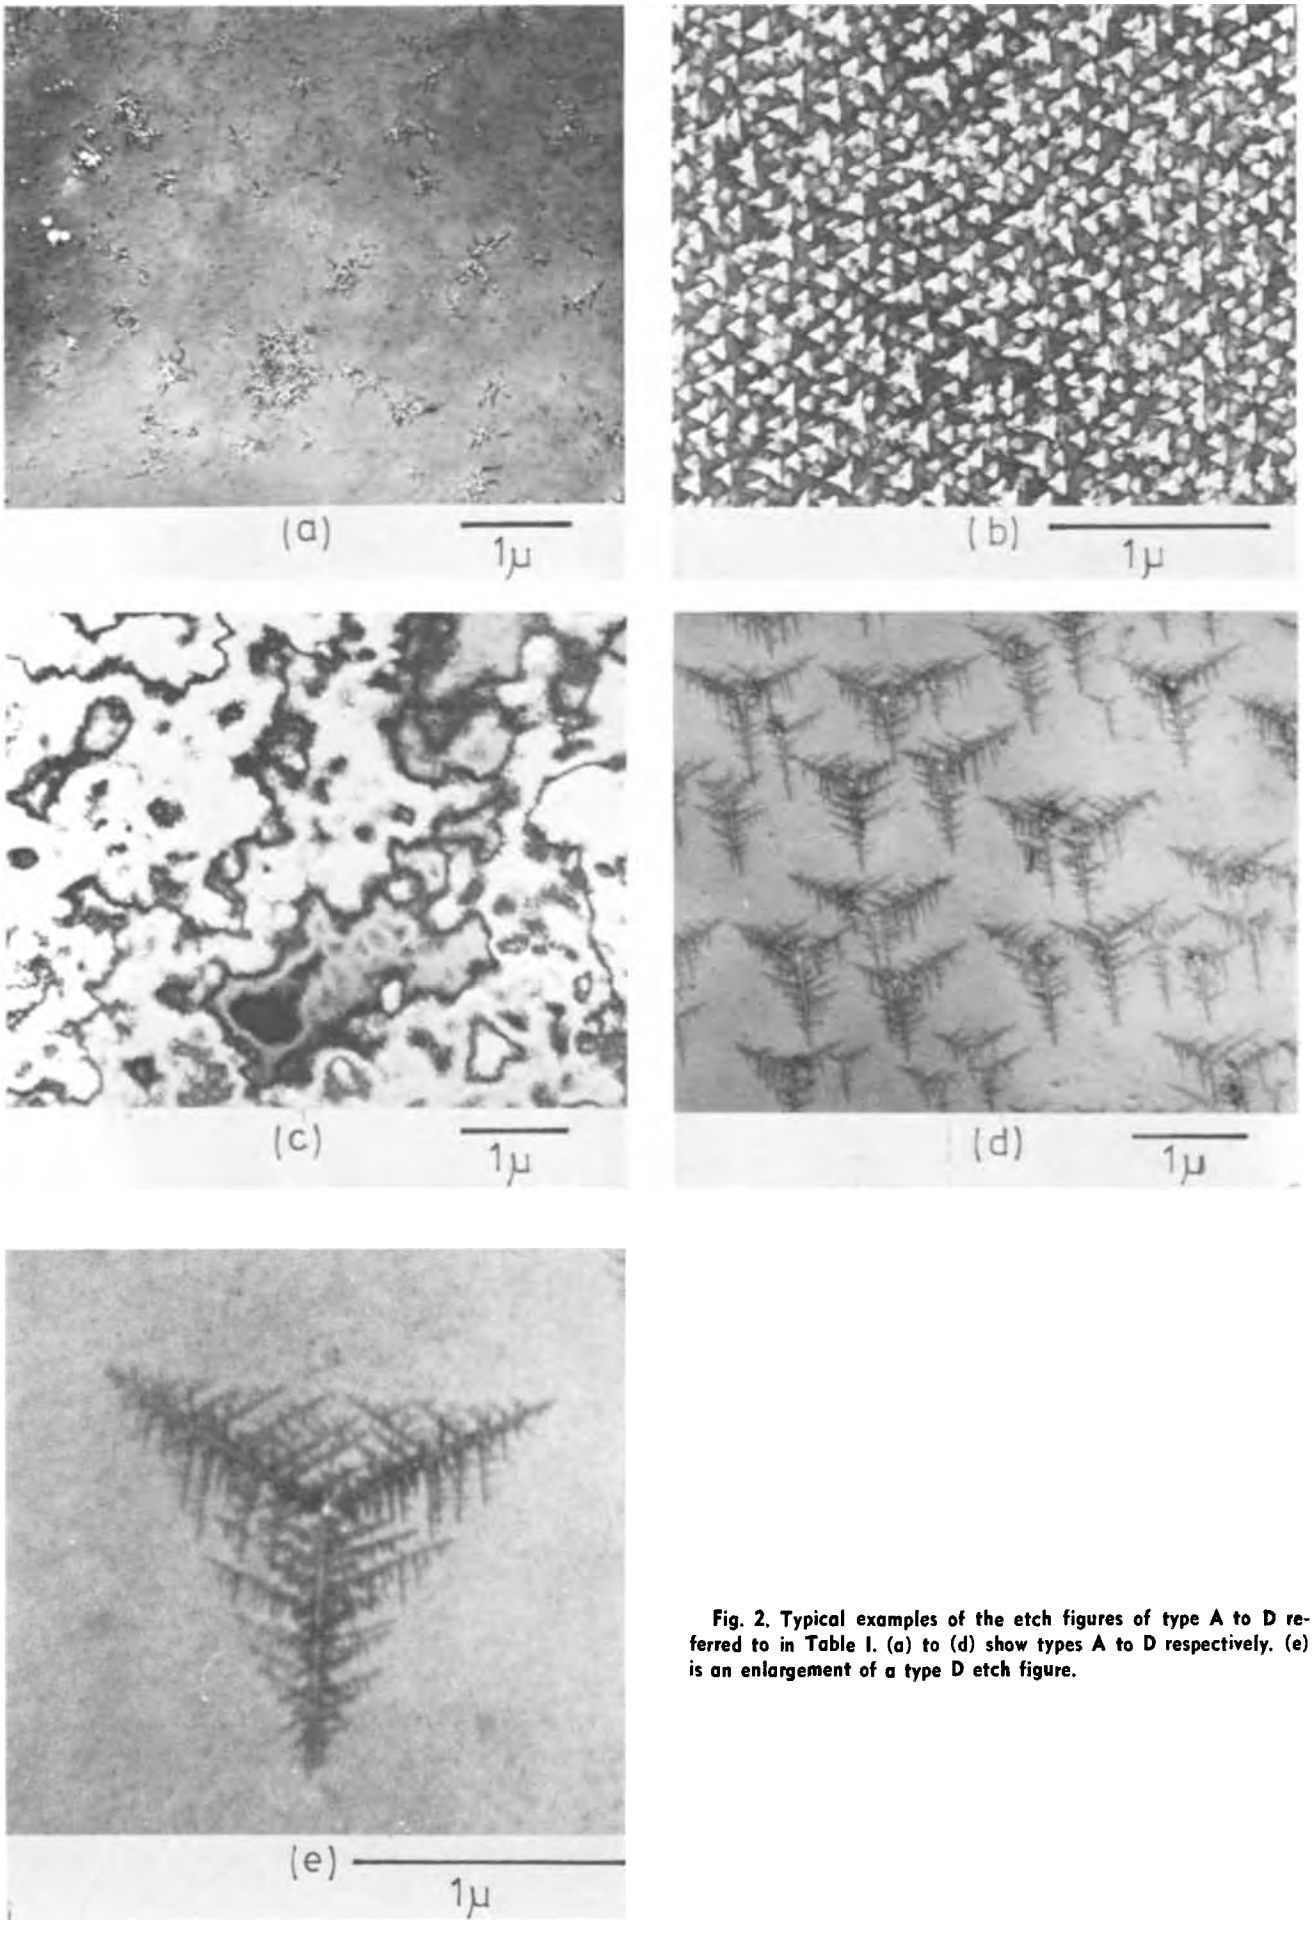

Fig. 2. Typical examples of the etch figures of type A to D referred to in Table I. (a) to (d) show types A to D respectively. (e) is an enlargement of a type D etch figure.

Table I

Resistivity and type	Applied voltage, V					
	3	6	10	20	45	100

100 ohm-cm, n	F	A	A	A	A	E
10 ohm-cm, p	F	F	A	—	—	—

ing resistivity ρ, applied voltage V, and etching time. The transmission-electron microscope observations on specimens of several resistivities are summarized in Table I, where the following symbols are used: A, small rounded tunnels having some directional character; B, sharp triangular etch pits; C, over-all removal of Si, but surface rough on the TEM scale; D, sharp tunnels lying in <100> directions with branches also lying in the same directions; E, surface optically rough with large approximately triangular holes too coarse to study by TEM; and F, no etching detected.

Typical examples of these various Types A to D are shown in Fig. 2(a) to 2(d). Types A and B are both partially developed figures where the voltage was too low to produce the sharp figures of Type D. The exception to this is 0.1 ohm-cm etched at 10V where the triangular holes may well be due to over-all removal of Si competing with the production of Type D figures. Figure 2(c) shows only thickness contours where each fringe corresponds to $\xi_{2\bar{2}0} \simeq 750$Å surface unevenness due to the electropolishing. Figure 2(e) is an enlargement of one sharp star-shaped figure of Type D. Many branches and sub-branches are seen, all lying in <100> directions. This was determined by tilting the specimen 54° in the microscope goniometer stage, until one main arm of the tunnels was parallel to the electron beam. A (100) pole was then also parallel to the electron beam.

Since the etch figures observed in the TEM were always in the form of tunnels where material had been preferentially removed, the contrast was obtained from these by using an approximately 3 or 4 beam-diffracting condition close to the (111) pole. The variations of total specimen thickness through which the electrons pass due to the empty regions inside the sample are then seen as intensity variations relative to the background. In the examples shown here the diffracting conditions were chosen to give dark figures on a lighter background. Stereoscopic pairs of micrographs were taken of several Type D etch figures and the complete three-dimensional tunnel structure could be clearly seen. The depth to which the tunnel networks penetrated below the Si surface was measured from such stereoscopic pictures using a Zeiss Standard Spiegelstereoskop N 2, and for instance in the case of 10 ohm-cm n-type Si etched at 45V for 6 min, this depth was 9500Å ± 500Å. Specimens thicker than about 1 μm are difficult to study in a 100 keV TEM as used here. The depth of the deepest tunnels was proportional to the etching time as expected.

A few samples were etched for much longer times than required for TEM specimens, and these contained a low density of much deeper tunnels similar to those reported previously (5). Metallographic cross sections from these specimens were examined by optical microscopy and the tunnel directions determined by Laue x-ray photographs to be <100> and not <110> as reported in Ref. (3, 5). Uhlir (4) has also reported preferential attack along <100> directions in anodically etched Ge.

In the majority of specimens the distribution of etch figures was apparently random. In some cases, however, this was not so, and one example is shown in Fig. 3 where Type D etch figures are associated with an optically visible scratch caused during mounting.

Fig. 3. An example of nonuniform distribution of etch figures, due to the presence of a surface scratch.

In the few TEM specimens which happened to contain a dislocation, an etch figure formed at the intersection of the dislocation with the surface, but these etch figures were not different from the many others in surrounding dislocation-free areas.

Discussion

At low voltages electrochemical attack at a Si-electrolyte interface is clearly not uniform. Assuming that electrical inhomogeneities do not exist in the electrolyte, then the etching at the interface must be due to inhomogeneities in the silicon. Obviously lattice strain or broken bonds resulting from surface damage provide nucleating sites for attack (Fig. 3) but other smaller crystal defects must be capable of doing this in the absence of grosser defects. We have seen that dislocations are certainly not the cause of the etching figures, as the dislocation density was orders of magnitude smaller than the density of etch figures seen here.

Once the etching has started an explanation for the preferential etching in <100> directions can be found. The (100) type surface has a higher density of free bonds than other planes, and the chemical dissolution rate is known to be proportional to the density of free bonds (8). In the case of electrochemical dissolution it has been pointed out (4) that at a concavity in a surface, the electric field is increased and therefore the necessary dissolution conditions are reached preferentially at such points. Thus a combination of these two factors could provide a feasible explanation for the details of the figures and their voltage dependence.

No attempt has been made here to understand the etching process in detail as has been done previously (9, 10). For instance, only the total voltage across the cell was measured and no reference electrode was used. We may conclude however from the above results that transmission-electron microscopy is a useful method for examining electroetched surfaces of semiconductors, and that if the etching conditions are carefully controlled, then it is likely that useful information concerning the homogeneity of the electrical properties at a silicon-electrolyte interface can be obtained.

Finally it should be mentioned that the jet-electrochemical thinning of Si specimens for the TEM now operates entirely satisfactorily. An electrolyte of 20 ml 40% HF + 8g NaF in 1 liter H_2O is forced through a 0.5 mm diameter jet onto the specimen and 300V is applied between specimen and a tungsten wire in the jet. Strong illumination speeds up the dissolution and is necessary for high resistivity n-type samples. Thinning times vary between 10 and 30 min for specimens of ~400 μm thickness. The method is extremely reliable and controllable producing specimens with more than 100 μm diameter transparent areas every time. The only material which cannot be thinned is Si highly doped with heavy metals, *i.e.*, with very short carrier lifetimes.

Acknowledgments

The author would like to thank Drs. W. Zimmermann and R. Sittig of this laboratory for useful discussions and Mr. A. Frey for much skill and patience with the specimen preparation.

Brief Communications

Resistivity of Doped Polycrystalline Silicon Films

A. L. Fripp*

Langley Research Center, Hampton, Virginia 23365

and L. H. Slack

Department of Metals and Ceramics, Virginia Polytechnical Institute and State University, Blacksburg, Virginia 23601

Chemical deposition of polycrystalline silicon on oxidized silicon wafers is an important process in the fabrication of silicon gate (1) and shielded silicon gate (2) MOSFET's, two-phase CCD's (3), and dielectrically isolated circuits (4). Silicon has been deposited on oxidized silicon wafers by the pyrolytic decomposition of silane. Diffusion (5), oxidation (6), Hall-effect (7), and preferred orientation (8) investigations have been made on polycrystalline deposits. The resistivity of undoped polycrystalline (9) and amorphous films (10) has been measured. The purpose of this communication is to report the resistivity dependence on the doping concentration in polycrystalline silicon films.

Experimental

The wafers were polished 1 ohm-cm single crystals oriented within 2° of the (111) face. They were oxidized in a quartz tube furnace at 1100°C by the wet-oxidation process. The oxide films were approximately 6000Å thick. To prevent possible errors in measuring resistivity, boron-doped wafers were used for phosphorous deposits and phosphorous-doped wafers were used for boron deposits.

The films were deposited by the pyrolytic decomposition of silane in a horizontal, induction-heated, reactor. The films were doped during deposition by adding either phosphine or diborane, in regulated quantities, to the gas stream. The silane flow rate was 50 cm^3/min and it was mixed with hydrogen to produce an atmosphere of 0.37% by volume of silane.

Data were taken on runs made at temperatures of 1070° and 1170°C for phosphorous-doped films and at 1070°C only for boron-doped films (corrected from optical pyrometer measurements). The wafers were given a 4-min, 1170°C preheat in hydrogen before deposition. The deposition time of 10 min produced a film approximately 7μ thick for the 1070°C runs and approximately 3μ thick for the 1170°C runs. After deposition, and a 1 min flush, the wafers were cooled rapidly in hydrogen.

The standard four-point probe technique was used to measure resistivity. Film thickness was measured by beveling; no staining was necessary since the oxide-silicon interface was quite distinct.

The doping concentration in the polycrystalline films was arrived at by simultaneously depositing an epitaxial layer on a single-crystal substrate. The resistivity of the epitaxial layer was measured and the doping concentration obtained by referring to Irvine's graphs (11). Since both the clean single-crystal and the oxide-coated wafer are at the same temperature and both offer a silicon surface, after the initial deposition, for reacting the doping gas, it is assumed that both will have the same doping concentration within the normal variation of epitaxial depositions.

Results and Discussion

The resistivity as a function of impurity concentration for both polycrystalline and single-crystal films

* Electrochemical Society Active Member.

Key words: polycrystalline silicon, microelectronics, resistivity.

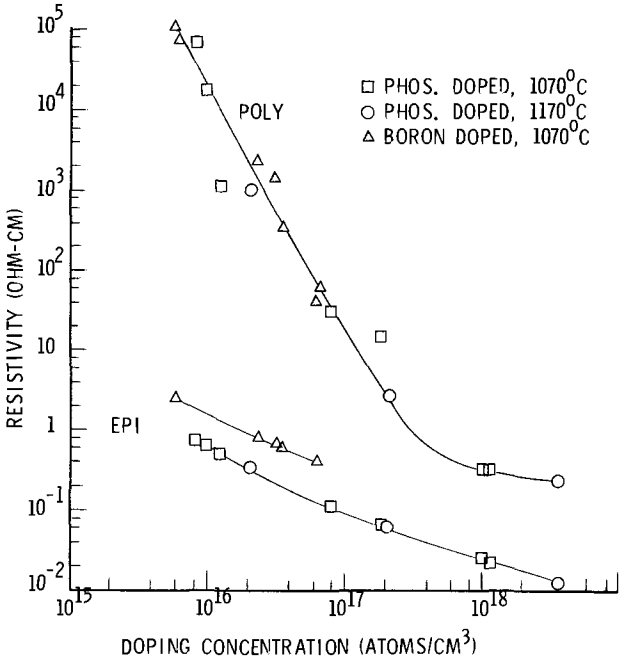

Fig. 1. Resistivity dependence of both single-crystal and polycrystalline silicon on doping concentration.

are shown in Fig. 1. The legend indicates impurity type and temperature of deposition. These data indicate that at concentrations above 10^{17} atoms/cm^3 the concentration dependence of the resistivity substantially decreases and approaches the single-crystal dependence.

The data presently available are insufficient to conclude that the value of concentration dependence in polycrystalline silicon becomes the single-crystal value. However, since resistivities of polycrystalline silicon are not expected to be lower than an equally doped single crystal, such a decrease in doping level dependence would be expected.

The grain boundaries in polycrystalline silicon offer possible sinks for both doping atoms and charge carriers. Carrier trapping in silicon has been discussed by others (7, 12) as being defect-induced, but further work is needed in which the structure of the films is modified and carrier-activation energy, especially in the low doping concentration region, is measured before commencing upon model development.

Diffusivity Summary of B, Ga, P, As, and Sb in SiO_2

M. Ghezzo* and D. M. Brown*

General Electric Corporate Research and Development, Schenectady, New York 12301

Many investigations have reported data on the diffusivity of semiconductor dopants in SiO_2. However, in many of these papers these data have usually not been considered of primary importance and there was a need for a paper, like this, which summarizes the diffusivities of these impurities in SiO_2.

A difficulty in the earlier and present literature is that the diffusivities of those elements in SiO_2 can be extremely concentration and ambient dependent. B is a fine example of this since its concentration dependence and ambient dependence are definitely marked. In fact, after a preliminary investigation on the oxide-masking properties done by Frosh and Derick (1) the diffusivities of III-V impurities or their carrying species in SiO_2 were determined by many authors using widely different experimental conditions.

The summary of diffusivities in SiO_2 is presented in Table I, which was prepared using the same format of Kendall and DeVries (2) in their tabulation of diffusion coefficients in Si. Whenever the pre-exponential diffusion constant, D_o, the activation energy, Q, or the diffusivities at 1100° and 1200°C were not explicitly given in a reference, the experimental data were fitted to an Arrhenius curve using the least squares method, and the above parameters were derived therefrom. Also included in Table I are the dopant concentrations at which the experiments were performed, the type of source utilized, and the diffusion ambient.

Inspection of Table I shows that the values of the activation energy for B diffusivity in SiO_2 are rather consistent among different investigators and average 3.5 eV, the only exceptions being the values of Thurston *et al.* (3) (2.38 eV) and Schwenker (4) (2.82 eV). The pre-exponential diffusion constant is highly dependent on the boron concentration in the diffusion source, regardless whether it is a vapor or a glass, and increases nearly three orders of magnitude in passing from low to high B concentration diffusions, as apparent from the data of Brown and Kennicott (5) and Schwenker (4). In an earlier work Horiuchi and Yamaguchi (6) reported an increase of the B diffusivity in SiO_2 at 1200°C from 3.2×10^{-16} cm^2/sec to 6.2×10^{-15} cm^2/sec due to an increase of the B_2O_3 vapor pressure, and attributed this phenomenon to a change in the composition of the diffused oxide layer resulting in the formation of a "glassy layer." Similarly Brown and Kennicott (5) referred to B diffusions through SiO_2 from borosilicate glass sources containing more than 18 mole per cent (m/o) B_2O_3 as rapid "melt through SiO_2 diffusions" as explained by relative decreases in viscosity and the B_2O_3-SiO_2 phase diagram (7). Yet oxide masking can still be used in "melt through" diffusions with a borosilicate glass source because the transformation of a thick oxide layer into glass by the "melt through" process is limited by the

C_0 = Dopant concentration in the source expressed in mole per cent.
C_s = Surface concentration on silicon after diffusion from the specified source and ambient in absence of oxide barrier.
* = Computed by fitting an Arrhenius curve to the experimental data using the least squares method.
** = Recomputed, because of disagreement with value computed in the reference.

dilution of the B_2O_3 concentration in the glass and further B penetration through the oxide is achieved at a B diffusivity at least two orders of magnitude smaller. Furthermore, three orders of magnitude increase in diffusivity of B in SiO_2 have been reported by Grove *et al.* (8) whenever diffusions are carried out in H_2 ambients. The importance of eliminating H_2 from diffusion ambients whenever B-doped polysilicon gate devices are formed cannot therefore be overemphasized.

The diffusivity of Ga in SiO_2 reported by Grove *et al.* (9) is by far the largest in Table I, assuming a value at 1100°C of 5.2 × 10^{-11} cm^2/sec, which is from 2 to 6 orders of magnitude larger than the diffusivities of B, P, As, or Sb in SiO_2. Besides Ga diffusivity in SiO_2 is higher than in Si [1.7 × 10^{-13} cm^2/sec at 1100°C according to Kurtz *et al.* (10)] preventing the use of SiO_2 as a mask for Ga in device fabrication.

Diffusion constants and activation energies for P diffusions in SiO_2 are widely scattered, the only reasonable agreement existing between the activation energy values computed from the data of Thurston *et al.* (3) (4.21 eV) and Barry (11) (4.03 eV). At 1100°C the diffusivities reported by Allen *et al.* (12) (1.4 × 10^{-15} cm^2/sec) and by Thurston *et al.* (3) (1.7 × 10^{-15} cm^2/sec) for similar surface concentrations of P in Si closely match, but are about five times larger than Barry's value (11) (2.9 × 10^{-16} cm^2/sec) and over two orders of magnitude smaller than the value of Sah *et al.* (13) (2.0 × 10^{-13} cm^2/sec). A justification for this exceedingly high diffusivity reported by Sah *et al.* can be sought in the high P_2O_5 vapor pressure used in these experiments, which resulted in the formation of a glassy compound by reaction of P_2O_5 with the SiO_2 barrier as in the "melt through process" described for boron. Phosphorous glass "melt through" diffusions have also been discussed by Okabe and Tanikawa (14). A comparison with the P diffusivity in Si at 1100°C given by Fuller *et al.* (15) (3.0 × 10^{-13} cm^2/sec) shows that at low P concentrations the P diffusivity in SiO_2 is over two orders of magnitude smaller than in Si, but at high P concentrations the two diffusivities are nearly equal.

Recent investigations of As diffusion through SiO_2 from an arsenosilicate glass source (16) gave results consistent with those previously reported by Hsueh (17). The activation energy is 4.9 eV for low As concentration diffusions and decreases to 4.0 eV with an increase of the As_2O_3 concentration in the arsenosilicate glass source. The smaller increase of As diffusivity with concentration at 1100°C in Ar (from 2.6 × 10^{-16} cm^2/sec to 3.5 × 10^{-15} cm^2/sec) in comparison to B or P suggests that a "melt through process" is unlikely for high concentration As diffusions, considering also the limitation on As_2O_3 percentage in the glass required for avoiding damage. The diffusion ambient affects the As diffusivity in SiO_2, which is drastically reduced in the presence of oxygen as discussed at length by Ghezzo and Brown (18) in a paper on As diffusion properties in Si from arsenosilicate glass sources prepared by simultaneous oxidation of AsH_3 and SiH_4. In any case, As diffusivity in SiO_2 is always smaller than in Si, where at 1100°C in Ar it is close to 1.5-2.0 × 10^{-14} cm^2/sec (19, 20).

The only data available on Sb diffusivities through SiO_2 at different temperatures are given by Thurston *et al.* (3). A computation of the activation energy from these data results in a value of 8.75 eV, which is nearly twice as large than the second highest in Table I (4.9 eV) corresponding to As. Thus a change in diffusion temperature from 1100° to 1200°C corresponds to a very large increase in diffusivities (from 9.9 × 10^{-17} cm^2/sec to 1.5 × 10^{-14} cm^2/sec) and a reduction of the difference between Sb diffusivities in SiO_2 and Si due to the smaller value of the activation energy for Sb diffusion in Si [3.95 eV in Ref. (15)].

Summary

Available diffusivity data on B, Ga, P, As, and Sb in SiO_2 have been summarized and discussed. Agreements and discrepancies in the literature have been pointed out along with the importance of ambient and source conditions. These data have an importance to general device technology and a few examples of this have been pointed out in the text.

The Hexamethonium-Silver Iodide Reversible Cell

M. De Rossi,* M. L. Berardelli, and G. Fonseca

Istituto di Elettrotecnica, Università di Roma, Rome, Italy

ABSTRACT

The hexamethonium-silver iodide solid-state cell has a highly competitive cost, as compared with those having the $RbAg_4I_5$ as electrolyte. In addition, it seems to possess the characteristic of reversibility and a much less polarizations phenomena at the positive electrode. The results obtained on the cell confirm the property of the hexamethonium-silver iodide as a solid electrolyte.

In a recent paper (1) a new series of compounds of the type $I^- R_3N^+-(CH_2)_n-{}^+NR_3\ I^-$ and in particular the hexane-1,6-bis-trimethylammonium iodide (hexamethonium iodide, $(CH_3)_3N^+-(CH_2)_6-{}^+N(CH_3)_3\ 2I^-$ hereinafter given as $HexI_2$), capable of forming solid electrolytes with AgI and having the peculiar characteristic of high electrical conductivity (comparable to that of compounds of the type M Ag_4I_5 where M = Rb, K, NH_4) has been described. These compounds, as compared with the electrolytes of the type $RbAg_4I_5$, known to date, have a highly competitive cost.

It was, however, necessary to find out whether these new solid electrolytes were suitable for forming a cell; that is if, in addition to the characteristic of a high ionic conductivity, they also had a small amount of electronic conductivity.

In this paper we report the experiments carried out to verify some electric characteristics of these new solid electrolytes and in particular the behavior of the Ag-I_2 electrical cell made with it.

The cell in its essential structure may be represented thus

$$Ag/HexAg_{12}I_{14}/I_2,\ C \qquad [1]$$

Considering the value of the emf and the nature of the end product of the reaction, we believe that the prevailing over-all reaction which takes place in cell [1] is

$$Ag + \tfrac{1}{2}\ I_2 \rightleftharpoons AgI$$

The theoretical value of the emf is 0.688V derived from the thermodynamic free energy of formation of silver iodide.

Experimental

All the chemicals used were reagent grade (Fluka). The solid electrolyte $HexAg_{12}I_{14}$ was prepared according to the method described by De Rossi and co-workers in a previous paper (1). Voltage and current values were determined by a Keithley Model 610 C with high internal impedance (10^{14} ohms). The conductivity measurements were carried out with a 4896 Tinsley conductivity bridge with oscillographic resetting (545 B Tektronix).

The main problems in cell [1] are the contact polarizations which have been reduced, in the present case, by the use of an anodic mixture made of powdered silver and electrolyte and of a cathodic mixture made of powdered graphite, iodine, hexamethonium iodide and electrolyte.

The function of $HexI_2$ in the cathodic mixture is to make addition compounds with iodine in order to prevent reactions by free iodine on the electrolyte when the cell is not operative (2, 3). Iodine is released by $HexI_2$ during discharge and retained during charge.

The actual cell [1] structure is therefore

$$Ag/HexAg_{12}I_{14}/I_2,\ HexI_2,\ C \qquad [2]$$

The cell [2] structure is shown in Fig. 1. The cell consists of a thin silver disk in contact with a silver powder and electrolyte pellet in the ratio of 1:1 (diameter ~ 2.5 cm; thickness ~ 0.1 cm). Another pellet

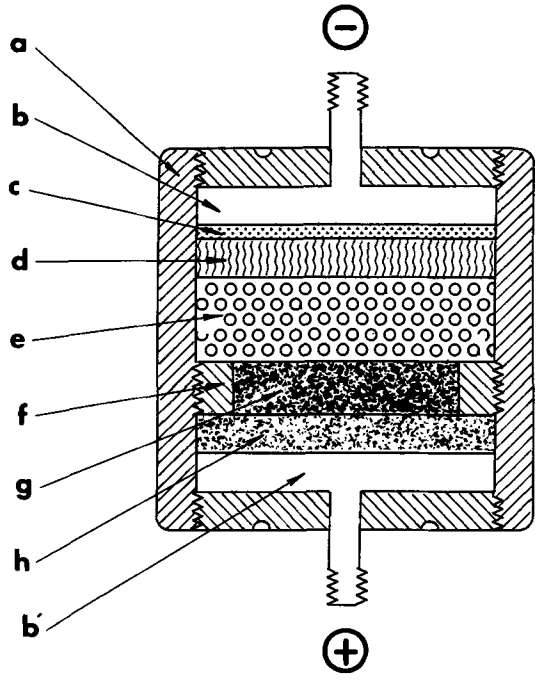

Fig. 1. Cell structure, where a is a polyvinyl-chloride container; b, b' are the external electrical contacts; c a silver disk; d the anodic mixture; e the solid electrolyte; f an insulating ring of PVC; g the cathodic mixture; h the graphite disk.

Key words: solid-state electrochemistry, solid electrolyte, solid-state battery, silver iodide, hexamethonium iodide.

made of the electrolyte alone is compressed on top of this one (diameter ~ 2.5 cm; thickness ~ 0.1 cm). The anode and the electrolyte so formed are put in contact with the cathodic mixture pellet (iodine, $HexI_2$, graphite, and electrolyte in the weight ratio respectively of 2:1:4:7; diameter ~2.2 cm, thickness ~ 0.1 cm). The electrolyte and the cathodic mixture are partially insulated by a polyvinyl-chloride ring in order to prevent possible contacts between the electrodes. A graphite cathode contact terminal electrode is used to complete the cell. The actual weights of the cell components are: 1g of silver powder anode; 1.2g of cathodic mixture; 2.8g of the electrolyte pellet.

Results

The specific conductance of the solid electrolyte has been found to be 0.029 $(ohm \times cm)^{-1}$, the same value as that reported in a previously mentioned paper (1).

The Ag^+ transport number in $HexAg_{12}I_{14}$ at 25°C has been determined by passing a known amount of charge through a cell made of two silver electrodes in contact with a solid electrolyte pellet and comparing the corresponding coulombs with those obtained by measuring the loss in weight of the anode. This method is similar to the one used by Bradley and Greene for the KAg_4I_5 solid electrolyte (4). The transport number of the Ag^+ thus determined is 0.99 ± 0.01, a value that shows how the contribution to the passage of the current within the electrolyte is essentially due to migration of Ag^+ ions alone.

Figure 2 shows a typical current-voltage curve, obtained at 25°C with the electrolyte compressed between two platinum electrodes. The decomposition potential of $HexAg_{12}I_{14}$ is 0.67 ± 0.01V, obtained by back-extrapolating the linear part of the curve.

The OCV of cell [2] is 0.635V at 25°C and its variation with temperature is shown in Fig. 3. The temperature dependence is 0.0002 V/°C in the range −40° to +50°C.

From current-voltage plots at room temperature (Fig. 4) the internal resistance of the cell has been determined at about 15 ohms. Such value is considerably in excess of the resistance due to the pellet alone (about 2 ohms), so that it can be concluded that the remaining internal electric resistance of the cell (about 13 ohms) is due to the effects of contacts to the electrodes.

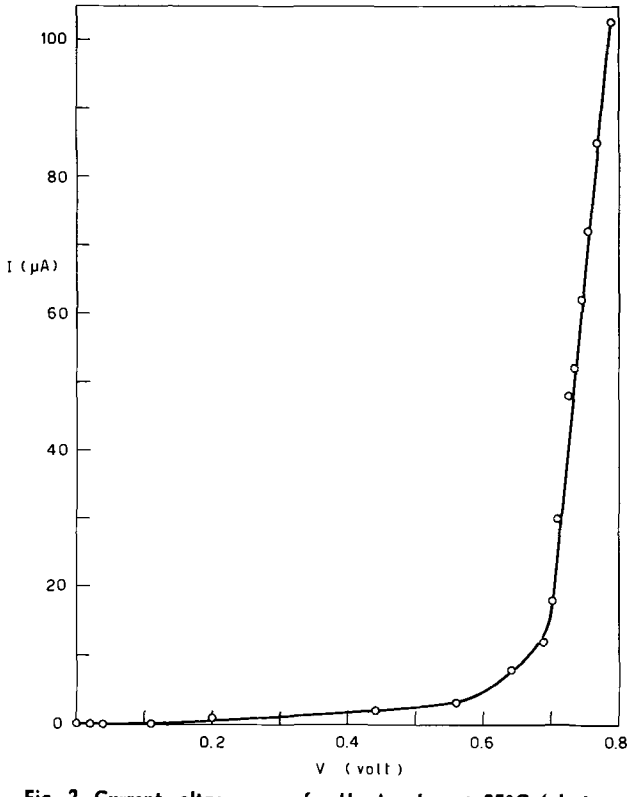

Fig. 2. Current-voltage curve for $HexAg_{12}I_{14}$ at 25°C (platinum electrodes).

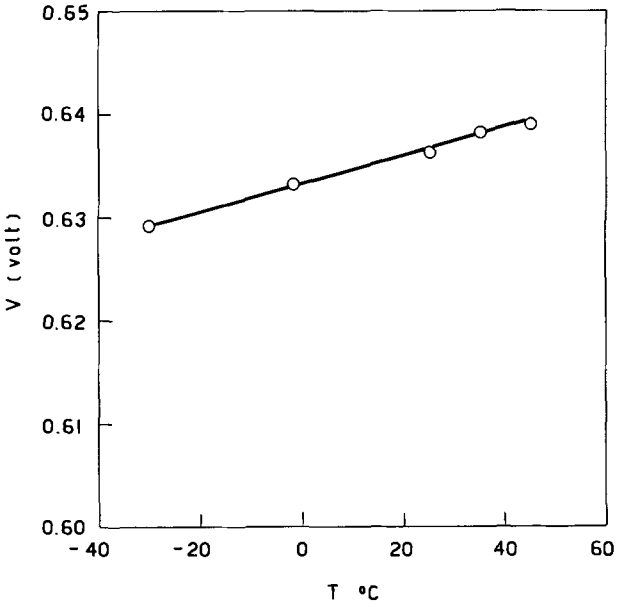

Fig. 3. Temperature dependence of the OCV of cell [2]

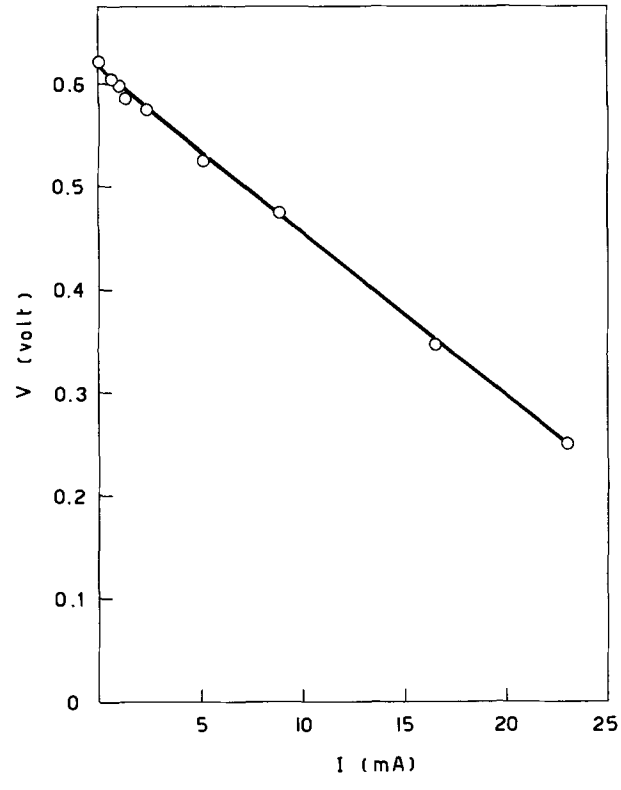

Fig. 4. Current-voltage curves for cell [2] at room temperature

Figure 5 shows typical discharge curves through various loads relating to the component weights as mentioned before; therefore the silver anode efficiency is 10 to 5% from highest intensity discharge rates to the lowest ones.

Figure 6 shows a charge-discharge cycle at 25°C and at a constant current of 0.2 mA.

From the data here reported it can be inferred that the polymethonium-silver iodide compounds (in this case $HexAg_{12}I_{14}$) have a high electrical conductivity almost exclusively ionic. Furthermore, the cell made with it shows reversibility characteristics and can be

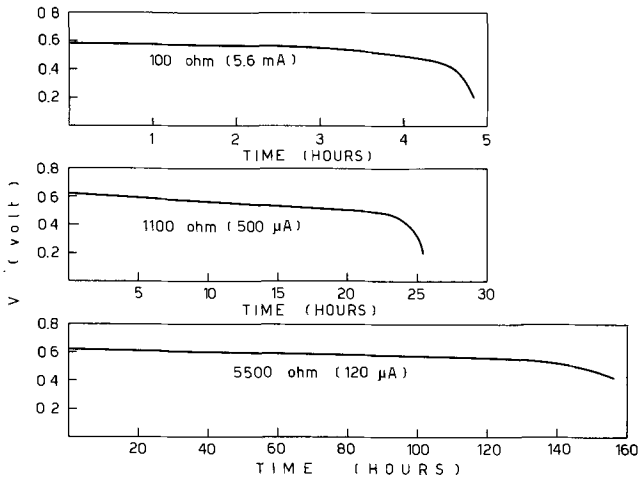

Fig. 5. Typical cell [2] performances at various constant loads at room temperature. As current intensity, an average value is reported.

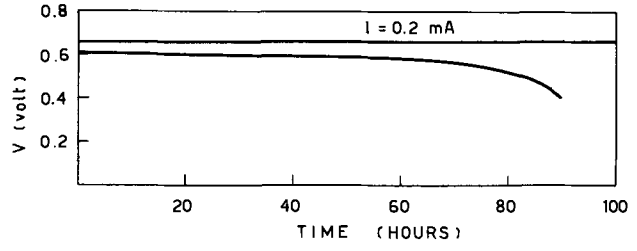

Fig. 6. Charge-discharge cycle of cell [2] at 0.2 mA constant current and at room temperature for efficiency determination.

discharged and charged without apparently altering the efficiency and the state of the operative potential at least within a consistent number of cycles (so far in our experiment 20 complete identical charge and discharge cycles have been carried out).

The capacity output based on iodine has been 90% on the average and that in energy higher than 80% with a value of the average operative voltage of 0.646V in charge and 0.595V in discharge. The stability in the charged state of the cell has been checked at the end of each cycle. The cell in the charged state presents a remarkable stability even after several cycles which in addition to the discharge curves of the cell show the solid electrolyte character of the substance we have studied. Experiments are in progress in order to determine the best weights of the electrode materials and the over-all efficiency of the charge-discharge cycles of the cell.

Summary

A solid-state reversible cell of the type Ag/$HexAg_{12}I_{14}/I_2$, $HexI_2$, C has been developed. The anodic and cathodic contact polarizations have been reduced by the use of a mixture of powdered silver and electrolyte and the use of a suitable mixture of hexamethonium iodide, iodine, graphite and electrolyte, respectively. The cell has an open-circuit voltage of 0.635V at 25°C, an internal resistance of 15 ohms, and is rechargeable with high coulombic efficiency. The above experiments were carried out in order to confirm the property of the $HexAg_{12}I_{14}$ as a solid electrolyte.

Current Distribution in the Porous Lead Dioxide Electrode

Daniel Simonsson

Department of Chemical Technology, The Royal Institute of Technology, Stockholm, Sweden

ABSTRACT

A theoretical analysis of initial current distribution in the porous lead dioxide electrode is made by application of the macrohomogeneous model for porous electrodes. The parameters in the model have been determined experimentally for the investigated lead-dioxide battery plates. The theoretical results are in good agreement with experimental determinations by means of electron microprobe analysis of the $PbSO_4$-distribution within partly discharged positive lead-acid plates. The experimental studies of current distribution shows that at high current densities the electrode reaction takes place mainly in the outer layers of the electrode. At low discharge currents, the initial current distribution is uniform while after the first quarter of discharge, the outer layers are more utilized than the inner parts. A mechanism for the passivation of the positive plate in the lead-acid battery is proposed.

The behavior of porous battery electrodes is to a large extent governed by current distribution and reactant depletion. Optimizations of porous electrodes must therefore be based upon some model able to predict how these phenomena influence the discharge behavior. During the last decade various mathematical models have been proposed for the theoretical analysis of electrode reactions in porous media (1-4). While the theoretical work in this field has been extensive, comparatively few applications of these models have, however, been made to practical electrodes. In the case of the practically important lead dioxide electrode, used as positive electrode in the lead-acid cell, theoretical and experimental investigations of current distribution have given contradictory results (5-9).

The purpose of the present paper is to study the current distribution in the porous lead dioxide electrode in solutions of sulfuric acid theoretically and experi-

Key words: lead-acid battery, porous electrode, current distribution.

mentally, and to offer an explanation for the earlier contradictions between theory and experiments.

Choice and Description of Theoretical Model

Various theoretical models have been used to describe the processes in flooded porous electrodes mathematically. Winsel (2) has suggested a model consisting of circular cylindrical pores with constant radius, parallel to each other and perpendicular to the outer surface. Other authors (1) have used a model represented by electrical equivalent circuits. In this way the behavior of the electrode can be simulated with a network of ohmic and charge-transfer resistances.

These two models both have their disadvantages. The first model cannot be used with electrodes of cylindrical shape or with electrodes which must be considered as two-dimensional, since in these cases complications arise concerning the direction of the pores.

The second model has been applied by Euler to some practical electrodes, among them the lead dioxide electrode (6). However, this model makes use of a linearized polarization equation and is thus realistic only for small current densities, while it becomes unrealistic for large current densities where the polarization equation is of exponential type (3, 10). Furthermore it is difficult to include the influence of concentration changes in the electrical model.

Most of the disadvantages of the two mentioned models are eliminated in the so-called continuous or macrohomogeneous model (3, 4). This model disregards the actual geometric detail of the pores and describes the porous electrode as a superposition of two continuous phases, liquid and solid. This model resembles real electrodes when particle and pore dimensions are of the order of micrometer. Under these circumstances the concentration of the electroactive species depends only on time and distance from the outer surface of the electrode.

Because of its mentioned advantages, the macrohomogeneous model will be used in this study. The average pore diameter in the type of lead dioxide plates used in this work was determined by means of mercury porosimetry to 0.3-0.4 μm and the electrodes can therefore be regarded as macrohomogeneous media in accordance with the concepts of the model.

A complete analysis of the discharge behavior of the positive plate in the lead-acid cell requires rather rough approximations concerning the composition of the electrolyte and the basic equations for mass transfer. Furthermore the formation of a passivating reaction product, lead sulfate, in the pores complicates the analysis of the transient behavior. However, an exact analytical solution for the current distribution can easily be obtained in the simplified case of uniform concentration, uniform porosity, and uniform specific surface area, corresponding to the initial moments of discharge. The comparison between theoretical and experimental determinations, which is the primary goal in this work, will therefore be restricted to this special case.

It is easy to show that under these circumstances the current distribution is governed by the following two equations (see Appendix)

$$\bar{i}_2 = \kappa_1\kappa_2 \nabla E/(\kappa_1 + \kappa_2) + \kappa_2 \bar{I}/(\kappa_1 + \kappa_2) \qquad [1]$$

$$\nabla \cdot \bar{i}_2 = Sf(c,E) \qquad [2]$$

The first equation gives the current density, $\bar{i}_2$, in the pore electrolyte as a function of the electrode potential gradient, ∇E and the effective conductivity of the electrode matrix, κ_1, and the pore electrolyte, κ_2.

In the second equation $f(c, E)$ is an electrode kinetic expression of Volmer/Erdey-Gruz type or simply an empirical relation calculated from the polarization curve.

Before the initial current distribution can be calculated from these two equations, the actual values of the parameters appearing in the equations above must be determined by suitable experiments.

Experimental Determination of the Parameters in the Model

The electrodes investigated in this study were positive plates manufactured for use in automobile batteries. These electrodes are manufactured with grids of lead-alloy as current collectors.

To determine actual current distributions from the equations given above, knowledge is required about the parameters κ_1, κ_2 and the rate of the charge transfer process. The actual values of these parameters were determined experimentally for the electrodes under investigation.

Determination of κ_1.—Lead dioxide is a semiconductor with almost metallic conductivity. However, the conductivity of the porous matrix in the electrode depends also on the contact between the particles. A rough estimate of this effective conductivity of the porous lead dioxide was made by simply measuring the voltage drop across a piece of electrode material of known dimensions, when a current of known magnitude was forced through this specimen. For fully charged plates the conductivity was measured by this method to about 5-20 mho/cm. The order of magnitude is in good agreement with an effective resistivity of 0.1 ohm-cm reported by Euler (6).

During discharge the conductivity of the electrode material decreases.

The conductivity measured for fully charged plates is, however, prevailing up to more than 25% of complete discharge and will therefore be sufficient for the analysis of the initial current distribution.

Determination of κ_2.—The effective conductivity of the electrolyte phase in porous electrodes depends on the conductivity of the free electrolyte, the porosity of the electrode, and the tortuosity of the pores. The simplest way to measure this parameter has been described by Euler and Rieder (11). They proposed that the effective resistivity of the electrolyte in the pores could be determined by measuring the electrolyte potential difference between the two sides of the electrode when a direct current passes through the electrolyte in the pores. The potential difference is measured by two reference electrodes with Luggin-capillaries and is corrected for the voltage drop in the free electrolyte. The disadvantage of this simple method is that a certain fraction of the current passes through the solid electrode phase by an anodic electrode reaction on one side of the electrode and a cathodic reaction on the other side. At small currents this fraction is, however, rather small. Romanova and Selitsky (12) determined it to less than 5% for potential differences smaller than 20 mV. A correction for this fraction is not made in this work since the variation of the effective conductivity with different cycles proved to be of much greater magnitude.

A graphical representation of potential difference *vs.* current density yielded a straight line (Fig. 1). The effective conductivity, κ_2, can be calculated from the slope, K, of this line by using the formula

$$\kappa_2 = 2L/K$$

where $2L$ is the thickness of the electrode. The conductivity of 5M H_2SO_4 in the positive plates used in this study was determined to 0.07 $\pm$ 0.01 mho/cm. The great uncertainty is due to variations from cycle to cycle and from electrode to electrode. The measured average of the conductivity is in good agreement with the results of Romanova and Selitsky (12), while it is three times greater than the value reported by Euler (6). The measured effective conductivity is thus only about a tenth of the conductivity of the free electrolyte. This great reduction is probably due to oxygen left in the pores after excess charge. Romanova and Selitsky

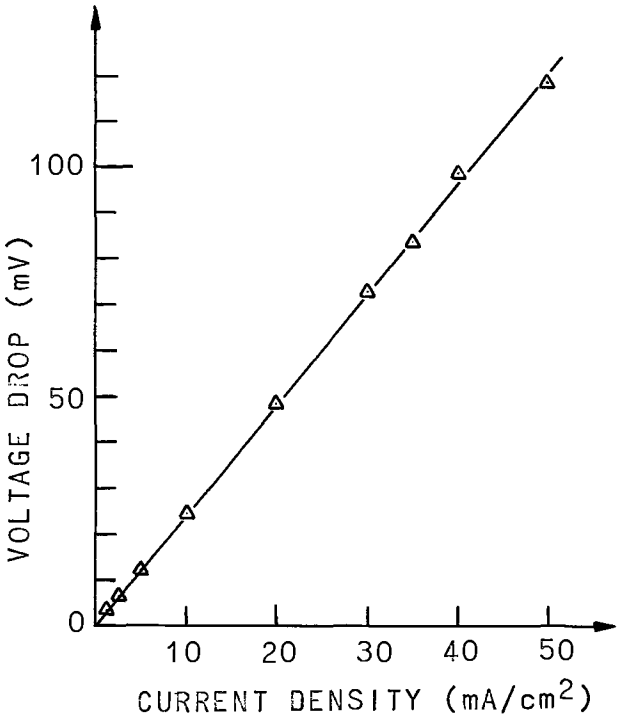

Fig. 1. Voltage drop across a positive lead-acid plate as a function of applied current density in the pore electrolyte.

(12) thus observed a doubling of the conductivity, after the removal of oxygen at reduced pressure.

The Current-Overvoltage Relation for the Lead Dioxide Electrode

There are fairly many reports in literature on the kinetics of the cathodic discharge of the lead dioxide electrode in sulfuric acid

$$PbO_2(s) + 4H^+ + SO_4^{2-} + 2\,e^- \rightleftharpoons PbSO_4(s) + 2H_2O \quad (1)$$

The results are, however, partly divergent and a definite rate equation cannot be found. New experiments were therefore carried out, with the restricted goal to determine the prelogarithmic Tafel coefficient in the region of high overvoltage. The experimental method was galvanostatic discharge of a lead dioxide surface formed by anodic oxidation of a smooth lead sheet (analytical grade from MERCK, Darmstadt) in 5.0M H_2SO_4 (analytical grade in bidistilled water). The electrode was subjected to repeated cycles of charge and discharge to increase the thickness of the lead dioxide layer and consequently decrease the self-discharge of the electrode. The anodic oxidation was carried out with 1.0 mA/cm² for successively increasing times up to 1 hr for the last formation cycles. Care was taken to avoid excess charge leading to flaking of the electrode surface. The self-discharge of the thus formed test electrode was equivalent to a cathodic current of less than 0.01 mA/cm². Microscopic investigations showed, however, that the lead dioxide surface formed in this way was porous, something which is mostly unsuitable in kinetic studies. The thickness of this porous layer is, however, very small (about 0.01 mm), and thus the current distribution in this layer may be expected to be uniform. (This case corresponds to a very low value of the parameter a, appearing in the equation for current distribution in the next section.)

This very thin porous electrode may thus be expected to give lower overvoltages than a smooth lead dioxide electrode but the same Tafel slope at high overvoltages.

As a further control of the Tafel slope, the same experiments were also carried out with a nonporous lead dioxide surface formed by electrodeposition of β-PbO_2 on a smooth (polished) Pt-surface from a solution of $Pb(NO_3)_2$ (10 g/liter) and HNO_3 (15%). The deposition was carried out in 15 min with 3 mA/cm². The deposit was checked by x-ray diffraction to be β-PbO_2.

The galvanostatic discharges were carried out at 20° ± 1°C, and the electrode potential was measured against a mercury-mercurous sulfate reference electrode with a digital voltmeter. The overvoltage was defined as the difference between the maximum, rather constant electrode potential obtained after the initial drop of potential at the beginning of discharge and the equilibrium open-circuit potential. Correction was made for the ohmic potential drop between the surface and the end of the Luggin capillary. The results are illustrated in Fig. 2. The electrode formed by anodic oxidation of a lead surface proved to give much lower overvoltages than the electrode formed by deposition of β-PbO_2 on platinum. This is just what might be expected in consideration of the much larger true surface area for the former electrode. However, the slope of the logarithmic polarization curve was found to be nearly the same for both electrodes, 30 ± 5 mV/decade. From the experimental results above follows that the rate equation for the electrode reaction

$$PbO_2(s) + 4H^+ + SO_4^{2-} + 2e \rightleftarrows PbSO_4(s) + 2H_2O \quad (1)$$

may be written

$$j = -j_o \cdot \exp[-2F\eta/(RT)] \quad [3]$$

for overpotentials between 30 and 90 mV and Eq. [2] may consequently be written

$$\nabla \cdot \bar{i}_2 = -Sj_o \exp[-2F\eta/(RT)] \quad [4]$$

Theoretical Analysis of the Initial Current Distribution

The equations given above can now be applied to the lead dioxide plates under investigation. These electrodes are of grid-type and would therefore require a complicated two-dimensional representation in a coordinate system (Fig. 3).

However, the effective conductivity of the fully charged porous matrix was shown above to be about a hundred times greater than that of the electrolyte in the pores. In comparison to the electrolyte the solid

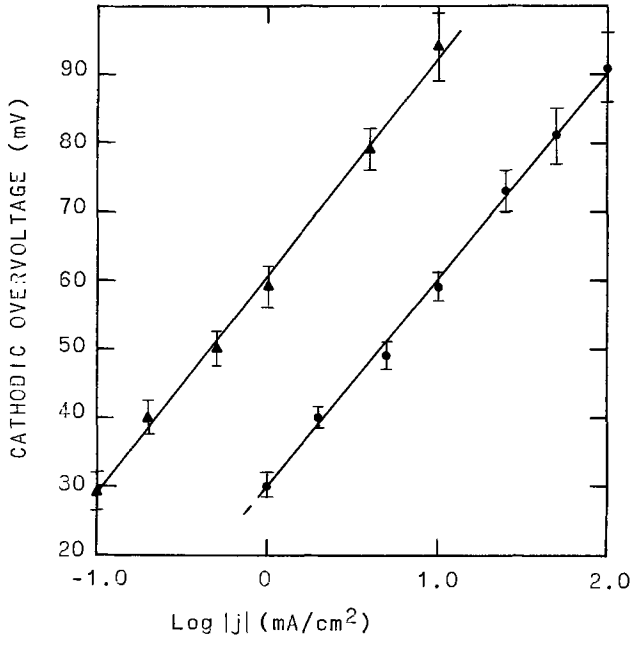

Fig. 2. Tafel plots for lead dioxide electrodes in 5M H_2SO_4. PbO_2 formed by: ●, anodic oxidation of Pb and ▲, electrodeposition of β-PbO_2 on Pt.

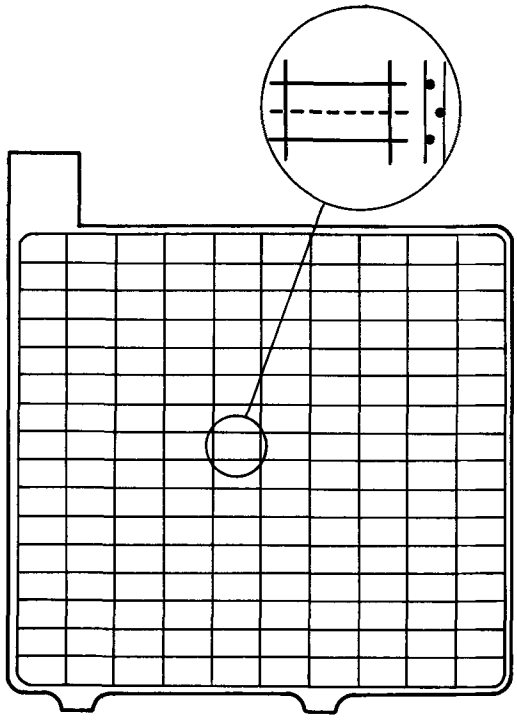

Fig. 3. Porous lead dioxide electrode with grid.

phase can therefore be regarded as an equipotential surface, and the electrode may consequently be regarded as one-dimensional, at least during the first quarter of discharge. The coordinate x is taken $= 0$ at the center of symmetry of the electrode and $= L$ and $-L$ respectively at the two outer surfaces.

Let us now consider the conditions at the first moments of discharge, after the electrolytic double layer has been charged, but before the concentration has changed significantly from its initial uniformity. The current is cathodic, $I < 0$.

Since now

$$\kappa_2 << \kappa_1 \quad \text{and} \quad dE/dx = d\eta/dx$$

Eq. [1] can be written

$$i_2 = \kappa_2 \, (d\eta/dx) \qquad [5]$$

while the rate equation, Eq. [4] can be expressed

$$di_2/dx = -Sj_0 \exp[-2\mathbf{F}\eta/(RT)] \qquad [6]$$

By differentiating Eq. [6] and eliminating $d\eta/dx$, one obtains

$$d^2 i_2/dx^2 + 2\mathbf{F}/(RT\,\kappa_2)\; i_2\, di_2/dx = 0 \qquad [7]$$

To use dimensionless variables instead, the quantities

$$z = x/L, \quad i = i_2/I \quad \text{and} \quad a = -2\mathbf{F}IL/(RT\,\kappa_2)$$

are introduced, whereupon Eq. [7] is transformed into

$$d^2i/dz^2 - ai\, di/dz = 0 \qquad [8]$$

The boundary conditions are then $i = 0$ at $z = 0$ and $i = 1$ at $z = 1$. The solution to this nonlinear differential equation is

$$i = \sqrt{2d/a} \tan (\sqrt{ad/2}\, z) \qquad [9]$$

where $d = di/dz$ at $z = 0$.

A finite current density in the electrode requires that

$$0 < \sqrt{ad/2} < \pi/2$$

The current distribution is obtained by differentiating Eq. [9]

$$di/dz = d \sec^2 (\sqrt{ad/2}\, z) \qquad [10]$$

The value of d is not given for the nonlinear, boundary value problem, Eq. [10] and must therefore be calculated. Putting $z = 1$, $i = 1$ in Eq. [9] gives an equation for d

$$d = a \cot^2 (\sqrt{ad/2})/2$$

from which d can be calculated by means of some numerical method, for example the Newton-Raphson iteration method.

The initial current distribution in a porous PbO_2-electrode at different discharge rates calculated from Eq. [10] is shown in Fig. 4. From the graphs we see that for low current densities (small a), the current distribution is rather uniform, while for higher current densities (increasing a) the electrode reaction takes place mainly near the outer surface of the electrode.

Experimental Investigation of the Initial Current Distribution

To determine the validity of the applied theoretical model, the calculations for the case of constant concentration made above, must be compared with experimental determinations of the initial current distribution. For this purpose there is obviously a need for a practical specification of the concept "initial." In the case of the porous lead dioxide electrode the initial conditions may be regarded as prevailing up to 25% of the total discharge time. There are two arguments for this interpretation: (*i*) The first fourth of the discharge curve is rather flat. (*ii*) Keeping the acid concentration constant by pumping electrolyte through the pores does not produce significant deviations from the normal discharge curve during the first fourth of discharge.

This interpretation allows a direct comparison between the theoretical results in Fig. 4 and the experimental results by Haebler, Panesar, and Voss (9), who measured the distribution of the reaction product, $PbSO_4$ within partly discharged positive lead-acid plates using a scanning x-ray microprobe with sulfur-

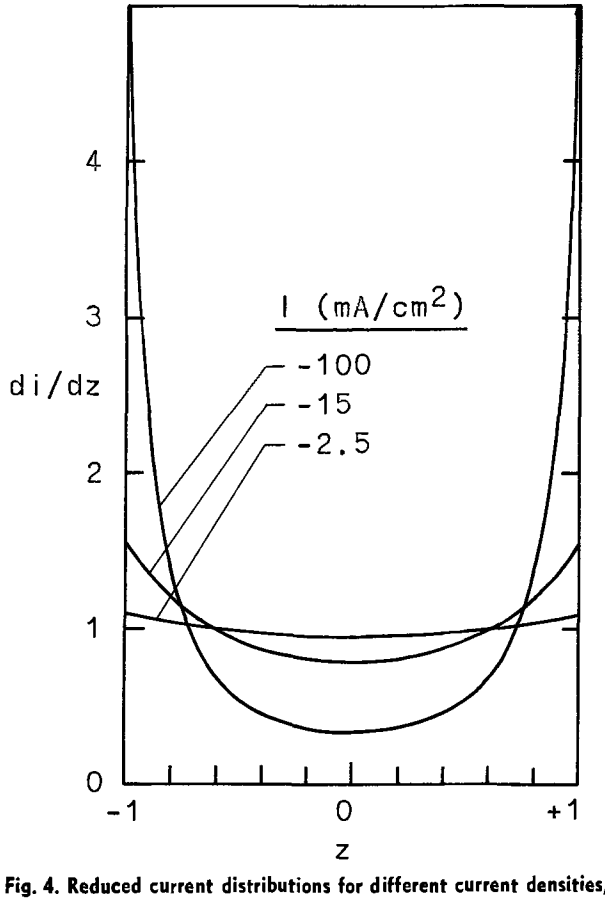

Fig. 4. Reduced current distributions for different current densities, $L = 0.09$ cm, $\kappa_2 = 0.07$ mho/cm.

K_α radiation. These experiments showed that the discharge to $PbSO_4$ in the first fourth of discharge (with -180 mA/cm^2) took place mainly in the interior of the plates. The microprobe analyses made by Bode, Panesar, and Voss (8) gave distribution curves which decreased strikingly near the outer surfaces of the electrode at all discharge rates.

Obviously these experimental results reveal a complete failure of the theoretical predictions. Furthermore the measured distribution curves can hardly be explained at all on the basis of conventional theories of current distribution. This serious contradiction between theory and experiment can, however, also be attributed to some experimental error.

It was thus found necessary in this work to investigate whether the preparation of the specimens for analysis, *i.e.*, soaking of the sulfuric acid in the pores with distilled water, might affect the original distribution of lead sulfate. The underlying idea was that when electrodes containing sulfuric acid of 1-5M are soaked in distilled water, the sulfuric acid concentration at the interface will become very low. The reversible electrode potential will therefore be much lower (up to 100 mV) at the outer surface than in the depth of the pores. This would produce leveling currents resulting in charge of the outer parts of the electrode and discharge of the inner parts. By this process the distribution of sulfate would be shifted to lower values at the interface and higher values in the interior of the electrode. This hypothesis would also explain the strange fall of the distribution curves within a zone of about 0.2 mm depth, observed by Bode *et al.* (8).

Experimental Procedure

The cell used in the experimental investigations consisted of a positive plate of grid-type with dimensions 50 × 50 × 1.8 mm placed symmetrically between two negative (Pb−) plates in 5.0M H_2SO_4. The electrolyte was in great excess to keep the concentration in the bulk almost constant. The potential of the positive plate was recorded against a mercury-mercurous sulfate electrode, and the end of discharge was defined to be at a total overvoltage of 1V. To keep the current load symmetrical on the two sides of the electrode, two different galvanostatic circuits were used, one for each side of the positive electrode and the corresponding counterelectrode. Positive plates were discharged to 25% with -100 mA/cm^2 on each side at 21° ± 1°C. After discharge a portion of the positive plate was soaked in a beaker with periodically renewed distilled water for two days. The plate was dried and a sample from the middle of the plate was subsequently examined using an electron microprobe. The lead sulfate distribution across the electrode was measured by the intensity of the S-K_α-radiation.

To investigate the effect of pretreatment other portions of the electrode were freed from sulfuric acid in another way. The method consisted in moulding a piece of the partly discharged electrode in an epoxy resin, grinding and polishing the cross section of the sample, and then soaking with periodically renewed distilled water for two days. With this method the leveling currents are acting in a direction perpendicular to the cross section of the electrode, thus affecting the absolute height of the distribution curves, but not their form.

Results

The experimental results, Fig. 5, appeared to be dependent on the method of pretreatment. Conventional soaking of the electrode gave a rather uniform distribution of lead sulfate, in accordance with the results obtained by Haebler *et al.* (9). The other method, however, gave a distribution in good agreement with the theoretical prediction. Both methods were checked by analyses of samples from completely charged, electrolyte-filled electrodes, giving low, uniform intensities. These results led to the important conclusion that

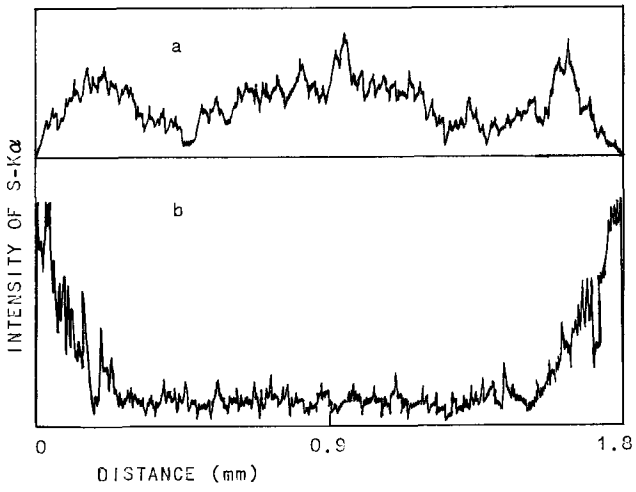

Fig. 5. The dependence of the method of soaking on the obtained distribution curves of sulfur. (a) "Conventional" soaking with H_2O and (b) soaking perpendicular to the cross section.

conventional soaking of the electrode strongly affects the distribution of lead sulfate within the electrode.

The experimental results reported below were therefore obtained with samples soaked with distilled water in the direction perpendicular to the cross section.

The measured distributions of lead sulfate in PbO_2-electrodes discharged with two different current densities to 25% are illustrated in Fig. 6. These curves are in good agreement with the theoretical calculations of initial current distribution (dashed lines).

Changes in current distribution during discharge.— It may be expected that the current distribution undergoes considerable changes during discharge. The

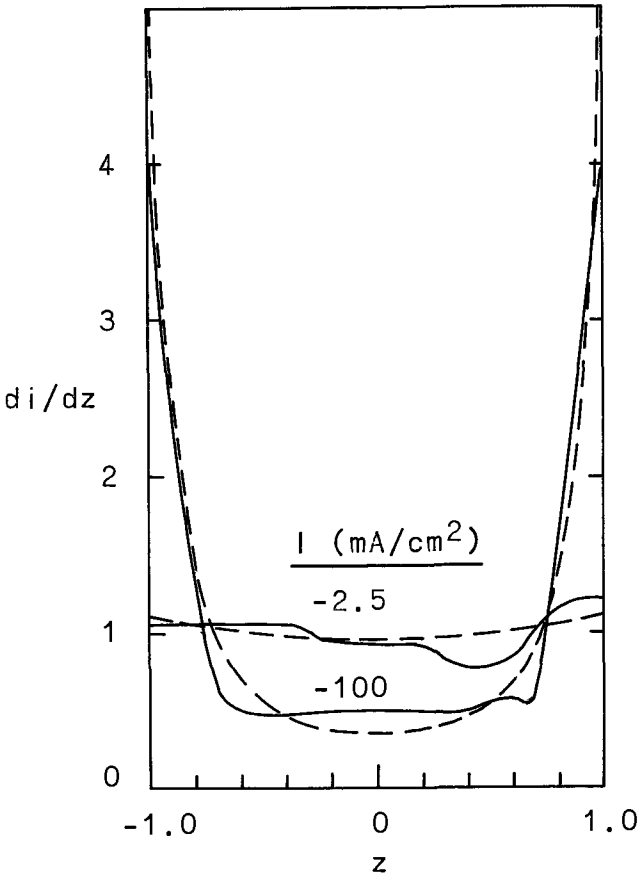

Fig. 6. Reduced current distributions at low- and high-current densities. Comparison between theoretical (dashed lines) and experimental (solid lines) results (L = 0.09 cm, κ_2 = 0.07 mho/cm).

distribution of lead sulfate was therefore measured also at higher degrees of discharge. The results obtained at different discharge rates are illustrated in Fig. 7 and 8.

It is evident from Fig. 7 that in cases of high current densities it is relevant to introduce the concept of a "reaction layer," proceeding from the interfaces of the electrode into the interior parts during discharge. At lower current densities the distribution of lead sulfate is uniform at the beginning of discharge, while the outer parts are somewhat preferred after the first quarter of discharge.

Discussion

The macrohomogeneous model for porous electrodes proves to be a valuable mathematical tool for the prediction of initial current distribution in porous lead dioxide electrodes.

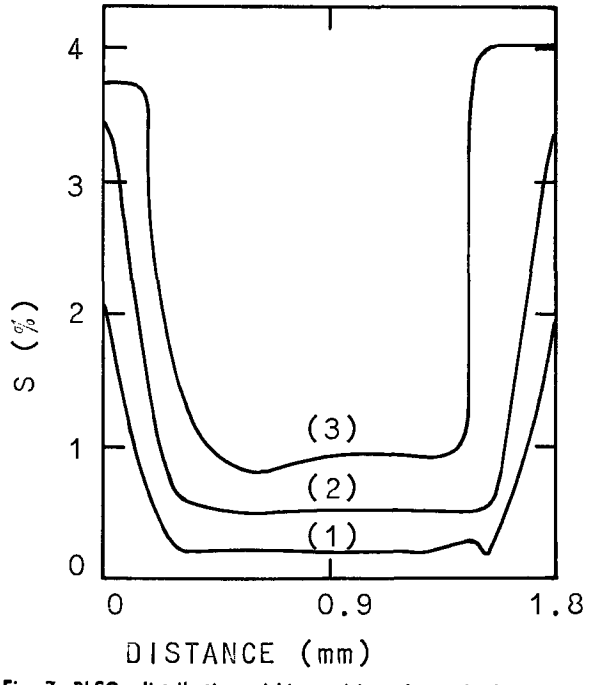

Fig. 7. $PbSO_4$-distribution within positive plates discharged with −100 mA/cm² to: 1, 25%; 2, 50%; and 3, 100%.

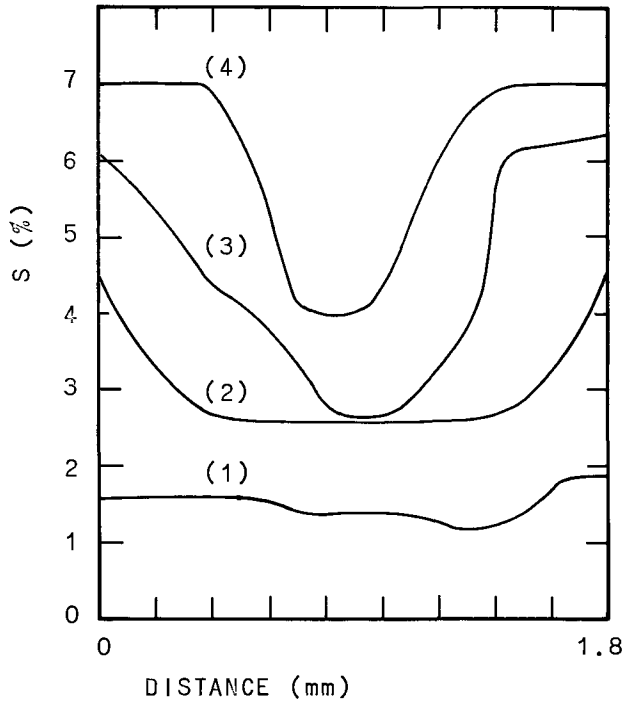

Fig. 8. $PbSO_4$-distribution within positive plates discharged with −2.5 mA/cm² to: 1, 25%; 2, 50%; 3, 75%; and 4, 100%.

The accuracy of the theoretical calculations of initial current distribution is limited by the accuracy with which the input parameters can be experimentally determined. In the present case the greatest uncertainty lies in the determination of the effective conductivity of the electrolyte, which varies considerably (up to 15%) from cycle to cycle and from electrode to electrode.

In this work the electrode kinetics is represented by a Tafel expression. As pointed out by Grens and Tobias (13) such an approximation may be dangerous, since the overvoltage existing over much of the depth of the electrode may be too small to permit the disregarding of the reverse reaction term in the Volmer expression. It is therefore necessary to check that the calculated local overvoltage is everywhere within the range of the validity of the Tafel approximation. In this work the calculated overvoltage profiles were found to be within the Tafel region for the current densities used, although at the smallest current density (2.5 mA/cm²) the electrode interior was operating near the lower limit of this region.

Experimental investigation of the current distribution by means of analysis of the distribution of the reaction product, $PbSO_4$, proved to be successful only under conditions where soaking with distilled water does not produce local concentration cells which redistribute the lead sulfate in the direction perpendicular to the interfaces of the electrode.

The experimental studies of current distribution lead to some important conclusions concerning the mechanism of the passivation of positive plates in lead-acid batteries. At high discharge currents a reaction layer is moving inwards into the electrode due to gradual insulation of the surface by covering lead sulfate crystals. From Fig. 7 it is clear that this reaction layer has not reached the interior parts before the voltage has broken down. Thus, the capacity at high current loads is not limited by a complete passivation of the electrode surface, since there is still active material left in the depth of the electrode. This fact leads to the conclusion that the acid in the depth of the pores is depleted (locally or extensively) during discharge, thus loosing its conductive property. The current can no longer reach the remaining active material in the inner parts, nor be transferred across the electrode surface in the outer parts insulated by lead sulfate crystals, so the voltage consequently breaks down.

At low current densities the total utilization of the active material is higher than at high current densities. However, even at low current densities there still remains active material in the middle of the electrode after the discharge is completed. This is probably due to plugging of the pores.

APPENDIX

Derivation of Eq. [1] and [2]

The current density in the matrix, $\bar{i}_1$, is given by Ohm's law

$$\bar{i}_1 = -\kappa_1 \nabla \phi_1 \qquad [A\text{-}1]$$

In the case of uniform concentration the current density in the pore electrolyte, $\bar{i}_2$, is also given by Ohm's law

$$\bar{i}_2 = -\kappa_2 \nabla \phi_2 \qquad [A\text{-}2]$$

The conservation of charge requires that the sum of these current densities is equal to the total apparent current density $\bar{I}$

$$\bar{i}_1 + \bar{i}_2 = \bar{I} \qquad [A\text{-}3]$$

The electrode potential is defined as $E = \phi_1 - \phi_2$ and consequently, with Eq. [A-1], [A-2], and [A-3]

$$\bar{i}_2 = \kappa_1\kappa_2 \nabla E/(\kappa_1 + \kappa_2) + \kappa_2\bar{I}/(\kappa_1 + \kappa_2) \qquad [1]$$

Finally, the relation between $\bar{i}_2$ and E is given by the actual electrochemical kinetic expression

$$\nabla \cdot \bar{i}_2 = Sf(c,E) \qquad [2]$$

Equation [2] expresses the rate of the electrode reaction per unit volume of the electrode as proportional to the specific active surface area, S, and to an appropriate expression for the local rate of charge transfer, $f(c, E)$. The appropriate boundary conditions are at the current collector $\bar{i}_2 = 0$ and at the interface of the electrode $\bar{i}_2 = \bar{I}$.

Monolayer Formation in the Reduction of Nickel and Silver Ions from the LiCl-KCl Eutectic

G. J. Hills,* D. J. Schiffrin,[1] and J. Thompson[2]

Chemistry Department, The University, Southampton, England

ABSTRACT

The deposition of nickel and silver on platinum from the LiCl-KCl eutectic at 400°C has been studied using the chronopotentiometric, cyclic voltammetric, and potential step techniques. An observed predeposition of nickel on platinum was observed to take place at 0.5V anodic to the equilibrium potential between nickel in bulk and the solution of its ions. The predeposition process was studied by an a-c impedance method and delineated as the formation of an adsorbed monolayer. A similar but less well-defined predeposition step was observed with silver at 0.1V anodic to the reversible potential. Notwithstanding the predeposition phenomena, diffusion coefficients for both metal ions were determined by each of the voltammetric techniques and found to be in reasonable agreement with each other and with previously reported values.

Electrode processes involving the deposition of metals from molten salt systems are known to be kinetically very fast, and many previous studies have therefore been concerned mainly with the evaluation of the diffusion coefficient of the metal ions involved (1) employing a variety of voltammetric techniques (2).

In aqueous systems, the deposition of a monolayer of the metal at potentials significantly anodic to that of the bulk deposition has been observed in many instances, *e.g.*, for Tl^+ on silver (3); Cu^{2+} on platinum (4), and Ag^+, Tl^+, and Cu^{2+} on gold (5). The same type of phenomenon has been recognized for many years in the hydrogen evolution reaction on platinum,

where a monolayer of adsorbed hydrogen atoms is a stable precursor to the hydrogen evolution reaction.

Monolayer formation processes in molten salts were briefly considered by Schmidt (6) as part of a study of the deposition of Ag^+, Pb^{2+}, Ni^{2+}, and Cd^{2+} ions on platinum from a LiCl-KCl eutectic melt, using alternating square current pulses.

The purpose of the present work was the study of both monolayer formation and metal deposition processes for Ni^{2+} and Ag^{2+} in a LiCl-KCl eutectic melt at 400°C. The reduction of these ions in this melt has been previously studied using polarographic (7), chronopotentiometric (8), and linear sweep methods (9, 10).

Experimental

LiCl-KCl eutectic (59:41 mole per cent (m/o) melting point, 352°C) was prepared from "Analar" grade KCl and reagent grade KCl, using a purification technique similar to that of Laitinen *et al.* (11). A known weight of eutectic mixture was heated to 200°C overnight in vacuum to remove excess water. This was followed by treatment for several hours with dry HCl gas (B.D.H. 99%) during which period the temperature was gradually increased to above the melting point of the eutectic. HCl was removed by evacuation and replaced by dry nitrogen. Following this dehydration procedure, metal ion impurities were next removed by pre-electrolysis under vacuum for 4 hr at 2.5V, using a stainless steel cathode and a carbon anode. During this time the residual current decreased to 0.1-0.2 mA cm^{-2} and this was assumed to be an acceptable level of reducible impurities. No other test was made for the absence of other impurities. Finally, the melt was filtered through a porosity 4 silica frit directly into a silica pot situated in the bottom of the cell assembly. The filtration unit was removed and the cell head, containing sockets for the reference, working and counter electrodes, Chromel-Alumel thermocouple, and nitrogen bubblers were attached.

A Pt/Pt^{2+} (0.01M) reference electrode was used in the studies of the nickel system, and was prepared by anodizing a Pt wire into a calibrated volume of melt contained in a small compartment separated from the bulk melt by a glass frit. For the silver deposition work, a Ag/Ag^+ (0.01M) reference electrode was employed and prepared in a similar manner. In both cases, a carbon rod counterelectrode was used, also contained in a separate compartment and joined to the bulk melt by a glass frit. Platinum electrodes, both in the form of thin wires and small spheres, were sealed into Pyrex glass after being first cleaned with HCl and annealed at white-red heat for 1 hr using a d-c voltage applied directly across a length of platinum wire.

Silver ions were introduced into the melt by a quantitative anodization of a Ag wire, and nickel was added as anhydrous $NiCl_2$ following the dehydration of $NiCl_2\ 6H_2O$ with dry HCl gas.

Potentiostatically controlled experiments were carried out using a potentiostat (Chemical Electronics, Type 70/2A) in conjunction with a waveform generator (Chemical Electronics, Type R.B.1). Cyclic voltammograms at slow sweep rates were recorded on a Y-T recorder (Bryans) and at high sweep rates on a storage oscilloscope (Tektronix, Type 564). Photographs of the transients were taken with a Polaroid camera (Tektronix, Type C 30). A simple constant current source for the chronopotentiometry measurements consisted of a high-voltage dry battery connected in series with decade resistors; chronopotentiograms were recorded on an oscilloscope (Tektronix, 545B), and photographed with a Thompson-Land polaroid camera.

For the study of the electrode impedance of the nickel system, a potentiostat and phase-sensitive detection system were employed (12, 13). Although the uncompensated resistance was very low (a convenient feature of molten-salt systems), a small amount of positive feedback was employed (12) to render negligible the in-phase component of the current at a potential sufficiently anodic to that of the monolayer formation peak. The a-c signal generator was an oscillator (Associated Instrument Manufacturers, A.I.M., Type P.F.O.) generally operating at 1000 Hz and which provided also the in-phase and quadrature reference channels for the phase-sensitive detector (A.I.M., Type P.S.D. 122) used. The potentiostat was constructed from Philbrick operational amplifiers, and its design will be described elsewhere (14). A block diagram of the measuring circuit is shown in Fig. 1. The potentiostat ensures that a current flows across the interface of magnitude sufficient to force the reference electrode potential to follow the applied a-c signal. We represent the interface as a parallel combination (Fig. 2a), since the potential is the controlled variable, and the current is the measurable quantity. If the current were controlled and the potential measured, then a series combination would be a more convenient representation of the interface. Since the instrument had originally been designed to be used with a dropping mercury electrode (14), the former configuration was employed. The P.S.D. output gives the components of the current both in-phase and in quadrature with the exciting potential. When the uncompensated resistance is zero, the current flowing across the interface is given by

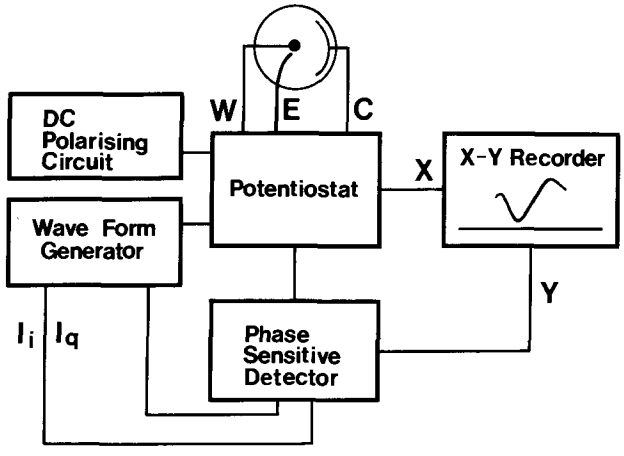

Fig. 1. Block diagram of the potentiostatic-phase detection system used for the impedance measurements. W = working electrode; C = counterelectrode; E = reference electrode; I_i = in-phase reference channel; I_q = quadrature reference channel; X = potential; Y = P.S.D. output.

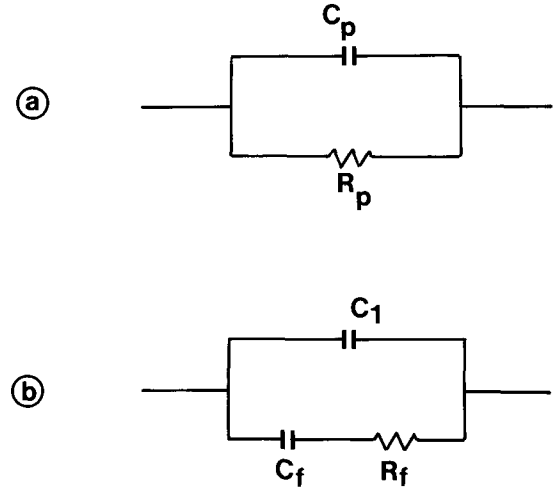

Fig. 2. (a) Parallel components of the interfacial impedance directly measurable by the potentiostatic-phase detection method. (b) Model of the interface for the hydrogen ionization equilibrium [6]; C_1 = double-layer capacitance; C_f = pseudo-capacity, and R_f = charge transfer resistance.

$$i = V\left(\frac{1}{R_p} + j\omega C_p\right) \quad [1]$$

where V is the applied potential, R_p and C_p are the equivalent parallel interfacial resistance and capacitance, and ω is the angular frequency. The P.S.D. outputs are thus

$$V_q = (GV)\,\omega\,C_p \quad [2]$$

and

$$V_i = (GV)\,\frac{1}{R_p} \quad [3]$$

where V_q and V_i are respectively the quadrature and in-phase potential outputs of the P.S.D., and G is the instrumental gain. For a given a-c signal amplitude, the product (GV) is a constant of the instrument, easily evaluated with a dummy cell made of precision components.

From [2] and [3], it is seen that it is a simple matter to record directly, either on an X-Y recorder or with a data logger, the parallel components of the impedance. This technique has been described here in some detail because of its patent applicability to molten-salt studies and because it involves standard items of equipment. In the present case, C_p and $1/R_p$ were directly recorded on an X-Y recorder at different frequencies.

Results and Discussion

Nickel

Chronopotentiometry.—Chronopotentiograms at several current densities were obtained for the reduction of Ni^{2+} at 400°C at three different concentrations: 6.3, 8.8, and 18.4 mM. A typical transient is shown in Fig. 3. A small transition is noted occurring at potentials ~0.4V anodic to the main reduction wave. The transition time corresponding to the main reduction process is plotted against the reciprocal current in Fig. 4, and the expected linear relationship predicted by the Sand equation (15) is observed, *i.e.*

$$\tau^{1/2} = \frac{z\pi^{1/2}\mathbf{F}AcD^{1/2}}{2i} \quad [4]$$

where z is the number of electrons involved in the reduction, $\mathbf{F}$ is the faraday, A the electrode area, c is the concentration, D the diffusion coefficient, and i the current. From the results presented in Fig. 4, the value of $\tau^{1/2}/Ac$ was found to be constant within 3%, and the calculated diffusions coefficient values are given in Table I.

Table I. Diffusion coefficient of nickel ion, $D_{Ni^{2+}}$, in LiCl-KCl eutectic at 400°C

30-50			2.4 (450°C)	6
2.5-15	4.14 (500°C)			7, 8

The transient observed before the main deposition wave, was studied in greater detail by using much lower current densities. Some typical galvanostatic curves are shown in Fig. 5. Stirring of the solution during the recording of the transient was found to have no effect on the transition time or on the shape of the chronopotentiogram for the predeposition step, indicating that this process is not diffusion controlled and that the definition of the transition time in the usual sense cannot be used. For this reason, the transition time was taken as the time for the potential to scan from −0.1 to −0.6V (*vs.* the Pt/Pt^{2+} electrode), in order to evaluate the monolayer charge. These potential limits were chosen so as to exclude both the oxidation of platinum and the deposition of nickel in bulk. These potential limits were also evident from the admittance measurements. Table II shows the calculated monolayer charges (Q_m) at different current densities for the three concentrations studied. The

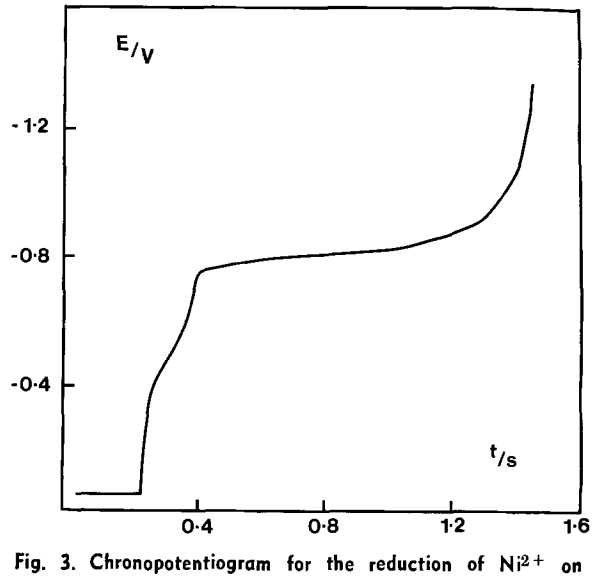

Fig. 3. Chronopotentiogram for the reduction of Ni^{2+} on Pt from a LiCl-KCl molten eutectic. Concentration = 6.3 mM; temperature = 400°C; current density = 3.94 × 10^{-3} A cm^{-2}.

100	690	690	646
120	650	650	568
140	630	620	505

Q_m values should be compared with that calculated on the assumption of a close packed layer in which one atom of deposited metal effectively covers a square on the electrode surface of side $2r_a$ (r_a = atomic radius) (16). This is given by

$$Q_m = \frac{ze}{(2r_a)^2} \qquad [5]$$

where e is the electronic charge. Taking $r_a = 1.15$Å for nickel (17), then $Q_m = 606$ μcoulombs cm^{-2}. This value compares reasonably well with the experimental quantity; Q_m results in Table II were calculated from the apparent electrode area of the platinum sphere used without taking surface roughness effects into consideration. Q_m is seen to be fairly independent of both the concentration and the current density which is in support of the formation of a close packed monolayer. There is, however, a definite decrease in Q_m with increasing values of the current density. Several effects might be responsible for this: (*i*) the presence of trace impurities in the melt (notice that the values of the current used here are very low); (*ii*) slowness of the attainment of equilibrium in the last stages of complete coverage, and (*iii*) a certain degree of diffusion of the deposit into the platinum substrate favored by the high temperature at which the experiment is performed. It is not possible from this work to distinguish between these possibilities.

Potential step method.—Potential step transients were recorded for the same three nickel ion concentrations as before. The current-time transient for cylindrical diffusion at short times of electrolysis is given by (15)

$$i = zFADc\left(\frac{1}{\pi^{1/2}D^{1/2}t^{1/2}} + \frac{1}{2r_o}\right) \qquad [6]$$

where r_o is the radius of the wire used. Linear plots of i *vs.* $t^{-1/2}$ were obtained (Fig. 6) having finite extrapolated intercepts at $t = \infty$ in agreement with the predictions of Eq. [6] for the times of electrolysis considered. The diffusion coefficients evaluated from the slopes of Fig. 6 are seen to be in good agreement with the chronopotentiometry results (Table I). However, in any experiment where a wire of finite length is used, the electrode geometry cannot be equated to a semi-infinite cylinder, and the diffusional problem should approach that of a sphere. In this limiting case though, the intercept is twice that of a semi-infinite cylinder and therefore, in any real situation, the intercept should lie somewhere between these two extremes. However, it should be noted that for the 18.35 mM solution a value of D of 1.25×10^{-5} cm^2 sec^{-1} can be calculated from the value of intercept assuming cylindrical diffusion which is in reasonable agreement with the evaluation from the slope.

The formation of a monolayer would be expected to result in a current-time growth transient showing a maximum when the potential is stepped to a value corresponding to monolayer formation. This type of transient is a common occurrence in the electrochemical formation and growth of films (18, 19) and the corresponding theory has been extensively discussed

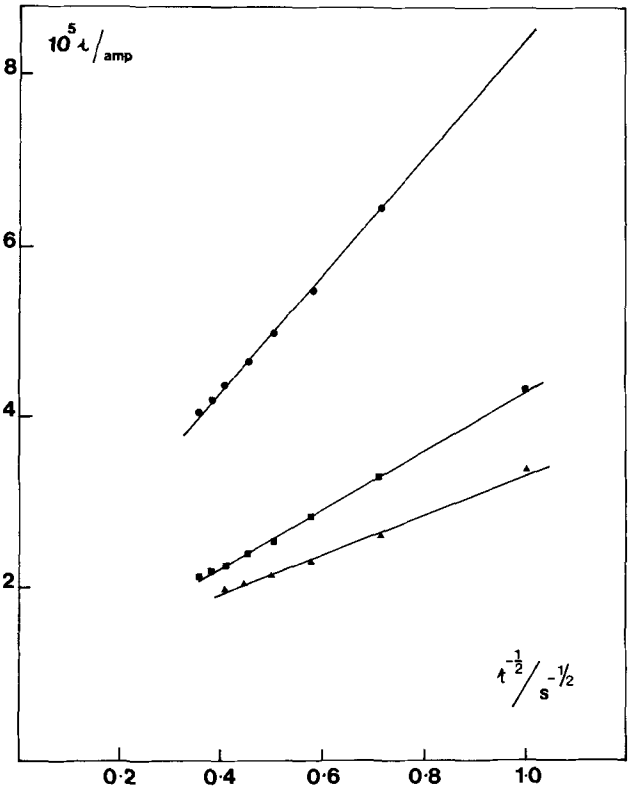

Fig. 6. Potentiostatic current *vs.* (time)$^{-1/2}$ plots for the deposition of Ni^{2+} from the LiCl-KCl eutectic at different concentrations: ▲, 6.3 mM; ■, 8.8 mM; ●, 18.4 mM $NiCl_2$.

(20). However, in the present case, at all the overpotentials studied in the monolayer region, falling transients were observed, even at very short times after pulsing the potential (<100 μsec). It might be concluded that a large number of nuclei are formed at short times, resulting in a limited two dimensional step line propagation growth of patches (20) but no direct evidence of this was observed. There was some indication of a slow attainment of the final equilibrium for times greater than 4 msec, a result in agreement with the lower values of Q_m obtained at high current densities in the galvanostatic study (cf. below, the results from cyclic voltammetry).

Cyclic voltammetry.—Cyclic voltammograms were recorded at different sweep rates between 0.04 and 200 V sec^{-1} for the same concentrations that were used in the chronopotentiometric work. Figures 7a, b, c, and d show typical voltammetric scans for this system at several sweep rates. From the integration of the current, it was found that all the charge deposited in the cathodic sweep was anodically stripped. The sharp anodic dissolution peak is similar to that observed for other systems (3). Here, diffusion control is unlikely to occur, and the current will increase until all the deposited metal is stripped (21). At fast sweep rates, a prepeak corresponding to monolayer formation is observed (see below), at ~0.5V anodic to the main peak, as previously reported (6).

The main cathodic peak potential (E_p) was found to be constant up to sweep rates of 4-8 V sec^{-1}, but an appreciable change was noted at higher sweep rates. It is unlikely that this is caused by the uncompensated resistance between working and reference electrodes. For example, the peak current for the 18.4 mM solution at a sweep rate of 322 V sec^{-1} was 1.76 mA, and the uncompensated resistance of the order of 1 ohm or less, thus introducing an instrumental uncertainty of at most 2 mV. The reason for the change in E_p at high values of v is unclear: little evidence has been found to indicate the existence of a significant nucleation overpotential, as is observed for other systems (22),

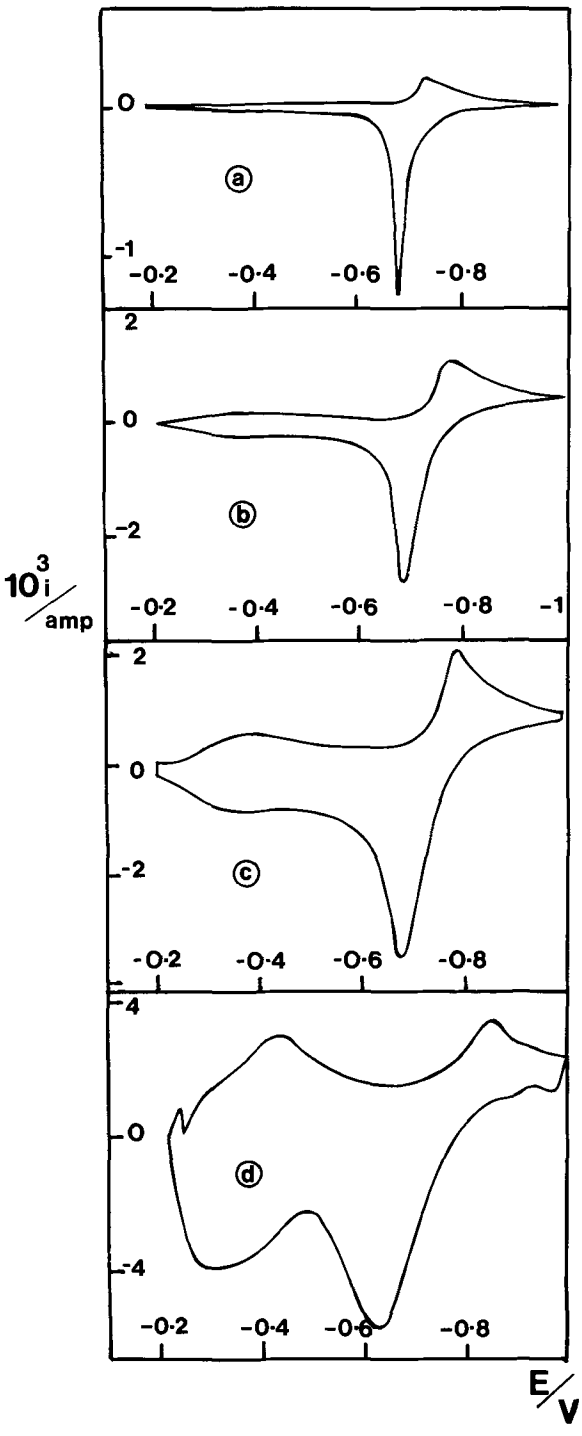

Fig. 7. Cyclic voltammograms of $NiCl_2$ in LiCl-KCl eutectic at 400°C. Concentration = 18.4 mM; electrode area = 0.0105 cm^2. Potentials vs. a Pt/Pt^{2+} (0.01 M) reference electrode: sweep rates: (a) 0.16 V sec^{-1}; (b) 8 V sec^{-1}; (c) 32 V sec^{-1}; (d) 192 V sec^{-1}.

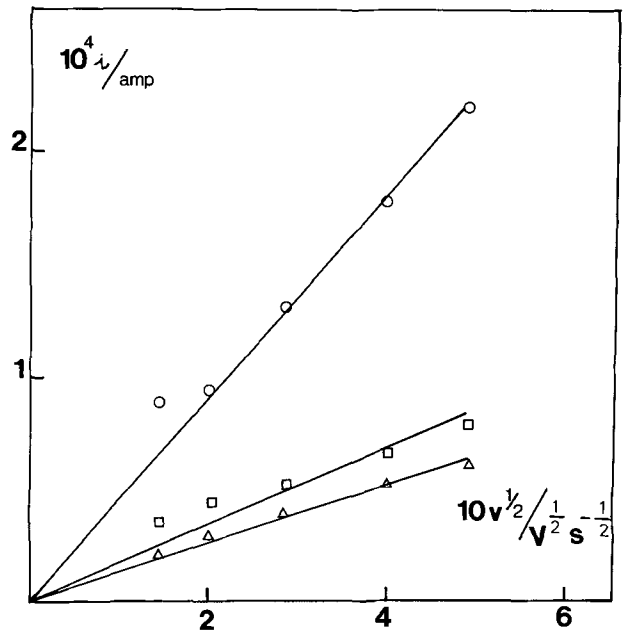

Fig. 8. Cyclic voltammetric peak currents (i_p) vs. (sweep rate)$^{1/2}$ for the reduction of Ni^{2+} on Pt in LiCl-KCl eutectic at 400°C at different concentrations: △, 6.3 mM; □, 8.8 mM; and ○, 18.4 mM $NiCl_2$. Electrode area = 0.0105 cm^2.

although in the galvanostatic transients a very small crystallization overpotential can be seen after the monolayer formation transition time (Fig. 3). Also, no growth region at overpotentials slightly cathodic to the Ni deposition potential was observed. A probable reason for this discrepancy could be the nonuniformity of the deposit.

As predicted by the theory for the reversible deposition of a solid metal (23), the peak current was found to be a linear function of the sweep rate, as shown in Fig. 8. The peak current is given by (23)

$$i_p = \frac{0.610\, z^{3/2} F^{3/2} A\, c\, D^{1/2} v^{1/2}}{R^{1/2} T^{1/2}} \qquad [7]$$

where i_p is the peak current and v the sweep rate. The values of the diffusion coefficients calculated from the slopes in Fig. 8 and Eq. [7], are given in Table I, and are in good agreement with those obtained by the other techniques. A difficulty in this analysis is in the correct subtraction of the capacitance current which can be large; this is particularly important for the high sweep rate scans, which limited the range of values of v that could be used in this analysis.

Figure 9 shows the monolayer region in greater detail. There are two points to notice here: (*i*) the peak current is a linear function of the sweep rate (Fig. 10), as would correspond to a pure capacitative current, and (*ii*) the peak potential is a function of the sweep rate. This would be unexpected if the equivalent circuit corresponding to a monolayer formation could be regarded as an additional pure capacitance in parallel with the double layer. This is considered to be the case in the adsorption of some organic compounds on mercury (15) but it is clearly not true when the adsorption process involves the simultaneous transfer of charge.

The charge deposited between −0.2 and −0.6V obtained by integration of the voltammograms was found

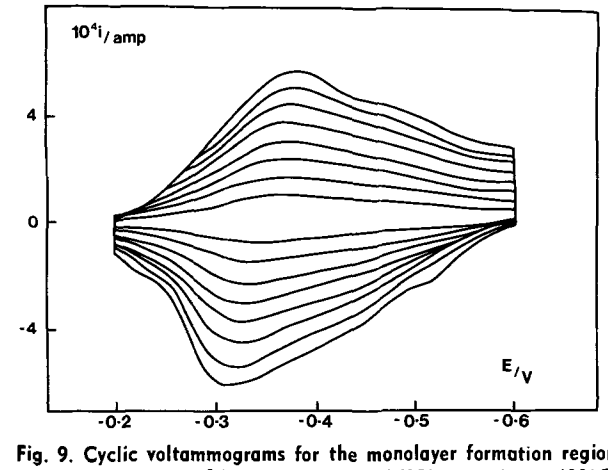

Fig. 9. Cyclic voltammograms for the monolayer formation region in the reduction of Ni^{2+} on Pt in a LiCl-KCl eutectic at 400°C. Sweep rates (from top to bottom) = 8; 16; 24; 32; 40; 48; 56; and 64 V sec^{-1}. Electrode area = 0.0105 cm^2.

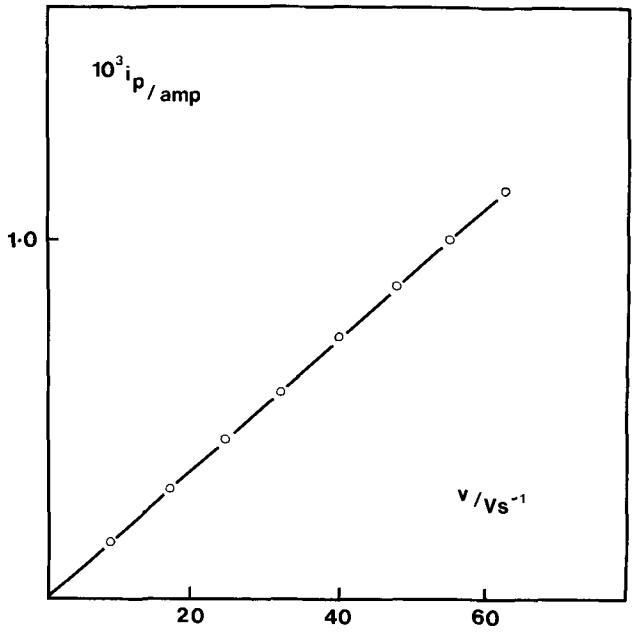

Fig. 10. Peak current as a function of sweep rate for the monolayer formation region in the Ni^{2+} reduction. Electrode area = 0.0105 cm^2.

to be lower than that obtained from chronopotentiometry and some sweep rate dependence of Q_m was noted. Values obtained ranged from 480 to 420 μcoulombs cm^{-2} for sweep rates from 5 to 64 V sec^{-1}. The reason for this difference is not altogether clear, but it should be noted that the cyclic voltammetry results refer to much faster transients than those recorded in the chronopotentiometry experiments, and some of the effects earlier discussed might be responsible for this.

Electrode impedance.—A close correlation can be established between the present case and the hydrogen ionization equilibrium since both involve the same kind of elementary process. In this context, if the equivalent circuit for the hydrogen ionization equilibrium is considered (24) (Fig. 2b), it is easy to see that E_p should now depend on sweep rate [see also Ref. (25)]. Figure 11 shows the parallel components of the interfacial impedance measured at 1000 Hz. The C_p values were found to have a considerable scatter with frequency which was later traced to defects in the phase-shifting system. The in-phase measurements leading to R_p were not affected and it is possible to compare $1/R_p$ with the same quantity for the hydrogen ionization equilibrium calculated from data in the literature (26) (cf. Fig. 12). At infinite frequency $1/R_p$ at the potential of the peak (−0.4V) extrapolates to a value of ~4 ohm^{-1} cm^2 leading to a value of the exchange current of 0.2-0.3 A cm^{-2}. It is an interesting coincidence that the value of the charge transfer resistance is of comparable magnitude in both cases (Fig. 12), especially when it is considered that they correspond to completely different temperatures, solvents, and systems. The results from this work while of only semi-quantitative significance nevertheless show the usefulness of data-acquisition phase-detection techniques. It should be pointed out also, that the difference between the shapes of the voltammetric waves and the admittance results, is due to the different equivalent circuits to which these two methods refer; the latter measures the components of the impedance of the interface taken as a parallel combination, whereas the former measures the over-all electrical response of the actual interface (Fig. 2b, when the solution resistance can be neglected) to a voltage range. The relationship between the two will not be discussed here.

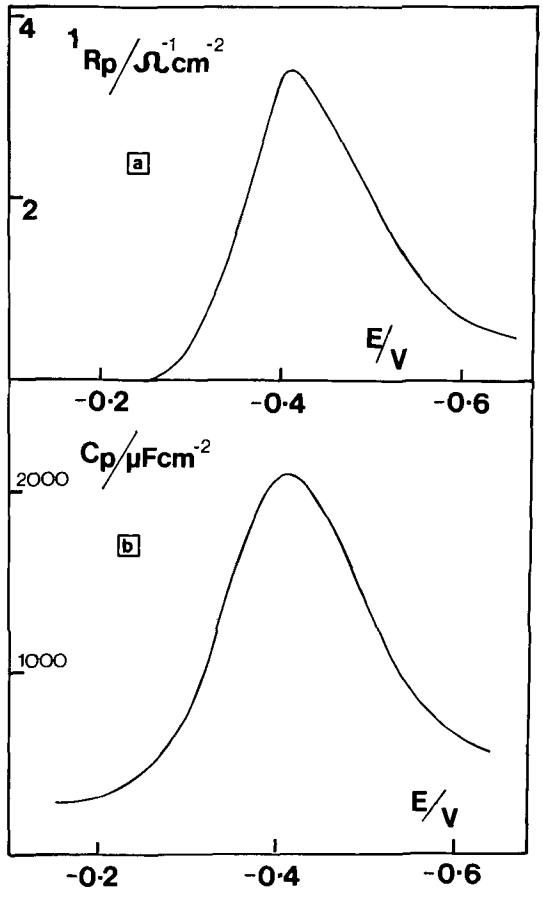

Fig. 11. Parallel components of the electrode impedance for the monolayer formation region for the reduction of Ni^{2+} at 400°C. Silver

A voltammetric study was also made of the reduction of Ag^+ in the LiCl-KCl eutectic at 400°C. Figure 13a shows a typical transient at slow sweep rates and the presence of a small prepeak is again observed but at a potential less anodic, *i.e.*, ~100 mV to the peak potential corresponding to bulk deposition of Ag^+, than in the case of nickel. At higher sweep rates (Fig. 13b) the close proximity of the prepeak to the main peak is seen to distort the shape of the latter and a quantitative analysis of peak currents at higher sweep

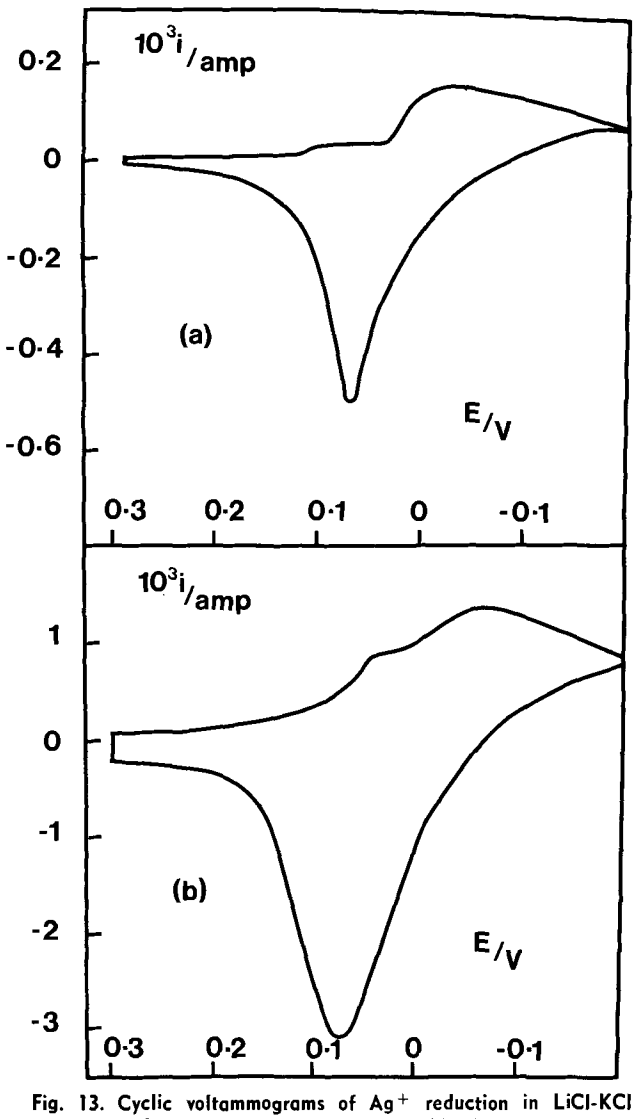

Fig. 13. Cyclic voltammograms of Ag^+ reduction in LiCl-KCl eutectic at 400°C. Concentration = 12.8 mM. Electrode area = 0.0252 cm^2. Potentials *vs.* Ag/Ag^+ (0.01M) reference electrode. (a) Sweep rate = 0.12 V sec^{-1}; (b) sweep rate = 12.0 V sec^{-1}.

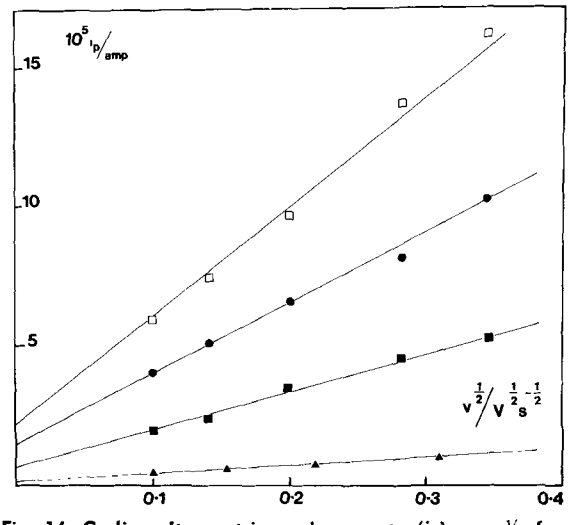

Fig. 14. Cyclic voltammetric peak currents (i_p) *vs.* $v^{1/2}$ for the reduction of Ag^+ on Pt in LiCl-KCl eutectic at 400°C at different concentrations: ▲, 1.06 mM; ■, 4.25 mM; ●, 8.50 mM; □, 12.8 mM. Electrode area = 0.0252 cm^2.

rates is therefore made difficult. Consequently Fig. 14 shows a plot of $i_p v^{1/2}$ only for sweep rates in the range 0.01-0.35 V sec^{-1} where a linear relationship is observed. The intercept on the i_p axis at $v = 0$ is not properly understood but is again probably associated with the prepeak. At these sweep rates the peak potential was found to be independent of sweep rate.

Table III. Diffusion coefficient of silver ion, D_{Ag^+}, in LiCl-KCl eutectic at 400°C

c_{Ag^+}/mM	$10^5 D_{Ag^+}/cm^2\ s^{-1}$ Cyclic voltammetry	Potential step	Chronopotentiometry	Reference
1.06	2.37			
4.25	2.69	3.19	(5.08)	This work
8.50	2.42	2.96	(5.11)	This work
12.76	2.51	3.53	(5.19)	This work
Mean	2.50 ± 0.10	3.23 ± 0.20	(5.13 ± 0.04)	This work
2-50			2.6 (450°C)	27
30-50			3.3 (450°C)	6
—			4.6 (480°C)	8

From the gradients of the i_p *vs.* $v^{1/2}$ plots the diffusion coefficient of Ag^+ was calculated from Eq. [7] at each concentration and is presented in Table III. Potential step current-time transients were recorded from potentials in the region of the prepeak to those cathodic to the main peak. In the potential region of silver predeposition, no growth characteristics corresponding to monolayer formation were observed indicating an instantaneous nucleation process at all available sites on the surface. At potentials cathodic to the bulk deposition step, normal diffusion-controlled transients were obtained giving linear i *vs.* $t^{-1/2}$ plots from which the diffusion coefficient was again calculated using Eq. [6] (Table III).

Chronopotentiometric transients did not exhibit a pretransition since the two steps were insufficiently separated, and hence it was not possible to calculate the charge required for the predeposition step. For this reason also an impedance analysis could not be performed. Diffusion coefficients were calculated from the gradients of linear plots of $\tau^{1/2}$ *vs.* i^{-1} using Eq. [4] and are presented in Table III for three concentrations. Although the values of D_{Ag^+} obtained by each technique at different concentrations are self consistent, Table III shows some discrepancies between the different techniques. While the value of D_{Ag^+} obtained from cyclic voltammetry and the potential step method are in reasonable agreement with other reported values, the chronopotentiometric diffusion coefficient is rather higher. Although it is not possible to quantify the effect of the predeposition the most reasonable explanation in this case, in view of the self consistency of the chronopotentiometric data, is an error in the measurement of effective electrode area. This was also indicated by a separate experiment carried out at 470°C when a value for D_{Ag^+} of 3.87×10^{-5} cm^2 sec^{-1} was obtained. Assuming an approximate value of 4 kcal $mole^{-1}$ for the activation energy of the diffusion process this leads to a value of 3.0×10^{-5} cm^2 sec^{-1} for D_{Ag^+} at 400°C which agrees more closely with the values reported in Table II.

Capacitance Measurements on Lithiated Nickel Oxide Electrodes

Dennis M. Tench*,[1] and Ernest Yeager*

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

Differential capacitance measurements have been used to study mosaic lithiated nickel oxide electrodes and to obtain information concerning the potential distribution between the space charge region within the semiconductor and the Helmholtz layer in the electrolyte. Plots of $1/C^2$ *vs.* E have been found to exhibit linear behavior over substantial ranges of potentials in accord with the Mott-Schottky treatment. The slopes are somewhat higher than expected from the Li content although they approach the Mott-Schottky values for electrodes prepared with shorter Li doping times. At potentials anodic to 1.0V-0.059(pH)V re SHE the change in electrode potential appears principally across the Helmholtz plane.

The understanding of the electrochemical properties of a semiconductor requires a knowledge of the potential distribution across the interface and the space charge characteristics within the semiconductor. This paper involves the use of capacitance measurements to gain such information for lithiated nickel oxide electrodes.

Nickel oxide is a semiconductor of the mixed valency type usually with p-type conduction occurring by electron transfer between Ni^{+2} and Ni^{+3} states (1). Introduction of univalent cations such as lithium into the lattice at cation sites results in the formation of Ni^{+3} states in a 1:1 ratio to maintain charge neutrality. In a recent review article, Adler (2) has summarized the existing theoretical models for conduction in NiO and has examined their applicability in terms of the available experimental data. Adler concludes that the conduction process probably involves a band structure. The dependence of the Hall mobility on temperature, however, is still in doubt and at the present time the exact nature of this band structure cannot be unambiguously ascertained.

The intrinsic voltammetric behavior of mosaic NiO(Li) electrodes in aqueous solutions has been investigated by Rouse and Weininger (3), Yohe *et al.* (4, 5), and also in this work. This electrode exhibits two voltammetry peaks in both acidic and basic solutions when no easily oxidizable or reducible species are present. These peaks are of considerable importance to the interpretation of the capacitance measurements. In 1.0*N* H_2SO_4 (see Fig. 1), one peak occurs at 0.95V re SHE (peak I) and the other at 1.4V (peak II). Both have a pH dependence of −60 mV/decade over the pH range 0-14 (5). At slow sweep rates (4 V/min) these peaks have been found to be reversible (*i.e.*, anodic and cathodic peak potentials coincide). Even at sweep rates up to 1.0 V/sec, the peak separation is still less than 50 mV (6).

Yohe *et al.* (4) have compared the voltammetry results with the thermodynamic data compiled by Pourbaix (7) and concluded that peaks I and II probably correspond to the oxidation of Ni^{+2} to Ni^{+3} and Ni^{+3} to Ni^{+4}, respectively, coupled with the removal of protons from adjacent oxygen ions. These reactions appear to occur only at the electrode surface since the total charge under both peaks corresponds to less than a monolayer (65%) of the charge for the (100) plane, assuming one electron per Ni^{2+} ion and an idealized (100) surface orientation with no surface roughness. The difficulty of converting all surface Ni^{2+}

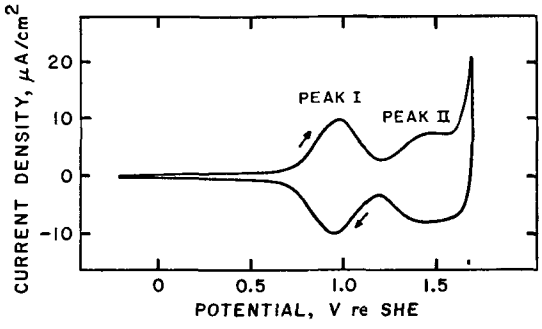

Fig. 1. Linear sweep voltammetry curve at 4.0 V/min for mosaic NiO(0.36 cation % Li) in He-saturated 1.0*N* H_2SO_4 at 25°C. Electrode area: 0.128 cm².

ions to a higher valency state is not surprising since complete conversion would probably involve very large surface excess charge.

Both Rouse and Weininger (3) and Yohe *et al.* (4, 5) have reported capacitance data for NiO(Li) electrodes in acid sulfate solutions at potentials anodic to the reference reversible hydrogen electrode (RHE). The capacitance passes through a maximum at a potential near that of voltammetry peak I and decreases with increasing frequency in the audio range. This capacitance maximum also was observed in the present work and is presumably related to the faradaic process occurring in this potential region. Neither of the aforementioned authors extended their capacitance measurements to more cathodic potential. Rouse and Weininger (3) observed an appreciable cathodic faradaic current near the reversible hydrogen potential and, therefore, did not extend their capacitance measurements cathodic to this potential. In the work of Yohe *et al.* (4, 5) and also the present study, however, the NiO(Li) electrode was found to remain ideally polarizable even at very cathodic values (*e.g.*, in 1.0*N* H_2SO_4 out to −0.5V re SHE). The hydrogen reduction current observed by Rouse and Weininger was probably due to impurities on or in the electrode, which provided adsorption sites for hydrogen atoms or possibly disturbed the semiconductor space charge layer. These workers used platinum to line the crucibles employed in the doping process (8) at temperatures 1500°-1600°C and it is probable that this procedure resulted in some platinum contamination of the NiO(Li).

Experimental

Electrode fabrication.—Mosaic NiO crystals were prepared by the method of Cech and Alessandrini (9), *i.e.*, hydrolysis of $NiBr_2$ at elevated temperatures with the epitaxial growth of NiO on a (100) facet of single-crystal MgO. Details have been given elsewhere (4, 10). After stripping by dissolving the MgO in 20% H_2SO_4 at 95°C, the NiO was doped by diffusion of lithium at high temperatures (~1500°C) in sealed alumina crucibles containing lithiated NiO powder, using a furnace with alumina walls. The mosaic crystals used for electrodes were rectangular with an area of about 0.1 cm^2 and thickness of 80-150μ.

Electrical contact was made to the rear side of the NiO(Li) electrode in the following way. A thin layer of silver (500-100Å) was evaporated *in vacuo* (<0.5μ Hg) onto the backside of the mosaic crystal at room temperature. The Ag was diffused into the surface by thermal treatment at 960°C in a helium atmosphere. This side of the crystal was then painted with Ag-epoxy resin and an Ag-coated copper wire was attached.

Evidence exists that this procedure yields an ohmic contact. The ferri-ferrocyanide couple was found to exhibit linear plots of ln $[i/(i_d - i)]$ *vs.* E over the anodic branch with the slope and intercept independent of rotation rate using the rotating disk method (i_d = diffusion limiting current density). This constancy of slope and intercept is only possible if there are no appreciable voltage drops within the semiconductor or the electronic contact to the rear surface. Such was not true in the earlier work in the authors' laboratory (5).

The mosaic crystals were molded into Kel-F cylinders so that the electrode surface was flush with the end of the cylinder (6). The lithiated NiO electrodes were then usually cleaned by a dissolution treatment at 0.95V re SHE in helium saturated 1.0*N* H_2SO_4 at 90°C for 30 min. This treatment in most instances had no effect on the intrinsic voltammetry curves in acid solution but for some electrodes it improved the reproducibility of the voltammetry curves.

The chemical analysis of the NiO for Li was carried out by flame spectrophotometry on a 10 mg sample of mosaic NiO(Li) dissolved in azeotropic HCl. The flame spectrophotometric measurements had a relative precision of ±10% and were performed by Union Carbide Corporation (Parma Technical Center, Parma. Ohio).

Electrolytes.—All electrolytes were prepared from doubly recrystallized salts, triply distilled water, and redistilled acid. Before use, each solution was treated overnight with cocoanut charcoal (Barnebey-Cheney) which had been purified with azeotropic HCl in a Soxhlet extractor for at least four weeks. All electrolytes were saturated with helium which was passed through hot copper turnings to remove O_2 and traps containing Linde molecular sieves (3A and 13X) at liquid N_2 temperatures to remove other contaminants.

Electrochemical cell.—The main compartment of the cell (Fig. 2) contained the NiO(Li) working electrode and a mercury pool counterelectrode (12 cm^2 area) in contact with 40-50 ml of electrolyte in this compartment. Separate compartments for the reference electrode and Pt auxiliary counterelectrode were connected to the main compartment through sintered glass plugs. Triply distilled mercury (Bethlehem Apparatus, Inc., Hellertown, Pennsylvania) was used for the internal counterelectrode. A helium atmosphere was maintained inside the cell by bubbling this gas through the solution.

The impedence was measured between the NiO(Li) electrode and the Hg pool counterelectrode, located about 2 cm apart. Since the area of the Hg pool was many times (100-200) larger than that of the NiO(Li) electrodes, its contribution to the total impedance was negligible. The Pt external counterelectrode was used to control the d-c potential of the NiO(Li) electrode.

Electronic equipment.—The a-c impedance between the NiO(Li) electrode and Hg pool counterelectrode was determined with an audio frequency Wheatstone bridge arrangement (6). The balance point was detected by means of a Tektronix Type 543 oscilloscope with a Type 1A7 pre-amp unit. At the null point, the a-c signal across the working and counter (internal) electrodes was always less than 5 mV and usually less than 2 mV. Measurements of the potential difference between the working and reference electrodes were made with a Hewlett-Packard 419A voltmeter.

For some of the impedance measurements the Hg pool counterelectrode was biased to cathodic potentials (using the external counterelectrode) with a Wenking Model 61R potentiostat to eliminate the possibility of anodic dissolution of the Hg counterelectrode under some circumstances. The same results were obtained, however, regardless of whether the Hg pool was biased cathodically or not. Therefore, since potentiostating of the Hg counterelectrode increased the noise level,

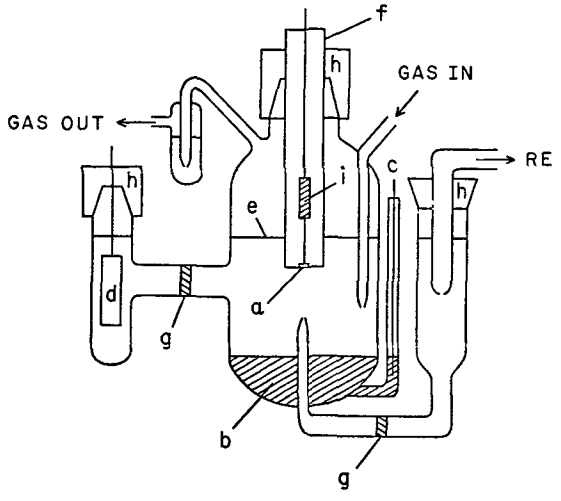

Fig. 2. Pyrex a-c impedance cell. a, NiO(Li) working electrode; b, Hg pool internal counterelectrode; c, Pt wire; d, Pt foil external counterelectrode; e, electrolyte level; f, Teflon enclosed brass tube with concentric Cu wire; g, sintered glass plugs; h, Teflon plugs in standard taper joints; i, spring-cap electrical contact.

it was not used for all of the measurements. Those in 1.0*N* H_2SO_4 were obtained with the Hg pool biased at −1.00V re SHE and the other measurements were made with the Hg pool unbiased. The addition of 10^{-3}M Hg_2SO_4 to the sulfate solutions (*p*H = 2.9) had no effect on the impedance of a NiO(0.21 cation % Li) electrode over the accessible potential range.

Reference electrodes.—In the acidic solutions the Hg/Hg_2SO_4 electrode was used with the same solution as the supporting electrolyte in the cell, whereas a saturated calomel electrode was used in the neutral solution. All potentials are reported relative to the standard hydrogen electrode (SHE).

Experimental Results

The series capacitance at 1 and 20 kHz for a mosaic NiO(0.48 cation % Li) electrode is plotted as a function of electrode potential in Fig. 3 for sulfate solutions of varying pH values. The same trends also were observed at 2 kHz but these curves are not shown because the overlap of points would cause serious complications in the graph. The data in Fig. 3 extend to much more cathodic potentials than those reported heretofore (3-5) for this system. In agreement with the earlier work, the capacitance-potential curves exhibit a peak which is less pronounced at the higher frequency. The frequency dispersion in the present work is less than that observed by earlier workers, however, perhaps because of the nonohmic electrical contact to the NiO(Li) in the earlier work.

The inverse square of the capacitance at various frequencies is plotted *vs.* electrode potential in Fig. 4 for an NiO(Li) electrode in 1.0*N* H_2SO_4. At all frequencies, a straight line is obtained from −0.5 to +0.3V re SHE, and at more anodic potentials the plots deviate from linearity. The slope increases with frequency with relatively little difference between the results at 1 and 2 kHz. Similar behavior has been found also in potassium sulfate solutions of *p*H 2.9 and 6.5 (see Fig. 5 and 6). The intercept with the potential axis does not change with frequency for this NiO(Li) electrode with 0.48 cation % Li but with electrodes containing less lithium, the intercept as well as the slope are frequency dependent (see Fig. 7 and 8). The slope is essentially independent of *p*H in contrast to the earlier findings of Rouse and Weininger (3). The intercept shifts approximately 0.1 V/*p*H.

The lithium concentration dependence of the $1/C^2$ vs. *E* plots is shown in Fig. 9 for 1 kHz. Lower lithium concentrations are not represented because the large frequency dispersion at lower concentrations interferes with such a comparison. Both the slopes and the intercepts are dependent on the lithium concentration.

The addition of 10^{-3}M $ZnSO_4$ or KI to a solution of 0.495M K_2SO_4 + 0.005M H_2SO_4 had no detectable

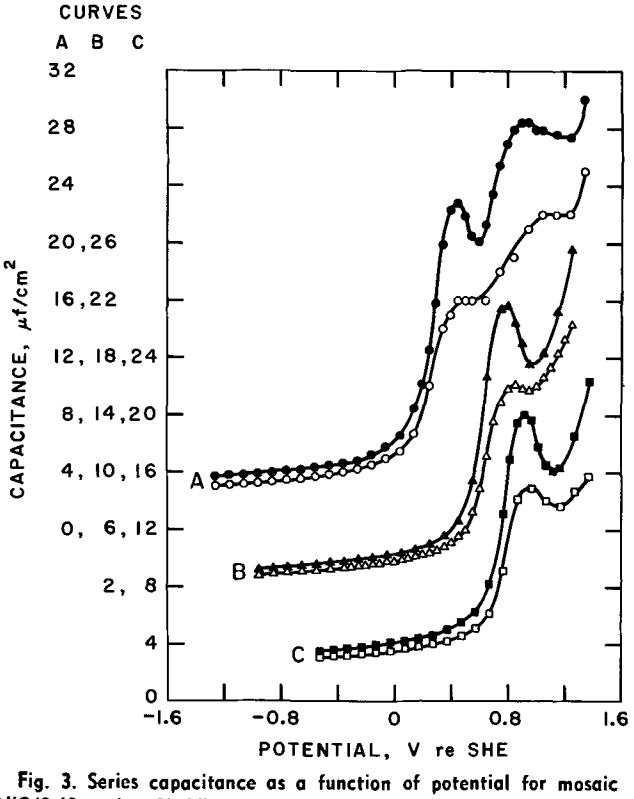

Fig. 3. Series capacitance as a function of potential for mosaic NiO(0.48 cation % Li) in He-saturated sulfate solutions at 25°C. Electrode area: 0.0416 cm². Solid symbols designate the values at 1 kHz and open symbols those at 20 kHz. Circles represent data in 0.50M K_2SO_4 (scale A), triangles in 0.495M K_2SO_4 + 0.005M H_2SO_4 (*p*H = 2.9, scale B), and squares in 1.0*N* H_2SO_4 (scale C).

effect on the capacitance of a NiO(0.21 cation % Li) electrode in this system over the potential range from 0.95 to 1.25V re SHE. This implies that Zn^{+2} and I^- ions are not strongly specifically adsorbed on the NiO(Li) surface, at least at potentials cathodic to peak I.

The total series resistance was found to decrease with increasing frequency and also slowly with increasing anodic potentials. These trends are illustrated in Table I for a NiO(0.48 cation % Li) electrode in 1.0*N* H_2SO_4. The same general behavior was observed for samples containing less Li except the resistance at a given potential was higher; *e.g.*, 31 ohm-cm^2 at 1 kHz for NiO(0.13 cation % Li) in 1.0*N* H_2SO_4.

On the basis of the cell geometry and the resistivity of the electrolyte, the resistance value of 1.3 ohm-cm^2 listed in Table I for 1.27V and 20 kHz appears to correspond to only the electrolyte resistance. Ohmic drop within the bulk of the electrode phase should

Table I. Series resistance for NiO(0.48 cation % Li) in 1.0N H_2SO_4 as a function of frequency at various potentials re SHE

E (V)	Resistance (ohm-cm²) 1 kHz	2 kHz	20 kHz
−0.53	4.3	2.9	1.5
0.07	4.0	2.8	1.4
0.67	3.6	2.6	1.4
1.27	2.3	1.8	1.3

be negligible for such a high Li concentration and thin electrodes (~100μ). If this series resistance is subtracted from the other resistances listed in Table I, the resistance values so obtained should be associated with the electrode-electrolyte interface provided the metal-oxide rear interface makes no appreciable ohmic contribution to the measurements. The diffuse metal junction used to make electronic contact to the NiO(Li) should eliminate such a contribution. The values of tan δ (δ = phase angle) have been calculated from the capacitance data and the resistance values in Table I after subtracting the resistance of the electrolyte. In the linear range of Fig. 5, tan δ is $8 \pm 1 \times 10^{-2}$ at frequencies of 1 and 2 kHz. The resistance data at 20 kHz are not sufficiently accurate to permit the evaluation of tan δ after subtraction of the electrolyte resistance from the values in Table I.

Rouse and Weininger (3) also observed a decrease of the series resistance with increasing frequency for essentially the same lithium concentrations and potentials, but the resistance values were approximately three times higher than those reported here after correction for electrolyte resistance. The phase factor tan δ also was not constant in their work. The slopes of their plots of $1/C^2$ *vs.* E differed by several fold from those found in the present work and were strongly pH dependent. These differences may be due to nonuniform distribution of lithium, nonohmic electrical contact to the NiO(Li), and/or platinum contamination in the work of Rouse and Weininger. Also, it should be noticed that Rouse and Weininger obtained data only at relatively anodic potentials where, in the present work, large deviations from the Mott-Schottky approximation were found to occur.

Discussion of Results

A simplified equivalent circuit for the semiconductor-electrolyte interface is shown in Fig. 10, where R_B and R_o represent the bulk resistance for the semiconductor and solution, respectively; R_{sc} is the space charge resistance; C_{sc}, C_H, and C_{dl} are the capacitances of the space charge region, Helmholtz layer, and diffuse part of the ionic double layer, respectively; and C_{ss} and R_{ss} are the capacitance and resistance due to surface states. In the present work C_H and C_{dl} are large compared to C_{sc} in the linear $1/C^2$ *vs.* E potential range, and hence do not contribute appreciably to the observed capacitance over this range.

The linear $1/C^2$ *vs.* E behavior observed at more cathodic potentials suggests that an exhaustive depletion layer is involved with the observed differential capacitance corresponding to C_{sc}. In the exhaustive depletion range, C_{sc} is expected to follow the Mott-Schottky equation

$$\frac{1}{C_{sc}^2} = \frac{8\pi}{\epsilon_{sc} e N}\left(E - E_{fb} - \frac{1}{f}\right) \qquad [1]$$

where E is the electrode potential *vs.* a suitable reference, E_{fb} is the flatband potential, ϵ_{sc} is the dielectric constant in the space charge region, N is the concentration of charge carriers, and $f = \mathbf{F}/RT$ where $\mathbf{F}$ is the Faraday constant. The existence of an exhaustive depletion layer is supported by the behavior of various electrochemical couples on NiO(Li) electrodes. Studies of a number of electrochemical processes on such electrodes (4, 6, 11) indicate that oxidation as well as reduction processes do not proceed at appreciable rates at potentials cathodic to voltammetry peak *I* by more than ~0.2V until the onset of H_2 evolution at 0.5V re SHE.

The deviation from linearity in the $1/C^2$ *vs.* E plots at more anodic potentials is probably caused principally by the faradaic capacitive component associated with voltammetry peak *I*.

Possible sources of frequency dispersion.—The frequency dependence of the capacitance data seriously complicates the interpretation of the data. Measurements over a much wider frequency range are needed to establish the nature of this frequency dependence. Possible sources of this frequency dispersion include the following: (*i*) nonuniform a-c distribution on the electrode due to edge effects, (*ii*) impedance contributions from the electrical contact to the rear of the NiO(Li) electrode, (*iii*) grain boundary effects associated with the mosaic nature of the NiO(Li), (*iv*) slow surface states, and (*v*) slow response of some of the charge carriers in the space charge region to the applied alternating potential.

Flat electrodes mounted flush in an insulator exhibit frequency dispersion at audio frequencies as a consequence of nonuniform a-c distribution on the electrode surface. Randin and Yeager (12) have examined such frequency dispersion on pyrolytic graphite electrodes of dimensions and capacitance per square centimeter comparable to those involved with the NiO(Li) electrodes represented in Fig. 4-6. For an electrolytic solution (0.9M NaF) of resistivity close to that involved in Fig. 6 the capacitance was found to decrease by 11% between 1 and 20 kHz because of nonuniform a-c distributions. The decrease in capacitance within the linear $1/C^2$ *vs.* E range in Fig. 6 is comparable. On the other hand, the frequency dispersion is much greater at lower Li concentrations corresponding to smaller capacitances. If only nonuniform current distribution were responsible for the frequency dispersion, it should become less as the capacitance decreases. Thus more than just nonuniform current distribution is involved.

The electrical contact to the rear of the NiO(Li) electrode is not a likely source of frequency dispersion since no appreciable impedance is expected with the diffuse metal junction used in the present work. The kinetic studies cited earlier provide some evidence to support this view for NiO(Li) electrodes with Li concentrations greater than 0.1 cation %. At lower Li concentrations, the contact is probably still ohmic but it is difficult to verify this from the kinetic studies because of appreciable ohmic drop within the bulk of the NiO(Li) electrode.

Grain boundaries and space charge effects associated with these boundries may lead to a complex distributive impedance for the bulk of the NiO(Li) electrodes. This source of frequency dispersion would be expected to become more pronounced at lower lithium concentrations because of the higher resistance component within the bulk of the semiconductor and the greater extent of the space charge regions within the individual grains or crystallites. At high lithium concentrations (>0.1 cation % Li), this source of frequency dispersion is probably not important since the

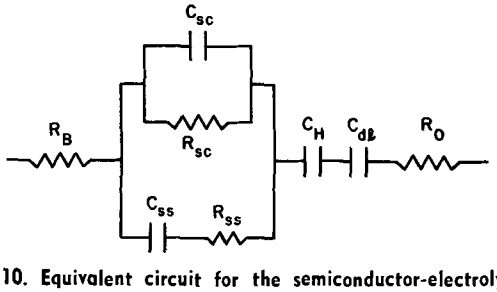

Fig. 10. Equivalent circuit for the semiconductor-electrolyte interface. (Symbols defined in text.)

total resistance loss within the bulk of the NiO(Li) is very low ($<10^{-1}$ ohm-cm^2).

Surface states are expected to contribute substantially to the capacitance over only a relatively limited potential range (*e.g.*, a few tenths of a volt). Further, such states do not contribute appreciably to the observed capacity over the potential range where a linear $1/C^2$ *vs.* E plot is obtained since otherwise such a linear relationship would not be observed. Thus slow surface states are probably not a major source of the frequency dispersion over the linear $1/C^2$ *vs.* E range.

Bosman and Crevecoeur (13) have shown that the activation energy for conduction in NiO(Li) is due primarily to the charge carrier dissociation process and not to the low mobility of the carriers. A slow ionization step can cause frequency dispersion but, in view of the small dissociation energy (0.3 eV), such frequency dispersion would be expected only at frequencies much higher than involved in the present work.

Protons probably penetrate from the solution into the NiO lattice at least a distance large compared to the very thin space charge region involved in the present study. The mobility of protons within the lattice would be much less than that of the Ni^{3+} p-carriers and the trapping energy for protons on oxide ions adjacent to Li^+ cations is probably greater than the dissociation energy of Li^+-Ni^{3+}. Consequently, protons within the lattice may be relatively slow in their response to the a-c field and may cause audio frequency dispersion.

Of these various factors, nonuniform a-c distribution and the slow response of protons in the space charge region of the NiO(Li) seem the most likely sources of the frequency dispersion. If this is correct, the measurements at the lower frequencies should be the more suitable for comparison of the $1/C^2$ *vs.* E slopes with the lithium concentrations. The current distribution should become more uniform at lower frequencies as the interface impedance rather than electrolyte resistance becomes controlling. Furthermore, the lithium concentration corresponds to the sum of the Ni^{3+} carrier plus proton concentrations and only at low frequencies will the full contribution of the protons to the capacitance be realized.

While it would have been desirable to have capacitance data below 1 kHz, this frequency is probably sufficiently low for at least a semiquantitative comparison of the slopes of the $1/C^2$ *vs.* E plots with the lithium concentration for the NiO electrodes containing more than 0.2 cation % Li. These electrodes have quite small frequency dispersion between 1 and 2 kHz.

Mott-Schottky slopes.—In Table II the carrier concentrations (expressed in cation per cent) determined from the Mott-Schottky slopes at 1 kHz are compared with the Li concentrations as determined by flame spectrophotometry. The values obtained from the capacitance data are smaller than those from chemical analysis in every case. Since surface roughness has not been taken into account, the difference may be even somewhat larger. Nonetheless, moderately good agreement is found in Table II for short lithium doping times (< 30 hr) and relatively thin electrodes (*e.g.*, runs 1 and 2). Weininger (8) has determined the doping profile of lithium in mosaic NiO(Li) crystals by flame spectrophotometric analysis of material sand-blasted from the crystal surface. He found that for long doping times (> 25 hr) the surface was less doped than the center of the crystal. It was assumed that this inversion was caused by a depletion of lithium inside the crucible with time, followed by loss of lithium from the mosaic crystal surface. In order to prevent loss of lithium through chemical attack of the alumina doping crucibles by Li_2O vapor, Weininger lined them with platinum metal. This practice was not employed in the present work because of the possibility of contamination of the NiO(Li) surface with platinum. It is probable, therefore, that the surface region of the NiO(Li) used for the present studies was less highly doped than the bulk. This explains why the value of the doping level obtained from the Mott-Schottky slope is smaller than the value determined by chemical analysis.

Table II. Comparison of values for cation % Li determined by a-c impedance in 1.0*N* H_2SO_4 and from flame spectrophotometric analysis for NiO(Li) crystals doped at 1500°C

Run No.	Doping time (hr)	Doping mixture cation % Li	Crystal thickness (μ)	Cation % Li	
				Impedance	Analysis
1	~12	1	80	0.25	0.29
2	30	5	125	0.48	0.55
3	31	10	145	0.30	0.43
4	41	20	90	0.36	0.49
5	41	5	100	0.13	0.29

Mott-Schottky intercept.—The intercept of the $1/C^2$ *vs.* E plot with the potential axis becomes more cathodic as the doping concentration of the electrode decreases (see Fig. 9 but not the plots in Fig. 8 which have a large frequency error). This intercept is expected to depend on the doping concentration when carrier recombination becomes important but to a much less extent than observed. Electrostatic interactions between the charge carriers and surface protons as well as some residual frequency dispersion offer possible explanations for the large dependence of the intercept on doping concentrations. At potentials cathodic to peak I (and to a less extent at anodic potentials), the NiO(Li) surface is covered with a layer of protons (associated with oxygen ions) which tend to repel charge carriers electrostatically in the vicinity of the surface. The thickness of the space charge in the semiconductor becomes smaller (for the same electrode charge) as the doping concentration becomes greater. This results in greater electrostatic repulsion of p-carriers by the adsorbed protons for higher doped samples. Thus it requires more anodic potentials to attain the flatband condition for samples with higher doping concentrations.

From the preceding considerations the intercept with the potential axis should become more anodic at lower *p*H values since the degree of surface protonation should increase. At the intercept, all of the potential drop should be across the Helmholtz plane and hence ideally the potential dependence should be 0.059 V/*p*H unit [see, *e.g.*, Ref. (3)]. The observed dependence from a comparison of Fig. 4-6 is ~0.10 V/*p*H unit.

The determination of the true "flatband" potential for NiO(Li) is complicated by the presence of surface states associated with voltammetry peak I. Extrapolation of $1/C^2$-E plots to potentials anodic to this peak is not valid since the potential distribution is changed by the formation of Ni^{+3} states at the surface. These surface states can compensate much of the charge in the Helmholtz plane as the potential is changed, thus making the effective thickness of the space charge layer smaller. The flatband potential, in this case, is more cathodic than predicted from the Mott-Schottky intercept and probably occurs in the vicinity of peak I.

Potential distribution across the interface.—If the effects of carrier recombination, surface states, and the ionic double layer are neglected, then the potential drop across the Helmholtz layer is given by (14)

$$\phi_s - \phi_2 = \pm \frac{\sqrt{2} d_H \epsilon_{sc}}{f \epsilon_H L_{sc}} [\exp f(\phi_B - \phi_s) - f(\phi_B - \phi_s) - 1]^{1/2} \quad [2]$$

where $\phi_s - \phi_2$ and $\phi_B - \phi_s$ represent the potential drops across the Helmholtz layer and semiconductor space charge layer, respectively, (see Fig. 11); d_H is

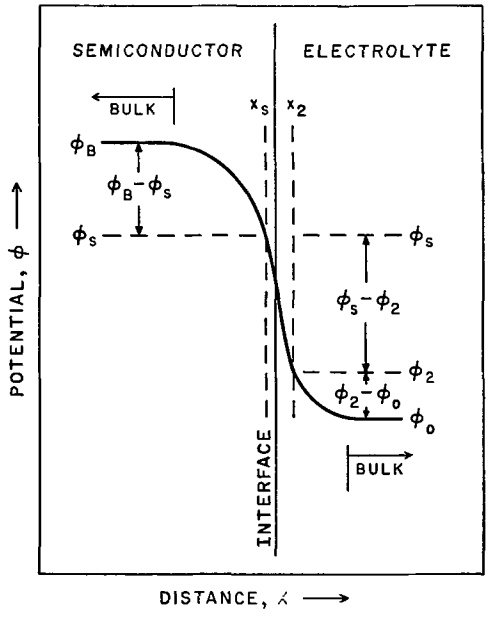

Fig. 11. Potential distribution at the semiconductor-electrolyte interface for a p-type semiconductor with a space charge depletion layer. The distance of closest approach of p-carriers to the surface is taken as the interface and is represented by x_s, whereas, the Helmholtz plane is represented by distance x_2. Inner potentials ϕ_B, ϕ_s, ϕ_2, and ϕ_0 are the values for the bulk of the semiconductor, distance of closest approach of p-carriers to the surface, Helmholtz plane, and bulk of the solution, respectively.

the thickness of the Helmholtz layer, ϵ_H and ϵ_{sc} are the dielectric constants in the Helmholtz layer and space charge region, respectively; and L_{sc} is the Debye length of the space charge region and is given by

$$L_{sc} = \left(\frac{\epsilon_{sc} kT}{4\pi N e^2} \right)^{1/2} \quad [3]$$

The carrier concentration in the NiO(Li) electrode used in the present work is very high (10^{19}-10^{20} carriers/cm^3). Under these circumstances Eq. [2] can only be considered semiquantitative at best. Nonetheless, it is still useful for establishing in what region most of the potential change between the electrode and solution phase should occcr. For a 0.40 cation % Li electrode ($N = 2.4 \times 10^{20}$ carrier/cm^3), the value of L_{sc} is calculated by Eq. [3] to be 2.6Å at 25°C if the dielectric constant in the space charge region is taken to be 12, the same as in the bulk of the semiconductor (15). The value of ϵ_H is assumed to be 6, reflecting the estimate of Bockris (16) for water between the Helmholtz plane and a metal electrode surface. The value of d_H has been taken as 3Å in the absence of specific adsorption. The potential drops in the space charge region and Helmholtz layer, calculated from Eq. [2], are plotted as a function of the rational electrode potential (relative to the flatband potential) in Fig. 12. At potentials anodic to the flatband potential (E_{fb}) most of the change in potential is manifested across the Helmholtz layer. Cathodic to E_{fb}, comparable potential drops occur in the space charge region and the Helmholtz layer with that in the space charge region larger at rational electrode potentials cathodic to about −0.5V.

In the absence of surface states or other mitigating effects, Fig. 12 indicates that only at extremely cathodic potentials (< −2.0V) will most of the potential change occur across the space charge region. Nonetheless, the linearity of the $1/C^2$ *vs.* E plots over a substantial range of potentials indicates that such does occur at much less cathodic potentials. This discrepancy may be caused by the fact that Eq. [2] does not take into account the protonation of the lattice $O^=$ ions at the interface. The $O^=$ ion is a very strong

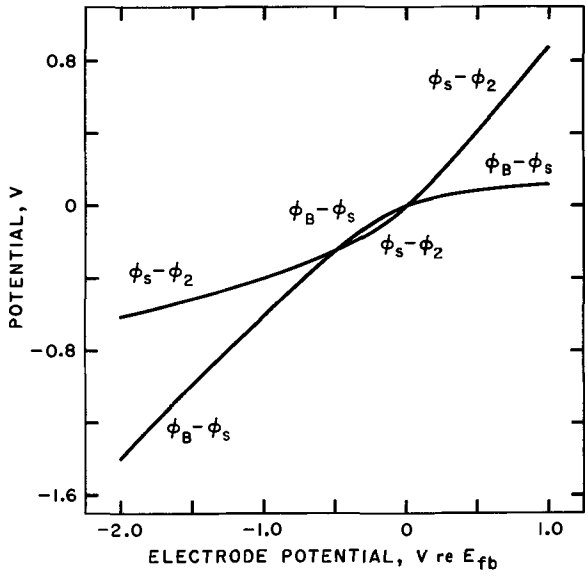

Fig. 12. Potential drops in the space charge region ($\phi_B - \phi_s$) and Helmholtz layer ($\phi_s - \phi_2$) vs. electrode potential (neglecting $\phi_2 - \phi_0$) according to Eq. [4] for NiO(0.40 cation % Li). L_{sc} = 2.6Å; $\epsilon_{sc} = 12$; $d_H = 3$Å; $\epsilon_H = 6$.

base and hence the surface $O^=$ ions of the lattice normally should be protonated. The abnormal surface charge density arising from this adsorption of protons should strongly repel the p carriers (Ni^{3+}) from the surface region and hence increase the fraction of the potential drop across the space charge region. Other specifically adsorbed cations would have a similar effect. Apparently this effect is sufficiently great that an exhaustive depletion layer situation is approached.

A Solid-State Reserve Battery

John H. Kennedy,* Fred Chen,* and Ronald C. Miles*

Department of Chemistry University of California, Santa Barbara, California 93106

ABSTRACT

A solid-state reserve battery concept has been demonstrated in which anode/electrolyte and cathode/electrolyte components are separated during storage and pressed together for activation. The concept was shown using the cell Ag/Ag_3SBr/$AuBr_x$ where $x = 2.4 \pm 0.1$. The open-circuit voltage of 0.84V was achieved at a pressure of about 1 psi. Pressures of about 25 psi were required to reach 96% of high-pressure performance during current drain. The cell could store about 10 W-hr/lb of electrical energy.

Until recently, the conventional approach to a long storage life battery has been the "reserve" type in which the battery is kept inactive during storage. The inactive state is normally accomplished by storing the electrolyte separately from the electrodes. With the advent of high current density solid-state batteries using electrolytes of $RbAg_4I_5$ (1), Ag_3SI (2), or $(CH_3)_4NI$:4 AgI (3), a new type of long storage life battery now exists since a solid-state battery can often be kept in its active state for a long period of time.

Our work has focused on still another possibility, a solid-state reserve battery. Many, otherwise acceptable, solid-state batteries cannot be stored for long periods of time because of low level electronic conduction through the electrolyte, either intrinsic or caused by impurities. Self-discharge can also occur by electrode material diffusing through the electrolyte reaching the other electrode and reacting chemically (4). Inactive storage of such batteries makes them feasible for application and could improve storage life of all solid-state batteries. The inactive state is accomplished by forming anode/electrolyte and cathode/electrolyte sections with the electrolyte layers separated during storage. Activation is accomplished (as shown in Fig. 1) by simply pressing the electrolyte layers together under a moderate pressure of a few lb/in.^{2}. This type of reserve battery may be activated and deactivated many times, unlike most conventional reserve batteries.

The silver/gold bromide electrochemical cell was used for demonstrating the reserve battery concept. Gold bromide was chosen since it met the requirements that a cathode material should: (*i*) be highly oxidized, so that the voltage of its reaction with silver will be reasonably high; (*ii*) be unreactive with the electrolyte; (*iii*) support reasonable current densities during battery discharge, and (*iv*) exhibit a low vapor pressure at room temperature. Silver was chosen as the anode since the current was carried by silver ions in the electrolyte.

The theoretical voltage of an Ag/$AuBr_3$ cell is calculated from the following couples using free energies of formation

$$3Ag \rightarrow 3Ag^+ + 3e^- \qquad \text{(anodic reaction)}$$

$$3Ag^+ + AuBr_3 + 3e^- \rightarrow Au + 3AgBr \qquad \text{(cathodic reaction)}$$

with Ag^+ migrating through the electrolyte to the cathode and reacting with Br^- to form AgBr. The over-all cell reaction is

$$3Ag + AuBr_3 \rightarrow Au + 3AgBr \qquad E = 0.91V \quad \text{[Ref. (5)]}$$

A possible reaction taking place simultaneously is

$$Ag + AuBr \rightarrow Au + AgBr \qquad E = 0.83V \quad \text{[Ref. (5)]}$$

The theoretical energy density of an Ag/$AuBr_3$ cell is 43.5 W-hr/lb. In place of $AuBr_3$, $KAuBr_4$ was considered as a cathode material. Its advantage would be a lower vapor pressure, but its theoretical energy density with a silver anode is only 33.8 W-hr/lb. Some of the cathode couples that have been used with silver electrolytes are listed in Table I with their voltages and energy densities.

Silver sulfide bromide was chosen as the solid electrolyte because of its higher decomposition potential than those of silver iodide complex salts (0.84V *vs.* 0.67V) (1, 2, 9).

Experimental

Gold bromide was prepared by treating gold powder, 99.99% (Wilkinson Company), with excess liquid bromine for 5 days at 60°C. After this period of time, excess unreacted bromine was removed by flowing dry nitrogen through the reaction vessel. Any residual bromine present was removed by evacuating ($<10\mu$ pressure) the reaction vessel for 5 days. The dark brown gold bromide crystals were then ground and stored over silica gel until used. The amount of bromine that reacted with gold was calculated from weight gained by the gold and by weight loss when a known amount of gold bromide was decomposed at 200°C for more than 12 hr. The average nonstoichiometric composition was found to be $AuBr_{2.4\pm0.1}$.

Gold bromide obtained by treating gold powder with liquid bromine at room temperature gave variable gold to bromine ratios ranging from 0.85 to 2.6. In addition to this variability, these samples lost bromine with ease when placed under vacuum. Only gold bromide prepared at elevated temperatures was stable under vacuum.

Silver sulfide bromide was prepared as previously reported (9). Silver powder was obtained from Engelhard Industries. Anhydrous gold tribromide and potassium tetrabromoaurate(III) were obtained from Research Organic/Inorganic Chemicals, Sun Valley, California. Graphite powder was treated with Durite-5143 (Borden Company) in order to make it pressable (10).

The anode/electrolyte and cathode/electrolyte pellets were prepared with a Perkin-Elmer evacuable KBr die (186-0025), 13 mm diameter. As an example of anode/electrolyte pellet preparation: 0.2g of silver and 0.2g of silver sulfide bromide were mixed and then pressed at 6000 psi. On top of the pellet, 0.2g of silver sulfide bromide was added and pressed at 6000 psi and finally a pressure of 60,000 psi was applied to the whole pellet.

An example of cathode/electrolyte pellet preparation is as follows: 0.2g of silver sulfide bromide was pressed at 6000 psi, followed by pressing 0.4g of a gold bromide, silver sulfide bromide, and graphite mixture at 6000 psi, and finally applying a pressure of 60,000 psi to the whole pellet. The gold bromide, silver sulfide bromide, and graphite mixture had an 8:8:1 weight ratio. The exact weight ratio compositions for the cathode mixture were arbitrarily chosen for laboratory convenience although based on other battery studies. The cathode and anode mixtures were mixed with a Crescent Dental Company "Wig-L-Bug" for about a minute before pressing.

To discharge the battery, the anode and cathode components were placed in a plastic jig with graphite current collectors. A representation of the cell is shown in Fig. 2. Test cells were usually 1.6 mm thick, weighed 1.2g, and contained about 120 C of charge based on one electron/bromine atom in the gold bromide. The energy density of a typical test cell with $AuBr_{2.4}$ as cathode material was determined to be 9.7 W-hr/lb based on the cathodic charge and the weight of the electrodes plus electrolyte. With $AuBr_3$ as the cathode material, the energy density of the test cells was determined to be 10.4 W-hr/lb. These energy density values are comparable to the energy densities of other solid-state batteries.

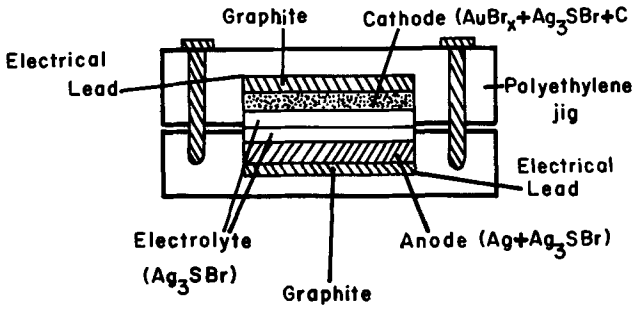

Fig. 2. Schematic diagram of a cell during discharge

X-ray powder diffraction patterns of gold bromide were taken with a Philips x-ray diffraction unit with CuK_α radiation. A Philips Type 52572 scintillation counter with chart recorder was used for x-ray diffractometer measurements.

An Associated Testing Laboratory SW-5101 environmental chamber was used for temperatures other than ambient. A General Radio Incorporated 1650 Impedance Bridge with an 0.5V rms and 1 kHz signal was used for resistance measurements, and General Radio Decade Resistors Type 1433-P were used as resistance loads. The open-circuit voltage and voltage during discharge of the batteries were measured with a Hewlett-Packard VTVM Model 412A. A Hewlett-Packard 7100B strip-chart recorder with 17501 plug-ins was used for recording voltmeter output.

Results and Discussion

Gold bromide.—X-ray diffraction data for commercial anhydrous $AuBr_3$ and $AuBr_{2.4}$ are given in Table II. $AuBr_3$ and $AuBr_{2.4}$ were found to decompose in a very similar way when heated. First, they decomposed into a yellow compound, which according to Campbell (11) was gold monobromide. The yellow compound subsequently decomposed to metallic gold. Both $AuBr_3$ and $AuBr_{2.4}$ were hygroscopic and somewhat soluble in acetone and ethanol.

Ag_3SBr reacted readily with liquid and gaseous bromine, and aqueous HBr:

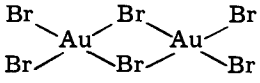
$$Ag_3SBr + Br_2 \rightarrow 3AgBr + S \quad [1]$$

$$Ag_3SBr + 2HBr \rightarrow 3AgBr + H_2S$$

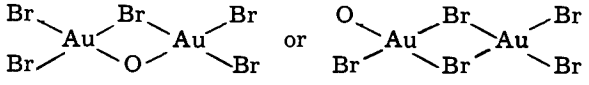
These reactions were exothermic and proceeded readily at room temperature. The decomposition reaction of Ag_3SBr with Br_2 is analogous to the decomposition reaction of Ag_3SI with I_2 (7). However, Ag_3SBr did not react (no decomposition was observed from x-ray diffraction patterns after several months at room temperature) with anhydrous $AuBr_3$ or with $AuBr_{2.4}$.

The crystal structure of $AuBr_3$ has not been reported in the literature, however, $AuBr_3$ has been reported by Burawoy and Gibson (12) to be a dimer



Burroway and Gibson based their results on ebullioscopic measurement in the elevation of bromine's boiling point when a known amount of $AuBr_3$ was dissolved in bromine.

The similarity in properties of $AuBr_{2.4}$ and $AuBr_3$ suggests that $AuBr_{2.4}$ may also be a dimer. The lower ratio of Br:Au may be due to the formation of bromide vacancies (O) such as



Battery characteristics.—Little pressure was needed to activate the batteries. The relationship between applied pressure, open-circuit voltage, and voltage of a cell with a 50 k-ohm load is shown in Fig. 3. Under high pressure, the open-circuit voltage was 0.84V, about equal to the decomposition potential of the electrolyte, the highest value which can be obtained under equilibrium conditions. As can be seen, at less than 1 psi the open-circuit voltage was over 90% of the cell voltage at high pressure. However, this was not the case when a load was applied to the cell. Even at a pressure of 1 psi the cell voltage under 50 k-ohm load was only 40% that observed under an applied pressure of 1000 psi. The voltage under load rose rapidly above 1 psi, and a pressure of 25 psi was sufficient to activate the battery for current drain (96% of the voltage observed at high pressure). This pressure of about 25 psi needed to activate the battery, *i.e.*, for the cell to have a good electrolyte/electrolyte interface contact, was still much less than the 60,000 psi pressure needed to achieve a good electrode/electrolyte contact (9).

Deactivation of the battery was accomplished by removing the applied pressure. Even cells that were activated with pressures of 2000 psi were deactivated with extreme ease.

Reactivation of a cell required less pressure than in the initial activation. Electrolyte surfaces at the electrolyte/electrolyte interface had been conditioned by the applied pressure during the initial activation and apparently were not damaged during cell deactivation and storage.

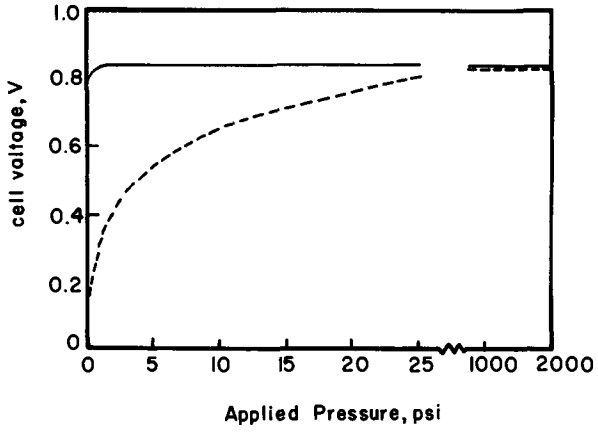


Fig. 3. Cell voltage dependence on applied pressure: (solid line) open-circuit voltage; (broken line) 50 k-ohm load.

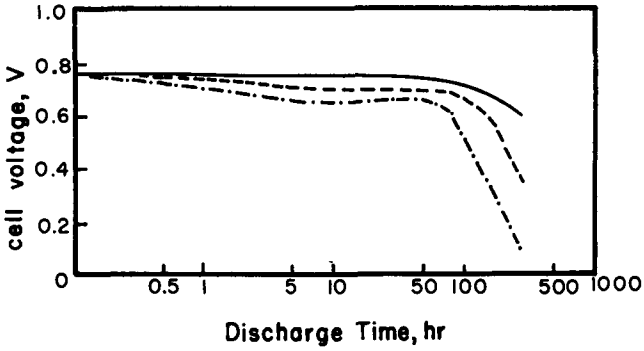

Fig. 4. Discharge curves for Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/AuBr_{2.4}$ + Ag_3SBr + C cells under constant load at 0°C. Initial cathode charge was 100C. (—) 33.2 k-ohm, (- -) 20 k-ohm; (· - · -) 10 k-ohm.

The a-c resistances of several batteries are listed in Table III. Usually nonreserve batteries had lower resistances than the reserve batteries by about 2 ohms. This difference in resistance was attributed to the electrolyte/electrolyte interface of the reserve batteries. In general, after a battery had been completely discharged, its resistance increased to about 7000 ohms. The increase in resistance was attributed to the presence of AgBr produced in the cathodic reaction.

Several cells were discharged until their voltages were 0.1V. The per cent battery charge recovered for the cells is listed in Table IV. Four different nonstoichiometric gold bromides were used as cathodes. Best results were obtained with $AuBr_{2.4}$ for which efficiencies of up to 80% were obtained. The per cent of anodic charge that was recovered when the anode was the limiting reactant was above 80%.

The voltages of cells under continuous load discharge at 0°, 21°, and 40°C are shown in Fig. 4-6. Load curves for temperatures between −30° and +40°C are shown in Fig. 7.

Table III. Resistance of solid-state reserve battery cells

Composition of cell	Resistance, ohms
Ag + Ag_3SBr/Ag_3SBr*/Ag_3SBr + $AuBr_{2.4}$ + C	28
Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/Ag_3SBr$ + $AuBr_{2.4}$ + C	30
Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/Ag_3SBr$ + $AuBr_2$ + C	1200
Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/Ag_3SBr$ + $AuBr_3$ + C	90
Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/Ag_3SBr$ + $KAuBr_4$ + C	2500

* The amount of Ag_3SBr used for the electrolyte layer of this cell was twice the amount for individual electrolyte layer of the other cells. The total amount of electrolyte used in all cells was the same.

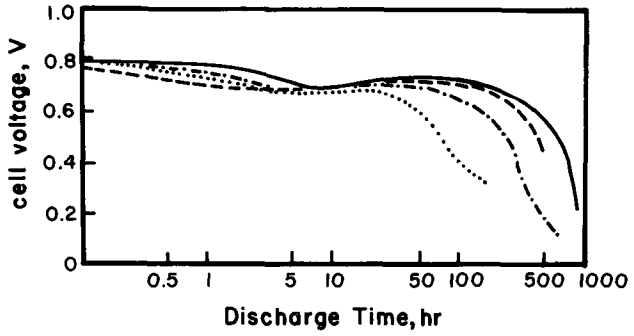

Fig. 5. Discharge curves for Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/AuBr_x$ + Ag_3SBr + C cells under constant load at 21°C. Initial cathode charge was 119C. (—) x = 2.4; 20 k-ohm load. (- -) x = 3; 20 k-ohm load. (- · - · -) x = 2.4; 10 k-ohm load. (· · · ·) x = 2; 10 k-ohm load.

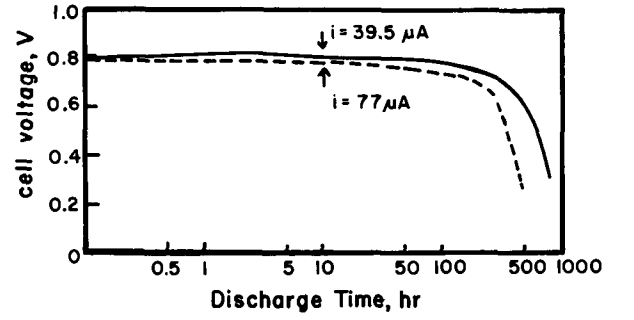

Fig. 6. Discharge curves for Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/AuBr_{2.4}$ + Ag_3SBr + C cells under constant load at 40°C. Initial cathode charge was 119C. (Solid line) 20 K ohms; (broken line) 10 K ohms.

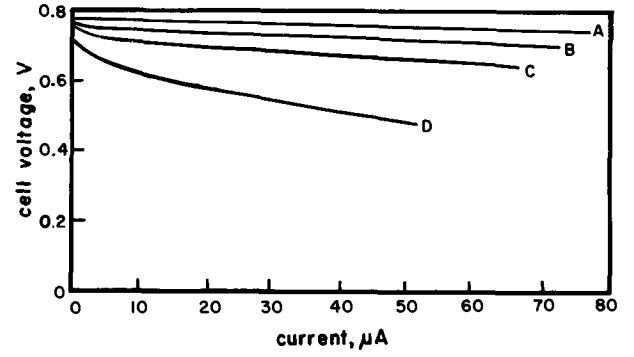

Fig. 7. Load curves for Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/AuBr_{2.4}$ + Ag_3SBr + C cell at various temperatures. (A) 40°C; (B) 21°C; (C) 0°C; (D) —30°C. Initial cathode charge was 243C.

Cathodic reaction.—Two mechanisms can be proposed for the cathodic reaction

$$AuBr_x \rightleftarrows AuBr_{x-1} + Br(g)$$
$$\downarrow\ Ag^+ + e^- \longrightarrow AgBr \quad [A]$$

$$AuBr_x + Ag^+ + e^- \rightarrow AuBr_{x-1} + AgBr \quad [B]$$

The first step of mechanism [A] is the formation of gaseous bromine atoms followed by their reaction with silver ions and electrons. In mechanism [B], the cathodic reaction is a solid-state reaction and proceeds whenever there is a silver ion and an electron present at a reaction site.

According to mechanism [A], less stable gold bromides with high vapor pressures should perform better as cathodes than $AuBr_{2.4}$ or $AuBr_3$. However, at room temperature, all gold bromides had about the same average power output. In addition, the per cent cathodic charge recovered with $AuBr_{2.4}$ was significantly more than the other gold bromides (Table IV). Aside from $AuBr_{2.4}$, the poor performance of the other nonstoichiometric gold bromides was due to their instability with the formation of bromine gas, which was lost by diffusion to the atmosphere and by reacting with the electrolyte, reaction [1]. Although the formation of bromine gas with the unstable gold bromides supports the possibility of reaction via mechanism [A]; mechanism [B] must be the predominant cathodic reaction with the more stable gold bromides, considering the amount of charge that was recovered (Table IV), and the fact that $AuBr_{2.4}$ and $AuBr_3$ did not react with Ag_3SBr while the less stable gold bromides did.

The presence of bromide vacancies in the proposed structure of $AuBr_{2.4}$ should facilitate the migration of bromide ions to the reaction sites. An alternative mechanism would be the possible ability of silver ions to migrate into the $AuBr_{2.4}$ because of the bromide ion vacancies. These might explain the better performance of $AuBr_{2.4}$ under load compared to $AuBr_3$ (Fig. 5). In contrast, $KAuBr_4$, a compound without bromide vacancies, behaved poorly as cathode material. In Fig. 8 the voltage of a cell with $KAuBr_4$ as the cathode material is shown as a function of time.

The crystal structure of $KAuBr_4$ has been reported by Cox and Webster (14). They found $AuBr_4^-$ to be planar with the gold ion bonded covalently to four bromides. The passivity of $KAuBr_4$ may be due to the stability of the $AuBr_4^-$ ion in the solid-state since the reaction

$$AuBr_4^- + 3Ag \rightarrow Au + 3AgBr + Br^- \quad E^\circ = 0.79V$$

is thermodynamically favorable in acid solution (5). The passivation of the $KAuBr_4$ cathode took place after all the loosely bound bromide ions initially present at reaction sites were used. The stability of the $AuBr_4^-$ ion structure prevented the formation of any mobile bromide ions, and the absence of bromide vacancies made it difficult for any loosely bound bromide in the bulk to migrate to the reaction sites and form AgBr.

Conclusion

Although the solid-state reserve concept was demonstrated on only one cell system, there is no reason why it could not be applied to any solid-state battery in which electrolyte/electrolyte contact can be made at relatively low applied pressure.

Putting the concept into practice requires an activation technique which will vary with specific application. Single cells can be manually activated and deactivated easily, but batteries require a separator in the electrolyte which can be effectively removed when the battery is activated. One technique which was successful for 4-6 cell batteries was to use compressible plastic spheres positioned in grooves in the electrolyte layers. The applied pressure was sufficient to activate

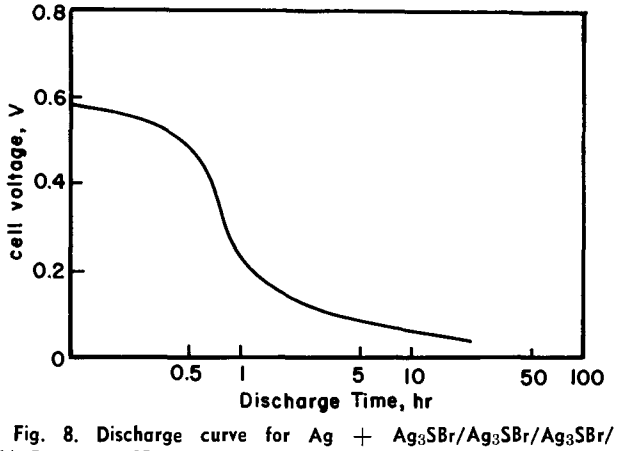

Fig. 8. Discharge curve for Ag + $Ag_3SBr/Ag_3SBr/Ag_3SBr/KAuBr_4$ + Ag_3SBr + C cell under 500 K ohms load at 21°C. Initial cathode charge was 250C.

the battery while the sphere's elasticity was sufficient to deactivate the battery when the applied pressure was removed.

On Accelerated Pitting and Crevice Corrosion Tests

Jörgen Degerbeck

Uddeholms Aktiebolag, Hagfors, Sweden

ABSTRACT

Accelerated electrochemical and chemical pitting and crevice corrosion tests have been carried out in order to gauge the validity of the tests in predicting the corrosion resistance of stainless steels in a specific sea-water environment and to determine the relationship between the tests performed. The relationship was investigated by means of regression and correlation analyses. Number of steels investigated, tests performed, and parameters measured were 20, 10, and 20, respectively.

The purpose of this report is to contribute to the recent discussion [*e.g.*, (1-4)] concerning different accelerated pitting corrosion tests, chemical and electrochemical, and their validity in predicting the performance of stainless steels under working conditions in sea-water environment.

Some twenty austenitic and ferritic-austenitic stainless steel grades, standardized and nonstandardized, have been investigated in ten different tests, *i.e.*, field test and accelerated chemical and electrochemical pitting and crevice corrosion tests, and the relationship between the tests has been investigated by means of regression and correlation analysis.

When deciding on a selection of laboratory tests and their evaluation, consideration has been given to their ease and speed of performance as well as their prevalence.

It has not been possible to study the relationship between all combinations of test measurements made for all combinations of steels. Only the relationship found to be of the greatest interest after a rather short initial survey of the results of the corrosion tests has been examined and discussed.

Materials

The material used in the investigation was grouped into the following types: Type 18/9, Type 18/13-3 Mo, Type 18/14-4 Mo, Si-alloyed 18/8 steel, Type 18/20-4 Mo, Type 20/25-Mo-Cu, and ferritic-austenitic stainless steels.

The steels within the different groups were alloyed with more or less varying contents of Ni, Mo, Si, Cu, Ti, Nb, and N. Table I shows the grouping and composition of the different grades.

The test material was taken from sheet and flat bars originating from production and laboratory heats. The production heat material was in the as-delivered condition, *i.e.*, solution heat-treated and pickled, and the laboratory material was solution heat-treated, 1050° and 980°C, for the austenitic and ferritic-austenitic material, respectively, and pickled in the laboratory. The austenitic steels were pickled in an HF/HNO_3 bath and the ferritic-austenitic steels in an HF/H_2SO_4 bath.

As regards the austenitic and ferritic-austenitic steels, the results of the metallographic examination were to a great extent as expected for respective grades and no specimen had a structure that differed from a representative solution-annealed structure for its grade to such an extent that exclusion from the investigation was justified.

Dimensions and surface treatment of the specimens for the different tests: see the section on Experimental and Table II.

Experimental

All corrosion tests performed in this investigation are listed in Table II, regarding type of test, test designation, test duration, test conditions, specimen condition, and measurements made. The tests can be divided into three main groups: field test, test A; electrochemical pitting potential tests, tests B, C, D, E, F; and chemical pitting and crevice corrosion tests, tests G, H, I, K. Within the electrochemical pitting potential test group the differences in test conditions were not very large. This is shown later on. Except for the field test only one test, K, included crevices.

Key words: stainless steel, test methods, pitting, crevice corrosion, sea water.

** D = Production heat, L = laboratory heat.

The electrochemical tests were supposed to give information about the resistance to pitting initiation by measuring the potentiodynamic pitting potential, whereas the field test and the chemical laboratory tests were supposed to give the total effect of resistance to pitting initiation and pit propagation by measuring the number of pits (indicative of resistance to passivity breakdown) and pit depth and weight loss (both to a greater or lesser extent related to propagation resistance). More elaborate measures as "mean value of pit depth" or "percentage attacked crevice area of total crevice area" have not been used.

Before explaining the different tests performed some general information concerning specimen condition and test solution will be given.

An important fact concerning this investigation is that for each grade of steel the laboratory specimens for all the tests were taken from the same piece of sheet or flat bar, *i.e.*, from the field test specimens. The flat surfaces of the specimens, which have in all cases

Table II. Tests performed

Test	Type of test	Test conditions: Corrosive environment	Temp, °C	Duration	Start potential, mV E_{SCE}/time, min	Pol. rate, mV/min	Specimen: Dimension, mm

* C = crevice corrosion, P = pitting, G = general corrosion.

been the main or the only test surfaces, have always been parallel to the prior flat surfaces, *i.e.*, the rolled surfaces of the hot rolled sheets or bars.

The specimens were washed and degreased in ethanol.

Passivation treatment was performed in 20% HNO_3 at 40°C for half an hour.

The electrolytes were made from deionized water and reagent grade chemicals.

Deaeration of electrolytes was achieved by bubbling nitrogen through the solution for half an hour prior to the test.

The accuracy of the electrolyte temperature was ±1°C.

The electrochemical experiments were performed by using a Wenking 61 KTR potentiostat.

The specimens for the electrochemical tests, 13 × 13 × 2 mm, were mounted in plastic resin[1] with a single exposed surface, ground, surface treated, and finally masked with plastic resin[1] to a surface of 10 × 10 mm. The test surface was prepared not to get preferential attack at the interface between sample and plastic mount. Still some specimens were attacked at these areas, possibly because of crevices. However, the test results of these specimens were excluded and new tests were performed.

The specimen with its polyethylene-sheathed copper conductor was mounted together with a platinum counterelectrode, a Luggin capillary connected to a saturated calomel reference electrode (SCE), and a gas dispersion tube in the all-glass cell as shown in Fig. 1. One exception to the arrangement shown in Fig. 1 appeared when investigating the pitting potential in 5% HCl, tests B and C. In these cases the test surface was vertical and with the Luggin capillary as close to the specimen as in the "horizontal case," *i.e.* approximately 2 mm.

(20 × 10 × 2 mm, ground on 80 paper) to the steel by rubber bands

mens, 200 × 40 × 2 mm. Short samples without drilled holes, 100 × 40 × 2 mm.

One or, in a few cases, both the flat sides of the pickled samples were ground with 220 paper. All the samples were then passivated in 20% HNO_3 at 40°C for 0.5 hr.

Measurements of surface roughness of the pickled and ground surfaces showed that the ground surfaces on an average were smoother. The average of the roughness value CLA was approximately 1.0 for the pickled surfaces and 0.5 for the ground surfaces.

Two types of specimen were used, single specimen and double specimen. The double specimen consisted of two samples, one long and one short, of the same grade joined by putting two ground flat sides together. The crevice between the ground surfaces was intended to give an idea of the tendency of the steel to crevice corrosion. The two plates were joined together by wire, 1.5 mm diameter in grade UHB[2]) SS 24.

The single sample consisted only of a long specimen.

The test plates were mounted in a frame by specimen holders consisting of two rods, 13 mm diameter, covered with PVC-tubing. The rods were threaded through the drilled holes of the plates and each specimen was fixed on to the specimen holder by middle-pieces made from coarse PVC-tubing. Both the sample holder and the extension casing were manufactured from UHB SS 24, 17/12-3 Mo. The sample holder was placed in the frame so that the longitudinal direction of the samples was vertical.

A description of the samples and their attachment to the specimen holder is given in Fig. 2.

With reference to the crevice geometry it should be pointed out that no more was known for the different crevices than the fact that these had been formed through a close clamping of steel to steel and PVC to steel.

The test station, Bohus-Malmön, is situated on the west coast of Sweden. The raft to which the test frames were fixed was anchored approximately 5m from the shore where the depth is approximately 3m.

The specimens were lowered approximately 1m below the surface and the tests for the austenitic stainless steels lasted from the end of September 1968 to mid-August 1969. The ferritic-austenitic steels were lowered into the sea just after the austenitic steels had been taken up and they were tested almost exactly one year, *i.e.*, they were taken up in mid-August 1970.

[2] Trade mark for Uddeholms Aktiebolag.

Conditions in these coastal waters are: at a depth of less than 5m the salt content varies between 2.2 and 2.8% with a tendency to a higher salt content during the coldest month (February). The pH of the water is approximately 8 and the temperature/time curve reaches a trough of 2°C around February-March and a peak of 18°C around July-August.

After a year's testing the fouling was very heavy. On the whole the test surfaces were completely covered by various sea organisms. The predominant species were balanids,[3] mussles, and algae.

The different grades of steel and surfaces had more or less the same degree of fouling by the various species of sea organisms.

Electrochemical tests, tests B-F.—All of the electrochemical tests performed aimed at investigating the potentiodynamic pitting potential in 5% NaCl or 5% HCl. The critical anodic current density was also investigated in the HCl tests, tests B and C.

The only difference in test condition between these two tests, B and C, was the temperature, 30° and 40°C, respectively.

The potentiodynamic pitting potential in HCl, when scanning in the noble direction with a rate of 20 mV/min from −600 mV E_{SCE}, was defined as the potential in the passive region at which the current starts to increase sharply and not as the potential at which the current density exceeds a certain value; for the NaCl-tests, 10 $\mu A/cm^2$. This is because of the rather varying current density-potential curves in the passive region for the different steels investigated in HCl.

Of the three tests performed in NaCl, D, E, and F, tests D and E differed only in respect to surface treatment, number of trials per grade, and measurements made. See Table II. Otherwise the temperature of the oxygen-saturated NaCl solution was 60°C, and the scanning in the noble direction started at the corrosion potential and at a rate of 10 mV/min for these two tests. Test F, partly performed according to (1), was performed in oxygen-free NaCl solution at a scanning rate of 200 mV/min between −1500 and −300 mV E_{SCE} and 10 mV/min thereafter. At −300 mV E_{SCE} there was a holding time of 15 min. Except from oxygen concentration and electrochemical parameters this test was identical with test E.

Chemical pitting and crevice corrosion tests, tests G-I, K.—Test G was performed in 10% $FeCl_3$, pH 1.3,

[3] Barnacle of the genus Balanus.

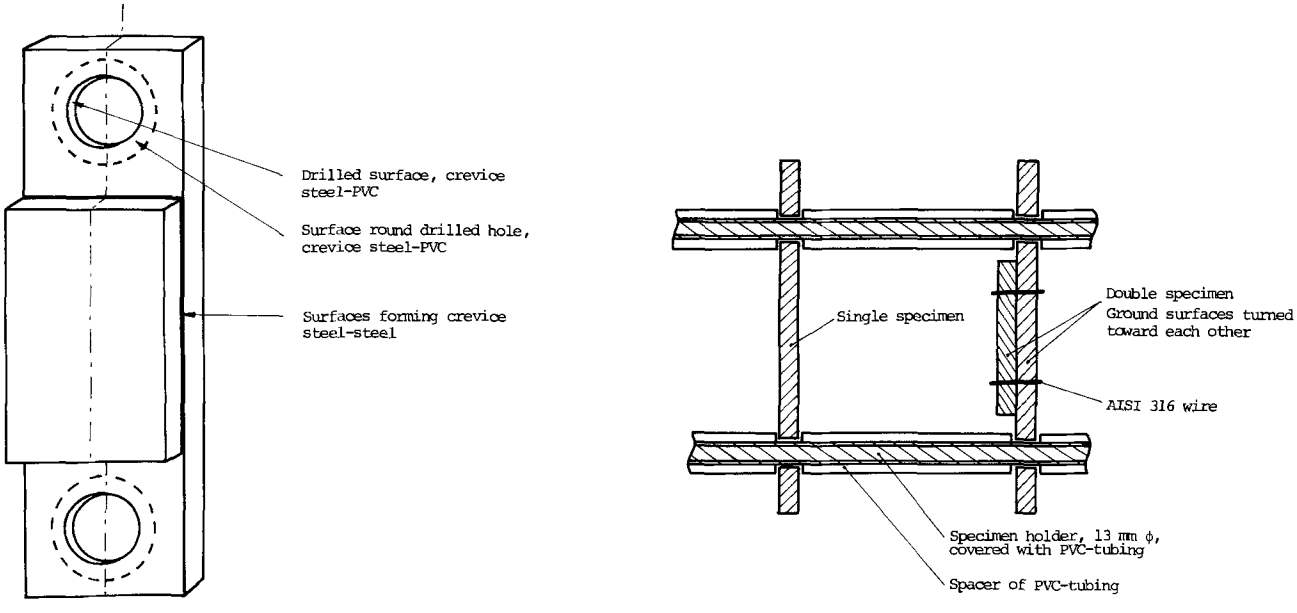

Fig. 2. Mounting of field test specimen; Fig. 2a (right) is double specimen section

at 30°C for 4 hr with one specimen per steel, 50 × 20 × 2 mm, and all surfaces mechanically polished and passivated. Measurements made were number of pits on all surfaces, on rolled surfaces, and weight loss.

Test H was partly performed according to (6). The test media consisted of 0.33 mol Al^{3+}/liter, 0.30 mol Fe^{3+}/liter, 1.81 mol Cl^-/liter, and 3.8 mol H_2O/liter in a solvent of 50% ethanol and 50% glycerol. Solution temperature was 22°C, and test duration 2 hr. The specimen was mounted in plastic resin like the specimens for the electrochemical tests. Thus, one flat side of the specimen was tested. Surface finish was mechanically polished and measurement made was number of pits per unit area.

Test I was performed in 2 and 15% HCl at 22°C with specimens, 50 × 20 × 2 mm, ground on 150 paper and passivated. Test duration for the 2 and 15% HCl solution was 140 and 24 hr, respectively. Total weight loss was measured.

Test K was the only one of the chemical tests which included crevices. These were formed through a close clamping of a flat PVC specimen, 20 × 10 × 2 mm and ground on 80 paper, to one of the flat surfaces of the steel specimen, 50 × 20 × 2 mm and ground on 220 paper, by means of rubber bands. The test was performed in synthetic sea water according to ASTM-D 1141-52 and with 10g $K_3[Fe(CN)_6]$/liter and 10g $K_4[Fe(CN)_6]$/liter added to the water. The temperature was 35°C and the test duration 24 hr.

Measurements made were number of corrosion attacks under the PVC-plate and rubber bands and the relative strength of these attacks. The attacks belonging to the worst ones according to depth and area got the value 3 and those belonging to the intermediate group and the best group, hardly noticeable attacks, got the value 2 and 1, respectively. All attacks on the five tested specimens per investigated steel were divided into these three groups and the number of attacks was multiplied by its group value. Finally these three amounts were added giving the total mark for the steel investigated: *e.g.*, a steel having 3 heavy, 5 medium, and 4 weak attacks got a total mark of $3 \times 3 + 5 \times 2 + 4 \times 1 = 23$.

The regression and correlation analysis was performed in a computer, assuming linear relationship between the different quantities measured. The four ferritic-austenitic steels were excluded from this analysis.

Results and Discussion

The results of the corrosion tests performed are shown in Table III, and those of the regression and correlation analysis, *i.e.*, correlation coefficient (r), intercept, regression coefficient, and standard error of estimate in Table IV.

Field test, test A.—All attacks had taken place on surfaces which during the experiment had formed crevices between steel-PVC tubing and steel-steel and on surfaces covered by balanids, *i.e.*, crevice corrosion. Other surfaces were completely free from local corrosion. The crevice corrosion had taken place mainly round the surface of the drilled holes which had formed a split with the PVC-spacer tubing. Crevice corrosion on the drilled surface itself, crevice steel-PVC, and on the ground surfaces forming a crevice steel-steel was not quite so common.

Normally, the crevice corrosion on the surfaces of the drilled holes covered a comparatively small part of the circumference while the corrosion on the surfaces forming crevice steel-steel was comparatively widespread. In some cases the corrosion on the surfaces of the drilled holes consisted of deep pits in areas with crevice corrosion. Crevice corrosion under fouling organisms, *i.e.*, balanids, took place primarily on the Si-alloyed 18/8 steels.

With regard to maximum depth of attack and number of attacks the following applies to the austenitic stainless steels.

The best group had no attacks with a depth > 0.1 mm. The austenitic steels with Ni contents varying between 13 and 25% and alloyed with Mo combined with N, N plus Si, or Cu were included in this group, *i.e.*, steels 4, 12, 15, and 16.

The second group with few attacks and a maximum depth of corrosion of 0.2-0.4 mm consisted of the 18/8 steels alloyed with Mo combined with N or Si, *i.e.*, steels 3, 10, and 14.

The third group consisted of 18/8 steels alloyed only with Mo and the steel 18/18-2 Si. It should be noted that the steel 18/24-4 Mo is also included in this comparatively poor group, despite its high Ni content. The maximum depth of attack for these steels was between 0.5-1.0 mm. The number of attacks was relatively large. Steels 2, 5, 6, 7, 8, and 13 belonged to this group.

The 18/8 steels without further alloying or alloyed with only Si and/or N were clearly the worst group with maximum depth of attack of 1.5-2 mm and a large number of attacks. Steels 1, 9, and 11 belonged to this group.

The correlation between maximum depth of attack, which is related to propagation resistance, and number of attacks, which is indicative of resistance to passivity breakdown, was rather good, $r = 0.80$.

The well-known beneficial effect of molybdenum as to pitting initiation and propagation [there are certain similarities between the mechanism of formation of pitting and crevice corrosion (7, 8)] and molybdenum combined with nitrogen and/or silicon as to pitting initiation (7, 9-12) is thus clearly shown in this field test, although smaller discrepancies occurred within the groups mentioned, *e.g.*, steel 3 (18/13-3 Mo-N) was somewhat better than steel 14 (18/20-4 Mo-N) with a higher molybdenum content, and steels 6 and 7 with approximately the same composition differed rather widely in respect of maximum depth of attack. One reason for these discrepancies might be that differences in steel structure and composition and distribution of slag inclusions overshadow the effect of minor deviations in steel composition.

This rather good agreement between the field test results and those expected with regard to the composition of the steels and the important fact that the laboratory specimens had been taken out from the field test specimens, *i.e.*, practically the same test surface for all tests performed, make it interesting to let the field test results serve as a reference for the results of the laboratory tests.

It is, however, not quite clear that other sea-water environments, higher temperatures, longer testing times, other evaluation techniques, etc., would have given exactly the same sequence when rating the steels in order of merit.

For more detailed information of the field test results, see (5).

Electrochemical tests.—The scatter, maximum value-minimum value, of the pitting potential results from the tests performed in NaCl was large: mean scatter value of approximately 150 mV.

One contributory explanation of this could be that the specimens, due to their small test area, might or might not expose especially weak points in respect to pitting initiation, *e.g.*, sulfide slag inclusions of dangerous type, *i.e.*, manganese-rich ones. The negative effect of sulfides, especially the duplex and manganese-rich ones as to pitting resistance is clearly shown (13-17).

Although the scatter was large, the results can be regarded as reasonably consistent. This is supported by the good correlation between the tests with large scatter; tests E (5% NaCl, O_2) and F (5% NaCl, N_2).

** *i.e.* 10 in the statistic analysis.
† No passivation occurred.
‡ Critical anodic current density, μA/cm².
§ Pitting potential mV E_{SCE}.

Correlation coefficient, r, for minimum, mean, and maximum pitting potential was 0.79, 0.96, and 0.90, respectively.

Out of the three tests performed in NaCl, *i.e.*, tests D, E, and F, not one agreed very well with the field test results if one sees to the mean value of pitting potential and number of attacks on the field-test specimen; r −0.42, −0.55, −0.65, respectively. Test D was least good, probably due to the smaller number of specimens tested.

The correlation between number of attacks and maximum value of pitting potential is still worse: r −0.40 and −0.49 for tests E and F, respectively. The agreement is, however, not too bad when comparing the minimum value of pitting potential with the number of attacks in the field test, r −0.68 and −0.83 for tests E and F, respectively.

The probable reason for the minimum value of pitting potential being more valid than the mean or maximum value of pitting potential is connected to the distribution in the steel of weak points in respect to pitting initiation, *e.g.*, sulfides, and the differences in specimen area used in the field test and the electrochemical tests, respectively. As the area of the electrochemical specimens was much smaller than the crevice area of the field-test specimens and as the smaller the test area the less risk of exposing a weak point belonging to the most dangerous ones, the electrochemical specimen having the lowest pitting potential value ought to correspond better to the crevice surfaces attacked in the field test in respect to weak points than the electrochemical specimens having the highest pitting potential or pitting potentials in the range of mean value.

The tests performed in HCl, tests B and C, agreed very well as far as the critical anodic current density is concerned, r 0.99, and these current density values correlated not too badly with the maximum depth of attack in the field test; r 0.75 and 0.76 for tests B and C, respectively. Both these measured values are to a greater or lesser extent related to propagation resistance.

The correlation between the pitting potential in HCl, according to test B, and number of pits in the field test (both values related to pitting initiation resistance) was good, r −0.91. This is surprising, considering the fact that the pitting potential according to the other HCl test, test C, correlated badly with the number of pits in the field test, r −0.52. The only difference between test B and test C was the temperature, 30° and 40°, respectively.

Having in mind that the tests in HCl were only performed with one specimen per steel, that the highest correlation coefficient related to pitting initiation was achieved with results from the HCl, test B, and that electrochemical tests in HCl give information about propagation resistance, it seems as if HCl is at least as interesting a test solution as NaCl.

The potentiodynamic pitting potential tests performed in HCl and NaCl did not agree very well, r values about 0.5.

Chemical tests.—The results of the accelerated chemical pitting and general corrosion tests did not correspond very well with those of the field test. The correlation coefficients investigated varied between 0.14 and 0.72. Best results were obtained with the ferric-chloride test, but then only with the value "number of pits on rolled surfaces," and the chemical crevice corrosion test K performed in synthetic sea water:

Number of attacks in the field test against relative resistance according to test K, r 0.70.

Maximum depth of attack in the field test against number of pits on rolled surfaces in $FeCl_3$, r 0.67.

Maximum depth of attack in the field test against relative resistance according to test K, r 0.65.

The ferric-chloride test gave some interesting results. When evaluating the results the following was measured: number of pits per square centimeter on rolled surfaces, G_1, number of pits per square centimeter of total surface, G_2, and weight loss, G_3. As mentioned before, G_1 correlated rather well with the results of the field test, while G_2 and G_3 did not. The correlation between G_1 and G_2 was extremely poor, r 0.04, and that

between G_2 and G_3 quite good, r 0.93. Obviously the normally much less pitting-resistant edge surfaces contribute to the poor correlation between G_3, the standard value measured for this type of test, and the results of the field test. It is, however, somewhat surprising that the relative effect of alloying elements, *i.e.*, different steels, on the pitting resistance is not the same for the rolled surfaces and the edge surfaces of the specimen. There are possible reasons for this. One could be that when the flat, elongated slag inclusions, *i.e.*, sulfide slag inclusions, are to a more or less extent dissolved during the passivation treatment in nitric acid, dangerous crevices will be formed on the edge surfaces and not on the flat surfaces. Thus the type, shape, distribution, and number of inclusions could be of much greater importance to the result than the chemical composition of the steel.

The chemical pitting test H, *i.e.*, corrosion in a solution of Al^{3+}, Fe^{3+}, and Cl^- ions in ethanol and glycerol and especially the chemical pitting and general corrosion test I, *i.e.*, corrosion in HCl, seemed to be of little value.

The correspondence between the different accelerated chemical pitting and crevice corrosion tests was poor. None of the calculated correlation coefficient values exceeded 0.55.

Relation between electrochemical and chemical tests.—A comparison of electrochemical and chemical tests shows that the relationship between the two types of test is not very good, r_{max} 0.76.

Some of the more interesting relationships are listed below:

Mean value of pitting potential in NaCl, test E, against relative resistance according to chemical crevice corrosion test K: r −0.76.

Minimum value of pitting potential in NaCl, test E, against relative resistance according to chemical crevice corrosion test K: r −0.69.

Pitting potential in HCl, test B, against number of pits in chemical pitting test H: r − 0.66.

Minimum value of pitting potential in NaCl, test E, against number of pits in chemical pitting test H: r −0.59.

Mean value of pitting potential in NaCl, test E, against weight loss in $FeCl_3$, test G: r −0.38.

Mean value of pitting potential in NaCl, test F, against number of pits on rolled surfaces in $FeCl_3$, test G: r −0.18.

Comparison of tests when rating the steels in order of merit.—As could be expected from the generally poor correlation between the different tests, the sequence when rating the steels in order of merit differs rather widely when comparing the tests.

It seems that the difference in content of alloying elements has to be rather great to achieve a good agreement between the tests. Thus when steels No. 1 (18 Cr-9 Ni), No. 2 (18 Cr-12.5 Ni-3 Mo), No. 7 (17 Cr-14.5 Ni-4.5 Mo), and steel No. 14 (17.5 Cr-19.5 Ni-4.5 Mo-N) are ranked in order of merit according to the different test values measured, the sequence will be the same for 16 out of 20 test values. Those test values which did not agree with the others were I_1, *i.e.*, weight loss in HCl, G_1 and G_2, *i.e.*, number of pits according to the test in $FeCl_3$, and E_3, *i.e.*, maximum value of pitting potential in NaCl.

If another steel with a composition within the range of the composition of the above-mentioned group of steels or with somewhat other content of alloying elements, *e.g.*, silicon and nitrogen, is included in the comparison, problems would arise.

Conclusions

According to the results of this investigation the effect of minor deviations in content of alloying elements in stainless steels on the resistance to localized corrosion in calm natural sea water cannot be evaluated with any degree of certainty by means of the accelerated electrochemical or chemical tests performed.

The agreement between the tests is not acceptable unless the difference in steel composition is at least

as great as that between the following steels: 18/9, 18/13-3Mo, 17/15-4.5Mo, and 18/20-4.5Mo-N.

The rather poor correlation between most of the test combinations thus makes it difficult to predict the corrosion resistance in the sea-water environment in question on the basis of just one accelerated test or to relate different tests to each other.

Assuming the results of the field test are representative of the investigated steels in most sea-water environments, the following seems to be true for the accelerated tests performed in regard of their reliability in ranking steels in order of merit for sea-water service:

The electrochemical tests are to be chosen in preference to the chemical tests, when resistance to passivity breakdown is to be investigated.

The minimum value of pitting potential is more reliable than the mean or maximum values.

Pitting potentials obtained in hydrochloric acid are probably more valid than those obtained in sodium chloride.

When investigating the resistance to pitting and crevice corrosion of flat products and tubes in 10% $FeCl_3$ (pH 1, 30°C), it is important that the effect produced on the specimen surfaces perpendicular to the rolled surfaces is excluded from the final evaluation.

An Optical Study of the Growth and Oxidation of Nickel Hydroxide Films

M. A. Hopper* and J. L. Ord*

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

The formation and oxidation of nickel hydroxide films under a variety of experimental conditions are studied using *in situ* ellipsometric measurements. Two forms of the hydroxide, which we assume to be the α and β forms reported by other workers, are found. The α- and β-hydroxide layers are both transparent with real refractive indices of 1.52 and 1.46, respectively, at 6328Å. Upon oxidation the two forms of hydroxide convert to different oxides, both of which absorb light. The process involved in the conversion of the β-hydroxide appears to be similar to the process postulated for the charging of the nickel battery electrode.

The complex conversion processes that occur during the charging and discharging of the nickel electrode in a nickel-alkaline battery have been the subject of extensive study over the past fifty years (1). Only recently, however, were some of the details of the mechanism elucidated. In particular x-ray (2, 3) and infrared (4) techniques were applied, with some success, to the determination of the structure and modifications that occur in the solid-state phases involved in the conversion reaction.

Electrochemical investigations of the system are generally performed on nickel electrodes covered with relatively thin films of oxide or hydroxide. The films on the nickel surface are formed using a variety of techniques including deposition of hydroxide from solutions of nickel nitrate (3, 5) and direct oxidation and reduction of the electrode (6, 7). The variation in the behavior reported for the different methods indicates that the properties of the films formed may depend on growth conditions.

In contrast to the extensive studies using ellipsometric methods on the formation of anodic films on nickel in acidic solution (8, 11), only Chernykh and Yakovleva (12, 13) have presented results obtained in strongly basic solution. The present investigation using *in situ* ellipsometric measurements combined with simultaneous studies of the electrical behavior was carried out to determine whether optical techniques could supply additional information on the nature of the process of oxidation of nickel hydroxide in basic solution. This process is of fundamental importance to the understanding of the conversion reactions that occur on charging and discharging the nickel battery electrode. In addition it was hoped that optical methods could determine if the films of nickel hydroxide formed under different conditions showed a similar behavior when oxidized and reduced in basic solution.

Experimental

The self-nulling ellipsometer used in this investigation has been described in detail elsewhere (14). The instrument has a resolution of 0.01° and a typical nulling time of 1 sec for the films formed on nickel in this study. A low-power helium-neon laser is used as the light source for the instrument and all refractive indices reported in this paper are pertinent to its wavelength, 6328Å. All optical measurements were taken with an angle of incidence of 60°. The ellipsometric data were analyzed using a computer program written in BASIC and run on the laboratory HP 2114B computer.

An equilateral hollow glass prism fitted with standard-taper joints for mounting the electrode holder, platinum counterelectrode, mercurous sulfate reference electrode (fitted with a 0.1*N* K_2SO_4 salt bridge), and a gas dispersion tube was used as the electrochemical cell. Argon could be bubbled through the solution but this was not found to have an appreciable effect on the experimental results. All experiments were performed at room temperature (23°).

Single-crystal and polycrystalline samples of nickel were prepared in the form of cylinders and mounted between Teflon washers in the electrode holder. A flat on one side of the cylinder was used as the surface for optical studies. In this configuration approximately 1.2 cm^2 of the metal surface is exposed to the electrolyte. No differences were detected between results obtained with the two types of sample.

Prior to each experiment the nickel surface was chemically polished and then cathodically reduced in the cell to remove any oxide formed on the electrode during the polishing process. In the experiments involving deposition of hydroxide from nickel nitrate solutions, a special procedure was adopted to ensure that the optical readings were disturbed as little as possible after completing the deposition and commencing the oxidation. The method involved draining the cell with the electrode in place, rinsing with distilled water, then adding the solution to be used in the oxidation studies.

The electronic circuitry used with the cell consists of a set of five operational amplifiers, three of which are used to apply constant currents, constant potentials, and linear potential sweeps to the cell. Of the remaining two, one is used in the current-to-voltage converter mode to monitor the cell current and the other as a potential follower.

Results and Discussion

The first experiments were designed to determine the characteristics of the layers formed directly on a nickel substrate by oxidation and reduction in a 5*N* KOH solution. The optical and electrical data obtained on anodically oxidizing the electrode at a current density of 40 $\mu A/cm^2$ followed by cathodic reduction at the same current density are shown in Fig. 1. In the upper section of the figure the polarizer null readings, *P*, are plotted *vs.* the analyzer null readings, *A*. In the lower section of the figure the variation of the potential with time is recorded. The data points start at point A and trace out the curve A-B-C-D-E on oxidation and E-F-G on reduction.

On anodic polarization the optical data show two distinct regions, the section A-B and the section C-D-E. This indicates that layers of different index are formed on the surface in these two regions. On reduction the optical data (E-F) almost retrace the curve C-D-E but the end point of the reduction, point

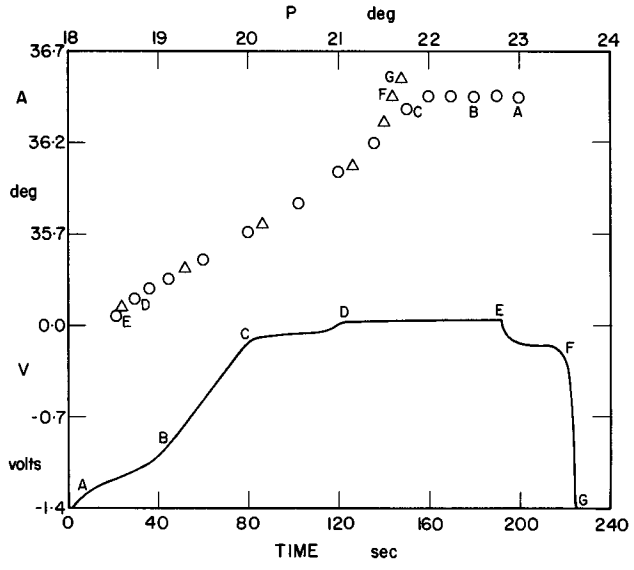

Fig. 1. Anodic oxidation (A-B-C-D-E) and reduction (E-F-G) of nickel at 40 μA/cm^2 in 5*N* KOH.

G, lies at a much lower value of *P* than either points A or B. Further reduction after point G results in no change in the optical data, implying that at this point the surface is covered by a layer of material that cannot be removed by cathodic reduction.

The largest optical changes are observed to occur along CD and EF, corresponding to the plateaus in the potential-time plot. Optical changes of this type are normally interpreted as resulting from growth along CD of a layer of constant index, and removal of the layer along EF. A range of refractive index values can be found which enable the data to be fitted to a process of this type. The values are all complex, indicating that if a film grows along CD it must absorb light. The k values in the complex index, $n - ik$, are on the order of unity for all but the lowest values of n.

Other explanations of the optical data in Fig. 1 are possible. (The major difficulty in interpreting results obtained in ellipsometric studies of thin films is that a unique interpretation of the data is usually impossible.) The charging and discharging of the nickel battery electrode are generally thought to involve conversion between nickel hydroxide and a higher oxide by a mechanism involving proton diffusion (1, 5). Regions CD and EF in Fig. 1 can be fitted to a conversion process, but many parameters can be varied in such a process, and no definite conclusions can be drawn from the fitting.

To decide whether the process is one of layer conversion rather than layer growth and removal, it is necessary to obtain optical data on thicker films. Using thicker films it is possible to determine unique refractive index values for the layers involved, thus permitting a distinction to be drawn between growth and conversion processes.

We found that much thicker layers could be grown on nickel in 5*N* KOH by a process involving prolonged reduction of the electrode combined with repeated cycling between the reduced and oxidized forms of the film. (Prolonged oxidation was found to cause little layer growth.) The optical results obtained using the above procedure to grow thick films are presented in Fig. 2. Points A, E, and G correspond to the same points plotted in Fig. 1. The electrode was subjected to cathodic polarization at 100 μA/cm^2 for a minute followed by anodic oxidation at 40 μA/cm^2 to oxygen evolution, and reduction at this current density until hydrogen evolution begins. This procedure was then repeated with progressively longer periods of cathodic polarization at 100 μA/cm^2. Although ellipsometric readings were recorded continuously during the ex-

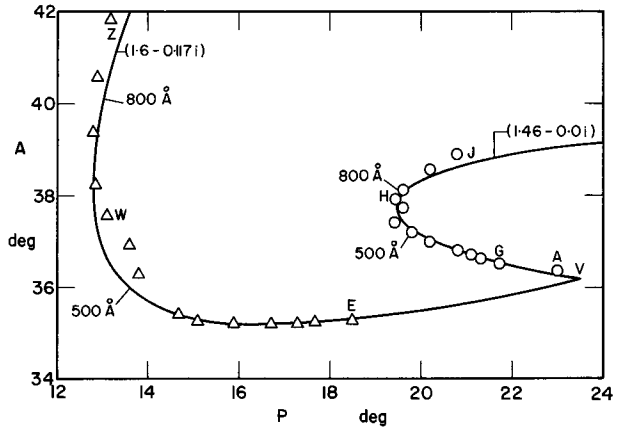

Fig. 2. Optical data on the growth of thick films on a nickel electrode produced by cycling between oxidation (triangles) and reduction (circles) in 5*N* KOH.

periment, only the loci of the optical readings obtained in the fully oxidized state, curve VWZ, and in the state produced on reduction at 40 μA/cm^2, curve VHJ, are plotted in Fig. 2. The data obtained in the reduced state (curve VHJ) are shown fitted to the growth of a film of index 1.46-0.0*i*. The points for the oxidized state (curve VWE) are fitted to the growth of a layer having an index of 1.60-0.117*i*. The value of the refractive index used for the nickel substrate was 2.13-4.31*i*.

The results summarized in Fig. 2 show that the process involved in the oxidation and reduction of a nickel electrode in 5*N* KOH is a conversion from one layer into another of different index, rather than film growth and dissolution. The thickness of both forms increases as the experiment progresses which would indicate that very little film dissolution occurs. Using the values of the refractive index that give the best fit to the locus of the experimental points we find that the thickness of the layer remains almost constant on cycling between the oxidized and reduced forms. For thicknesses greater than 400Å the oxidized layer appears to be thinner than the reduced layer by approximately 10%.

The thin film optical results can be explained by the conversion mechanism using the refractive indices determined from the thick film results. The optical data from Fig. 1 are replotted in Fig. 3 along with theoretical curves for the growth of layers having refractive indices of 1.46-0.0*i* (curve VH) and 1.60-0.117*i* (curve VW) corresponding to the reduced and oxidized forms of the film, respectively. The line shown connecting points D and F is the locus the optical results would take if the process involved uniform growth of a higher oxide film to a thickness of 180Å at the ex-

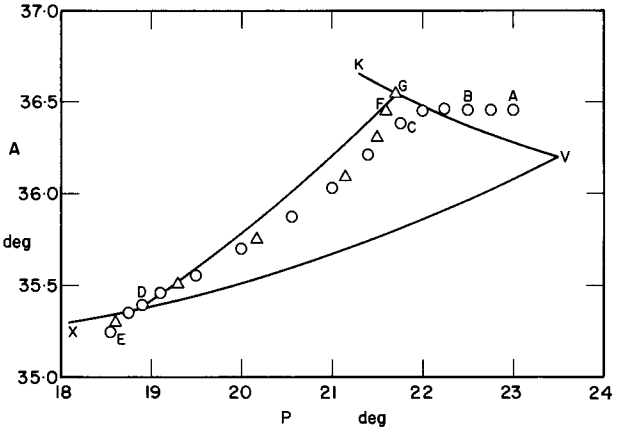

Fig. 3. Optical data from Fig. 1 fitted to the theoretical curves from Fig. 2. G-D is the curve traced out if 180Å of hydroxide are converted to 180Å of oxide.

pense of a layer of hydroxide of initial thickness 180Å and zero final thickness. The experimental data in regions CD and EF fall approximately on this line, indicating that even the first oxidation-reduction cycle involves conversion between layers of nearly equal thickness. The theoretical conversion curve in Fig. 3 is not sensitive to which layer is next to the metal and which is next to the electrolyte. To try and answer this question it is necessary to consider the conversion of a thicker film.

Figure 4 is a plot of the optical data recorded during the oxidation-reduction cycle whose end points are plotted at H and W in Fig. 2. The cycle begins at H with 800Å of hydroxide on the surface, and the data trace out H-C-W on oxidation at 40 μA/cm^2. The thickness of the oxidized film at point W is 730Å. The data trace out W-R-H on reduction at 40 μA/cm^2 to hydrogen evolution. The curves plotted in Fig. 4 are the theoretical loci expected for two models of the conversion process. Curve H-S-W results from a process in which the conversion is initiated at the film-electrolyte interface and proceeds by sweeping the boundary between the oxidized and reduced component layers across the film toward the metal surface. Curve H-B-W results from a similar process initiated at the metal surface and proceeding outward toward the electrolyte.

The data in Fig. 4 fit neither of the plotted processes very closely. Both the oxidation and reduction data exhibit a curvature similar to curve H-B-W over most of the conversion region. The only segment of the data at all similar to curve H-S-W is the final segment of the reduction data. The curvature in the data appears to favor a model for the conversion process which places the hydroxide layer next to the electrolyte and the oxidized layer next to the metal, with the interface between them moving toward the electrolyte on oxidation and toward the metal on reduction. If the data are interpreted as supporting this model, two reasons can be advanced for their poor fit to the model: the presence of a third component not treated in the analysis, and nonuniform progress of the conversion process.

The design of the ellipsometer enables it to detect certain types of nonuniformity in surface films. The stepping-motor drive units produce mechanical vibrations which cannot be damped completely. The vibrations pose no serious problem when uniform films are studied, but with nonuniform films the photomultiplier signal at null has a microphonic component. The recorded data show no evidence of this, but the operator is very conscious of the microphonic signal, having to set the photomultiplier gain and level detector hysteresis to take account of it. The photomultiplier output has a microphonic component across the middle of the conversion regions in Fig. 4, but not at the end

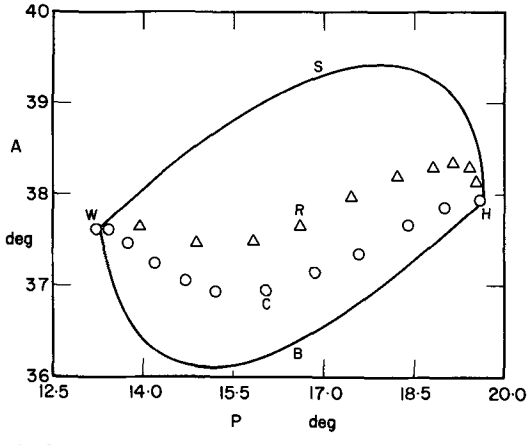

Fig. 4. Conversion of an 800Å film of hydroxide on oxidation (H-C-W, circles) and reduction (W-R-H, triangles) in 5N KOH. The curves represent conversion processes with the higher oxide under (H-B-W) or on top of (H-S-W) the hydroxide film.

points, indicating that during the conversion the surface film is not made up of two component layers of uniform thickness. If the process does not proceed uniformly, no theoretical curve can be calculated for the process, and any conclusions drawn from data obtained during conversion are open to question.

One might expect the oxidation of an anodic oxide film to a higher oxidation state to begin at the interface with the electrolyte, the source of the extra oxygen required. In our experiments we start with a film of hydroxide which can be oxidized without the addition of oxygen from the electrolyte. The hydrogen ions which are also products of the oxidation reaction are thought to migrate to the electrolyte by a diffusion-limited process (1, 5). If this model is valid for the conversion process the oxidation of the hydroxide layer would start at the metal surface and proceed outward toward the electrolyte as the hydrogen ions diffuse out of the film. The interpretation of the data in Fig. 4 as favoring a model with the hydroxide next to the electrolyte and the higher oxide next to the metal, although open to some question, does support a model of this type for the conversion process.

Very similar results to those presented in Fig. 2 were found on applying the same growth procedure to a nickel electrode in 0.2N KOH. This was taken as indicating that the same oxidized and reduced forms occur in this solution as occur in 5N KOH.

Bode *et al.* (3) have shown that nickel hydroxide exists in two forms designated α and β. They state that the α-hydroxide converts into the β-hydroxide on standing in strong KOH solution. In order to determine whether the reduced form of the layer produced in the experiments described above was of the α- or β-form, we next studied the deposition of α-nickel hydroxide films from solutions of nickel nitrate.

The optical data on the growth of α-nickel hydroxide obtained during cathodic deposition at 100 μA/cm^2 are presented in Fig. 5. The film growth starts from point A and traces out the loop A-B-C-D-E as the layer thickens. At point E the optical data have almost returned to the initial conditions, behavior characteristic of a real-index film. Such a film, if grown uniformly, gives cycles of optical data which retrace the initial loop. The data in Fig. 5 retrace the first cycle except at high values of P. We attribute the failure to retrace at high P-values to nonuniformity in the deposition, and fit the data to the curve in the figure for the growth of a film of index 1.52-0.0i. This curve fits the data well up to a thickness of about 1500Å (point C). Each optical cycle represents the deposition of over 3300Å of a film of this index, and we feel that our assumption of film nonuniformity on the second and third cycles is reasonable.

The index of the hydroxide determined in the above experiment is higher than that which we found for the

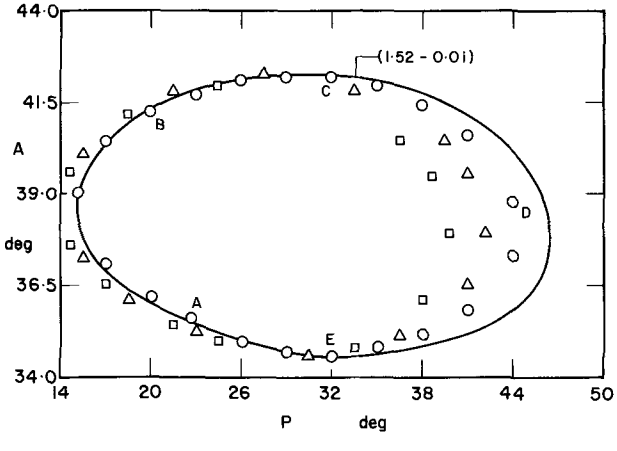

Fig. 5. Three cycles (circles, then triangles, then squares) of optical data on the cathodic deposition of nickel hydroxide onto a nickel substrate from a nickel nitrate solution.

reduced form produced in KOH solutions. This result and the work of Bode *et al.* (3) and MacArthur (5) lead us to assume that the reduced form produced in KOH solution may be identified with the β-hydroxide.

MacArthur (5) has shown that it is possible to oxidize the α-hydroxide to a species called γ-NiOOH in KOH solution, but that repeated cycling between the oxidized and reduced forms is not possible due to the conversion of the α-hydroxide to the β-form. Figure 6 presents the results of an experiment to determine the optical changes that occur on oxidizing α-$Ni(OH)_2$ in 5*N* KOH solution. The small loop A-B-C shows the optical results obtained during the cathodic deposition of approximately 3200Å of α-$Ni(OH)_2$ on the nickel electrode. This curve is shown fitted to the growth of a layer of index 1.52-0.0*i* on a substrate of index 2.12-4.02*i*. The solution of nickel nitrate was then drained from the cell and replaced by a 5*N* KOH solution, without altering the optical alignment of the electrode. On anodic oxidation of the deposited hydroxide at 40 $\mu A/cm^2$ in the KOH solution the optical results trace out the curve D-E-F. Approximately the same path is retraced in the direction F-E-D on reduction of the layer back to the hydroxide form.

Results of experiments similar to that plotted in Fig. 6 but starting with different thicknesses of $Ni(OH)_2$ deposited on the electrode give different values for the refractive index of γ-NiOOH. The real components fall in the range from 1.5 to 2.1 and the imaginary components are all quite significant ranging between 0.4 and 0.8. The variation in the refractive index indicates that the oxidized form is not a homogeneous layer of γ-NiOOH.

The curve D-E-F proved impossible to fit using any relatively simple theoretical model that could describe the conversion process. Following MacArthur (5) and Bode *et al.* (3) we assumed that the conversion is probably from the α-$Ni(OH)_2$ form to γ-NiOOH. Using this model we attempted to fit the observed optical data assuming a two-layer model and allowing uniform conversion of the hydroxide of index 1.52-0.0*i* to the oxidized form both by the formation of an absorbing film on top of and underneath the existing hydroxide. No choice of the thickness conversion ratio for the two forms allows the experimental data to be fitted with this model. In addition, a model assuming that the whole layer converts uniformly from an index corresponding to that of the hydroxide to that of the oxidized form cannot fit the data.

In view of the difficulties described above in determining the refractive index of γ-NiOOH, an alternative method of growing this phase was sought in the hope that this might help determine its optical properties with greater certainty. Guided by the results of experiments we have carried out on nickel electrodes in solutions of different *p*H, we chose a 0.1M sodium borate solution for an attempt at growing γ-NiOOH.

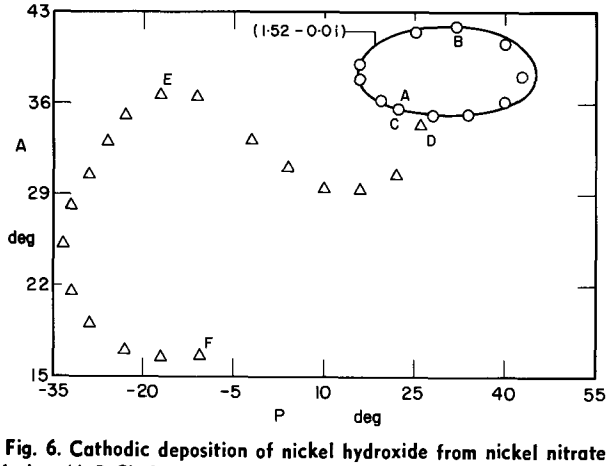

Fig. 6. Cathodic deposition of nickel hydroxide from nickel nitrate solution (A-B-C) followed by anodic oxidation (D-E-F) at 40 $\mu A/cm^2$ in 5*N* KOH.

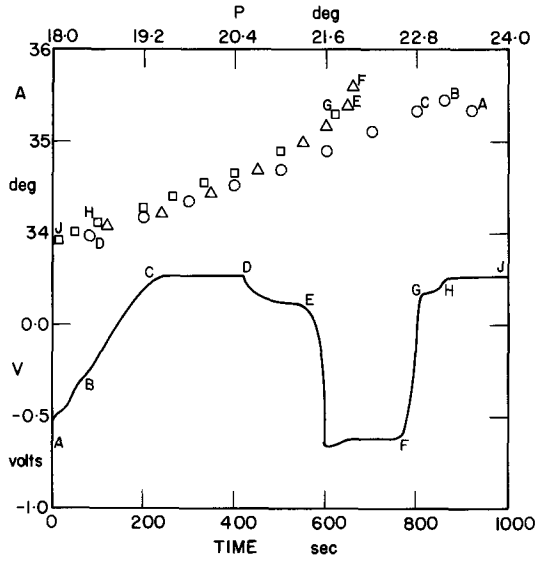

Fig. 7. Anodic oxidation (A-B-C-D, circles), reduction (D-E-F, triangles), and reoxidation (F-G-H-J, squares) of nickel at 20 $\mu A/cm^2$ in 0.1M sodium borate.

The optical and electrical results obtained on oxidizing, at 20 $\mu A/cm^2$, reducing at the same current density and reoxidizing a nickel electrode in 0.1M sodium borate are presented in Fig. 7. The optical results are presented in the upper portion of the figure and the potential-time results in the lower section. The results trace out the curve A-B-C-D on oxidation, D-E-F on reduction, and F-G-H-J on reoxidation. Unlike the oxidation of nickel in 5*N* KOH solution (Fig. 1) there is no evidence of a conversion plateau in the potential-time plot on the first oxidation cycle. The plateau is seen to appear on the first reduction and second oxidation cycles. The lack of a plateau in the potential-time plot for the first oxidation cycle suggests that little $Ni(OH)_2$ forms on the surface in the region A-B-C. In the region C-D a considerable optical change is observed presumably due to the direct formation of an oxide of nickel. On reduction it appears that the oxide is reduced to what is probably a hydroxide. Prolonged reduction does not return the optical results to point A (the "bare" substrate starting point) and it must be concluded that some nonreducible layer remains on the electrode. The second oxidation traces out the curve F-G-H-J and little optical change is observed until point G is reached. A rapid optical change is observed in the region G-H followed by a slower change from H to point J. If anodic polarization is continued after point J optical changes are still observed; these continue for many hours.

Prolonged oxidation of nickel in the sodium borate solution results in the formation of a black film covering the surface. Figure 8 presents the results of an optical experiment on the formation of the thick film by prolonged oxidation. In addition to determining the locus of the optical results for the oxidized film, we reduced the film at intervals during the oxidation to determine the optical properties of the reduced form of this oxide. The curve A-B-C-D in Fig. 8 shows the results obtained for the oxidized species formed in sodium borate, and the curve A-E-F shows the results for the reduced layer. The reduced form is fitted to the growth of a film of index 1.52-0.0*i* on a substrate of index 2.14-4.02*i*. This index is identical to that determined for the film deposited onto nickel from nickel nitrate solutions, and we assume the reduced form of the layer formed in sodium borate to be α-$Ni(OH)_2$. The curve traced out by the oxidized form produced in this solution cannot be fitted to the growth of a uniform layer of constant refractive index. This oxidized layer exhibits optical behavior similar to that of the

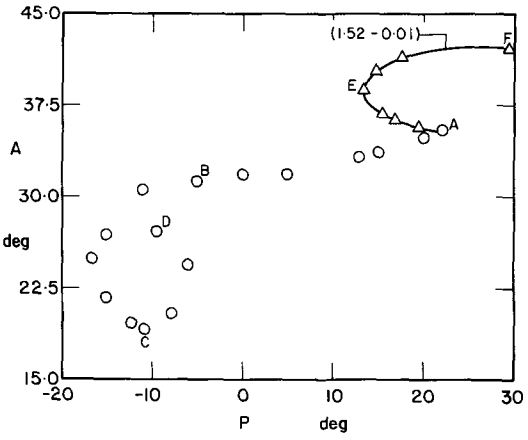

Fig. 8. Optical data on the growth of a thick film (circles for the oxidized form, triangles for the reduced form) produced by extended oxidation of nickel at 40 μA/cm^2 in 0.1M sodium borate.

layer formed by oxidation of the cathodically deposited α-Ni(OH)$_2$, and, although a definite value cannot be determined for the refractive index in either case, we conclude that both films are inhomogeneous layers made up mainly of γ-NiOOH. Curve A-B-C-D in Fig. 8 is produced by the growth of the γ-NiOOH layer in borate electrolyte whereas curve D-E-F in Fig. 6 is produced by conversion of deposited α-Ni(OH)$_2$ to γ-NiOOH.

Conclusions

Using ellipsometric measurements we have shown that two different forms of Ni(OH)$_2$ may be grown on a nickel substrate under appropriate conditions. The α-form, of refractive index 1.52-0.0i, may be grown by cathodic deposition from solutions of nickel nitrate or by reduction of the film produced by prolonged oxidation of a nickel electrode in sodium borate solution. The β-form, of refractive index 1.46-0.0i, may be produced by direct oxidation and reduction of a nickel electrode in concentrated solutions of KOH.

On anodic oxidation the two forms of nickel hydroxide are converted into absorbing films with different refractive indices. The α-Ni(OH)$_2$ converts to an inhomogeneous film which absorbs light strongly, but whose index we are unable to determine. We assume that this layer is composed mainly of γ-NiOOH. The β-Ni(OH)$_2$ converts to a layer of refractive index 1.6-0.11$7i$ which we assume to be β-NiOOH. During conversion of the β-Ni(OH)$_2$ the optical analysis is complicated by nonuniformity in the thicknesses of the component layers, but the data generally favor a model with the β-Ni(OH)$_2$ next to the electrolyte and the β-NiOOH next to the metal.

Our conclusions differ from those reached by Chernykh and Yakovleva (12, 13) in a study of the potentiostatic oxidation of nickel in 2N KOH carried out using a conventional ellipsometer with light of wavelength 5461Å. A comparison of our work with theirs illustrates the problems involved in interpreting thin-film ellipsometric data. They follow the approach which Bockris, Reddy, and Rao (9) used in interpreting optical data obtained in acid electrolyte. In this approach, the surface is assumed to be covered by a single layer whose thickness, real index component, and imaginary index component can all vary with potential. They assume an unspecified value between 2.8 and 3.3 for the real component of the index of the layer formed in 2N KOH, and conclude that (*i*) the layer thickness increases considerably as the potential is raised, and (*ii*) the imaginary index component first decreases then increases due to a change in the nature of the conductivity as the potential is raised. In our analysis of thin-film data, we use refractive index values determined from measurements on thicker films and find that the data fit a process in which one layer converts to another of approximately the same thickness.

Passivity and Pitting of Al, Ni, Ti, and Stainless Steel in $CH_3OH + H_2SO_4$

Florian Mansfeld*

North American Rockwell Science Center, Thousand Oaks, California 91360

ABSTRACT

The polarization behavior of Ti and Ti alloys, Ni, Al 6061, stainless steel Type 304, Fe, Cu, and Pt has been studied in methanolic solutions containing sulfuric acid. As in solutions of $CH_3OH + HCl + H_2O$, pitting occurs on Ti alloys in solutions of H_2SO_4 in CH_3OH. Addition of 1% H_2O to 0.1*N* H_2SO_4 in CH_3OH leads to a broad region of passivation. Addition of 1% H_2O to 0.1*N* H_2SO_4 in CH_3OH does not effect the polarization curves of nickel in the cathodic region and the region of active dissolution. The water addition leads, however, to passivation on further anodic polarization. Pitting is observed after polarization in the transpassive region. Iron cannot be made passive in 0.1*N* H_2SO_4 in CH_3OH with additions of up to 10% H_2O. Stainless steel is readily passivated in 0.1*N* H_2SO_4 in CH_3OH without addition of water, but pitting is observed after polarization in the transpassive region. Al 6061 suffers from severe pitting when polarized anodically in 0.1*N* H_2SO_4 in CH_3OH free of water additions. Copper shows no active-passive transition in CH_3OH-H_2SO_4 solutions. Experiments with Pt show that methanol is decomposed at potentials higher than +1.0V *vs.* SCE. Contrary to susceptibility in aqueous solutions containing halides, Ti is more susceptible to pitting in CH_3OH containing H_2SO_4 than Al 6061, Ni, and stainless steel 304.

In a previous paper (1), it was shown that water plays a crucial role in determining whether titanium can become passive in solutions of CH_3OH and HCl. In anhydrous solutions Ti could not be passivated even upon anodic polarization. Upon addition of small amounts of water, passivity was observed but pitting occurred at potentials only slightly noble to the corrosion potential. With increasing water content, the pitting potential became more noble. It has also been shown elsewhere that water has a pronounced effect on the stress corrosion cracking (SCC) behavior of Ti alloys (2). Depending on the stress level and the resulting type of failure, water can increase or decrease the rate of crack propagation (3).

The studies concerning the anodic behavior of Ti alloys have now been extended to methanolic solutions containing sulfuric acid. These solutions are of particular interest, since it was shown by Mori and co-workers (4) that SCC of Ti occurs in methanol solutions containing HCl or H_2SO_4. On the other hand, it is usually believed that chloride ions but not sulfate ions cause SCC and a patent has been issued (5) which describes inhibition of SCC of Ti alloys by adding oxyanions such as sulfate to aqueous or methanolic solutions containing chlorides. Studies of passivation characteristics in these solutions are also of interest, since they might indicate whether the oxygen used to form the passive film comes from the sulfate ion as suggested by Evans (6) or from the water molecule.

Since initial experiments with Ti in 0.1*N* H_2SO_4 in CH_3OH provided some rather unusual results, additional experiments were carried out with Ni, Fe, Cu, Al 6061, and stainless steel 304. The results of these investigations are reported in this paper.

Experimental

Unlike the case of methanolic solutions containing HCl, anhydrous solutions of $CH_3OH + H_2SO_4$ cannot be prepared. The solution of 0.1*N* H_2SO_4 in CH_3OH used for most tests contains only 0.04% H_2O, while a solution of 1.0*N* H_2SO_4 in CH_3OH contains 0.4% H_2O as determined by Karl Fischer titration.

Potentiostatic polarization curves were obtained by increasing the potential stepwise every 30 sec in 10, 20, or 40 mV increments; the step height depending on the rate of the anodic or cathodic reaction. In most experiments a cathodic polarization curve was recorded first, the potential was then made more positive, and an anodic curve was recorded. Solutions were either air saturated (but unstirred) or deaerated and stirred by argon. All potentials were measured *vs.* SCE, which was positioned in a separate compartment to avoid contamination of the electrolyte by chloride ions or water. A Luggin capillary was used to minimize the *iR*-drop. After each experiment the electrodes, which were in the form of cylinders, were examined in an optical microscope.

Results

Titanium and Ti alloys.—Polarization curves were obtained for pure Ti (iodide), Ti-75A, and Ti-6Al-4V. No significant differences in the polarization behavior were observed for different alloy compositions. Figure 1 shows polarization curves for pure Ti in 0.1*N* H_2SO_4 in CH_3OH. In the absence of water starting from the corrosion potential, a cathodic polarization curve has been obtained with a Tafel slope of $b_c \approx 0.09$V. This cathodic polarization apparently resulted in reduction of the surface oxide and a lowering of the hydro-

gen overvoltage as can be seen from the cathodic curve obtained on shifting the potential in the more noble direction. This effect might also result from formation of Ti hydrides which are assumed to have a hydrogen overvoltage lower than oxide covered Ti (16). On the anodic branch of the curve, a short region of passivity can be detected, at about −0.24V *vs.* SCE a sharp increase of the current occurs. Examination of the electrode after the experiment showed that localized attack in the form of pitting had occurred (Fig. 2).

When 1% of water was added to the test solution, the Ti electrode apparently was in the passive state. The anodic current remained small and constant up to about +0.7V (Fig. 1). At higher potentials the current increased steadily, but not as sharply as in water free solutions. These findings are similar to those reported for CH_3OH + HCl (1).

Nickel.—Figure 3 shows the effect of water on the polarization behavior of pure nickel (99.9%) in 0.1*N* H_2SO_4 in CH_3OH. The cathodic branches and the anodic branches of the polarization curves were identical up to +0.2V for solutions with 1% H_2O and without added H_2O. A decrease of the current was observed upon further anodic polarization indicating passivation in the solution containing added water, while only a very small decrease of the current was observed at +0.35V in solutions where no water had been intentionally added. These results show that water has no influence on the kinetics of the hydrogen evolution reaction

(HER) and on active dissolution. The water plays, however, a decisive role in passivation. Figure 4 shows the effect of H_2SO_4 concentration in methanol. While an increase in acid concentration leads to an increase in the critical current density (C.D.) for passivation, it also leads to a decrease of the passive C.D. The latter effect most likely results from the higher water content inherent in the solution of 2*N* H_2SO_4 in CH_3OH. Pitting of the electrode was observed after the anodic polarization experiments in 2*N* H_2SO_4 in CH_3OH (Fig. 5).

Iron.—The next transition metal studied was pure iron. No passivation occurred in 0.2*N* H_2SO_4 or 2*N* H_2SO_4 in methanol up to a potential of +0.8V *vs.* SCE. The effect of water addition is different than that in the case of Ti or Ni. Additions of water up to 10% did not produce passivation upon anodic polarization, but increased the rate of anodic dissolution reaction (Fig. 6). The corrosion rate of iron in 0.1*N* H_2SO_4 in CH_3OH was very high compared to that of Ti or Ni in the same medium. Using polarization resistance measurements and extrapolation of potentiostatic polarization curves to the corrosion potential, an average corrosion C.D. of 0.32 mA/cm² was measured for iron, which corresponds to 800 mdd (mg/dm² day).

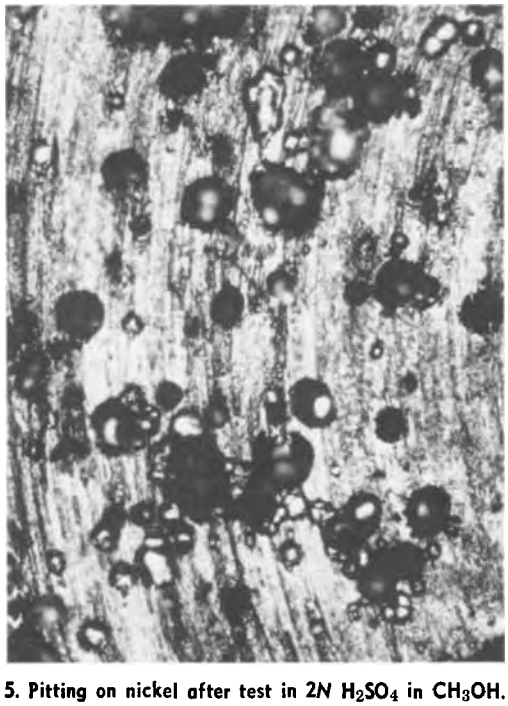

Fig. 5. Pitting on nickel after test in 2*N* H_2SO_4 in CH_3OH. Magnification approximately 180X.

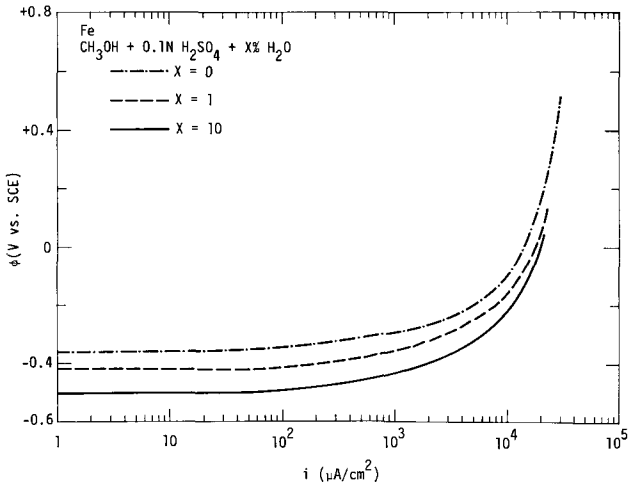

Fig. 6. Potentiostatic polarization curves for Fe in solutions of 0.2*N* H_2SO_4 + X% H_2O (X = 0, 1, or 10) in CH_3OH.

Stainless steel Type 304.—Contrary to iron, stainless steel Type 304 is readily passivated at rather low potentials in 0.1*N* H_2SO_4 (Fig. 7) or 1.0*N* H_2SO_4 in CH_3OH. The active to passive transition in Fig. 7 is only observed after cathodic reduction of the surface film formed in air or in solution. At potentials higher than +1.1V *vs.* SCE a rapid increase of the current was observed. Microscopic observation of the surface of the test specimen showed that pitting had occurred (Fig. 8a). The area around the pits appears to be attacked as shown in Fig. 8b, unlike the results for Ti, Al, and Ni.

Al 6061.—The corrosion rate of Al 6061 in 0.1*N* H_2SO_4 in CH_3OH was low (about 0.2 mdd). The potentiostatic polarization curve is shown in Fig. 9. When the specimen is polarized in the cathodic direction, the current starts to increase continuously with time at potentials more negative than −1.0V. This leads to the loop in the cathodic polarization curve shown in Fig. 9. Upon anodic polarization, the Al alloy is in the passive state up to about 0.0V when the current increases very sharply due to pitting. Gas evolution from the pits is observed under these conditions. Very large pits are observed as shown in Fig. 10. Similar results were obtained in 1.0*N* H_2SO_4 in CH_3OH. The effect of water additions has not yet been studied.

Copper.—The anodic polarization curve for Cu (Fig. 11) was similar to that observed in aqueous H_2SO_4. No active-passive transition was observed up to an applied potential of +2.0V. The anodic current at potentials more noble than about 0.0V *vs.* SCE increased when the solution was stirred by argon, indicating that the anodic process is limited by mass transport in this potential region.

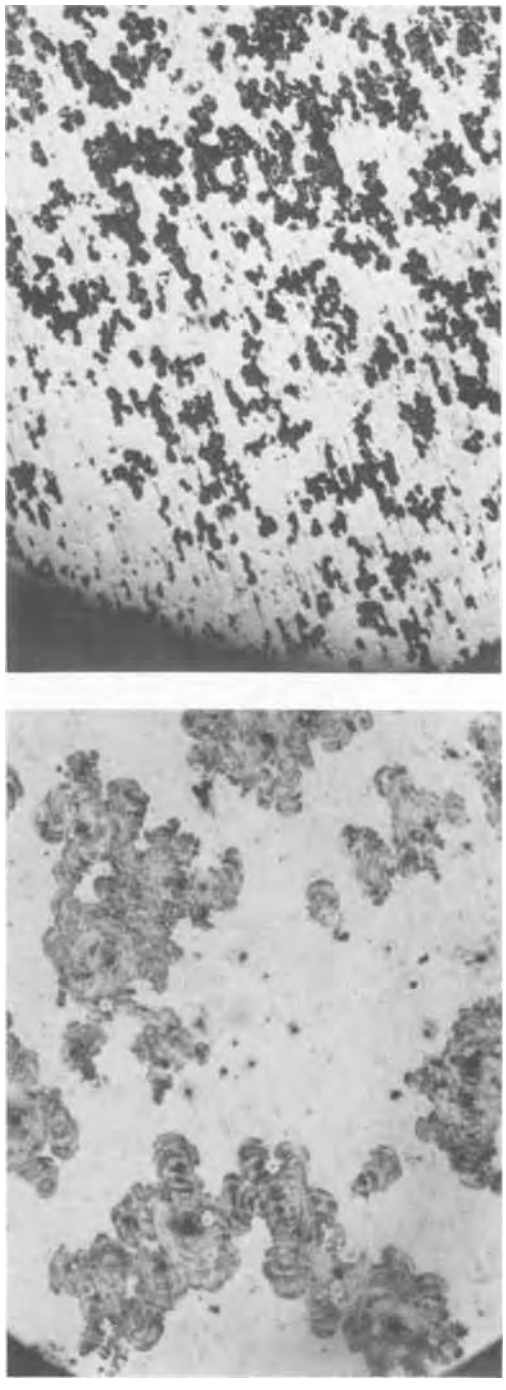

Fig. 8. Pitting on Type 304 stainless steel after anodic polarization in 0.1*N* H_2SO_4 in CH_3OH (Fig. 7). a (top). Magnification approximately 45X. b (bottom). Magnification approximately 180X.

Platinum.—Experiments on platinum were carried out in order to investigate the stability of the electrolyte. Figure 12 shows a polarization curve which was started at −0.8V *vs.* SCE. Tafel behavior with a Tafel slope of b_c = 45 mV is observed over 4 decades, the deviations at higher C.D. are most likely due to uncompensated *iR*-drops. The anodic current remains low up to about +1.0V, from where it increases continuously. This is most likely due to oxidation of methanol as also observed by Stolica on Pt in LiCl-CH_3OH-H_2O solutions (7). No oxygen evolution has been observed on Pt or any other metals studied.

Discussion

Since only potentiostatic polarization curves have been presented here, no conclusions concerning the mechanisms of the hydrogen evolution reaction, passiv-

ity, and/or pitting can be drawn. The results obtained here and in Ref. (1) have shown, however, that studies in methanol containing H_2SO_4 or HCl can result in valuable contributions toward a better understanding of basic corrosion reactions.

Effect of water.—In a recent paper (1), it has been shown that for Ti in CH_3OH + HCl the oxygen needed for the formation of the passive film comes from the water molecule. Experiments on Ti in 0.1*N* H_2SO_4 in CH_3OH (Fig. 1) show that water also has a passivating effect in these solutions. It cannot be decided unambiguously whether the small region of passivity observed in 0.1*N* H_2SO_4 in CH_3OH containing about 0.04% H_2O results from adsorption of the oxygen from the sulfate or from the water. By analogy with the results obtained in HCl-CH_3OH solutions and because of the large effect of the addition of 1% H_2O on passivity, it seems logical that the initial step in the passivation reaction on Ti is

$$Ti + H_2O \rightarrow Ti \cdot O_{ads} + 2H^+ + 2e^- \qquad [1]$$

where $Ti \cdot O_{ads}$ represents oxygen adsorbed on Ti.

The results obtained for Ni (Fig. 3) support the assumption that water is responsible for passivation. For iron, on the other hand, no passivation could be observed even with water additions of up to 10% (Fig. 6). Additions of water in fact increased the anodic dissolution current in the potential range studied. A similar behavior was found by Kiss and co-workers (8) for iron in acetic acid containing 0.5M HC_3COONa or 0.5M $HClO_4$. Additions of water in each case accelerated the rate of active dissolution. The authors concluded that in sodium acetate solutions passivation occurs only in the presence of water, while in solutions containing perchloric acid passivation occurred only in the absence of water. For stainless steel 304 it was found in the present study (Fig. 7). that very small amounts of water (about 0.04%) are sufficient for passivation. These results show that many factors determine the ability of a metal to passivate. These may include the electronic structure (14), the relative affinity to oxygen (9), and the characteristics of ion pairs formed in solution (8).

When the results for nickel and iron are compared, it becomes evident that water molecules also have a different effect on the region of active dissolution of these metals. While the rate of the anodic dissolution reaction is not affected by water in the case of nickel (Fig. 3), it increases with increasing water content in the case of iron (Fig. 6). An increase in the acid concentration apparently increases the rate of anodic dissolution of nickel and the critical C.D. for passivation (Fig. 4). In the passive region, the passivating effect of the higher water concentration is stronger

than the activating effect of the higher acid concentration in 2*N* H_2SO_4 in CH_3OH.

Pitting produced by sulfate ions.—It has been observed in this investigation that all metals which undergo passivation also suffer from localized attack in the form of pitting. This is a very surprising result since pitting is usually observed only in the presence of halides, especially chloride ions. Anions like sulfates, nitrates, perchlorates, and chromates have been shown by Uhlig and co-workers to inhibit pitting of iron (10), 18Cr-8Ni stainless steel (11), and Al (12) in aqueous solutions containing halides. Tousek (13) recently pointed out, however, that there is no apparent reason why some of these anions should not lead to pitting. It was shown (13), that under certain conditions pitting can be produced by sulfates on iron and nickel in aqueous acid solutions containing both sulfate and chloride ions. Tousek also mentions briefly that "some sort of pitting corrosion" by sulfate ions occurs in a solution of 2*N* H_2SO_4 and 2% H_2O in CH_3OH resulting in a polarization curve which is similar to that shown in Fig. 4.

Since pitting on nickel and stainless steel is observed at potentials where methanol decomposition occurs ($\phi > 1.0$V) as shown on Pt (Fig. 12), it cannot be concluded solely from the increase of the anodic current that localized attack has occurred. Microscopic observation (Fig. 5 and 8) has confirmed, however, that pitting occurred in both cases. The possibility of reaction between oxidation products of methanol (HCHO, HCOOH) and the passive film has not yet been studied.

It is quite remarkable that Ti, which is so resistant to pitting in aqueous solutions containing halides, is more susceptible to pitting than Al 6061, nickel, and stainless steel in H_2SO_4-CH_3OH. The degree of susceptibility of Ti is similar in H_2SO_4-CH_3OH and HCl-CH_3OH (1). Although this author does not believe that SCC results from a pitting-type attack, there is a striking resemblance in the susceptibility of Ti to pitting and SCC in these solvent systems. This behavior suggests that the nature of the passive film and its rate of formation is different in aqueous solutions (NaCl) and methanolic solutions containing small amounts of water. Recent results by Smith and Mansfeld (15) have shown, however, no differences of film properties in these two media, as measured by ellipsometry.

The Interpretation of Impedance Changes on Oxide-Coated Aluminum Produced by Immersion in Inhibitive and Corrosive Aqueous Media

J. A. Richardson[1] and G. C. Wood

Corrosion and Protection Centre,
University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The time dependencies of capacitance and dissipation factor, for aluminum specimens supporting air-formed or anodic films, have been measured at 10^3 Hz during immersion in near-neutral chromate, dichromate, chloride, bromide, iodide, fluoride, and sulfate solutions. Supporting observations have been made using optical microscopy and scanning and conventional electron microscopy. Behavior in chromate and dichromate solutions is interpreted in terms of the healing of "mechanical" flaws originally present in air-formed films and the thinning of anodic films down to a passive film thickness of about 25Å. Results in bromide, iodide, and especially chloride solutions are interpreted in terms of pitting by dissolution of transiently exposed metal at the bases of flaws and subsequent undermining of the surface oxide film, which plays a relatively inert role throughout the process. A quantitative model, describing the effects of pit development from flaws on measured specimen impedances, is presented. Relatively little attack occurs in sulfate solution, whereas in fluoride solution the impedance changes are consistent with rapid removal of the surface oxide film and its replacement by a complex oxyfluoride. The general degree of aggression of the anions toward oxide-coated aluminum increases in the order of dichromate, chromate, sulfate, iodide, bromide, chloride, fluoride.

Pryor and co-workers (1-5) have investigated changes in the dielectric properties of anodic alumina films, immersed in various inhibitive and corrosive media, presenting their data largely in terms of resistivity *vs.* thickness profiles. In terms of the capacitance and dissipation factor of the films, Pryor *et al* have observed the following changes in properties of 240Å barrier-type anodic films, formed in neutral tartrate solution, after exposure to near-neutral M chromate, halide, and sulfate solutions:

1. In chromate solutions the anodic films thinned uniformly down to the passive film thickness, without any evidence of preferential attack. Air-formed films thickened slightly by anodic polarization appeared to have developed crystalline oxide on the outer surface, which affected the impedance characteristics at 10^3 Hz but not at 10^5 Hz.

2. In chloride solution, substantial increases in measured dissipation factor of the films occurred at 10^3 Hz without any accompanying change in capacitance. No such changes were observed at 10^5 Hz, nor was any change in surface topography of the films revealed by electron microscopy in 25 hr.

3. In fluoride solution, immersion for periods of 10-300 min revealed substantial increases in both measured dissipation factor and capacitance at 10^3 Hz, accompanied by the growth of a gross (up to 7000Å) contaminating phase on the metal surface. This phase consisted of nonuniformly distributed crystals of an oxyfluoride.

4. In sulfate solution, little or no change in measured dissipation factor, capacitance, or surface topography occurred in 25 hr.

Pryor *et al.* (1-5) have interpreted their film-thinning in chromate results in terms of a detailed distribution of lattice defect structure through the anodic film, involving four zones. Their data in corrosive solutions have been interpreted as involving ion-exchange processes between the aggressive halide species in solution and oxide ions in the oxide lattice, resulting in the creation of an excessively n-type deficient oxide lattice, and a consequent lowering in ionic resistance of the anodic alumina. The film does not change visibly during an "induction" period while ion penetration occurs, but thereafter localized pitting in the case of chloride, or more general attack in the case of fluoride, is said to establish itself at regions of particularly low ionic resistance. Sulfate ions are not considered able to exchange with oxide ions from the lattice, and thus do not reduce the corrosion resistance of the film.

In contrast, the present paper discusses the changes in impedances of air-formed and anodic aluminas, produced upon immersion in aggressive halide solutions, in terms of a relatively simple model (6, 7) involving both penetration and lateral attack of transiently revealed metal at the bases of pre-existing flaws in the relatively inert surface oxide films. Behavior in inhibitive or less aggressive media, such as chromate and sulfate solutions, is also described in similar terms.

Experimental

Specimens of 99.99% aluminum, of at least 6 cm^2 area, were masked on the edges with Lacomit and were then prepared and coated with air-formed or 240Å anodic films (6). Electropolishing was not used as a prior treatment because of possible complications in the properties of the subsequent films (8).

Impedance-time measurements were made at 10^3 Hz only, because the effects are more pronounced at relatively low frequencies. The data are presented, uncorrected for measuring solution and double layer losses, to permit comparison with earlier results. The inhibitive or corrosive medium in question was used as the measuring electrolyte.

Data for air-formed films were obtained from triplicate specimens of area 0.193 cm^2, which were immersed individually in 80 ml of the nominally stagnant medium, contained in a covered 100 ml beaker at 25°C. A platinum counterelectrode of area 25 cm^2 was inserted into each beaker when required and the dissipation factor and capacitance were recorded. This

Key words: impedance, pitting, aluminum, halide.

approach prevented any alteration to the properties of the air-formed film by washing and drying. Impedance-time data for anodic films were obtained by immersing each of a batch of 30 identical specimens of area 6 cm^2 as for the air-formed films. At appropriate times, triplicate specimens were removed, washed in distilled water, dried, and stopped off to 0.193 cm^2 with tape. Their capacitances and dissipation factors were measured directly in a cell containing the test medium as a measuring electrolyte. Care was taken to select areas for measurement typical of the whole surface. However, for specimens in fluoride solution, measurements were made on triplicate specimens, masked with tape to 0.193 cm^2 prior to immersion as for the air-formed films, thus allowing the very rapid changes in the impedance to be followed.

When dissipation factor and capacitance are plotted as a function of time in certain of the diagrams, scatter bands are sometimes used to give the most representative results. However, the outlines of the scatter bands are themselves individual curves for specimens showing extreme behavior.

Results and Interpretation

Immersion in chromate and dichromate solutions.—Air-formed films.—The capacitance of specimens covered by air-formed films, when immersed in M sodium dichromate solution, adjusted with M chromate solution to *p*H 6.0, (Fig. 1a), or sodium chromate solution, adjusted with M dichromate solution to *p*H 7.0, (Fig. 1b), showed little or no time-dependence, beyond a slight over-all decrease after long immersion periods. Generally, the values for the *p*H 6.0 solution were perhaps slightly lower than the corresponding measurements in the *p*H 7.0 solution. The dissipation factors in both solutions (Fig. 1a and b) were initially irreproducible at about 0.15 ± 15%, exhibited a marked reduction with time, and reached reproducible limiting values of 0.085 ± 0.002 in *p*H 6.0 solution (within 10 hr) and 0.089 ± 0.002 in *p*H 7.0 solution (within 8 hr). The specimen electrode potential trends generally correlated with the dissipation factor changes.

240Å anodic films.—The capacitances and dissipation factors generally exhibited slight but reproducible increases initially in both *p*H 6.0 and 7.0 solutions (Fig. 1c and d). Thereafter, they exhibited sharp, but irreproducible, increases as the film thinned, and the metal-oxide interface was approached. The irreproducibility can be attributed to the differing thinning rates of nominally identical specimens. In the two cases where thinning appears to have proceeded to completion, (Fig. 1c and d), the final capacitance and dissipation factor values were reproducible and comparable to the limiting values obtained for the air-formed films (Fig. 1a and b). The film potential gave trends (6) consistent with the impedance changes, showing itself more sensitive than impedance in sensing changes within flaws in the original film but less sensitive to thickness changes. Replica electron microscopy of partially thinned films showed that the thinning process was not very uniform, particularly when the solution was not replenished frequently.

The measured impedances in Fig. 1c and d therefore showed an apparent dependence on film thickness as the sample thinned, which it did more rapidly in *p*H 7.0 than in *p*H 6.0 solution. However, when such data are corrected for solution and double layer losses (6), the film dissipation factors are thickness-independent.

Immersion in chloride solution.—Air-formed film.—The capacitances of all specimens carrying air-formed films, when immersed in M potassium chloride solution, adjusted to *p*H 6.0 with a few drops of 0.01M hydrochloric acid, showed a slight rise during the early stages of immersion, but remained fairly steady thereafter, displaying a slight tendency to fall in the later stages of immersion (>300 hr) (Fig. 2a). The dissipation factors of all specimens were virtually invariant with time of immersion (Fig. 2a).

The pits visible optically on all specimens, after about 500 hr immersion, were relatively few in number (<1/cm^2), and were relatively small. The pits often showed a definite tendency to be associated with scratch lines in the metal surface. The pits showed no systematic preference for the edges of the specimen. Specimens were not removed for examination during the runs, so it is difficult to say when the pits first appeared.

Anodic film.—The capacitances and dissipation factors of the corresponding specimens with 240Å anodic films were identical to those measured in chromate and dichromate solutions initially (Fig. 2b). After more than 25 hr immersion the impedances were strongly

dependent on the degree of breakdown of the surface, and thus on the particular specimen area selected for measurement. Three general types of behavior could be discerned:

1. Specimens without optically visible signs of breakdown generally exhibited virtually identical capacitances and dissipation factors as the as-formed films. Occasionally, however, such a specimen was found to exhibit a slight increase in capacitance, accompanied by a disproportionately larger increase in dissipation factor than that expected from film thinning.

2. Specimens with slight, but visible, signs of breakdown exhibited increases in capacitance, accompanied by disproportionately large increases in dissipation factor.

3. Specimens with relatively severe breakdown (*i.e.*, many pits) showed capacitances and dissipation factors similar to those observed for specimens carrying air-formed films, immersed in potassium chloride solution at pH 6.0.

Referring generally again to Fig. 2b, the initial film breakdown was therefore reflected, if at all, in substantial increases in dissipation factor, with relatively slight increases in capacitance. Thereafter, as breakdown proceeded, the dissipation factors continued to increase toward a value characteristic of the corrosion-affected air-formed film, and breakdown progressively affected the capacitances of the specimens more. Eventually, the capacitance increases "caught up" the increases in dissipation factor, and the net impedance after 500 hr was characteristic of a corrosion-affected, air-formed film for all specimens. For periods up to 80 hr, even though by now all specimens showed signs of breakdown somewhere on their surface, areas of surfaces could be selected for impedance measurements with identical dielectric properties to the as-formed films.

The present results differ from the previous short-term (up to about 17 hr) results of Pryor and co-workers (1-4) on three counts:

(*a*) The impedances of specimens remained unaffected for immersion periods less than 25 hr.

(*b*) Where effects were observed, no specimen underwent the impedance change described by Pryor *et al.*, namely a substantial increase in dissipation factor without any corresponding change in capacitance. Some specimens did, however, almost show this behavior, displaying a substantial increase in dissipation factor accompanied by only slight increases in capacitance.

(*c*) The implication of Pryor *et al.* that immersion in neutral chloride solution causes continuous, and relatively reproducible, increases in the dissipation factors of anodic films contrasts sharply with the present findings. Here, the impedance changes were erratic, grossly irreproducible, and dependent on the test area selected.

All specimens were quite heavily pitted after 500 hr immersion and indeed pits were optically visible on many specimens after more than 33 hr. It is virtually impossible to assess the visible pit density after 500 hr, owing to the great variation from specimen to specimen, and indeed from area to area, on any particular specimen. Generally, more pits were visible on anodized specimens than on specimens carrying air-formed films, although the pits tended to be smaller and showed less preferential association with either scratch lines or specimen edges (7).

Immersion in bromide and iodide solutions.—Air-formed film.—In potassium bromide solution, with pH adjusted to 6.0 with a few drops of 0.01M potassium hydroxide solution, the capacitance, after an initial slight rise, dropped to about 2-2.5 μF/cm^2 over 500 hr, while the dissipation factor remained virtually constant (Fig. 3a). After 500 hr the specimens showed only slight signs of pitting, relative to the chloride-treated specimens. Typically, a central "pit" was surrounded by a "ring" of mounds of corrosion product, which were probably hydrated alumina and below which small pits probably resided. Also, the center surface around the corroded region was covered by a thin film of hydrated alumina, giving rise to interference colors when viewed optically, probably explaining the observed time-dependence of impedance. A fall in capacitance without corresponding change in dissipation factor indicated either over-all film thickening, via some type of field-induced "electrorecrystallization" mechanism, or more likely localized film thickening, resulting from hydrolysis and precipitation of initially soluble corrosion products. Thus, the results for bromide solutions suggest that pitting was much slower than in chloride solutions.

In potassium iodide solution with pH adjusted to 6.0 with a few drops of hydriodic acid (Fig. 3b), the capacitance showed a distinct rise to about 5.5-6.5 μF/cm^2 over 500 hr, with the dissipation factor remaining relatively constant. From the outset, the specimens showed signs of localized brown staining, with the stain "nuclei" developing laterally with time into extensive stained patches. Over-all, the surfaces appeared to suffer general corrosion rather than pitting, consistent with the previous work of Pryor (9). The stains were obviously due to free iodine, and indeed the bulk solution changed color from colorless to straw-yellow over the 500-hr period, so invalidating any direct comparison with the chloride and bromide results. Mounds of hydrated alumina corrosion product were again evident, beneath which were probably pits. The surface appeared to be coated generally with a film of corrosion product, within which cracks and holes were evident. The marked increase in capacitance without any notable increase in dissipation factor points to an increase in real area of the specimen during immersion, as a result of "general" rather than "localized" corrosion.

Anodic film.—During 300 hr in bromide solution, little if any change in the capacitances was evident, except for a slight rise if a pitted area was selected for measurement (Fig. 3c). The dissipation factor, however, tended to rise to values typical of the corrosion-affected, air-formed film after about 25 hr. Indeed, in bromide solutions impedance changes of the Pryor type (1-4) in chloride solutions were evident, namely a distinct rise in dissipation factor without any corre-

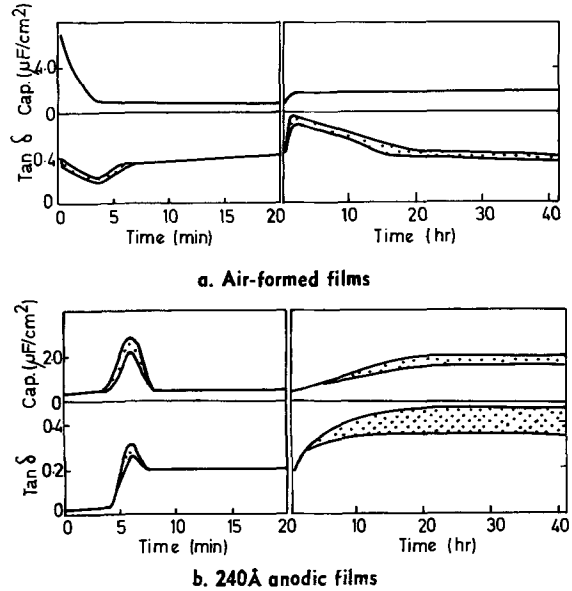
sponding change in capacitance. After 500 hr the specimens were only slightly pitted relative to chloride-treated specimens, and the corrosion was similar to that on surfaces supporting air-formed films.

Capacitance and dissipation factor measurements in iodide were highly dependent on the area selected for measurement. Little iodine staining was evident before about 50-hr immersion, when little or no change in capacitance and only slight increases in dissipation factor were evident. Thereafter, however, as the staining increased, areas of high capacitance and dissipation factor (over stained regions), or low capacitance and dissipation factor (over intact film), could be selected. Even after 500 hr certain areas showed little, if any, impedance change. As with air-formed films, the iodine staining phenomenon commenced at incipient points on the surfaces and spread laterally, rather than in depth. The morphology of attack was much the same as for air-formed films.

Immersion in fluoride solution.—Air-formed film.— Rapid rises in both capacitance and dissipation factor were observed from the very point of immersion in M potassium fluoride solution at pH 8.5 which proved difficult to follow accurately on the a-c bridge. A reliable balance was not possible until after about 30 sec had elapsed, by which time the capacitance and dissipation factor values (Fig. 4a), were both high relative to values for specimens supporting air-formed films in other solutions. Subsequently, both showed drops to minima after 3-4 min. The minimum capacitance value corresponded to an anodic oxide film thickness of about 70Å, although the corresponding measured dissipation factor was much higher than expected for such a film. After about 3-4 min immersion, both the capacitance and particularly the dissipation factor values showed a distinct rise. The dissipation factor gave a maximum of 0.7-0.8 after about 100 min, showing a gradual decline to 0.4 thereafter, during a period of relatively constant capacitance. Corresponding potential measurements (10) exhibited an initial active surge (corresponding to the high capacitance and dissipation factor values), followed by a surge in the noble direction (corresponding to the minimum in capacitance and dissipation factor) before steadying out. Thereafter, the potential tended to move slightly in the active direction.

Replica electron microscopy suggested that, immediately after immersion, a crystalline "film" nucleated at discrete sites, growing in thickness and laterally until, after about 10 min, the entire surface was covered. At this stage, changes in surface morphology were not visible optically. After about 100 min, relatively gross areas of white, flocculent corrosion product appeared on the specimen surfaces, tending to mask the crystalline order of the film beneath. These gradually thickened and spread until, after 40 hr, relatively gross corrosion had obviously occurred.

Anodic film.—Both capacitance and dissipation factor values measured immediately after immersion in fluoride solution agreed very closely with the corresponding values measured in chromate or other halide solutions (Fig. 4b). Thereafter, both parameters showed an ever-rising rate of increase to maximum values, coincident in time with an active peak in corrosion potential (10), after about 6-7 min immersion. As with



a. Air-formed films

b. 240Å anodic films

Fig. 4. Capacitance and dissipation factor as a function of time in potassium fluoride solution, pH 8.5.

the corrosion potential, the time dependencies of both capacitance and dissipation factor beyond 6-7 min were similar to those for surfaces originally supporting air-formed films, excepting the absence of a peak in the time-dependence of dissipation factor for the surface supporting a 240Å anodic film originally.

Replica electron microscopy and visual observation confirmed similar morphological changes on the surface to those on specimens with air-formed films, although changes perceptible to the naked eye appeared to take longer with the anodized specimens so that, even after 100 min, the "film" consisted almost exclusively of the "crystalline" material. However, the flocculent material gradually aggregated and, after 40 hr, both types of specimen appeared identical, with evidence of gross over-all corrosion.

Immersion in sulfate solution.—Air-formed film.— The capacitance and particularly the dissipation factor values both showed slight drops during the very early stages in M sodium sulfate solution with *p*H adjusted to 6.0 with a few drops of 0.01M sodium hydroxide solution, comparable to behavior in chromate and dichromate solutions (Fig. 1a and b). Both parameters then showed little or no time-dependence throughout a 50-hr immersion period. Subsequently, some general corrosion did occur but this was accompanied by complicated microbiological effects. No changes in the specimens were evident visually or by electron microscopy up to 50 hr. The relative insolubility of sodium fluoride and potassium sulfate in water precluded the use of salts with a common cation for all the experiments.

Anodic film.—The capacitance and dissipation factor, originally at values typical of a 240Å film as initially measured in any other solution, showed little or no increase during about the first 80-hr immersion. Subsequently some more general corrosion of a complicated nature occurred.

Discussion

Impedance models for pitted electrodes.—Before discussing the effects of immersion in the various solutions on the general impedance characteristics, an impedance model is developed for a film containing flaws to cover the case where the flaws are developing into pits, propagating beneath the surface film. Consider an oxide-coated aluminum surface beneath which pits have been developing during natural immersion in an aggressive medium. The specimen is removed, washed and dried, and placed in a measuring cell to determine its impedance. It is assumed in Fig. 5a and the corresponding equivalent circuit in Fig. 5b that the typical pit exhibits crystallographic morphology, that the surface oxide film over its mouth remains intact apart from the original flaw beneath which propagation has occurred, and that, after removal and drying, the pit surface is covered by an air-formed or passive alumina film, 25Å thick (7).

The impedance change produced by immersion in the aggressive medium can be relatively easily calculated. In what follows, it is important to distinguish measured impedance data from corrected data, *i.e.*, measured data to which corrections for solution and double layer losses have been applied. The following corrected data (6) have assumed for the alumina film on the pit surface; C_s (pit) = 3.0 μF/cm^2, R_s (pit) = 4.6 ohm · cm^2, R_p (pit) = 600 ohm · cm^2, and tan δ (pit) = 0.088. It is assumed that the data obtained at 10^5 Hz for a platinum electrode in the measuring solution (6) provide the best available estimate of R_s (flaw), *i.e.*, the resistance of the solution within the flaw, when suitably corrected for the flaw length and area. These data have been treated as follows to provide a predicted measured value of the impedance of a pitted surface, carrying a 240Å film:

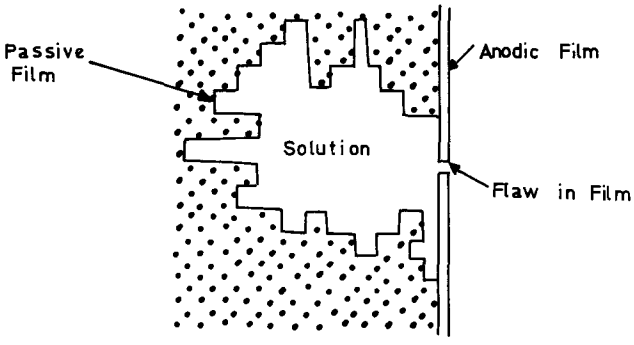


Fig. 5a. Section of model of pit used in impedance calculations

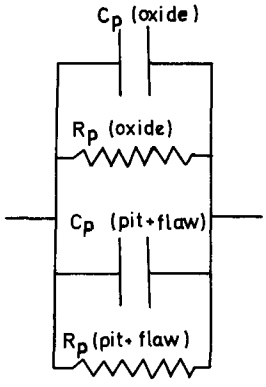

Fig. 5b. Equivalent circuit for pit model shown in Fig. 5a.

1. The value of R_s (pit) is added to R_s (flaw) to give an R_s (pit + flaw) value.

2. From R_s (pit + flaw) and C_s (pit) for the pit surface, a value of tan δ (pit + flaw) can be calculated from the relationship

$$\tan \delta = \frac{1}{\omega R_p C_p} = \omega C_s R_s \qquad [1]$$

3. Corresponding C_p (pit + flaw) and R_p (pit + flaw) values are calculated using the equations

$$\frac{C_p}{C_s} = \frac{1}{1 + \tan^2 \delta} \qquad [2]$$

and

$$\frac{R_p}{R_s} = \frac{\tan^2 \delta + 1}{\tan^2 \delta} \qquad [3]$$

4. R_p (pit + flaw) and C_p (pit + flaw) values are then compounded with R_p (film) and C_p (film) values (*i.e.*, corrected values) for a 240Å film. Thus corrected R_p (pitted film) and C_p (pitted film) values are obtained for a 240Å film containing a pit beneath one of its flaws. From these latter values a corrected tan δ (pitted film) is calculated using relationship [1].

5. Finally the corrected parameters for the pitted film thus obtained are compounded with the R (solution) value for the measuring electrolyte between working and counterelectrodes in the measuring cell, giving predicted measured values of the impedance of the measuring cell, containing a pitted oxide electrode. Against these values the experimental data, such as Fig. 2, may be assessed.

Calculations have been performed for the following systems:

(*a*) A 240Å film containing a single pit/cm^2, variable in surface area in the range 10^{-10}-10^{-1} cm^2, beneath a single flaw, variable in surface area in the range 10^{-10}-10^{-2} cm^2. The predicted measured tan δ and capacitance values for the pitted, filmed surfaces are plotted against pit area in Fig. 6a-g. To put the data in context, an area of 10^{-10} cm^2 is the average area of a typical "residual" flaw in an anodic film (6). Some of the larger areas of flaw are included to illustrate possible effects of larger "mechanical" flaws. Also, a large pit area/flaw area ratio is quite possible in

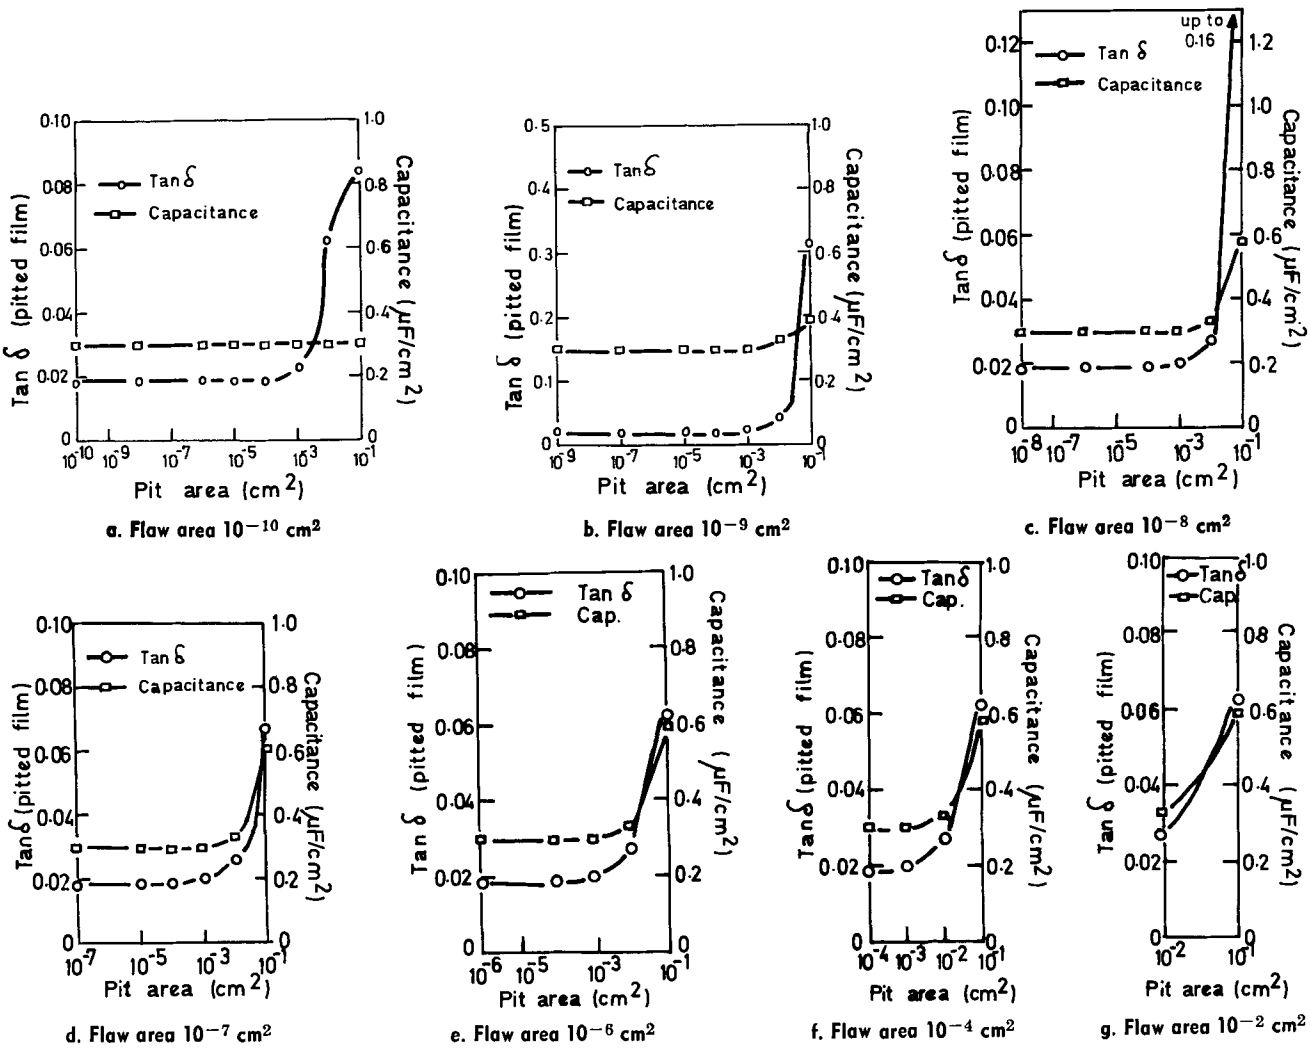

Fig. 6. Calculated effect of pit area beneath flaw on measured capacitance and dissipation factor of a 240Å anodic film

practice, particularly where crystallographic pitting and tunneling are evident.

Closer inspection of Fig. 6a-g shows that the (pit + flaw) combination functions largely as a capacitor at low pit areas (*i.e.*, its impedance resides largely at its base) but, as the pit area/flaw area ratio increases, the combination tends to a more resistive impedance (*i.e.*, the impedance is determined to a greater extent by the resistance of the flaw itself). This manifests itself by changes in tan δ rather than in capacitance. Large increases in tan δ are possible with little or no increase in capacitance occurring.

The (pit + flaw) combination functions as a low-loss capacitance at low flaw areas and as a low-loss, high valued capacitance at high flaw areas, via a medium-valued but high-loss capacitance. Thus, the degree of resistive or capacitative impedance offered by the combination is crucially dependent on the relative pit and flaw areas.

(*b*) A 240Å oxide film containing a variable number of pits/cm² of area 10^{-1} cm² beneath flaws of area 10^{-5} cm². The predicted measured tan δ and capacitance values for the pitted film surface are plotted against pit density in Fig. 7. The capacitance of the pitted film increases linearly with pit density and thus with total pit area, while the measured tan δ value rises steadily at first, leveling out at that value typical of an air-formed film. In more general terms, these calculations show the effect of varying the total area affected/cm² at a constant pit area/flaw area ratio. Thus, they apply whether the pit population density itself increases, or merely the absolute area of an individual pit or pits.

(c) The effect of having a single pit/cm² of variable area beneath a flaw of area 10^{-6} cm² in a 2000Å anodic film. The predicted measured impedance data are plotted as a function of pit area in Fig. 8. Upon comparing the results with those for a 10^{-6} cm² area flaw in a 240Å film (Fig. 6), it is clear that much larger effects are evident for a given pit area/flaw area ratio in the case of the 2000Å film. This means that the effects of a given pit are detected at an earlier stage when the anodic film is thicker.

(d) The effect of having a single pit/cm² of variable area, supporting faradaic processes, beneath a

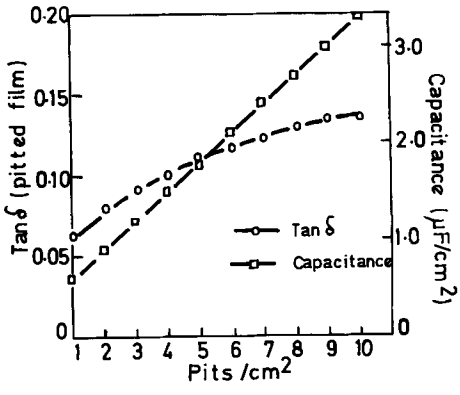

Fig. 7. Calculated effect of pit density on measured capacitance and dissipation factor of a 240Å anodic film, taking the area of the pit beneath the flaw as 10^{-1} cm² and the area of the flaw above the pit as 10^{-5} cm².

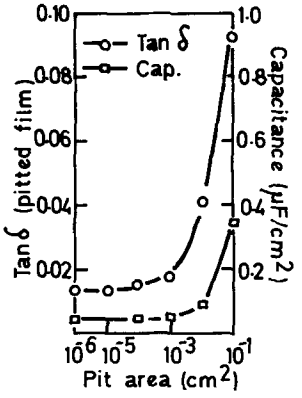

Fig. 8. Calculated effect of pit area beneath flaw, of area 10^{-6} cm², on measured capacitance and dissipation factor of a 2000Å anodic film.

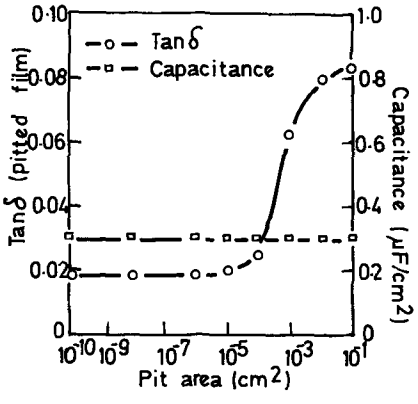
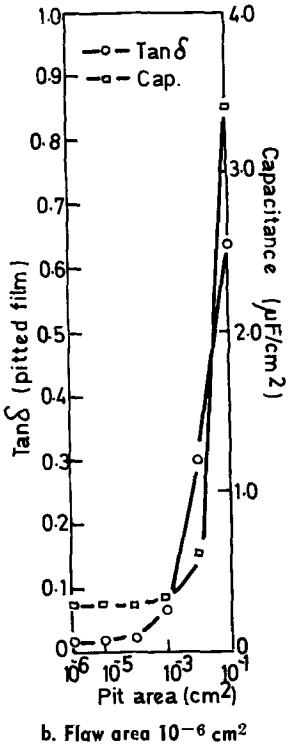
flaw of known area. Data are presented for flaw areas of 10^{-10} cm² and 10^{-6} cm² in Fig. 9a and b, respectively. The appropriate data for faradaic processes are those obtained using a platinum electrode (6).

For small flaws, much the same pattern emerges as with an oxide-coated pit, but the changes in tan δ are



a. Flaw area 10^{-10} cm²



b. Flaw area 10^{-6} cm²

Fig. 9. Calculated effect of pit area beneath flaw on measured capacitance and dissipation factor of a 240Å anodic film, for the case of flaw bases supporting faradaic processes.

evident at much lower pit area/flaw area ratios. Thus, very small pits would give a large increase in tan δ. For larger flaws, massive increases in tan δ and capacitance are observed. Such models with faradaic processes are probably not particularly realistic for aluminum samples which have been removed and dried prior to measurement, nor are they expected to cover large areas of propagating pit surfaces. They are, however, applicable where "bare" metal in pits or at flaw bases is obtained transiently as a result of crack/heal type processes, or possibly when the *p*H has dropped to a very low level in a propagating pit. They could also be more relevant for other metals whose surfaces do not repassivate or oxidize so readily, or where the passive film is removed rapidly in the measuring cell.

Immersion in chromate and dichromate solutions.— There is little doubt that in the case of anodic films, increases in capacitance without corresponding changes in corrected dissipation factor, during immersion in both solutions, resulting from film thinning. For air-formed films, however, substantial decreases in dissipation factor without corresponding changes in capacitance, during the early stages of immersion in both solutions, suggest healing of flaws, rather than film thickness changes. Significantly, the dissipation factors of thinned anodic films, and air-formed films subjected to prolonged immersion in chromate/dichromate solutions, are virtually identical. Immersion, and anodizing, would thus appear to effect the same structural changes in an air-formed film, and the most likely effect of both is considered to be a reduction in initially available flaw area. The latter is perfectly consistent with the slight reduction in capacitance of air-formed films, resulting from immersion in the chromate/dichromate solutions. As the available flaw area reduces, so also does the consequent contribution of double layer or semiconducting oxide capacitance at the flaw bases to the total measured capacitance. The available evidence (6, 11, 12) suggests that there are two types of flaws in surface films, one associated with regularly distributed residual defects in the metal surface, *e.g.*, impurity segregates, inclusions, etc., and the other with less evenly distributed, grosser defects of a more "mechanical" nature, *e.g.*, scratches, rough areas of surface, step edges, etc. Air-formed films contain many more mechanical flaws than anodic films, although all films contain "residual" flaws, the density of which is less dependent on the nature or thickness of the surface film. It is considered that the impedance changes suffered by air-formed films during the early stages of exposure in chromate or dichromate solutions are associated with the healing of largely mechanical flaws.

The mechanical flaws are not persistent bare metal but rather occur by crack-heal type processes upon immersion of the filmed sample. Healing occurs by passivation of the bare metal and partial plugging of the mechanical flaws with alumina. Eventually less crack/heal events occur as stress is relieved. The impure oxides at the bases of residual flaws, although healed by contact with chromate or dichromate solutions, remain largely semi-conducting in character and act as cathodes initially in any electrochemical reactions, although they can in time become sites for corrosion too. There are, of course, a complete range of flaws, incorporating features of the basic mechanical and residual types, giving a complete spectrum of behavior with respect to healing in chromate solution or corrosion in halide solutions. Throughout any sequence of events, the oxide covering the main surface of the electrode, between the flaws, is considered to play a relatively inert role, functioning largely as an insulator (7). This is particularly true for anodic films but would also apply to any films produced by overall thickening of air-formed films in the corrosive solution.

Heine and Pryor (5) thickened the passive film on aluminum to around 40Å by anodizing in chromate solution and then obtained resistivity profiles through the thickened film at 10^3 and 10^5 Hz by making impedance measurements during thinning in chromate solution, pH 7.0. Their measurements indicated that the outer regions of the thickened film exhibit a higher resistance at 10^5 Hz than a thermal film of the same thickness but a remarkably lower resistance at 10^3 Hz. Following the theory of their earlier papers (2-5) they attributed the low "ionic" resistance of the thickened passive film at 10^3 Hz to the formation of crystalline γ-Al_2O_3 of very low ionic resistance at the oxide-electrolyte interface, and the high "electronic" resistance at 10^5 Hz to the inclusion of some protons in the passive film.

Their interpretation is open to two major criticisms:

1. Only slight thickening of a passive film by anodizing would heal many weak spots present in the original film. Even if weak spots are considered to be absent, it does not follow that the structure of the anodic film would reflect the properties of the pre-existing passive or air-formed film.

2. The resistance-thickness profiles are uncorrected for solution and double layer losses, whereas substantial correction to the measured profiles is required for 40Å films at both 10^5 and 10^3 Hz (6). It is doubtful whether any significant contribution from the oxide is sensed at all at 10^5 Hz, in view of the large contribution of the resistance of the measuring solution to the total measured impedance at that frequency (>95%).

Immersion in chloride solution.—On the basis of the strong evidence for flaws presented elsewhere (6, 10-12), and the morphological evidence from scanning electron microscopy (7), pitting is considered to initiate at the bases of flaws in the surface oxide film. Mechanical flaws are considered to support anodic attack more readily than residual flaws, which are predominantly cathodic in nature, at least initially. Once bare metal is exposed, albeit transiently, the metal either repassivates, as in chromate or dichromate solutions, or active dissolution of the exposed area commences as suggested for chloride solutions. Thus, pitting attack is considered to proceed from the very point of immersion in the chloride solution, as is further evidenced by potential measurements (10, 13, 14). Pitting then proceeds by a process of undermining of the relatively inert surface oxide film.

Thus, a surface supporting an anodic film exhibits the following changes in impedance, upon exposure to a pitting environment:

1. Initially there is no measurable effect but the first changes become evident in the measured tan δ value as the active pit areas increase, and the impedances of (pit + flaw) combinations are determined by the flaw dimensions in the surface film over the pit mouth.

2. As the pits increase in size, and the surface films over their mouths becomes less intact due to rupture etc., the impedance of the pitted film tends to become more capacitative, and the latter value rises.

3. As the pits become still larger, and the overlying surface film less intact, the impedance of the specimen is "seen" merely in the pits themselves, and the latter "short-out" the remainder of the anodic film. At this stage, the specimen shows characteristics typical of a corrosion-affected air-formed film and indeed, on heavily pitted surfaces, the capacitance of the specimen might well exceed that characteristic of the geometric area.

All three phenomena described above are realized in practice, and are preferred to alternative explanations of the phenomena such as field-induced anion ingress (16) or anion exchange (1-4). Further changes observed are scarcely due to over-all thinning of the oxide film on the surface, particularly as Khan (15) has shown that the thickness of unpitted oxide does not change, even upon prolonged exposure to neutral chloride solutions.

Rather, the observations of Pryor *et al.* (1-4) constitute a special case of the more general trends in impedance variation demonstrated here. They represent the measured effects of tiny, largely resistive (pit + flaw) combinations on the impedance of an apparently unpitted, anodized specimen. Furthermore, the correlation between impedance data from etched and electron microscopical data for electropolished surfaces, invoked by Pryor *et al.*, are not considered valid for two reasons:

(*a*) Films stripped from pitted surfaces at the relatively early stage, and examined by transmission electron microscopy, would not be expected to show any signs of pitting, in view of their being undermined rather than dissolved during pitting.

(*b*) Electropolished aluminum (10) or stainless steel (17) surfaces are known to possess somewhat different pitting characteristics from etched or mechanically polished surfaces.

In an attempt to simulate the conditions considered to prevail during the experiments of Pryor *et al.* (1-4), a specimen supporting a 240Å anodic film was scratched minutely with a razor blade, thus rupturing the surface film. The film was then thinned in chromate solution, pH 7.0, and the variation in measured capacitance and dissipation factor with time during thinning is shown in Fig. 10a. These data are replotted in the form of average resistivity as a function of thickness in Fig. 10b. During the early stages of film thinning, healing of the base of the mechanical rupture in the film occurs simultaneously, giving an initial decrease in measured dissipation factor, associated with an increase in measured capacitance. A comparison of the data of Fig. 10b with those of Heine, Keir, and Pryor (4) points strongly to the presence of small mechanical flaws (*i.e.*, pits) in the anodized surface, rather than an anion-exchanged film.

Finally, to establish the validity of the present model further, an anodized surface was subjected to galvanostatic polarization for a sequence of consecutive time intervals at 1 μA/cm^2. The measured capacitance and dissipation factor are shown as a function of charge

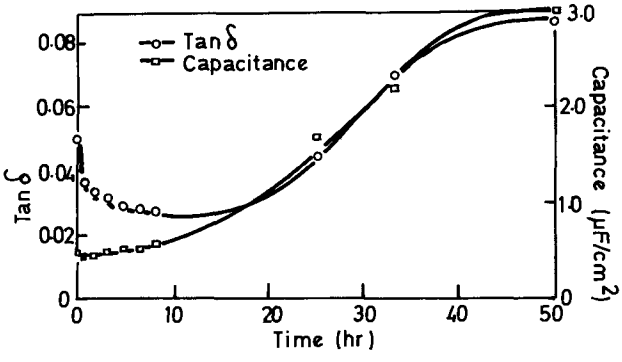


Fig. 10a. Capacitance and dissipation factor of a scratched 240Å anodic film as a function of time, in sodium chromate solution at pH 7.0.

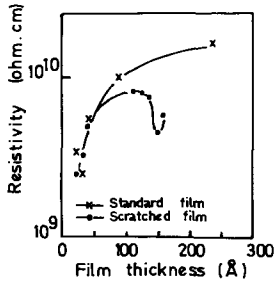

Fig. 10b. Data of Fig. 10a, replotted as resistivity as a function of film thickness.

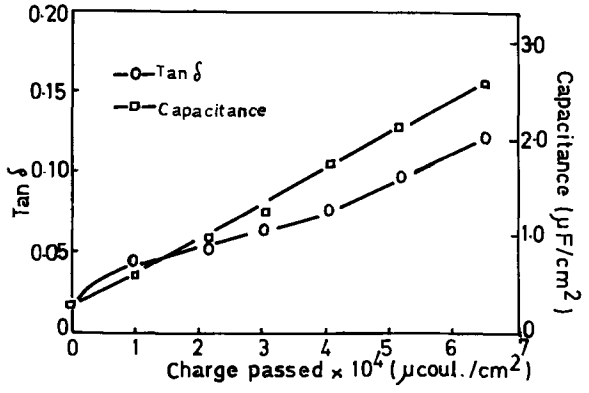

Fig. 10c. Variation of impedance of a 240Å anodic film with extent of pitting, due to galvanostatic polarization in potassium chloride solution, pH 6.0.

passed (an approximate measure of the degree of pitting of the surface) in Fig. 10c. Comparison of Fig. 7 and 10c yields good evidence for the proposed model.

Immersion in bromide and iodide solutions.—Generally, the considerations of the previous section apply. Under conditions of "natural" immersion, there is little doubt that the case of breakdown of oxide-coated aluminum proceeds in the order

$$Cl^- > Br^- > I^-$$

Not surprisingly, therefore, the bromide results reflect in general the early stages of breakdown of air-formed and anodic aluminas, in the former case localized film thickening rather than increased specimen area due to pitting being observed in the capacitance, and in the latter the type of impedance changes described by Pryor *et al.* for chloride solution, and associated with tiny pits beneath flaws in the anodic film. A complicating feature of breakdown in iodide solutions is that they are known to oxidize spontaneously in the presence of dissolved oxygen to liberate free iodine (18), according to the reaction

$$4I^- + O_2 + 2H_2O = 2I_2 + 4\,OH^-$$

The liberated iodine, rather than the iodide ion itself, appears to be the cause for the "anomalously" high corrosion rates observed for aluminum in iodine solutions [see also Ref. (9)]. Probably the iodine attacks the basis metal, rather than the surface oxide film itself, in view of the extensive use of alcoholic iodine for stripping alumina films.

Immersion in fluoride solution.—The surface oxide once again plays a relatively inert role throughout the corrosion initiation process. Attack commences at flaws in the existing surface film and rapidly spreads laterally beneath the original film, completely undermining it and removing it from the metal surface. Attack is extremely rapid and is supported by hydrogen evolution (20), even in relatively neutral solutions. The original surface film is completely replaced on the metal surface by an insoluble crystalline film, which appears to consist of a complex aluminum oxyfluoride (1, 2, 19), within a few minutes of immersion. The latter film then determines entirely the subsequent behavior of the specimen, and the nature of the initial oxide film soon becomes irrelevant. The corrosion rate is so fast because of the ability of the fluoride ion, unlike any of the other aggressive species considered, to complex aluminum, giving a series of well-defined complex salts with fluoride ions that range from AlF^{2+} to AlF_6^{3-} (21).

The proposed mechanism is considered consistent with the data of Fig. 4. The capacitance and dissipation factor in Fig. 4b measured immediately after immersion in fluoride solution, are a function of the presence of still partially intact original oxide film on the metal surface. As attack proceeds, the area of contact of the original oxide film with the surface decreases, and the corresponding area of the newly formed oxyfluoride film increases. Thus, the capacitance and dissipation factor increase, reflecting at their extreme values complete removal of the original surface film and the presence of a very thin layer of crystalline oxyfluoride film on the metal surface. The time required to reach the extreme values is longer for the anodic film (Fig. 4b) because of the smaller number of flaws at which attack can commence. As time proceeds beyond that required for complete removal of the original surface film (about 20 sec for air-formed films, 6-7 min for 240Å anodic films), the new surface film thickens to its limiting value. The capacitance and dissipation factor are then a function of the dielectric properties of the crystalline material and both decrease to limiting values as the film thickens. Later, corrosion would be expected to proceed at flaws, intercrystalline regions, etc., in the new surface film, and the longer-term processes of hydrolysis, deposition of hydrolyzed products, local pH changes, etc., to establish themselves, with consequently less reproducible effects on the capacitances and dissipation factors.

In an attempt to provide supporting evidence for the proposed theory 240Å anodic films were stripped from aluminum surfaces and immersed in fluoride solutions. Transmission electron microscopy revealed little or no change in structure or degree of intactness of the film for periods of immersion up to 10 min. Certainly no crystallization of the film was evident, nor any gross thinning. Thereafter, the film tended to disintegrate into small fragments, and presumably ultimately to dissolve in the fluoride solution.

It is therefore difficult to explain the drastic changes which occur in oxide-coated aluminum electrodes, during the very early stages of immersion, merely on the basis of chemical "modification" and "contamination" of the surface oxide film, involving extensive anion exchange between fluoride ions and the surface oxide ions (1, 2). Furthermore, the previous workers do not appear to have detected or reported these very significant initial changes in both capacitance and dissipation factor. Nor are the present results consistent with other studies, in which it was concluded that direct solution of the surface film is responsible for the initiation of corrosion in fluoride solutions (20).

Immersion in sulfate solutions.—Ignoring the complicated, apparently microbiological, corrosion in the late stages, it is evident that sulfate solution does not cause rapid corrosion of aluminum for long periods because no significant changes in dielectric properties or film appearance can be detected. Presumably the anion permits passivation at the bases of mechanical flaws, or else the rate of attack is too low to be detected.

Conclusions

1. In chromate and dichromate solutions, mechanical flaws originally present in air-formed films tend to be healed and anodic films are thinned to the passive film thickness. Little attack is detected in sulfate solution until after long periods.

2. In chloride solution, and to a lesser extent bromide and iodide solutions, pitting commences rapidly by preferential dissolution of metal transiently exposed at flaw bases in air-formed or anodic films. Undermining of the relatively inert surface film occurs. Good agreement is obtained between measured impedance data and values developed from a model in which pits develop from flaws.

3. In fluoride solution, the oxide film is removed, apparently largely by undermining, and is replaced by a complex oxyfluoride.

4. The general degree of aggression of the anions in the order dichromate, chromate, sulfate, iodide, bromide, chloride, fluoride, although complications occur

with sulfate after long periods and with iodide as a result of the release of free iodine.

Acknowledgments

The authors are indebted to Professor T. K. Ross for his interest and provision of facilities and to Dr. M. J. Pryor and colleagues, Dr. A. J. Brock, Mr. J. N. Wanklyn, Dr. P. J. Harrop, and Mr. W. H. Sutton for interesting discussions and valuable suggestions at various stages of the work.

Manuscript submitted July 23, 1972; revised manuscript received Oct. 6, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Cathode-Overpotential and Electrosorption Effects of Additives Containing Divalent Sulfur

R. O. Loutfy[1] and A. J. Sukava*

Chemistry Department, University of Western Ontario, London, Ontario, Canada

ABSTRACT

The cathode-overpotential and electrosorption effects during electrodeposition of copper of some simple compounds containing divalent sulfur (thiols, thioacids, and mercaptoacids), under galvanostatic conditions at current densities up to 20 mA-cm^{-2}, show a behavior consistent with the simple blocking theory, according to which overpotential increments arise directly from increased true current density due to additive adsorption. The calculated free energies of adsorption indicate a net repulsive interaction between adsorbed particles and a strong specific interaction between the sulfur-containing functional group and the copper surface. The adsorption behavior of the monofunctional thiols and thioacids agrees to a first approximation with the simple Traube's rule prediction for homologous series. The bifunctional mercaptoacids, with functional groups at terminal carbons, show an alternation in adsorbability with increasing length of hydrocarbon chain, indicating that the relative adsorbability is enhanced by an odd number of carbon atoms in the molecule. The *cis*-configuration in such cases presumably results in specific adsorption of both functional groups. Adsorption free energy contributions of the structural units of the additive molecules were estimated.

Previous reports (1-3) have indicated that the cathode-overpotential effects during electrodeposition of copper of low molecular weight monocarboxylic acids can be understood in terms of simple adsorption and blocking theory. The assumption is made that the only significant effect of such additives at low surface coverages, and under galvanostatic conditions, is to increase the true current density by blocking part of the electrode surface. This has the effect of increasing the charge-transfer overpotential when the electrodeposition conditions fall in the Tafel region, *i.e.*, when charge transfer is rate controlling. The free energy of adsorption is regarded as the sum of separate contributions by the carboxyl and methylene groups in the additive molecule (after correcting for lateral interaction).

The present report deals with overpotential increments caused by the more strongly adsorbed sulfur compounds of correspondingly simple monofunctional and bifunctional structure. Short-chain thiols, thioacids, and mercaptoacids were used to compare behavior with that of monocarboxylic acids, and also as a further test of the blocking theory. Three consecutive and homologous members of each series of compounds were chosen for study, with the number of carbons varying from two to four in each case.

Experimental

The experimental procedure, with cathode overpotentials measured under galvanostatic conditions by a Luggin-probe technique, was the same as described

* Electrochemical Society Active Member.
[1] Present address: University of Guelph, Guelph, Ontario, Canada.
Key words: adsorption, homologous additives, repulsive interaction, free energy.

previously (2), except that special precautions were employed in preparing the solutions. The sulfur-containing compounds were found to form precipitates with the copper sulfate electrolyte if they were added in pure form. To prevent this precipitation, the additives were introduced in dilute form by dissolving the requisite amount in the triply distilled water that was used in preparing the solutions. All compounds were obtained commercially except thiobutyric acid, which was prepared in this laboratory. The product was distilled twice and a fraction was collected to agree with literature specifications (4). All other additives were redistilled before use.

Copper anodes with a relatively large surface area were used to prevent any possible oxidation of the sulfur compounds during electrolysis. This was accomplished by using copper wire coiled in a spiral. Copper wire cathodes, about 2 mm in diameter, were used in all cases. These were cleaned before each experiment by a dip in 50% nitric acid followed by a thorough rinse with distilled water.

Steady-state cathode overpotential measurements were made at 25° ± 0.1°C and without stirring the solutions, *i.e.*, allowing only free convection at the cathode. Measurements made at various current densities up to 20 mA-cm^{-2} showed that the Tafel region occurred with nonacidified 0.5M copper sulfate solution (see next section) at current densities greater than about 14 mA-cm^{-2}. Accordingly, the 20 mA-cm^{-2} current density for which data are reported falls in the Tafel region. At this current density, the steady-state cathode surface is polycrystalline, characteristic of the electrolyte composition and the temperature.

Results

The three thioacids, thioacetic (TAA), thiopropionic (TPA), and thiobutyric (TBA), and also mercaptoacetic acid (MAA), showed a distinctly different behavior from most organic additives in that they caused a depolarization, *i.e.*, a decrease in cathode overpotential, during electrodeposition of copper from acidified copper sulfate solution (0.5M $CuSO_4$ and 1.0M H_2SO_4). [This depolarization by mercaptoacetic acid has been noted before (5)]. However, all of these compounds behaved as normal polarizers, *i.e.*, they increased the cathode overpotential, if the electrodeposition was carried out from neutral copper sulfate solution containing no added sulfuric acid. On the other hand, the three thiols, ethanthiol (ET), propanthiol (PT), and butanthiol (BT), and the other two mercaptoacids, β-mercaptopropionic (MPA) and γ-mercaptobutyric (MBA), caused only an increase in cathode overpotential whether the solution was acidified or not. It was found as well that the overpotential increments with the latter group of compounds were essentially independent of the sulfuric acid concentration, depending only on the nature and concentration of the additive at a given current density and temperature. Accordingly, the present report is based on data obtained with nonacidified 0.5M copper sulfate solution in which all the thiols, thioacids, and mercaptoacids caused the cathode overpotential to increase. The overpotential increments shown in Fig. 1-3 were obtained from steady-state total overpotentials reproducible to ±5%, at an apparent current density of 20 mA-cm^{-2}, at 25° ± 0.1°C, and with free convection at the cathode. These increments were obtained by subtracting from the total overpotential with additive present the total overpotential (50 ± 2 mV) obtained under the same experimental conditions with neutral additive-free 0.5M copper sulfate solution.

As the data indicate, the overpotential increased with increased concentration of additive in every case. The monofunctional thiols and thioacids caused a regular increase in overpotential with increasing length of carbon chain, while the bifunctional mercaptoacids showed evidence of alternation in relative effectiveness

with increasing number of carbon atoms in the molecule. A similar alternation has been observed with straight-chain dicarboxylic acids with the carboxyl groups at terminal carbons (6), indicating that bifunctional compounds in such a homologous series containing an odd number of carbon atoms are more effective

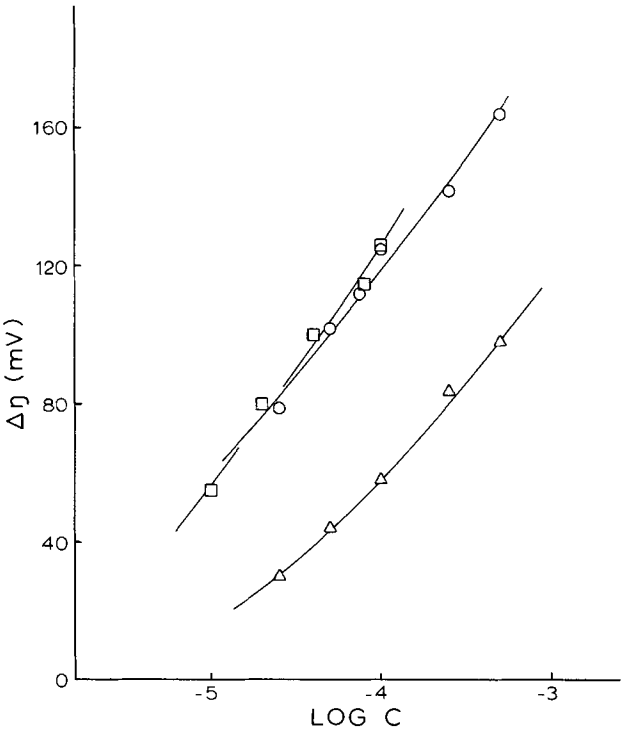

Fig. 3. Overpotential increment *vs.* logarithm of concentration, mercaptoacids: △, MAA; □, MPA; ○, MBA.

in increasing the cathode overpotential than those with an even number. This is particularly noticeable in the data for β-mercaptopropionic and γ-mercaptobutyric acids in Fig. 3.

Discussion

Methylene group adsorption and Traube's rule.— When the overpotential-increment and additive-concentration data are plotted in the form $\Delta\eta$ *vs.* log C as in Fig. 1-3, it is seen that the monofunctional thiols and thioacids behave in much the same manner as the normal monocarboxylic acids discussed previously (2). To a first approximation, and within the accuracy of the data, the $\Delta\eta$ *vs.* log C curves in Fig. 1 and 2 are parallel, indicating that Traube's rule is obeyed in the adsorption of these homologous compounds on a copper cathode. Therefore, assuming this parallelism to be correct,[2] an equation can be written by means of which the adsorption free-energy contribution of each methylene group in such molecules can be calculated directly from appropriate additive concentrations. This is done as described in Ref. (2), *i.e.*, by subtracting Eq. [5] in that reference for any two additives in a homologous series at a given overpotential increment. Accordingly, one can write for additives 1 and 2 in such a series, the simple equation

$$(x_2 - x_1)\Delta G^\circ_{CH_2} = RT \log(C_2/C_1) \qquad [1]$$

where $\Delta G^\circ_{CH_2}$ is the standard free energy of adsorption of each methylene group, including the terminal methyl, x_i is the number of methylene groups present in the molecule of additive i, and C_i is the concentration of i corresponding to a given $\Delta\eta$. Application of Eq. [1] to the data in Fig. 1 and 2 gives the value of $\Delta G^\circ_{CH_2}$ for the thiols and for the thioacids as about −760 and −790 cal/mole, respectively, which, considering the accuracy of the data, are in reasonably good agreement with the value −704 cal/mole found for monocarboxylic acids (2).

[2] It should be noted that the $\Delta\eta$ *vs.* log C curves would be expected to deviate from parallelism if the adsorbability of the methylene group is sufficiently sensitive to the change in cathode potential represented by $\Delta\eta$. The experimental data in this study are not sufficiently accurate to give conclusive evidence of such an effect.

The $\Delta\eta$ *vs.* log C curves for the mercaptoacids in Fig. 3 show that a greater, or enhanced, relative adsorbability occurs when the two functional groups at terminal carbons in such molecules are in *cis*-configuration, as they are in β-mercaptopropionic acid. This suggests that a simultaneous specific adsorption of both functional groups probably takes place, in contrast to compounds like mercaptoacetic and γ-mercaptobutyric acids in which the terminal functional groups are in *trans*-configuration, and in which these groups can therefore be expected to be more or less incapable of similar simultaneous specific attachment to the surface. It is interesting to note that if this interpretation is at least approximately correct, and if the adsorptive capabilities of the same structural units in MAA and MBA molecules are at least nearly the same, then the over-all adsorbabilities of these two compounds as indicated in Fig. 3 would be expected to differ primarily because of their difference by two methylene groups. Accordingly, in view of the approximate parallelism of the corresponding $\Delta\eta$ *vs.* log C curves in Fig. 3, Eq. [1] can be applied at any arbitrary $\Delta\eta$ to give the adsorption free energy contribution per methylene group. The value found is −710 cal/mole, which, once again, is in good agreement with the values found for thiols, thioacids, and monocarboxylic acids.

Calculation of standard free energy of adsorption.— If the blocking equation (7, 1, 2)

$$\theta = 1 - \exp(-\Delta\eta/b) \qquad [2]$$

can be applied to the data obtained for the divalent sulfur compounds in the present study, then the surface coverage θ can be calculated from the overpotential increment $\Delta\eta$ and the Tafel slope b (b was approximately 52 mV in these experiments). Then, in turn, the over-all standard free energy of adsorption can be calculated if an appropriate adsorption isotherm can be chosen. In previous work with homologous monocarboxylic acids (2), use was made of a modified version of the Bockris-Swinkels isotherm (8)

$$\frac{\theta}{(1-\theta)^n} \cdot \frac{\{\theta + n(1-\theta)\}^{n-1}}{n^n} = \frac{C}{55.5} \exp(-\Delta G^\circ_a/RT) \qquad [3]$$

in which a coverage-dependent parameter $g(\theta)$ was included by writing

$$\Delta G^\circ_a = \Delta G^\circ_p + x\ \Delta G^\circ_{CH_2} + g(\theta) \qquad [4]$$

where ΔG°_p is the standard free energy of adsorption of the polar functional group, $\Delta G^\circ_{CH_2}$ the free energy contribution of each methylene group, x the number of methylene groups present, and $g(\theta)$ a coverage-dependent apparent standard free energy attributable to lateral interaction between adsorbed molecules (2, 3, 9). Any potential dependence of the free energy of adsorption is considered in Eq. [4] to be incorporated primarily in the term ΔG°_p (3), since, to a first approximation, $\Delta G^\circ_{CH_2}$ can be considered sufficiently insensitive to potential change to the extent that the parallelism of the $\Delta\eta$ *vs.* log C curves such as those in Fig. 1 is correct. This means that ΔG°_p in [4] is coverage-dependent, along with $g(\theta)$, because the cathode potential (viz., $\Delta\eta$) is directly dependent on coverage under galvanostatic conditions.

Application of Eq. [2] and [3] to the sulfur compounds in the present study gave the results shown in Fig. 4 for ethanthiol, thioacetic acid, and mercaptoacetic acid. Free energy values were calculated at various coverages, taking the solvent displacement number as 2 since the projected cross-sectional area of these molecules can be expected to be nearly the same as for monocarboxylic acids (2). Free energy values were then calculated as well for $n = 1$, to give

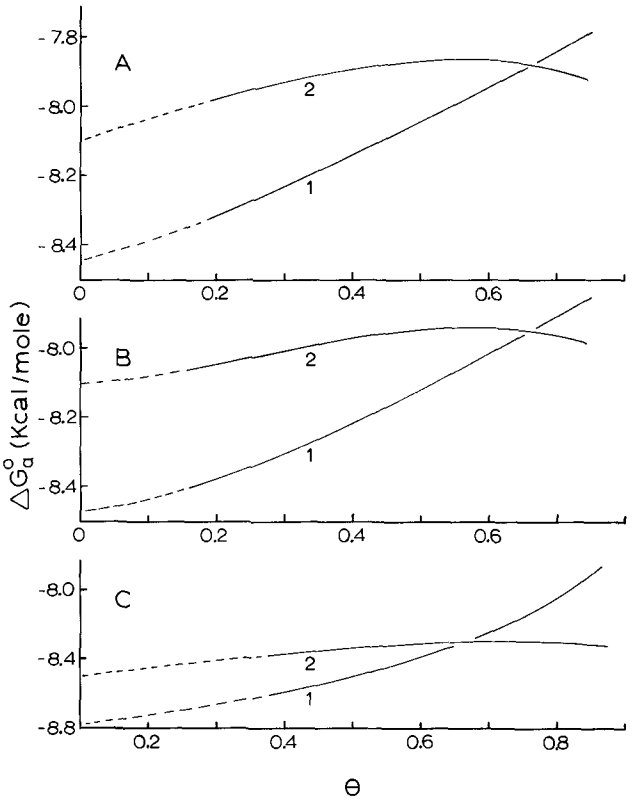

Fig. 4. Adsorption free energy vs. coverage: A, ET; B, TAA; C, MAA; 1, $n = 1$; 2, $n = 2$.

a comparison with what amounts essentially to use of the Frumkin isotherm (10)

$$\frac{\theta}{1-\theta} = \frac{C}{55.5} \exp\left[\frac{-\Delta G^{\circ}_{a}}{RT} + 2a\theta\right]$$

in which the interaction term $2a\theta$ corresponds to our $-g(\theta)/RT$. The two separate curves for each compound are shown in Fig. 4.

An important observation arising from Fig. 4 is that thiols, thioacids, and mercaptoacids undergo a net repulsive interaction when they are adsorbed on copper from neutral solution. The magnitude of the potential dependence of ΔG°_{p} has not been determined, but if it can be assumed that lateral interaction is the dominant influence in causing the coverage dependence of ΔG°_{a} as calculated from Eq. [3], then $g(\theta)$ in [4] will be opposite in sign to ΔG°_{p} and $\Delta G^{\circ}_{CH_2}$ for the sulfur compounds used. This is in contrast to the net attractive interaction found in the adsorption of monocarboxylic acids from acidified copper sulfate solution (2), where $g(\theta)$ has the same sign as ΔG°_{p} and $\Delta G^{\circ}_{CH_2}$.

Mutual lateral repulsion between adsorbed particles is easily understood, and can in fact be expected, in the case of thioacetic and mercaptoacetic acids in neutral solution. These compounds, in view of their acid ionization constants which are 4.7×10^{-4} and 4×10^{-4}, respectively, (4), will occur primarily in ionic form in the neutral copper sulfate solution and at the concentrations used in our experiments. Accordingly, a dominant ion-ion repulsion can be expected in the adsorbed phase. The free energies of adsorption of the functional groups in these compounds, *i.e.*, ΔG°_{p} in Eq. [4], should therefore be considered as applying to the anionic rather than the molecular form (see estimated values below). On the other hand, the much lower acidity of ethanthiol, for which $K = 2.5 \times 10^{-11}$ (4), means that the dissolved species at our experimental concentrations is primarily the molecular form[3] and so the net repulsive interaction as seen in Fig. 4 might be speculatively attributed perhaps to parallel orientation of dipoles, as would be the case if the molecules were adsorbed with the dipoles perpendicular to the surface. This point, admittedly, requires further study and clarification.

The rough extrapolations in Fig. 4 give estimates of ΔG°_{a} at zero coverage. These in turn give estimates of the limiting zero-coverage value of ΔG°_{p} in Eq. [4] since $\Delta G^{\circ}_{CH_2}$ is known from Eq. [1] and since $g(\theta)$ approaches zero as θ approaches zero. The ΔG°_{p}-values obtained correspond to the cathode-potential state (3) at which the overpotential is experimentally fixed at 50 ± 2 mV, the value found for the additive-free neutral copper sulfate solution at the experimental current density and temperature. The roughly approximate values for $n = 2$ are, in cal/mole: —SH, —6580; —COS^-, —7300; and HS----COO^-, —7740. For $n = 1$ they are: —SH, —6930; —COS^-, —7660; and HS----COO^-, —8090. The magnitudes of the free energies are indicative of physical adsorption forces. They indicate as well a relatively strong interaction between the functional groups in these additives and the copper surface.

Due to some uncertainties, no satisfactory explanation can be offered at present for the apparent maximum and the subsequent downward trend with increasing coverage in the curves for $n = 2$ in Fig. 4. Further study is required to examine not only the reliability of the experimental data but also the possible extent to which the blocking theory, Eq. [2], is inapplicable to charged adsorbates as in the present case (see below). In addition, information is required on the coverage (potential) dependence of ΔG°_{p}. Certainly, this kind of change from repulsive to attractive interaction would not be expected with thioacetic and mercaptoacetic acids if lateral interaction remains the dominant influence in the coverage dependence of adsorbability. These compounds are about 85 and 75% ionized, respectively, at the concentrations corresponding to the maxima in the curves in Fig. 4, and, accordingly, ion-ion repulsion would be expected to continue as a dominant effect in the adsorbed phase. Change in orientation of ethanthiol molecules might occur to account for a change in the nature of the interaction, but speculation of this kind is scarcely justified with present data.

Real and apparent surface coverage.—Ionic adsorbates such as the thioacids and mercaptoacids used in the present study can be expected to affect the surface activity of Cu^{2+} ions within the charge field of the adsorbate particles. The resulting effect on the true charge-transfer current density over uncovered portions of the cathode surface in such instances will mean that application of the blocking theory to galvanostatic overpotential increments will give surface coverages that are apparent rather than real. The adsorption free energies estimated for these compounds in this work should therefore be regarded as apparent to the extent that the adsorbate charge is important.

ABSTRACT

All of the monohalogenated nitrobenzenes have been studied in nonaqueous media using various electrochemical and spectroscopic methods. A mechanism involving halide elimination and hydrogen atom abstraction from the solvent to form nitrobenzene was verified by deuteration experiments employing electron paramagnetic resonance measurements. In addition to formation of nitrobenzene, azoxybenzenes and nitrobiphenyls could be generated under different experimental conditions. Possible electrosynthesis studies are also proposed based on these data.

Several years ago, Holleck and Becher noted anomalous polarographic waves in the reduction of *p*-bromo- and *p*-iodonitrobenzene (1). Earlier, Maki and Geske had also observed anomalous behavior with *p*-iodonitrobenzene and had been unable to obtain an electron paramagnetic resonance (EPR) spectrum for the reduced compound (2). Subsequently, several pathways were proposed for the electrochemical reduction of monohalogenated nitrobenzenes in nonaqueous media (3-7). Except for minor differences, they all entailed an over-all transfer of three electrons and the expulsion of a halide ion after the first electron transfer. Nitrobenzene anion radical was identified as the final product.

More recently, alternate pathways have been suggested based on data showing clearly that the over-all process involves two electrons and not three as previously proposed. This possibility was initially proposed by Seo and Nelson (8) and expanded upon by Lawless and Hawley (9). Basically, the electrode process was found to involve an initial one-electron reduction to the halonitrobenzene anion radical; the ensuing decomposition reaction consists of a loss of halide ion and extraction of a hydrogen atom from the electrochemical medium (8, 9), not necessarily in that order. The halogen elimination step has been proposed to be a reversible equilibrium process (9). Further studies are reported herein concerning the source of the abstracted hydrogen atoms and alternate reaction pathways of the intermediate nitrophenyl radicals.

Experimental

Chronoamperometric and chronopotentiometric measurements were made by using a transistorized version of a multipurpose instrument designed for experiments in electrochemistry (10). Data were recorded on a Hewlett-Packard Model 7035A X-Y plotter; short-time data were displayed on a Tektronix Type 535A oscilloscope with Type "D" plug-in unit and photographed. Controlled-potential electrolyses were carried out using a Wenking 61RH potentiostat and associated instrumentation (11).

The purification of the solvents, acetonitrile (AN), N,N-dimethylformamide (DMF), and propylene carbonate (PC), has been described (12, 13); benzonitrile was vacuum distilled and stored over Linde 4A molecular sieves. The supporting electrolyte was tetraethylammonium perchlorate (TEAP). Electrochemical cell design and electrodes have been described (12). All the halogenated nitrobenzenes were obtained from commercial sources and purified through recrystallization or distillation. Deuterated acetonitrile (99%) and deuterium oxide (99.9%) were obtained from Bio-Rad Laboratories and U.S. Nuclear Corporation.

The electron paramagnetic resonance studies were carried out using a Varian Associates Model E-3 spectrometer. *In situ* electrolyses in the microwave cavity were carried out at a platinum-gauze working electrode. The electrolysis cell for use in the solution compartment of a Cary Instrument Model 14 spectrophotometer has been described (14).

Results and Discussion

Electrochemical studies.—The data from cyclic voltammetry, chronoamperometry, and chronopotentiometry experiments carried out with all the isomeric halonitrobenzenes are summarized in Table I. The half-peak potentials, $E_{p/2}$, are in reasonable agreement with reported values obtained in AN at platinum (9) and DMF at a mercury working electrode (5, 7); some differences are to be anticipated from solvent and electrode effects due to the influence of chemical reactions associated with the electron-transfer processes (15). From the $i_p v^{-1/2} C^{-1}$, $it^{1/2} C^{-1}$, and $i\tau^{1/2} C^{-1}$ data, one can estimate the number of electrons involved in the first reduction step relative to nitrobenzene, a reversible one-electron redox process under the conditions of our experiments (16, 17). Note that the peak current and the chronoamperometric and chronopotentiometric quotient for most of the halonitrobenzenes approximate those of nitrobenzene. Also, cyclic voltammograms of these compounds show peak current ratios (cathodic to anodic) that are close to unity. The data indicate that these nitrobenzenes undergo a reversible (in an electrochemical sense) one-electron reduction to form their respective anion radicals. Verification is provided by EPR spectra obtained for these compounds by *in situ* electrolysis experiments; the spectra are readily interpretable in terms of the primary halonitrobenzene anion radicals (2, 3, 7, 16, 18, 19); slight variations in hyperfine splittings are attributable to solvent effects.

The other halonitrobenzenes exhibit electrochemical behavior that differs from that of nitrobenzene; for

[j] Increases with decreasing scan rate.
[k] Limiting two-electron value.

example, the value for the peak current function, $i_p v^{-1/2} C^{-1}$, increases with decreasing scan rate. Such behavior can be ascribed to an ECE (electrochemical-chemical-electrochemical) mechanism where the intermediate step (chemical reaction) is relatively slow (20).

The $i_p v^{-1/2} C^{-1}$ values for o-bromo- and o-iodonitrobenzenes are almost twice that for a one-electron process. This result is characteristic of a fast ECE process (the chemical reaction essentially goes to completion during the time span of the measurement) where both electrochemical steps involve a one-electron transfer. Both electrochemical steps occur at nearly the same potential or, in a reduction, the second occurs at less negative potential. The significance of these peak current data is that a total of two electrons are involved in the over-all process. Previously reported mechanisms required three electrons in the over-all reductions. The two-electron data from cyclic voltammetry are supported by exhaustive controlled-potential electrolysis. The major product is nitrobenzene anion radical.

In Fig. 1, the chronopotentiometric quotient, $i\tau^{1/2} C^{-1}$, is plotted as a function of current. The figure graphically illustrates the variations in chronopotentiometric behavior. All the compounds except o-iodonitrobenzene exhibit or approach one-electron reduction behavior at short transition times (high currents); the one-electron reduction corresponds to the first electrochemical step, the first "E" of the ECE process. The figure provides a qualitative picture of the relative stabilities of the intermediate reduction product (halonitrobenzene anion radical). The more stable the intermediate, the lower the current at which one-electron behavior is attained.

The data are consistent with the ECE mechanism previously proposed (8, 9) in which the halonitrobenzene undergoes (*i*) electrochemical reduction to its anion radical, followed by (*ii*) elimination of halogen and formation of nitrobenzene, and (*iii*) electrochemical reduction of the resulting nitrobenzene to its anion radical. Identification of the latter anion radical by EPR leaves no doubt as to its formation; this was done for all the isomers, although for several of the derivatives (1-6, 8) rather prolonged electrolysis was necessitated.

Controlled-potential electrolyses were carried out with the three iodonitrobenzenes because these compounds undergo very rapid elimination reactions, therefore permitting easier product analysis. None of the electrochemical or spectroscopic techniques detected the presence of any organic compound other than nitrobenzene and its anion radical as final product at low concentrations (10^{-3} M or less) of parent halo-

nitrobenzene. Neither isolation and analysis of products nor thin-layer chromatography of the electrolyte solution after exhaustive electrolysis indicated compounds other than starting materials and nitrobenzene.

The proposed mechanism is as shown in Eq. [1]-[4] above for *p*-iodonitrobenzene; all the halonitrobenzenes have similar reduction behavior.

The equilibrium in Eq. [1] has been inferred from more recent studies involving the coupling of anions with electrolytically generated nitrophenyl radicals (22) and is still debatable. In addition, the order of halogen elimination and hydrogen atom abstraction has not been unequivocally established, but it is clear that this process is a first-order ECE process with the chemical step involving decomposition of the halonitrobenzene anion radical and each electron transfer process being one-electron in nature. The rate constants for the intermediate decomposition reaction were measured with chronoamperometric data using digital simulation working curves (22, 23). Although the chemical redox process shown in Eq. [4] is of some importance in these systems based on the redox potentials of nitrobenzene and the halo derivatives, the working curve for the K = $^0/_0$ case was used. This case neglects the effects of any ECC (electrochemical-chemical redox-chemical) complications such as in Eq. [4] and considers the process as a pure ECE. The rate constants obtained are given in Table I; the values are ±20% for the very fast and very slow reactions, with better precision for the intermediate rates. Since the effect of the ECC "nuance" is not being accounted for, the absolute values of the rate constants are not completely valid; however, relative rates in the series can be examined with a good deal of confidence. In addition, these data cannot be compared directly with those of Hawley and co-workers since their rate measurements were done in the presence of added halide (9), or in DMF as solvent (24). The anion radicals of all three fluoronitrobenzenes and *m*-chloronitrobenzene have decomposition rates that are too slow to be measured in acetonitrile before convection sets in (10-12 sec). These compounds were studied in the more viscous solvent propylene carbonate. There is certainly a solvent effect on the rate constant values (9), but since the *k*'s for these compounds are only reported to one significant figure this is not considered a serious problem. The decomposition rate for the *o*-iodonitrobenzene system, on the other hand, is too rapid to be followed potentiostatically. Studies using rotating-disk electrode techniques for the determination were unsuccessful due to fouling of the disk by electrolysis products.

The data correlate nicely with the chronopotentiometric curves in Fig. 1. In terms of isomers, the rate constants follow the order, $k_m < k_p < k_o$; in terms of the halogen substituent, they follow the order, $k_F < k_{Cl} < k_{Br} < k_I$. For chloro-and fluoronitrobenzenes, the respective *ortho*- and *para*-isomers exhibit comparable decomposition rates, with the *ortho*-isomer having a slightly greater rate because of steric effects. However, the ratio of rate constants, k_o/k_p, increases substantially with the bromo and iodo isomers.

EPR studies.—A series of EPR experiments were devised in order to determine the source of the abstracted hydrogen atoms. When the various halonitrobenzenes are electrolyzed *in situ* in the EPR spectrometer cavity, nitrobenzene anion radical appears after varying electrolysis times. For the more stable halonitrobenzene anions, several hours are required before nitrobenzene anion radical is observed. For species with intermediate primary radical stability, one obtains mixed spectra representing the halonitrobenzene anion radical and a gradually increasing amount of nitrobenzene anion radical. Prolonged electrolysis leads to a spectrum of only the latter radical. When elimination is rapid, only the nitrobenzene anion radical spectrum is seen. Figure 2 shows a typical spectrum resulting from *o*-iodonitrobenzene reduction. The resolution is not outstanding, but the spectrum is undoubtedly that of nitrobenzene anion radical.

To determine if the loss of halide followed by hydrogen abstraction from water (or vice versa) represented the proper mechanism, experiments were carried out in which several of the halonitrobenzenes were electrolyzed in acetonitrile containing small amounts of deuterium oxide. If deuterium abstraction by a nitrophenyl radical occurred, deuterium would be incorporated into the nitrobenzene molecule and the EPR spectrum of the secondary anion radical would be different from that of nitrobenzene anion radical. A proton (I = ½) gives a doublet EPR splitting, whereas a deuterium (I = 1) in the same substituent position gives rise to a triplet with a coupling constant about 1/6th that of the proton. Therefore, if a deuterium were incorporated into the position of the eliminated halogen, a spectrum for deuterated nitrobenzene anion radical should result. Figure 3 shows the spectrum obtained from *m*-iodonitrobenzene in AN containing 1% deuterium oxide by volume. The amount of deuterium oxide is far in excess of the amount of water present in purified AN. Smaller amounts (0.1 to 1%) of D_2O gave similar results. Although a solvent effect results from the presence of deuterium oxide, changing the coupling constants slightly, the spectrum obtained is that of nitrobenzene anion radical; deuterium is not incorporated. Identical results were obtained for o- and *p*-iodonitrobenzenes.

Electrolysis of the three iodonitrobenzenes in perdeuteroacetonitrile, CD_3CN, led to spectra that could not be interpreted in terms of nitrobenzene anion radical. Figure 4 shows the spectrum obtained from electrolysis of *m*-iodonitrobenzene in CD_3CN; the spectrum is different from that of nitrobenzene anion radical and can be interpreted as that of *m*-deuteronitrobenzene anion radical. Similar results were obtained for the o- and *p*-iodonitrobenzenes in CD_3CN. In all cases, experimental spectra agreed with computer-plotted curves; over-modulated spectra were

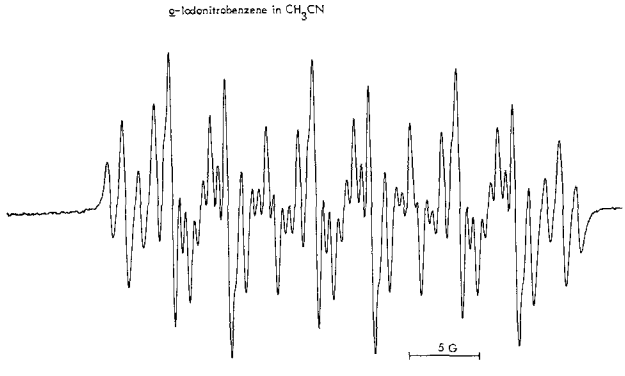

Fig. 2. EPR spectrum obtained from *in situ* electrolysis of o-iodonitrobenzene (1.0 x 10^{-3}*F*) in AN/0.1*F* TEAP at a platinum gauze electrode.

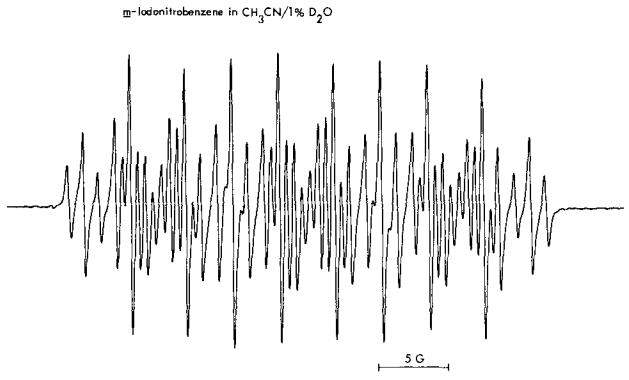

Fig. 3. EPR spectrum obtained from *in situ* electrolysis of *m*-iodonitrobenzene (1.0 x 10^{-3}*F*) in AN/0.1*F* TEAP containing 1 volume per cent D_2O. This is the secondary radical spectrum obtained at a platinum gauze electrode. The parent radical spectrum is observed first, but it is slowly replaced by the spectrum shown in the figure.

identical with those of Ward obtained from authentic deuteronitrobenzenes (25).

Electrolysis of nitrobenzene in CD_3CN produced only nitrobenzene anion radical, thus excluding rapid exchange of deuterium between the solvent and some nitrobenzene species.

Electrosynthesis considerations.—It was mentioned earlier that the only product detected in these systems is nitrobenzene; in fact, this is true only under very limited conditions, namely AN/TEAP with concentrations of halonitrobenzene at or below the millimolar level. As the concentration is increased the yield of nitrobenzene diminishes markedly and the system becomes more complicated. Since the nitrophenyl radical is a possible intermediate in these systems it was anticipated that at higher concentrations of halonitrobenzene one might observe coupling to form 4,4′-dinitrobiphenyl. In fact, the presence of 4,4′-dinitrobiphenyl was verified early in the electrolysis at these concentration levels (10^{-3}M) by its characteristic radical EPR and visible absorption spectra (purple radical). However, when 10^{-2} and 10^{-1}M solutions of *p*-iodonitrobenzene in AN/TEAP were exhaustively electrolyzed no 4,4′-dinitrobiphenyl could be isolated, although the color of the solutions suggested its presence early in the electrolysis. This is partially explained by the observation that electrolysis of authentic samples of 4,4′-dinitrobiphenyl produced a variety of color changes and it was apparent that the system was not completely reversible; in the time scale of a mass electrolysis any 4,4′-dinitrobiphenyl formed could decompose and thus not be isolated.

In an attempt to remove the source of hydrogen atoms and force generation of the dinitrobiphenyl, several electrolyses were run in benzonitrile/$NaClO_4$ solutions. Benzonitrile is a very poor solvent for electrosynthesis studies, primarily because it is so difficult to remove after electrolysis. The EPR spectra run on these solutions indicated the presence of a radical other than that of nitrobenzene; a great deal of fine structure was present on a spectrum consisting basically of a 3 × 3 × 3 pattern. It was suspected that the intermediate nitrophenyl radical was attacking the benzonitrile to form a substituted nitrocyanobiphenyl; although the EPR spectrum was rich in fine structure, it could not be sufficiently resolved for interpretation. This type of reaction pathway had been previously speculated upon in the electrochemical reduction of *o*-halonitrobenzenes (9) and is in keeping with reports of the propensity of nitrophenyl radicals for aromatic systems (26).

In an effort to verify this pathway by generating a known compound, *p*-iodonitrobenzene was electrolyzed in 50:50 mole per cent AN/benzene. Preliminary EPR and cyclic voltammetric studies indicated that, in fact, 4-nitrobiphenyl was being formed in appreciable amounts in millimolar solutions; spectral and electrochemical data were positively matched with an authentic sample of 4-nitrobiphenyl. Controlled-potential electrolyses of 10^{-2}M solutions yielded a 20% yield of the 4-nitrobiphenyl from *p*-iodonitrobenzene. The same process was also verified by EPR when *p*-iodonitrobenzene was electrolyzed in MeCN/toluene. Thus, this appears to be a rather general reaction pathway in which the intermediate nitrophenyl radical attacks substituted benzenes to form the corresponding nitrobiphenyls. Further studies are in progress to maximize yields in these systems and define the types of products that can be formed by this method.

It had been noted in early studies on these systems that in cases where the halogen did not appear to eliminate under electrochemical conditions nitrobenzene was formed by further reduction of the halonitrobenzene anion radical (3). This has been further verified by Lawless and Hawley, who reduced *p*-bromonitrobenzene in DMF/TEAP and found that at −2.0V dilute solutions (10^{-3}M) yielded appreciable amounts of nitrobenzene (27). In AN/TEAP, however, *p*-bromonitrobenzene yields nitrobenzene anion radical upon prolonged electrolysis past the first reduction wave (verified by EPR) as shown in Fig. 5. Exhaustive electrolysis of dilute solutions of *p*-bromonitrobenzene at −2.0V in AN/TEAP also yields nitrobenzene as the primary product, but as the concentration of the halonitrobenzene is increased to 10^{-2}M and above the presence of another product becomes increasingly prominent. Comparison of *IR* spectra, melting points, and cyclic voltammetric curves of the electrolysis product with an authentic sample showed it to be 4,4′-dibromoazoxybenzene, formed in a second-order process. This is obviously a multi-electron process and no attempt was made to investigate the mechanism. In addition, the yield of the azoxybenzene is contingent upon the applied potential and n-value, but is typically about 50-60%. These conditions were not tried with any other halonitrobenzenes, but it is likely that the same pathway will apply to any of the systems where the halogen elimination rate is slow.

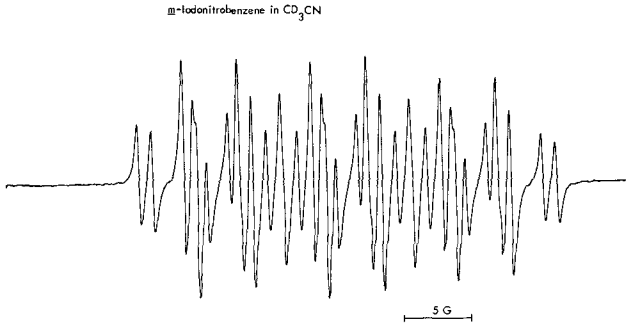

Fig. 4. EPR spectrum obtained from *in situ* electrolysis of *m*-iodonitrobenzene (1.0 x 10^{-3}*F*) in CD_3CN/0.1*F* TEAP at a platinum gauze electrode.

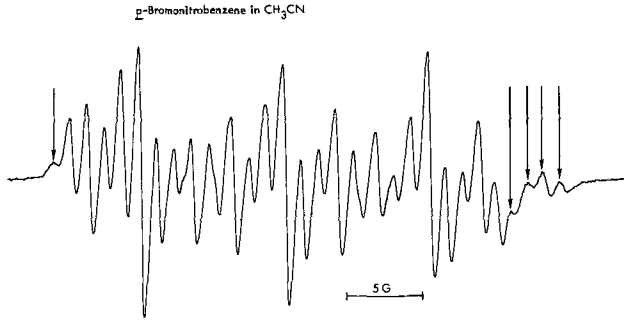

Fig. 5. EPR spectrum obtained from *in situ* electrolysis of *p*-bromonitrobenzene (1.0 x 10^{-3}*F*) in AN/0.1*F* TEAP at a platinum gauze electrode. Spectrum was recorded after 45 min electrolysis at −1.2V. The arrowed lines are due to nitrobenzene anion radical; the spectra are asymmetrical due to different g-values.

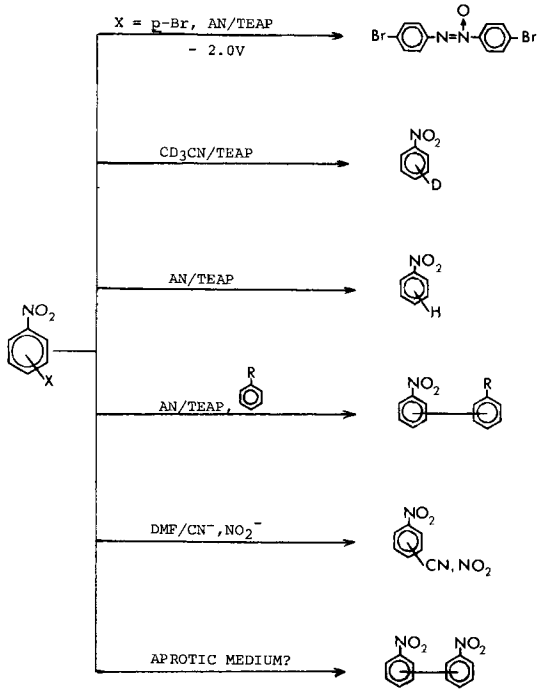

Fig. 6. Products obtained or potentially obtainable from halonitrobenzenes on a synthesis scale.

It has also been shown previously (24) that anions such as CN^- and NO_2^- can be added to the intermediate nitrophenyl radicals to form substituted nitrobenzenes. This type of reaction was not attempted on a synthesis scale, but studies are now in progress toward this end.

Attempts to generate appreciable yields of 4,4'- and 2,2'-dinitrobiphenyls from the corresponding halonitrobenzenes have been singularly unsuccessful. In order to do this, one would have to work in a solvent with a very low hydrogen atom availability (such as liquid SO_2) to avoid nitrobenzene formation. However, at concentrations suitable to electrosynthesis work, the competing reaction of azoxybenzene formation may become significant. Since the dinitrobiphenyls can also be synthesized in high yields by simple Ullmann reactions involving the chloronitrobenzenes this does not appear to be a promising electrosynthesis area.

From the viewpoint of synthesis studies, then, the halonitrobenzenes appear to be well suited to obtaining different products under variable electrolysis conditions. The products obtained, or potentially obtainable on a synthesis scale, are summarized in Fig. 6. Studies are now in progress to improve the yields in these systems and extend the range of products that can be obtained.

ABSTRACT

The preparation of vanadium by molten-salt electrolysis of a commercial vanadium carbide (VC) containing 84% vanadium was investigated. An electrolytic process was developed for the extraction of vanadium from VC in an LiCl-NaCl-VCl_2 electrolyte contained in a helium-atmosphere cell at 650°C. The effects of electrolyte composition, vanadium depletion of the VC, and cathode current densities on the process, as well as the effects on the quality of vanadium products, were determined. Vanadium of 99% purity was prepared with an 85% recovery of vanadium and a cathode current efficiency of 70%. The vanadium contained approximately 0.60% oxygen and had a 100 Rockwell B hardness. High-purity, ductile vanadium was prepared from the VC by electrorefining the extraction products in a separate cell or by combining the extraction and electrorefining processes in a single cell. In the combined process, the vanadium was first extracted from the VC and deposited on a cylindrical electrode; this vanadium was then electrorefined and deposited on a central cathode rod. Both methods yielded vanadium of 99.9% purity with 35-40 Rockwell B hardness. With limited tests in the combined process, 58% recovery of ductile vanadium from the VC was achieved.

Ductile vanadium (1-7) and vanadium with purity higher than 99.9% (8-12) have been prepared from various materials containing vanadium. A starting material for the production of vanadium is vanadium carbide, which is produced commercially for use as a replacement for ferrovanadium in the steel industry. The preparation of a vanadium carbon alloy from vanadium oxides for use as a steel additive was investigated by Downing and Merkert (13). Current commercial production of vanadium carbide is of the VC-type. This carbide contains approximately 14% carbon and 84% vanadium, with iron, nitrogen, and oxygen as the chief impurities.

A molten-salt electrolytic process was developed by the Bureau of Mines to extract and prepare ductile vanadium having a purity ranging from 98 to 99.6% from a commercial V_2C-type carbide containing 10% carbon, 85% vanadium, and 5% of other elements, including chromium, iron, and oxygen (14). Electrolytic efficiency in the process decreased as the anode composition changed from V_2C to VC as a result of the vanadium extraction. When metallic impurities such as chromium and iron were present in V_2C, they contaminated the vanadium product. Low electrolysis efficiency as well as deterioration in product quality also occurred in the electrorefining of vanadium prepared by carbothermic reduction of V_2O_5 (15). This was attributed to the change of anode composition from a carbide phase rich in vanadium to a VC phase. The successful preparation of vanadium from vanadium-carbon alloys was dependent on the development of an efficient process for treating VC-type carbide.

The phase diagram of the vanadium-carbon system (16) indicates that the carbon-saturated VC-type carbide is $VC_{0.88}$. Extraction of vanadium from the carbide should be feasible since it will not increase the carbon content of the $VC_{0.88}$ phase. The reaction and free energy change (17) are

$$VC_{0.88} \rightarrow V + 0.88C, \quad \text{and} \quad \Delta F^\circ_{1000^\circ K} = +23 \text{ kcal} \quad [1]$$

The energy requirement for the reaction to proceed is furnished by electrolysis.

Experimental

Vanadium was prepared by electrolysis of VC in a helium-atmosphere, electrolytic cell shown in Fig. 1. The cell consisted essentially of a lock, a slide valve, and an electrolyte chamber. The chamber was constructed of Hastelloy, 1.3-cm thick, 15-cm ID, 76-cm high, and equipped with a graphite liner encased by a molybdenum crucible. The slide valve provided a gas-tight seal between the chamber and the lock. The lock was used to cool the vanadium deposit. The cathode was a 1.1-cm diam molybdenum rod.

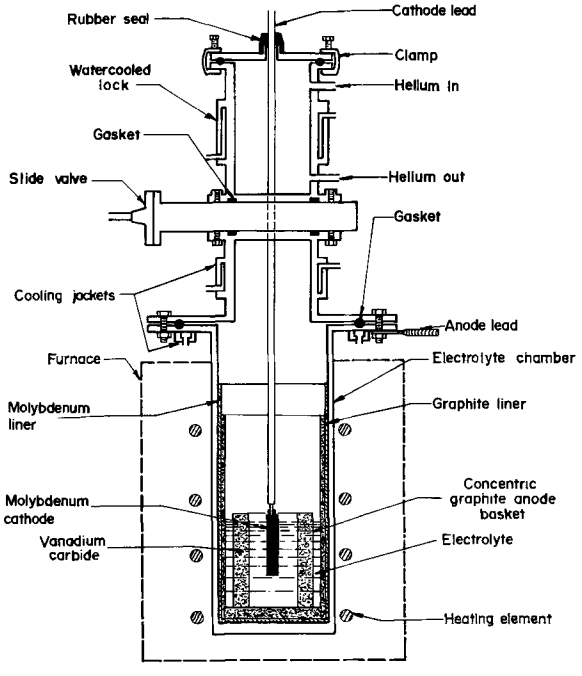

Fig. 1. Schematic diagram of the electrolytic cell

The vanadium carbide, in the form of 1.9 × 1.3-cm briquettes, was supplied by the Union Carbide Corporation. It was crushed into chunks of minus 3-, plus 4-mesh size and charged into a concentric graphite basket, 11.5-cm OD, 9-cm ID, and 30-cm high. The anode assembly was placed in the bottom of the graphite liner. Table I shows the analysis of the vanadium

Table I. Analysis of VC, %

Key words: vanadium, vanadium carbide, electrolysis, preparation, molten-salts.

carbide. The chief impurities in the carbide were iron and oxygen, totaling 1.5%; minor metallic impurities were aluminum and chromium. The major component was identified by its x-ray diffraction pattern as VC.

The electrolytes were composed of VCl_2 dissolved into molten mixtures of alkali chlorides, and alkaline-earth chlorides with alkali chlorides, and VBr_2 dissolved in a molten mixture of NaBr and KBr. Vanadium dichloride and bromide were formed by direct chlorination and bromination of vanadium at 750°C into the respective molten salt mixtures in separate cell chambers (7, 18). The solid electrolyte was transferred to the electrolytic cell, heated to 400°C in a 0.01 Torr vacuum, and then melted under a helium atmosphere. Approximately 7-9 kg of the electrolyte were used in the cell.

The direct current for electrolysis was furnished by a 15V, 30A constant voltage power supply, and by a 15V, 150A full-wave selenium rectifier with variable output. The electrolytic reaction for the preparation of vanadium by electrolysis of VC, with X representing the chlorine or bromine atom, was as follows

$$\text{Anode: } VC + 2X^- \rightarrow VX_2 + C + 2e^- \quad [2]$$

$$\text{Cathode: } VX_2 + 2e^- \rightarrow V + 2X^- \quad [3]$$

On completion of 60 A-hr of electrolysis, the deposit was withdrawn from the electrolyte and cooled to room temperature (25°C) in the lock. The slide valve was closed and the deposit removed. A new cathode was attached and placed in the lock; the lock was then evacuated and filled with helium. The slide valve was opened and the cathode lowered into the electrolyte for starting another deposition. A test in this report refers to the preparation of a single electrolytic deposition of vanadium on the cathode; a series refers to all depositions made with a single charge of the VC material, varying from 1-3 kg; and the term cathode current density refers to initial cathode current density.

The vanadium deposit was immersed for 12 hr in a 2% hydrochloric acid solution to leach out most of the electrolyte. The vanadium was stripped from the cathode, washed with water, then acetone, and dried at 75°C. Previous vanadium research (7, 14) indicated that the minus 80-mesh vanadium fraction of such deposits contained a higher proportion of impurity elements; therefore, the cathode product was sized by screening into plus and minus 80-mesh fractions.

The carbon in the vanadium carbide remained in the anode basket as a skeleton form of the original briquette. The carbon was removed from the cell upon removal of the anode basket at the completion of a series.

Results

Electrolyte composition.—Although an average of 81% vanadium recovery was achieved in the electrolysis of a V_2C carbide in a $BaCl_2$-KCl-NaCl-VCl_2 electrolyte at 670°C (14), electrolysis of VC in the same electrolyte yielded only a 50% vanadium recovery. Low recoveries were also obtained with the use of other electrolytes: 17% in a KCl-LiCl-VCl_2 at 620°C; 21% in an $MgCl_2$-KCl-$CaCl_2$-VCl_2 at 720°C; and 44% in a KBr-NaBr-VBr_2 at 700°C. Increased recoveries of vanadium were obtained in the electrolysis of VC in electrolytes composed of a mixture of NaCl and VCl_2 with other alkali chlorides. These electrolytes contained, in weight per cent (w/o): (*i*) 90 NaCl, 10 VCl_2; (*ii*) 51 KCl, 39 NaCl, 10 VCl_2; (*iii*) 50 CsCl, 40 NaCl, 10 VCl_2; and (*iv*) 45 LiCl, 45 NaCl, 10 VCl_2.

The effects of these electrolytes on the extraction process are compared in Table II. A series of tests was performed with each electrolyte, using 1.5-2.0 kg of VC. Potentials ranging from 0.1-0.6V, and initial cathode current densities from 460-4600 A/dm² were used for electrolyses. Each series was terminated when cathode current efficiencies of individual tests dropped below 30%. The data in Table II show that the LiCl-NaCl-VCl_2 electrolyte was superior to the other electrolytes with respect to lower operating temperature, better vanadium recovery, and a larger yield of plus 80-mesh vanadium. Although cathode current efficiencies of 70 and 72% were obtained in the KCl-NaCl-VCl_2 and NaCl-VCl_2 electrolytes, respectively, the yield of plus 80-mesh vanadium was lower compared with that in the LiCl-NaCl-VCl_2 electrolyte. With the exception of a low operating temperature, the CsCl-NaCl-VCl_2 electrolyte was not as efficient as the other electrolytes.

Plus 80-mesh vanadium, %	32	36	24	50
Minus 80-mesh vanadium, %	68	64	76	50
Cathode current efficiency, %	72	70	46	60

* All electrolytes contained 10 w/o VCl_2.

The average analyses of all the plus 80-mesh and minus 80-mesh products prepared in each electrolyte are shown in Table III. The chief impurities in the product were iron and oxygen. Higher iron contamination occurred in the products prepared in the NaCl-VCl_2 and KCl-NaCl-VCl_2 electrolytes. The advantage of employing a low-temperature electrolyte for the preparation of vanadium was indicated by the lower carbon and oxygen contents of the products produced from the LiCl-NaCl-VCl_2 electrolyte. The products from the latter electrolyte were >99% vanadium, whereas those prepared with other electrolytes were approximately 98% pure.

Vanadium depletion.—The effect of increasing extraction of vanadium from VC on the electrolytic process and the quality of vanadium products was determined in two separate series of tests with the LiCl-NaCl-VCl_2 electrolyte, using 1.4 and 2.6 kg of VC. Each deposit in the series was made with a constant-current electrolysis of 20A, corresponding to an initial cathode current density of 3200 A/dm². Each series was terminated when approximately 90% of the vanadium had been removed from the anode. Figures 2 and 3 show the effects of vanadium extraction on potential, cathode current efficiency, the yield of plus 80-mesh vanadium, and the dragout of electrolyte with deposits. The potential required for maintaining a constant-current electrolysis varied slightly with the extraction of vanadium. The cathode current efficiency, production of plus 80-mesh vanadium, and metal-to-salt drag-out ratio of deposits decreased with increasing extraction of vanadium from the VC. When the quantity of VC was increased, the efficiency of the electrolytic process improved and resulted in lower potential requirements, better cathode current efficiency, higher yield of plus 80-mesh vanadium, and less electrolytic drag-out. Figure 4 shows vanadium

deposits prepared at 5 and 90% vanadium extraction from 1.4 kg of VC.

The purity of the vanadium prepared by electrolysis of VC was governed by its iron and oxygen contents. Figure 5 shows the variations of iron and oxygen content of the vanadium with vanadium extraction. The VC contained 0.05% iron and 1.45% oxygen. Contamination of the vanadium products by these impurities was highest in the first 20% of vanadium extracted and lowest between 21 and 75%, then increased gradually with increasing depletion of vanadium from the VC anode. The best quality vanadium was produced in the middle of the extraction tests. An increase in the initial quantity of VC available for electrolysis lowered both the iron and oxygen content in the vanadium products. The average iron and oxygen content of all products was 0.12 and 0.70%, respectively, for the extraction of the 1.4 kg charge, and 0.07 and 0.58%, respectively, for extraction of the 2.6 kg charge.

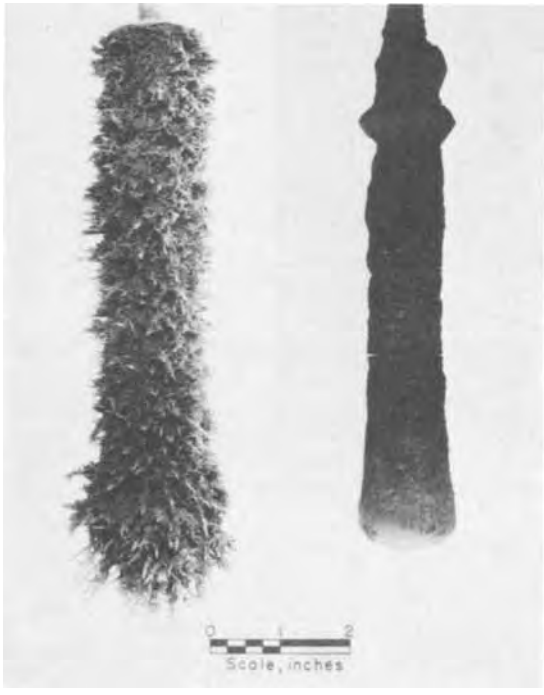

Fig. 4. Vanadium deposits prepared at (left) 5% and (right) 95% vanadium extraction.

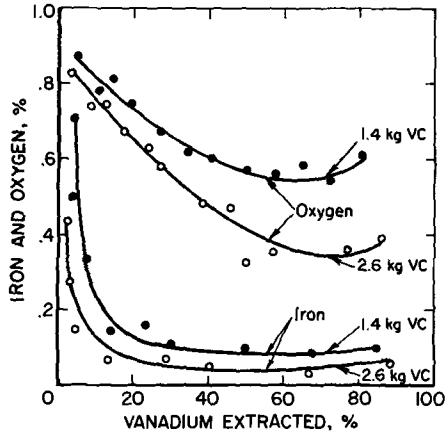

Fig. 5. Variation of iron and oxygen contents of vanadium with vanadium extraction.

Cathode current densities.—The use of various cathode current densities for the electrolyses of VC affected the cathode current efficiencies and yield of plus 80-mesh vanadium, as illustrated in Fig. 6. The values in the graphs were the average values obtained in each series of electrolyses conducted with currents of 5, 15, 20, 25, and 35A in the LiCl-NaCl-VCl_2 electrolyte. Each series was terminated after approximately 85% of the vanadium had been extracted from 1 kg VC. The cathode current efficiencies increased with cathode current densities from 990-3100 A/dm^2, reached a maximum at 3200 A/dm^2, and decreased thereafter with cathode current densities greater than 3300 A/dm^2. The yield of plus 80-mesh vanadium products was relatively constant with cathode current densities ranging from 930 to 3700 A/dm^2, then increased with increasing cathode current densities.

The plus 80- and minus 80-mesh products prepared in each of the series were similar in quality. The plus

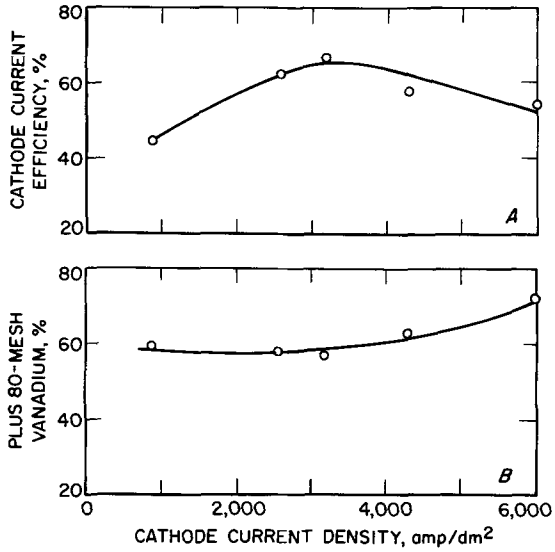

Fig. 6. Variation of (A) cathode current efficiency and (B) yield of plus 80-mesh vanadium with cathode current density.

80-mesh products were 99.2% vanadium, and the minus 80-mesh products were 98.8% pure vanadium. The quality of vanadium prepared with cathode current densities higher than 3700 A/dm² was slightly better than with lower cathode current densities, because larger quantities of plus 80-mesh vanadium were produced with the high cathode-current densities.

Optimum parameters for electrolyses.—The preparation of vanadium by electrolysis of VC was conducted in an LiCl-NaCl-VCl_2 electrolyte at 650°C, using the operating data show in Table IV. The optimum parameters had been determined in preceding tests. Eighty-five per cent of the vanadium was extracted from the VC. The average drag-out ratio of metal-to-electrolyte in the deposits was 0.6-1.0. The quality of the vanadium is shown in Table V. The process yielded an average of 99% vanadium by reducing the carbon, nitrogen, and oxygen contents of the VC. The vanadium was not ductile.

High-purity, ductile vanadium from VC.—High-purity, ductile vanadium was prepared from VC by electrorefining the extraction products in a separate cell or by combining the extraction and electrorefining processes in a single cell. In the first procedure, vanadium deposits which were obtained by electrolysis of VC in an LiCl-NaCl-VCl_2 electrolyte were electrorefined in a KCl-LiCl-VCl_2 electrolyte at 620°C. Electrolyte was not leached from the deposit prior to electrorefining. Previous research (9) showed that a mixture of KCl, LiCl, and VCl_2 was the best suited electrolyte for electrorefining vanadium. Figure 7 compares an extracted vanadium deposit with an electrorefined deposit. The extracted deposit was made with a cathode current density of 4600 A/dm² from VC in which 87% of the vanadium had been removed. The refined deposit was made with a cathode current density of 1300 A/dm². In the extraction 60 A-hr of electrolysis was used and in the electrorefining 32 A-hr of electrolysis was used. The extracted deposit contained approximately 35-40g of vanadium, which was refined to yield 29g of pure metal. Typical analysis of the extracted and refined vanadium is shown in Table VI. Electrorefining reduced the carbon, iron, nitrogen, and oxygen contents of the extracted products and produced 99.9% plus vanadium with a 35 Rockwell B hardness.

Fig. 7. Extracted vanadium deposit (right) and refined vanadium deposit (left).

In the combined process, the vanadium was first extracted from the VC and deposited on the inside of a cylindrical electrode; this vanadium was then electrorefined and deposited on a central cathode rod. Figure 8 shows the cylindrical electrode which was made of molybdenum sheet 0.08-cm thick, 13-cm OD, and 56-cm high. One end of the electrode was attached to a nickel flange, and a molybdenum cup was loosely fitted over the other end. The function of the cup was to prevent the extracted vanadium deposits from falling to the cell bottom and to permit the electrolyte to enter the center of the cylinder. This assembly was installed between the flanges of the chamber and the slide valve of the molybdenum-lined electrolytic cell. The VC was contained in a perforated graphite tube, 5.5 cm diam × 32 cm long, which was suspended in the center of the cylindrical electrode. Extractions were made with potentials of 0.2-1.2V, currents of 23-90A, and 1500-2300 A-hr to deposit the vanadium on the cylindrical electrode. The VC anode container was removed and replaced with a 1.1 cm diam molybdenum rod. Electrorefining of the extracted vanadium was made with a potential of 0.08V, a current of 10A, and 70 A-hr of electrolysis to deposit purified vanadium on the molybdenum rod. Optimum operating parameters were not determined in the combined process. Limited tests showed that the process was capable of producing 400g of refined vanadium from 850g of VC. Typical refined vanadium deposit from the combined process is shown in Fig. 9. The drag-out ratio of metal-to-electrolyte in

Conclusions

The preparation of vanadium by molten-salt electrolysis of a commercial vanadium carbide was demonstrated in a helium-atmosphere electrolytic cell. An LiCl, NaCl, and VCl_2 molten salt mixture was the best electrolyte tested for the preparation. A process was developed for the extraction of 99% pure vanadium by electrolysis of VC with cathode current densities from 3200-3700 A/dm^2 in an LiCl-NaCl-VCl_2 electrolyte at 650°C. The vanadium recovery at the cathode was 85% with 70% current efficiency.

High-purity, ductile vanadium was prepared from the VC by electrorefining the vanadium deposits from the extraction process in a separate cell or by combining the extraction and electrorefining processes in a single cell. Both procedures yielded vanadium of 99.9% purity with 35-40 Rockwell B hardness.

Thermal Behavior of a Plasma-Heated Tungsten Probe in the Presence of Tungsten Vapor

Paul Meubus

Chemical Engineering Department, Université du Québec à Chicoutimi, Chicoutimi, Province of Quebec, Canada

ABSTRACT

A tungsten metal probe is heated in an argon plasma containing variable amounts of tungsten vapor. It is observed that the metal surface temperature substantially decreases when the vapor concentration increases in the gas. All other conditions being equal, the difference residing in the presence of metal vapor in the plasma, the introduction of about 0.7% vapor in the argon gas decreases the probe surface temperature by 18%, while the presence of 8% metal vapor decreases the surface temperature by 28%, the gas temperature around the probe surface being respectively 9000 and 10,000°K. An equation is found, showing the probe temperature variations in terms of the total tungsten particle concentration as well as the gas temperature immediately around the probe. A possible explanation is given for the phenomena observed which involves the existence of a protective shield of tungsten atoms and ions in equilibrium along the saturation vapor curve for tungsten. Also, the presence of solid condensed particles around the probe, with relatively low thermionic work function, may provide a protective, positively charged shield against positive ion bombardment of the probe. This interpretation is supported, to a certain extent, by the equation found.

Thermal protection of solid surfaces submitted to very high temperatures has been extensively studied, especially in view of atmospheric re-entry problems associated with ballistic missiles and also for the protection of jet propulsive devices, turbine blades, etc. Ablation effects have been studied by Slattery (1) and others, while ceramics and refractory oxide coatings have been made the object of considerable work (2).

Also, heat exchange phenomena occurring in the presence of corona discharges (3), as well as heat effects around anodes in arc discharges, have been studied (4). However, the case of the thermal protection for a refractory metal exposed to very high temperatures (plasma gas), by means of a metal vapor of low vapor pressure at elevated temperature, does not seem to have been considered.

In the present work, a tungsten probe is used, one end of which is cooled at a constant rate while the other extremity is plunged in an argon plasma. The plasma gas temperature around the probe is obtained by a spectroscopic method using the intensity emission ratio of argon lines 4158.6Å and 4259.4Å as described in a previous article (5). The solid surface temperature is recorded by pyrometric observations and the validity of this method, which could be altered by the presence of a continuum emission from argon, has been controlled and found acceptable, using a method described elsewhere (6).

Tungsten vapor is supplied to the gas stream issuing from the plasma torch by means of a second tungsten probe exposed to the plasma flame and positioned between the gun outlet and the experimental probe previously described. The metal vapor is then released at a rate which is controlled by the gas temperature and by the relative position of the experimental probe. Also, the rate of cooling water used for avoiding rapid destruction of the probe may be used as a parameter for changing the amount of tungsten vapor present in the main argon gas. Finally a plasma may be obtained with variable amounts of tungsten vapor, it being possible to change the temperature of the gas surrounding the experimental tungsten probe. As the resulting gas flows around the experimental probe, the relationship between metal vapor concentration and probe surface temperature can be studied. Using the argon plasma, identical situations are compared, except for the presence of tungsten vapor at different concentration levels.

The purpose of this study is to examine the possibility of using metal evaporation techniques in order to provide thermal protection to vital equipment parts submitted to very high temperatures, in isolated conditions when heat sinks are not available. Pieces of metal adequately positioned could supply the necessary protective vapor component.

Key words: heat protection by means of metal vapor, heat protection at very high temperatures, heat transfer in high-temperature gas-metal vapor mixtures, heat protection by thermionic emission from high-temperature particles.

Theory

Determination of tungsten vapor concentration around the experimental probe.—Referring to Fig. 1, consider an argon plasma jet P of cylindrical symmetry and the tungsten cylindrical probes R_1 and R_2 described in the section on Apparatus and Mode of Operation. The amount of tungsten vapor in the main argon stream is obtained by evaporation from probe R_1 and the temperature T_S of the probe surface S is modified by either changing the probe position along the plasma axis or by varying the power supplied to the plasma jet.

Average radial spectral readings are made, immediately above the tungsten surface S, for the experimental probe R_2. In this way, average intensities are recorded for argon lines 4158.6 and 4259.4Å. The ratio of these intensities, after correction for absorption and sensitivity variation, leads to the knowledge of an average gas temperature above S. The temperature being known, one can now proceed to the determination of tungsten vapor concentration around the probe R_2 when the choice is made of a suitable tungsten emission line. In the case of the present study, the atomic excitation emission at 4008.8Å for tungsten is used.

Generally speaking, the absolute emission intensity for a given transition leading to an emission at frequency ν and temperature T, modified for absorption by a factor L, is given by

for tungsten

$$I_W = \frac{L_W A_W g_W h_{\nu W} n_W e^{-E_W/kT}}{Z_W(T)} \qquad [1]$$

for argon

$$I_{Ar} = \frac{L_{Ar} A_{Ar} g_{Ar} h_{\nu Ar} n_{Ar} e^{-E_{Ar}/kT}}{Z_{Ar}(T)} \qquad [2]$$

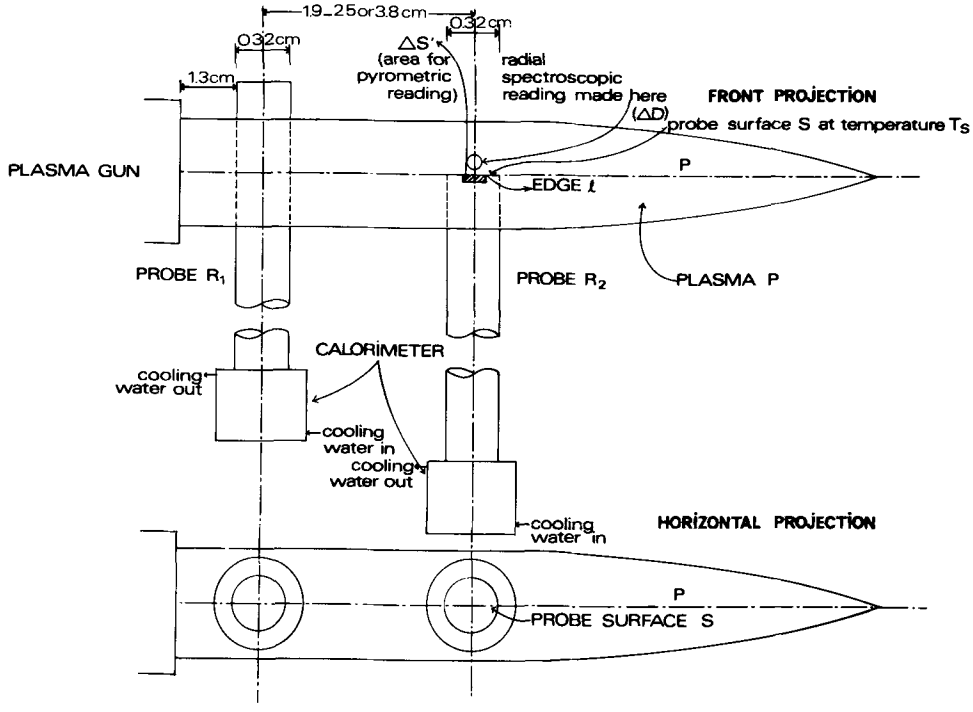

Fig. 1. View of the plasma, tungsten vapor source, and experimental probe.

Dividing [1] by [2] and affecting the results by indices 1 and 2 so as to describe two distinct temperature situations one obtains

$$\left(\frac{I_W}{I_{Ar}}\right)_1 = \frac{Z_{Ar}(T_1) L_W A_W g_W \nu_W}{Z_W(T_1) L_{Ar} A_{Ar} g_{Ar} \nu_{Ar}} \left(\frac{n_W}{n_{Ar}}\right)_1 e^{-\frac{1}{kT_1}(E_W - E_{Ar})} \quad [3]$$

$$\left(\frac{I_W}{I_{Ar}}\right)_2 = \frac{Z_{Ar}(T_2) L_W A_W g_W \nu_W}{Z_W(T_2) L_{Ar} A_{Ar} g_{Ar} \nu_{Ar}} \left(\frac{n_W}{n_{Ar}}\right)_2 e^{-\frac{1}{kT_2}(E_W - E_{Ar})} \quad [4]$$

When ν_W and ν_{Ar} are close enough and I_W comparable in intensity to I_{Ar}, then $L_W \approx L_{Ar}$ and division of [3] by [4] results in the following expression

$$(n_W)_2 = (n_W)_1 \frac{(n_{Ar})_2 (I_W)_2 (I_{Ar})_1 Z_{Ar}(T_1) Z_W(T_2)}{(n_{Ar})_1 (I_W)_1 (I_{Ar})_2 Z_{Ar}(T_2) Z_W(T_1)} e^{\frac{E_W - E_{Ar}}{k}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)} \quad [5]$$

Then, if one value for n_W can be ascertained, the concentration of tungsten neutral atoms n_W can be obtained from Eq. [5] for a set of experimental conditions, where temperature and tungsten total atom concentration are varied, provided $(n_{Ar})_2$ is known. It is to be noted that neither transition probabilities nor absolute spectral emission intensity values have to be known.

The following equations may be written:

1. Saha constant at temperature T for the system $W \rightarrow W^+ + e$

$$K_W = \frac{(n_e)(n_{W+})}{n_W} = 2\frac{Z_{W+}(T)}{Z_W(T)} \left(\frac{2\pi m_e kT}{h^2}\right)^{3/2} e^{-\frac{7.98}{kT}} \quad [6]$$

2. Saha constant at temperature T for the system $Ar \rightarrow Ar^+ + e$

$$K_{Ar} = \frac{(n_{Ar+})(n_e)}{n_{Ar}} = 2\frac{Z_{Ar+}(T)}{Z_{Ar}(T)} \left(\frac{2\pi m_e kT}{h^2}\right)^{3/2} e^{-\frac{15.76}{kT}} \quad [7]$$

3. Total number of particles at temperature T

$$K = (n_{Ar}) + (n_{Ar+}) + (n_W) + (n_{W+}) + n_e = \frac{P}{kT} \quad [8]$$

P being the pressure of operation.

4. Conservation of charge

$$n_{Ar+} + n_{W+} = n_e \quad [9]$$

if the assumption is made of negligible second ionization, which is quite valid in the considered study.

5. Dropping index 2 in Eq. [5], n_W can be obtained provided $n_{Ar}/(n_{Ar})_1$ is known. As a first evaluation, n_{Ar} can be calculated using Eq. [7], [8], and [9] written for argon only. As a result, a first approximation of n_W is available.

From Eq. [6] to [9] together with the value at hand for n_W, one can write

$$[n_W(K_{Ar} - K_W) - KK_{Ar}]\, n^2_{W+} + 2K_W K_{Ar} n_W n_{W+} + K^2_W n^2_W = 0 \quad [10]$$

Solving [10] for n_{W+} (discarding the negative root), the total number of tungsten particles n_{W_T} can be written

$$n_W + n_{W+} = n_{W_T} \quad [11]$$

From the knowledge of n_W and n_{W+}, together with Eq. [6], [7], and [8], a value of n_{Ar} should be found which is identical to the assumed one and an iteration method is applied until this requirement is fulfilled. In this way, a final value is obtained for n_{W_T} in the plasma gas mixture.

Energy dissipation around the experimental probe.— Referring to Fig. 2 which shows the sublimation and vapor equilibrium curve for tungsten, point B is representative of a situation in the plasma above the solid surface S at temperature $(T_S)_B$, the corresponding gas temperature being T_B and the total tungsten particles concentration $(n_{W_T})_B$. Since the flow conditions are turbulent, $(T_S)_B$ and $(n_{W_T})_B$ may be considered as

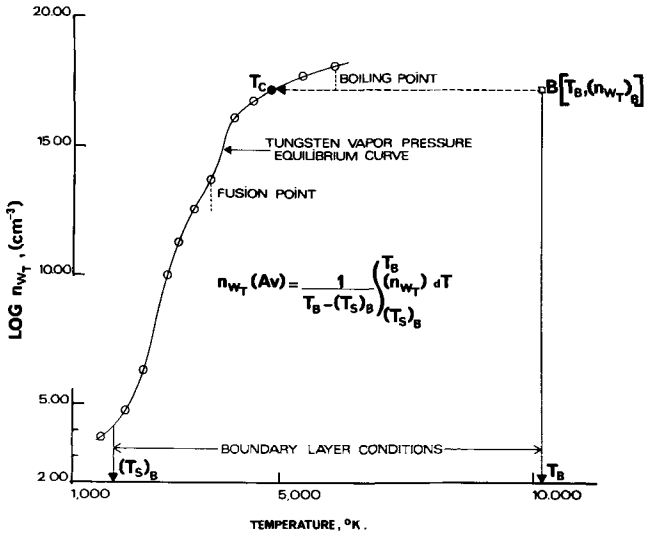

Fig. 2. Vapor and sublimation equilibrium curve for tungsten. Definition of an average value, for the total number of tungsten particles n_{W_T}(Avg) in the boundary layer, for a given concentration $(n_{W_T})_B$ of total tungsten particles in the main gas stream.

the upper limit conditions for, respectively, the temperature and tungsten concentration in the boundary layer adjacent to the surface S. Within this layer, $(n_{W_T})_B$ remains constant while temperature is decreasing until the equilibrium curve is met. Then tungsten vapor starts condensing and solidifying if equilibrium conditions are met.

An average value for n_{W_T} within the boundary layer may be written

$$n_{W_T}(\text{Avg}) = \frac{1}{T_B - (T_S)_B}\int_{(T_S)_B}^{T_B} n_{W_T}\,dT \quad [12]$$

Considering the situation within the boundary layer gas metal vapor, the collision frequency of argon and tungsten particles will depend on n_{W_T} and on the cross section for unlike particles. When momentum is transferred from argon to tungsten atoms, the latter are either repelled out of the boundary layer or condensed when entering a region of lower temperature. Thus, a possible means for avoiding direct heat transfer with the surface S is available. Assuming a maxwellian velocity distribution (which is approximate because of the presence of ions and species of different kinds), the collision frequency for unlike particles, at a given temperature, should be for one argon particle

$$N_{Ar\text{-}W} = \pi n_{W_T} d^2_{Ar\text{-}W}(\bar{v}^2_{Ar} + \bar{v}^2_W)^{1/2} \quad [13]$$

The thermal velocity $\bar{v}_W$ is equal to $\bar{v}_{Ar}\sqrt{m_{Ar}/m_W}$ so that Eq. [13] can be written

$$N_{Ar\text{-}W} = 1.12\pi n_{W_T} d^2_{Ar\text{-}W}\bar{v}_{Ar} \quad [14]$$

When argon particles only are present, the collision frequency is

$$N_{Ar} = 1.41\pi(n_{Ar} + n_{W_T})d^2_{Ar}\bar{v}_{Ar} \quad [15]$$

Taking into account that $d_{Ar} = 1.82$Å and $d_{Ar\text{-}W} = 1.62$Å, then the per cent collision with tungsten particles is of the order of 7% for a 10% tungsten concentration. The collisions between unlike atoms of the considered kind lead ultimately, as already mentioned, to momentum transfer to solid tungsten particles, as well as to ionic recombination, both effects adding up to avoid direct heat transfer with the probe surface.

Also, thermionic emission may possibly contribute to the thermal protection of the tungsten surface S. Considering a solid particle formed by tungsten vapor condensation, the current emission per unit surface is given by the Richardson equation

$$j = UT^2e^{-\phi/kT} \quad [16]$$

where j is the current emission per unit surface, while U and ϕ are, respectively, a constant and the thermionic work function for the considered emissive material. In the case of tungsten Eq. [16] becomes

$$j = 60.2T^2e^{-4.52/kT} \quad [17]$$

If the electrons escaping from the tungsten surface are assumed to take initially the average velocity corresponding to the surface temperature, then the electron concentration at the surface may be obtained from

$$n_{es} = j/e\bar{v}_e \quad [18]$$

and electrons will evaporate from the solid when $n_{es} > n_e$, where n_e is the electron concentration around the particle, leaving a positively charged surface which can play the role of a protective shield for the probe submitted to ion bombardment. This aspect is considered in the section on Results and Discussion.

Apparatus and Mode of Operation

The power supply, control panels, and plasma torch used have been described elsewhere (5). Referring to Fig. 3, the torch generates a plasma of cylindrical symmetry and is enclosed in a chamber C provided with quartz windows for spectroscopic observations. The

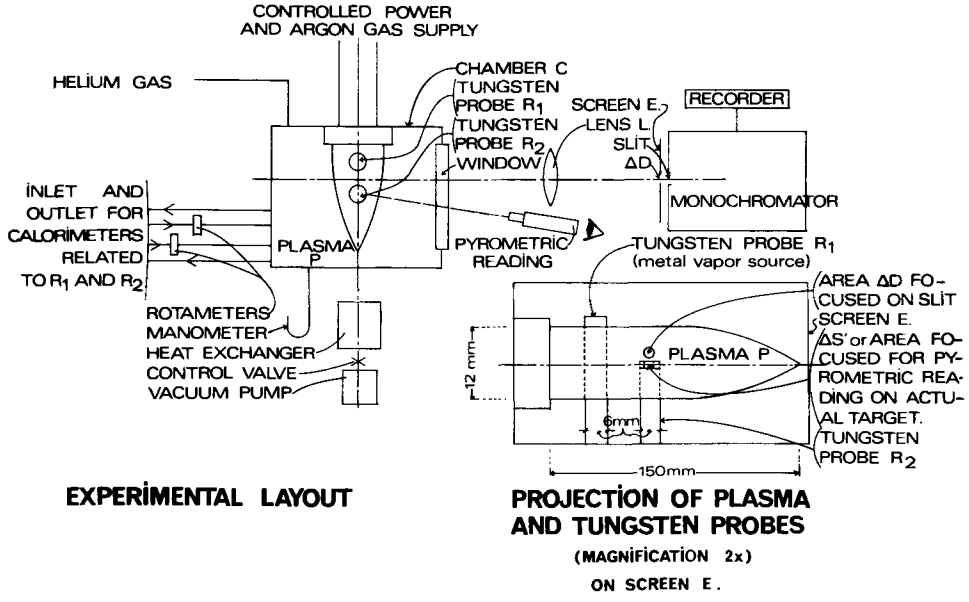

Fig. 3. Layout of the experimental set-up used, with a view of the plasma and probe projection on the monochromator screen E.

chamber is connected to a helium gas supply as well as to a vacuum pump so that it can be scavenged and filled with helium prior to operation.

Referring to Fig. 1, two tungsten probes R_1 and R_2, made of cylindrical rods 3.8 cm long and 0.32 cm diameter, are mounted on calorimeters and installed in such a way that the vertical plane of symmetry of the plasma contains the probe axes. Also, the position of rod R_2 is adjusted so that its upper horizontal surface S contains the axis of symmetry of plasma P. The probe R_1 is positioned across the flame and near the plasma gun outlet as indicated in Fig. 1. This probe is used to supply variable amounts of tungsten vapor to the main gas stream.

Highly turbulent conditions allow a rapid mixing of the metal vapor and plasma gas as may be concluded from relative tungsten vapor average concentration measurements along the plasma axis, in the downstream direction. Probes R_1 and R_2 are cooled at a constant cooling water flow rate in order to avoid rapid destruction and also to maintain identical conditions during the whole set of experiments. The water flow rates are 600 cm^3/min for R_1 and 80 cm^3/min for R_2.

The plasma is operated at 760 mm Hg and various power levels, varying between 4.5 and 6.5 kW, and the argon mass flow rate is kept constant at 500 g/hr for all the experiments made. For a given power input, R_2 is adjusted at three positions along the plasma axis, respectively, at 1.9, 2.5, and 3.1 cm from the probe R_1 which remains in a fixed position at 1.9 cm from the plasma gun nozzle. The geometrical conditions already stated are respected in all cases. As a result, various gas temperature conditions around R_2 may be obtained while the metal vapor concentration is also varied.

A screen E (Fig. 3) is placed in front of a monochromator (Jarrell-Ash 75-150), close to the slit plane, and a magnifying lens L projects an image of the plasma and probes on screen E. Prior to the experiments, rods R_1 and R_2 are adjusted in the plasma vertical plane of symmetry. Position along the plasma axis and adjustment of height are made from outside the chamber and can accurately be adjusted by viewing the image projection on screen E. Transverse and vertical motions of chamber C allow a given radial line in the plasma to be focused on the slit and spectroscopically analyzed. Spectrograms are recorded immediately above the surface S of probe R_2, at ΔD (Fig. 1 and Fig. 3), whose actual size is 1.25 mm in diameter (magnified two times on screen E) and through which a radial average spectrogram is taken.

In this way, intensities are recorded for neutral argon lines 4158.6 and 4259.4Å and for an atomic excitation line for tungsten at 4008.8Å. The wavelength proximity for these lines as well as the comparable magnitude of their intensity in many cases, validates the assumption that total absorption is similar for all the considered lines. An example of recorded spectrogram is given in Fig. 4. The argon lines 4259.4 and 4158.6Å are used for the gas temperature determination, while the 4158.6Å line is used as a reference line for tungsten concentration determinations by means of tungsten line 4008.8Å.

Pyrometric readings (Leeds and Northrup 8131F instrument) are made on $\Delta S'$ (Fig. 1) near the edge 1 of surface S and the observed temperature is considered as equal to the temperature existing on the probe surface S. The validity of the pyrometric reading, which could possibly record solid surface and gas continuum emissions at high gas temperatures, has been verified by using a method described elsewhere (6).

Results and Comments

Varying the heating conditions for probe R_1 as well as the position of probe R_2 resulted in the obtaining of a set of spectroscopic data for transverse readings just above the probe R_2, an example of which is given on Fig. 4. Also, pyrometric readings were taken in order to obtain the associated surface temperature T_S. Considering Eq. [5], the partition functions for atomic and ionized tungsten between 1500 and 11,000°K were calculated using energy levels from Ref. (7) and the correction for ionization potential lowering (8) was found negligible for the electron concentrations met in all the experiments made. The partition function values are found in Table I. For argon, the partition functions, within the useful temperature range, were available in the literature. The energy transition for the 4008.8Å emission was found equal to 3.10 eV.

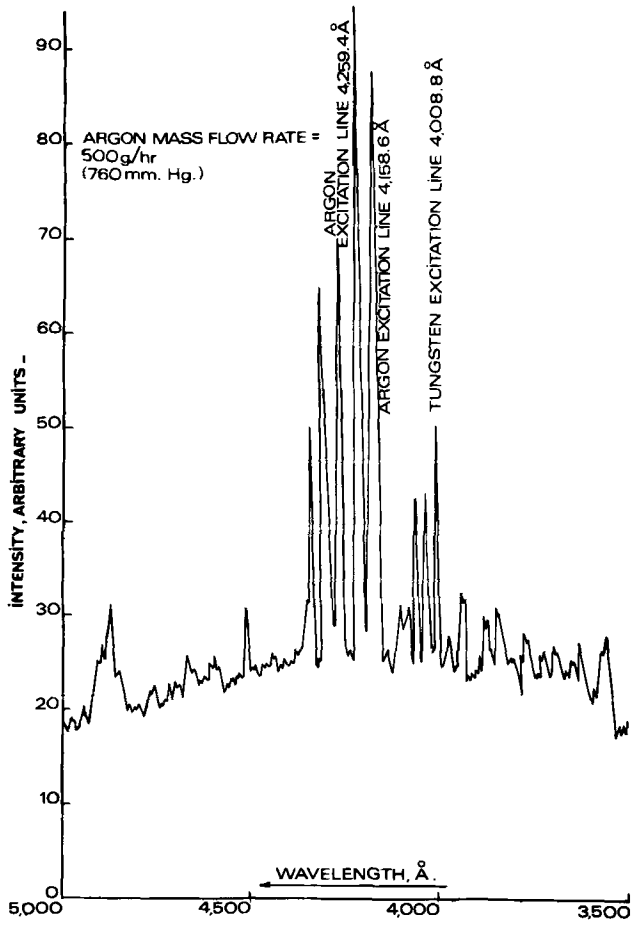

Fig. 4. Example of spectrogram taken immediately above the experimental probe surface and showing the 4259.4 and 4158.6Å lines for argon and 4008.8Å for tungsten.

The reference conditions identified by index 1 in Eq. [5] were taken at 6600°K. The argon line 4158.6Å was taken for defining $(I_{Ar})_1$ and more generally $(I_{Ar})_n$. Then, in order to evaluate $(n_W)_2$ or $(n_W)_n$, an evaluation of $(n_W)_1$ was made. From the projection of probe R_1 on screen E (Fig. 3) and measurement of an average temperature for the area exposed to plasma P, it could be found that a tungsten area of 3.22 cm^2, at a temperature of 3500°K, was available for tungsten evaporation in the argon main stream flowing at a rate

Table I. Partition functions calculated for atomic and ionized tungsten between 1500° and 11,000°K

Temperature, °K	Partition function: Atomic tungsten, Z_W	Partition function: Singly ionized tungsten, Z_{W^+}
1,500	2.60	13.40
2,000	3.53	14.40
3,000	6.20	16.90
4,000	9.35	20.12
5,000	12.78	23.60
6,000	16.77	28.10
7,000	21.92	32.90
8,000	27.38	38.35
9,000	34.20	44.00
10,000	42.26	50.30
11,000	52.20	56.60

of 500 g/hr. The vapor pressure at 3500°K is equal to 7.52 dynes/cm² (9) so that the total number of tungsten particles, n_{W_T}, in the gas stream above 3500°K can be calculated, assuming rapid evaporation equilibrium attainment. $(n_{W_T})_1$ was found equal to 2.13×10^{14} particles/cm³. Application of Eq. [10] and [11], with n_{W_T} being known instead of n_W, and using the iteration method already described, led to the value $(n_W)_1 = 1.30 \times 10^{13}$, the values of K_{Ar}, K_W, and K being represented on Fig. 5.

With this result at hand, all intensity measurements, at different temperatures, of the tungsten line 4008.8Å could be replaced by concentration values n_{W_T} from which total tungsten particle concentrations n_{W_T} could be determined in the argon stream.

The parameters used for describing the probe surface temperature T_S were the gas temperature T_B and an average $n_{W_T}(Avg)$ value for the tungsten particles in the so-called boundary layer, as defined in Eq. [12]. The results obtained for the experiments made are shown in Table II which includes the gas temperature T_B immediately above the probe surface and the corresponding average concentration $n_{W_T}(Avg)$ as well as the surface temperature T_S.

To obtain $n_{W_T}(Avg)$, it was necessary to determine, for tungsten, the sublimation curve obtained from data in Ref. (10), while the vapor equilibrium curve was calculated by means of Kistiakowsky's (11) equation for nonpolar substances

$$\Delta H_T = 8.75T + 1.987T \ln T \qquad [19]$$

together with the Clausius-Clapeyron equation for small temperature ranges

$$\ln \frac{(n_{W_T})_a}{(n_{W_T})_b} = -\frac{\Delta Ha,b}{1.987}\left(\frac{1}{T_a} - \frac{1}{T_b}\right) \qquad [20]$$

The complete equilibrium curve is shown in Fig. 2.

The variation of T_S with respect to $n_{W_T}(Avg)$ for different constant values of T_B appears on Fig. 6 while

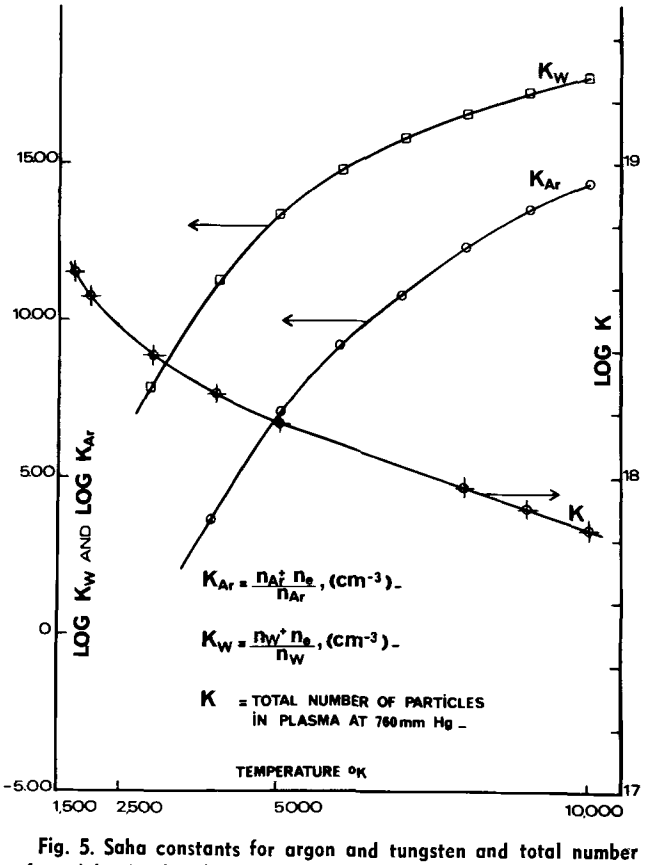

Fig. 5. Saha constants for argon and tungsten and total number of particles in the plasma, for different temperatures at a pressure of 760 mm Hg.

the derived rate of variation $\partial T_S/\partial T_B$ is shown on Fig. 7 as a function of log $n_{W_T}(Avg)$. It can be seen that, up to a value for $n_{W_T}(Avg)$ of approximately $n_{W_T}(Avg) = 1.5 \times 10^{15}$ particles and for temperatures T_B be-

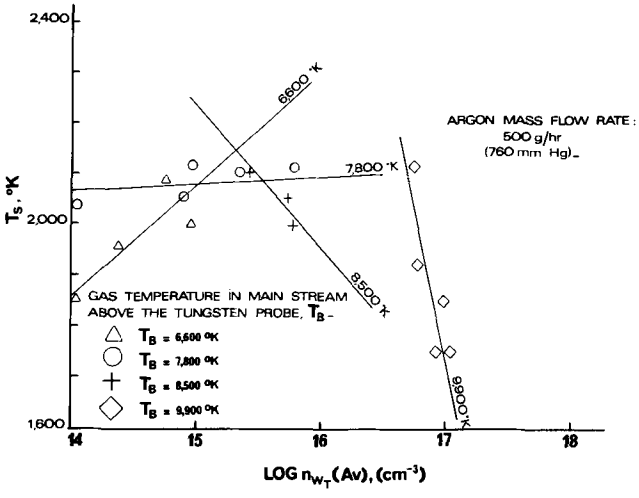

Fig. 6. Probe surface temperature T_S as a function of the average number of total tungsten particle concentration (log) in the boundary layer, for different main gas stream temperatures, T_B, above the probe.

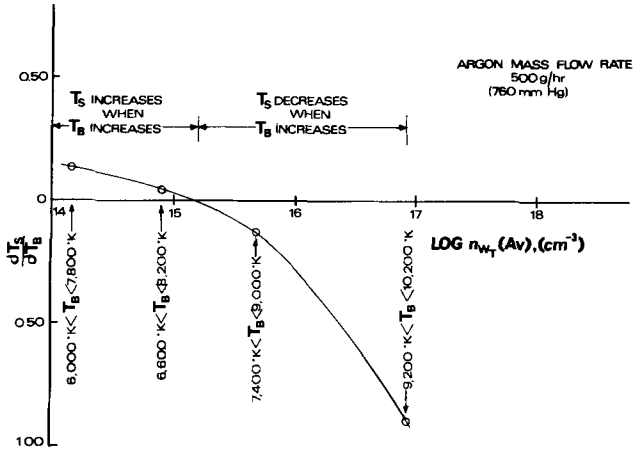

Fig. 7. Rate of variation $\left(\frac{\partial T_S}{\partial T_B}\right)$ as a function of log $n_{W_T}(Avg)$

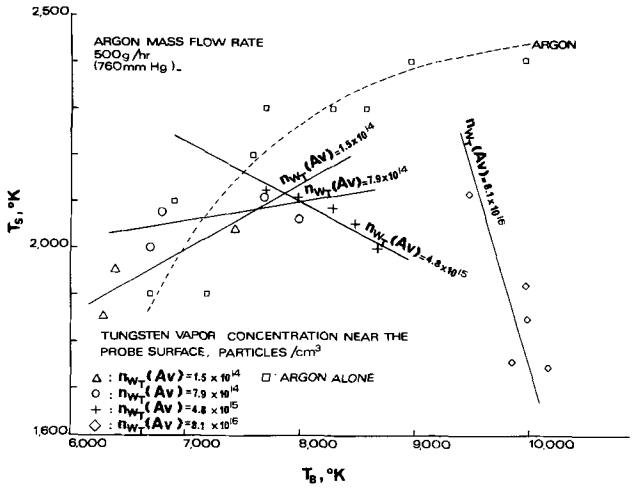

Fig. 8. Probe surface temperature, T_S, as a function of the main gas stream temperature, T_B, above the probe, for different values of the average number of total tungsten particle concentration in the boundary layer.

tween 6600° and 8200°K, the probe surface temperature T_S increases with T_B. For $n_{WT}(Avg) > 1.5 \times 10^{15}$ and temperatures higher than approximately 7000°K, T_S decreases when T_B increases. Figure 8 shows the variation of T_S as a function of T_B for different constant values of $n_{WT}(Avg)$. On the same figure, the variation of T_S against T_B is shown when argon only is present and it can be seen that T_S does increase continuously when T_B increases up to 10,000°K, T_S increasing well beyond the maximum attained by this temperature when tungsten vapor is present. At 9000°K, the presence of about 5×10^{15} tungsten particles per cubic centimeter, or 0.7% tungsten in the gas mixture, decreases the probe surface temperature by 18%, all other conditions being equal.

Figure 9 shows the variation of the rate of change $(\partial T_S/\partial \log n_{WT}(Avg))$ as a function of $\log n_{WT}(Avg)$, the trend being similar to the one already observed. T_S goes through a maximum when $n_{WT}(Avg)$ increases and then starts decreasing, the rate of decrease being higher when the temperature increases. Finally, T_S goes through a maximum for $n_{WT}(Avg) = 1.5 \times 10^{15}$ and $T_B = 7800$°K.

From Fig. 6 and 8, it may be deduced that

$$T_S = f_1(n_{WT}(Avg))\,T_B + f_2(n_{WT}(Avg)) \quad [21]$$

$$T_S = f_3(T_B)\log n_{WT}(Avg) + f_4(T_B) \quad [22]$$

from which

$$\frac{\partial^2 T_S}{\partial T_B\,\partial \log n_{WT}(Avg)} = \frac{df_1(n_{WT}(Avg))}{d\log n_{WT}(Avg)} \quad [23]$$

and

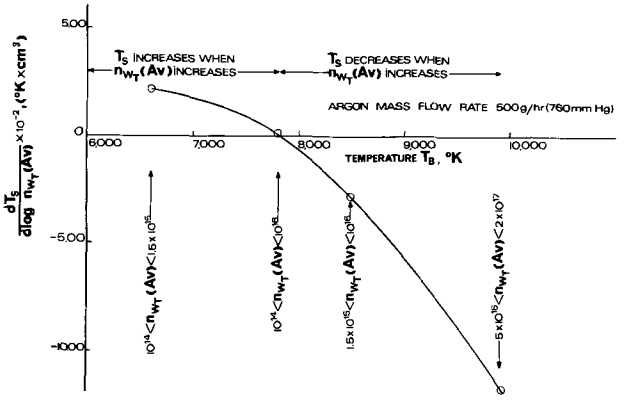

Fig. 9. Rate of variation $\left(\frac{\partial T_S}{\partial \log n_{WT}(Avg)}\right)$ as a function of T_B

$$\frac{\partial^2 T_S}{\partial T_B\,\partial \log n_{WT}(Avg)} = \frac{df_3(T_B)}{dT_B} \quad [24]$$

so that

$$\frac{df_1(n_{WT}(Avg))}{d\log n_{WT}(Avg)} = \frac{df_3(T_B)}{dT_B} = a \quad [25], [26]$$

where a is a constant.

As a result

$$T_S = (a\log n_{WT}(Avg) + b)T_B + f_2(n_{WT}(Avg)) \quad [27]$$

$$T_S = (aT_B + b_1)\log n_{WT}(Avg) + f_4(T_B) \quad [28]$$

From the identity of Eq. [27] and [28], one can write

$$T_S = aT_B \log n_{WT}(Avg) + b_1 \log n_{WT}(Avg) + bT_B \quad [29]$$

Using the experimental data available, it can be found that

$$T_S = -0.0217T_B \log n_{WT}(Avg) + 127.9 \log n_{WT}(Avg) + 0.340T_B \quad [30]$$

Table III shows experimental values for T_S and the corresponding values calculated from Eq. [30], together with the deviation from the predicted mean, this deviation being included between maxima of −8.2 and 9.5% from the predicted mean, the average deviations being +4.2 and −4.4%.

Considering the possible thermionic effects from solid tungsten particles, the electronic concentration n_{es} has been calculated from Eq. [18] for a point temperature around 3500°K in the boundary layer. Table IV shows, for these temperatures, the electron equilibrium concentration n_e in the gaseous phase at a point L, together with n_{es}, the ratio n_{es}/n_e, n_{WT}, and T_B. It can be seen that n_{es} is at least two orders of magnitude higher than n_e, so that it may be expected that positively charged solid particles are present around the surface probe, thus yielding a protective shield against ion bombardment. The importance of the shield depends, of course, on the total number of particles having condensed at point L, or $[(n_{WT})_B - (n_{WT})_L]$, which for all practical purposes is equal to $(n_{WT})_B$. In Table IV, n_{es}/n_e measures the trend toward formation of positively charged solid particles while $(n_{WT})_B$ is a measure of the total thermionic effect per unit gas volume, assuming constant average particle dimension in all cases.

Finally, the right-hand side member of Eq. [30] is made up of two expressions which may be briefly analyzed.

$$(a) \qquad F_1 = -0.0217T_B \log n_{WT}(Avg) \quad [31]$$

The function F_1 accounts for the momentum and thermionic effects already described in the section on Theory and is essentially related to the concentration

$n_{WT}(\text{Avg})$ in the boundary layer. If $n_{WT}(\text{Avg})$ is high, then the number of solid particles should also be high, thus increasing the thermionic protective effects described. But this effect should increase with an increase of ion content in the medium, which is a function of T_B and this justifies the presence of T_B in F_1.

$$(b) \qquad F_2 = 127.9 \log n_{WT}(\text{Avg}) + 0.340 T_B \qquad [32]$$

or

$$F_2 = \log[n_{WT}(\text{Avg})]^{127.9}\,[2.19]^{T_B}$$

Equation [32] implies an increase of heat exchange with the probe and consequently an increase of T_S, all other conditions being equal. This is, of course, related to an increase in transfer effects normally expected when the gas temperature increases. Larger heat transfer rates may also be the result of a thermal conductivity increase with temperature for partially ionized argon (12). Obviously, Eq. [32] is valid only for a temperature range such that 6000°K $< T_B <$ 10,000°K, which has been used in the present investigation.

The probe surface temperature T_S has been determined by means of pyrometric measurements so that an error of ±2% may be expected, which is well within the maximum (around 2400°K) and minimum (around 1700°K) temperatures recorded. The gas temperature should bear an error of ±5% which is normally expected for spectroscopic measurements made in this experiment. This does not essentially affect the conclusions of the present study.

Conclusions

The surface temperature of a tungsten probe heated by an argon plasma has been investigated in the presence of a metal vapor (tungsten) mixed in the plasma gas. The gas temperature near the tungsten surface was varied between 6000° and 10,000°K while the total tungsten atom and ion concentration varied between 10^{14} and 10^{17} particles/cm³ (at 760 mm Hg) or roughly 0.01 and 7% of the plasma gas. Similar tests have been conducted with the argon plasma alone.

Starting from 6000°K, the probe surface temperature goes through a maximum when the metal vapor concentration is about 1.5×10^{15} particles/cm³ (approximately 0.2%) and the gas temperature around 7800°K. At 9000°K, the presence of 5×10^{15} tungsten particles/cm³ decreases the surface temperature by 18% when the latter is compared with identical conditions employing argon alone. It is concluded that the presence of tungsten vapor contributes to a form of thermal protection. The reasons for this behavior are attributed to the formation of solid condensed particles which absorb energy, favor recombination effects, and may build up a protective layer of positively charged solid particles by means of a thermionic effect.

Solvent Equilibria of $AlCl_3$-NaCl Melts

L. G. Boxall,* H. L. Jones, and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

ABSTRACT

The solvent acid-base properties of $AlCl_3$-NaCl melts containing 50-70 mole per cent $AlCl_3$ at temperatures of 175°-355°C are fully described by the use of three equilibrium constants

$$2AlCl_{3(l)} = Al_2Cl_{6(l)} \qquad K_0$$
$$AlCl_4^- + AlCl_3 = Al_2Cl_7^- \qquad K_2$$
$$2AlCl_4^- = Al_2Cl_7^- + Cl^- \qquad K_M$$

At 175°C the K values on the mole fraction scale are 2.86×10^7, 2.4×10^4, and 1.06×10^{-7}, respectively. The ΔH and ΔS values for each equilibrium were found to be temperature independent and calculated values for previously unreported formation constants for the liquid $NaAlCl_4$, $NaAl_2Cl_7$, and Al_2Cl_6 species are reported. Emf data for the aluminum electrode

$$AlCl_4^- + 3e^- = Al\downarrow + 4Cl^-$$

determined as a function of the mole per cent $AlCl_3$, are used to evaluate the equilibrium constants. In the calculations it was necessary to use a variable $AlCl_4^-$ activity coefficient when the mole per cent $AlCl_3$ exceeded 50%. An experimental nondestructive *in situ* procedure for the determination of the exact composition and pCl of any melt is described. This procedure is essential when working in volatile melts.

The $AlCl_3$-NaCl melt can be considered as an acid-base system in which an acid is defined as a chloride ion acceptor and a base is defined as a chloride ion donor. The dissociation of the melt into Na^+ and $AlCl_4^-$ ions leads to an equilibrium involving $AlCl_4^-$

$$\underset{\text{Base}}{2AlCl_4^-} = \underset{\text{Acid}}{Al_2Cl_7^-} + Cl^- \qquad [1]$$

The electrode reaction at an aluminum reference electrode in these melts can be written as

$$AlCl_4^- + 3e^- = Al\downarrow + 4Cl^- \qquad [2]$$

and the electrode potential is given by

$$E = E^o - \frac{RT}{3F} \ln \frac{(a_{Cl^-})^4}{(a_{AlCl_4^-})} \qquad [3]$$

Several other electrode reactions can be written for this electrode; however, the inclusion of the appropriate equilibrium constants in the E^o term will reduce them to the simpler form given above (1). The $AlCl_4^-$ activity is approximately constant in the composition region near 50 m/o (mole per cent) $AlCl_3$; hence, in this region the aluminum electrode becomes a pCl electrode. The term mole per cent $AlCl_3$ throughout this paper refers to the over-all melt composition expressed in terms of the relative number of moles of $AlCl_3$ and NaCl. The amount of true chemical species in the melt is referred to as mole fractions. Several groups of workers have demonstrated that the response of an aluminum electrode to a change in pCl in the equimolar melt can be as large as 300 mV for a change in the mole per cent $AlCl_3$ from 50.0 to 50.4 (1-3). This response becomes less pronounced in the $AlCl_3$ or NaCl rich melts, *i.e.*, the mole per cent $AlCl_3$ is $>$ 50.2% or $<$ 49.8%, respectively. This behavior is analogous to the pH behavior in an aqueous strong acid-base titration.

The high volatility of the $AlCl_3$ inhibits the preparation of a melt of accurately known composition and a reference electrode with a known potential. The po-

Key words: fused salts, $AlCl_3$-NaCl melt, aluminum electrode, acid-base melts.

tential of an aluminum reference electrode in a melt saturated with NaCl (*ca.* 49.7 m/o $AlCl_3$ at 175°C) is extremely slow to stabilize and temperature dependent. The exact reason for the slow equilibration is unknown; however, a slow rate of dissolution of NaCl is suspected.

The purpose of this work was to calculate, at several temperatures, the thermodynamic constants required to completely describe the $AlCl_3$-NaCl melt over a composition range from the NaCl saturated melt to the 70 m/o $AlCl_3$ melt. The design of our electrochemical cell could not contain the high $AlCl_3$ vapor pressure which is present over melts containing more than about 70 m/o $AlCl_3$. The NaCl-rich melts are initially titrated by the electrical anodization of aluminum into the melt and then by the addition of solid $AlCl_3$. A mathematical procedure is developed which enables one to accurately determine the composition of the melt, as well as to adjust the composition of the melt to any desired value.

Experimental Section

Dried Fluka (A.G., anhydrous, iron free) aluminum chloride and Fluka (A.G.) sodium chloride were quantitatively weighed out into a Pyrex cell in a nitrogen-filled dry box. The details of the cell and the electrolysis purification procedure are described elsewhere (4). The final melt (*ca.* 50:50 m/o) was completely colorless and exhibited no irregularities in the current-voltage curves using a microtungsten indicator electrode. A large tungsten counterelectrode and an aluminum reference electrode compartment were then sealed into the cell by means of machined Teflon. A second 10-mm fritted compartment, which was changed for each trial, was used to isolate the aluminum electrode under examination from the rest of the system. The working aluminum electrode (99.999% purity) served both as a source of aluminum for the electrical titration portion of the experiment and as one-half of the aluminum concentration cell potentiometric measurement.

The $AlCl_3$ concentration in the working compartment was increased to about 51 m/o in small increments by constant current anodization. The potential of the working aluminum electrode *vs.* the arbitrary aluminum reference electrode was recorded after each increment in the $AlCl_3$ concentration. Above 51 m/o $AlCl_3$, small weighed amounts of $AlCl_3$ were added until the melt contained *ca.* 70 m/o $AlCl_3$. Cyclic voltammetry showed no appreciable change in the melt's impurity level after these additions. The melt was weighed after solidification to determine the exact amount of melt in the working compartment. No hysteresis in the equilibrium potentials was observed when the $AlCl_3$ mole per cent in the melt was cycled several times between 49.9 and 50.5 by the electrical addition or removal of aluminum. The potential of the aluminum electrode reached a constant value within 2 min after each addition of aluminum and remained constant for up to 10 hr (±0.5 mV). At high $AlCl_3$ concentrations (>65 m/o), there was a slow downward drift in the potential due to the diffusion of the $AlCl_3$ through the frit and the increased volatility of the melt.

A proportional thermoelectric controller was used to control the temperature of the melt to ±0.5°C. The temperature was measured using a Chromel-Alumel Pyrex-sheathed thermocouple and an L&N potentiometer. The precision of the L&N Student Potentiometer was better than ±0.1 mV compared to a precision voltage source.

Results

The following electrochemical cell was used to determine the equilibrium constants for the $AlCl_3$-NaCl system

$$Al/AlCl_3(C_{ref}),\ NaCl/\text{Fritted Pyrex}/AlCl_3(C),\ NaCl/Al \quad [4]$$

where C_{ref} is a constant but unknown reference electrode system. For the same reasons as those outlined by Torsi and Mamantov (2), the liquid junction potential across the Pyrex frit may be neglected in all of the calculations. Only the Na^+ ion needs to be considered in the theoretical calculation of the liquid junction potential since its mobility is much larger than that of the bulky anions in the melt. The Na^+ concentration in the 50 m/o $AlCl_3$ melt is about double that in the 66 m/o $AlCl_3$ melt. A Na^+ concentration profile of this magnitude in nitrate melts produces a junction potential of about 1 mV (5), hence neglecting the junction potential appears to be justified. Then from Eq. [3] the potential for cell [4] is given by

$$E = \frac{RT}{3F} \ln \left[\frac{(a_{AlCl_4^-})}{(a_{AlCl_4^-})_{ref}} \right] + \frac{4RT}{3F} \ln \left[\frac{(a_{Cl^-})_{ref}}{(a_{Cl^-})} \right] \quad [5]$$

It has been shown that the mole fraction activity coefficient for ions in melts remains constant provided that N, the mole fraction, remains below 0.1 (6). For regular solutions, γ_N may be expressed as

$$RT \ln (\gamma_N) = W_T(1 - N)^2 \quad [6]$$

where W_T is the work constant at temperature T. It has been shown experimentally that Eq. [6] is valid for multicomponent melts, as well as the simple binary melts (5). In our system the $AlCl_4^-$ concentration traverses the 1.0-0.1 mole fraction region and a γ value for the $AlCl_4^-$ species must be considered in all the calculations. (Although the $Al_2Cl_7^-$ mole fraction reaches a maximum value of approximately 0.7 in the 66.6 m/o $AlCl_3$ melt, the inclusion of any significant γ value for the $Al_2Cl_7^-$ species in the calculation produced a parabolic deviation between the calculated curve and the experimental curve in the 55-65 m/o $AlCl_3$ region. The best least squares fit to the experimental data was obtained by the use of only the $AlCl_4^-$ γ variation.) Equation [5] can now be simplified to

$$E = \frac{RT}{3F} \ln \left[\frac{\gamma(N_{AlCl_4^-})}{\gamma_{ref}(N_{AlCl_4^-})_{ref}} \right] + \frac{4RT}{3F} \ln \left[\frac{(N_{Cl^-})_{ref}}{(N_{Cl^-})} \right] \quad [7]$$

Other workers (1-3) have postulated that the $AlCl_3$-NaCl melts contain the following species

$AlCl_3$	$AlCl_4^-$	Na^+
Al_2Cl_6	$Al_2Cl_7^-$	Cl^-
	$Al_3Cl_{10}^-$	

Since the $Al_3Cl_{10}^-$ anion exists only in melts of very rich $AlCl_3$ content, we found its inclusion unnecessary for our system calculations. The following set of thermodynamic equilibria were used to interrelate these species in the various melts

$$2AlCl_{3(l)} = Al_2Cl_{6(l)} \qquad K_o \qquad [8]$$

$$AlCl_4^- + AlCl_3 = Al_2Cl_7^- \qquad K_2 \qquad [9]$$

$$2AlCl_4^- = Al_2Cl_7^- + Cl^- \qquad K_M \qquad [10]$$

The K_o values were calculated from vapor pressure data utilizing the procedure outlined by King *et al.* (3). The K_M value was determined from the "S" portion of the titration curve (49.7-51.0 m/o $AlCl_3$) and the K_2 value from the $AlCl_3$-rich portion of the curve (51-70 m/o $AlCl_3$). The K_M determination is almost independent of the initial estimate for the K_2 value, whereas the K_2 determination is moderately dependent upon the K_M value. Iterative procedures involving the K_M determination followed by the K_2 (and W_T) determination were repeated several times to give the best least squares fit to the experimental data.

The mathematical procedure outlined in Appendix I is used to calculate the composition of the melt at each

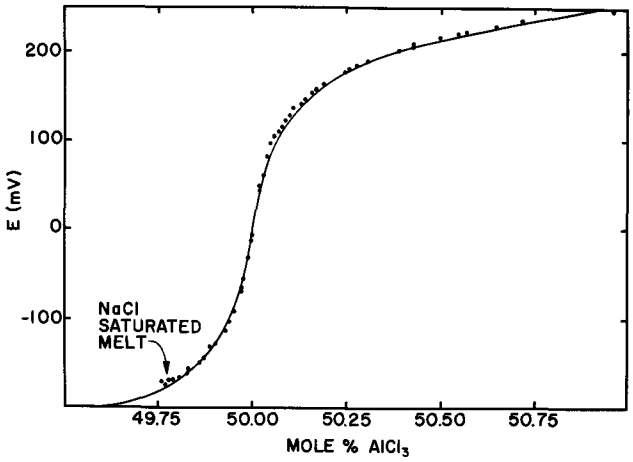

Fig. 1. Comparison of experimental and calculated aluminum electrode potential in a $AlCl_3$-NaCl melt at 175° ± 0.5°C as a function of melt composition (49.75 ≤ m/o $AlCl_3$ ≤ 51).

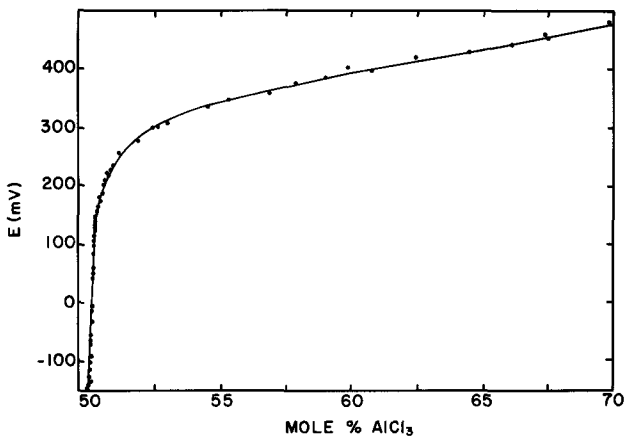

Fig. 2. Comparison of experimental and calculated aluminum electrode potential in a $AlCl_3$-NaCl melt at 175° ± 0.5°C as a function of melt composition (49.75 ≤ m/o $AlCl_3$ ≤ 70%).

experimental point along the electrical titration curve. The mathematical procedure given in Appendix II is now used to obtain a K_M value which gives a minimum least squares deviation between the calculated and experimental aluminum electrode potentials. A final K_M value is obtained by taking the average of the K_M values determined from at least four independent experiments. The data from all the independent experiments are combined by adjusting the potentials to one common reference electrode, *i.e.*, Al in a $NaAlCl_4$ (50:50) melt. The set of combined data in conjunction with the procedure given in Appendix III is used to calculate least square values for K_2 and W_T. Since the original K_M determination relied, to a small degree, on the estimated K_2 and W_T values, the entire computation was repeated until changes in the calculated K_M and K_2 values between two successive iterations were all $<0.1\%$.

The calculated curve for the "S" portion of the titration curve is compared to the experimental data in Fig. 1 and the fit for the entire composition range is given in Fig. 2. A portion of the final computer printout for all the data at 175°C is given in Appendix IV. The final results for all of the measurements are summarized in Table I along with a comparison with the K_M values reported by Torsi and Mamantov (2).

The temperature dependence of W_T is larger in this melt than that observed in other melts (6). This may be due in part to structural changes in the melt with temperature (Fig. 6) which may not be present in simpler melts. The relatively large error in the determination of W_T would also account for much of this apparent temperature dependency. The decrease in the W_T value with increasing temperatures is consistent with observed behavior in other melts (6).

The changes in entropy and enthalpy for the reactions [8], [9], and [10] were calculated using the relationship

$$\Delta G^\circ = -RT \ln K \qquad [11]$$

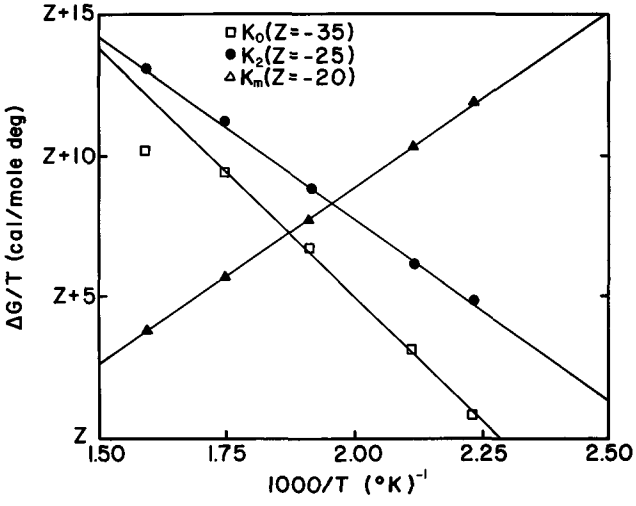

Fig. 3. Gibbs-Helmholtz plots for the determination of ΔH for the equilibria indicated; K_0 ($2AlCl_3 \rightleftarrows Al_2Cl_6$), K_2 ($AlCl_4^- + AlCl_3 \rightleftarrows Al_2Cl_7^-$), and K_M ($2AlCl_4^- \rightleftarrows Al_2Cl_7^- + Cl^-$).

and the Gibbs-Helmholtz equations

$$\Delta S = -\left(\frac{\partial \Delta G}{\partial T}\right)_P \qquad [12]$$

and

$$\Delta H = 1000\left(\frac{\partial(\Delta G/T)}{\partial(1000/T)}\right)_P \qquad [13]$$

The appropriate plots are given in Fig. 3 and the results are summarized in Table II. Cubic equations were used to fit the JANAF temperature dependency of the thermodynamic data (7) for NaCl, $AlCl_3$, and $NaAlCl_4$. The values given for the solid $NaAlCl_4$ in the JANAF Tables are estimates based on the data for solid $KAlCl_4$. No heats of fusion were given for the tetra-

chloroaluminate salts. The interpolated JANAF values and the reaction values given in Table II enabled us to calculate energies of formation for all the species in the $AlCl_3$-NaCl melt. The temperature dependencies of these thermodynamic values are given in Table III.

Discussion

The aluminum electrode is the reference electrode most extensively used in the published electrochemical studies on melts containing aluminum chloride. This electrode offers the advantage of a potential which is stable with respect to time and simplicity of construction and operation. The major disadvantage is the dependence on the melt composition as illustrated in Fig. 1 and 2. Fortunately, the major portion of the published work has been carried out in the 2:1 $AlCl_3$-NaCl melt in which the aluminum electrode is relatively insensitive to small changes in the $AlCl_3$ concentration. In a 2:1 melt, a 25 mV change in potential corresponds to a change of 100 mg of $AlCl_3$ per gram of melt. Since the melts are usually prepared by mixing given amounts of NaCl and $AlCl_3$, the high vapor pressure of the $AlCl_3$ during the fusion process and the uncertainties in the weights of the salts, due to moisture and/or impurities, prevent the accurate preparation of a precisely equimolar melt. In order to obtain a reproducible 1:1 melt (±10 mV reliability in the reference electrode), the weights must be accurate to at least 20 ppm with no volatilization of the $AlCl_3$. This procedure is equivalent to attempting to dissolve solid NaOH in concentrated HCl to produce a pH 7.0 ± 0.1 solution. Our experience indicates that during the purification procedure, enough $AlCl_3$ is lost to produce a melt having a composition of approximately 49.8 m/o $AlCl_3$ and a reference potential of *ca.* 169 and 160 mV *vs.* an aluminum reference in the 1:1 melt at 175° and 200°C, respectively. Increasing the temperature beyond 250°C results in additional loss of a small amount of $AlCl_3$ (*ca.* 0.25 m/o).

The use of an aluminum electrode in a NaCl saturated melt [*ca.* 49.75 m/o $AlCl_3$ (2)] is unattractive due to a slow NaCl solubility equilibrium. In addition, the melt composition is temperature dependent [49.75% at 175°C, 49.3% at 300°C (2)].

With the E_{50} program (Appendix I), an accurate nondestructive determination of the exact composition of the melt in the working electrode compartment can be performed. The ease and accuracy of the aluminum electrolysis addition method enables the adjustment of the melt composition to any desired value within the 50 m/o region. However, at higher $AlCl_3$ concentrations it is necessary to use the less accurate and less convenient method of solid $AlCl_3$ addition. The printout from the E_{50} program directly predicts the electrolysis time required to obtain an equimolar melt by the addition or removal of aluminum.

The K values determined in this work at 175°C are compared with the previously published values in Table IV. All of the new K values are flanked by the published values which contain errors of at least twice those quoted for our values. The computational methods used here permit a better than ±4 mV theoretical fit to the experimental emf data. The simpler procedure used by Mamantov (2) gives a reasonable fit for only the equimolar region (±1%) and generates a 190 mV error in the 2:1 melt. King (3) uses two semiempirical equations to fit the emf data (±12 mV) over the concentration ranges of 51-71 m/o $AlCl_3$ and 49.8-50.4 m/o $AlCl_3$. The concentration range of 50.4-51 m/o $AlCl_3$ is not covered by King's semiempirical equations and there appears to be a definite deviation between the fitted curve and the experimental data at the higher $AlCl_3$ concentrations. Even though King

gives an upper bound for K_3, he does not use it in his calculations. We observed an identical trend in our fit until we included the activity coefficient term for $AlCl_4^-$ species. Species composition diagrams constructed using the first part of the K_M program (Appendix II) are presented in Fig. 4 and 5. These diagrams are similar to King's (3) except that they show far greater detail in the equimolar region. Figure 5 shows that Mamantov's two assumptions (that the $AlCl_4^-$ concentration remains constant and that the melt contains no neutral aluminum chloride) were incorrect, as he suggests at the end of the paper (2). His assumptions were reasonable for the equimolar region but not for the $AlCl_3$-rich melts. This is borne out by the increasing deviation between his calculated emf values and the experimental values. The K_M values determined by Mamantov are equal to *ca.* 70% of our values over the entire experimental temperature range (Table I). Possibly at higher $AlCl_3$ concentrations (>70%), it may be necessary to acknowledge the presence of $Al_3Cl_{10}^-$ species as suggested from Raman work (8).

The melt composition temperature dependencies for both the 1:1 and 2:1 melts are illustrated in Fig. 6. As would be expected, both the NaCl and the Al_2Cl_6 species become more predominant with an increase in temperature. For the reaction

$$AlCl_3 + NaAlCl_4 = NaAl_2Cl_7 \qquad [14]$$

the free energy becomes positive at about 325°C, whereas for the reaction

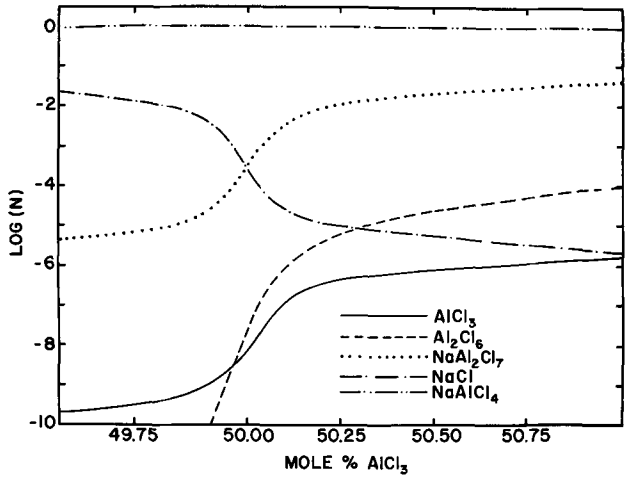

Fig. 4. Mole fraction of the species in the chloroaluminate melt at 175° ± 0.5°C as a function of the net $AlCl_3$-NaCl ratio (49.75 ≤ m/o $AlCl_3$ ≤ 51).

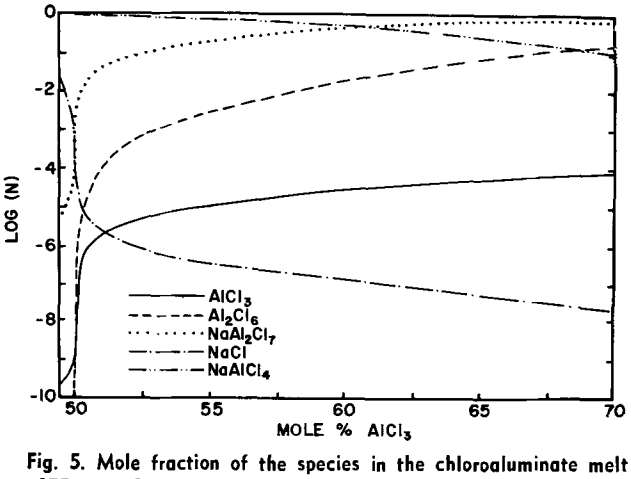

Fig. 5. Mole fraction of the species in the chloroaluminate melt at 175° ± 0.5°C as a function of the net $AlCl_3$-NaCl ratio (49.75 ≤ m/o $AlCl_3$ ≤ 70).

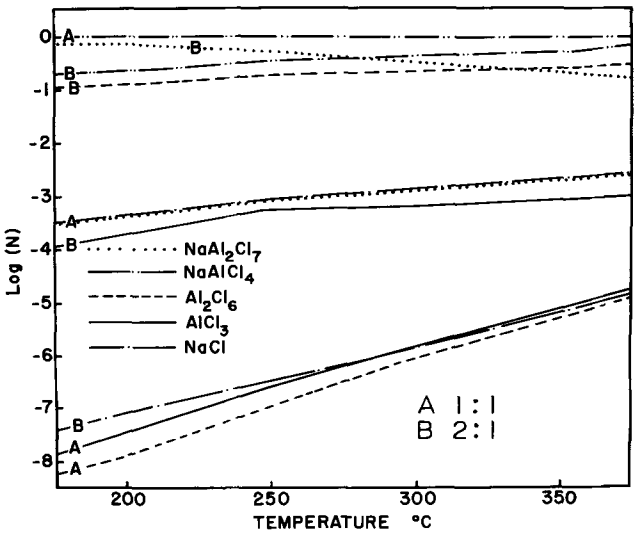

Fig. 6. Temperature variation of the composition of the 1:1 and 2:1 $AlCl_3$-NaCl melts.

$$AlCl_3 + NaCl = NaAlCl_4 \qquad [15]$$

ΔG remains negative until about 480°C. The useful temperature range for the equimolar melt is *ca.* 150°-500°C, but for the 2:1 melt it is 115°-500°C, where the lower temperature limits are literature melting points (14). The magnitude and temperature dependency of the γ values are in accord with that observed for other fused salt systems (5).

The heat of fusion for $NaAlCl_4$ is estimated to be 3.6 kcal $mole^{-1}$ from the entropy values. In the JANAF Tables, the $\Delta H°$ values for solid $NaAlCl_4$ (which were estimated from the $KAlCl_4$ values) appear to be about 10 kcal $mole^{-1}$ too positive. Previously unreported thermodynamic values for the liquid $NaAlCl_4$, $NaAl_2Cl_7$, and Al_2Cl_6 species are summarized in Table III.

The ability to vary the concentration of the chloride ion and the $AlCl_3$ species over four or five orders of magnitude provides a powerful tool to study various equilibria in these melts. Aluminum chloride melts are used in many organic reactions (9) and organic radical cations are stabilized in these melts (10). The acid-base character of amines can be easily studied by the variation of the pCl of the melt. Hames and Plambeck (11) report that the monovalent Cd and Hg species are stabilized by the 2:1 $AlCl_3$-alkali metal chloride melt. Our investigations show that this is not the case in the equimolar melts (4). It appears that the stabilization of these lower valency states is directly related to the acidity of the melt, *i.e.*, the concentration of the $AlCl_3$ and Al_2Cl_6 species. The presence of these low valency states complicates the interpretation of electrochemical results and causes unstable potentials (11). The main disadvantage of the equimolar system is that it is a completely unbuffered system which complicates any dynamic measurement. It may be possible to buffer this system by the addition of a weak acid or base such as $ZnCl_2$ or an organic chloride.

Numerous other inorganic salts (*e.g.*, $SbCl_3$, $FeCl_2$, $SnCl_4$) have vapor pressures high enough to produce the same uncertainty in melt composition as observed in the $AlCl_3$ melt. Workers in these melts must be aware of these problems and how they can affect the concentration of ions analogous to the Cl^- and $AlCl_3$ species. Bauer *et al.* (12) have investigated the $SbCl_3$ melts containing $AlCl_3$ and KCl in which $SbCl_3$ acts as a base

$$SbCl_3 = SbCl_2^+ + Cl^- \qquad [16]$$

$$K = [SbCl_2^+][Cl^-] = 1.2 \times 10^{-10} \quad \text{(mole fraction scale)} \qquad [17]$$

However, they assume that $AlCl_4^-$ exhibits no chloride ion donor or acceptor property. The K values for the $AlCl_4^-$ system indicate that the amount of Cl^- ion originating from the $AlCl_4^-$ would be *ca.* 1000 fold greater than that from the $SbCl_3$. Fortunately, the concentrations used and the accuracy claimed for their measurements minimize the seriousness of this oversight.

The experimental techniques and mathematical procedures developed here elucidate many of the properties and difficulties encountered in the use of the $AlCl_3$-NaCl melt. The ability to determine the exact melt composition by a nondestructive means, as well as to adjust the acidity of the melt to any desired value, makes this melt useful as a high temperature system in which to study numerous organic and inorganic reactions. In addition, the characteristic ability of this melt to dissolve most of the refractory metal oxides will greatly facilitate the quantitative analysis of those oxides (13). These techniques should be applicable to other acid-base fused salt systems.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

APPENDIX I

The following symbols are used throughout the mathematical derivations to differentiate between the number of moles and the mole fraction of a given species (see List of Symbols).

$$n_{NaCl} = \text{number of moles of NaCl} \quad \text{[A-I-1]}$$

$$[NaCl] = N = \text{mole fraction of NaCl} \quad \text{[A-I-2]}$$

In the equation

$$[NaCl] = \frac{(n_{NaCl})_i}{T_i} \quad \text{[A-I-3]}$$

T_i equals the total number of moles in the i^{th} composition of the system. The two neutral forms of $AlCl_3$ in the melt are interrelated by Eq. [8], hence

$$\frac{(n_{Al_2Cl_6})_i}{(n_{AlCl_3})_i^2} = \frac{K_0}{T_i} \quad \text{[A-I-4]}$$

The total amount of neutral aluminum chloride expressed in terms of $AlCl_3$ is given by the equation

$$TN_i = 2(n_{Al_2Cl_6})_i + (n_{AlCl_3})_i \quad \text{[A-I-5]}$$

Equation [9] relates the amount of $AlCl_3$ to the ionic species according to

$$(n_{AlCl_3})_i = \frac{(n_{Al_2Cl_7^-})_i T_i}{(n_{AlCl_4^-})_i K_2} \quad \text{[A-I-6]}$$

From Eq. [A-I-4], [A-I-5], and [A-I-6]

$$TN_i = \left\{ \frac{2K_0 (n_{Al_2Cl_7^-})_i}{K_2 (n_{AlCl_4^-})_i} + 1 \right\} \left\{ \frac{(n_{Al_2Cl_7^-})_i T_i}{K_2 (n_{AlCl_4^-})_i} \right\} \quad \text{[A-I-7]}$$

The number of moles of $AlCl_3$ and Al_2Cl_6 are, respectively

$$(n_{AlCl_3})_i = \frac{-1 + \sqrt{1 + 8K_0 TN_i / T_i}}{4K_0 / T_i} \quad \text{[A-I-8]}$$

and

$$(n_{Al_2Cl_6})_i = D_i = \tfrac{1}{2}\{TN_i - (n_{AlCl_3})_i\} \quad \text{[A-I-9]}$$

The chloride ratio between two different melt compositions, 1 and i, can be calculated from Nernst (Eq. [7]). Let E_1 be the potential of the aluminum electrode in melt composition 1 *vs.* a reference electrode and E_i the aluminum electrode potential in melt composition i *vs.* the same reference electrode.

In the 50 m/o $AlCl_3$ region (±1%), the activity coefficient for $AlCl_4^-$ ion can be considered to be unity and Eq. [7] can be rearranged to

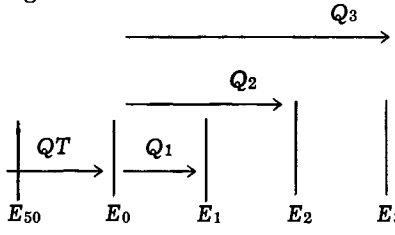
$$R_i = \frac{(n_{Cl^-})_i}{(n_{Cl^-})_1} = \frac{T_i}{T_1} \exp \left\{ \left[E_1 - E_i - \frac{RT}{3F} \ln \left\{ \frac{(n_{AlCl_4^-})_1 T_i}{(n_{AlCl_4^-})_i T_1} \right\} \right] \frac{3F}{4RT} \right\} \quad \text{[A-I-10]}$$

In order to simplify the calculations, all of the experimental data are normalized with respect to 1 mole of $NaAlCl_4$ plus QT moles $AlCl_3$. The electrolysis data are normalized by dividing the electrolysis time by a factor calculated by dividing the initial weight of the melt by (191.8 + QT (133.4)) where QT is the excess $AlCl_3$ in the original melt. In diagram [A-I-12], E_0 represents the original melt in the normalization procedure. During the first iteration QT is assumed to be zero since it is not known; however, in each successive iteration, the calculated QT value is used in the normalization procedure at the beginning of each iteration. If $3Q_i$ faradays of anodic electrical current are passed through the cell, the following will occur

$$3NaCl + Al - 3e^- \xrightarrow{Q_i} AlCl_3 + 3Na^+\uparrow \quad \text{[A-I-11]}$$

with $3Q_i$ moles of Na^+ ions leaving the fritted compartment. The mobility of the sodium ion is sufficiently greater than any of the other ions in the system to permit the assumption that it is the only current carrier in the system. The net result of the electrolysis is then the gain of Q_i moles of $AlCl_3$ and the loss of $3Q_i$ moles of NaCl from the half cell.

The computation procedure can be more easily understood by the use of the following potential-composition diagram



[A-I-12]

Experimentally, three potentials, E_1, E_2, and E_3, separated by two electrolysis periods, Q_2 and $Q_3 - Q_2$, are required for each determination of QT and E_{50}. At any E_i the melt's over-all composition can be expressed as

$$(1 - 3Q_i)NaCl + (1 + QT + Q_i)AlCl_3 \quad \text{[A-I-13]}$$

and the chemical reactions required to produce an equilibrium condition are

$$Cl^- + AlCl_3 \xrightarrow{A_i} AlCl_4^- \quad \text{[A-I-14]}$$

$$Cl^- + 2AlCl_3 \xrightarrow{J_1} Al_2Cl_7^- \quad \text{[A-I-15]}$$

$$2AlCl_3 \xrightarrow{D_i} Al_2Cl_6 \quad \text{[A-I-16]}$$

The total number of moles in the system are

$$T_i = 2 + QT - 2Q_i - A_i - 2J_i - D_i \quad \text{[A-I-17]}$$

where

$$(n_{AlCl_4^-})_i = A_i \quad \text{[A-I-18]}$$

$$(n_{Al_2Cl_7^-})_i = J_i \quad \text{[A-I-19]}$$

$$(n_{Cl^-})_i = 1 - A_i - J_i - 3Q_i \quad \text{[A-I-20]}$$

$$TN_i = 1 + QT + Q_i - A_i - 2J_i \quad \text{[A-I-21]}$$

$$TN_i = \left[\frac{2K_0 J_i}{K_2 A_i} + 1 \right] \left[\frac{J_i T_i}{K_2 A_i} \right] \quad \text{[A-I-22]}$$

since

$$A_i = 1 + QT + Q_i - 2J_i - TN_i \quad \text{[A-I-23]}$$

therefore

$$(n_{Cl^-})_i = J_i + TN_i - 4Q_i - QT \quad \text{[A-I-24]}$$

Using the equilibrium expression for Eq. [10] and Eq. [A-I-10], [A-I-18], [A-I-19], [A-I-23], and [A-I-24], the ionic species in the melt are interrelated by the expressions

$$\frac{(J_1)(J_1 + TN_1 - QT)}{(A_1)^2} = \frac{(J_i)(R_i)(J_1 + TN_1 - QT)}{(A_i)^2} \quad \text{[A-I-25]}$$

$$J_i = \frac{J_1(A_i)^2}{R_i(A_1)^2} = S_i J_1 \quad \text{[A-I-26]}$$

Combining Eq [A-I-10], [A-I-24], [A-I-26], and solving for QT gives

$$QT = \frac{J_1(R_i - S_i) + R_i TN_1 - TN_i + 4Q_i - 4Q_1R_i}{(R_i - 1)} \quad \text{[A-I-27]}$$

and

$$J_1 = \frac{(R_3 - 1)(TN_1R_2 - TN_2 + 4(Q_2 - R_2Q_1)) - (R_2 - 1)(TN_1R_3 - TN_3 + 4(Q_3 - R_3Q_1))}{(R_2 - 1)(R_3 - S_3) - (R_3 - 1)(R_2 - S_2)} \quad \text{[A-I-28]}$$

In melts containing 50 m/o $AlCl_3$ or less the concentrations of the neutral species are at least four orders of magnitude smaller than those of the ionic species and can be neglected. The procedure outlined above has limited usage in the NaCl-rich portion of the titration since it becomes necessary to find small differences between large numbers.

In order to obtain an equimolar melt from a NaCl-rich melt the required amount of aluminum to be added to the melt by electrolysis is

$$Q_{50} = \frac{-QT}{4} \quad \text{[A-I-29]}$$

The ionic concentrations in the equimolar melt would be

$$T_{50} = 1 + \frac{3}{4}QT \quad \text{[A-I-30]}$$

$$TN_{50} = 0 \quad \text{[A-I-31]}$$

$$J_{50} = \frac{(1 - \frac{3}{4}QT)(-2K_m + \sqrt{K_m})}{1 - 4K_m} \quad \text{[A-I-32]}$$

$$[AlCl_4^-] = (1 + \tfrac{3}{4}QT - 2J_{50})/T_{50} = A_{50}/T_{50} \quad \text{[A-I-33]}$$

$$[Al_2Cl_7^-] = J_{50}/T_{50} \quad \text{[A-I-34]}$$

$$[Cl^-] = J_{50}/T_{50} \quad \text{[A-I-35]}$$

and the aluminum electrode potential, E_{50}, *vs.* the reference electrode is

$$E_{50} = E_1 - \frac{RT}{3F}\ln\left\{\frac{A_1}{A_{50}}\left(\frac{T_1}{T_{50}}\right)^3\left(\frac{J_{50}}{(n_{Cl^-})_1}\right)^4\right\} \quad \text{[A-I-36]}$$

$$(n_{Cl^-})_1 = \frac{K_m A_1^2}{J_1} \quad \text{[A-I-37]}$$

The procedure above (Eq. [A-I-13] to [A-I-27]) indicates that if at least two of the data points are in the NaCl-rich portion of the titration curve an alternate procedure must be used [*i.e.*, the over-all number of moles of $NaCl(1 - 3Q_i)$ exceeds the over-all number of moles of $AlCl_3(1 + QT + Q_i)$].

In this case only reaction [A-I-14] needs to be considered and the following equations result

$$A_i = 1 + QT + Q_i \quad \text{[A-I-38]}$$

$$(n_{Cl^-})_i = -QT - 4Q_i \quad \text{[A-I-39]}$$

$$Ti = 1 - 3Q_i \quad \text{[A-I-40]}$$

$$R_i = \frac{QT + 4Q_i}{QT + 4Q_1} \quad \text{[A-I-41]}$$

$$QT = \frac{4(Q_i - R_iQ_1)}{R_i - 1} \quad \text{[A-I-42]}$$

$$J_1 = \frac{-K_m(A_1)^2}{QT + 4Q_1} \quad \text{[A-I-43]}$$

The location of the data points on the titration curve dictated which set of equations, [A-I-13] to [A-I-27], for the $AlCl_3$-rich portion and [A-I-38] to [A-I-43] for the NaCl-rich portion was used. An iterative procedure was repeated utilizing the appropriate set of equations until the change in J_1 became less than 0.01% of the previous J_1 value. Once this was accomplished, the QT and E_{50} values were added to their respective summations in order to provide average values at the end of the experimental data.

The final computer program input requires the temperature, the weight of the melt, the current used in the electrolysis, and estimates for the three equilibrium constants. The experimental data consists of pairs of points, the observed emf, and the cumulative electrolysis time in minutes. Every possible combination of three points is used to calculate the best average values for the entire data set. On the first pass, only every fourth combination is used to arrive at an estimate for the final E_{50} and QT values. In the second pass, every combination is used; however, if the results for a combination differ by more than 20% from the estimated values, they are not included in the final averaging procedure. The final results are printed out in terms of the observed emf and the required electrolysis time to obtain the equimolar melt. Since this procedure relies more on the shape of the curve than the exact values of the equilibrium constants, usually iteration of two or three times utilizing the K values determined in Appendices II and III was sufficient to obtain invariant values (±0.1%). The calculation of the melt composition at each of the data points is now possible.

These calculations were originally programmed in Focal-12 and then as an assembly program for a PDP-12 digital computer.

APPENDIX II

The calculations used to calculate the concentration of the various species in the $AlCl_3$-NaCl melt at any given $AlCl_3$:NaCl ratio are based on the equations

$$1NaAlCl_4 + QT\ AlCl_3\ (moles) \quad \text{[A-II-1]}$$

$$AlCl_3 + AlCl_4^- \xrightarrow{L} Al_2Cl_7^- \quad \text{[A-II-2]}$$

$$2AlCl_4^- \xrightarrow{J} Cl^- + Al_2Cl_7^- \quad \text{[A-II-3]}$$

$$2AlCl_3 \xrightarrow{D} Al_2Cl_6 \quad \text{[A-II-4]}$$

The total number of moles, T, and the total number of moles of neutral aluminum chloride, TN, expressed in terms of $AlCl_3$, are

$$T = 1 + QT - L - D \quad \text{[A-II-5]}$$

$$TN = QT - L \quad \text{[A-II-6]}$$

The amounts of the various species in the melt at equilibrium are

$$(n_{AlCl_4^-}) = 1 - L - 2J \quad \text{[A-II-7]}$$

$$(n_{Al_2Cl_7^-}) = L + J \quad \text{[A-II-8]}$$

$$(n_{Cl^-}) = J \quad \text{[A-II-9]}$$

$$(n_{AlCl_3}) = QT - L - 2D \quad \text{[A-II-10]}$$

$$(n_{Al_2Cl_6}) = D \quad \text{[A-II-11]}$$

From the $NaAlCl_4$ dissociation equilibrium [10] and the definitions

$$M = L - 4K_M\{L - 1\} \quad \text{[A-II-12]}$$

$$N = 4K_M\{L - 1\}^2\{1 - 4K_M\} \quad \text{[A-II-13]}$$

the value of J is given by

$$J = \frac{-M + \sqrt{M^2 + N}}{2 - 8K_M} \qquad \text{[A-II-14]}$$

The subtraction round-off error in the calculation of the $Al_2Cl_7^-$ concentration is avoided by the use of the dissociation equilibrium [10]. Equations [A-I-7] and [A-II-6] are then used to calculate the total amount of unreacted neutral aluminum chloride and to approximate L, respectively. This is repeated until the change in L between two successive iterations is <0.01% of L.

If N/M^2 is less than 0.001 (*i.e.*, in melts containing more than 50.8% $AlCl_3$), all the significance of the N term in the square root term is lost. Therefore, in these aluminum-chloride-rich melts, a different set of equations is required to maintain significance in the calculations. In this instance, J is approximately zero and its contribution in Eq. [A-II-7] and [A-II-8] can be neglected. The value for L must be between 0 and 1, and the mole amounts of the major species are given in Eq. [A-I-8], [A-I-9], and

$$(n_{AlCl_4^-}) = 1 - L \qquad \text{[A-II-15]}$$

$$(n_{Al_2Cl_7^-}) = L \qquad \text{[A-II-16]}$$

The equilibrium constant K_2 is used to set up an equation which can be solved for L in order to minimize the error Z.

$$Z = K_2 - \frac{4LK_0}{\{1 - L\}\{-1 + \sqrt{1 + 8K_0\,TN/T}\}} \qquad \text{[A-II-17]}$$

$$0 \leq L < 1 \qquad \text{[A-II-18]}$$

The J value is given by

$$J = \frac{K_M\{1 - L\}^2}{L} \qquad \text{[A-II-19]}$$

Finally, the concentrations of the neutral aluminum chloride species are calculated from Eq. [A-I-8] and [A-I-9].

The calculation of the aluminum electrode potential is achieved by first calculating the species compositions for the equimolar melt ($QT = 0$), then the composition of melt in question and substituting these values into Eq. [7].

The change in the $AlCl_4^-$ activity coefficient is compensated for in all the calculations wherever $[AlCl_4^-]$ appears by multiplying all the $[AlCl_4^-]_i$ values by γ_i

$$\gamma_i = \exp\left(\frac{W_T}{RT}\left[1 - \frac{n_{AlCl_4^-}}{T_i}\right]^2\right) \qquad \text{[A-II-20]}$$

γ_i is unity for melts containing less than 51 m/o $AlCl_3$; therefore, there is no need to consider it in the K_M calculations.

The data for the S portion of the titration curve ($49.7 \leq$ m/o $AlCl_3 \leq 51$) are used to obtain the best K_M and E_{50} values. These two parameters are adjusted according to the average deviations between the calculated and the experimental emf values (E_C and E_E, respectively, until a minimum standard deviation in E is obtained. The experimental error in the melt composition determination necessitates the use of the perpendicular distance between the experimental curve and the calculated curve, particularly in the 50 m/o region. The perpendicular distance automatically weights the variable which has the largest effect in the calculated error and prevents an over-adjustment in the QT values in the steep portion of the titration curve. This perpendicular value is obtained by multiplying the vertical value $(E_C - E_E)_i$ by a weight factor, WF_i, to obtain the correct error value, ER_i. For D data points, the correction applied to E_{50} in each iteration is

$$E_{50} = E_{50} - \frac{\sum_{i=1}^{D} ER_i}{D} \qquad \text{[A-II-21]}$$

and for K_M

$$K_M = K_M \exp\left\{\frac{8 \times 2.303}{D} \times \left[\sum_{i=1}^{D} \frac{(E_{Ci} - E_{50})ER_i}{|E_{Ci} - E_{50}|}\right]\right\} \qquad \text{[A-II-22]}$$

where

$$ER_i = (E_{Ci} - E_{Ei})WF_i \qquad \text{[A-II-23]}$$

$$FQT = |50 - \text{m/o } AlCl_3| \qquad \text{[A-II-24]}$$

$$WF_i = 1, \text{ if } FQT > 0.289 \qquad \text{[A-II-25]}$$

otherwise

$$WF_i = 18.637(FQT)^3 - 19.888(FQT)^2 + 6.8227(FQT) + 0.1817 \qquad \text{[A-II-26]}$$

The standard deviation in E, E_{SD}, is given by

$$E_{SD} = \sqrt{\frac{\sum_{i=1}^{D} (ER_i)^2}{(D - 1)}} \qquad \text{[A-II-27]}$$

APPENDIX III

The calculated E_{Ci} and ER_i values are determined by the same procedure as outlined in Appendix II. The K_M and E_{50} values are kept constant and the K_2 value is varied to obtain a minimum standard deviation between the observed and calculated potentials. The adjustment to K_2 at the end of each iteration is given by

$$K_2 = K_2 \exp\left\{\frac{8 \times 2.303}{D}\left[\sum_{i=1}^{D} ER_i\right]\right\} \qquad \text{[A-III-1]}$$

The W value for the activity coefficient calculation is then varied manually by units of 100 cal mole^{-1} until an over-all minimum in the standard deviations is realized.

LIST OF SYMBOLS

K_i	equilibrium constant for the ith chemical reaction
E	electromotive force
R	gas constant
T	temperature in degrees Kelvin
F	Faraday constant
a_i	thermodynamic activity of the ith species
γ_N	activity coefficient on the mole fraction scale
N_i	mole fraction of the ith species

W_T work constant at temperature T
G Gibbs free energy
S entropy
H enthalpy
n_i the number of ith species
$[i] = N_i$ = mole fraction of ith species
T_i total number of moles in the ith melt composition
TN_i total number of moles of nonionic $AlCl_3$ in the ith melt composition
D_i number of moles of Al_2Cl_6 in the ith melt composition
QT number of moles of $AlCl_3$ in excess equimolar $AlCl_3$-NaCl melt in the initial melt at the beginning of the experiment
R_i ratio of the number of moles of Cl^- in the ith melt composition to that in the composition designated as 1
Q_i the number of moles of Al^{3+} added electrically to the melt to change its composition from its initial value to that of the ith composition
E_i the emf of an aluminum electrode in the melt after Q_i moles of Al^{3+} have been added
E_{50} the emf of the aluminum electrode in an equimolar melt
A_i, J_i the number of moles reacting according to the given reaction to reach equilibrium in the ith melt composition
S_i the ratio between $Al_2Cl_7^-$ concentrations in the ith and 1 melt compositions
Q_{50} number of moles of Al^{3+} to be added in order to reach the equimolar composition
D, J, L the number of moles reacting in a given melt composition
M defined by Eq. [A-II-12]
N defined by Eq. [A-II-13]
Z defined by Eq. [A-II-17]
WF_i the weight factor to be applied to the error in the calculated fit of the ith data point
ER_i weighted error in the calculated fit of the ith data point

The Kinetics of Chlorine Evolution and Reduction on Titanium-Supported Metal Oxides Especially RuO_2 and IrO_2

A. T. Kuhn and C. J. Mortimer

Department of Chemistry and Applied Chemistry, University of Salford, Salford, Lancashire, England

ABSTRACT

Current-voltage curves were determined on precious metal oxide-coated titanium electrodes under conditions relevant to the chlor-alkali industry. Electrodes in which the oxide coating was of a base metal or only partly of a precious metal were also studied. Clear electrocatalytic effects were found, though in general, linear Tafel behavior was not observed. A possible explanation for the lack of linear Tafel plots in terms of a semiconducting oxide coating was suggested.

Recently there has been a growing interest in the electrochemical behavior of metal oxide films on a passive metal support such as titanium (1-6) following the introduction of electrodes using RuO_2 films into the chlor-alkali industry. Claims have been made that such films are semiconductive in nature (1, 2) but this is at variance with much conductivity data on RuO_2 (7, 8). To elucidate the role of the oxide film, the kinetics of chlorine evolution, and in some cases reduction, have been studied on thermally deposited films of RuO_2, IrO_2, their mixtures with TiO_2, and on films of TiO_2 with other metal oxides. There are clear electrocatalytic effects dependent on the nature of the oxides. Some of the data in both anodic and cathodic directions may suggest specifically semiconducting properties. Whereas work is still continuing, it is felt appropriate to present some of the data obtained to date as this presents a significantly different picture to the only other study (9) yet published.

Key words: semiconducting electrodes, chloralkali anodes, electrocatalysis.

Experimental Procedure

Instrumentation.—The anodic polarization measurements were carried out galvanostatically. This was permissible as no cases of passivation have been observed. The current was provided by a transistorized galvanostat capable of providing currents from 10 μA to 1A.

Since the current densities on different electrodes varied from 1 μA to 10 A $\cdot$ cm^{-2} various arrangements were used for eliminating the ohmic component of the steady-state measured overvoltage. For current densities up to 10^{-1} A $\cdot$ cm^{-2} a conventional Luggin

capillary was used (tip diam ca. 0.5 mm). Where necessary ohmic correction was applied by interrupting the current with a Hg reed switch (ERG HA/W) and recording the potential decay transient in the usual manner on a storage oscilloscope (Hewlett-Packard 141A). This technique was, however, inadequate at the higher current densities since the very active nature of the electrodes and the relatively high resistivity of sodium chloride solutions means that the correction to be applied becomes large in comparison with the value of η_{act}. Moreover, since the capacitance of the electrodes was not high in comparison with their activity, the initial rate of decay is large when such a transient is measured (for a typical capacitance of ca. 100 $\mu F \cdot cm^{-2}$, and a current density of 10 $A \cdot cm^{-2}$, $dV/dt = 10^5\ V \cdot sec^{-1}$). Such a rate of change cannot be followed by a fine Luggin capillary because the time constant of the capillary is included in the reference electrode-working electrode measuring circuit. A coarse capillary is therefore necessary (tip diam ca. 1 mm) and this must be placed at least 2 mm from the surface to avoid shielding effects. The result is now that the sensitivity of the oscilloscope when used in the conventional manner must be low to avoid overloading the amplifier with the total steady-state overvoltage. For this reason the oscilloscope input was switched, as suggested by Flinn (10), with a field effect transistor (FET) switch and a unity gain operational amplifier as a buffer, the latter capable of following $10^7\ V \cdot sec^{-1}$, in the reference circuit. Both the FET and the oscilloscope were triggered by the rise in potential across the galvanostat when this was open-circuited. All leads to the cell were kept as short as possible, and the leads in the current carrying working electrode counterelectrode circuit were twisted together to reduce ringing caused by stray inductances in the current carrying circuit. Substitution of a graphite counterelectrode for a Pt one changed the nature of the ringing from a damped oscillation to a critically damped decay which was more difficult to separate, presumably due to the higher resistance in the circuit. With this circuit the value of η_{act} could be read directly from the oscilloscope and was independent of the position of the Luggin, even when this was at distances of 1 cm. Measurement of the overvoltage by this technique does not necessarily separate potentials in the oxide film from those in the solution since the decay of the potential in the oxide film will also be associated with a R.C. time constant. In view of the high capacitance of anodic films on Ti (16) it is likely that potentials in the film are included in the measured overvoltages. Further work is being carried out in an attempt to clarify this point. Faita and Fiori (9), in a similar study, used the method of short circuiting the working electrode to the counterelectrode rather than open circuiting them. Whereas this will reduce stray capacitances to a minimum, the value of the ohmic overpotential recorded will be in error since the current will be in error because the current will not decay to zero, but rather take up some value in the other direction. It is simple to show that

$$\eta_{apparent} = \eta \cdot \frac{(1 + \text{final cell voltage})}{\text{initial cell voltage}}$$

where initial and final refer to the instant preceding and following the short circuiting. Thus the value of the ohmic drop measured will be a function of the cell resistance and the nature of the counterelectrode.

Cell.—The cell design was similar to that used previously in this laboratory (11). The electrolyte was maintained saturated with chlorine, and was slowly flowed through the cell to prevent any build-up of chlorate. The counterelectrode was of such a size that the main reaction occurring on it was chlorine reduction. The addition of a tap at the top of the Pt/Cl_2 reference compartment enabled electrolyte to be drawn up into the reference compartment from the main body of the cell and held there in a Cl_2-saturated state. All connections, taps etc., in contact with the electrolyte were of glass or PTFE and greaseless.

Trial runs on a rotating disk electrode showed that the only effect of rotation was to displace the η *vs.* log i curve to slightly lower values of log i, indicating a slightly greater surface area available on the rotating electrode. Individual measurements of η_{act} were also slightly more reproducible. However it was felt that in view of the number of electrodes studied, the advantage to be obtained was too small. In runs on stationary electrodes the lowest value of η_{act} measured consecutively at a given current density was taken as the value most representative of the bare surface.

Chemicals.—Brines were made up from GPR grade NaCl. No change in the polarization curves was found from those in an initial experiment using Analar grade NaCl. Chlorine was commercial grade from a cylinder.

Electrodes.—The electrodes were prepared from commercial CP titanium. Plate electrodes were spot welded onto Ti wire supports. All electrodes were etched in 10% oxalic acid at 100°C for 30 min to provide a key for the coating. Coatings were applied by brush and from solutions of precious metal chlorides in propanol, and anhyd. $TiCl_4$ or $Ti(OEt_4)$ in propanol. In applying multilayer coatings the individual layers were fired in air at 400°C for 5 min and the whole electrode for a definite period after that (usually 6 hr). The area of the electrode was defined by covering the support with heat shrinkable PTFE (Raychem Ltd.). In this manner, with 1 mm wire, electrodes down to 0.05 cm^2 can readily be obtained.

Results

Since most of the patent literature (1-6) refers to oxide coatings based on mixtures of RuO_2 and/or TiO_2; coatings of RuO_2 and IrO_2 alone were investigated to define the base from which to study other coatings.

Ruthenium oxide.—Two series of electrodes were prepared to investigate both the effect of the firing time and the coating thickness for RuO_2 coatings. Series (*i*) electrodes (No. 1-4) were coated with 6 coats of 0.4M $RuCl_3$ in propanol fired at 400°C for 1, 5, 20, and 50 hr respectively. Series (*ii*) electrodes (No. 5-8) were coated with 2, 4, 6, and 8 coats of $RuCl_3$ as before and fired at 400°C for 20 hr.

There was no systematic variation in the activity of electrodes 1-4, and only a marginal increase in activity of electrodes 5-8 in that order. A typical polarization curve is shown in Fig. 1 for 5M brine at 20°C.

The curve in Fig. 1 is seen to have two regions, a curved section below $\eta = 85$ mV and a Tafel line of 95 mV/dec. slope above that. Analysis shows that the curved section is longer than would be expected from a mechanism in which the forward and reverse reactions were controlled by a slope of $2RT/F$, without any change of mechanism above the reversible poten-

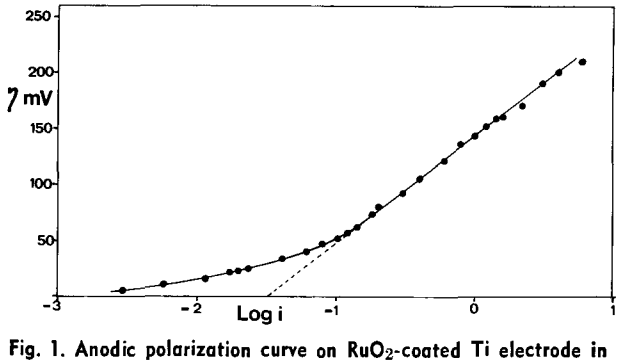

Fig. 1. Anodic polarization curve on RuO_2-coated Ti electrode in Cl_2 sat. 5M NaCl, 20°C. Current density in this and all subsequent figures is given in $A \cdot cm^{-2}$.

tial. This is confirmed by the fact that the calculation of the exchange current on similar electrodes (see below) from the value of the transfer resistance (r_t) in the linear portion of the η *vs.* i plot

$$i_o = \frac{RT}{n\mathbf{F} \cdot r_t}$$

gives a value of log $i_o = -2.2 \pm 0.5$. A tangent drawn from this point to the curve has a gradient of about $RT/2\mathbf{F}$. For the eight electrodes studied the value of the Tafel slope was 108 ± 12 mV/dec. and the value of log $i_o = -1.41 \pm 2$. The reproducibility of the polarization curve on any given electrode is of the order of slope ±5 mV and log $i_o \pm 0.15$.

The behavior of such electrodes at different temperatures in 5M brine is shown in Fig. 2. It is seen that the $2RT/\mathbf{F}$ slope moves to higher values of i_o as expected and that the potential at which it starts rises from about 60 mV at 20°C to 80 mV at 80°C. Measurements of log i_o from the near equilibrium transfer resistance show that this varies very little with temperature, which is consistent with the change in potential at which the $2RT/\mathbf{F}$ slope becomes rate controlling.

Attempts to study such electrodes at progressively more and more dilute brine strengths encounter a problem in so far as these electrodes catalyze the formation of chlorate to a greater extent than a platinum electrode. Thus as the brine becomes more dilute the rest potential, with respect to the reversible Cl^-/Cl_2 electrode on Pt, becomes more cathodic owing to the spontaneous reactions

$$6HClO + 3H_2O \rightarrow 3/2\ O_2 + 4Cl^- + 2ClO_3^- + 12H^+ + 6e^-$$

and

$$2e^- + Cl_2 \rightarrow 2Cl^-$$

Bubbles of oxygen can be seen rising from the electrode at the rest potential in chlorine-saturated 0.1M brine. These reactions account for the position of the curves in Fig. 3.

Current efficiency measurements to be published elsewhere (18) show that the amount of current going to O_2 is *ca.* 4% in 1M brine over the current range of Fig. 3, and 8% in 0.4M brine, before diffusion limitation of Cl^- sets in. In 0.1M brine diffusion limitation of Cl^- occurs at current densities above 0.8 A cm^{-2}. With respect to a RuO_2 counterelectrode

$$\frac{di}{d(Cl^-)\eta} = 0 \quad \text{for } 5M > [Cl^-] > 0.5M \text{ and } i < 100\ mA \cdot cm^{-2}$$

Figure 4 shows the temperature variation of the overpotential in 1M brine. It is seen that at low brine temperatures the overvoltages at current densities > 0.1 A · cm^2 are much higher in 1M brine than in 5M brine, but that at 80°C there is no significant difference.

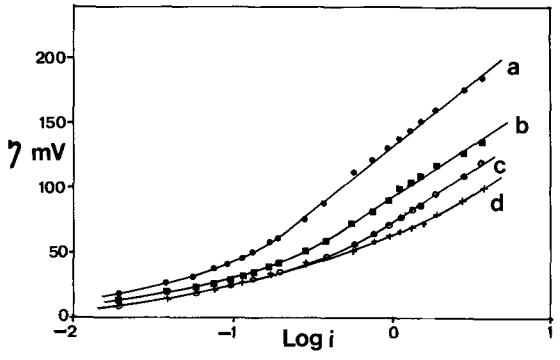

Fig. 2. Anodic polarization curves on RuO_2-coated Ti in Cl_2 sat. 5M NaCl at (a) 20°C, (b) 40°C, (c) 60°C, (d) 80°C.

Iridium oxide.—Figure 5 shows the polarization curve of an electrode coated with IrO_2 in 5M NaCl at 20°C. Such an electrode is black. It is interesting to note that this polarization curve may be compared directly with that for bright Ir which also exhibits a slope of $2RT/\mathbf{F}$. From this it can be concluded that the roughness factor of such electrodes is about 70× that of a bright electrode. Such a comparison cannot be made for Ru since Ru metal becomes coated with a thick coat of RuO_2 when chlorine is evolved on it (17). It is of interest that if the electrode is reduced to Ir with hydrogen at about 500°C the resultant polarization curve is identical to that in Fig. 5, as is the polarization curve of an IrO_2 coating on Ir reduced as above.

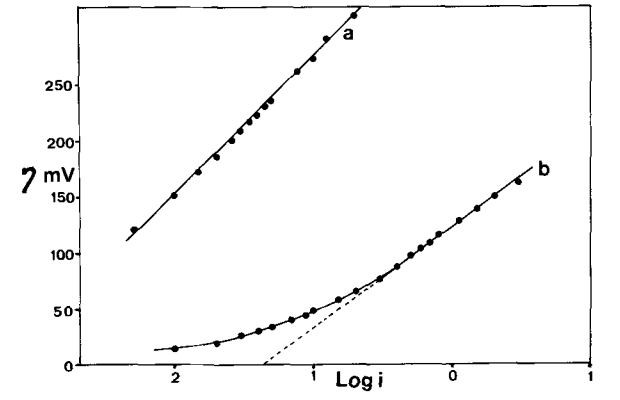

Fig. 5. Anodic polarization curves on (a) bright Ir and (b) IrO_2-coated Ti in Cl_2 sat. 5M NaCl at 20°C.

Mixed oxides.—Since much of the technical data have been concerned with mixed oxides it was decided to investigate coatings with different ratios of $(Ru/Ti)O_2$. A comparison of their activity using i_o derived from the transfer resistance near $\eta = 0$ gave results depicted in Fig. 6. It is to be noticed that with a Ru content greater than about 40 mole per cent (m/o) there is no significant change in the value of i_o. Also, that whereas a rise in temperature increases i_o on the electrodes poor in RuO_2, it has an insignificant effect with RuO_2 concentrations greater than 15-20 m/o RuO_2. However, when the whole polarization curves are plotted the picture is somewhat different (Fig. 7). It is to be noticed that there seems to be a current limiting phenomenon on the electrodes containing TiO_2 and they no longer exhibit the 120 mV slope. The difference between the polarization curves for pure RuO_2 and the mixtures with RuO_2 20% become much less with increasing temperature (Fig. 8). To investigate whether the effect was caused by the film resistance electrodes were prepared with TiO_2 coatings (8 coats) both over and under RuO_2 coatings (3 coats). It was found that placing the TiO_2 underneath resulted in an electrode with the activity of a pure RuO_2 coating. Thus simple resistance of these films would seem to be discounted. The result of placing the TiO_2 on top was rather surprising in that the result was as active as an electrode containing about 20% Ru. Presumably considerable diffusion must have taken place during the firing (20 hr at 400°C). Similar results were found for electrodes of IrO_2 and TiO_2.

In order to investigate a wider range of oxides a series of coatings were prepared containing 90 m/o Ti and 10% of the second metal. These were compared with RuO_2 and TiO_2 coatings (Fig. 9). It is interesting to note the current densities on thermally deposited

TiO_2 films. On anodically formed TiO_2 films the current densities are very much smaller.

Cathodic polarization curves.—Although the cathodic chlorine reduction curves on these electrodes are limited by chlorine diffusion in the case of the active electrodes, the less active electrodes show behavior which is difficult to explain on any simple basis (Fig. 8-10). There is, on electrodes containing up to 10%

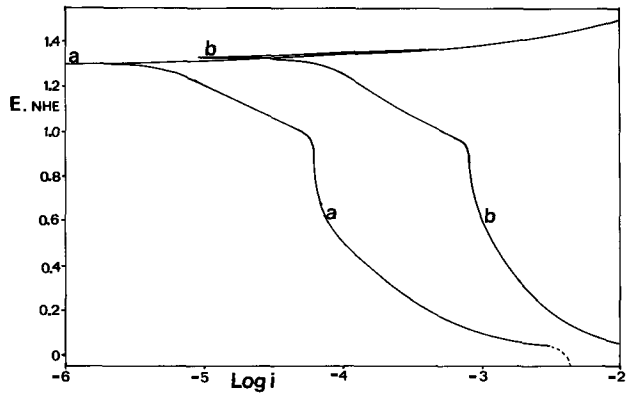

Fig. 10. Anodic and cathodic polarization curves in 5M NaCl at 20°C for an electrode coated with (0.5% Ru 99.5% Ti) oxide (a) in a solution purged with 1/20 atm Cl_2 in N_2 and (b) in Cl_2 sat. solution.

RuO_2, a definite current limitation in the cathodic sense; that this is not diffusion limited is demonstrated both by the diffusion limited curve (f) on Fig. 7, and by the fact that such curves are insensitive to stirring. Working with an electrolyte maintained at 1/20 atm by Cl_2 by means of a stream of Cl_2/N_2 it is seen that the order of reaction on one of these electrodes is almost unity (0.8) at constant E, for values of E between 1.3 and 0.6V NHE.

Introduction of tri- and penta-valent impurities into the oxide layer to alter the semiconducting properties of the film only complicates the polarization curve, and both sets of impurities increase the activity in the anodic sense (Fig. 11).

Discussion

Although there are still many problems in defining the activity of these electrodes with any accuracy since the activity of various batches can vary considerably, especially with electrodes containing only a few per cent of the platinum metal, a general picture has emerged. Only the pure IrO_2 and RuO_2 coatings show any Tafel behavior and then only in 5M brine. In general the activity of the electrodes in the cathodic direction is considerably less than in the anodic direction, but Fig. 9 shows interesting variations in this effect amongst different metal oxide mixtures.

As with any electrode a basic problem is the surface roughness. Trassati (12) asserts that this is not greater than that of the underlying metal, but our results on Ir would seem to contradict this, and would suggest a

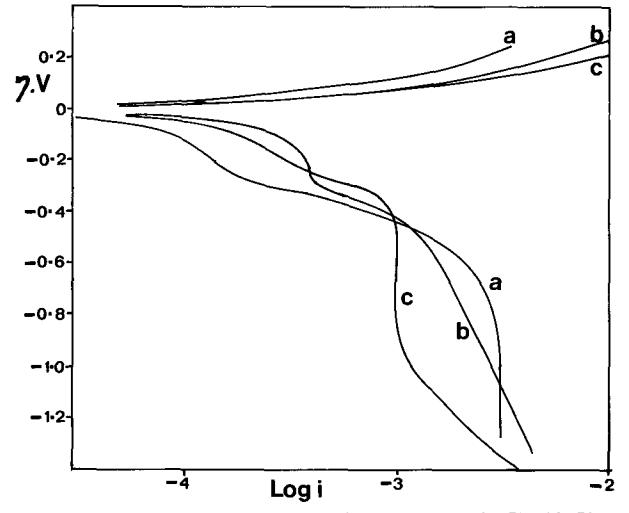

Fig. 11. Anodic and cathodic polarization curves in 5M NaCl at 20°C for electrodes coated with (a) (1% Ru, 99% Ti) oxide (b) (1% Ru, 5% Al, 94% Ti) oxide (c) (1% Ru, 5% Sb, 94% Ti) oxide.

surface roughness of the order of 70× that of bright Ir. A krypton BET that was done on *ca.* 10 cm^2 of RuO_2 coating on a Ti rod gave the surface roughness as 240. This would seem to be in good agreement if every surface atom is considered to be a krypton site, but only 1/3 of them sites for chlorine evolution on the Ir or Ru atoms, assuming that the stoichiometry of this solid extends to the surface.

A second problem concerns the electrical nature of the surface. Whereas both RuO_2 and IrO_2 in the pure crystalline state are metallic conductors due to overlap of the inner d-band electrons the situation for the RuO_2 films is rather different. Fletcher *et al.* (13) found that RuO_2 powder prepared by dehydration of precipitated RuO_2 at 650°C takes up water on exposure to air. The resistivity of the hydrate is about 0.3 ohm-cm when compressed to 40% theoretical density, as compared with 6×10^{-3} ohm-cm for the dry powder at 50% theoretical density. (The resistivity of the pure RuO_2 is 3.5×10^{-5} ohm-cm) (7, 8, 12). These values for the resistivity will not produce any simple ohmic resistance in a film of 1-2 μm thick but do suggest that the films must be classed as semiconductors, and it would be reasonable to assume semiconductors as a n-type. A further confirmation of this hypothesis is that the conductivity of RuO_2 films on silica is sensitive to the firing temperature and has a positive temperature coefficient (14). As the proportion of TiO_2 is increased, moreover, it would be expected that the resistivity would increase. The polarization curves can thus be accounted for by the fact that in a semiconductor there will be a diffuse double layer of charge in the solid. The potential across the layer will increase as the number of carriers in the semiconductor decreases in much the same manner as in dilute electrolytes owing to the depletion of carriers in the layer. The potential across this layer is not separable from that across the Helmholtz double layer since it is also associated with capacitance. For a n-type semiconductor this potential will increase as the electrode becomes more anodic and the increasing charge on the Helmholtz layer, and the increasing number of surface states deplete the interface of charge carriers.

The behavior of pure RuO_2 and IrO_2 can be accounted for by assuming that their conductivity is still high enough to exhibit essentially metallic behavior. This would explain the identical nature of the polarization curves on a layer of black IrO_2 and that on the same oxide when it has been reduced, and is presumably only covered with a monolayer of oxide.

The fact that a thick film of coherent oxide grows on Ru (17) when chlorine is evolved on it suggests that the oxide may have a lower conductivity when grown in this manner.

In the more dilute brines where there will be an increasing tendency to absorb oxygen or hydroxyl ions on the surface, the additional number of surface states may account for the change in behavior of RuO_2 to that observed on the less active electrodes in 5M brine.

The behavior of the RuO_2/TiO_2 mixtures can be divided into two types. When RuO_2 is greater than 20% the difference in activity from that on pure RuO_2 is slight at low current densities. On increasing the current density an additional overpotenital is found, which is greater the greater the concentration of TiO_2. However, this latter overpotential decreases on raising the temperature. This is what would be expected if this potential were located in the film since raising the temperature will increase the number of charge carriers. On these electrodes the effect of temperature on the low density region is slight as on the pure RuO_2 electrode, and one can assume the overpotential in this region to be in the Helmholtz layer. On the inactive electrodes $RuO_2 < 5\%$ the effect of temperature on their activity is marked even at low current densities (Fig. 6). On these electrodes the major part of the

overpotential observed may lie in the film, and is thus decreased with increasing temperature.

Industrially it is known that electrodes such as those may fail by oxide growth at the Ti/coating interface if used at too high an overpotential which would also suggest potentials in the film.

The fact that the film seems to have rectifying characteristics in the cathodic direction may be due to the shift from a mechanism in which electrons are being donated to the conduction band, to one in which they are being accepted by the valence band (15), but such a hypothesis is extremely tentative.

Trasatti has studied the amount of charge involved in charging and discharging a RuO_2 coating in $HClO_4$, obtaining values of "q" the charge-to-change electrode potential from 1.54 to 0.3V between 20-90 mC. This charge depended linearly on the thickness of the films and it was suggested that this represents some change in the bulk of the film. Such charging, involving between 2-7% of the Ru atoms in the crystal might also account for the cathodic behavior observed by changing the stoichiometry of the oxide and therefore its conductivity from one type to another, as the amount of Ru^{III} increases.

Generally, similar results have been noted on anodic TiO_2 films where the capacitance of thick films may be greater than the double layer capacity and increases with the thickness of the film (16). In the latter study the capacitance was decreased by cathodic polarization apparently by protonation of the film. However, the film could be restored by anodic polarization without any apparent change in the film thickness. We have noted a general tendency for films to become less active when taken to high anodic potentials, this activity is restored by cathodic polarization without any apparent permanent damage. Changes in the proton content of the film and thus the Ru^{III}/Ru^{IV} balance as envisaged by Trasatti might account for this.

The difference between this work and that of Faita and Fiori (9) can, we believe, be explained as follows: (*i*) the method for ohmic correction that they used may have affected their results especially at low current densities, (*ii*) they worked in a cell that was not saturated with chlorine, but had a steam of N_2 flowing over the top, presumably to protect the rotating disk mechanism. This means that the readings at the lower current densities will be referred to a more cathodic reversible potential than the reading at higher current densities. Such a curve may be seen in the anodic direction in Fig. 10, and would suggest a Tafel slope of about $RT/2\mathbf{F}$ over at least two decades of current. It is otherwise difficult to explain why their electrodes should have such high overpotentials in comparison with generally similar electrodes in this study at low current densities, *i.e.*, 50 mV *vs.* 5 mV at 1 mA · cm^{-2} in 5M NaCl at 20°C.

The Piezogalvanic Effect

Gerald D. Mitchell* and Charles Feldman

Applied Physics Laboratory, The Johns Hopkins University, Silver Spring, Maryland 20910

and Robert T. Foley*

Chemistry Department, The American University, Washington, D. C. 20016

ABSTRACT

The "piezogalvanic effect" is an electrical response produced by the application of an asymmetric external force to a symmetrical solid electrolyte cell. An experimental study of this effect in a solid ionic conductor has been conducted. Parameters controlling the effect were found to be fabrication procedures, electrodes, and stress produced by the applied force. Tests demonstrated that the effect was present under both static and cyclic conditions. Observations lead to the conclusion that the piezogalvanic effect is established by an interfacial (faradaic) process rather than any process associated solely with the mechanical and physical properties of either the electrolyte or the electrode.

When a unidirectional force is applied to one face of a symmetrical solid electrolyte cell such as Ag/AgI/Ag a potential is generated and a current flows in an external circuit connecting the two electrodes. This pressure-induced potential in solid electrolytes was reported by Mrgudich (1) in an experimental study and a theoretical explanation was put forward by Hunger (2) in terms of the defect structure of the

* Electrochemical Society Active Member.
Key words: piezogalvanic effect, solid electrolyte cycling test.

solid electrolyte (AgI). We have termed this effect the "piezogalvanic effect." This refers to the potential difference and the accompanying flow of current induced by unsymmetrical stress on the electrodes of a galvanic cell. This definition is applicable to galvanic cells employing liquid and solid electrolytes.

The effect of stress on electrodes in aqueous solutions has been studied by a number of investigators (3-24) and the effect of stress on ionic conduction in crystals has also been considered (25-32). New observations on stress-induced effects in solid electrolytes should, of course, be related to these prior studies.

In this report, experiments that (*i*) evaluate fabrication parameters, (*ii*) determine the sign and magnitude of the potential and current, and (*iii*) assert the reproducibility of the signal obtained in solid electrolyte cells are described. A second paper will deal with the theoretical interpretation of the effect.

Experimental

Cell construction.—The cell under investigation consists of a Ag electrode, a AgI electrolyte, and another Ag electrode. The electrodes were made from pressed Ag powder or vacuum-deposited Ag metal. The AgI used in this study was obtained commercially and purified in our laboratory except where otherwise indicated. "Purified" AgI from Fisher Scientific Company was washed several times with hot deionized water and dried at 125°C for 24 hr. Ag electrodes were prepared from different types of material, precipitated Ag powder, Ag paste, and "liquid" Ag, a viscous suspension of finely divided Ag in organic solvents. All electrode materials were used without any further purification or treatment. Pressing of powders was accomplished with a 24-ton hydraulic press with an evacuable die 1¼ in. in diameter.

A number of techniques for fabricating the cells were explored: (*i*) pressing of individual layers of Ag and AgI powder and subsequent assembly of the three pressed disks, (*ii*) consecutively compacting the three individual layers followed by pressing of the complete cell, (*iii*) method (*ii*) except that the die was heated to about 120°C during pressing, (*iv*) vacuum deposition of Ag onto pressed AgI, (*v*) cementing of prepressed Ag electrodes onto the pressed AgI disk with conductive Ag filled epoxy resin, and (*vi*) painting and subsequent firing of Ag paste and/or "liquid" Ag onto a pressed AgI disk.

Methods (*ii*) and (*iv*) were most successful and used for studies reported here. In a preliminary study, the influence of "forming pressure" was evaluated. No significant advantage was observed with using a hot die [method (*iii*)]. A typical cell prepared by method (*ii*) contained 10g of AgI and 3g of Ag powder for each electrode. The complete cell measured 3.1 cm in diameter and 2.3 mm thick. A typical cell prepared by method (*iv*) contained 10g of AgI and vacuum-deposited electrodes 4000Å thick. Thin Ag wires were soldered to the electrodes with indium for electrical measurements.

Cell Testing

Static measurements.—The cell was mounted on the base plate of a John Chatillon and Sons Model HTC press as pictured in Fig. 1. The cell was placed on a recessed lip 2.3 mm in width. Force was applied through a Plexiglas rod. A Brown and Sharpe deflection gauge with a deflection sensitivity of 2×10^{-4} cm/division was mounted in contact with the sample 5.6 mm from the point of application of the force (Fig. 2). No strain measurements or calculations were made; only deflection data were used. The open-circuit voltage and the resistance of the cells were measured. Cell voltages were measured with a high impedance Keithley Model 610 electrometer.

A typical voltage-time response that describes the time frame of the effect is shown in Fig. 3. The measurement was performed by loading the cell with a 2-kg force and then dropping a 1-kg weight on a plate attached to the top of the test apparatus. This technique of preloading the cell was only used in this particular measurement in order to avoid possible lag in the apparatus. The voltage rises to a peak at about 1 min after dropping the weight and then decays to

Fig. 1. Test apparatus

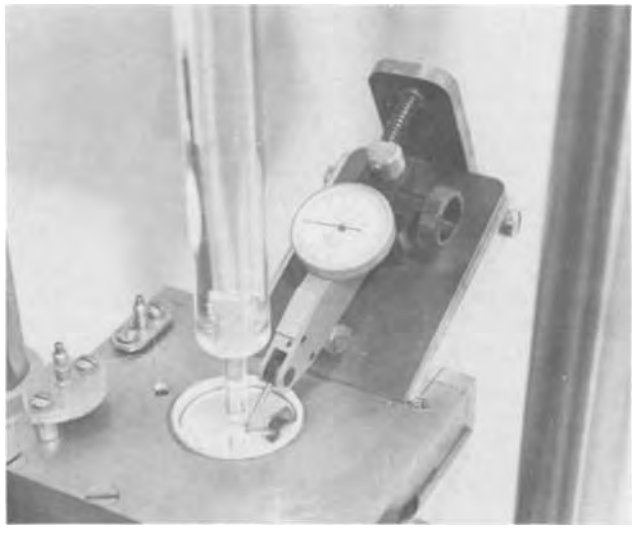

Fig. 2. Close-up view of test apparatus

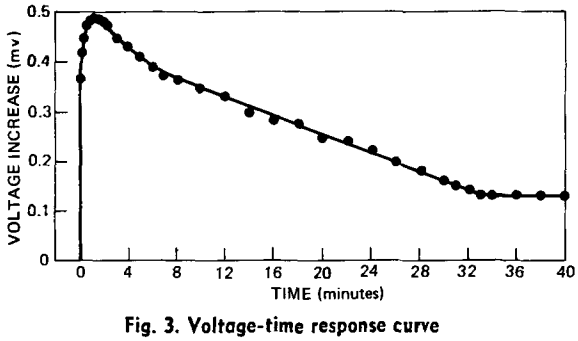

Fig. 3. Voltage-time response curve

a new equilibrium under constant load in approximately 40 min. The peak or maximum voltage is used in all data presented in this work.

Electrical resistances given in this report, except where noted, were measured on a ESI Model 250 DA impedance bridge operated at 1 kHz frequency. In several experiments the resistance under cyclic stress, the dynamic resistance, was measured by observing the resistance necessary to reduce the cell voltage to one-half the open-circuit value. The dynamic resistance was measured at a frequency of less than 1 Hz.

The temperature dependence of the piezogalvanic potential and cell resistance was measured over the range of 24°-212°C. Cells were mounted in an oven and stress was applied through the top of the oven by means of weights.

Cyclic Testing

"Cyclic testing" similar to that reported by Mrgudich (1) was conducted in order to evaluate the mechanical behavior and reversible character of cells over an extended period of time. The apparatus used for the cyclic testing is shown in Fig. 4. The cell was mounted on a cold-rolled steel bar (1 x 17 x 0.045 in.). The motors housed in boxes were Gleason Avery synchronous 30 rpm right-hand rotation motors. A Hewlett-Packard Model 7100B strip chart recorder (Model 17501A plug-in units) with a voltage range of 1.0 mV full scale recorded the piezogalvanic potential change. The one most successful technique for attaching cells to the oscillating steel bar consisted of attaching the cells directly to the bar by a nonconducting epoxy resin. The samples were tested by continued oscillation for a period between 200-300 hr without interruption.

Results

Evaluation of cell preparation methods.—The influence of forming pressure on the following properties was evaluated: (*a*) density of pressed electrolyte, (*b*) breaking force of the cell, (*c*) piezogalvanic signal at a 3 kg (arbitrary) load, and (*d*) maximum piezogalvanic signal at the breaking load.

Table I summarizes these electrical and mechanical properties of the cell with two types of electrodes, vacuum-deposited and pressed Ag powder. Samples with deposited electrodes and with AgI pressed with a force of 22 tons/in.^{2} show the maximum voltage response. For cells with deposited electrodes the maximum voltage output due to an applied force and the force needed to break the cell increased with forming pressure. Cells prepared using pressed electrodes showed essentially no change in the voltage response as a function of forming pressure. Cells so prepared exhibited higher breaking forces than cells prepared with deposited electrodes due to the greater amount of material (Ag) incorporated into the cell.

Table I. Summary of the electrical and mechanical properties of cells with varying types of electrodes

Sample No.	Type of electrode	Forming pressure (tons)	Per cent single crystal density	Voltage change under a 3 kg force (mV)	Breaking force (kg)	Voltage change at breaking point (mV)
AgI-1	Deposited	1	88.2	0.55	4.00	0.68
AgI-2	Deposited	4	95.2	1.70	3.75	2.40
AgI-3	Deposited	8	97.2	1.40	5.00	2.80
AgI-4	Deposited	12	98.6	1.84	5.50	3.41
AgI-5	Deposited	16	99.3	1.52	5.00	2.56
AgI-6	Deposited	20	98.8	1.85	9.50	5.00
AgI-7	Deposited	22	99.3	1.85	10.50	4.60
AgI-8	Pressed	1		0.20	6.50	1.25
AgI-9	Pressed	4		0.05	15.50	0.63
AgI-10	Pressed	8		0.09	13.25	0.41
AgI-11	Pressed	12		0.10	16.00	0.53
AgI-12	Pressed	16		0.06	16.50	0.41
AgI-13	Pressed	20		0.13	18.00	0.69
AgI-14	Pressed	22		0.07	20.00	0.57

The density of the compacted AgI was measured as a function of forming pressure using cells prepared with 10g of AgI and with vacuum-deposited electrodes. The density of the pressed electrolyte asymptotically approaches the theoretical with increased forming pressure. A maximum density of 5.64 g · cm^{-3} equivalent to 99.3% of the single crystal density for AgI (33) was achieved.

Dependence of Signal on Deflection and Force

Cells with varying amounts of AgI electrolyte were constructed using deposited Ag electrodes. The test stand and deflection gauge shown in Fig. 1 were used to determine the peak voltage response as a function of applied force and deflection of the cells. A potential difference is developed across the cell during fabrication. This potential difference is referred to here as the bias voltage. The bias voltage associated with the cells tested ranged from a few tenths of a millivolt to as much as 10 mV. All voltage changes reported have been normalized for the existing bias voltage. Figures 5 and 6 show the piezogalvanic response for cells of varying thicknesses of electrolyte material. In Fig. 5 there is a linearity between voltage response and deflection. In the thicker cells, the curves are offset from zero but exhibit the same slope, that is, 1.8 mV/μ. This offset is attributed to a portion of the applied force

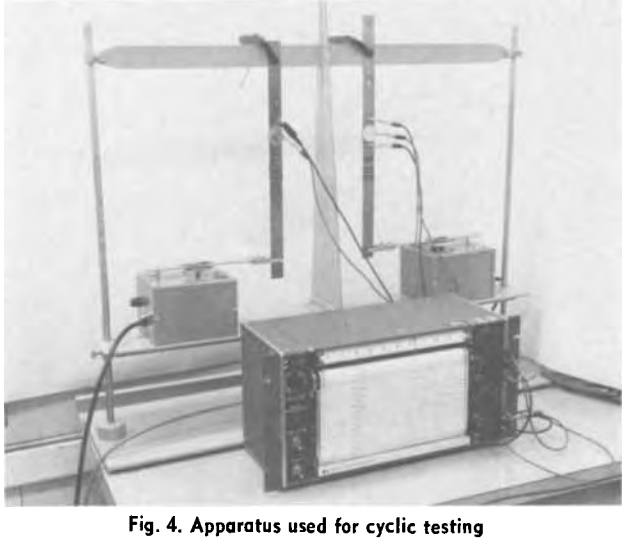

Fig. 4. Apparatus used for cyclic testing

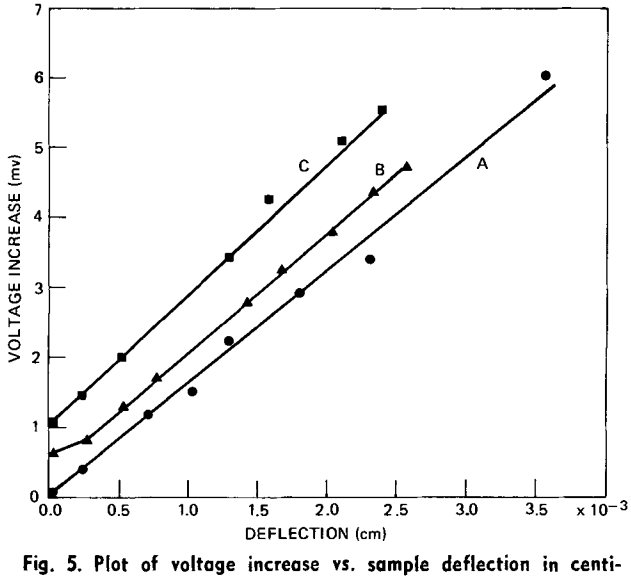

Fig. 5. Plot of voltage increase vs. sample deflection in centimeters. Curve A, cell thickness 1.50 mm; bias voltage + 1.10 mV. Curve B, cell thickness 3.20 mm; bias voltage + 2.00 mV. Curve C, cell thickness 2.40 mm; bias voltage — 0.30 mV.

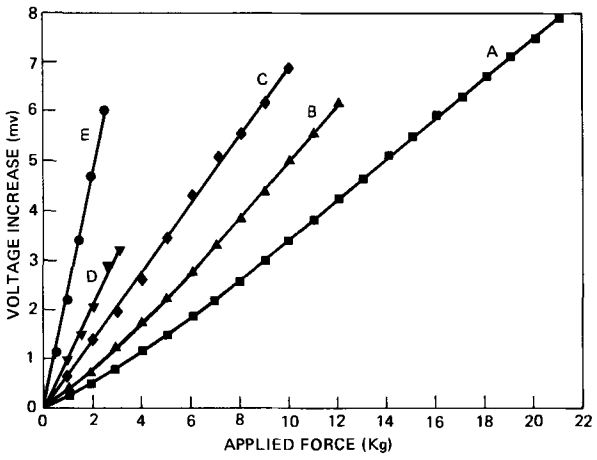

Fig. 6. Plot of voltage increase vs. applied force for cells of various thickness. Curve A, cell thickness 4.20 mm; bias voltage −3.15 mV. Curve B, cell thickness 3.20 mm; bias voltage + 2.00 mV. Curve C, cell thickness 2.40 mm; bias voltage − 0.30 mV. Curve D, cell thickness 1.85 mm; bias voltage + 1.30 mV. Curve E, cell thickness 1.50 mm; bias voltage + 1.10 mV.

going into compressing the electrolyte rather than bending the entire cell. Figure 6 demonstrates linearity of voltage response as a function of applied force for cells of varied thickness. The sensitivity or slope for Fig. 6 is greatest for the thinner sample. For example, a cell 4.2 mm thick shows a slope of 0.50 mV/kg, while a cell of 1.5 mm exhibits 2.5 mV/kg.

Temperature dependence of conductivity and voltage response.—The electrical conductivity and the voltage response of cells was measured over the range 24°-212°C. AgI (99.999% pure) from Semi-Element Corporation was used as the electrolyte and the electrodes were vacuum-deposited. Arrhenius-type plots are shown in Fig. 7 from which activation energies may be estimated.

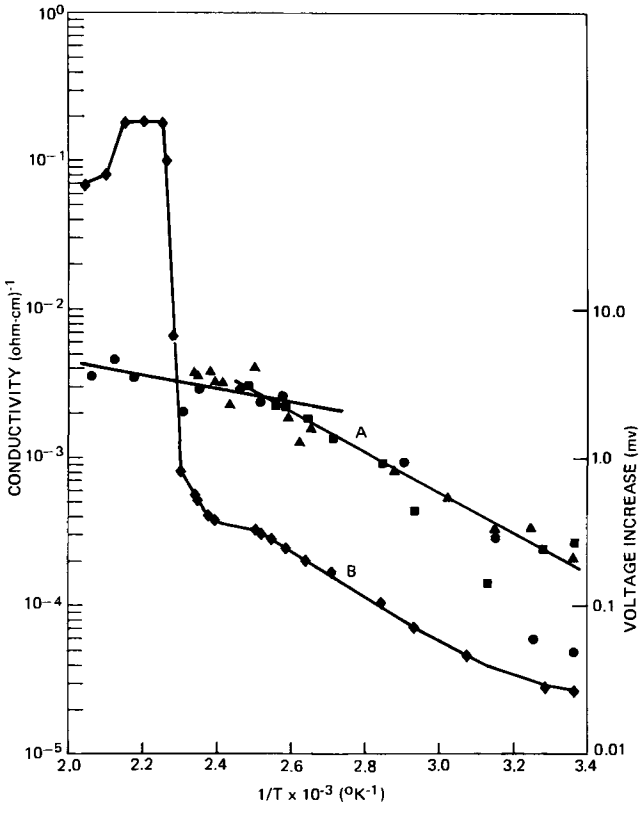

Fig. 7. Temperature dependence of conductivity and piezogalvanic voltage. Curve A, plot of voltage increase vs. 1/temperature. Curve B, plot of conductivity vs. 1/temperature.

The activation energy for the conduction process, ΔE^*_c is calculated from

$$\sigma = \sigma_0 e^{\frac{-\Delta E^*_c}{RT}}$$

where σ is the conductivity and σ_0 is an experimentally determined constant (34). The rapid change in the slope of the curve at about 150°C is due to the $\beta \rightarrow \alpha$ phase transition of AgI. Using the slope of the curve from 100° to 147°C, an activation energy of 15.5 kcal was calculated. This agrees with the activation energy of 15.7 kcal reported in the literature for conduction in β-AgI over the temperature range of 20°-146°C (35).

The activation energy for the piezogalvanic potential, ΔE^*_p was calculated from

$$\Delta V = \Delta V_0 e^{\frac{-\Delta E^*_p}{RT}}$$

where ΔV is the piezogalvanic potential at temperature T and ΔV_0 is a constant. The activation energy derived from the low temperature data (from 24° to 100°C) is 13.4 kcal. Above about 100°C the process becomes almost temperature independent with an activation energy of less than 1 kcal. From Fig. 7 it is evident that there is no corresponding increase in piezogalvanic signal above 150°C to correlate with the $\beta \rightarrow \alpha$ phase transition.

Cyclic behavior of cells.—Cells were tested for extended periods of time with stresses exerted in a cyclic manner with the apparatus shown in Fig. 4. A typical trace from a recording is shown in Fig. 8. In this experiment the cell was mounted 12.7 cm, and the drive attachment, 35.5 cm from the point of attachment. The amplitude of the bar swing was 3.8 cm. The symmetry of the voltage oscillation is evident from this curve as is the linearity of the effect with stress. During the testing period of over 200 hr, no appreciable change in open-circuit voltage output occurred. The dynamic resistance of the cells were also measured and determined to be approximately 200 ohms.

Cells with dissimilar electrodes.—Cells were prepared with the following configurations

Ag/AgI/Ni and Ag/AgI/Au

Forces were applied to the Ag and Ni (or Au) electrode side of the sample by the apparatus shown in

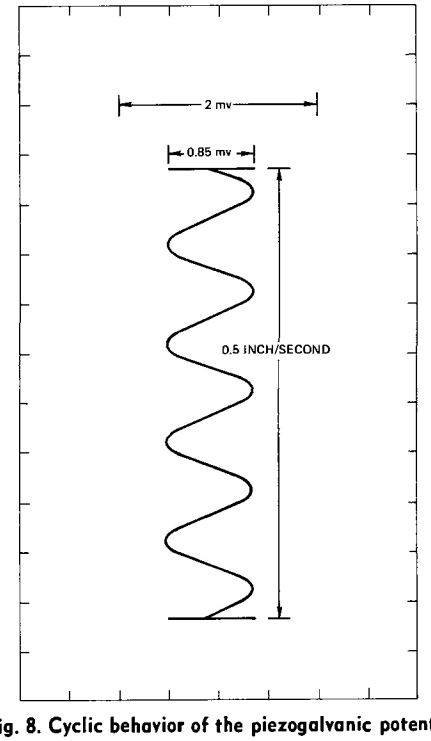

Fig. 8. Cyclic behavior of the piezogalvanic potential

Table II. Piezogalvanic effect with cell of dissimilar electrodes

	Force (kg)	(mV)	(mV)
		$\Delta V_{Ag(stressed)}$	$\Delta V_{Ni(stressed}$
Sample No. 1 Ag/Ni (formed at 22 tons)	1	0.60	0.20
	2	1.40	0.60
	3	1.95	1.10
		$\Delta V_{Ag(stressed)}$	$\Delta V_{Au(stressed}$
Sample No. 2 Ag/Au (formed at 20 tons)	1	0.50	0.10
	2	1.35	0.20
	3	1.15	0.40

Fig. 1. Table II shows the behavior of these cells with applied forces up to 3 kg.

The behavior of the cells depended on the electrode receiving the applied force. Changes in voltage were consistently larger when the Ag electrode received the applied force rather than the Ni or Au electrode.

Discussion

The progress in understanding the piezogalvanic effect has been hampered by a lack of quantitative information with respect to the parameters determining the magnitude of the effect (both voltage and current). This research was intended to correct that situation and from these experiments it is possible to make certain observations.

In the literature describing potential-stress experiments in aqueous solutions two types of effects have been reported. The first has been that of the transient type wherein a transient voltage peaks and decays in times less than 1 sec after the electrode is plastically strained. Such an effect has been reported by Funk *et al.* (9). The second type described by Fryxell and Nachtrieb (12) consists of a "stable and reversible" voltage response persisting for many minutes after plastic strain. The effects reported in this study are in the second category. On sudden loading the voltage rises rapidly to a peak in about a minute and decays over an extended period of time up to 1 hr.

The magnitude of the piezogalvanic effect depends on the method of preparation and the mechanical properties of the cell. It is of particular interest that the voltage signal is determined in a significant way by the type of electrode. Cells constructed with vacuum-deposited electrodes yield voltage signals greater by an order of magnitude than those prepared with pressed powder electrodes. This would tend to make unrealistic a theoretical explanation based only in terms of the electrolyte.

A systematic study of the dependence of the signal on deflection and force showed that the effect is linear with force. Sensitivity, in terms of millivolts per kilogram loading, is a function of cell thickness. Sensitivity in terms of millivolts per micron deflection, however, is independent of cell thickness. Equal changes in electrode deflection, regardless of sample thickness, produced equal piezogalvanic voltages. (The slopes of the curves in Fig. 5 are essentially equal.) Cells containing thicker electrolytes appear less sensitive than ones containing thinner electrolytes because more force is required to achieve the same deflection change. This implies that electrode and/or interface stress plays a major role in the effect.

The temperature dependence of the piezogalvanic voltage change when compared with the temperature dependence of conductivity yields two significant conclusions. The conductivity in solid AgI increases when the beta form is transformed into the alpha form at 146°C. However, a corresponding increase in piezogalvanic voltage is not observed. Thus, the piezogalvanic effect is not determined by the conductivity of the solid ionic conductor. The dynamic resistance of the cell is larger than the cell (AgI) resistance. These resistances were measured at different frequencies. The frequency dependency of resistance should provide a significant clue to the theoretical basis of the effect and for that reason is now under investigation.

The activation energies for both the conduction process and the piezogalvanic effect appear to be similar at low temperatures. The energies are such as to suggest a diffusion process as the rate limiting process. However, above 100°C the piezogalvanic effect shows a very low activation energy and apparently processes that limit the rate at the lower temperature do not occur at the higher temperature.

The cyclic tests demonstrate that the effect is reversible. On this basis it is difficult to attribute the effect entirely to the composition of the electrolyte. Hunger (2) has proposed that the source of the piezogalvanic effect resides in the crystal lattice itself. According to Hunger's mechanism, the mechanical force produces edge dislocations. The impurities within the crystal exist as impurity-ion-cation vacancy complexes. The movement of edge dislocations breaks up these complexes and produces point defects (cation vacancies) which increase the mobility of silver ions. To our knowledge there is no evidence for such a process being reversible. Rather, it would be expected that the defects would tend to coalesce or migrate to the surface. The similarity of the piezogalvanic effect obtained with liquid and solid electrolytes also provides evidence against attributing the effect to crystal structure. On the other hand, an interfacial process would be reversible.

Cells fabricated with electrodes other than Ag indicated that the magnitude of the signal is related to an electrode couple, *i.e.*

$$Ag = Ag^+ + e^-$$

in the case where the Ag electrode in contact with the AgI electrolyte receives the force. This suggests a faradaic process with current passing through an interface. If the source of the piezogalvanic effect was entirely in the solid ionic conductor, the magnitude of the signal should be independent of the nature of the metal electrode. Such is not the case.

These observations lead us to conclude that the piezogalvanic effect is established by an interfacial (faradaic) process rather than any process associated solely with the mechanical and physical properties of either the electrolyte or the electrode.

Electrogenerated Chemiluminescence

XI. Electrochemistry and Electrogenerated Chemiluminescence in Scintillator Dye Melts

Csaba P. Keszthelyi* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Melts of scintillator compounds which are solid at room temperature, such as 2,5-diphenyloxazole (PPO) and 2,5-diphenyloxadiazole (PPD) containing several quaternary ammonium salts as supporting electrolytes, were examined as solvents for electrochemical and electrogenerated chemiluminescence (ECL) studies. Although the resistance of these solutions was high, cyclic voltammetry of 9,10-diphenylanthracene and rubrene in PPO showed the production of stable radical anions and cations for both compounds, and the ECL emission was essentially the same as the fluorescence emission of these compounds in PPO. ECL of rubrene was also observed in molten phenanthrene, PPD, thianthrene, and p-terphenyl, as well as in mixtures of PPO with 1- or 2-methylnaphthalene.

There has been much interest in recent years in the application of nonaqueous solvents in electrochemistry (1). Many of these solvents have the advantage of rather wide potential limits before the solvent itself or the supporting electrolyte undergoes reduction or oxidation at an inert electrode; these solvents are also often less likely to react with electrogenerated species. Most solvents employed are liquid at room temperature [*e.g.*, N,N-dimethylformamide (DMF), acetonitrile (ACN)] while several liquefy at low temperatures (SO_2, NH_3). Only a few studies of organic systems have employed as solvents compounds which are solid at room temperature; these include dimethylsulfone (mp 127°C) (1, 2), molten ethylammonium chloride (3), and the $AlCl_3$-KCl molten salt system (4). Recent studies involving aprotic solvents include electrogenerated chemiluminescence (ECL) of aromatic compounds, where electrogenerated radical anions ($R^{\cdot -}$) and radical cations ($R'^{\cdot +}$) react to form excited state species

$$R^{\cdot -} + R'^{\cdot +} \rightarrow R^* + R' \text{ or } R'^* + R \qquad [1]$$

We have recently reported on the ECL of the scintillator material 2,5-diphenyl-1,3,4-oxadiazole (PPD) with thianthrene in acetonitrile solutions (5) and also on the ECL of several other scintillator materials, including 2,5-diphenyloxazole (PPO), 2,5-diphenylfuran (PPF), and p-terphenyl (PTP) (6).

Because PPO has a low melting point (70°C), we thought it of interest to investigate the ECL of molten PPO itself, using a quaternary ammonium salt as a supporting electrolyte. We had additional reason to investigate ECL in molten PPO itself, because, although the ECL of PPO in nonaqueous solvents is of a very unsatisfactory nature (6), showing low intensity, unstable spectral distribution of the emitted light and poor stability of the electrogenerated cation radicals, we have also found that the presence of a 10-fold molar excess of PPO with respect to DPA increases the DPA ECL intensity when only $DPA^{\cdot +}$ and $DPA^{\cdot -}$ are electrogenerated in an ACN-0.1M TBAP solution. In the course of these studies we also investigated PPO and related compounds as solvents for electrochemical and ECL studies of other organic species. Although molten scintillator compounds have been used as nuclear reactor coolants (7), to our knowledge they have not been used previously as solvents for electrochemical or spectroscopic studies.

Experimental

Chemicals.—Scintillation grade 2,5-diphenyloxazole (PPO) was obtained from Aldrich Chemical Company and from Nuclear Equipment Chemical Corporation (NEC). Phenanthrene, 98+%, obtained from Aldrich, was purified by four recrystallizations alternately using spectroscopic grade methanol and hexane. A portion of this purified sample was vacuum sublimed with no detectable improvement in the phenanthrene sample. Thianthrene (TH) was obtained from Aldrich, and it was used without further purification after its properties were compared with specially purified thianthrene samples (5). The p-terphenyl (PTP), scintillation grade, was supplied by NEC. Scintillation grade 2,5-diphenyl-1,3,4-oxadiazole (PPD), rubrene (puriss), and one of the 9,10-diphenylanthracene (DPA) samples were obtained from Aldrich. A second sample of DPA was obtained from City Chemical Corporation. The 1- and 2-methylnaphthalene were obtained from Aldrich, and together with the scintillation grade compounds, they were used without further purification after no electrochemical or fluorescent impurities could be detected. Because vacuum sublimation actually leads to considerable decomposition of rubrene and DPA, that technique was abandoned in favor of recrystallization from spectrograde hexane. Several experiments were conducted using as-received rubrene or DPA and there was no observable difference between these results and data obtained using samples purified by recrystallization from spectrograde hexane. Tetraphenylporphin (TPP) was obtained from Mad River Chemical Company and was used without furthur purification. Tetra-n-butylammonium perchlorate (TBAP), tetraethylammonium perchlorate (TEAP), tetramethylammonium perchlorate (TMAP), tetra-n-butylammonium fluoborate ($TBABF_4$), and tetramethylammonium fluoborate ($TMABF_4$), all polarographic grade, were obtained from Southwestern Analytical Chemicals, Inc., and used without further purification; they were dried for 48 hr at 90°C in a vacuum oven and stored in a desiccator over anhydrone. In most experiments TBAP was used as a supporting electrolyte, although all other supporting electrolytes (except those containing chloride anion) behaved satisfactorily in molten PPO.

Apparatus.—For preliminary and spectroscopic experiments a cell having a detachable Pyrex or quartz ground glass bottom compartment, a central electrode compartment, and a vacuum adapter (8) was used; when luminescence was a result of optical excitation, the central section housing the electrodes was removed, so that the possibility of interference with the right angle excitation process could be eliminated. The cell used in most ECL experiments is shown in Fig. 1 (a silver wire reference electrode, similar in size and position to the platinum working and auxiliary electrodes, is not shown in the drawing). Through a vacuum adapter the cell can readily be evacuated to 10^{-6} Torr when empty due to the absence of the more numerous ground glass joints used in usual cell construction. Since the solvent-supporting electrolyte system is solid at room temperature, the usual freeze-pump-thaw deaeration procedure is replaced by a pump-melt-freeze (PMF) cycle; the pressure over the ECL mixtures was reduced to $<10^{-5}$ Torr by several PMF cycles. We have previously reported (9) that a silver wire was an acceptable reference electrode in the case of dimethylformamide-TBAI solutions; the use of a silver reference electrode in molten salt electrochemistry has also been described (10). The applied potential or current was controlled using a PAR Model 170 Electrochemistry System (Princeton Applied Research Corporation) which could be linked with a Wavetek Model 114-G function generator for fast electrogeneration. The ECL emission was detected using an Aminco-Bowman spectrophotofluorometer (SPF) in conjunction with a Hamamatsu TV Corporation R-456 photomultiplier tube (PMT) which is required for spectral measurements extending beyond 580 nm. To detect the very low intensity ECL of TPP the SPF was modified to allow operation of the PMT at 1100V d.c. rather than at the original 700V d.c. The ECL cell was placed in a temperature-controlled cell compartment (Aminco-Bowman part No. 4-8262) and hot water was circulated using a Labline-controlled temperature bath. In the case of phenanthrene it was found necessary to boost the heating rate obtained from the constant temperature bath by using a heating tape powered by an auto transformer, around the constant temperature cell compartment in addition to the hot water. The signal from the SPF was fed either into a Moseley 7005A X-Y recorder, or to a Tektronix storage oscilloscope equipped with a Polaroid camera. An alternate heating arrangement, mainly used for electrochemistry and visual observation of ECL, involved use of a small Pyrex bath filled with water or mineral oil, and heated with an immersed Nichrome coil. In a typical experiment the constant temperature bath and the controlled temperature cell compartment of the SPF are heated to reach the desired temperature (commonly 95°-97°C for the Labline bath and 75°-80°C for the cell compartment heated by the circulating hot water) while the clean cell is evacuated on a vacuum line to a pressure less than 10^{-6} Torr. The solid compounds are next introduced (usually 1.000g PPO, 0.100g TBAP, and 10.0 mg DPA or rubrene), and the cell is evacuated again. Several PMF cycles are carried out before the cell is permanently sealed using a natural gas-oxygen torch. Cells so prepared remain in an apparently contamination-free state for as long as 18 months as attested by essentially identical electrochemical and ECL results obtained at various time intervals. The stability of the silver wire reference electrode in these systems appeared very satisfactory.

Results and Discussion

Electrochemistry of the melts.—In selecting a solvent for electrochemical work, it is necessary that the potential limits of the solvent-supporting electrolyte system, *i.e.*, the potentials at which the electrode-solvent system shows reduction and oxidation, are wide enough to encompass the potential region of interest. The potentials at which several of the scintillator compounds and solutes of interest reduce and oxidize in ACN solutions containing 0.1M TBAP are shown in Fig. 2. (The structures of these compounds and other compounds that are discussed in this work are shown in Fig. 3.) These potentials suggest that the pure scintilator compounds, such as PPO and PPD, will have sufficiently wide potential ranges to be useful solvent systems. Some of the more useful molten solvents and their approximate potential ranges are given in Table I.

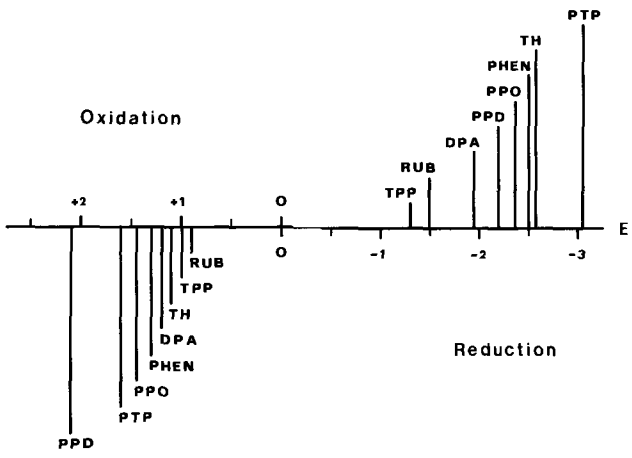

Fig. 2. Oxidation-reduction potentials of scintillator dyes and solutes. The oxidation and reduction limits of DMF and ACN *vs.* the Ag reference electrode are +1.7 to −2.8 (DMF) and +2.3 to −2.9 (ACN-TBAP).

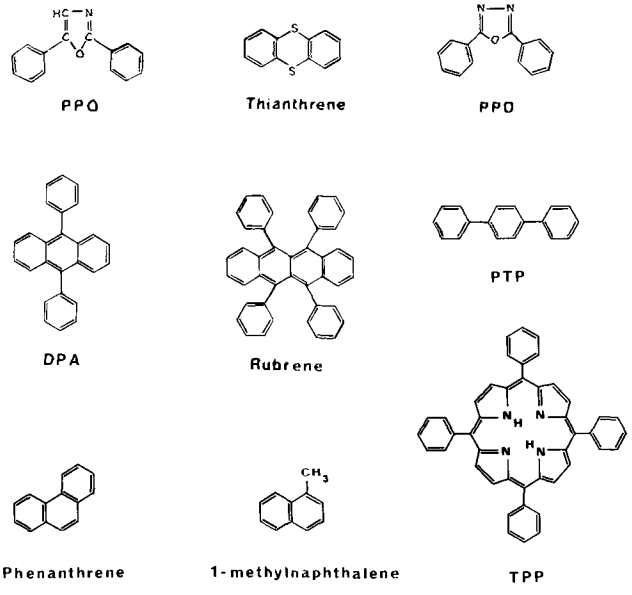

Fig. 3. Structural formulas. Accepted abbreviations (11) are used where possible in naming the compounds.

In ECL experiments attempted in the molten scintillator solvent systems without added solutes other than supporting electrolytes (*e.g.*, Table II, 5 and 18), no light emission was observed.

Electrochemistry of rubrene and DPA in melts.—The melts could be employed as solvents for the aromatic hydrocarbons rubrene and DPA conventionally used in ECL studies. Typical cyclic voltammograms in molten PPO-TBAP are shown in Fig. 4 and 5. These voltammograms are similar in shape to those found in DMF and ACN and show that the radical anion and cation of rubrene and DPA are stable in PPO under these

Table I. Some of the molten solvents used and their useful potential ranges

Solvent (MP)	Electrolyte	Oxidation-reduction limit (V *vs.* Ag reference electrode)
PPO (70-72)	TBAP	+1.5/−2.2

conditions. The differences of the peak potentials of the forward and reversal waves are larger than those for nernstian electrode reactions at these temperatures (*e.g.*, for rubrene reduction $E_{pc} - E_{pa} = 400$ mV (exp); compared to 67 mV [theoretical]). However, the resistance of these solutions is high so that uncompensated resistance effects are probable. The cyclic voltammograms all show an increase in peak currents under continuous cycling (which is opposite to the usual behavior observed for multiple scans) as well as a decrease in the separation of the forward and reversal E_p-values. This effect may be caused by some kind of filming of the platinum wire electrode in molten PPO, a film which is being removed under continuous cycling, accompanied by an increase in the active area on the electrode. It is also possible that the stable electrogenerated cations and anions make a contribution to the total ionic population of the solution, especially in the vicinity of the electrode and decrease the uncompensated iR.

The relatively high resistance of these molten solutions was evidenced by very high uncompensated iR losses; for example, when currents as low as 200 μA were passed, the full iR compensation of the PAR had to be applied.

ECL in molten solvents.—The major effort in this research was directed toward a study of ECL in the molten systems. Important requirements in observing ECL are that the excited state species formed by the radical ion annihilation reaction [1], are not quenched

to a large extent by the solvent molecules and that the solvent does not absorb the emitted radiation. To investigate these effects a study of the fluorescence of the solvent PPO, and of solutions of rubrene and DPA in PPO was undertaken. The fluorescence spectrum obtained in molten PPO itself, shown in Fig. 6, consists of a single peak shifted to the red with respect to PPO emission obtained in dilute solutions at 3800 nm. In cyclohexane solutions upon change of the PPO concentration from 0.1 to 25 g/liter, the fluorescence emission peak decreases in height and broadens toward the red region of the spectrum (11); this broadening, which is usually attributed to excimer formation, is not found in the pure PPO melt. The attenuation of certain wavelengths of the emission beam in traversing the *ca.* 6 mm of molten PPO from the center of the cuvette where excitation occurs may also be a factor. It is also possible that the observed fluorescence is caused by a trace impurity in the PPO, although the shape of the fluorescence emission spectrum is independent of excitation wavelength from 2800-3800 nm. Both DPA and rubrene exhibit fluorescence spectra in PPO (Fig. 7 and 8) which are very similar to those seen for these compounds in dilute solutions of ACN.

When the platinum working electrode in a molten PPO-TBAP solution containing either DPA or rubrene is pulsed between potentials where $R^{-\bullet}$ and $R^{+\bullet}$ are formed ECL results; typical ECL emission spectra for pulse lengths of 0.05-1 sec are shown in Fig. 9 and 10. The ECL spectra are virtually the same as the fluorescence spectra in PPO and hence, nearly the same as the ECL spectra in ACN and DMF, so that there is no evidence for interaction between the PPO and the excited states. Neither is there a temperature effect on the ECL spectra for DPA or rubrene in PPO as compared to ECL in ACN or DMF, although there is a small shift of the rubrene ECL peak toward the red. The emitted ECL light was very steady with time on repeated cycling for both rubrene (Fig. 11a) and DPA (Fig. 11b), showing stability of the radical ion species in this medium. Experiments involving other supporting electrolytes ($TBABF_4$, TEAP, TMAP) in PPO and other scintillator melts (PPD, PTP, TH, PHEN) are shown in Table II. We also tried molten supporting electrolytes (*e.g.*, TBAP, TBACl) themselves as solvents. The electrochemical behavior of rubrene and

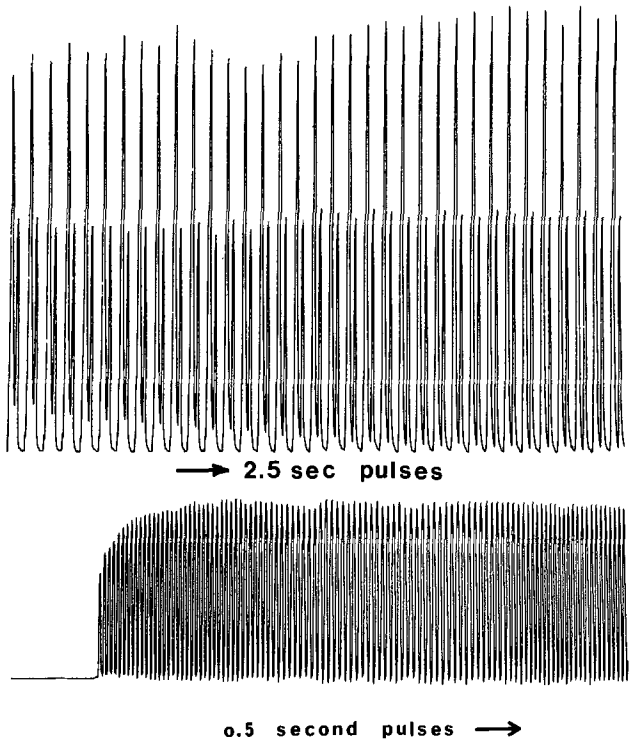

Fig. 11. Intensity-time characteristics of the rubrene (*a*, top) and 9,10-diphenylanthracene (*b*, bottom) ECL emission at the wavelength of spectral maximum in molten PPO-TBAP.

DPA in these was generally unsatisfactory and no ECL was observed with them. In molten TBAP the cyclic voltammetric behavior of both DPA and rubrene was characterized by irreversible waves and unstable radical ions. In molten TBACl the reduction of DPA shows reversible cyclic voltammetric behavior at −1.4V *vs.* Ag reference electrode; the oxidation background limit of TBACl occurs at +1.5V *vs.* Ag reference electrode, so that oxidation of DPA or rubrene to the cation radical cannot be observed. As shown in Table II, all of the following molten scintillator-TBAP-rubrene systems produced ECL: PPD, TH, PHEN, and PTP. Not all compounds with seemingly acceptable properties were usable, however; N,N-diphenylformamide, for example, was found to be unsuitable to observe rubrene ECL. Also, the PPD^{-}/TH^{+} pair, which has good ECL characteristics in ACN-TBAP (5), was found to yield no detectable luminescence in molten PPO-TBAP. No luminescence was observed in binary PPO-TBAP, PPD-TBAP, TH-TBAP, or PHEN-TBAP under any conditions in the absence of DPA or rubrene.

In some experiments "pre-annihilation" ECL was observed for PPO-TBAP solutions containing rubrene or DPA, when the potential was stepped to one where the anion (or cation) radical was produced and then stepped to potentials insufficient to produce the oppositely charged species. For example, when rubrene cation radical was produced first, light could be detected when the electrode was stepped back to potentials more negative than −1.0V *vs.* Ag, although rubrene anion radical is not produced until −1.7V. Similar pre-annihilation effects were found for initial production of rubrene anion and DPA ion radicals. Some unusual effects on the pre-annihilation ECL, such as the variation of the ECL intensity with applied potentials that are still short of the foot of the wave, similar to what we have found in the case of thianthrene pre-annihilation ECL (5), may also involve nonuniform current densities and uncompensated iR effects in these highly resistive media.

As seen from experiments 23 and 24 in Table II, the addition of 25% by weight of 1- or 2-methylnaphthalene to the PPO-TBAP solution resulted in an approximately two-fold increase in rubrene ECL emission compared to PPO solutions not containing methylnaphthalene. We have noticed similar increases in ECL intensities upon addition of less polar solvents, such as benzene or toluene, to ACN solutions (6). A systematic investigation of the effect of solvent on ECL efficiency is currently under way.

Although the experiments described using the usual three-electrode, potential step, technique are most appropriate for obtaining electrochemical data, ECL can also be produced in the two-electrode mode, employing voltage or current steps. In fact in some circumstances, particularly at higher frequencies or when reaction products can cause shifts in the potential of the silver wire reference electrode, the two electrode mode, with the voltage span adjusted empirically to give maximum light output and the applied program an asymmetric square wave with the potentiostat reference and auxiliary leads connected together, can produce larger light intensities than the three-electrode mode. In practical devices employing ECL, the two-electrode mode would, of course, be preferred.

Although this work was not concerned with the construction of ECL devices, some possible applications of molten scintillator systems can be mentioned. The melting point of these compounds, or of their mixtures, is constant within a few degrees centigrade, and a range from room temperature to over 200°C can be covered by varying the composition. The ohmic resistance of a frozen mixture is very high while the melts have a much lower resistance (less than 1000 ohms in the cells used here) so that a circuit incorporating one or several of these mixtures can behave as a temperature sensing device. Addition of DPA or rubrene to

Kinetics of Iron Deposition on a Rotating Platinum Disk Electrode

A. A. El Miligy, F. Hilbert, and W. J. Lorenz*

Institute of Physical Chemistry and Electrochemistry, University of Karlsruhe, Karlsruhe, Germany

ABSTRACT

The kinetics of iron deposition from acid solutions under steady-state conditions have been studied using a rotating platinum disk electrode. The data obtained in the pH range between 1.8 and 3.8 can be explained on the basis of two reaction mechanisms. The noncatalyzed mechanism is applicable at pH $\leq$ 2.4, while the catalyzed one is applicable at pH $\geq$ 3.3. In between there is a transition from one mechanism to the other. Measurements of electrochemical reaction order as a function of the pH indicate the existence of the catalyzed mechanism at pH $\geq$ 3.3. In this pH-range the ferrous ion discharge takes place in the charge transfer region of the HER and consequently the pH at the electrode surface is the same as in the bulk of the solution. At pH $<$ 2.4 such measurement shows that the pH at the electrode surface is different from that in the bulk of the solution. This is attributed to the fact that the ferrous ion discharge takes place at the onset of the transfer controlled region of the HER. These results are in good agreement with an earlier investigation on the iron deposition on a rotating gold disk electrode.

The kinetics of iron dissolution and deposition are of considerable interest. Consistency, however, of obtained results and hence offered reaction mechanism remained a subject of controversy. The reasons for this inconsistency and an experimental method for its avoidance have been offered and carried out (1, 2). Gold in the form of a rotating disk electrode (RDE) was used in the cathodic iron deposition investigation (2). It is suitable as a working electrode for such cathodic studies because of low value for the exchange current of the hydrogen evolution reaction (HER), which constitutes a big hindrance in such studies. Also on gold the iron deposition takes place in the Tafel range of the HER. Consequently the hydrogen ion concentration will be the same at the electrode surface as that in the bulk of the solution. This is very important because the kinetics of iron deposition is a function of the pH at the electrode surface.

Taking this dependence into consideration the kinetic data obtained on gold showed the existence of two reaction mechanisms. The noncatalyzed mechanism, first proposed by Bockris *et al.* (3), takes place in a pH range between 1.8-2.4 and the catalyzed one, initially proposed by Heusler *et al.* (4), between pH 3.3-3.8.

Beyond pH = 3.8, the hydrolysis products will interfere and below pH = 1.8, the HER is dominating to a great extent. The agreement between the kinetic data obtained on gold experimentally and those calculated theoretically is good.

Another feature in such studies may then arise when using platinum as a working electrode. One reason is that the exchange current of the HER on platinum is relatively high compared to that on gold and, second, the iron deposition will probably take place in the diffusion-controlled range of the HER. Consequently there will be an overlap between the activated-controlled iron deposition and the diffusion-controlled discharge of protons and HSO_4^--ions (5). This will lead to a pH difference between the electrode surface and the bulk of the solution. An insight in the characteristics of the iron deposition under such conditions may then be obtained.

Experimental

Solutions, cell, apparatus, and experimental procedure have been described in detail earlier (2). It remains here to mention that the working electrode is a rotating disk of platinum having a radius of 0.375 cm. The rotating speed was 4140 rpm. Evaluation of the results has been carried out only for the steady state, the current densities are referred to square centimeter and the potentials to normal hydrogen electrode. All experiments were carried out at 25°C.

The partial current densities for iron deposition were estimated by potentiostatic anodic stripping method, which is described elsewhere (2). The anodic stripping potential is 100-150 mV more positive then the corrosion potential. In this range practically the whole current is used for the anodic dissolution of iron, because the stripping potential is more negative than the equilibrium potential of the H_2/H^+-electrode in the same solution. This was confirmed by spectroscopic measurements.

Results

Figure 1 shows the behavior of the measured total current density, $i_{-,\,\text{total}}$, as a function of the electrode potential, ϵ, for different pH values of the solution between 1.8-3.8. It can be seen that there are three types of behavior. The first is represented by curves 1, 2, and 3 for solution pH = 1.8, 2.08, and 2.4, respectively, where the curves show at the beginning a gradual increase of the C.D. with potential. The second type is represented by the curves 4, 5, and 6 for solution pH = 3.3, 3.5, and 3.8, respectively, where the curves show at first an almost linear behavior followed by a sudden rise in C.D. before reaching a kind of plateau. The third type, represented by curves 7 and 8 for pH = 2.77 and 2.96, shows a behavior lying between the first two types. Here the curves show a gradual increase in C.D. over larger period of potential than the first group and the rise to the plateau is not as sudden as in the second one. As will be seen later, this rise is attributed to an increase in the absolute value of the partial current density (P.C.D.) of iron, $i_{-,\,Fe^{++}}$, as compared to that of hydrogen, $i_{-,\,H^+}$. It may also be noticed on Fig. 1 that at the very beginning of all the curves where $i_{-,\,Fe^{++}} \ll i_{-,\,H^+}$, a correlation between the HER and the pH of the solution may be observed, *i.e.*, $i_{-,\,\text{total}}$ decreases when the pH of the solution increases.

The P.C.D.'s for the discharge of iron and hydrogen were calculated using the results obtained from the potentiostatic anodic stripping method described in detail elsewhere (2).

Key words: corrosion, iron deposition, charge transfer mechanism of iron, platinum substrate, rotating disk electrode.

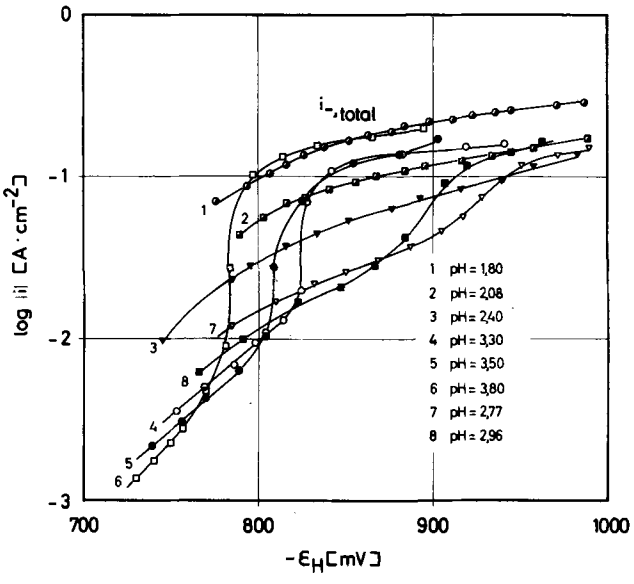

Fig. 1. Total current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4. Curve 1, pH = 1.8; curve 2, pH = 2.08; curve 3, pH = 2.4; curve 4, pH = 3.30; curve 5, pH = 3.5; curve 6, pH = 3.80; curve 7, pH = 2.77; curve 8, pH = 2.96 (T = 298°K).

Figure 2 shows the P.C.D.-potential curves $i_{-,Fe^{++}}$ and i_{-,H^+} *vs.* ϵ obtained from curves 1, 2, and 3 of Fig. 1. The charge transfer controlled iron deposition, as represented by Tafel lines, lies at the onset of the diffusion-controlled range of the HER, which means that the pH at the electrode surface is a function of the electrode potential and not equal to that in the bulk of the solution. The Tafel lines have a slope of $b_{-,Fe^{++}} = -85 \pm 3$ mV. The experimental results seem to show an increase of the P.C.D. of iron with the pH of the solution in the range of transport controlled HER. Possibly this effect is due to a powdery deposition of the metal (6). The resulting roughness of the electrode surface will lead to turbulent flow of the solution and hence an increase of the limiting diffusion current density (L.D.C.D.).

The P.C.D.'s $i_{-,Fe^{++}}$ and i_{-,H^+} obtained from curves 4, 5, and 6 of Fig. 1 are shown in Fig. 3. Here, as in the case of gold as a RDE discussed elsewhere, the ferrous ion discharge takes place mainly in the charge transfer controlled range of the HER. The slope of the Tafel lines of the HER has the expected value of $b_{-,H^+} = -115 \pm 5$ mV (7) whereas that for the ferrous ion discharge shows a value of $b_{-,Fe^{++}} = -36 \pm 4$ mV in agreement with earlier results obtained on gold (2). The sudden rise of the $i_{-,Fe^{++}}$ is due to nonstability of the pH at the electrode surface when the L.D.C.D. for the HER is reached. The scattering of the results for the HER in the L.D.C.D. region may be attributed to this behavior and possibly also the above-mentioned increase of roughness of the electrode surface. Contrary to the above-mentioned case for pH < 2.4 in Fig. 2, the deviation of the L.D.C.D. for iron discharge lies within the experimental error. Here, however, there is a decrease in the magnitude of L.D.C.D. with increasing negative potential. This behavior, which may be correlated to electron tunneling from the electrode surface and thereby decreasing the iron yield, is discussed thoroughly elsewhere (6, 8).

Figure 4 shows the P.C.D.'s obtained from curves 7 and 8 from Fig. 1. The slope of the Tafel line is $b_{-,Fe^{++}} = -56$ mV and -76 mV, respectively. It shows a systematic change between the two mentioned ranges. The change of $i_{-,Fe^{++}}$ from charge transfer to diffusion control takes place gradually and the magnitude of L.D.C.D. for the ferrous ion agrees satisfactorily with those from Fig. 3.

Figure 5 shows the logarithm of the partial current densities $i_{-,Fe^{++}}$ as a function of the pH of the solution at constant electrode potentials. From the slope one can get the electrochemical reaction orders related to the pH.

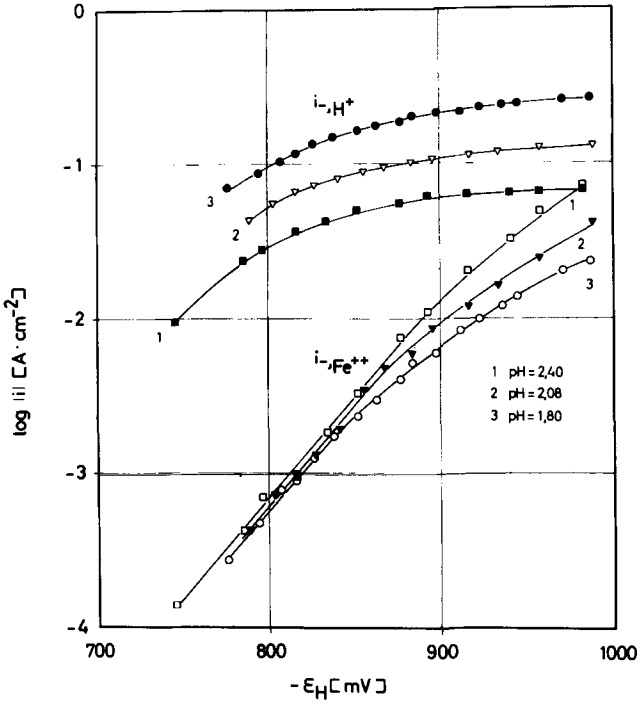

Fig. 2. Partial current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4. pH = 1.8. 2.08. 2.4 (T = 298°K)

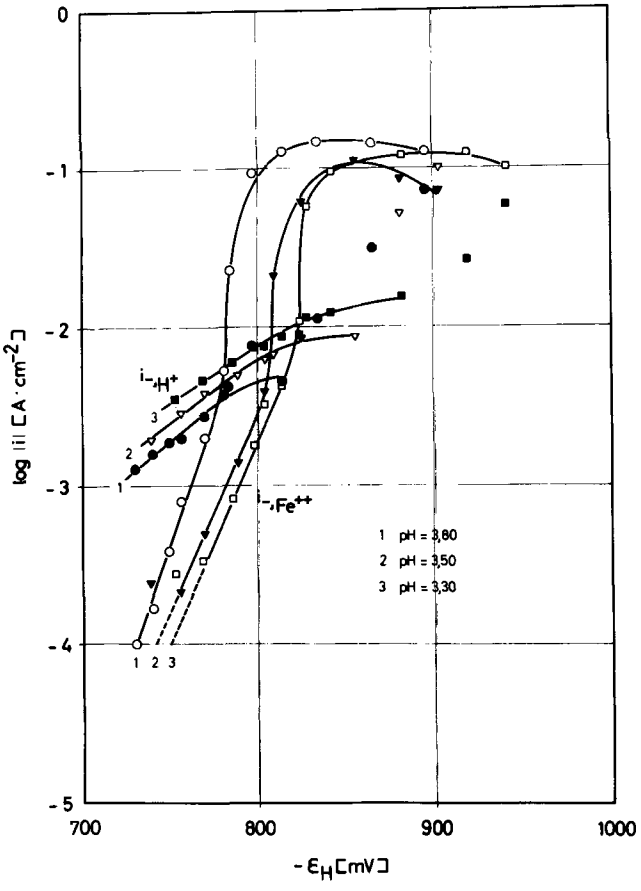

Fig. 3. Partial current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4. pH = 3.30, 3.5, 3.8 (T = 298°K).

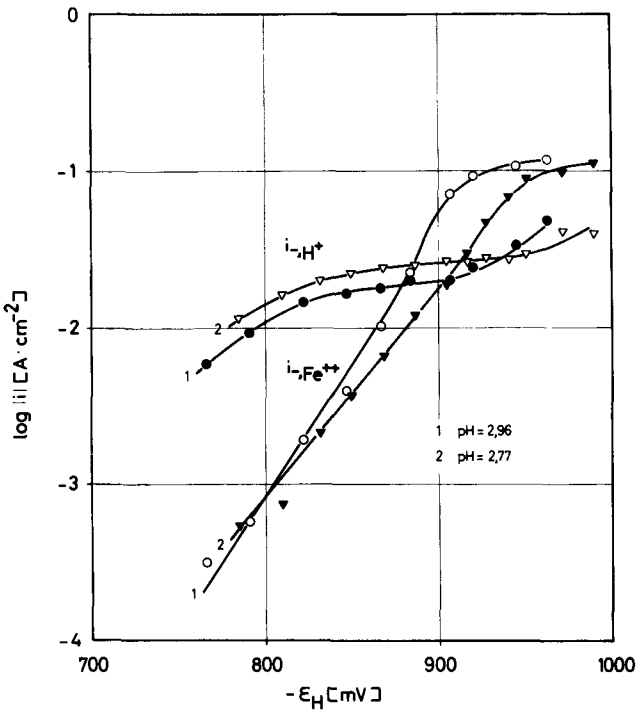

Fig 4. Partial current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4. pH = 2.77, 2.96 (T = 298°K).

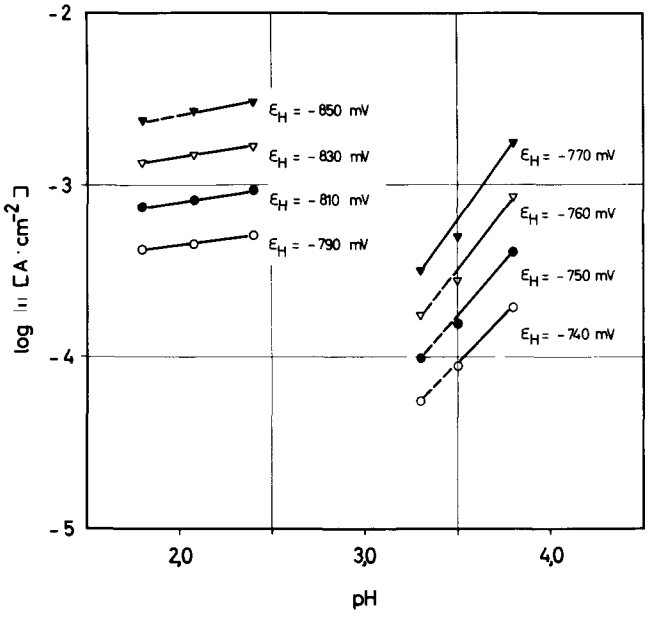

Fig. 5. Partial current densities $i_{-,Fe^{++}}$ as a function of pH for determination of the electrochemical reaction order of iron deposition related to pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4 (T = 298°K).

For pH > 3.3, the value for $n_{-,pH} = 1.4 \pm 0.2$. For pH < 2.4 $n_{-,pH}$ has a value which deviates from zero in the positive direction, but is, however, too small to be determined accurately (about 0.17).

Discussion

It has been shown in Fig. 2 that for pH < 2.4, the ferrous ion discharge takes place at the onset of the L.D.C.D. of the HER. Consequently the concentration of protons in the double layer is decreasing, *i.e.*, the pH at the electrode surface is not constant, which must be taken into consideration in derivation of the kinetic equation.

The noncatalyzed mechanism (3) is given by the following sequence

$$Fe^{++}{}_{aq} + H_2O \rightleftharpoons FeOH^+ + H^+ \quad [1]$$

$$FeOH^+ + e^- \rightleftharpoons (FeOH)_{ads} \quad [2]$$

$$(FeOH)_{ads} + H^+ + e^- \rightleftharpoons Fe + H_2O \quad [3]$$

Steps [1] and [3] are fast reactions while step [2] is a slow one and hence the RDS. The current density-overvoltage relation for this mechanism is given by (1, 2)

$$i_{Fe^{++}} = 2\, i_{0,2} \left[\frac{A}{B} \exp\left(\frac{(1+\alpha_2)F\eta}{RT} \right) - C \exp\left(-\frac{(1-\alpha_2)F\eta}{RT} \right) \right] \quad [4]$$

where η is the total overvoltage.

The expressions for A, B, and C are

$$A = \frac{a_{Fe}}{\bar{a}_{Fe}} \cdot \frac{a_{H_2O}}{\bar{a}_{H_2O}}, \quad B = \frac{a_{H^+}}{\bar{a}_{H^+}}, \quad C = \frac{a_{FeOH^+}}{\bar{a}_{FeOH^+}}$$

The expression C can be replaced by the following terms according to the chemical equilibrium [1]

$$C = \frac{a_{Fe^{++}}}{\bar{a}_{Fe^{++}}} \cdot \frac{a_{H_2O}}{\bar{a}_{H_2O}} \cdot \frac{\bar{a}_{H^+}}{a_{H^+}} = D \cdot \frac{1}{B} \quad [5]$$

Under the condition[1]

$$a_i = \bar{a}_i$$

i.e., A, B, C, $D = 1$ then the overvoltage is only charge transfer overvoltage ($\eta = \eta_t$)

$$i_{Fe^{++}} = 2\, i_{0,2} \left[\exp\left(\frac{(1+\alpha_2)F\eta_t}{RT} \right) - \exp\left(-\frac{(1-\alpha_2)F\eta_t}{RT} \right) \right] \quad [6]$$

From Eq. [6] the Tafel slope for the cathodic process ($\eta << 0$) can be obtained

$$b_{-,Fe^{++}} = \left(\frac{\partial \eta_t}{\partial \log/i_{-,Fe^{++}}/} \right)_{a_i = \bar{a}_i} = -\frac{2.303\,RT}{(1-\alpha_2)F} = -118.3\ \text{mV} \quad [7]$$

with $\alpha_2 = 0.5$ and $T = 298$°K.

From Eq. [4] the electrochemical reaction orders related to the pH or to the activity of Fe^{++}-ions can be derived

$$n_{-,pH} = \left(\frac{\partial \log/i_{-,Fe^{++}}/}{\partial\, pH} \right)_{a_i,\,\epsilon} = +1 \quad [8]$$

$$n_{-,Fe^{++}} = \left(\frac{\partial \log/i_{-,Fe^{++}}/}{\partial \log a_{Fe^{++}}} \right)_{a_i,\,\epsilon} = +1 \quad [9]$$

Under the conditions

$$a_{Fe} = \bar{a}_{Fe}$$

$$a_{H_2O} = \bar{a}_{H_2O}$$

$$a_{Fe^{++}} = \bar{a}_{Fe^{++}}$$

$$a_{H^+} \neq \bar{a}_{H^+}$$

from Eq. [4] follows

$$i_{Fe^{++}} = 2\, i_{0,2} \left[\frac{1}{B} \exp\left(\frac{(1+\alpha_2)F\eta}{RT} \right) - \frac{1}{B} \exp\left(-\frac{(1-\alpha_2)F\eta}{RT} \right) \right] \quad [10]$$

[1] $\bar{a}_i$ = equilibrium activity of the species i at $\epsilon = \epsilon_0$.

The current density-overvoltage relation for the cathodic process ($\eta << 0$) is given by

$$i_{-,Fe^{++}} \cong -2\, i_{0,2} \cdot \frac{1}{B} \cdot \exp\left(-\frac{(1-\alpha_2)\mathbf{F}\eta}{RT}\right) \quad [11]$$

or

$$\eta = \frac{RT}{(1-\alpha_2)\mathbf{F}} (\ln 2\, i_{0,2} - \ln/i_{-,Fe^{++}}/ - \ln B) \quad [12]$$

For $a_{H^+} = \bar{a}_{H^+}$, *i.e.*, $B = 1$, it follows $\eta = \eta_t$ and from Eq. [12] the same Tafel slope as in Eq. [7] is obtained.

On the other hand for $B \neq 1$ the Tafel slope will be derived from Eq. [12] as follows

$$\left(\frac{\partial \log/i_{-,Fe^{++}}/}{\partial \eta}\right)_{a_i} = \frac{1}{b_-} = -\frac{(1-\alpha_2)\mathbf{F}}{2.303\,RT} - \left(\frac{\partial \log B}{\partial \eta}\right)_{a_i} \quad [13]$$

This will be the case, if the simultaneous HER is controlled by charge transfer and diffusion.

For the HER

$$H^+ + e^- \rightleftharpoons \frac{1}{2} H_2 \quad [14]$$

the current density-overvoltage relation for the cathodic process ($\eta << 0$) is given by

$$i_{-,H^+} \cong i_{0,H} \cdot B \exp\left(-\frac{(1-\alpha_H)\cdot \mathbf{F}\eta}{RT}\right) \quad [15]$$

or

$$\eta = \frac{RT}{(1-\alpha_H)\mathbf{F}} (\ln i_{0,H} - \ln/i_{-,H^+}/ + \ln B) \quad [16]$$

Only in a certain overvoltage range, where $B \neq 1$, *i.e.*, $\eta = \eta_t + \eta_d$ for the HER, then Eq. [13] shows that $b_{-,Fe^{++}}$ will be changed. Considering only the overpotential range for which $i_{-,H^+} = i_{-,L.D.C.,H^+} =$ constant the variation of B is given by

$$\left(\frac{\partial \log B}{\partial \eta}\right)_{a_i} = \frac{(1-\alpha_H)\mathbf{F}}{2.303\,RT} \quad [17]$$

Substituting Eq. [17] in Eq. [13] one gets the Tafel slope of the iron deposition reaction in this overvoltage range

$$b_{-,Fe^{++}} = -\frac{2.303\,RT}{(1-\alpha_2)\mathbf{F}} - \frac{2.303\,RT}{(1-\alpha_H)\mathbf{F}} \quad [18]$$

For $\alpha_\alpha = \alpha_H = 0.5$ and $T = 298°K$ then $b_{-,Fe^{++}} = -59.2$ mV.

The experimental results for pH < 2.4 showed that the measured range of the curves lies just at the onset of the diffusion-controlled range of the HER. Consequently, the contribution from the second term on the right side of Eq. [13] will be relatively small compared to the case when the L.D.C.D. of the HER is fully reached. Therefore the measured slope, $b_{-,Fe^{++}} = -85 \pm 3$ mV of the Tafel lines is between the calculated above, $b_{-,Fe^{++}} = -60$ mV and that for charge transfer controlled HER, $b_{-,Fe^{++}} = -120$ mV (2). Also the fact that the determination of the electrochemical reaction order $n_{-,pH}$ in this pH range is rather difficult may be considered as a confirmation for the difference between the electrode surface pH and that in the bulk of the solution.

The catalyzed reaction mechanism which is supposed to explain the results of pH > 3.3 is given by (1, 2)

$$Fe^{++}{}_{aq} + H_2O \rightleftharpoons FeOH^+ + H^+ \quad [1]$$

$$[Fe(FeOH)] + FeOH^+ + 2e^- \rightleftharpoons [Fe(FeOH)] + Fe + OH^- \quad [19]$$

and the parallel reaction to [19]

$$Fe + FeOH^+ + e^- \rightleftharpoons [Fe(FeOH)] \quad [20]$$

The current density-overvoltage equation under steady-state conditions for this mechanism, taking into consideration that step [19] is the RDS is given by (1, 2)

$$i_{Fe^{++}} = i_{0,19}\left[\frac{a_K}{\bar{a}_K} \cdot \frac{A}{B} \cdot \exp\left(\frac{2\alpha_{19}\mathbf{F}\eta}{RT}\right) - \frac{a_K}{\bar{a}_K} \cdot C \exp\left(-\frac{2(1-\alpha_{19})\mathbf{F}\eta}{RT}\right)\right] \quad [21]$$

with K = [Fe(FeOH)].

For $\eta << 0$ one can write

$$i_{-,Fe^{++}} \cong -i_{0,19} \cdot \frac{a_K}{\bar{a}_K} \cdot C \exp\left(-\frac{2(1-\alpha_{19})\mathbf{F}\eta}{RT}\right) \quad [22]$$

Under steady-state conditions

$$\frac{da_K}{dt} = -\frac{i_{20}}{z_{20}\cdot \mathbf{F}} = 0 \quad [23]$$

The expression for i_{20} is

$$i_{20} = i_{0,20}\left[\frac{a_K}{\bar{a}_K} \exp\left(\frac{\alpha_{20}\mathbf{F}\eta}{RT}\right) - \frac{a_{Fe}}{\bar{a}_{Fe}} \cdot C \cdot \exp\left(-\frac{(1-\alpha_{20})\mathbf{F}\eta}{RT}\right)\right] \quad [24]$$

From Eq. [23] and [24] using [5] one can write

$$\frac{a_K}{\bar{a}_K} = \frac{D}{B} \cdot \frac{a_{Fe}}{\bar{a}_{Fe}} \exp\left(-\frac{\mathbf{F}\eta}{RT}\right) \quad [25]$$

Substituting [25] into [22] one gets

$$i_{-,Fe^{++}} \cong -i_{0,19} \cdot \frac{a_{Fe}}{\bar{a}_{Fe}} \cdot \left(\frac{D}{B}\right)^2 \cdot \exp\left(-\frac{[1+2(1-\alpha_{19})]\mathbf{F}\eta}{RT}\right) \quad [26]$$

From [26] one derives the following kinetic data

$$b_{-,Fe^{++}} = \left(\frac{\partial \eta_t}{\partial \log |i_{-,Fe^{++}}|}\right)_{a_i = \bar{a}_i} = -\frac{2.303\,RT}{[1+2(1-\alpha_{19})]\mathbf{F}} = -29.6 \text{ mV} \quad [27]$$

with $\alpha_{19} = 0.5$ and T = 298°K, furthermore

$$n_{-,pH} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial\, pH}\right)_{a_i,\epsilon} = +2 \quad [28]$$

$$n_{-,Fe^{++}} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial \log a_{Fe^{++}}}\right)_{a_i,\epsilon} = +2 \quad [29]$$

Following the same procedure as above in the case of the pH at the electrode surface not being constant, for the Tafel slope $b_{-,Fe^{++}} = -20$ mV when putting $\alpha_{19} = \alpha_H = 0.5$ at $T = 298°K$. Assuming, however, that the pH is constant at the electrode surface, which is the case when the ferrous ion discharge takes place in the charge transfer controlled range of the HER, then the Tafel slope according to Eq. [27] is found.

The agreement is satisfactory between the measured Tafel slopes and the calculated value based on the last assumption. From Fig. 5 follows an electrochemical reaction order related to the pH of $n_{-,pH} = +1.4 \pm 0.2$. This value is not in good agreement with the calculated one according to Eq. [28]. The deviation is possibly due to the fact, that the absolute value of measured slope for the Tafel lines is somewhat higher than the theoretical one, which may be attributed to an $\alpha_{19} \neq 0.5$. However, the experimental value $n_{-,pH}$ is not

equal to one, which may then correspond to the non-catalyzed mechanism. Therefore the measured Tafel slopes as well as the determined electrochemical reaction order related to the pH indicate the existence of the catalyzed mechanism.

Conclusions

The comparison between the results obtained in this work and those in the previous one (2) shows

1. The substrate of the working electrode (gold or platinum) has obviously no influence on the mechanisms of the iron deposition reactions themselves.
2. On the contrary the substrate influences the HER, because the exchange current density of the hydrogen electrode is much greater on platinum than on gold or iron. Therefore in the case of platinum electrode at pH < 2,4 the HER is partially controlled by diffusion in the potential range of iron deposition.
3. Consequently the simultaneous deposition of iron and evolution of hydrogen lead in the case of platinum at pH < 2.4 to an increase of pH at the electrode surface. This does not change the iron deposition mechanism, however, the measurable electrochemical kinetic data will be changed.
4. Under our measuring technique (2) in the case of platinum at pH < 2.4 the electrode coverage with iron is apparently incomplete under steady-state conditions. The measured iron efficiency values are very small in this range, *i.e.*, $|i_{-,Fe^{++}}| << |i_{-,H^{++}}|$.

Technical Notes

The Triangular Voltage Sweep Method for Determining Double-Layer Capacity of Porous Electrodes

Part I. Theory

L. G. Austin*,[1] and E. G. Gagnon*,[2]

Material Sciences Department, The Pennsylvania State University, University Park, Pennsylvania 16802

Scientific analysis of the behavior of porous battery electrodes is greatly aided by a knowledge of the electrochemically active area of the electrode. The measurement of double-layer capacity in concentrated electrolytes is the most direct measurement of the electrode area in contact with electrolyte. If the double-layer capacity of an electrode is compared to that of a known, smooth area of the same material, a relative measure of area is obtained. The capacitance per unit area (1) for clean negatively charged metal surfaces is 15-20 $\mu F/cm^2$, and for positively charged surfaces is 30-40 $\mu F/cm^2$. In general, this comparison is best made under the same conditions of electrolyte concentration, voltage, temperature, etc. However, a major problem in the measurement of double-layer capacity for porous electrodes is the effect of distributed capacity. Ohmic resistance in electrolyte in the pores has the effect of making it easier for the mouth of the pore to charge, or discharge, while the back of the pore lags behind (2). Another problem is to eliminate or allow for faradaic current, which is often caused by processes which are complex and difficult to describe mathematically, such as the removal of impurities at an electrode or the adsorption of species present in the electrolyte.

A number of cases have been treated by Posey and Morozumi (3), but they do not treat the case of linear or triangular voltage sweep in the presence of a significant external *IR* drop. It will be shown that this is a particularly useful technique since it enables an approximate correction to be made for faradaic current. Johnson and Newman (4) have formulated general

mass and current balances, but the equations are too complex to be of use for simple double-layer capacity measurement; when reduced for the case considered here, their expressions lead to our starting equation.

Physical Model and Assumptions

Consider the physical situation illustrated in Fig. 1, where a Luggin capillary is positioned a distance, d, from the surface of a porous electrode having a thickness, L. Only one face of the electrode is exposed to the electrolyte to ensure uniform current through the face. It is assumed that the porous system is so highly interlinked that the concentration of species dissolved in the electrolyte flooding the pores of the electrode is constant over plane x in the electrode. Similarly, the electrode potential is constant over plane x. It is further assumed that the potential gradients are one-dimensional (along x), which is true when the thickness, L, of the electrode is much greater than the pore diameters (10 to 20 times). It is assumed that the electronic conductivity of the electrode material is large compared to the ionic conductivity of the electrolyte within the pores, so that the absolute potential of the electrode material is constant along x. The electrolyte is assumed to be concentrated, so that diffuse double-layer effects are negligible. In the absence of faradaic current, there are no changes of concentration of species along x. These assumptions are reasonable for many cases of practical interest.

Theory

The differential equation (2, 3) governing the distribution of potential in one-dimensional porous electrodes with the above assumptions is given by

$$\partial V(x,t)/\partial t = (L/\rho C)\,(\partial^2 V(x,t)/\partial x^2) \qquad [1]$$

L is the thickness of the electrode (cm); ρ is the effective resistance of the electrolyte in the porous system of the electrode (ohm-cm); C is the double-layer capacity per unit external, plane area of electrode (farads/cm^2); $V(x,t)$ is electrode-electrolyte potential at position x (volts). (If the true double-layer per unit surface area is c, and the specific surface area is a, then $C = caL$.) At $t > 0$, the current density through the face at L is i, and $i = i(L,t) = (1/\rho)[\partial V(x,t)/\partial x]_{x=L}$.

When a linearly increasing voltage is applied from rest conditions, the initial condition is $V(x,0) =$ constant $= V_0$, and the boundary condition is $V_m = kt + V_0$. The resistance, R_e, between test electrode and reference tip includes that of the electrolyte between the face of the electrode and the tip (see Fig. 1), and $V_s = V_m - iR_eA$, where A is the plane area of the electrode. Then

$$i = (1/\rho)[\partial V(x,t)/\partial x]_{x=L} = (V_m - V_s)/R_eA$$

or

$$[\partial V(x,t)/\partial x]_{x=L} + h(V_s - V_m) = 0$$

where

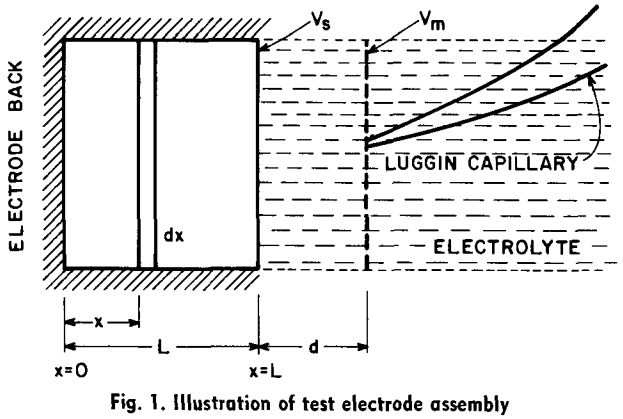

Fig. 1. Illustration of test electrode assembly

$$h = \rho/R_eA \qquad [2]$$

The effective specific resistance is $\rho = \lambda\rho_{free}$, where λ is the labyrinth factor. If R_e is due mainly to the electrolyte path of length d between test-Luggin tip, $R_eA = \rho_{free}d$, and $h = \lambda/d$.

The solution of Eq. [1] for these conditions (5) is

$$V(x,t) - V_0 = kt - \frac{k[h(L^2 - x^2) + 2L]}{2h(L/\rho C)} + \frac{2hk}{(L/\rho C)}\sum_{n=1}^{\infty}\frac{\exp(-tL\alpha_n^2/\rho C)\cos\alpha_n x}{\alpha_n^2[(h^2 + \alpha_n^2)L + h]\cos\alpha_n L} \qquad [3]$$

where α_n values are the positive roots of $\alpha_n\tan(\alpha_n L) = h$. Hence

$$i = i(L,t) = \beta kC \qquad [4]$$

where

$$\beta = 1 - \sum_{n=1}^{\infty}\exp\left(-\frac{t}{\rho CL}m_n^2\right)\cdot\left[\frac{2\psi^2}{m_n^2[\psi^2 + m_n^2 + \psi]}\right] \qquad [4a]$$

with

$$m_n = L\alpha_n$$
$$m_n\tan m_n = \psi$$
$$\psi = Lh = L\rho/R_eA$$

The values of β *vs.* $t/\rho CL$ as a function of ψ (calculated by digital computation) are given in Fig. 2. It is readily shown (6) that Eq. [4] reduces to the well-known result

$$i = kC[1 - \exp(-t/R_eC)] \qquad [5]$$

for ψ small, that is, a very thin electrode and to

$$i = kC - \frac{8kC}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}\cdot\exp\left(\frac{-(2n+1)^2}{4}\pi^2\frac{t}{\rho CL}\right)\left(\sin\left(\frac{2n+1}{2}\right)\pi\right) \qquad [6]$$

for ψ large, that is, R_e small, the case similarly treated by Posey and Morozumi (3).

If the direction of voltage scan is sharply reversed at some voltage, that is, a triangular voltage pulse is used, the general solution to the following voltage-distance-time curve is complex (7), and is obtained from

$$V_m(t_1) - V(x,t) = u(x,t) + w(x,t)$$

where $V_m(t_1)$ is the controlled potential at the Luggin tip at the time t_1 of voltage reversal, t is time measured from t_1 and

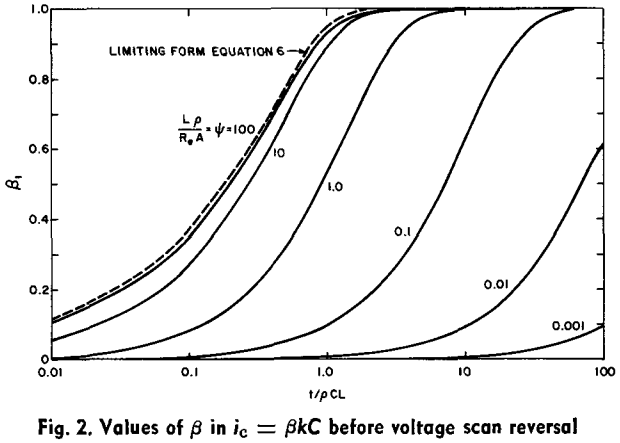

Fig. 2. Values of β in $i_c = \beta kC$ before voltage scan reversal

$$w(x,t) = kt - \frac{k[h(L^2 - x^2) + 2L]}{2h(L/\rho C)} + \frac{2hk}{(L/\rho C)} \sum_{n=1}^{\infty} \frac{\exp(-tL\alpha_n^2/\rho C)\cos \alpha_n x}{\alpha_n^2[(h^2 + \alpha_n^2)L + h]\cos \alpha_n L}$$

$$u(x,t) = 2 \sum_{n=1}^{\infty} \exp(-k\alpha_n^2 t) \cdot \frac{h^2 + \alpha_n^2}{(\alpha_n^2 + h^2)L + h} \cos \alpha_n x \int_0^L f(x)\cos \alpha_n x dx$$

with

$$f(x) = V_m(t_1) - V(x,t_1) = (kt_1 + V_0) - V(x,t_1) = \frac{k[h(L^2 - x^2) + 2L]}{2h(L/\rho C)} - \frac{2hk}{(L/\rho C)} \sum_{n=1}^{\infty} \frac{\exp(-tL\alpha_n^2/\rho C)\cos \alpha_n x}{\alpha_n^2[(h^2 + \alpha_n^2)L + h]\cos \alpha_n L}$$

This general solution is considerably simplified when the initial voltage sweep is maintained long enough for the summation term in Eq. [3] to become negligible ($\beta \rightarrow 1$), giving the voltage distribution through the electrode at time t_1 as

$$f(x) = \frac{k[h(L^2 - x^2) + 2L]}{2h(L/\rho C)}$$

Then, it can be shown that

$$i = i(L,t) = \gamma kC \qquad [7]$$

$$\gamma = \beta_1 - \beta_2$$

where β_1 is obtained from Eq. [4a] and

$$\beta_2 = \sum_{n=1}^{\infty} \exp\left(-m_n^2 \frac{t}{\rho CL}\right)\left(\frac{\psi^2 + m_n^2}{m_n^2 + \psi^2 + \psi}\right) \cdot \left(\frac{2}{m_n^2}\right) \sin^2 m_n \qquad [7a]$$

The limits for long time are $\beta_1 = 1$, $\beta_2 = 0$, and for zero time, $\beta_1 = 0$, $\beta_2 = 1$; so after voltage gradient reversal the current goes from kC at $t = 0$ to $-kC$ at long time. Values for γ are shown in Fig. 3, again as a function of $t/\rho CL$ and ψ.

Discussion

Figure 4 illustrates a typical set of values. It is clear that in the absence of faradaic current it is easy to determine C from an experimental result of this form, using the constant values of i. In addition, by matching the experimental values of β *vs.* time against the theoretical results of Fig. 2, it is possible to estimate the best value of the unknown, ρ. Then, since

$$\rho = \rho_{free}\lambda \qquad [8]$$

the labyrinth factor λ can be calculated. Alternatively, knowing rough estimates of the parameters it is possible from Fig. 2 to estimate the time at which β tends to one, t_1 say, and hence determine the sweep rate necessary to obtain C from constant i values for a given voltage excursion, ΔV

$$k = \Delta V/t_1 \qquad [9]$$

Part II of this paper will show that there is good agreement between theory and experiment, in the absence of faradaic current.

On the other hand, it is commonly observed that the current does not always reach a truly horizontal value (Fig. 5) due to faradaic current which increases as the voltage scans from the zero-current starting point. Such faradaic current rarely behaves as if an ideal faradaic resistance were present. This makes it impossible to determine C from a horizontal portion, just as it would be impossible to determine it from a galvanostatic test which did not give a linear V-t curve after some time. However, the triangular voltage sweep enables an estimate of C to be made, as follows.

At the point at which the voltage gradient reverses, the faradaic current is about the same before and just after the reversal. Thus, if i_f is not too large compared to i_c

$$i_1 = i_f + kC$$
$$i_2 \approx (-\gamma)kC - i_f$$

and

$$i_1 + i_2 \approx kC(1 - \gamma) \qquad [10]$$

from which C can be estimated by a trial and error matching of the experimental results with the theoretical values. A trial estimate of C is made as shown in Fig. 5, and by comparing the results with Fig. 2 a value of ψ can also be estimated. Assuming that a small faradaic current does not change Fig. 3 much, the

value of γ at t_2 is estimated, and a second estimate of C made using Eq. [10], and so on.

It will be shown in a later publication that these techniques work well when the faradaic current at the point of reversal is not too large compared to the capacitive current. Often this can be achieved experimentally by keeping the voltage excursions small. It will not, of course, eliminate a reversible pseudocapacity due to a reversible build-up/removal of species on the surface, $S + R^+ + e^- \rightleftarrows S[R]$, since faradaic current due to a reversible process of this kind will reverse as the voltage gradient reverses.

Influence of Steric Effects upon Redox Potentials of Cyanine Dyes

Tadaaki Tani

Research Laboratories, Ashigara, Fuji Photo Film Company, Minami-ashigara, Kanagawa, Japan

In earlier reports (1, 2) it has been indicated that the lowest vacant electronic energy levels ϵ_{lv} and the highest occupied ones ϵ_{ho} of simple cyanine dyes calculated by Hückel-approximation molecular orbital (HMO) method can be related to their reduction potentials E_{red}, oxidation potentials E_{ox}, excitation energies E_{ex} by the following equations

$$\epsilon_{lv} = -E_{red} + C \quad [1]$$

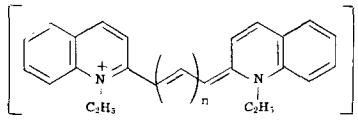
$$\epsilon_{ho} = -E_{ox} + C' \quad [2]$$

$$\epsilon_{lv} - \epsilon_{ho} = E_{ex} = \frac{hc}{\lambda_{max}} \quad [3]$$

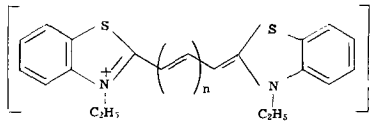
where λ_{max} is the wavelength of maximum absorption of a dye, and C and C' are electrochemical constants.

Although some steric effects are thought to exist in monomethine cyanine dyes, they are not amenable to the HMO treatment (1). In this paper, rather strict comparison has been made between the calculated and experimental values of simple cyanine dyes with various methine chain lengths in terms of Eq. [1]-[3], in order to obtain knowledge of the influence of steric effects upon the electronic structures of the cyanine dyes. The cyanine dyes studied are as follows

Key words: steric effect, redox potential, cyanine dye.



n = 0; 2,2′-quinocyanine ($2Q_0$)
n = 1; 2,2′-quinocarbocyanine ($2Q_1$)
n = 2; 2,2′-quinodicarbocyanine ($2Q_2$)
n = 3; 2,2′-quinotricarbocyanine ($2Q_3$)



n = 0; thiacyanine (S_0)
n = 1; thiacarbocyanine (S_1)
n = 2; thiadicarbocyanine (S_2)
n = 3; thiatricarbocyanine (S_3)
n = 4; thiatetracarbocyanine (S_4)
n = 5; thiapentacarbocyanine (S_5)

The experimental and calculated values of these dyes were already reported (1-5).

Figure 1 shows the relations between reduction potentials and the lowest vacant electronic energy levels, and between oxidation potentials and the highest occupied levels of these dyes. As shown in this figure, the

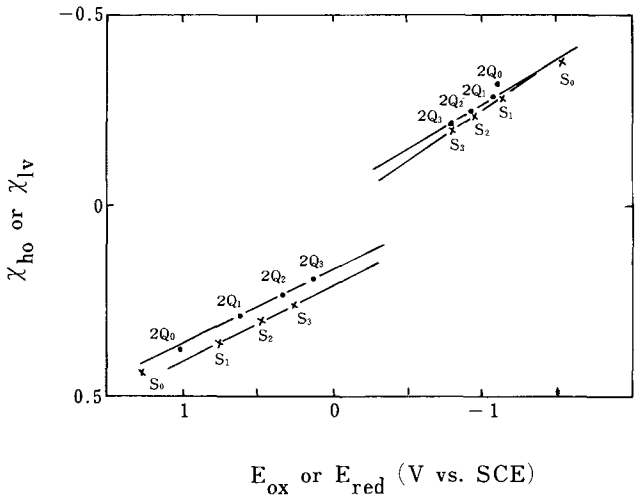


Fig. 1. The relation between the calculated electronic-energy levels and the observed redox potentials of simple cyanine dyes. χ_{ho} and χ_{lv} are $(\epsilon_{ho} - \alpha)/\beta$ and $(\epsilon_{lv} - \alpha)/\beta$, respectively.

observed reduction potential of 2,2′-quinocyanine is more positive, and that of thiacyanine is more negative than expected by the HMO method. On the other hand, the observed oxidation potential of 2,2′-quinocyanine is more negative, and that of thiacyanine is more positive than expected by the HMO method.

Figure 2 shows the relation of the observed excitation energies with the magnitude of the calculated energy gap between the lowest vacant and the highest occupied electronic energy levels of these dyes. The observed excitation energy of 2,2′-quinocyanine is

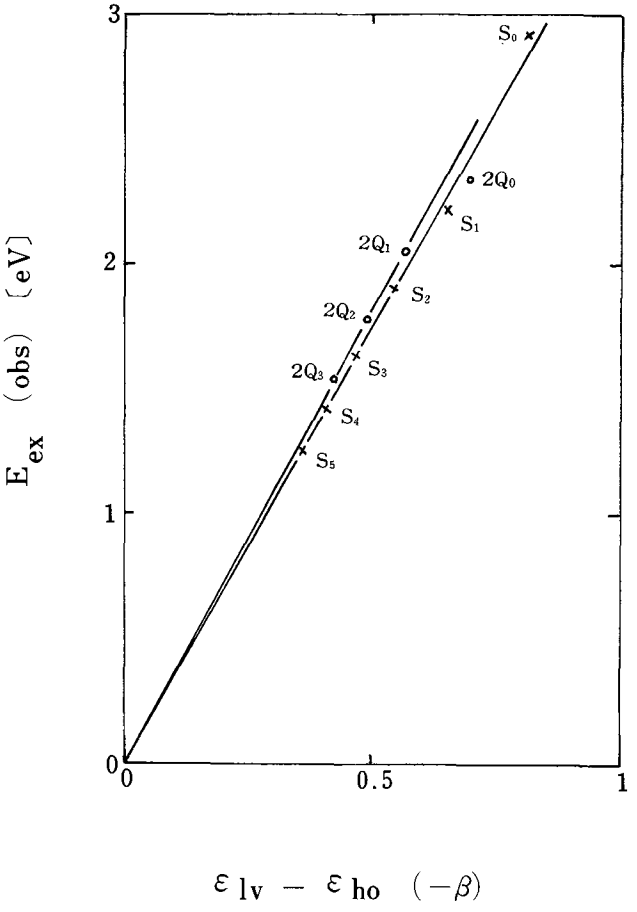

Fig. 2. The relation between the observed excitation energies and the magnitude of the calculated energy gap between the lowest vacant and the highest occupied electronic-energy levels of simple cyanine dyes.

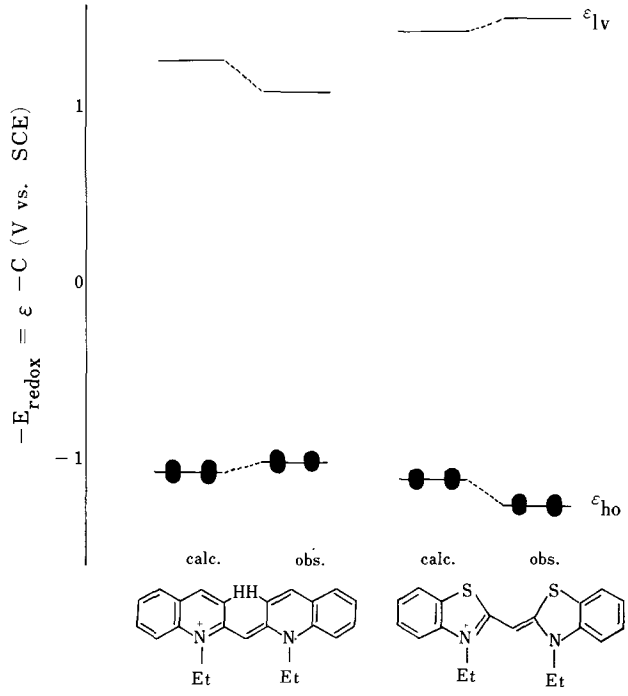

Fig. 3. The electronic-energy level diagram of 2,2′-quinocyanine and thiacyanine calculated by the HMO method and estimated by the experimental data, in terms of redox potentials.

smaller, and that of thiacyanine is larger than expected by the HMO method. This result is thought consistent with the results shown in Fig. 1, under the light of Eq. [1]-[3].

These results are thought to suggest the existence of some steric effects in 2,2′-quinocyanine and thiacyanine. Figure 3 shows the electronic-energy levels of these dyes given by the HMO calculation and their reported redox (reduction and oxidation) potentials. It is thought that the calculated electronic-energy levels correspond to those of the dyes in the absence of the steric effects, and the energy levels estimated from the experimental data correspond to those in the presence of the steric effects.

According to the x-ray diffraction analysis by Dammeier and Hoppe (6), and by Nakatsu and co-workers (7), a 2,2′-quinocyanine molecule is nonplanar, owing to its intramolecular steric hindrance (the hindrance between hydrogen atoms at 3 and 3′ positions). Since the highest occupied level was bonding, and the lowest vacant one was antibonding, according to the HMO method, the nonplanarity of this dye is expected to cause the unstabilization of its highest occupied level, and to cause its stabilization of the lowest vacant one. This view is consistent with the results shown in Fig. 1-3.

According to Nakatsu and co-workers (8), a thiacyanine molecule is planar, and the distance between sulfur atoms in the molecule is 2.994Å, being smaller than the sum of the van der Waals' radii of two sulfur atoms (*ca.* 3.7Å). This fact suggests the existence of the interaction of electronic orbitals between two sulfur atoms in the molecule. Since it was suggested from the HMO method that the molecular orbital interaction between the two sulfur atoms in the molecule was bonding at the highest occupied level, and antibonding at the lowest vacant one, the interaction is thought to cause the stabilization of the highest occupied level, and to cause the unstabilization of the lowest vacant one. This view is consistent with the results shown in Fig. 1-3.

The Error in Measurements of Electrode Kinetics Caused by Nonuniform Ohmic-Potential Drop to a Disk Electrode

William H. Tiedemann*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

and Douglas N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

Newman, in his treatment of the current distribution on a rotating disk electrode (1,2), has implied that the nonuniform ohmic, potential drop will lead to errors in the determination of kinetic parameters unless special corrections are applied. Because the error will be relatively larger for high exchange-current densities and low solution conductivities, linear electrode kinetics have been chosen to assess the magnitude of the effect. The complexity of the results is simplified by restricting the analysis to the same geometry—a disk electrode of radius r_0 in a large insulating plane, with the counterelectrode at infinity—and ignoring concentration variations. The apparent surface overpotential is taken to be that measured by a reference electrode, with the ohmic-potential drop being determined by interruption of the current. Three particular reference-electrode positions are used to illustrate the effect. The results are qualitatively applicable for other electrode geometries afflicted with a similar nonuniform ohmic potential drop.

Analysis

The potential in solution outside the doublelayer, in the absence of concentration variations, satisfies Laplace's equation

$$\frac{\partial}{\partial \xi}\left[(1+\xi^2)\frac{\partial \Phi}{\partial \xi} \right] + \frac{\partial}{\partial \eta}\left[(1-\eta^2)\frac{\partial \Phi}{\partial \eta} \right] = 0 \quad [1]$$

where the rotational elliptic coordinates η and ξ are related to cylindrical coordinates r and z by

$$z = r_0 \xi \eta \qquad r = r_0[(1+\xi^2)(1-\eta^2)]^{1/2} \quad [2]$$

[see Ref (3)]. The boundary conditions adopted for the disk electrode are (1)

$$\frac{\partial \Phi}{\partial \eta} = 0 \text{ at } \eta = 0 \text{ (on the insulating plane)}$$

$$\Phi = 0 \text{ as } \xi \to \infty \text{ (far from the disk)} \quad [3]$$

Φ well behaved at $\eta = 1$ (on the axis of the disk)

The solution to Eq. [1] satisfying boundary conditions [3] can be expressed as (1)

$$\Phi = \frac{RT}{\mathbf{F}} \sum_{n=0}^{\infty} B_n P_{2n}(\eta) M_{2n}(\xi) \quad [4]$$

where $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$ and $M_{2n}(\xi)$ is a Legendre function with known properties (1).

For sufficiently small current densities (linear polarization), the relationship between the surface overpotential and the local current density is

$$i(r) = i_0(\alpha_a + \alpha_c)\frac{\mathbf{F}}{RT}\eta_s = -\kappa_\infty \frac{\partial \Phi}{\partial z} \text{ at } z = 0,\ r < r_0 \quad [5]$$

where $i(r)$ refers to the local current density, η_s refers to the local surface overpotential (which is characteristic of the local current density) and $i_0(\alpha_a + \alpha_c)\mathbf{F}/RT$ relates to the local kinetics of the faradaic reaction, taken here to be linear. The local surface overpotential is given by

$$\eta_s = V - \Phi(r,0) \quad [6]$$

where V is the electrode potential (assumed to be uniform) and $\Phi(r,0)$ is the potential in the solution just outside the double layer.

The overpotential measured experimentally usually contains an ohmic contribution which must be removed by either a numerical calculation (1,3) or use of an interrupter technique (4). Newman (5) has shown that the ohmic potential measured by the interrupter technique corresponds to an average potential characteristic of the primary current distribution. A nonuniformly charged double-layer is associated with a nonuniform ohmic-potential drop during the passage of current. Immediately after the current is interrupted, the double layer remains charged, and the potential just outside the double-layer changes by a uniform amount over the entire surface of the disk

$$V' - \Phi'(r,0) = V - \Phi(r,0) \quad [7]$$

where primes denote quantities after interruption. The potential at an arbitrary point in the solution is

* Electrochemical Society Active Member.
[1] Present address: Globe-Union, Incorporated Milwaukee Wisconsin 53201.
Key words: ohmic-potential drop, electrode kinetics, disk electrode, current distribution.

$$\Phi'(r,z) = \Phi(r,z) - \bar{\Phi}(r,z) \quad [8]$$

where $\bar{\Phi}(r,z)$ represents the local ohmic drop associated with the primary distribution for the same current. The surface overpotential as measured by the current interrupter method with the reference electrode at r,z can be written as

$$\eta_{s,app} = V - \Phi(r,z) - \bar{\Phi}(r,0) + \bar{\Phi}(r,z) \quad [9]$$

It is assumed that one who does not take into account the nonuniform current distribution would calculate an apparent exchange current density, $i_{o,app}$ with the linear polarization expression based on the average current density and apparent surface overpotential

$$i_{avg} = i_{o,app}(\alpha_a + \alpha_c)\frac{\mathbf{F}}{RT}\eta_{s,app} \quad [10]$$

The difference between Eq. [5] and [10] is a consequence of the nonuniform ohmic drop to the disk electrode which is unavoidably contained in Eq. [10]. Substitution of Eq. [4] and [9] into Eq. [10] gives an expression for the error one might expect in the exchange current density

$$i_o/i_{o,app} = \frac{\pi J}{4}\left[\frac{4\kappa_\infty r_o V}{I} - 1 - \sum_{n=1}^{\infty}\frac{B_n}{B_o}P_{2n}(\eta)M_{2n}(\xi)\right] \quad [11]$$

where

$$J = (\alpha_a + \alpha_c)\frac{\mathbf{F}r_o i_o}{RT\kappa_\infty}$$

$$B_o = \frac{\mathbf{F}}{RT}\frac{I}{4\kappa_\infty r_o}$$

and the B_n values have been determined in Ref. (1). Equation [11] is valid for any arbitrary position of the reference electrode.

Let us now examine three special cases. With the reference electrode at infinity, Eq. [11] can be expressed as

$$i_o/i_{o,app} = \frac{\pi J}{4}\left[\frac{4\kappa_\infty r_o V}{I} - 1\right] \quad [12]$$

With the reference electrode adjacent to the work electrode

$$i_o/i_{o,app} = i(r)/i_{avg} \quad [13]$$

a general result applicable to other geometries as well. Placing the reference electrode close to the working electrode decreases the ohmic-potential drop, but it also permits the extremes in the error for the exchange-current density. Near the center, $i(r)$ has its smallest value, and the error can be expressed as

$$i_o/i_{o,app} = \frac{\pi J}{4}\left[\frac{4\kappa_\infty r_o V}{I} - \sum_{n=0}^{\infty}\frac{B_n}{B_o}\right] \quad [14]$$

Near the edge, $i(r)$ has its largest value, and

$$i_o/i_{o,app} = \frac{\pi J}{4}\left[\frac{4\kappa_\infty r_o V}{I} - \sum_{n=0}^{\infty}\frac{B_n}{B_o}P_{2n}(0)\right] \quad [15]$$

With the reference electrode farther from the surface, the error can actually be expected to lie between these extremes. Figure 1 contains the numerical results of the error in the exchange-current density for several positions of the reference electrode as a function of the dimensionless exchange-current density J. For the values of J considered, the error in i_o can range from -50 to more than 300%.

Discussion and Conclusions

The most important result of the paper is that serious errors in the measurement of electrode kinetic parameters (*i.e.*, i_o) can result from an electrode which is characterized by a nonuniform current distribution. The magnitude of this error depends on the position of the reference electrode relative to the working electrode. For the cases shown in Fig. 1, the errors associated with nonuniform current distribution are smallest when the reference electrode is located far from the disk. However, decreasing the error in this manner increases the ohmic drop which must be compensated for by an interrupter technique. Under certain experimental conditions, the compensated ohmic potential can be as large as 90% of the total measured overpotential, with a consequent decrease in the accuracy of the surface overpotential. There are cell designs (6, 7) which provide a uniform primary current distribution over the surface of the electrode and at the same time position the reference electrode in the plane of the working electrode in such a manner as not to disturb the local current distribution. Also, the use of a spherical electrode, as pointed out by Newman (2), can be used to eliminate current distribution problems.

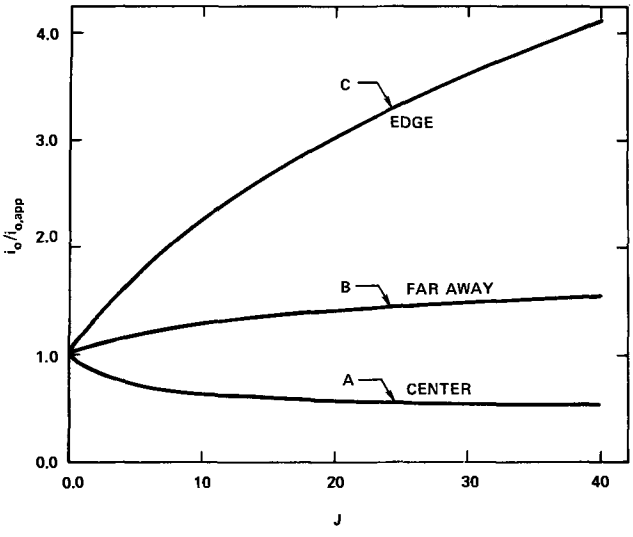

Fig. 1. Correction in i_o determination for linear polarization for various positions of the reference electrode relative to the disk electrode. Curve A approaches 0.5 for large J, while curve C approaches infinity.

A second result of this work is that for the reference electrode positions shown in Fig. 1, one needs only to measure the value of J for the system in question to assess the degree of error in i_o. For other reference electrode positions, Eq. [11] can be evaluated to assess the error in i_o. The results in this paper can be used qualitatively to assess the error for configurations other than the disk electrode. Equation [13] can be used on any electrode system provided that $i(r)$ is known.

High-Temperature Dielectric Behavior of TiO_2(Rutile)

M. A. Seitz, R. T. McSweeney, and W. M. Hirthe

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The dielectric behavior of "a" and "c" orientation single crystals of TiO_2 (rutile) was investigated as a function of frequency, from 100 Hz to 500 kHz, and temperature, over the interval from 500° to 1000°C. The a-c conductivity at low applied voltages was found to be due to electronic carriers throughout the frequency and temperature range studied. The dielectric polarization processes occurring in this material were found to depend on the temperature and frequency ranges being investigated. At frequencies above 10^5 Hz, electronic and lattice polarization was found to predominate throughout the temperature interval investigated. The lower frequency data could be rationalized on the basis of a space-charge polarization model involving mobile point defects, which are blocked or partially blocked at the electrodes, and electronic carriers, which are able to pass through the electrode. At temperatures below 750°C, the "c" orientation specimens were found to exhibit an anomalous behavior that was felt to be the result of a thin barrier layer in the vicinity of the specimen electrodes.

The rutile crystalline modification of TiO_2 is a representative metal oxide of commercial importance which is also of interest from a research standpoint. Various high- and low-temperature measurements including conductivity (1-6), weight change (7, 8), thermoelectric power (3, 4), diffusion (9-11), transient conductivity (12-14), Hall effect (15-20), and dielectric measurements (21-26) have been made for the purpose of elucidating its defect structure and physical properties.

High-temperature measurements (1-8) have qualitatively confirmed the presence of nonstoichiometric defects resulting in n-type behavior, although the species, concentration, and ionization states are still somewhat in doubt.

Previous dielectric measurements (21-26) on rutile have been restricted to relatively low temperatures. Most of this work has been performed at room temperature after heat-treatment at elevated temperatures in either an oxidizing or reducing atmosphere. Dielectric dispersion and relaxation have been observed at room temperature by several investigators, but their data does not agree, and a consistent model has not been determined. The experiments of von Hippel *et al.* (24) are an exception in that they were performed at temperatures up to 500°C. This temperature, however, is still less than one-fourth the melting point of rutile, and impurities and quenched-in defects could play a major role in controlling the behavior.

To avoid the inconsistencies evident in the low-temperature investigations of rutile, dielectric measurements were performed at as high a temperature as feasible using a technique developed in our laboratories. Under these conditions the nonequilibrium conditions noted in the literature could be minimized or possibly avoided. Analysis of high-temperature data should lead to information about the defect structure and its role in controlling the dielectric behavior.

Key words: dielectric behavior, TiO_2 (rutile), polarization.

Experimental Procedure

In our early attempts to measure high-temperature dielectric behavior, it was noted that the specimen conductance, G_{sp}, exhibits a much stronger temperature dependence than the specimen capacitance, C_{sp}. This results in a dissipation factor which increases significantly with increasing temperature. For rutile, tan δ approached 10^3 to 10^4 at 1000°C and, therefore, a special technique had to be developed to perform the dielectric measurements. This substitution technique, where corrections are made for parasitic capacitances and inductances associated with the system, was the subject of a previous paper (27). With this technique the capacitance of specimens having a total resistance of greater than 100 ohms and a dissipation factor less than 10^4 can be measured to ±15%. For mid-range frequencies (1-50 kHz) the error is less than ±5%.

Single crystal titanium dioxide boules purchased from the National Lead Company (see Table I) were oriented to within ±2° of the "a" or "c" axis by the Laue back reflection x-ray technique. Specimens ranging in thickness from 0.23 to 0.6 cm and in surface area from 0.4 to 0.7 cm^2 were cut from boule slices. The surface area to thickness ratio ranged from 0.5 to 1 cm. All surfaces were mechanically polished with No. 600 grit silicon carbide or boron carbide to remove irregularities and to provide reproducible surface conditions. Three to five coats of Engelhard liquid bright platinum paint No. 05 were applied to the plane parallel surfaces perpendicular to the orientation direction and baked at 500°C between each application. An additional three to five coats of Engelhard fluxed platinum paste No. 6082 were applied to the surfaces and baked at 850°C between applications. Care was taken to use thin coats of paint and paste and to heat the specimen slowly so that the layers would not bubble or crack. When the resistance between any pair of points on the contact surface was

reduced to less than 1 ohm, the platinum paste applications were terminated and the specimen placed into the holder shown in Fig. 1.

The specimen was allowed to equilibrate at temperature in various partial pressures of oxygen provided by oxygen-argon tank mixtures. Equilibrium was assumed when the capacitance and resistance changes over a several hour period were less than those due to the variation in temperature. Measurements of the capacitance and resistance were made at selected frequencies in the range 100 Hz to 500 kHz. The specimen temperature was increased or decreased at approximately 50°C intervals and the above procedure repeated.

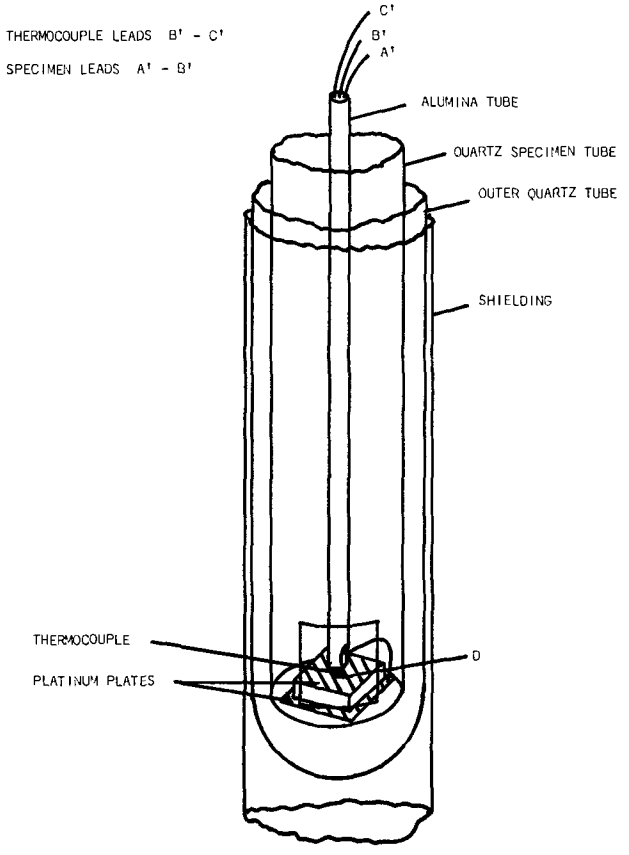

Fig. 1. Specimen holder

Results and Discussion

Isothermal dielectric measurements were performed in the range 100 Hz to 500 kHz over the interval 500°-1000°C at several oxygen partial pressures. The apparent dielectric constant, K', as a function of frequency for "a" and "c" orientations is shown in Fig. 2 and 3, respectively. No dispersion in conductivity was noted over the ranges of frequency and temperature investigated; consequently, isothermal conductivity *vs.* frequency data were not included. From Fig. 2 and 3 it can be seen that the large apparent dielectric constant evident at low frequencies decreases monotonically with increasing frequency over the entire range. At high frequencies a constant value of K' is approached, K'_∞, which is independent of temperature. The decrease in K' with frequency followed the relationship $K' \alpha \omega^{-x}$ where x is 5/4 ± 1/4. A maximum static dielectric constant, K_s, was not obtained since the dielectric constant continues to increase with decreasing frequency.

Figures 4 and 5 show the dependence of K' on reciprocal absolute temperature for "a" and "c" orientations, respectively. The linear segments of these plots suggest that the apparent dielectric constant is controlled by a thermally activated process. For the "a" orientation at low frequencies, K' followed the relationship $K' \alpha \exp(-E/RT)$ over the temperature range investigated. In contrast to this, K' for the "c" orientation exhibited a negative temperature dependence in the range 500° to approximately 750°C followed by a positive temperature dependence at higher temperatures.

Two probe a-c (1 kHz) and d-c ($I_{dc} < 15$ μA) conductivities *vs.* the reciprocal of absolute temperature for the "a" and "c" orientations are shown in Fig. 6

and 7, respectively. The a-c and d-c conductivities for the "a" orientation were identical and exhibited an exponential temperature dependence with an activation energy of 1.6 ± 0.2 eV. The "c" orientation behaved in a similar manner at temperatures above 750°C, but below this temperature the a-c conductivity approached a constant value, whereas the d-c conductivity exhibited an exponential temperature dependence. Therefore, at temperatures below 750°C the conductivity is frequency dependent. These conductivity data were reproducible to within ±2% upon thermal cycling except for the "c" orientation data below 750°C which was dependent on history.

The conductivity and dielectric constant were dependent on oxygen partial pressure over the range 1-10^{-5} atm at 950°C. They were proportional to $P_{O_2}{}^{-1/n}$ where n was approximately equal to 6. This oxygen partial pressure dependence was not evident at lower temperatures. This would indicate that either quenched-in nonstoichiometric defects or impurities controlled the conductivity behavior of TiO_2 at lower temperatures. The former seems more attractive due to the agreement of the conductivity data with previous measurements (6). Partial pressure studies were not continued because the platinum contacts degraded with further reduction of the specimen. The values of dielectric constant and a-c conductivity did not exhibit a dependence on the magnitude of the applied a-c field at less than 50 V/cm. The dissipation factor calculated from these data are shown in Fig. 8 and 9. It is observed that tan δ is very large, and also that tan δ_{max} is a strong function of temperature.

An understanding of the high-temperature dielectric behavior of TiO_2 may be obtained from the data presented in Fig. 2-9. The exponentially dependent a-c and d-c conductivities are in good agreement with four-probe d-c conductivities reported in the literature (6), and this indicates that the platinum contacts acted in an ohmic fashion. The imaginary part of the dielectric constant, K'', was always much greater than the real part, K', which suggests that the dielectric losses were associated with electronic conduction rather than relaxation processes.

The variation of K' with frequency and temperature at elevated temperatures indicates that similar polarization processes are responsible for the dielectric behavior in the "a" and "c" orientations.

Electronic and atomic polarization mechanisms are active in rutile at all temperatures and frequencies of this investigation. The frequency and temperature independent dielectric constant, K'_∞, at high frequencies is controlled by atomic and electronic polarization processes. The high-frequency dielectric constants, K'_∞,

reported by Parker (28) at 1 MHz and 300°C were 170 in the "c" direction and 86 in the "a" direction. These values compare well with the high-frequency data of this study. The low-frequency data of this investigation were analyzed in terms of barrier layer and space-charge polarization models in addition to the constant contribution expected from electronic and atomic polarization processes.

Various interfacial barrier layer models have been considered by Volger (29), and others (30, 31). Only two of the special cases considered by Volger could explain the large values of K' observed in this investigation. In these limiting cases the dielectric constant of the barrier layer, K'_1, and the bulk material, K'_2, are assumed to be identical. The large apparent dielectric constants are shown to result from resistivity and resistance differences between the barrier layers and the bulk of the specimen. When both the resistivity of the interfacial material, ρ_1, and the barrier layer resistance, $\rho_1 d_1/A$, are much larger than that of the bulk,

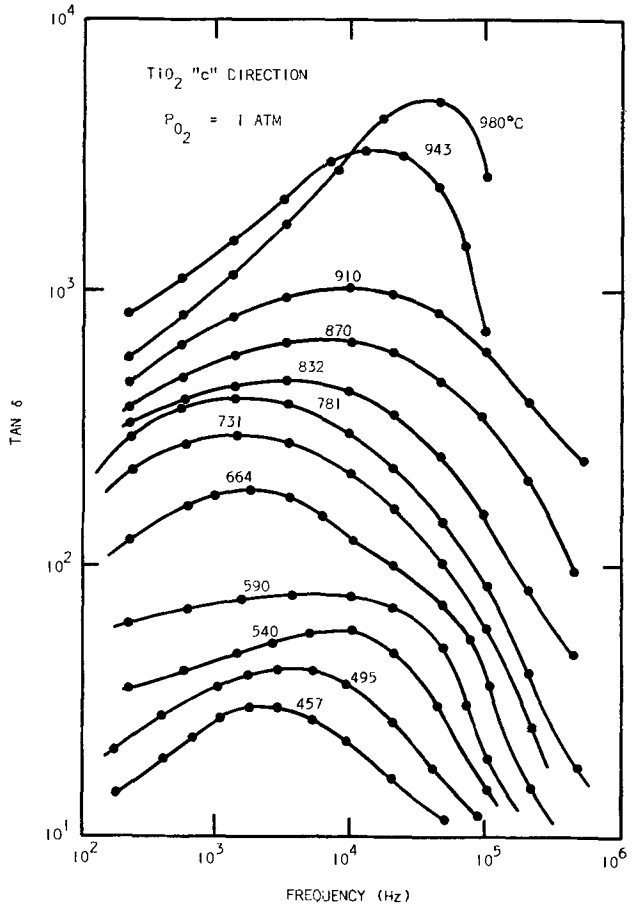

Fig. 9. Tan δ vs. frequency over the range 457°-980°C for the "c" direction and $P_{O2} = 1$ atm.

i.e., $\rho_1^2 d_1 >> \rho_2^2 d_2$ and $\rho_1 d_1 >> \rho_2 d_2$, the ratio of the static to the bulk dielectric constant equals the ratio of the bulk thickness, d_2, to the barrier thickness, d_1, *i.e.*

$$\frac{K'_s}{K'_\infty} = \frac{d_2}{d_1} \qquad [1]$$

In this case a large dispersion in conductivity is also predicted.

In the second model, the resistivity of the interfacial material, ρ_1, is assumed to be much larger than that of the bulk, ρ_2, *i.e.*, $\rho_1^2 d_1 >> \rho_2^2 d_2$, but the barrier layer resistance is negligible when compared with the bulk resistance, *i.e.*, $\rho_1 d_1 << \rho_2 d_2$. The ratio of the static to the bulk dielectric constant equals the ratio of the interfacial to bulk resistivities, *i.e.*

$$\frac{K'_s}{K'_\infty} \simeq \frac{\rho_1^2 d_1}{\rho_2^2 d_2} \qquad [2]$$

A conductivity dispersion is not predicted for this situation.

Space-charge processes can also lead to significant polarization as the result of the motion of electronic or atomic point defects in an initially homogeneous material. In order to have space-charge polarization, two requirements must be fulfilled. Charge-carrying species must be mobile and blocked or partially blocked from passing through the specimen electrodes. These charge-carrying species could be electronic defects, in which case they would be blocked at the electrodes by non-ohmic processes; or atomic defects, for which electrode porosity and slow rates of chemical reaction would result in charge-carrier blocking.

Jaffe (32), Friauf (33), Macdonald (34-36), and Beaumont and Jacobs (37) have developed theoretical relationships describing the effect of space-charge polarization on the conductivity and dielectric constant. Three basic models have been developed, one of these involves a single mobile charge-carrying species which is blocked or partially blocked at the specimen electrodes (37). The others (32-36) deal with two mobile charge-carrying species of opposite sign, where either both or only one of the charged species are blocked or partially blocked at the electrodes. The single-carrier model requires a dispersion in the conductivity, which was not observed, while the second case does not appropriately describe the observed frequency dispersion. The last case is deemed the most appropriate when considering the high temperature dielectric behavior of TiO_2 and will be expanded here.

The model as presented by Friauf involving two charge-carrying species one of which is blocked at the specimen electrodes can readily be applied to the observations for TiO_2. Negatively charged species are assumed to pass through the electrodes while positively charged species are blocked at the electrodes. The equivalent parallel circuit capacitance, C, and resistance, R, per unit area of the specimen can be expressed as a function of frequency, ω, as

$$-\Delta\left[\frac{1}{R}\right] = \omega C = \frac{e\mu_n c_o}{\sqrt{2}\,L^2}\left[\frac{D_n + D_p}{2D_n}\right]^{1/2}\left[\frac{D_p}{\omega}\right]^{1/2} \qquad [3]$$

Here, D_n and D_p are, respectively, the diffusion coefficients of the negative and positive charge-carrying species of charge e, c_o is the equilibrium concentration of defects, $2L$ is the specimen thickness, and μ_n is the mobility of the negative species. It is to be noted that Eq. [3] was derived for a case where both charge-carrying species have approximately the same mobility. For TiO_2, however, the negative charge-carrying species are assumed to be electrons which would have a much larger diffusion coefficient than the positively charged species which are assumed to be positive ions. Using the inequality, $D_n >> D_p$, the Einstein equation

$$\frac{\mu_n}{D_n} = \frac{e}{kT} \qquad [4]$$

along with the relationship

$$C = \frac{K'\epsilon_o}{2L} \qquad [5]$$

Eq. [3] reduced to

$$K' \simeq \frac{e^2 c_o}{\epsilon_o L k T}\left[\frac{D_p}{\omega}\right]^{3/2} \qquad [6]$$

Here, K' is the effective dielectric constant and ϵ_o is the permittivity of free space.

The high-temperature ($T > 750$°C) dielectric behavior found for TiO_2 could not be rationalized using the concept of a thin barrier layer having a resistivity and resistance greater than that of the bulk material. Although Eq. [1] does predict a large dispersion in K', no associated dispersion in conductivity was observed.

A model involving a thin barrier layer, which has a resistivity greater than and resistance less than the bulk material, also, does not seem to explain the data. First, it is noted that K' does not approach a constant value, K'_s, at low frequencies as predicted by Eq. [2]. Neither did K' obey the Debye-type dispersion as predicted by Volger (29). In addition, the increase in the dissipation factor with increasing temperature, shown in Fig. 8 and 9, is not in agreement with this limiting case of the barrier layer model. According to Volger, the maximum value of tan δ is dependent only upon the relative thicknesses of the bulk and barrier layers. A further argument discounting this barrier layer model will be presented when the low temperature dielectric data for the "c" orientation is discussed.

The high-temperature dielectric behavior of TiO_2 seems to be best described by a space-charge polarization model involving two charge-carrying species of opposite sign. Here, electrons are assumed to be the

negatively charged species and are able to freely pass through the electrodes, while ionic point defects are taken to be the positively charged species which are blocked or partially blocked at the specimen electrodes.

According to Eq. [6] the effective dielectric constant should vary as $\omega^{-3/2}$ at high temperature and low frequency where ion migration can predominate the polarization processes in TiO_2. At higher frequencies diffusion distances would be shorter and atomic and electronic polarization mechanisms would predominate. This qualitatively agrees with what is observed in Fig. 2 and 3b. The conductivity as observed in Fig. 6 and 7 would not necessarily vary with frequency as described in Eq. [3] due to the large electronic contribution in TiO_2. It is noted that K' varies with $\omega^{-5/4\pm1/4}$ as opposed to that predicted by Eq. [6]. This could be due to some degree of electronic depolarization, unequal charge-carrier mobilities, or the fact that the electrodes do not totally block the positively charged species. The degree of charge-carrier blocking would depend upon the nature of the diffusing species, electrode material, and electrode reactions occurring in the specimen. If decomposition reactions of the type [$TiO_2 \rightleftarrows Ti_i + O_2(g)$] and [$Ti_L + O_2(g) \rightleftarrows TiO_2$] occurred at the specimen electrodes then only partial blocking would result.

The diffusion coefficient of the positive charge-carrying species could be calculated from Eq. [6] if its concentration were known. Since the nature of the migrating point defect is unknown, a quantitative evaluation of D_p using Eq. [6] is not possible. If the mobile point defect were assumed to be an interstitial impurity or a quenched-in interstitial nonstoichiometric defect, an activation energy of motion of 0.5 eV would be obtained from the variation of K' with temperature. This value of energy is consistent with the values found for interstitial diffusion of Li^{+1} and B^{+3} in TiO_2 (9, 10). The calculated energy of motion would be significantly less than 0.5 eV if a defect-formation energy were to be included in this calculation (4, 6). This would seem unreasonable in light of the previously reported diffusion results.

Thus, the dielectric behavior of rutile at elevated temperatures (*i.e.*, from 500° to 1050°C for the "a" orientation and 700° to 1050°C for the "c" orientation) can be rationalized using the concept of field-enhanced atomistic migration and space-charge polarization. It should be noted that although the type of defects (*i.e.*, monovalent, ionic defects existing in equal concentrations) which were assumed to be responsible for the space charge polarization in Friauf's analysis are not equivalent to the types of defects expected in rutile (*i.e.*, electrons and polyvalent positively charged ionic defects existing in unequal concentrations), the frequency and temperature trends exhibited by the data are still in reasonable qualitative agreement with theory.

However, the dielectric behavior of the "c" orientation specimens below approximately 750°C did not follow all the previously mentioned trends. Although K' increased with decreasing frequency, the low-frequency values decreased with increasing temperature. The apparent a-c conductivity became frequency dependent and temperature independent below 750°C as is seen in Fig. 7. The d-c conductivity, however, was found to maintain the same exponential dependence that existed in the higher temperature region.

These data seem to indicate that, at lower temperatures, a barrier layer process as described by Eq. [2] exists, *i.e.*, $\rho_1 >> \rho_2$ and $R_1 >> R_2$. However, as the temperature is increased, the resistivity of the barrier layer decreases until the conditions laid out for Eq. [2] are met, *i.e.*, $\rho_1 > \rho_2$ and $R_1 \simeq R_2$. Upon further increase in temperature ρ_1 approaches ρ_2 and the barrier layer disappears completely. It should be noted that the subsequent increase of K' at higher temperatures could, thus, not be accounted for on the basis of barrier-layer polarization.

The high frequency or bulk conductivity in the "c" direction seems to be controlled by impurities at temperatures below about 750°C, while the d-c or barrier-layer conductivity followed a similar behavior as observed at higher temperatures. It has been observed that for TiO_2 a n to p transition, due to departures from stoichiometry, occurs in this oxygen partial pressure and temperature range (4). Thus, acceptor centers might lead to compensation at the external face of the specimen. This would not occur in the interior of the specimen due to limited diffusion at low temperatures.

The general behavior seen at low temperatures in the "c" orientation was not observed in the "a" direction. Several factors might contribute to this difference. First, the a-c data in the "a" direction was not taken at as low a temperature due to the strong history dependence found in this data for the "c" direction. It is also noted that although the "a" and "c" orientation specimens were cut from the same boule, their absolute conductivities and, also, impurity concentration might differ. Finally, it has been reported that diffusion occurs in the "c" direction more readily than in the "a" direction (38, 39). Therefore, any barrier layers that might form due to compensation at low temperatures for the "a" orientation would be quite thin and might not be observed in the measurements, *i.e.*, $\rho_1 > \rho_2$ but $R_1 << R_2$.

A further explanation for the existence of a barrier layer at low temperature might involve a Schottky barrier (40). The low-temperature data reported here were very dependent on history and, therefore, further experimentation in this region did not seem pertinent to this investigation.

The effects of biasing were studied at 800°C using the three electrode configuration with platinum electrodes shown in Fig. 10. It was generally noted that upon biasing, the a-c conductivity and capacitance at low frequency increased between the middle and negative electrodes of the specimen, while the reverse occurred between the middle and positive electrodes. These observations are consistent with the multiprobe transient conductivity studies of Blumenthal *et al.* (39). These results were interpreted in terms of positive ions migrating to the negative end and carrying along their associated electronic charge. Thus the increase in capacitance observed in this study could be associated with a larger ion concentration in the vicinity of the negative electrode while the increase in conductivity would be due to the larger electron concentration in this vicinity.

Along with the above observations, volt-ampere characteristics using various values of constant current were recorded between various probe pairs as

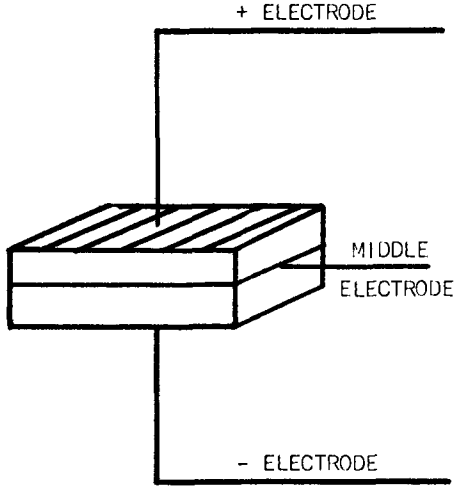

Fig. 10. The three-probe d-c configuration.

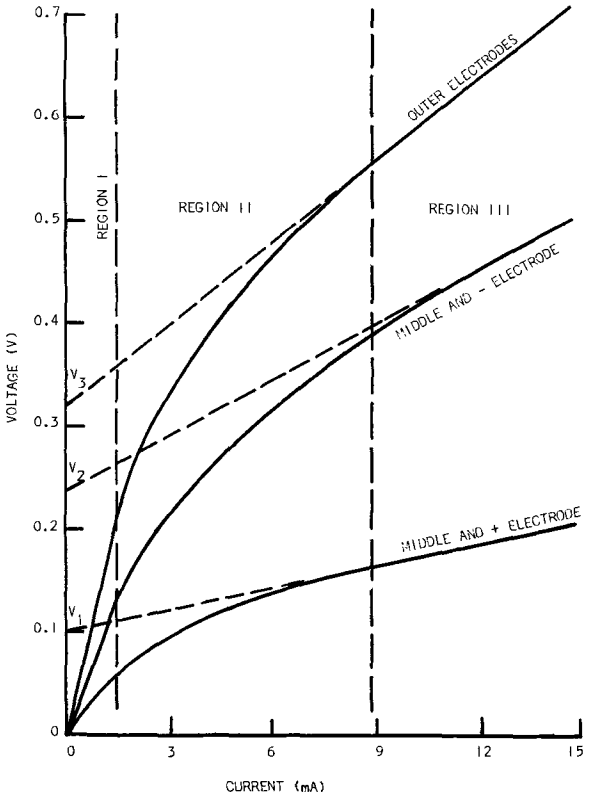

Fig. 11. The three-probe voltage vs. current d-c data.

shown in Fig. 11. These results, although very history dependent, provide a qualitative interpretation consistent with the previously discussed dielectric behavior. It is noted that the data can be characterized by three distinct regions. In region I Ohm's law was obeyed and the incremental d-c resistance, $\Delta V/\Delta I$, was approximately equal to the a-c resistance. At higher currents and/or fields, a nonohmic region exists, *i.e.*, $I \propto V^n$. In region III the current is a linear function of voltage; however, the incremental d-c resistance, $\Delta V/\Delta I$, was much smaller than the a-c resistance in this region which was equal to the incremental d-c resistance in region I. These data are similar to previously reported nonohmic studies for TiO_2 (12).

These results can also be interpreted in terms of moving point defects. In region I the current is most probably due to electron motion only and therefore, if no barrier layers were present, one would expect identical ohmic behavior for both a-c and d-c conductivity studies. The nonohmic behavior of the type depicted in region II was interpreted by Greener and Whitmore (12) as being due to space-charge-limited currents. However, their interpretation required that the mobility of electrons in TiO_2 be the order of 10^5 $cm^2/V\text{-}sec$, which is much greater than the measured values of 10^{-1} $cm^2/V\text{-}sec$ (18). The behavior observed in region II might also be interpreted as resulting from a combination of both electron and ion currents. In this region the field impressed across the sample, and the surface concentration of defects could be of such a magnitude that the decomposition reactions ($TiO_2 \rightleftarrows Ti_i + O_2(g)$) and ($Ti_L + O_2(g) \rightleftarrows TiO_2$) could be driven at the anode and cathode, respectively. Thus, the electrodes would not be totally blocking to the flow of ions as was assumed in the interpretation of the aforementioned dielectric studies, *i.e.*, a Faradaic type component of current would exist (41, 42). Region III might then be interpreted as the result of electron and ion flow. The voltage intercepts obtained upon extrapolating region III to $I = 0$ would be a measure of the decomposition potential required to drive the electrode chemical reactions. Further qualitative interpretation of this data would seem fruitless due to the strong history dependence encountered.

Mitoff and Charles (43) have invoked the concept of a Warburg (44) impedance to rationalize the magnitude of capacitance and its dispersion which they observed in beta alumina, soda-lime glasses, and single crystals of sodium chloride. The arguments presented by these authors were explored with respect to the results observed for TiO_2 at elevated temperatures. Mitoff and Charles pointed out that, if the space charge polarization model is to be valid, the magnitude of the measured capacitance, C_{sp}, should lead to a reasonable Debye length. The maximum value of capacitance and the Debye length, L_D, can be related by the equation

$$C_{spmax} = \frac{K'_\infty \epsilon_0 A}{L_D} \qquad [7]$$

Here, A is the area of the specimen, ϵ_0 is the permittivity of free space, and K'_∞ is the high-frequency relative dielectric constant. The largest value of specimen capacitance, C_{spmax}, observed for TiO_2 in this study was approximately 0.5 μf. Using the appropriate values of $K'_\infty \simeq 100$, $A = 1$ cm^2 and $\epsilon_0 = 8.85 \times 10^{-12}$ Fcm^{-1}, a value of $L_D \simeq 2 \times 10^{-5}$ cm results. This Debye length is reasonable and also suggests that the space-charge polarization model is appropriate at elevated temperature for TiO_2.

If a Warburg impedance is to be present, then electrode reactions of the type $M^+ + e \rightleftarrows M^o$ would have to occur in the vicinity of the electrodes, *i.e.*, a Faradaic current would have to exist (41, 42, 44). The interpretation of the results of Fig. 11 suggests that appreciable electrode reaction or Faradaic current does not exist until a critical voltage or surface concentration of defects is reached. Therefore at the low voltages used in the dielectric measurements, it is expected that the Warburg impedance would not be an important contribution to the dielectric dispersions observed.

Conclusions

The dielectric behavior of TiO_2 (rutile) can be rationalized on the basis of electronic and lattice polarization mechanisms at frequencies above 10^5 Hz. In the frequency interval 10^2-10^5 Hz, dielectric polarization for the "a" orientation and the "c" orientation above 750°C can be rationalized on the basis of a space-charge polarization model. Here, electrons, the negatively charged mobile species, were assumed to pass through the electrodes, while positively charged mobile ionic point defects were assumed to be blocked at the electrodes. The nature of the mobile ionic point defects could not be determined, however, their activation energy for motion was of the order of 0.5 eV. At temperatures below 750°C, the dielectric polarization processes occurring in the "c" orientation specimens seem to be controlled by a thin-barrier layer.

The measured a-c conductivity data agreed with four-probe d-c conductivity data reported in the literature, where electrons were assumed to be the charge carrying species. The d-c volt-ampere characteristics for a "c" orientation specimen of TiO_2 at 800°C were recorded. Three regions were noted in this curve. At low currents, Ohm's law was obeyed and the conductivity was, again, in agreement with previously reported results. At intermediate currents, a nonohmic behavior was observed, while at higher current values a second Ohm's law region appeared. The conductivity calculated for the latter region was found to be higher than that for the low-current region. The conductivity at low currents can be ascribed to electronic carriers. The larger conductivity found in the second Ohm's law region can be rationalized on the basis of a Faradaic process or a decomposition reaction leading to an ionic contribution to the conductivity.

Charge Trapping in Polymers

D. K. Davies and P. J. Lock

Electrical Research Association, Leatherhead, United Kingdom

ABSTRACT

An investigation is described of the role of unsaturated groups in the molecular structure on charge trapping in synthetic polymers. An attempt has also been made to quantify the effect on carrier migration of doping these materials with halogens. Using a surface charge decay technique carrier mobility has been determined *in vacuo* for a number of synthetic polymers and also for both high- and low-density polyethylenes doped with halogens. These data are presented together with an account of concurrent measurements of optical absorption in the same materials. The data indicate a tendency for "pure polymers" with known higher unsaturation content to exhibit a lower carrier mobility. Increased mobility was observed with either bromine or iodine impregnation of polyethylene. The optical data show that the iodine enters the polymer as neutral molecules most of which emerge under atmospheric conditions. The remainder, however, form charge exchange complexes at unsaturation sites in the polymer. The role of complexes in carrier transport is discussed.

The charge storage property of insulating materials—as exemplified in the electret—is becoming of widespread technological importance from microphones (6; and references therein) to prostheses (1). The elucidation of the underlying charge injection and carrier migration processes in synthetic polymers is vital to the future utility of these materials in almost any capacity.

Modern experimental techniques are yielding increasingly more definitive models of the basic mechanisms. It has been shown (3, 7) that carrier mobility

Key words: polymers, carrier mobility, conduction.

in low conductivity polymers is extremely small, the carriers being predominantly located in traps. Carrier migration is described by a hopping process. Recently published data (2) indicate that both polymer crystallinity and molecular symmetry significantly affect the electret stability, that is, charge trapping, and further, that phenyl and unsaturated groups in the molecular structure can form traps. Previous work (4) has also shown that carrier mobility in these materials may be greatly increased by impregnating the polymer with iodine. This effect has been interpreted by postulating charge exchange complex formation in the polymer, the complexes effectively reducing trapping effects by "handing-on" the carriers. A charge exchange complex in the present context means an interaction between two species, the strength of which lies between a full chemical bond and a small orbital overlap.

The present paper describes an investigation of the role of unsaturated groups in carrier trapping and an attempt to quantify the effects of doping on the transport mechanism. Using a surface-charge decay technique, carrier mobility has been determined *in vacuo* for a number of synthetic polymers and also for both high-density (HDPE) and low-density (LDPE) polyethylenes impregnated with halogens. An account of concurrent measurements of optical absorption in the same materials is also presented.

The experimental results show a tendency for carriers in polymers with known higher unsaturation content to exhibit a lower mobility. Carriers in polymethylene have a significantly higher mobility than in either HDPE or LDPE but the mobility extrapolated to room temperature is still 3½ orders of magnitude lower than that observed for octacosane ($C_{28}H_{58}$).

Mobility increases were observed with both LDPE and HDPE doped with either bromine or iodine, the affect being greater with the latter impregnant. Spectrophotometric measurements in the u.v./visible show that iodine enters the polymer as neutral iodine molecules some of which form charge exchange complexes with the polymer. Absorption measurements in the infrared range show that the complexes are associated with sites of unsaturation yielding a picture consistent with the data obtained for the "pure" polymers.

It is concluded from these mobility and optical absorption data that carrier trapping is associated, at least in part, with unsaturated sites in the polymer. The earlier conclusion that the enhanced mobility produced by doping results from charge exchange formation is confirmed and the carrier transport model is elaborated.

Experimental Techniques

Mobility determination.—The method of determining carrier mobility in low conductivity polymers has been described previously (Davies, 1967). A surface charge is injected into the free surface of the polymer specimen mounted on the flat top of an earthed, temperature-controlled cell. The specimen is maintained at a fixed temperature and the remanent charge on the surface is determined, using a calibrated probe technique, at intervals appropriate to the rate of dissipation. The mobility is calculated directly from these charge density data and the measurements repeated at several temperatures.

Specimen preparation.—Specimens of all the "pure" materials examined were cut from sheet samples. The specimens were washed with isopropanol and fixed onto the cell using Eccobond 59C electrically conducting adhesive. No significant differences were observed in the results obtained from specimens mounted in this way from those obtained with specimens relaxed onto the cell as was done in previous experiments.

Halogen-doped materials were obtained by maintaining samples in the halogen vapor at elevated temperatures. The actual temperature was significant only in determining the rate of halogen absorption, a value around 60°C being usually employed. Doped specimens were subsequently cut, washed, and mounted as described earlier.

Optical absorption measurements.—The optical absorption spectra of all the materials investigated were obtained in both the u.v./visible and infrared ranges using Beckman DB-GT and Grubb-Parsons Spectromaster spectrophotometers, respectively.

Experimental Results

"Pure" polymers.—Carrier mobility has been determined for HDPE, LDPE, octacosane, polymethylene, and polypropylene. The experimental values of mobility in some of these materials are plotted against inverse of absolute temperature in Fig. 1. Despite considerable scatter in the data there are significant differences in the mobilities. It was concluded previously that the mobility in HDPE was smaller than that in LDPE owing to the greater crystallinity of the former. Some doubt has been cast on this conclusion by observation of a density change from 0.96 to 0.98 in a sample of HDPE held at 120°C *in vacuo* for some days with no apparent change in mobility.

It is known that HDPE contains some 1.5-2 terminal unsaturated groups per 1000 carbon atoms; each chain being terminated by 1 vinyl and 1 methyl group. In LDPE the density is about an order of magnitude less although this material also contains significant numbers of pendant unsaturated groups. Both polymethylene and polypropylene, which should virtually contain no such groups, exhibit a higher mobility. It may be concluded, therefore, that the terminal vinyl group contributes significantly to the trapping. That the vinyl group only contributes to the over-all carrier impedance is underlined by the observation that the mobility in polymethylene extrapolated to room temperature is still some 3½ orders of magnitude smaller than that in octacosane.

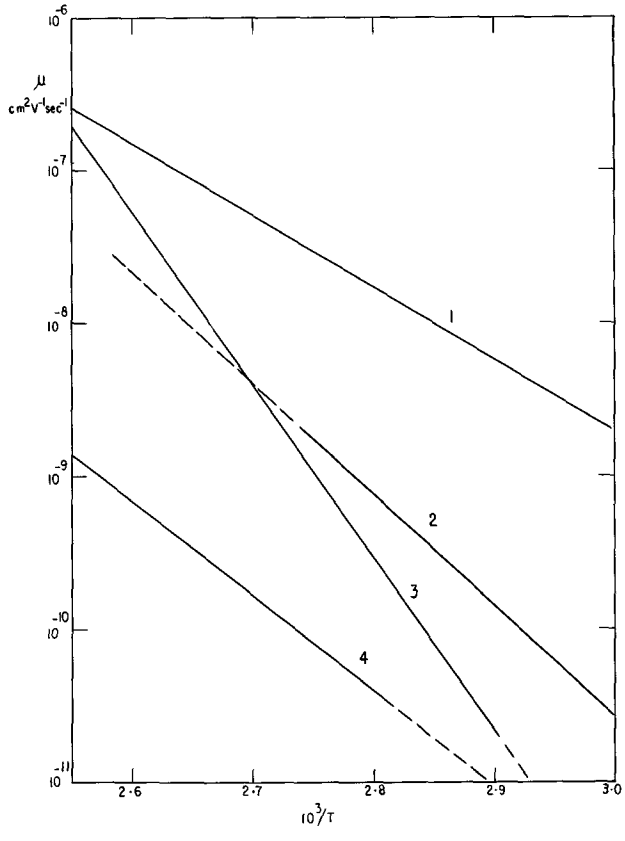

Fig. 1. Average values of carrier mobility obtained for 1 polymethylene, 2 LDPE (XDG33), 3 polypropylene, 4 HDPE (Rigidex 50), plotted against the inverse of absolute temperature.

Table I

Material	μ_0	W (eV)
Polymethylene	1.2×10^5	0.91
WNC18 } LDPE	2.8×10^5	0.99
XDG33 } LDPE	2.4×10^{11}	1.45
'Rigidex' 50 } HDPE	1.3×10^7	1.24
'Rigidex' 002.47 } HDPE	1.1×10^{18}	1.72
Polypropylene	1.0×10^{22}	2.23

Hopping carrier transport may be described by the expression, $\mu = \mu_0 \exp(-W/kT)$, where W, k, and T are the activation energy, Boltzmann constant, and absolute temperature, respectively. The values of μ_0 and W calculated from the experimental data are given in Table I.

In the simple "hopping" model the constant $\mu_0 = e/kT\ \nu/N^{2/3}$, where N is the trap density, e the electron charge, and ν a lattice vibration frequency. Using conventional values for these parameters, the value of μ_0 obtained for polypropylene yields a trap density of less than 1 cm^{-3}. Clearly this is unacceptable and hence the simple model is not valid. Examination of the values of W and μ_0 shows an interdependence in these parameters, *i.e.*, $\mu_0 = fn\ (W)$. This compensation affect is familiar for organic semiconductors (5). This could indicate a consistent transport mechanism for all polymers with the hop distance being related to the height of the potential barrier. Clarification of this effect, however, must await more extensive data.

Doped polymers.—Mobility increases were observed with both LDPE and HDPE doped with either bromine or iodine. The values of mobility obtained with doped HDPE ("Rigidex" 50) are plotted against the inverse of absolute temperature in Fig. 2, together with the data for the "pure" polymer. Clearly iodine has the greater effect.

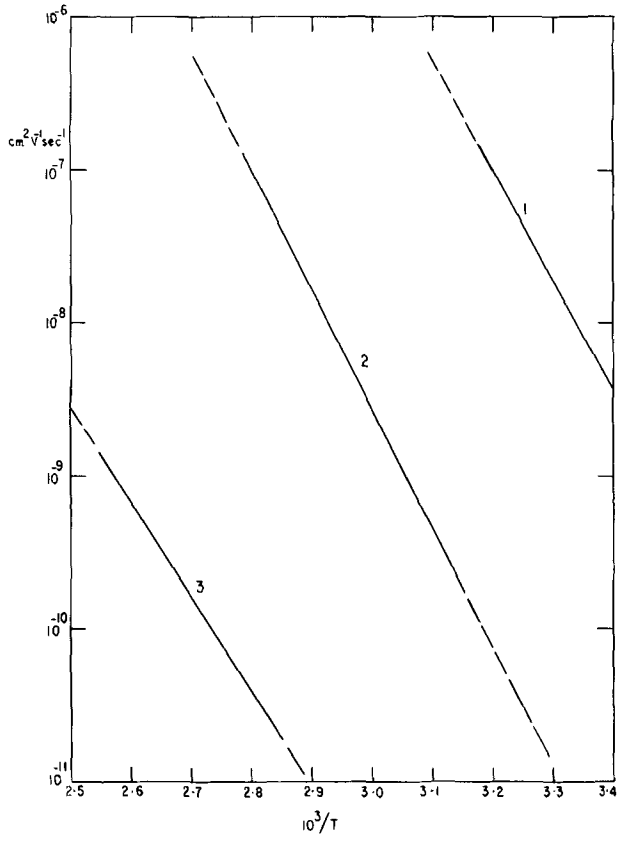

Fig. 2. Average values of carrier mobility obtained for 1 HDPE (Rigidex 50) doped with iodine, 2 HDPE (Rigidex 50) doped with bromine, and 3 HDPE (Rigidex 50), plotted against the inverse of absolute temperature.

Typically LDPE takes up 3-4% of iodine w/w, (weight for weight) this being reduced to an equilibrium 1% weight increase on standing in air or on evacuating. The corresponding figures for HDPE are 2.5% and 1.5-2%, respectively. The color changes which occur during this desorption show an interesting effect when examined spectrophotometrically. Figure 3 shows typical optical absorption traces in the u.v. visible obtained with iodine-doped HDPE, trace 1 being obtained immediately after doping and trace 2 with the same specimen after standing some 30 min in air. The absorption peak centered on 515 nm, which decreases with time (cf. traces 1 and 2), is attributed to molecular iodine which has a broad absorption band centered around 520 nm. This indicates that the iodine diffuses into the polyethylene as neutral molecules—most of which re-emerge on standing in air. The other band centered around 270 nm, which is permanent, is interpreted as charge exchange complex formation between iodine and the polymer.

Optical absorption data in the infrared range obtained with the same materials are presented in Fig. 4. Trace (a) shows the spectrum in the 8-13 μm range for the "pure" HDPE, the absorption peaks at about 11 μm (910 cm^{-1}) and 10 μm (993 cm^{-1}) being conventionally assigned to vibrations of the terminal double bond groups, $-CH = CH_2$ (vinyl group). Traces (b) and (c) exhibit the effect of introducing iodine, the latter trace being obtained after a longer "soak" in the iodine vapor. The double bond group vibrations are reduced and eventually disappear while two new peaks are generated at 9.3 μm (1079 cm^{-1}) and 12.3 μm (812 cm^{-1}). This is interpreted as indicating that the complexes are formed in association with the terminal double bond groups.

Bromination is also associated with the vinyl groups, similar changes being observed in the polyethylene infrared spectrum. Witenhafer and Koenig (8), who brominated crystals of "Marlex" 6050, observed reductions in the vinyl band intensities and concluded that these unsaturated groups lay largely outside the crystal lattice.

The uptake of iodine is roughly equivalent to the unsaturation concentration in HDPE. It is found that the original mobility characteristics of the "pure" polymer can be measured on dissolving an iodine-doped specimen in xylene and recasting a film. This confirms that the iodine forms loosely coupled complexes with HDPE rather than react chemically forming a new species. In LDPE, however, the bond appears much stronger since the iodine-doped material is insoluble in xylene.

Conclusions

It is concluded from these experimental data that the terminal vinyl groups contribute significantly to carrier trapping in polyethylene. The earlier model of trapping being associated with the crystalline/amorphous interface is reaffirmed, since the vinyl groups lie outside the crystalline regions. The halogens clearly associate with the double bonds in the terminal groups. Their effect on the carrier mobility is envisaged as releasing a "hole" into relatively unimpeded motion along the molecule chain, this lying largely within a crystalline structure.

This is a "discrete" model, the trapping effects discussed contributing only to the over-all carrier impedance. The "continuum" implied by a compensation effect, where trapping characteristics of all polymers are identical—the individual properties of each material being defined by an interrelated activation energy and hop distance—is intriguing. Within the latter context, the model currently presented appears as a defect property of the materials. Further investigations of this compensation effect are indicated, the data allowing interpretation of the presently somewhat nebulous parameter, μ_0.

Polymethyl Methacrylate as an Electron Sensitive Resist

R. A. Harris[1]

Electrical Engineering Laboratories, University of Manchester, Manchester, M13 9PL, England

ABSTRACT

The effect of the molecular-weight distribution of polymethyl methacrylate on its performance as a resist material for electron beam exposure is investigated with the aid of gel-permeation chromatography. The solubility of PMMA in a developer comprising a 3:1 ratio of isopropyl alcohol to methyl isobutyl ketone is determined, and the need for post-development washing of substrates in isopropyl alcohol is shown to be due, in part, to the liberation of insoluble polymer molecules from the film during development. Removal of very high molecular weight molecules, which are dominant in determining intrinsic viscosity, is found to lend considerable improvement to the rate of dissolution of PMMA in solvents, ease of filtration, and quality of spin-coated films. The optimum molecular-weight distribution is determined as being one which contains very few molecules with weights below about 50,000 or above a few hundred thousand. The preparation of PMMA with such a distribution by fractionation is outlined, and 10% concentrations of the resulting fractions are found to dissolve in methyl isobutyl ketone at 21°C in 2-3 min. The effectiveness of fractionated PMMA as a resist against chemical etchants is also found to be considerably better than that of broadly distributed polymers. Baking of films prior to exposure is considered with regard to its effects on substrate adhesion, molecular-weight distribution, and the rate at which films dissolve in solvents. Preliminary results on the use of polymer hydrolysis as a method of improving adhesion of the polymer to substrates are reported, an order of magnitude improvement being easily achieved.

Electron beams are being used increasingly as a means of fabricating microelectronic devices (1). The use of conventional photoresists for electron-beam exposure has been investigated and their resolution shown to be limited (2, 3). However, several polymers which can be used as positive-acting resists have been described by Haller *et al.* (4), and one, polymethyl methacrylate (PMMA) has been shown to be well suited to electron-beam exposure. The polymer is currently in general use as an electron resist and several papers describing its use for the fabrication of devices with submicron linewidths have been published during recent years, of which Ref. (5-7) are typical.

The effect of radiation on polymers, including PMMA, has been described by Charlesby (8) and an investigation of the effects of electron irradiation on PMMA has been reported by Shultz *et al.* (9). Ku and Scala (10) have discussed the effect of electron beams on polymers which can act either as positive or as negative resists and have shown that the molecular-weight distribution of a polymer is an important factor in determining its performance as a resist material.

This paper describes the effect of the molecular-weight distribution of PMMA on its performance as an electron resist. Preliminary results on the use of hydrolysis as a method of improving adhesion are also reported.

Key words: molecular weight, adhesion, polymer, methacrylate, resist.

Method of Investigation

Molecular-weight distribution analysis by gel-permeation chromatography (GPC) has been used for all results reported in this paper and values are limited in accuracy to about ±10% by errors inherent in GPC. However all the results are self-consistent and good for comparison. Values for the number-averaged molecular weights M_n, weight-averaged molecular weights M_w, and weight distribution of molecular weights were obtained by computer analysis of the chromatographs using the procedure described by Pickett *et al.* (11).

Degradation and Development

The use of PMMA as a positive-acting resist is based on two effects: (*i*) degradation on exposure to an electron beam and (*ii*) removal of the exposed areas using a developer based on the principle of soluble fraction. When PMMA is exposed by an electron beam with an exposure charge density in the region of 5×10^{-5} to 5×10^{-4} coulombs/cm^2, random scission of the molecular chains occurs and the average molecular weight decreases. The exact exposure range depends on a number of factors of which the most significant is electron-beam accelerating voltage (3, 7). At high-charge den-

sities crosslinking is predominant and the exposed areas are insoluble.

Development of the resist is achieved by using a poor solvent which will dissolve away molecules of low molecular weight but leave unaffected those of high molecular weight. Such a solvent can be obtained by mixing together a liquid which is a good solvent for any molecular weight of the polymer with one which will not dissolve even the very low molecular weights. For PMMA a developer comprising isopropyl alcohol (IPA) as nonsolvent and methyl isobutyl ketone (MIBK) as solvent is frequently used, and Hatzakis (7) has referred to a solution comprising 1 part MIBK and 3 parts IPA as being "standard developer," the development time being 1½-2 min at 21°C.

Charlesby (8) and Saito (12) have shown that the distribution of the molecular weights in a degraded polymer is largely independent of the initial distribution if the number of scissions is large. This is the case for PMMA when exposed with typical charge densities and Ku and Scala (10) have calculated the most probable distribution for exposed PMMA and shown that a value of a few thousand for M_n is to be expected.

The integral molecular-weight distribution of a 0.5 μm thick film of PMMA exposed at 10 kV with 10^{-4} coulomb/cm^2, as determined by GPC, is shown in Fig. 1 together with the distribution of the unexposed polymer. The degraded polymer sample was obtained by exposure of 625 separated millimeter square areas on each of 20 substrates, this number being necessary to obtain a sufficient weight of polymer for GPC analysis (5-10 mg). Separation from the unexposed material was achieved by developing the films for 1½ min at 21°C in standard developer and then soaking in IPA for 5 min, following the procedure outlined by Hatzakis. The polymer extracted by the two solutions was then combined to form the sample for analysis. To prevent thermal degradation during exposure each substrate was coated with 1 μm of aluminum to ensure rapid heat dissipation (13). Industrial polymers often contain plasticizers and copolymers and to ensure that pure PMMA was used the original polymer was prepared by polymerization of monomer methyl methacrylate using benzoyl peroxide as catalyst.

The value of M_n for the degraded polymer, determined by analysis of the GPC data, is 2400 and the value of 3600 calculated following the method of Ku and Scala shows that the theoretical calculation can be regarded as providing a good order of magnitude estimate of the peak of the distribution of the degraded polymer. Figure 2 shows the theoretical integral distribution of the degraded polymer; comparison with curve B in Fig. 1 shows moderately good agreement. The main error in the calculation arises from the assumption of a uniform rate of loss of energy of an elec-

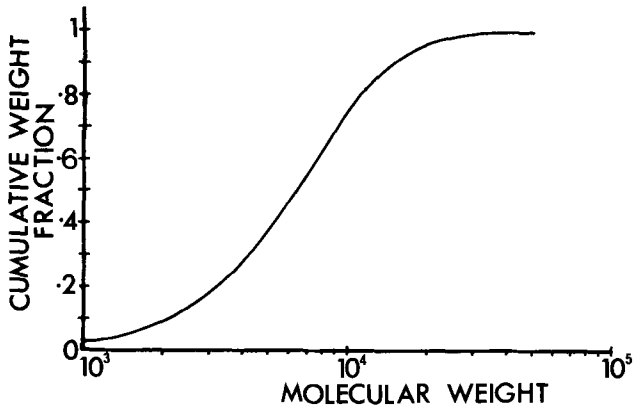

Fig. 2. Theoretical molecular-weight distribution of a 0.5 μm thick film of polymethyl methacrylate exposed at 10 kV with 10^{-4} coulomb/cm^2. (Initial M_n = 563,000; final M_n = 3600).

tron passing through the film. The actual rate of loss increases rapidly with depth (14) and accounts for the rather broad GPC distribution which has a dispersity of 3.4 compared with a dispersity of 2 for the most probable distribution. A significant feature of the degraded distribution is that it extends to molecular weights in excess of 50,000. Although molecules of this weight have been extracted from the film by the development procedure it does not necessarily follow that they are readily soluble in developer. This point will be discussed more fully in a later paragraph.

Due to the Gaussian cross-sectional density distribution of an electron beam and scattering in the polymer film the number of scissions in the molecules at the edges of exposed areas falls gradually to zero (14). Therefore at these edges a range of molecular weights exists of which only some are soluble in developer; furthermore, not all of the soluble molecules are removed by the developer since some will be held in place by neighboring high molecular-weight molecules. Figure 3 shows the GPC distributions of the PMMA remaining on the substrates after development. Distribution A is the polymer removed by spraying the substrates with chloroform, which is a good solvent for all molecular weights. This procedure did not remove all of the polymer from the substrates and distribution B shows the remaining polymer removed by prolonged soaking in chloroform. Spraying the substrates served to remove the most readily soluble PMMA and distribution A is largely comprised of those scission fragments not removed by developer, whereas distribution B mainly consists of unexposed polymer.

Distribution A shows that scission fragments with molecular weights between the initial and degraded

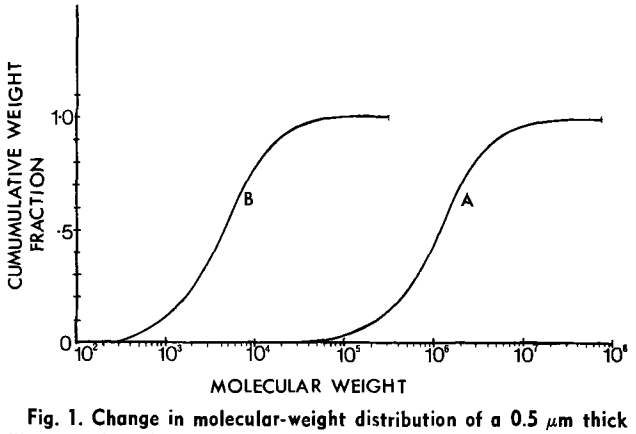

Fig. 1. Change in molecular-weight distribution of a 0.5 μm thick film of polymethyl methacrylate due to an electron dose of 10^{-4} coulomb/cm^2 at 10 kV. A—Distribution before exposure (M_n = 5.63 × 10^5; M_w = 2.26 × 10^6); B—distribution of exposed polymer removed by standard developer (M_n = 2370; M_w = 8160).

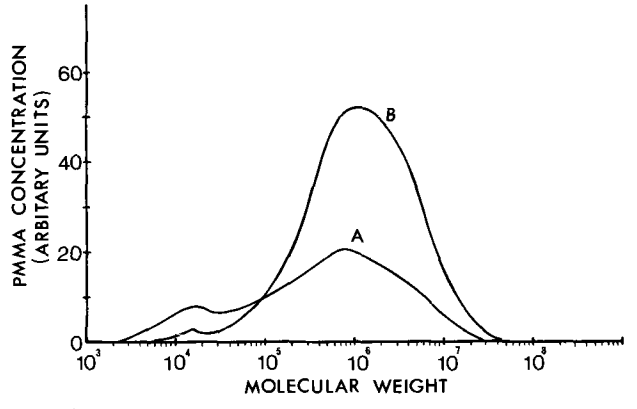

Fig. 3. Concentration of polymethyl methacrylate remaining on the substrates after development as a function of molecular weight. A—Polymer removed by spraying with chloroform (M_n = 5.6 × 10^4; M_w = 1.32 × 10^6); B—remaining polymer removed by soaking in chloroform (M_n = 2.47 × 10^5; M_w = 2.04 × 10^6).

PMMA distribution peaks are generated. These will mainly consist of the insoluble scission fragments formed round the edges of the exposed areas. Small peaks occur at a molecular weight of about 15,000 in both distributions. This value is well within the range extracted by the developer and corresponds to soluble scission fragments trapped by higher molecular-weight molecules. Few of the very low molecular-weight molecules are retained in this way since most are not directly adjacent to the bulk of the insoluble polymer.

To investigate the solubility in standard developer PMMA with a range of molecular weights extending from 2,000-110,000 with a peak at 25,000 was prepared by fractionation, as described below. 0.5g of this polymer was completely dissolved in 500 ml of standard developer by heating the solution to 50°C. The solution was then allowed to cool over a period of 24 hr to the normal development temperature of 21°C. During this time insoluble molecules were precipitated onto the walls of the flask. The solution containing the soluble fraction was decanted off and the PMMA precipitated by addition of excess methyl alcohol (nonsolvent).

Figure 4 shows the integral molecular-weight distributions of the soluble and insoluble fractions together with the distribution of the initial polymer. Although 50% of the initial polymer consists of molecules with weights above 25,000 these comprise only 30% of the soluble fraction, indicating that they are not fully soluble in the solution. The peak of the molecular-weight distribution of the soluble fraction occurs at 20,000 and molecular weights above this must therefore gradually decrease in solubility with complete insolubility of weights above about 65,000.

The molecules with molecular weights above about 50,000, which are extracted from the exposed resist by the development process, must, as suggested earlier, have a very low solubility in developer and are probably washed away as insoluble particles. However, Fig. 3 indicates that many low solubility molecules remain on the substrate and their removal will therefore still be in progress when the substrate is withdrawn from the developer. The presence of this material must in part account for the need to wash substrates in a nonsolvent, usually isopropyl alcohol, after development and before drying. Such a procedure serves to remove any loose insoluble material before it can become reattached to either the remaining film or the substrate.

Molecular-Weight Distribution

Table I lists GPC data on typical PMMA molecular-weight distributions. The polymers designated C1, C2, and C3 correspond to three of the most commonly used commercial forms of powdered PMMA in Britain. PMMA in sheet form has not been considered because

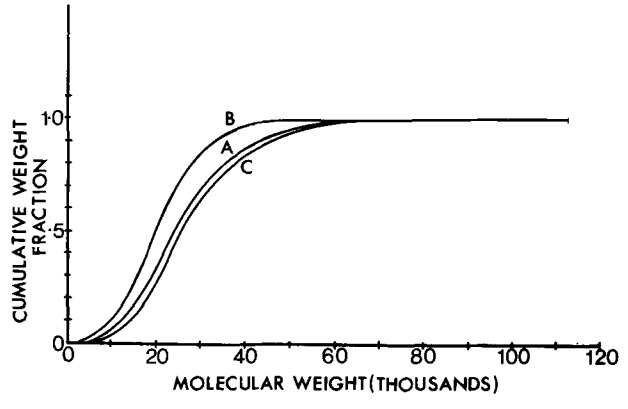

Fig. 4. Integral molecular-weight distribution indicating the solubility of polymethyl methacrylate in standard developer. A—Initial polymer (M_n = 21,500; M_w = 27,000); B—soluble fraction (M_n = 17,500; M_w = 21,000); C—insoluble fraction (M_n = 23,800; M_w = 28,800).

Table I. Typical molecular-weight distribution data for polymethyl methacrylate[a]

Polymer	M_n	M_w	Molecular weight range	Percentage weight of polymer with molecular weight <20,000
C1	35	71	1-1,000	17.3
C2	127	415	2-6,900	2.3
C3	304	1064	6-17,000	0.6
L1	191	516	15-17,000	0.5
L2	563	2257	18-75,000	0.008

[a] Molecular weights in thousands.

it takes appreciably longer to dissolve. Polymers L1 and L2 were prepared in this laboratory using benzoyl peroxide as catalyst; L2 is the undegraded polymer used for the experiment on degradation described above. The percentage weight of each polymer with molecular weights below 20,000 provides an indication of the amount of each polymer that is readily soluble in standard developer at 21°C.

PMMA with only a small percentage weight of molecules soluble in developer will not exhibit pinhole formation during development because the molecules will be held in place by the much larger number of insoluble high molecular-weight molecules. However C1 is unsuitable for use as a resist and C2 was found to form pinholes when developed, especially in films of less than 3000Å thickness.

To avoid pinhole formation in thin films due to low molecular-weight material it is necessary to use polymer C3, L1, or L2. However, these all contain molecules of a very high molecular weight which are dominant in determining the intrinsic viscosity and solubility of the polymers in any solvent. The intrinsic viscosity η is related to the molecular weight M by $\eta = KM^a$ where K and a are constants for any one solvent and temperature (for methyl ethyl ketone at 25°C $K = 6.8 \times 10^{-5}$ and $a = 0.72$).

Methyl ethyl ketone or methyl isobutyl ketone are suitable as solvents for PMMA when preparing a solution for spin-coating, although of the two MIBK is to be preferred since it evaporates more slowly during the coating process. However, the intrinsic viscosities of C3, L1, and L2 in MIBK are very high and they are very difficult to dissolve, prolonged heating and stirring being required (typically 12 hr). The high intrinsic viscosities also result in the thickness of spin-coated films being nonuniform and nonrepeatable. The polymers dissolve more readily in MEK and film quality is better but is limited by the faster evaporation rate of the solvent. Polymers C1 and C2 dissolve in MIBK in about 12 hr if left standing at room temperature and both produce a good quality of film on substrates.

Using the five types of PMMA, tests were made on undeveloped films of various thickness to examine the variation of etch resistance and adhesion with molecular-weight distribution. These showed that decreasing M_n corresponds to better adhesion and a more prolonged resistance to etchants. This is to be expected because of the better spin-coating characteristics of lower molecular-weight polymers.

The optimum molecular-weight distribution of PMMA for use as an electron resist must therefore be a compromise between two conflicting requirements. Increasing the molecular weight reduces pinholes generated during development and improves edge definition, but causes a decrease in over-all etch resistance, adhesion, and film quality. Furthermore, the polymer becomes harder to dissolve and the resist difficult to filter. The best molecular-weight distribution of PMMA for use as a resist must therefore be one which has a narrow molecular-weight range with a sharp cutoff at both low and high molecular weights.

An optimum distribution is one containing little or no molecules with weights below 40,000-50,000 or above a few hundred thousand and would ideally be monodisperse (*i.e.*, $M_w/M_n = 1$). However, the most probable distribution for PMMA is a Poisson distribution with a dispersity of 2, although there are polymerization processes which can produce nearly monodisperse distributions (15). The most readily available and the most simply polymerized forms of PMMA have a dispersity equal to or greater than 2, as can be seen from Table I, and narrow distributions are in general more conveniently obtained by fractionation.

To investigate the performance of PMMA with narrow distributions as resist, 20g of polymer C1 was fractionated to remove the high molecular-weight material and then refractionated into the five fractions whose distribution data is given in Table II. The PMMA was dissolved in 2 liters of toluene and fractionated by a combination of nonsolvent addition and cooling, with 40°-60°C petroleum ether as nonsolvent. For each fractionation the solution was initially raised to a temperature sufficient to dissolve the PMMA fully (40°-55°C) and then cooled to 25°C over a 24 hr period, after which the precipitated fraction was removed.

A low starting concentration is necessary in order to obtain narrow fractions, and because of this it is difficult to fractionate quantities of PMMA in excess of 20g on a laboratory scale since the final volume is often about 10 liters. To obtain fractions of a usable quantity the initial polymer must therefore be one whose distribution contains a large percentage weight of molecular weights in the region of the desired fraction. Of the polymers listed in Table I only C1 is suitable in this respect but because of its large content of low molecular weights, significant quantities have appeared in all the fractions. Fractions 4 and 5 contain too much of this material to be useful; however, further fractionation of fractions 1, 2, and 3 can be used to remove most of the low molecular-weight material from them.

An investigation of the performance of these fractions as resists confirmed the trends found with unfractionated polymers with respect to adhesion, etch resistance, and resolution. All fractions produced films of a very high quality, well in excess of all types of unfractionated PMMA. Furthermore, all fractions were readily soluble in MIBK; for example 10% concentrations of fraction 1 could be dissolved at room temperature in 2-3 min. The solutions were also easily filtered. This considerable improvement in film quality, solubility, and ease of filtration, associated with the reduction in intrinsic viscosity, is sufficient to make the use of fractionated PMMA highly advantageous. In addition, some improvement in adhesion is attained and further fractionation to remove most of the low molecular-weight molecules eliminates pinhole formation during development and produces a resist with very good etch resistance and edge resolution.

Table II. Molecular-weight distribution data for fractionated polymethyl methacrylate

Fraction number	M_n	M_w	Molecular weight range	Percentage weight of polymer with molecular weight <20,000	Weight fraction (g)
1	61	91	4-650	5	4.92
2	43	62	4-346	13	3.33
3	38	51	2-346	12	3.46
4	29	41	2-346	27	2.13
5	21	27	2-113	37	1.84
Residue	15	19	1-68	76	1.04

[a] Molecular weights are in thousands.

Baking

Baking films at 170°C for 20-30 min before exposure is generally used as a means of improving adhesion. At this temperature, which is well in excess of the glass-transition temperature of PMMA (typically T_g = 100°-110°C), the polymer exhibits a rubber-like elasticity and molecules are able to slide over each other enabling strains generated during the coating process to be released.

The ease with which the molecules slide increases with temperature. Films must be heated to at least 160°C before the polymer is sufficiently soft to allow solvent remaining in the film after the coating process to be released (16). At temperatures above 190°C the rate of thermal degradation of PMMA becomes appreciable and 170°C therefore allows for solvent evaporation with a minimum of thermal degradation. GPC analysis of films baked at 170°C for 30 min shows the amount of degradation is insignificant.

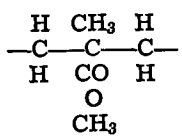
Baking films removes solvent, water, or monomer present in the polymer. This raises the glass-transition temperature, makes films harder and more brittle at temperatures below T_g, and reduces the surface area to weight ratio. A reduction in the rate of dissolution of the films in solvents results, and it is possible to use a developer with a higher solvent to nonsolvent ratio without increasing pinhole formation. Hatzakis (7) has described the use of 100% MIBK as a developer for films baked at 170° for at least 1 hr.

Adhesion

Failures of PMMA resist in etch baths are mainly due to the polymer film lifting off the substrate because of poor adhesion. Even when baked the adhesion is still relatively poor and any improvement would lead to a reduction in resist failure in etch baths. It should be noted, however, that the adhesion is adequate for the lift-off metalization technique (4, 7); indeed an improvement in adhesion might be detrimental to the process.

To compare adhesion of different PMMA samples a technique used by Long (17) with purified photoresists was adopted. Films are placed in an ultrasonic water bath, preheated to 60°C, and examined for evidence of lifting at regular time intervals. Films of all types of PMMA listed in Table I and II were tested in this way and the increase of adhesion with decreasing M_n was established. After 15 min about 50% of each film of polymer type L2 had lifted off glass substrates, but only 5% of each film of polymer type F5. However, Long reported photoresists which showed no lifting after 45 min after which time all types of PMMA film were almost completely stripped.

Photoresists generally contain molecules with localized regions of high polarity; in particular hydroxyl groups are often present (18). The latter form hydrogen bonds with the substrate and thereby considerably increase molecular, and hence resist, adhesion. However PMMA, which has the structure



contains no hydroxyl groups. Furthermore, the molecules have very little polarity, and Van Der Waals forces between them and the substrate are therefore very weak. This absence of any strong bonding between the molecules and the substrate accounts for the relatively poor adhesion of PMMA.

The adhesion can be improved by introducing a number of hydroxyl groups onto each molecule by hydrolysis. To investigate the effect of PMMA hydrolysis on adhesion, two samples of polymer of type F1 in Table II were hydrolyzed, one by acid hydrolysis using the procedure described by Robertson and Har-

wood (19), and the other by base hydrolysis following the method of Bains and Bevington (20). The adhesion of these two polymer samples was then compared with that of the initial polymer using the technique already described. The acid-hydrolyzed sample showed no significant improvement in adhesion, but films of the base-hydrolyzed polymer showed no signs of lifting after ultrasonic agitation for periods in excess of 2 hr. This represents more than an order of magnitude improvement in adhesion and it may be concluded that hydrolysis is a powerful method for improving adhesion.

The resist sensitivity and resolution were found to be unchanged by hydrolysis but etch resistance was considerably improved. The reason for the failure of the acid-hydrolyzed films was found to be due to the presence of insoluble submicron particles generated during hydrolysis. More careful control of the process might eliminate this problem; alternatively, one of the many other methods described in the literature could be tried.

Conclusions

A general indication of the effect of the molecular-weight distribution of PMMA on its performance as an electron resist has been given. It has been shown that a developer comprising 3 parts isopropyl alcohol to 1 part methyl isobutyl ketone used at 21°C will readily dissolve molecules with weights below 20,000, and that over 90% of polymer molecules exposed at 10 kV with a dose of 10^{-4} coulomb/cm have molecular weights below this value. However, a small quantity of molecules with weights of up to about 65,000 are dissolved by the developer and 1% of the molecules removed by the development process were found to have weights above 50,000, with some in excess of 100,000. Therefore, to avoid pinhole formation during development it is essential to use PMMA which has a very low percentage of molecules with weights below 20,000, and preferably very few below 50,000.

It has also been shown that the removal of very high molecular-weight molecules, which are dominant in determining intrinsic viscosity in solution, produces PMMA with properties which considerably enhance its performance as a resist. It has therefore been concluded that the optimum distribution of PMMA for use as a resist is one which contains little or no molecules with weights below about 50,000 or above about 600,000, and the preparation of such a distribution by polymer fractionation has been outlined.

Optimizing the molecular-weight distribution has been found to considerably improve the rate of PMMA dissolution in solvent, ease of resist filtration, film quality, and etch resistance. It has also been established that hydrolysis can provide a means by which the adhesion of PMMA to a substrate is considerably improved. It is therefore suggested that hydrolyzed PMMA with an optimized molecular-weight distribution provides a material which can be used as a very high quality electron resist. For use with the lift-off technique the use of resist which has not been hydrolyzed may be preferred.

Acknowledgments

The author wishes to thank Dr. C. Booth and Mr. R. L. Bartosiewicz for supplying the GPC data-analysis program and for many helpful discussions. Thanks are also extended to Dr. D. Machin for his help with polymer fractionation and hydrolysis, and to Mr. D. Roy for his technical assistance.

Manuscript submitted Aug. 28, 1972; revised manuscript received Oct. 16, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Annealing Activation Energies of Sputtered Ge Films

S. Mardix and D. K. Paul

University of Rhode Island, Electrical Engineering Department, Kingston, Rhode Island 02881

ABSTRACT

Ge films were sputtered on water-cooled substrates. Conductivity was measured during isothermal and step-annealing experiments. These measurements indicate that activation energies for annealing increase from about 0.9-1.4 eV. A linear relationship was found between the activation energy for annealing and the change of conductivity at a certain reference temperature. The results are discussed and a mechanism is suggested in which a transformation from microcrystallinity to randomly disordered networks occurs in the low-temperature annealing mode.

Associated with annealing of amorphous Ge films is a decrease in conductivity, which can be lowered by a few orders of magnitude from its initial value (1-3). Si, Te, and SiC behave in a similar manner (3-5). Although there is evidence that this phenomenon is related to an atomic reorientation process, the mechanism involved in the annealing of the conductivity is still not quite understood. Activation energies of annealing can give some insight to the process taking place during annealing, and conversely models suggested for this process should predict the values found for the activation energies. Annealing activation energies for Ge evaporated films were found by Longini and Pansino to be in the range of 0.1 eV (6). This low-activation energy is compatible with a process involving slight reorientation of atoms in the amorphous films. Mogab and Kingery (5) found for SiC films the range of activation energies for annealing to be 0.4-2.3 eV. This led the authors to the conclusion that a variety, and perhaps a continuum, of defect types or configurations are present in their films.

It is not clear from the research noted above whether there is a basic difference between the rearrangement processes in Ge and SiC, or the low range of activation energies found for Ge is just a part of a wider spectrum similar to the situation for SiC. In this paper we attempt to resolve this question and report the results of annealing activation energy measurements of Ge amorphous sputtered films. The results are discussed on the basis of an analysis introduced by Primak (7).

Experimental

The samples were prepared by rf-sputtering of intrinsic Ge on water-cooled glass or quartz substrates. The sputtering took place in an atmosphere of 4 mTorr argon at a rate of 360 Å/min. The temperature of the film during sputtering was about 40°C. The final thickness of the films was measured by an interferometric technique or calculated from *IR* interference fringes. The thickness was around 1.5 μm for the different samples. The films appear smooth and shiny under a Normarsky-interference Zeiss microscope; x-ray diffraction photographs of the films were taken and do not show any indication of crystallinity. The optical constants near the absorption edge were calculated, using a method proposed by Baldini *et al.* (8). These are plotted in Fig. 1 together with the values found by Dash and Newman (9) for Ge crystals, and those of Clark (10) and Donovan *et al.* (11) for amorphous Ge.

From the above results we conclude that our films are amorphous. This is common for films deposited at or below room temperature (12). The conductivity during annealing was measured between previously sputtered Mo electrodes using a lock-in amplifier. In order to form the Mo electrodes a tungsten ribbon of about 0.7 mm wide was placed on top of the glass substrate. The sputtered Mo formed two electrodes, the thickness of which was about 0.8 μm. As some of the Mo was sputtered under the edges of the ribbon, they were tapered towards the gap which was about 0.5 mm wide. The contacts between the Ge layer (about 1 cm wide) and Mo electrodes were found to be ohmic before and after annealing. No cracks or other irregularities could be detected in the contact regions. Some of the specimens were annealed in an He atmosphere while others were immersed in silicon oil during annealing. No appreciable difference was found in the general behavior of the conductivity changes during annealing. If there are differences, they are small in comparison to the conductivity changes due to annealing. As some crystallization might occur even at low temperatures (13) we did not exceed 220°C at any stage of annealing, thus reducing the possibility of effects due to partial crystallization.

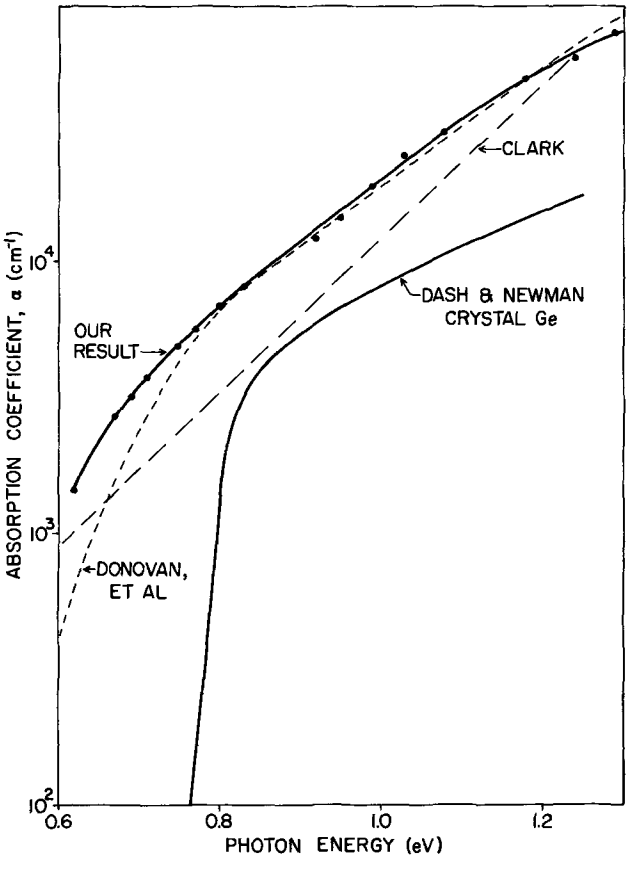

Fig. 1. Absorption constant of our sputtered Ge films before annealing. Curves of absorption constant of crystalline Ge reported by Dash and Newman (9), and those for amorphous Ge found by Clark (10) and Donovan et al. (11) are given for comparison.

Theoretical Considerations

The calculations involved in evaluating the activation energies and the discussion of the results are based on the theory reviewed and developed by Primak (7).

We assume that the conductivity is a property that is proportional to the concentration of the possible kinetic processes that take place during annealing. The conductivity σ is a function of time for isothermal annealing and is given by

$$\sigma(t) = \int_0^\infty s_0(\epsilon)\, \theta_n(\epsilon,t)\, d\epsilon \qquad [1]$$

where t is the time measured from the beginning of the annealing; ϵ is the activation energy; $s_0(\epsilon)$ is the conductivity distribution function (the spectrum) at $t = 0$; θ_n is termed the "characteristic isothermal-annealing function" and is given by

$$\theta_n = [1 - (1-n)Bte^{-\epsilon/kT}]^{1/(1-n)} \qquad [2]$$

where n is the order of reaction; B is a quantity having the dimension of frequency and may depend on ϵ; k is Boltzmann's constant; T is the absolute temperature.

According to Primak (7), the dependence of B on ϵ can be neglected for a broad activation spectrum; the measured activation energy E_a is approximately equal to the energy ϵ_0 at the inflection point of θ_n and is given by[1]

$$E_a \cong \epsilon_0 \cong kT \ln (Bt) \qquad [3]$$

also

$$\frac{d\sigma}{dt} \cong -s_0(\epsilon_0)\frac{d\epsilon_0}{dt} \qquad [4]$$

putting $x = \ln t$ we have from [3] and [4]

$$\frac{d\sigma}{dx} = -kT\, s_0(\epsilon_0) \qquad [5]$$

The characteristic activation energies of annealing can be measured by the step-annealing procedure. The rate of annealing R_1 is measured at the end of an isothermal-annealing experiment at temperature T_1. The temperature is raised rapidly to T_2, starting a new isothermal-annealing process with a rate of annealing R_2. Accordingly, ϵ_0 is given approximately by

$$\epsilon_0 \cong k\frac{T_1T_2}{T_2 - T_1}\ln\frac{R_2}{R_1} \qquad [6]$$

Results and Discussion

Isothermal-annealing curves for a number of specimens are given in Fig. 2. These specimens were annealed in different atmospheres and temperatures. In Fig. 2 $1/kT\ (\sigma/\sigma_0)$ is plotted against log t (σ_0 is the conductivity value at $t = 0$).[2]

It is seen that the slopes of all curves start with small values and after annealing reach a constant value which is almost the same for all of them. According to Eq. [5], the slopes of the curves in Fig. 2 should be proportional to the initial conductivity-distribution function at the characteristic activation energy ϵ_0. This means that the initial distribution function $s_0(\epsilon)$ has very small values up to a certain value of ϵ, then rises to a constant value and remains constant in the range of activation energies scanned by ϵ_0.

The activation energies for annealing were evaluated by the step-annealing method using Eq. [6]. The conductivity data for sample 35 are given in Fig. 3, and the calculated values of the activation energies E_a after each step of annealing are plotted in Fig. 4 against the change in conductivity $(\sigma_0 - \sigma)$ at the reference temperature of 84.3°C. Here σ_0 refers to the conductivity at the beginning of the first step of the step-annealing experiment.

The activation energy E_a is seen to increase approximately linearly with the change in conductivity. From Eq. [4] one gets for an isothermal-annealing process

$$\frac{d\sigma}{d\epsilon_0} \cong -s_0(\epsilon_0) \qquad [7]$$

This relation holds for each step of the step-annealing

[1] This is because the processes having activation energies around ϵ_0 make the maximum contribution to the change of conductivity.

[2] As the value of σ is temperature dependent, σ_0 is used here as a normalization factor for comparing isothermal annealings at different temperatures. Thus σ/σ_0 is, to a good approximation, independent of temperature for a certain state of annealing of the specimen. More accurately, if we start from two identical specimens and anneal them at two different temperatures (for different time lengths) so that both reach the same characteristic activation energy, we assume that both have the same value of σ/σ_0; σ and σ_0 are measured for each specimen at its annealing temperature.

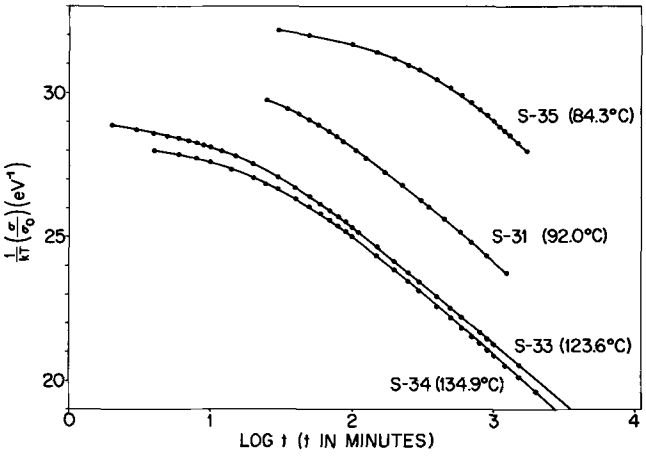

Fig. 2. Isothermal-annealing curves of normalized conductivity vs. log time for specimens S-31, annealed in an He atmosphere, S-33 annealed in transformer oil, and S-34 and S-35 annealed in silicon oil. Temperatures of annealing are given in the figure.

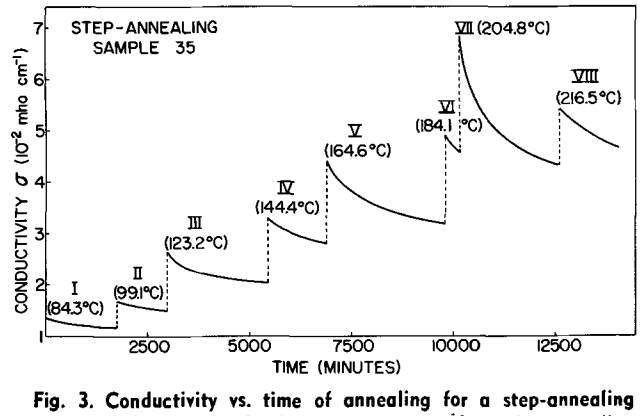

Fig. 3. Conductivity vs. time of annealing for a step-annealing experiment of S-35. Conductivities are measured at the annealing temperatures; these are indicated in the figure.

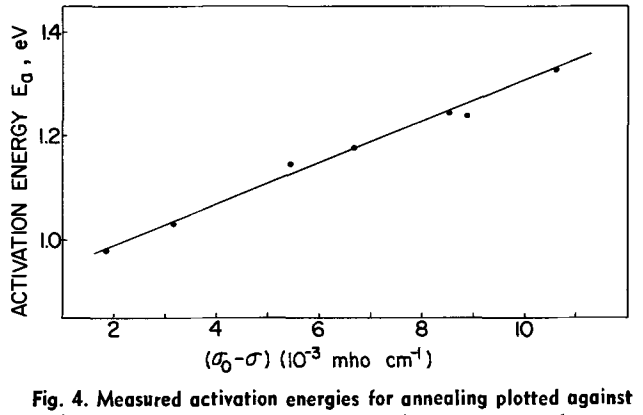

Fig. 4. Measured activation energies for annealing plotted against the change in conductivity at 84.3°C during a step-annealing experiment.

procedure. In accordance with the assumption on which the step-annealing procedure is based, there are no changes in the spectrum taking place while the temperature is raised between the steps, so that Eq. [7] holds also for a step-annealing procedure.[3] The linear relationship found in Fig. 4 follows from Eq. [7] if $s_0(\epsilon)$ is constant throughout the range of activation energies that ϵ_0 acquires during the experiment. From the first and last steps of annealing, we get a value of about 0.9 eV for the initial activation energy and about 1.4 eV for the final value. The data of Fig. 3 are replotted in Fig. 5 to give $1/kT$ (σ/σ_0) as a function of log t, with $t = 0$ for the beginning of each step of annealing. The curves of Fig. 5 are similar to those for the different specimens given in Fig. 2, which is in accord with the assumption that $s_0(\epsilon)$ is constant in the given energy range. It is to be noted that putting $t = 0$ in the beginning of each step is equivalent to taking the initial distribution function as that reached at the end of the former step. This new distribution function is different from $s_0(\epsilon)$ mainly in its low energy part. Instead of a constant value, it will now have an increasing one. This accounts for the fact that the curves in Fig. 5 reach their linear part only after some annealing took place. We plotted the activation energies calculated from the step-annealing experiment (Fig. 3) against the absolute temperature[4] (Fig. 6). According to Primak (7) a consequence of Eq. [3] is that such a plot would be linear for a constant spectrum. Thus Fig. 6 gives further support to the claim that $s_0(\epsilon)$ is constant.

[3] We neglect the change of shape of the rising part of the spectrum in the successive steps.

[4] The temperature associated with each activation energy is taken as the average of the annealing temperatures of the two steps from which the activation energy is calculated.

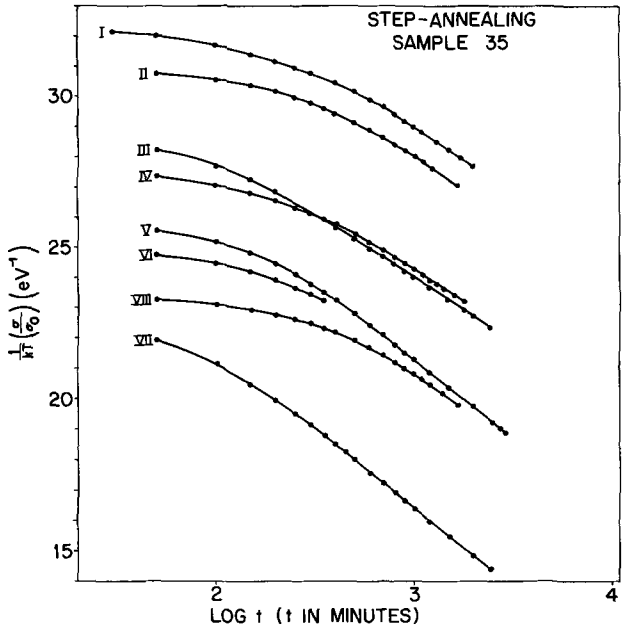

Fig. 5. Normalized conductivity data for step-annealing experiment of S-35, where $t = 0$ for each step. Annealing temperatures for the various steps are given in Fig. 3.

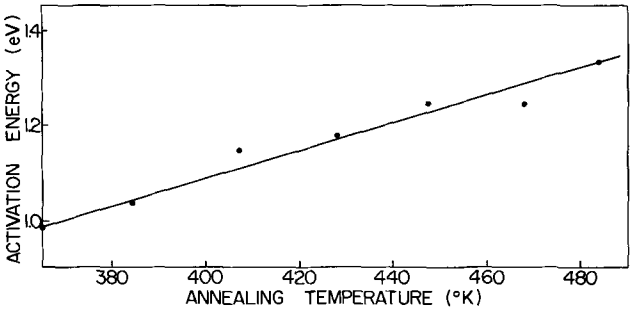

Fig. 6. Activation energy vs. absolute annealing temperature for the step-annealing of sample S-35.

From step-annealing experiments the value of the frequency factor (B in Eq. [2]) can be evaluated (7). Values of B calculated from the data of the different steps of annealing of sample S-35 given in Fig. 3 fall in the range 3×10^8 to 3×10^9 sec^{-1}, with no apparent correlation to the temperature of annealing or activation energy.

The continuous increase of the characteristic activation energy and the corresponding decrease in conductivity indicate that (*i*) the process of annealing in the range of temperatures investigated remained essentially the same during the various stages of annealing, and (*ii*) the annealing mode characterized by a sharp irreversible increase in conductivity was not reached.

The results given demonstrate that the behavior of the annealing process in the beginning, in contrast to the behavior after a long time of annealing, is essentially dependent on the history of the sample. Another consequence is that the term "properly annealed" at a given temperature occasionally used in the literature has a doubtful meaning as to the state of annealing of the sample, as long as the falling part of $s_0(\epsilon)$ is not reached. The fact that no annealing seems to take place after a certain time of annealing at a given temperature, might be due to the almost linear dependence of σ on log t which changes slowly with time. However, it does not have an asymptotic value characteristic of the annealing temperature. The same reasoning applies also to the evaluation of σ from a plot of σ *vs.* t. It is suggested that in addition to other information given about a specimen annealed for a long time, the value of the characteristic activation energy should also be used to characterize the state of annealing of the sample.

The discrepancy between our results and those of Longini and Pansino (6) who found a range of activation energies around 0.1 eV, may be due to the fact that their specimens were evaporated on a liquid-nitrogen cooled substrate. Thus, the specimens were in an early stage of annealing with ϵ_0 at very low energies. If the samples were not annealed for a sufficiently long time, then low values of calculated activation energies are expected.

The activation energies found with annealing range from about 0.9-1.4 eV and presumably extend to higher values. This range is within that found by Mogab and Kingery for SiC (5), namely 0.4-2.3 eV which might be an indication that a similar mechanism of annealing operates in both materials.

The high values of the characteristic activation energy indicates that the mechanism of low-temperature annealing is not restricted to a slight "reordering diffusion process" as suggested by Longini and Pansino (6). It seems that the reordering process involves groups of atoms.

In a recent paper (14) Rudee and Howie present evidence for the microcrystalline structure of amorphous Ge in contrast to the random network structure (15). According to Rudee and Howie, Ge amorphous films consist of hexagonal microcrystallites of about 14A. As the cubic phase is the stable one at low temperatures and pressures, a stabilizing force is necessary for the existence of the hexagonal phase. This force is provided by the grain-boundary surface tension.

We suggest that the low-temperature annealing process is associated with the collapse of the hexagonal microcrystallites. Thermal agitation can reduce momentarily the distances of atoms on both sides of a grain boundary, thus reducing the surface energy of the microcrystallite. If this energy falls below a certain value, the atoms of the microcrystallite will rearrange. As the microcrystallite is surrounded by randomly oriented neighbors, it will not necessarily transform

into the cubic structure but rather to a random network with a large percentage of second nearest neighbors in or near cubic positions. In this rearrangement, the rebonding of dangling bonds present in the grain boundary is easily conceived. During annealing, islands of random networks are created in the film. The high-temperature annealing process is associated with the recrystallization of the random networks to cubic crystallites. The activation energies measured are thus the activation energies initiating the rearrangement process described. These activation energies will depend on the microcrystallite's size and neighbors and as such are expected to fall in a broad spectrum. High-activation energies are quite reasonable for this mechanism. The decrease in the number of unpaired electrons found experimentally (16, 17) is also explained. The diffraction pattern is not expected to change much during annealing as the new arrangement is also a random one, in accord with experimental results (6).

An experiment similar to that of Rudee and Howie (14) on films in different stages of annealing might confirm or disprove our model. As the annealing behavior of Si and SiC resembles that of Ge, it is possible that a similar mechanism of annealing is operative also in these materials.

Summary

Activation energies for annealing of Ge films were found to be about 0.9 eV after sputtering at room temperature and to increase up to 1.4 eV after annealing. This range is similar to that found for SiC and can be explained by a distribution of the annealing processes in activation energy. A rearrangement mechanism is suggested for the low-temperature annealing mode wherein a microcrystalline structure is transformed into groups of random networks.

Ce^{3+} Activated $Y_3Al_5O_{12}$ and Some of Its Solid Solutions

T. Y. Tien,* E. F. Gibbons, R. G. DeLosh, P. J. Zacmanidis, D. E. Smith, and H. L. Stadler*

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The systems $Y_{3-x}Ce_xAl_5O_{12}$, $Y_{3-x}Ce_xAl_{5-z}Ga_zO_{12}$, and $Y_{3-x-z}Gd_zCe_xAl_5O_{12}$ were studied. It was found that the solid solubility of Ce^{3+} in $Y_3Al_5O_{12}$ varies with the atmosphere during firing. Only 2 mole per cent (m/o) of Ce^{3+} can be dissolved in the yttrium aluminum garnet in air while almost 6% Ce^{3+} enters the garnet lattice when fired at 1450°C under a hydrogen atmosphere. Complete solid solutions were observed in the systems $Y_3Al_5O_{12}$-$Gd_3Al_5O_{12}$ and $Y_3Al_5O_{12}$-$Y_3Ga_5O_{12}$. The cathodoluminescence emission-peak position of the Ce^{3+} ion in $Y_3Al_5O_{12}$ host shifted to a longer wavelength while the latttice parameter of the solid solution expanded when Gd^{3+} ions were substituted for Y^{3+}. On the other hand, the emission-peak position shifted to a shorter wavelength when the garnet host contained Ga^{3+} ions in the Al^{3+} position. The lattice parameter of the solid solution increased with Ga concentration.

Ce^{3+} activated phosphors are known to have very short decay times. Most of the Ce^{3+} activated phosphors show a blue or nearly ultraviolet emission band; however in the yttrium aluminum garnet host a yellow band was reported by Blasse *et al.* (1).

In $Y_3Al_5O_{12}$ the ionic radius similarity between Y^{3+} and Ce^{3+} suggests that the Ce^{3+} activator ions will occupy the Y^{3+} sites. Blasse *et al.* (1) reported that 10 atomic per cent (a/o) of Ce^{3+} could be accommodated in the $Y_3Al_5O_{12}$ solid solution and no difference in luminescent properties were observed whether the material was fired in air, oxygen, nitrogen, or hydrogen. No study of different activator concentrations has been reported. Holloway and Kestigan (2) prepared single crystals of yttrium aluminum garnet solid solutions containing La^{3+}, Lu^{3+}, or Gd^{3+} presumably in the Y^{3+} sites and Ga^{3+} in the Al^{3+} site. All these single crystals were actviated with Ce^{3+} of unknown concentration. It was found that the Ce^{3+} emission peak under cathode-ray excitation shifted in these

* Electrochemical Society Active Member.
Key words: luminescence, phosphors, rare earth activation.

solid solutions. Substitution by larger ions in the Y^{3+} site shifted the emission peak to a longer wavelength while larger ions in the Al^{3+} sites shifted the emission peak to a shorter wavelength.

Because of a specific application in this laboratory, the luminescence characteristics of the Ce^{3+} activated Y_3AlO_{12} at different activator concentrations and the effect of the solid-solution compositions were studied.

Experimental

All compositions used in the study were prepared using the coprecipitation method. All starting materials used were 99.9% pure or better. Mixtures of 0.4*N* metallic nitrate solution in the determined cation ratio were added to 0.4*N* NH_4OH solution. The final compositions were checked with x-ray fluorescence, comparing with standard mixtures of known concentration. The *p*H value of the final solutions were always kept at a value slightly higher than 9. For the compositions containing Ga^{3+} the *p*H was kept at the value at which the Ga^{3+} has its lowest solubility. The precipitates were then filtered and dried without washing. The dried powder was fired in an alumina crucible in a tube furnace with flowing gas at 300 ml per min. The gases used were nitrogen, hydrogen, or dry air. The fired samples were analyzed by x-ray diffraction. Cu $K\alpha$ radiation with a graphite diffracted beam monochrometer was used on a Norelco diffractometer. The diffractometer was operated at a scanning rate of ⅛° 2θ per min for lattice parameter determination. The peak positions of the (116), (120), (128), (152), (176), and (180) diffraction lines were measured and results were plotted *vs.* $\cos^2\theta$ and extrapolated to 180° The indexing of the garnet lattice was taken from the ASTM card index.

The cathodoluminescence (C.L.) data were obtained in a demountable electron-beam gun system operated at 3 kV. Samples were mounted at the focal point of an optical system which then refocused the emitted light on the entrance slit of a ¾m Czerny-Turner spectrometer. The output from a photomultiplier (P.M.) tube, located at the exit slit of the spectrometer, was amplified by means of a synchronous detector and displayed on an x-y recorder. The required periodic signal for the P.M. tube was obtained by applying a 13 Hz square wave to the horizontal deflection plates of the electron-beam gun, thus providing a 50% excitation duty cycle on the sample. The same square-wave generator provided the reference signal for the synchronous detector.

The excitation spectra were taken in a system utilizing a xenon light source focused through a mechanical light chopper onto the entrance slit of a ¾m spectrometer. The emission from the sample, coming from the exit slit, was recorded by means of a photomultiplier tube, the output of which was amplified by means of a synchronous detector and displayed on an x-y recorder. Appropriate filters were used in front of the sample and the P.M. tube and the spectra shown were corrected for system response.

Results

(*i*) $Y_3Al_5O_{12}$:Ce. The solid solubility of Ce^{3+} in $Y_3Al_5O_{12}$ depends on the atmosphere in which the powder was fired. At 1450°C in hydrogen, 6 m/o of Ce^{3+} can be accommodated in the $Y_3Al_5O_{12}$ lattice. At higher cerium concentrations, the perovskite phase, $CeAlO_3$, appears together with the garnet $Y_3Al_5O_{12}$. The lattice parameter increased with increasing Ce^{3+} concentration as shown in Fig. 1. At 1450°C in air, the solid solubility is only 2 m/o. At higher cerium concentration, the CeO_2 phase was observed. However, within the solid-solubility limit, the cerium ions exist in the trivalent state because identical emission spectra were observed for the samples fired in air and in hydrogen for the composition containing 2% cerium.

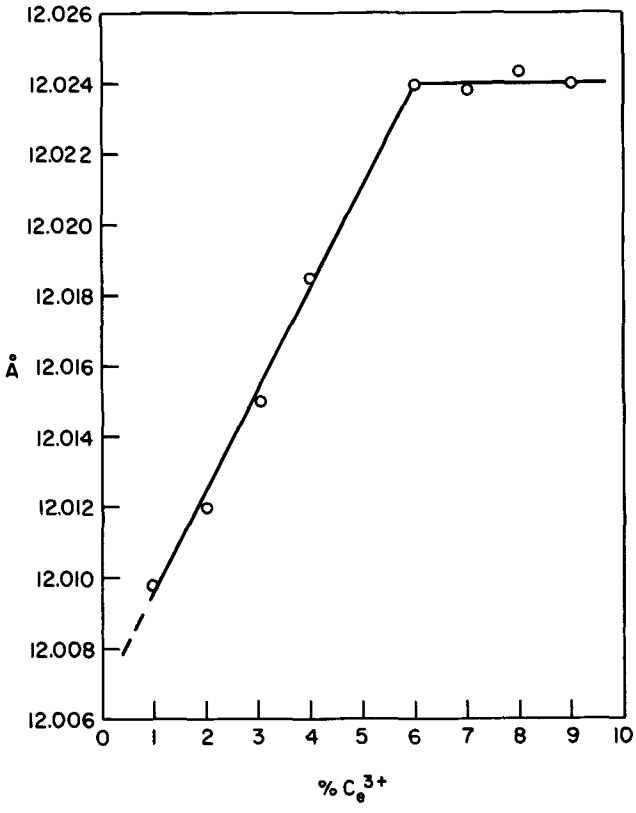

Fig. 1. Ce^{3+} concentration *vs.* lattice parameter for $Y_3Al_5O_{12}$:Ce^{3+}

The general shape of the excitation and emission spectra of the Ce^3 activated yttrium aluminum garnet are given in Fig. 2. The emission peak position under C.L. excitation shifted to a higher wavelength at higher Ce^{3+} concentration as shown in Fig. 3.

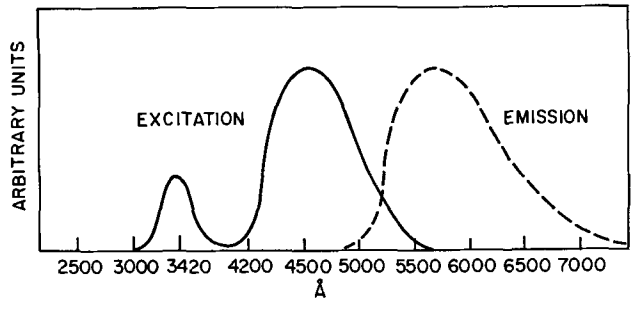

Fig. 2. Excitation and emission spectra for $Y_3Al_5O_{12}$:Ce^{3+}

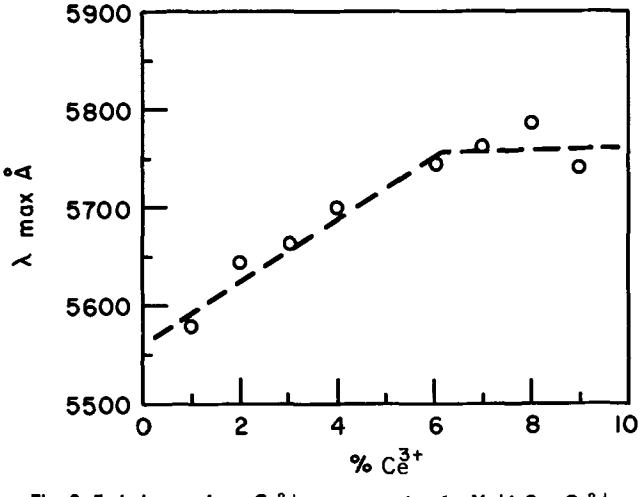

Fig. 3. Emission peak *vs.* Ce^{3+} concentration for $Y_3Al_5O_{12}$:Ce^{3+}

The electronic transition in Ce^{3+} has been assigned by Blasse *et al.* (1) as a 5d → 4f transition and the two peaks in the excitation band are attributed to the splitting of the 5d levels of the Ce^{3+}. The dependence of the low energy excitation-peak position on Ce concentration in $Y_3Al_5O_{12}$:Ce is shown in Fig. 4. The high-energy peak (at about 3470Å) does not shift appreciably as the Ce^{3+} concentration increases.

Decay times were measured with C.L. and u.v. excitations. It was found that the decay has 1/*e* time of about 70 nsec for C.L. excitation and about 50 nsec for u.v. excitation. The u.v. excitation decay curve is very nearly exponential; however the C.L. excitation decay curve is highly nonexponential, exhibiting a tail which differs considerably depending on the firing method used in the phosphor preparations. A detailed discussion will be published separately.

(*ii*) The systems $Y_3Al_5O_{12}$ and $Gd_3Al_5O_{12}$ are known to crystallize in the garnet structure (3). The compositions in the system were fired at 1450°C in hydrogen and furnace cooled. All compositions contained 2 m/o of Ce^{3+}. The lattice parameter data are given in Fig. 5. As shown in this figure, a complete series of solid solution was observed with the lattice parameter increasing from 12.017Å for $Y_3Al_5O_{12}$:Ce to 12.12Å for the compound $Gd_3Al_5O_{12}$:Ce. As expected, the emission peak of the Ce^{3+} under C.L. excitation shifted to a longer wavelength. The results are shown in Fig. 6. The intensity of the emission decreased with increasing Gd^{3+} concentration. The excitation spectra of the $(Y, Gd)_3Al_5O_{12}$:Ce are the same shape as that shown in Fig. 2 with the low energy peak position shift given in Fig. 7. Again, the shift of the high energy peak position was not appreciable.

(*iii*) The system $Y_3Al_{5-x}Ga_xO_{12}$:Ce. Complete solid solution in this system with 2 m/o Ce^{3+} was observed. The lattice parameter data are shown in Fig. 8. The lattice parameter increases from 12.01Å for the composition $Y_3Al_5O_{12}$:2 m/o Ce to 12.29Å for the composition $Y_3Ga_5O_{12}$:2 m/o Ce. Figure 9 shows that the emission peak positions of these solid solutions under C.L. excitation are shifted to a shorter wavelength as the Ga^{3+} concentration increases until the composition

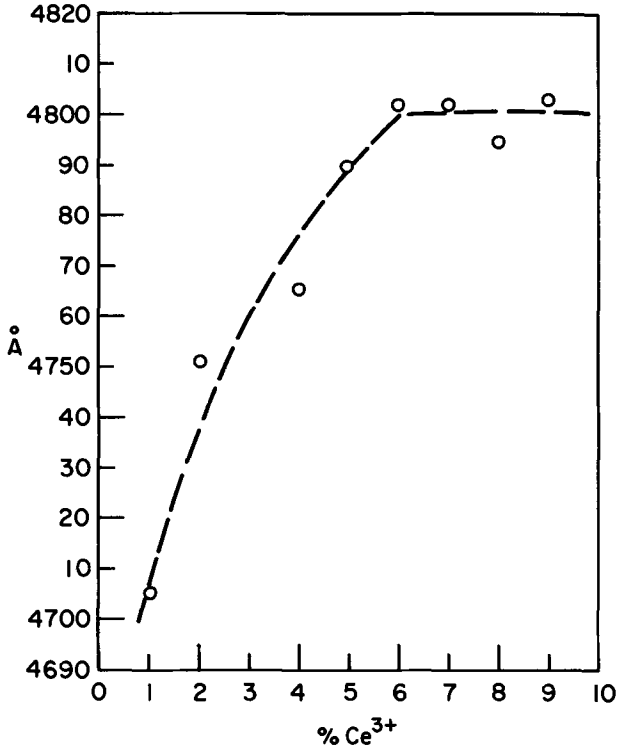

Fig. 4. Excitation-peak position vs. Ce^{3+} concentration for $Y_3Al_5O_{12}$:Ce^{3+}

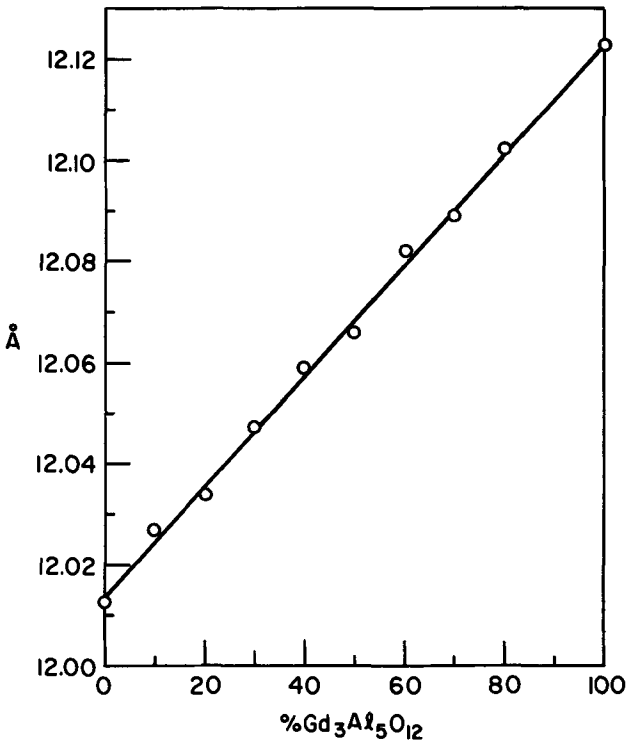

Fig. 5. $Y_3Al_5O_{12}$-$Gd_3Al_5O_{12}$ lattice parameters

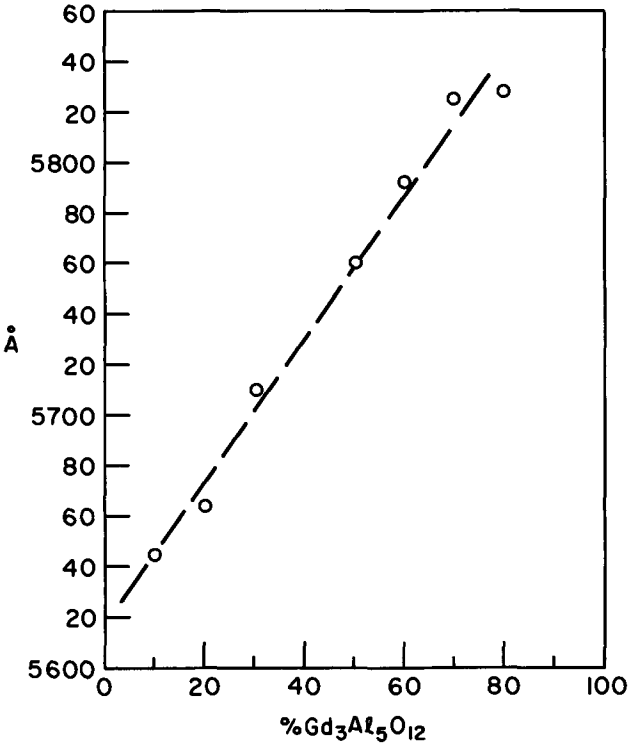

Fig. 6. Emission peak vs. Gd concentration for $Y_{3-x}Gd_xAl_5O_{12}$: Ce^{3+}

containing 40 m/o Ga is reached. Beyond 40% Ga, the emission-peak position remained at a constant wavelength even though the lattice parameter kept increasing. In the garnet structure, there are two different Al^{3+} sites (3). Forty per cent of the sites are six-fold coordinated and the other 60% are four-fold. It is therefore assumed that the Ga^{3+} preferentially occupies the six-fold site until all such sites are filled, and that the emission-peak position is only affected by the substitution of the Ga^{3+} in the six-fold site. The low energy excitation-peak position as a function of the Ga^{3+} concentration is given in Fig. 10. It is observed that the

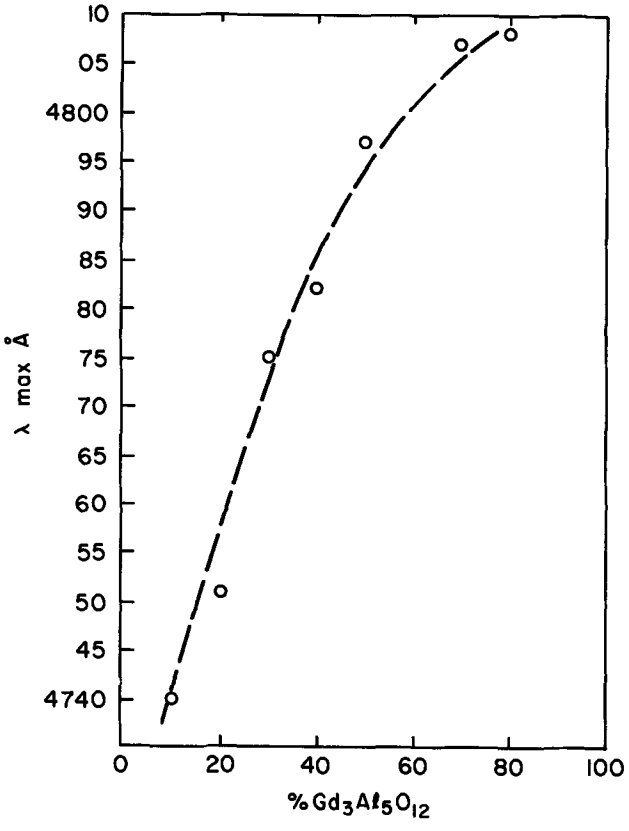

Fig. 7. Excitation peak vs. Gd concentration for $Y_{3-x}Gd_xAl_5O_{12}$:Ce^{3+}

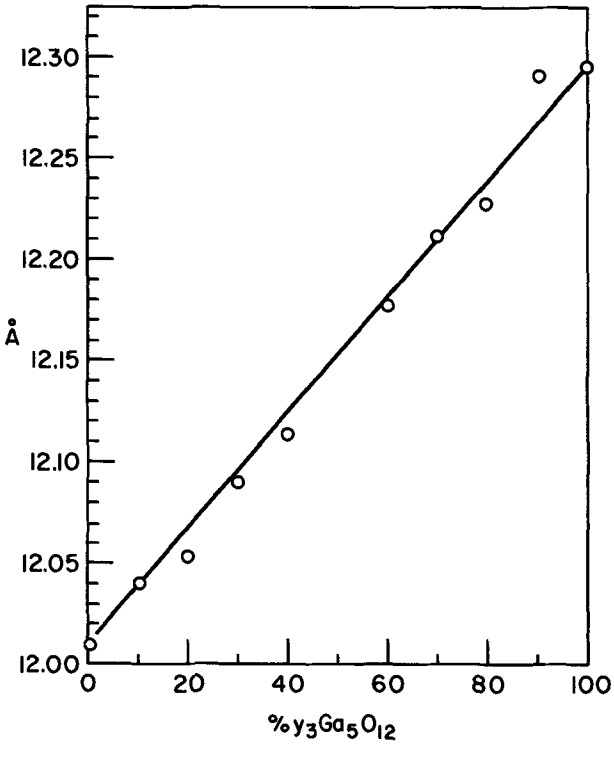

Fig. 8. $Y_3Al_5O_{12}$-$Y_3Ga_5O_{12}$ lattice parameter

break in the curve occurs at the same composition as in Fig. 9.

Summary

It has been shown that the solubility of Ce^{3+} in $Y_3Al_5O_{12}$ is highly dependent on the firing atmosphere, increasing from 2-6% when the atmosphere is changed from oxidizing to reducing. Also, the Ce^{3+} emission and excitation peaks show a continuous shift with increasing Ce^{3+} concentration.

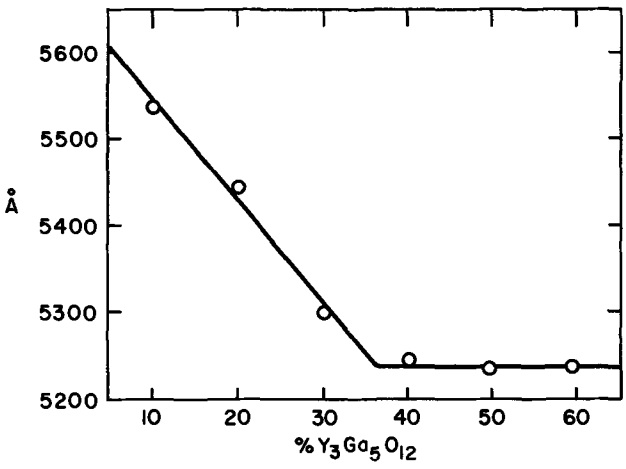

Fig. 9. Emission peak vs. Ga concentration for $Y_3Al_{5-x}Ga_xO_{12}$:Ce

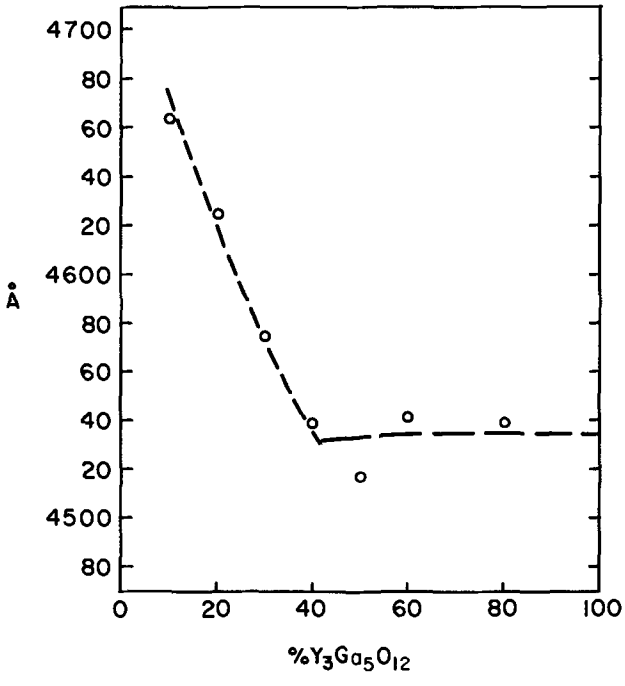

Fig. 10. Excitation peaks vs. Ga concentration for $Y_3Al_{5-x}Ga_x$ O_{12}:Ce

These peak positions are also influenced by the substitution of Gd^{3+} for Y^{3+} and Ga^{3+} for Al^{3+}. The Gd^{3+} substitution moves the Ce^{3+} emission peak to longer wavelengths while the Ga^{3+} substitution moves the emission peak to shorter wavelengths. The latter effect appears to arise only from the influence of Ga^{3+} in six-fold coordinated sites.

A High-Gain Light-Intensifying Device Incorporating a Fiber-Optic X-Ray Intensifying Faceplate

Kenneth L. Reifsnider and Jesse J. Brown, Jr.*

College of Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

The results of initial attempts to apply a new concept to the development of an x-ray sensitive image-intensifying device are reported. The new device consists of an x-ray sensitive fiber-optic faceplate which converts x-ray photons into visible light. The fiber-optic fluorescent plate replaces the powder-fluorescent screen common to such techniques, with a subsequent improvement in resolution and in the per cent of absorbed incident radiation. The resolution and x-ray stopping power of the fluorescent fiber-optic plate are not coupled as is the case for powder-fluorescent screens. A resolution of 28 line pairs per millimeter (lp/mm) is demonstrated in the present work.

A number of time-resolved x-ray systems have been developed in the past and have recently been reviewed by Green (1). It appears that the multiple-stage, image-intensifier system coupled to a fluorescent screen is the most sensitive to x-rays and at present is the "only truly instantaneous system" (1). This type of system, which includes commercial medical radiographic devices, uses a powder-fluorescent screen which requires a trade-off between intensity (enhanced by thick screens) and resolution (enhanced by thin screens).

The present work reports the successful removal of the polycrystalline fluorescent screen restrictions by replacing it with a fluorescent fiber-optic bundle. The resolution of the bundle is determined by the fiber size and is independent of the thickness of the screen. The resolution and sensitivity of the system are essentially "de-coupled."

Related Literature

X-ray detection system.—The development of suitable equipment to achieve a time-resolved display of x-ray diffraction images such as to allow immediate viewing (or recording) has been along three basic lines, all of which involve electro-optical devices and convert an x-ray photon image to a more intense image in the visible spectrum. The first of these methods involves a raster device which is itself sensitive to x-ray photons, *e.g.*, a silicon diode array vidicon or lead oxide vidicon so called Plumbicon (2-4). These devices are relatively insensitive to x-rays but the resolution can be very good, of the order of 15μ.

A second line of development has resulted in the use of raster tubes which are not x-ray sensitive, but are made so by coupling with a fluorescent screen which converts x-rays to visible light at low intensity. Tubes such as the SEC vidicon, or the orthacon with a single state intensifier added in front, are used to process and display the image on a monitor (5, 6). Such devices usually have less resolution (of the order of 30-50μ) and medium sensitivity to x-rays.

The most sensitive of all types of systems (and the only truly time-resolved systems) use a high-gain optical image intensifier tube coupled to a fluorescent screen which converts x-rays to visible light as in the raster systems (7-9). The resolution is limited by the fluorescent screen that converts the x-rays.

Radiographic sensitizing screen.—The majority of current x-ray image conversion systems rely upon a phosphor to detect and convert x-ray photons to blue-violet-ultraviolet wavelengths, with the quality and detail of the image limited by the quality and construction of the sensitizing screen. The most common sensitizing screen is the powder (polycrystalline) screen which is prepared by mixing an x-ray sensitive phosphor with a suitable binder and spreading the mixture on a thin x-ray transparent substrate. By design, the thickness of the phosphor layer upon drying is of the order of 100-300μ, which is arrived at by balancing light output and resolution. Typical x-ray generating machines emit radiation whose effective energy range is 30-70 keV. In order to maximize light output, one would like to absorb nearly 100% of the incident x-ray beam. This would require a bed of phosphor up to 1 in. thick, but this thickness is prohibitive because scattering of the light (by reflection, refraction, dispersion, and absorption) emitted by the phosphor as it passes through the bed limits resolution. In the case of $CaWO_4$, a 100-300μ thick layer represents a compromise. The resolution of about 10 line pairs per millimeter (lp/mm) and the amount of incident x-ray energy absorbed by the phosphor is 10-20%. Moreover, the energy efficiency, *i.e.*, per cent of energy absorbed which is actually converted to visible radiation, of $CaWO_4$ is about 3%, which gives an over-all efficiency for the system of only 0.3-0.6%. It is also noteworthy that there are other secondary factors that contribute to resolution and light output such as phosphor efficiency and particle size of the phosphor.

Other inorganic phosphors used in sensitizing screens include lead-activated barium sulfate, and silver or copper-activated zinc (or zinc-cadmium) sulfide. These phosphors have high mass-absorption coefficients, their blue-violet-ultraviolet emissions and energy efficiencies ranging from 3% for $CaWO_4$ to about 20% for ZnS:Ag. (These numbers, however, can be misleading because the ability to absorb x-rays is strongly dependent upon the energy of the x-rays and varies greatly from phosphor to phosphor. Calcium tungstate, for example, has an absorption band at about 70 keV and is a markedly poorer absorber at lower energies.)

A 1961 patent (10) advanced a phosphor-binder combination designed to reduce the internal scatter of the emitted radiation by the use of thallium-activated alkali iodides in aluminum stearate binders. This, together with the minimized internal scatter of the luminescence permitting thicker screens) enabled exposure time reductions of four over comparable $CaWO_4$ screens.

In recent years considerable interest has been directed towards rare earth-activated phosphors (11, 12). Of special interest are matrices activated by ions which allow 5*d* to 4*f* electronic transitions such as the blue emitting Ce^{3+} and divalent rare earth ions. The emis-

sions from these ions are broad band with fairly short lifetimes (decay times of a fraction of a microsecond).

Because the scattering of light is one factor responsible for the resolution limit in polycrystalline screens, single-phase materials such as the single crystal and the thick film are attractive. There are, however, basically two problems inherent in these screens. Firstly, the production of luminescent single crystals suitable for screens is very costly. Secondly, these screens also have a resolution dependency on thickness. This can be seen when one considers the excitation mechanism (Fig. 1). The volume of phosphor excited by each x-ray photon is dependent upon the range of the secondary electrons (13) which in turn are related proportionally to the energy of the incident x-ray photon (14). For example, a 35 keV x-ray might produce a channel about 3μ long and 0.9μ in diameter in ZnS (13). The luminescent flux density from such an emission channel will be considerably higher in the forward and reverse directions than radially because of the fiber alignment. However, as the thickness of the screen increases from the 3μ level, dispersion of the emitted light will result. Although this provides an improvement over the polycrystalline case, realistic single phase screens 300-500μ thick still possess an unsatisfactory inherent resolution limit.

The fiber-optic sensitizing screens, the third type of sensitizing screen and the type advanced in this paper, is constructed from small (20μ diameter) luminescent glass fibers. The fibers are clad with a low refractive index glass, and pressed together under mild heating to form bundles with hexagonal cross sections of about 5 mm diameter. These rods can subsequently be pressed together in a similar fashion in any practical thickness. Slices ½-1 in. thick are then cut from these rods, which in turn are ground and polished, and one side receives a reflector coating. The result is a fluorescent fiber-optic faceplate that can be used as an x-ray sensitizing screen, (Fig. 2).

This idea was first described by Hilton and Squire (15) where they pointed out some of the advantages of a fiber-optic sensitizing screen. In essence, improved resolution is a result of the channeling (light piping) effect of the fibers. The excitation channel in a sense is the limiting parameter on the resolution. However, this limit is 3-4μ for a 35 keV x-ray photon, and a screen made from fibers this small would provide resolution capabilities beyond the statistical limit of most existing intensifying systems. Not only is the resolution improved by the fiber-optic screen, but it is independent of screen thickness. This results from the high transmission of light by the glass. Most significant is the fact that the sensitizing screen can be made sufficiently thick to absorb all of the incident x-ray photons with only small losses in resolution.

Experimental Apparatus and Procedure

Image intensification was provided by a modified RCA 8606 three-stage cascaded optical image intensifier tube. The tube is electrostatically focused and has a magnification of 1:1. Details of the operation of the tube and the manner in which it is incorporated into a time-resolved x-ray diffraction or radiographic device have been described previously [see Ref. (16)]. The input and output faceplates of the image-intensifier tube are fiber-optic bundles which are flat on the exterior ends. In order to convert the x-ray image into a visible light image for intensification, an x-ray fluorescent fiber-optic faceplate was mounted in direct contact with the input fiber-optic bundle of the image-intensifier tube. The image intensifier tube used for the present work increased the luminous flux of the visible light image produced by the fluorescent fiber-optic screen by a gain of about 77,200. The on-center measured resolution of the tube itself was 36 lp/mm with a peripheral value of 30 lp/mm. The tube had a useful cathode diameter of 37.5 mm.

The results shown in the following section were obtained by direct photographic recording of the image which was displayed at the rear of the intensifying tube. Various commercial x-ray fluorescent fiber-optic faceplates were used which ranged in thickness from 2 to 10 mm, and in diameter from 1 to 3 cm. The individual glass fibers in the fiber-optic faceplates were about 7μ in diameter and were placed on approximately 15μ centers. The spacing of the individual fibers sometimes varied up to as much as 25μ. At the corners of these hexagonal bundles there are disturbances in the fiber spacing of up to 60μ. Such a screen should have the ability to resolve details spaced apart by between 20 and 25μ, *i.e.*, it should be capable of a resolution of between 40 and 50 lp/mm.

If the resolution of the x-ray fluorescent fiber-optic faceplate is taken to be 45 lp/mm and the resolution of the image tube is taken to be 36 lp/mm, then the resolution of the image system consisting of those two components used in tandem should be about 28 lp/mm.

Such a system would be expected to resolve detail spaced apart by slightly less than 35μ.

Experimental Results

A series of tests was run to determine the feasibility of the new concept in the time-resolved x-ray devices described above. The objectives of these tests were to determine the resolution and sensitivity of the best available device at this point of development, since those characteristics are the most critical to applications of the method.

In order to check the resolution of the system accurately, several different types of tests were conducted. The most straightforward type of resolution test is provided by radiographic examination of wire meshes. The results of such a test are shown in Fig. 3. The wires in the screen were 51μ in diameter and spaced apart by 74μ. Therefore, the resolution illustrated by Fig. 3 is between 20 and 25 lp/mm. No wire mesh screen was available to test the exact value of 28 lp/mm predicted in the previous section. A Cu target at 20 kV and a few milliamperes was used to obtain the picture.

A second test of resolution was made in connection with the application of time-resolved x-ray radiography to the study of dynamic-material response in our laboratory. For such tests, it is useful to have a time history of the chronology, duration, and general character of the breakage of reinforcing fibers in the interior of opaque reinforced materials. Such a breakage is shown in Fig. 4. The white horizontal region is the section of the specimen which was radiographed. The two dark vertical lines in the radiographed section are "shadows" of two reinforcing fibers. The reinforcing fiber on the right is broken as indicated by the small white horizontal bar in the vertical shadow. A fiber-optic fluorescent screen was used to make the photograph shown in Fig. 4a, and a powder-fluorescent screen used to make the photograph shown in Fig. 4b. It should be emphasized that both images were displayed on the rear of the image-intensifying tube with sufficient intensity to be recorded on cine film at standard framing rates (30 frames/sec). The reinforcing fibers were 1 mm diameter tungsten wires embedded in a matrix of aluminum. The specimens were plate-shaped, so that the thickness through which the x-rays were passing was 1.56 mm. Figure 4b is the best previous radiograph of the breakage obtained using a fluorescent-powder screen in contact with the input fiber-optic bundle of the image-intensifying tube used in the present work as described in Ref. (16). The radiograph in Fig. 4a, taken at 30 kV and 15 mA, shows a distinct improvement in general clarity. This is to be expected since the resolution in Fig. 4a is about three times that of the powder screen in Fig. 4b. This increase in resolution is of critical importance to this application, since it is useful to examine the breakage of much smaller fibers than those shown in Fig. 4.

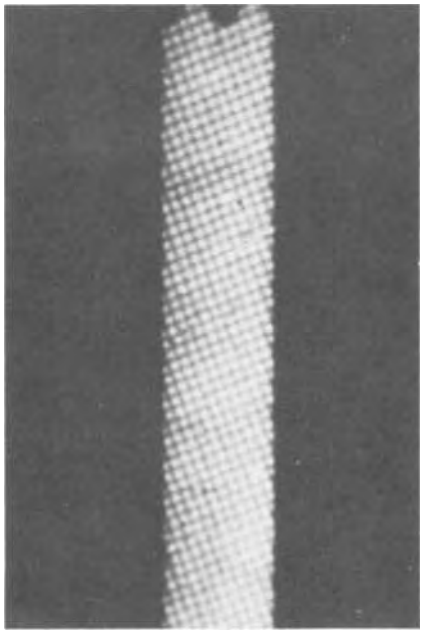

Fig. 3. Radiograph of wire mesh showing about 20-25 lp/mm resolution taken using a fluorescent fiber-optic x-ray sensitive faceplate (X20).

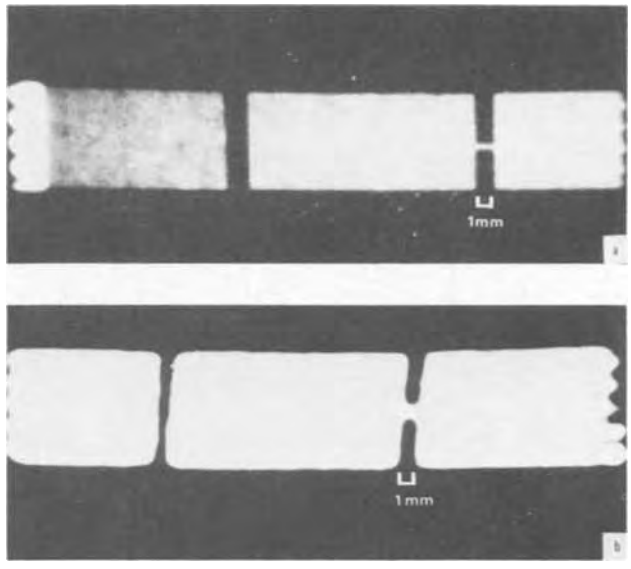

Fig. 4. Radiograph of 0.2 mm break in one of two adjacent fibers in a metal matrix composite tensile specimen, (a) taken using fluorescent fiber-optic faceplate (X20), (b) best previous radiograph taken using a powder screen (X14).

In an effort to compare resolution of the present system with that of another system previously reported, a third test was conducted. A chip of the same silicon-crystal integrated circuit used by Rozgonyi, *et al.* to demonstrate the resolution of their silicon-diode array camera in Ref. (2) was kindly supplied by the author of that paper. An optical photograph of part of that integrated circuit is shown in Fig. 5a. On the basis of our previous discussion, it would be expected that the present system should resolve the 38μ strips with 76μ spacing quite clearly. In the area where the strips double in number so that the spacing between strips drops to 19μ, delineation of that detail would require greater than 30 lp/mm. Hence, we would not expect these areas to be clearly delineated by the present system. Figure 5b shows a radiograph of the silicon chip made with the present device. The x-ray focal spot size was 0.4 $\times$ 0.4 mm at a distance of 40 cm from the chip. As expected, the 38μ strips are quite distinct, but the detail in the area of double strips cannot be clearly discerned. It should be mentioned that visual observation of this pattern as displayed on the rear of the image-intensifying tube using a microscope revealed that the 19μ spacings of the 38μ strips could, in fact, be clearly observed and counted. However, the extreme criticality of focus requirements for the cameras available to the authors, which magnified the image to a much lesser degree, served to prevent perfect recording of that detail. At any rate, the resolution of the present system is at least as high as the value predicted in the previous section. Considerable care was taken to mount the incident x-ray collimator and fluorescent fiber-optic faceplate almost in contact with opposite sides of the silicon chip so as to insure a 1:1 comparison between dimensions observed on the optical photograph and those displayed on the radiographic pattern.

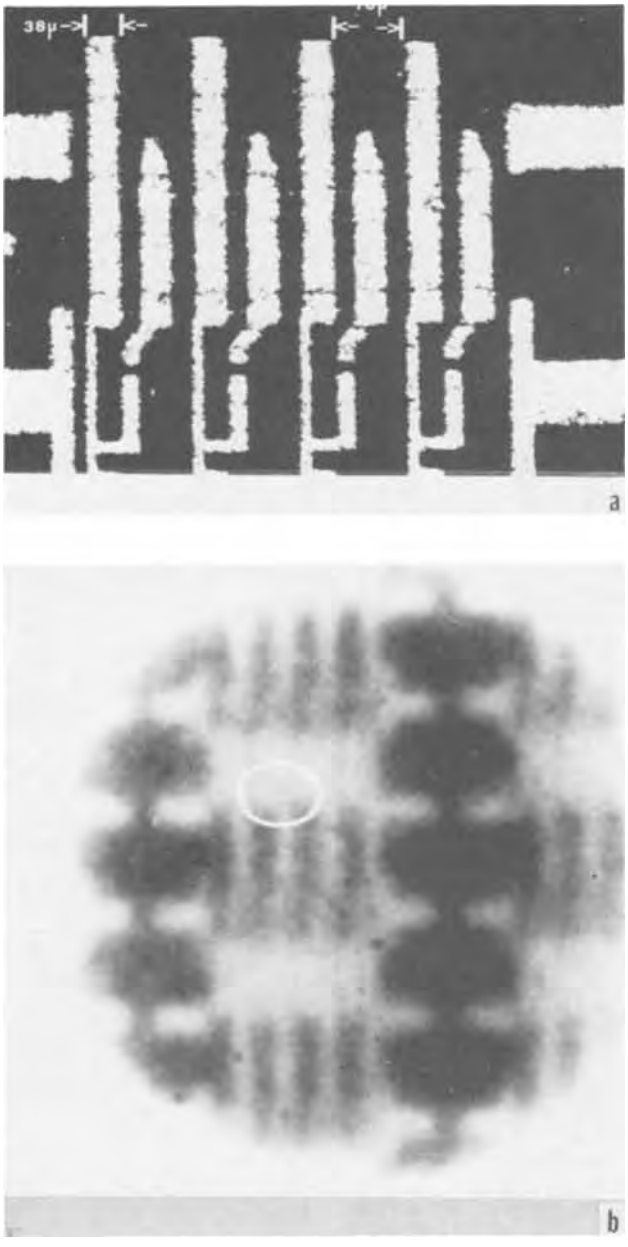

Fig. 5. Optical photograph (a), and x-ray radiograph (b), of silicon integrated circuit [same crystal as used by Rozgonyi *et al.*, see Ref. (3)]. Radiograph was made using fluorescent fiber-optic x-ray sensitive faceplate.

While questions of resolution can be settled by radiographic techniques, the questions of sensitivity are more easily examined by attempting to study various x-ray diffraction patterns. The sensitivity of the present device has not yet been optimized, and is the subject of present development efforts. Using the 900 VA x-ray source available to the author, it was impossible to display instantaneously x-ray topographs. Since the image on the image-intensifying tube used in the present system cannot be intensified by integrating the input over various time periods as has been done by various other investigators, no x-ray topographs could be recorded. However, Laue patterns of various types were recorded using smaller x-ray target-to-specimen distances and less collimation than is needed for topographic work. An example of a recorded diffraction spot is provided in Fig. 6. Only one diffraction spot was recorded, since the most sensitive fluorescent fiber-optic screen available was only 1 cm in diameter. The crystal which produced the diffraction was 1.56 mm thick 5 nines aluminum, and the pattern recorded was obtained using a standard Laue transmission

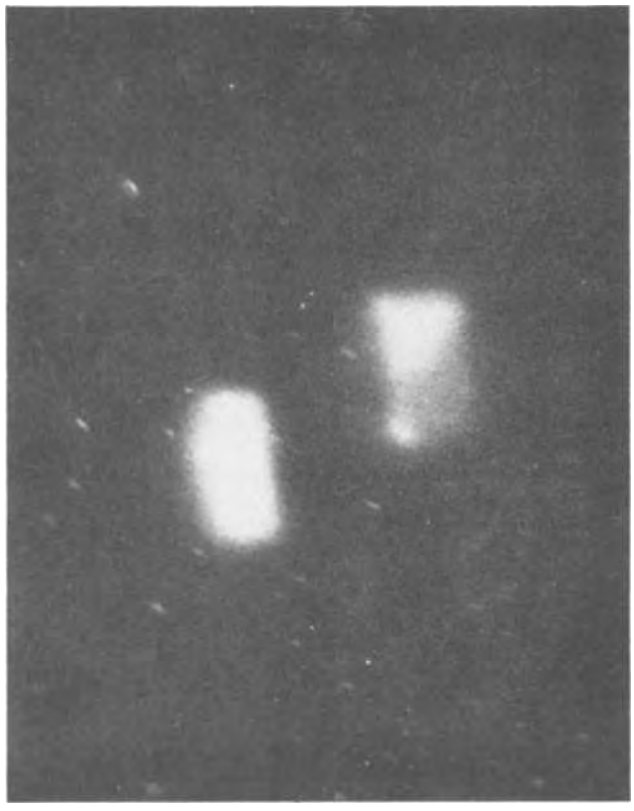

Fig. 6. Laue diffraction spot (on the right) and transmitted direct beam from a 1.56 mm thick aluminum single crystal shown on a photograph made using a fluorescent fiber-optic screen. (40 kV 20 mA, 20 sec exposure on ASA 150 film from back of image intensifying tube) (X10).

arrangement. The x-ray target-to-specimen distance was 12 cm and the final collimater size was 1 mm × 0.5 mm. The x-ray tube was operated at 40 kV and 20 mA. More complete Laue patterns with ellipses which can be analyzed for orientation purposes have been obtained using somewhat less collimation. Interestingly enough, observation of Fig. 6 reveals that the diffraction spot shows distinct intensity variations and represents, in some sense, a topograph of that area of the aluminum crystal. The real significance of the photograph in Fig. 6, however, is to provide evidence of the sensitivity of the present method. Even at this point in development, the conversion efficiency of the fiber-optic x-ray fluorescent faceplates is sufficient to provide instantaneous time-resolved recording of very weak x-ray diffraction patterns. It is estimated that the present low value of conversion efficiency for the fiber-optic screens results in a sensitivity to x-rays which is about one order of magnitude less than that of the same system operating with a fluorescent-powder screen having about 10 lp/mm resolution as described in Ref. (16).

Discussion

The successful application of a radically new type of x-ray sensitive fluorescent screen which converts x-rays to visible light is described. The new screen differs from previous types in that the visible light image is created and conducted by fluorescent glass fibers which are assembled in a bundle in a standard manner to form a fiber-optic plate. In the present work, the fiber-optic x-ray fluorescent plate was placed in direct contact with the fiber-optic bundle which formed the faceplate of the input end of an image-intensifier tube. The resulting system has a resolution of about 28 lp/mm and a sensitivity sufficient for truly instantaneous recording of x-ray radiographic and diffraction images. The sensitivity of the present device is

about one order of magnitude less than the best previously reported system (16). The brightest fiber-optic fluorescent faceplate used in the present work was found to emit 11.4% of the white light intensity of a Dupont Cronex Lightning Special powder-fluorescent screen with identical incident x-ray flux.

While sensitivity is still being optimized, the fact that we have recorded transmission x-ray diffraction patterns through 1.56 mm thick aluminum single crystals at 800 VA indicates that even now the system has better sensitivity than many other available time-resolved systems. However, it should be noted that, with development, the present system has the potential of being much more sensitive to x-rays than any system using a fluorescent-powder screen. Equally important is the fact that the present system also has the potential to reach the theoretical limitation on resolution imposed by statistical variations in the x-ray flux incident on the system. These potentialities come about because of the additional absorption of the fiber-optic screen. If the conversion efficiency of the glass fibers can be increased to a point where they are just half as efficient in converting x-ray photons to visible light, the fiber-optic screen would then be twice as sensitive to x-rays as a powder screen with even 10 lp/mm which absorbs, at most, 25% of the x-rays incident upon it. There is every reason to believe that glass fibers with conversion efficiencies at least that high can be developed. If such sensitivity is obtained, the quantum statistical variations in the incident x-ray beam will be the limiting factor on image formation. This limitation is determined by the theoretical signal-to-noise ratio which can be obtained for a given detail spacing with a specified number of photon events in the picture element area (17). No amount of intensification by subsequent image systems will exceed this limit. The theoretical high-contrast resolution limit for x-ray intensities common to applications discussed in the present work is about 35 lp/mm [see Ref. (11)]. A fiber-optic fluorescent faceplate with a resolution which exceeds this value could easily be constructed.

The per cent of incident x-ray photons absorbed, and the conversion efficiency of the fiber-optic fluorescent screen are of equal importance in the face of statistical fluctuations in the incident image to resolution arguments. If it is assumed that the variation in the incident x-ray photon flux with time is given by a Poisson distribution (as is commonly done), then the photoemission (output) of the fluorescent layer can be characterized by a signal-to-noise ratio (SNR) given by the following expression, $SNR = (\eta \times \bar{n})^{1/2}$, where η is the conversion efficiency of the fluorescent fibers (defined as the probability that an optical photon will be emitted when an x-ray photon strikes) and $\bar{n}$ is the average number of x-ray photons which strike the fluorescent fibers per unit time. The conversion efficiency consists of two parts, the percentage of incident photons stopped (or absorbed) by the fibers times the quantum efficiency of converting the absorbed x-ray photons into visible light photons.

The system reported here is presently being used to monitor fiber breakage in fiber-composite reinforced specimens during continuous testing radiographically, and to record the changes in diffraction patterns during continuous deformation of aluminum single crystals.

Acknowledgments

The authors would like to thank G. P. Rozgonyi for the silicon crystal used in some of the present work. They would also like to thank Kenneth McCauley and Robert Davis for their assistance in constructing the equipment and carrying out the tests. Further thanks goes to Pat Blackley for typing this manuscript.

This work was supported in part by grant number GK-4741 from the National Science Foundation.

Measurement of Si Epitaxial Thickness Using a Michelson Interferometer

Paul F. Cox and Arnold F. Stalder*

Texas Instruments Incorporated, Corporate Research and Engineering, Dallas, Texas 75222

ABSTRACT

A system has been designed to measure the thickness of silicon epitaxial material using a scanning Michelson interferometer rather than a conventional dispersive *IR* spectrometer. The sampling capacity of this system with a 5-6 sec sampling time exceeds that of several dispersive instruments. The long-term precision on a single machine (3σ) is $\pm$ (0.05 μm + 0.005t), where t is the film thickness. Computer processing of the reflection interferogram from an epitaxial wafer provides film thickness data by a Fourier transform method. This method is shown to be mathematically equivalent to the method used for dispersion spectrometers as given by ASTM procedure F95-68T. The two measurements are in agreement within the published interlaboratory precision of the ASTM method: $\pm$ (0.25 μm + 0.025t) for P-type material and $\pm$ (0.25 + 0.005t) for N-type. The lack of moving mechanical parts in the interferometer system contributes to making this type of instrument very reliable. Down time due to system failure has been minimal, and two systems have been in operation a total of over 4 machine years.

Silicon and germanium have been commonly used in semiconductor device fabrication. Recent developments in the optoelectronics area have introduced new materials such as GaAs, GaP, and GaAsP. Epitaxial structures have been used with all of these materials. Effective use of this type of material requires knowledge of the epitaxial layer thickness as well as the electrical properties of the material. The system described in this paper was intended for use with silicon epitaxial material, although the same method could easily be applied to other materials.

Kane and Larrabee (1) have described several ways to measure silicon epitaxial film thickness. One type of destructive determination involves angle lapping and staining the material. If a selective stain is chosen, the layer thickness can be determined with a calibrated microscope, or an interference microscope. Another method involves the use of an etch solution that etches selectively along crystal defects and exposes the source of stacking faults. In epitaxial material a great number of faults will originate at the layer-substrate interface, and the size of the etch pits associated with these may be used to determine the layer thickness.

The substrates generally used for epitaxial layer growth are quite heavily doped, with resistivities on the order of 0.005-0.020 ohm-cm. The layer material is much less heavily doped. The presence of high doping levels in the substrate causes an abrupt change in the optical properties of the material at the layer-substrate interface, in the infrared region of the spectrum. This change in the extinction coefficient caused by free carrier absorption is only apparent at long wavelengths in the infrared, and is difficult to observe at wavelengths less than 10 μm. The change in the optical properties of the epitaxial material at the interface permits nondestructive optical interference methods to be used for film thickness measurements. Ellipsometry at 54.6 μm has been employed by Hilton and Jones (2). Despite the potential of ellipsometry, the lack of a strong monochromatic radiation source in the long wavelength *IR* region has limited its use to laboratory experiments.

The method most commonly employed to measure epitaxial thickness has been *IR* interferometry using the reflection interference spectrum obtained on an *IR* spectrometer. This method was reviewed recently by Severin (3) and has been exploited extensively during the last 10 years (4-10). A standardized procedure based on *IR* interference has been adopted by the American Society for Testing Materials (11).

Even though *IR* interferometric measurements have done a great deal to simplify the measurement of epitaxial films, a few disadvantages do exist where a large number of samples must be measured routinely. The time required for a manually operated instrument and the simplest data processing is approximately 1 min per sample. Even a commercial system using a computer coupled scanning spectrometer requires 30 sec to measure one sample.[1] The time is determined by that required to scan the spectrum. However, coupling 4 spectrometers to the computer allows a very good measuring rate of 8 samples/min to be attained.

One problem not alleviated by computer data processing is that of mechanical wear caused by repeated rapid cycling of the spectrometer mechanism. Ten years of experience at the authors' company coupled with the information obtained from others in the semiconductor industry indicate that this is a very serious problem. Even the best commercial spectrometers suffer a great deal of down time after extended use, in spite of extensive maintenance programs.

The advantages of using the nondestructive *IR* interferometric technique can be retained while virtually eliminating the problem of mechanical wear and long sampling time if the data are collected with a scanning Michelson interferometer. The data handling with this system requires Fourier analysis to extract all of the available spectral information, but if an automated system using a small computer is desired this is no handicap. The only moving part in the scanning Michelson interferometer is the translation drive on the scanning mirror. In the case of one commercial interferometer, this is composed of the solenoid drive mechanism from an audio speaker and has proven to be very reliable under normal operating conditions.[2] The spectral resolution of the least expensive scanning Michelson systems capable of reasonable scanning rates is very low, around 20-40 cm^{-1}, but for the epitaxial thickness measurement this is no drawback. The optical system in a Michelson interferometer offers two advantages over a conventional dispersive system which greatly enhance the signal/noise ratio and allow

[2] Digilab, Inc., Model 196TC.

the data to be collected very quickly (12-14). Since no restrictive slit mechanism is required and a reasonably wide angular aperture can be used without impairing performance, the radiation throughput of the system is quite large. In addition, Fellgets multiplex advantage is applicable. All wavelengths are viewed simultaneously by the detector, and in a detector noise limited system this multiplexing of the spectrum will greatly improve the signal/noise ratio.

A complete system for the measurement of epitaxial layer thickness utilizing a scanning Michelson has been developed in this laboratory. A similar system has subsequently been marketed commercially.[3]

Application of the Michelson Interferometer to Epitaxial Measurements

A schematic of the optical system used for *IR* interferometry with a Michelson interferometer is shown in Fig. 1. The single beam incident upon the sample is split into beams A and B upon reflection from the epitaxial sample. Beam B is out of phase with A by an amount Δ, due to the path through the layer and phase shifts upon reflection at both surface and layer-substrate interfaces. The beam splitter (M_3) in the interferometer splits each beam into two equal amplitude components. These go to either the fixed mirror (M_1) or the scanning mirror (M_2) where they are reflected back to the beam splitter. The beams recombine at this point and travel to the detector (D). The scanning mirror translates about the point at which the two paths in the interferometer are of equal length. The scanning range of the mirror must be able to introduce a phase difference between the two legs of the interferometer that exceeds the phase difference Δ introduced by the sample. Since each beam traverses a leg of the interferometer twice, it means that the mirror must travel a distance that introduces a phase shift of $\pm\Delta/2$, in order to be useful in making an epitaxial measurement. The maximum sample thickness that can be measured is determined by the limits of the mirror travel. The range can be extended on some instruments by adjusting the mirrors so that the scanning is done only on one side of the equal path position, thus doubling the useful thickness range for a given scanning distance.

An example of an interferogram produced by a system such as that described in Fig. 1 is shown in Fig. 2. The a-c signal intensity is plotted *vs.* the phase shift introduced by the scanning mirror. The phase shift is related to mirror movement by the relationship

$$\text{phase shift} = \frac{2\pi x}{\lambda} = 2\pi\nu x \qquad [1]$$

where x is the optical path difference in the interferometer, λ is the wavelength of the radiation, and $\nu = 1/\lambda$. A maximum signal occurs at the point where the phase shift for most wavelengths is zero. This would occur where $x = 0$, if no distortion were present in the signal. Signal distortion has caused the asymmetry in the interferogram shown in Fig. 2. The satellite peaks occur where the phase shift introduced by the interferometer is $\pm\Delta$, and cancels that introduced by the sample. Beams A_2 and B_1 combine to produce a satellite at $+\Delta$, and A_1 and B_1 produce the peak at $-\Delta$.

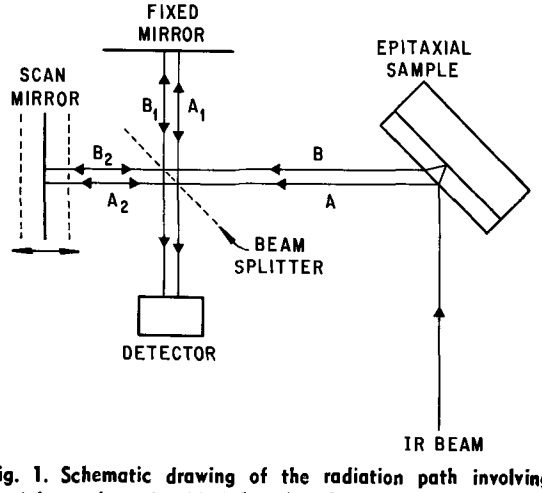

Fig. 1. Schematic drawing of the radiation path involving an epitaxial sample and a Michelson interferometer.

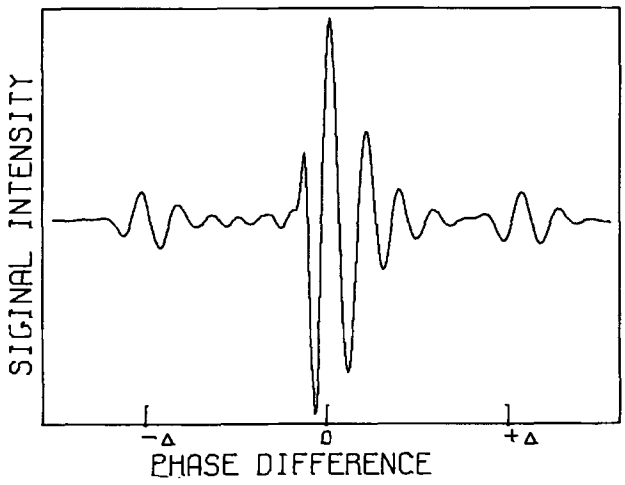

Fig. 2. Unprocessed interferogram of reflection from a 12.5 μm epitaxial film.

The mirror position at any point in a scan can be accurately determined, and hence locating the satellites relative to the central peak will yield a measured value of Δ. If the phase shifts introduced upon reflection at the surface and layer-substrate interfaces were the same, the film thickness could be derived from the simple equation

$$t = \frac{\Delta}{2n_1 \cos\theta} \qquad [2]$$

where n_1 is the refractive index of the film, t the film thickness, and θ the angle of refraction.

For epitaxial semiconductor material a phase shift correction is necessary to obtain an accurate film thickness measurement. The phase shift at the layer-substrate interface for silicon epitaxial material and the general method for correcting the thickness measurement made with a dispersion spectrometer have been published (9, 11). Thickness measurements using an interferometric spectrometer must also include a similar correction for reflection phase shifts to obtain accurate measurements and to be compatible with existing measurement techniques.

Experimental

The epitaxial film thickness monitor constructed at Texas Instruments was called the EPILOG system. A block diagram of the EPILOG system is shown in Fig. 3. Data collection was handled by the optical unit, which included the source, source optics, and Michelson interferometer. The amplified signal was converted to digital data and stored in a computer memory. The film thickness extracted from the data was presented on a digital readout or printed by a typewriter or strip printer.

The development of the EPILOG system has so far resulted in two systems. The second system, EPILOG II, surpassed the first model in performance and only this system will be described in detail. Data from both systems, however, will be shown later to demonstrate the improvements obtained with the more advanced system. A third model, EPILOG III, using a more compact and faster computer[4] is currently under con-

[4] Texas Instruments Model 960A.

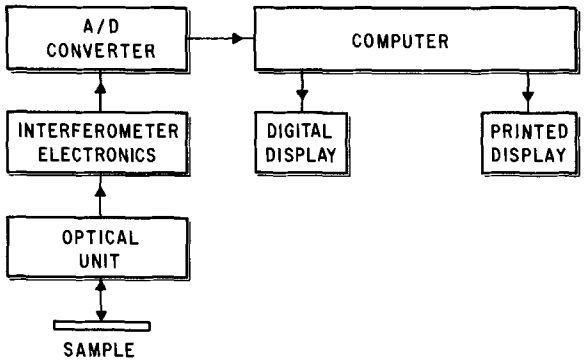

Fig. 3. Block diagram of EPILOG system

struction, but will be essentially the same in all performance parameters as EPILOG II, the only exception being in that a faster computation in EPILOG III might slightly shorten the sampling time.

The optical schematic for the second system is shown in Fig. 4. In this case a 1:1 image of the globar was formed on the sample surface, with no prefiltering of the radiation. The radiation reflected from the sample was partially collimated before being sent into the interferometer. The interferometer used was again the Block 196TC. The image of the globar on the sample was about ¼ × ¾ in. Provisions were made to reduce this to ¼ × ½ in. for profiling the thickness over a large slice. The data processing in this case was handled by a Texas Instruments Model 861 process control computer, with a 24 bit, 8K memory, and hardware arithmetic. The additional computational capability permitted a fairly sophisticated calculation of the film thickness, using a Fourier transform technique. The details of this computation will be described in the next section. Film thickness was displayed on a digital display, with the option of a permanent record on a strip printer. In this system the interferometer scanned 4 times per second and the number of scans averaged before data processing was 16. The computation time varied somewhat from one slice to another, depending on the film thickness, but the average time required to measure a film thickness was ~6 sec.

The reliability of both systems has been excellent. The Michelson interferometer heads which are kept under a dry nitrogen purge have caused no down time at all. The EPILOG I system was put into extensive use in June of 1969, and EPILOG II in July of 1970. Both are currently still in use.

Fourier Transform Analysis

The computer used for the EPILOG II system permitted the use of a sophisticated data analysis. The method developed utilized the Cooley-Tukey (16) fast Fourier transform (FFT) algorithm and can be shown to be mathematically equivalent to the ASTM procedure.

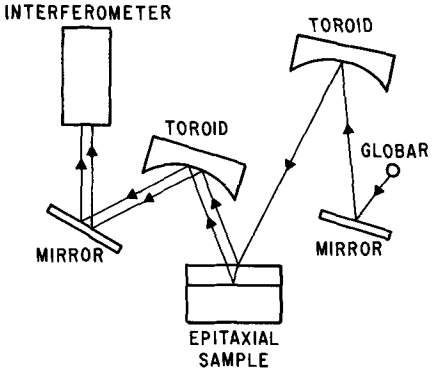

Fig. 4. Source and collection optics for EPILOG II

When a single beam of radiation enters a Michelson interferometer, the signal at the detector is a function of the frequency distribution of the radiation, $A(\nu)$, and the phase difference between the components which are separated and recombined in the interferometer. This signal intensity can be expressed by

$$I(x) \sum_{\nu} A(\nu) \cos(2\pi\nu x) \quad [3]$$

where x is the optical path difference between the two rays in the interferometer and ν is the optical frequency, $1/\lambda$.

For the system shown schematically in Fig. 1, the radiation entering the Michelson interferometer consists of two beams, differing in phase by an amount Δ. The signal intensity at the detector in this case is given by

$$I(x) = \sum_{\nu} (A(\nu) + B(\nu)) \cos(2\pi\nu x) + \sum_{\nu} 2\sqrt{A(\nu)\,B(\nu)} \cos(2\pi\nu x \pm \Delta) \quad [4]$$

where $A(\nu)$ and $B(\nu)$ are the frequency distributions of the radiation reflected at the first surface and layer-substrate interface, respectively. The first term in the summation produces the center feature shown in the interferogram in Fig. 2. The satellites shown at phase shift of $\pm\Delta$ in Fig. 2 are generated by the second term in Eq. [4]. Equations [3] and [4] imply that the interferogram should be symmetrical about $x = 0$; the data shown in Fig. 2 obviously are not. Some of the asymmetry can be attributed to imperfect compensation in the interferometer optical system but most is the result of distortions in the detector electronics at the high-scan velocities used. The distortions are most apparent at high-signal frequencies, which are generated by shorter wavelength radiation. An optical filter was used on the EPILOG I system to remove most of these high-frequency components and permit accurate identification of features in the interferogram with a minimum of computation.

In the EPILOG II system it was desired to include the shorter wavelength radiation in the analysis to permit the measurement of thinner samples. In this case it was necessary to remove the distortions seen in Fig. 2 prior to data analysis. The properties of the Fourier transform can be easily utilized to remove these phase distortions and generate an idealized, symmetrical interferogram. The original interferogram consisted of 1024 data words collected at 1.0 μm increments of interferometer path difference. The Fourier transform of this raw interferogram yielded a complex function of ν.

$$I(x) = \sum_{\nu} (N(\nu) + iM(\nu))\, e^{-2\pi i\nu x} \quad [5]$$

These complex coefficients occur because there is no wavelength-independent content in the distorted interferogram. These complex coefficients were then replaced by the real amplitude of the vector they represent. The transformed interferogram was apodized to remove contributions from wavelengths shorter than 8 μm since no information of the epitaxial layer thickness can be obtained in this spectral region. The reverse transform on the real, apodized coefficients yielded a symmetric, filtered interferogram. The data used to generate Fig. 2 is shown again in Fig. 5 after symmetrization and filtering. While most of the data analysis time was spent in this step, the time required was more than offset by improved signal/noise ratio and hence reduced sampling time. Since the interferogram was then symmetrical and contained no contributions from wavelengths shorter than 8 μm, it could at that point be described by a single sided interferogram

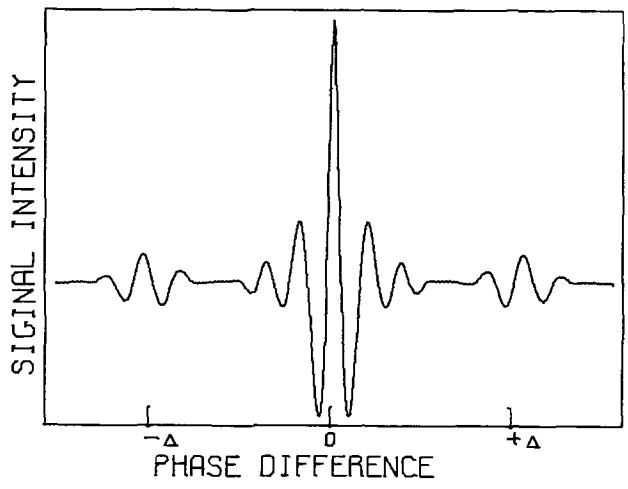

Fig. 5. Symmetrized interferogram from a 12.5 μm epitaxial film

of 128 points; each point corresponding to 4 μm increments of interferometer path difference.

The accurate analysis of the reflection interferogram depends critically on the isolation of the satellite fringes from the central fringe. All of the information concerning the epitaxial layer thickness is contained in the satellite fringes, and their complete characterization is very important. The sample used to generate the interferograms in Fig. 1 and 5 had a 12.5 μm epitaxial layer, and the central and satellite fringes were well separated. The satellite fringes can be easily isolated and identified in this case. However, samples with thinner epitaxial layers will exhibit satellite fringes shifted toward the central fringe, and when the layer becomes thin enough the three fringes will merge and location of the satellites will be impossible without further data manipulation. This merging of the fringes occurs with film thicknesses less than 8 μm. Extraction of film thickness information for thin samples can only be carried out after the contribution of the central fringe is removed from the interferogram.

The central fringe is composed of radiation reflected from both the first surface and the epitaxial layer-substrate interfaces. The amplitude and wavelength distribution of the central fringe depend on the optical constants of the epitaxial layer and the substrate and hence on the impurity type and resistivity in both areas. It has been found that the central fringe of a wide variety of samples can be approximated by a linear combination of the reflection interferogram from a clean high-resistivity silicon slice and an average of the central fringes of thick samples previously measured on the system. In this case thick samples are defined as having a layer thicker than 10 μm. The coefficients for the linear combination are chosen so that after subtraction from the sample interferogram the signal amplitude at the zero mirror displacement position and at a wavelength of 8 μm are both zero. The amplitude at 8 μm is determined from the Fourier transform of the interferogram. The residual noise left in the center of the interferogram after this subtraction is very small relative to the satellite amplitude. The satellites can be easily located after this subtraction step, and samples as thin as 0.6 μm have been analyzed reliably. For samples thinner than 0.6 μm the satellites themselves overlap at the center of the interferogram, and they cannot be separated by any computations currently in use in this system. Physically, at this point the optical thickness of layer is less than ½ the wavelength of the observing radiation and no strong interference effects can be characterized.

The mathematical representation of a single satellite can be given by

$$I(x)_{SAT} = \sum_{\nu} 2\sqrt{A(\nu)\,B(\nu)}\cos(2\pi\nu x - \Delta) \quad [6]$$

The term Δ can be expanded to

$$\Delta = \phi_{01} - \phi_{12} + 2\pi\nu n_1 t\cos\theta \quad [7]$$

where $\phi_{01} = \pi$ is the phase shift at the air-layer interface, ϕ_{12} is the phase shift at the layer-substrate interface, n_1 is the refractive index of the layer, t the film thickness, and θ the angle of refraction.

Both ϕ_{12} and $B(\nu)$ are functions of the optical constants of the substrate, n_2 and k_2, where these are the real and imaginary parts of the refractive index. At this point the mathematical representation of the satellite can be better expressed in complex notation as

$$I(x)_{SAT} = \sum_{\nu} G(n_1, n_2, k_2, \nu)\,H(n_1, t, \theta) \quad [8]$$

where

$$G(n_1, n_2, k_2, \nu) = 2\sqrt{A(\nu)\,B(\nu)}\,e^{-i(\phi_{01} - \phi_{12})} \quad [9]$$

and

$$H(n_1, t, \theta) = e^{-2\pi i(x - n_1 t\cos\theta)} \quad [10]$$

The function G will determine the shape of the satellite; it is independent of film thickness but dependent on the optical constants of the substrate. The function H will determine the location of the satellite as determined by the film thickness and refractive index, but it is independent of the substrate parameters. In Fig. 6 the change in satellite shape with substrate material is shown for both P- and N-type material. This demonstrates the effect of the function G. In Fig. 7 the thickness independence of the satellite shape, again expected from the function G in Eq. [8], is demonstrated. The data shown in Fig. 6 and 7 are measured data, after symmetrization of the interferogram and central fringe removal.

The satellites shown in Fig. 6 and 7 are quite asymmetric for the most part. This asymmetry made it impossible to use any single feature of a satellite to define its location. The asymmetry in this case was due to the phase-shift difference between the surface and layer-substrate reflections rather than the measurement system as discussed previously. The phase shift correction factors have been calculated and published, and can be used when the substrate type and resistivity are known (9, 11).

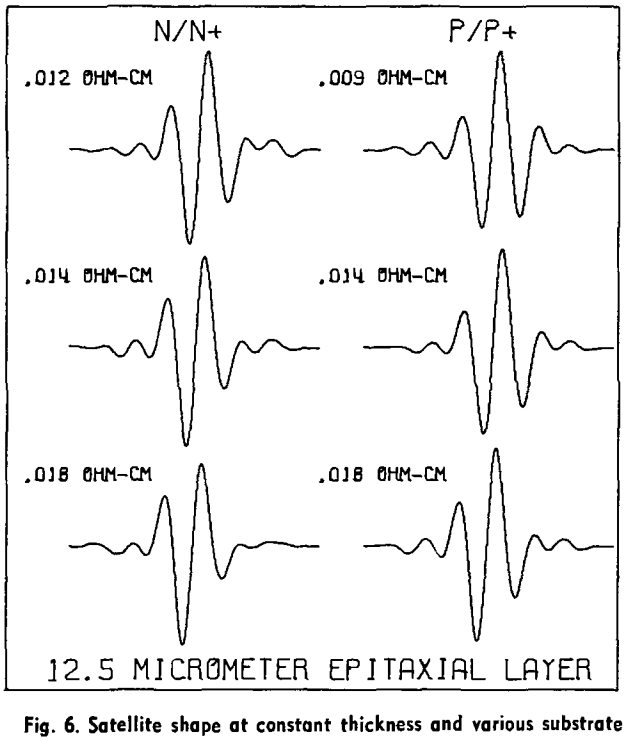

Fig. 6. Satellite shape at constant thickness and various substrate resistivities.

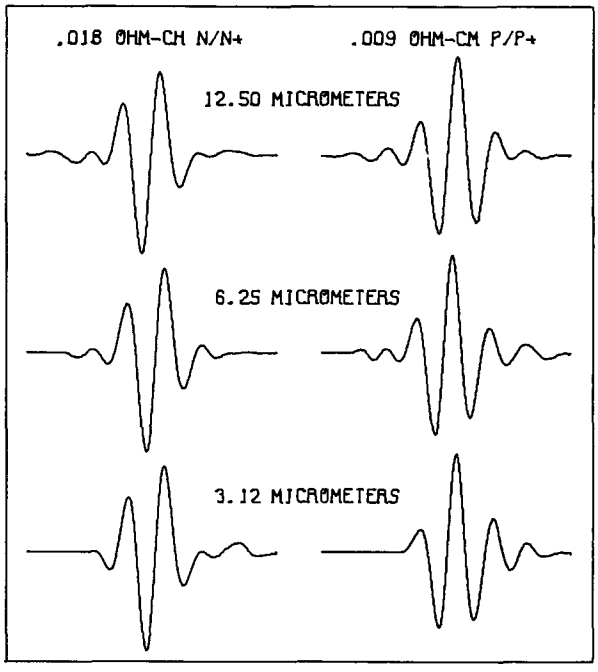

Fig. 7. Satellite shape for various thicknesses and constant substrate resistivity.

Using these published values for ϕ_{12}, we can define a function P, such that

$$P(x) = \sum_{\nu} e^{+i(\phi_{01}-\phi_{12})} \quad [11]$$

The convolution of $P(x)$ with $I(x)_{SAT}$ will yield

$$P(x) * I(x)_{SAT} = \sum_{\nu} 2\sqrt{A(\nu)\,B(\nu)}\; e^{-2\pi i\nu(x-n_1 t\cos\theta)} \quad [12]$$

This function, $P(x) * I(x)_{SAT}$, is symmetric with its maximum at

$$x_{max} = n_1 t \cos\theta \quad [13]$$

The effect of the convolution is shown in Fig. 8, with measured data of both P- and N-types. The location of the satellites was then easily accomplished by locating the point of maximum signal intensity. This location was used to derive the film thickness from Eq. [13]

$$t = \frac{x_{max}}{n_1 \cos\theta} \quad [14]$$

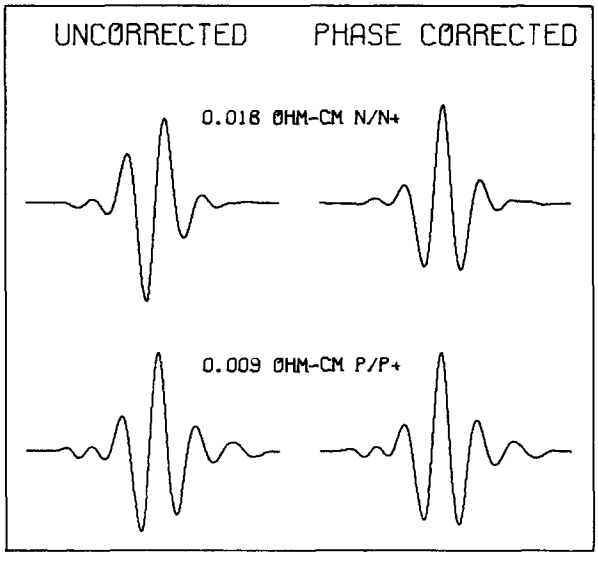

Fig. 8. Satellite shape after convolution.

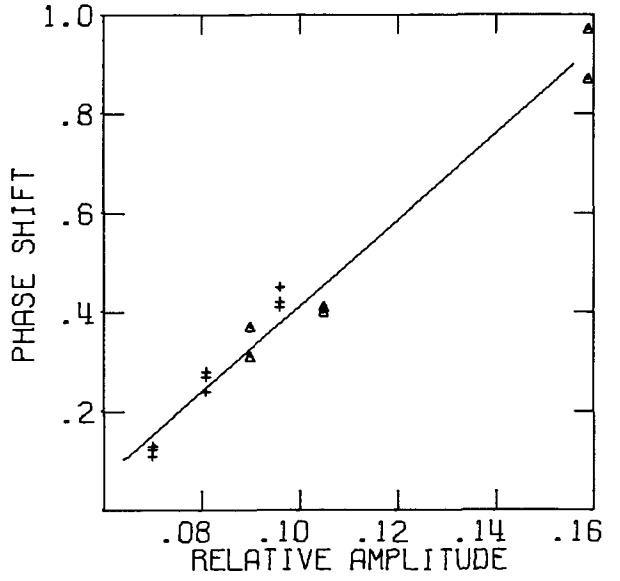

Fig. 9. Correction of layer-substrate phase shift with satellite amplitude.

For routine measurements, it is not desirable to require that the operator enter the type of resistivity of each sample. In many cases, the operator may only know the type and a resistivity range for a given lot of epitaxial samples. It was found that an excellent correlation exists between the relative amplitude of the reflection from the layer-substrate interface at a given wavelength and the calculated phase shift (9) at that wavelength. A plot of this empirical correlation at 16 μm is shown in Fig. 9. These data include both P- and N-type material, so that neither type nor resistivity need be entered by the operator. This empirical estimation of the reflection phase shift is now used on all routine measurements with the EPILOG systems.

Results and Conclusions

The use of a scanning Michelson interferometer to measure epitaxial film thickness is simply a modification of standard *IR* interferometry. An evaluation of the method can best be made by comparing the results from an EPILOG type system with those obtained using ASTM procedure F95-68T. To expedite this comparison a set of samples including both P- and N-type material was collected. The reflectance spectra were obtained on a Perkin-Elmer 221 spectrometer with KBr optics, and film thicknesses calculated according to the ASTM procedure. In Table I the ASTM thicknesses are compared with those obtained on both EPILOG systems. The term $|\delta|$ is the magnitude of the difference between an ASTM and EPILOG measurement. The interlaboratory precisions (3σ) given for the ASTM procedure are $\pm(0.25\ \mu m + 0.025t)$ for P-type material and $\pm(0.25\ \mu m + 0.005t)$ for N-type. The

Table II

	IR	EPILOG I	EPILOG II
Thickness range	1.0-100 μm	30-70.0 μm	0.75-70.0 μm
Sampling time	30 sec-15 min	5 sec	6 sec
Precision (3σ)	$\pm$ (0.25 μm + 0.025t)	$\pm$ (0.15 μm + 0.015t)	$\pm$ (0.05 μm + 0.005t)
Profiling capability	yes	no	yes

numbers obtained with both EPILOG systems fall within this range. The precisions obtained with the two EPILOG systems were somewhat better than the interlaboratory precision for the ASTM method. Repeated measurements on a set of four P-type samples over a period of several months yielded 3σ precisions of $\pm(0.15 + 0.015t)$ for EPILOG I and $\pm(0.05 + 0.005t)$ for EPILOG II.

The computational procedure used with the EPILOG systems was actually mathematically equivalent to the ASTM calculation, with the exception of the empirical determination of the phase shift correction.

Some of the important features of the EPILOG systems are compared to the standard *IR* method in Table II. The upper thickness limit is determined by the available resolution in the *IR* technique. In an interferometer the resolution is limited by the available mirror travel. Hence the upper limit for the EPILOG system is less than that of a good *IR* spectrometer, although it is of no practical importance since little material thicker than 70 μm is used in device fabrication. The shortest sampling time for an *IR* spectrometer is probably available in the Beckman system, although a manually scanned system followed by a full ASTM calculation would probably take about 15 min. This accounts for the wide range of sample times shown for the IR technique in Table II.

In summary, it appears that a computer data processing station coupled to a scanning Michelson interferometer can provide rapid and accurate epitaxial film thickness measurements. Where the sample volume can justify the initial equipment investment, the improvement in hardware reliability and measurement speed is well worthwhile. The precision that arises out of computer data processing exceeds that possible with the standard ASTM procedure carried out manually.

Acknowledgment

The authors wish to thank Jack Whichard for his invaluable services in the design and construction of the EPILOG systems.

Photoresist Cleaning

F. P. Laming[1] and R. E. Straile

Bell Laboratories, Murray Hill, New Jersey 07981

ABSTRACT

Filtration and centrifugation methods for cleaning KTFR and KMER photoresists have been quantitatively compared using a light-scattering technique to monitor both processes. It was found that material of a given purity can always be prepared more easily by centrifugation. In particular, KMER, comparable in purity to KTFR, can readily be prepared without adjusting resist viscosity prior to centrifugation, though centrifuging times are reduced by dilution of the material. Typically, centrifugation for 25,000 g-hr produces good quality KMER from 1:1 material. Centrifuged KMER is capable of resolving better than 1μ lines. Because of the superior adhesion of KMER, compared to KTFR, it should prove useful in applications where high resolution is required.

Photoresist cleanliness is a major factor influencing the resolution of the photolithographic process. Clearly, the presence of large particles of polymeric material or foreign matter will result in severe degradation of the developed image. The most common method of reducing particulate contamination of the resist is filtration immediately prior to application. Naturally the efficiency of this cleaning method depends on the ease of filtration, which, in some cases, can prove a major obstacle. Undiluted Kodak Thin Film Resist (KTFR), for example, can only be conveniently filtered through a 14μ filter, or through a 1.2μ filter if diluted 1:1. Filtration is even more difficult for Kodak Metal Etch Resist, and is virtually impossible with undiluted material;

Key words: nephelometry, photolithography, filtration.

therefore, unpurified KMER is not used for high-resolution work in spite of its greater adhesion (1) as compared to KTFR and consequent potential for high-resolving power. A somewhat complex purification procedure to prepare usable KMER was developed a few years ago by Harrel of Texas Instruments (2).

In this work we describe a quantitative comparison between filtration and centrifugation techniques for cleaning both KTFR and KMER. The cleanliness of the resists was determined and monitored during the course of cleaning by measuring the intensity of light scattered from the solutions. Light scattered in this way is primarily a function of particle size and concentration; contributions from the solvent are relatively small and could be ignored. Since cleaning of the resist is largely a matter of eliminating pre-crosslinked material and particles of foreign matter, light scattering is, thus, a good measure of resist cleanliness.

The truth of this proposal can readily be ascertained from Fig. 1, where scattering-filtration data are compared for old and new samples of KTFR. Presumably the difference between the curves results from the fact that the old sample contains thermally cross-linked material.

Experimental

The light scattering apparatus has been described in detail elsewhere (3). In this work a He/Ne laser operating at 6328Å was used as a light source and scattering measured at a fixed angle of 90°. All scattering intensities were normalized against the intensity measured at the same angle for pure xylene. The standard was measured before and after each resist measurement.

Filtration is normally performed immediately prior to resist application, using syringe-mounted filters operated by hand. This was not a practical solution here because we wished to use fine porosity filters and to filter relatively large volumes. We, therefore, designed a filter holder capable of operating to pressures of 500 psi. Nitrogen was used as the pressurizing gas, and solutions were filtered directly into a glass-scattering cell having three windows positioned at 0°, 90°, and 180° to the incident light.

For centrifugation we used a small centrifuge capable of producing 1300g at the center of 50 ml centrifuge cells. Initially we used conventional glass tubes, the material subsequently being transferred to the filtration-scattering cell for monitoring purposes. This method resulted in spurious readings because the solutions were unavoidably disturbed during transfer so that centrifuged residue reappeared in suspension. This problem was overcome by using the specially designed centrifuge-scattering cells illustrated in Fig. 2. The three quartz windows were mounted from the inside and supported by shoulders to withstand the centrifugal pressure; the body of each cell was machined from aluminum, anodized, and dyed black to reduce internal reflections. In operation each cell was filled to at least one centimeter above the top edges of the windows in order to reduce reflections from the liquid-air interface. Covers were used to minimize evaporation.

Results

Because filtration of resists through fine porosity filters is virtually impossible even at high pressure, each resist was diluted to 5% of its original concentration for these experiments. This diluted material was then filtered sequentially through seven filters varying in pore size from 3-0.05μ; scattering intensity was determined after each filtration step. Figure 1 shows the results of such an experiment for one sample tested immediately after receipt from the manufacturer, and for another after three years of storage. The difference between the two is readily apparent and is clearly due to presence of thermally cross-linked material in the old sample. Notice that after filtration through a 0.8μ filter, however, there remained little difference between the two samples.

The filtration curve for KMER is shown in Fig. 3, together with scattering data from the centrifugation experiment. Again, these results were obtained from 5% solutions, but here the limiting filter size was 0.2μ, through which KMER passed only with great difficulty even at a pressure of 500 psi. The curves clearly demonstrate that the resist cleanliness, attained only with difficulty by filtration, is attained in ½ hr and with ease by centrifugation.

A similar result is obtained when filtration and centrifugation are compared for KTFR, as in Fig. 4. Again, the centrifuged material seems to equal in cleanliness that obtained with greater time and difficulty by filtration.

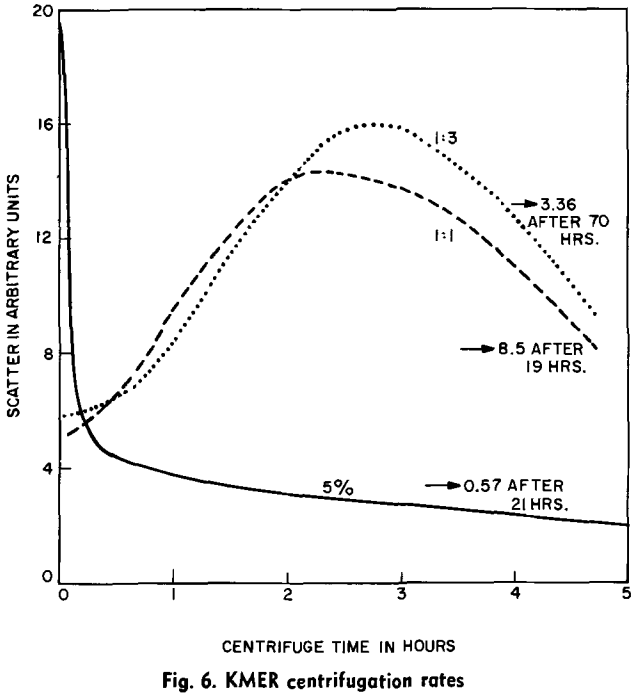

Fig. 6. KMER centrifugation rates

So far we have described cleaning procedures which would result in material which could not be used directly for photolithography because the solutions are too dilute. In practice it is more usual to use material which has been diluted to only 25 or 50% of the supplied concentration. The greater solids content and higher viscosities of such solutions would then result in both centrifugation and filtration being more difficult. Dilute resist solutions can be returned without degradation to their original concentrations by vacuum distillation, but this procedure would be inconvenient to accomplish in production. An alternative solution is to use brute force methods to clean the resists at their normal concentrations. For KTFR, as has been previously described, filtration can be used in this way with moderate success, but for KMER filtration at high-concentration levels is impossible. In both cases, however, centrifugation of the more concentrated material produces excellent results; though naturally longer times are required for the higher viscosities.

Scattering curves for centrifuged samples of various concentrations of KTFR and KMER are shown in Fig. 5 and 6, respectively. The maxima observed in the KMER curves result from multiple scattering; the material is so dirty that both the incident-scattering beam and the scattered light are severely attenuated prior to purification, so that an apparent increase in scattering intensity is observed at first as the resist is purified. A similar, but less pronounced, maximum can be seen in the KMER data of Fig. 3. It is apparent that the cleaning process is still progressing even at these high viscosities. In fact, the curves level off at virtually the same degree of cleanliness, taking into account the difference in particle concentration and therefore final scattering intensities at different dilutions. Thus, a scattering intensity of 0.57 from a 5% solution of KMER after 21 hr centrifuging would be equivalent to an intensity of 5.7 from 1:1 solution, providing scattering is directly proportional to concentration. In fact, the 1:1 KMER solution had a scattering value of 8.5 after 19 hr centrifuging.

The solids content of solutions used in these studies were determined by evaporation of weighed samples

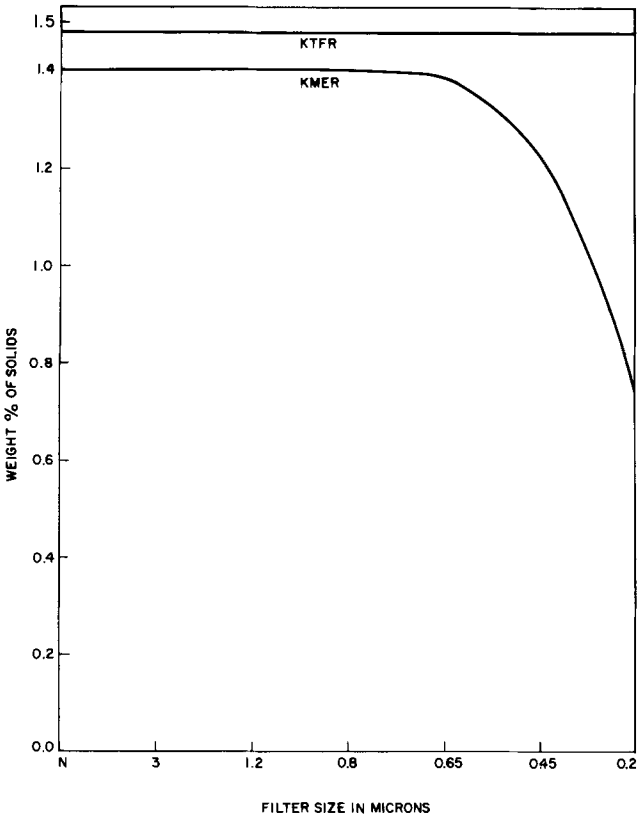

Fig. 7. Variation of solids content of KMER and KTFR during filtration of 5% solutions.

in small aluminum containers. The effect of filtration on solids content of 5% solutions of KMER and KTFR is illustrated in Fig. 7. The nonfiltered values shown here correspond to weight per cent (w/o) solids content in the undiluted solutions of 28.0 for KMER and 29.6 for KTFR. The manufacturer gives values in the range of 24.7-27.3 for KMER and 27.2-28.8 for KTFR. Filtration does not seem to affect the solids content of KTFR, and this is confirmed by the scattering data of Fig. 1 (for the new sample). Apparently there are not many particles larger than 0.2μ in crude KTFR. The solids curve for KMER is also in good agreement with scattering data (see Fig. 3) and suggests that a considerable proportion of this material consists of particles sized in the range 0.2-0.65μ. The weight per cent solids content of KMER after filtering through the 0.2μ filter has been reduced to 11.6 (computed for the initial concentration). Such a reduction might be expected to have an adverse effect on adhesion; however, our measurements indicate that centrifugated KMER is superior in adhesion to KTFR by a factor of approximately 2. We have also demonstrated that the purified KMER is at least capable of matching KTFR for pattern generation. Clean 1μ lines have been resolved.

Conclusion

We have demonstrated that light scattering can be used as an effective monitor of photoresist cleanliness. The technique was used to follow in detail, and to compare, filtration and centrifugation procedures for cleaning both KMER and KTFR.

Results are most significant for KMER which is impossible to clean effectively by filtration but which can be easily and effectively cleaned by centrifugation. The material may be centrifuged at the same dilution at which it would normally be employed, *e.g.*, KMER diluted 1:1 would require centrifuging for approximately 25,000 g-hr.

We recommend the use of centrifuge cleaned KMER in all applications where KTFR would normally be used for high-resolution work.

Optical Properties of Silicon Nitride

Herbert R. Philipp

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The optical properties of silicon nitride layers formed by the pyrolysis of a mixture of SiH_4 and NH_3 are presented. These results are used together with published data for SiO_x materials to formulate a bonding model for SiN_x and SiO_xN_y which quantitatively describes their optical characteristics. The basic units of this structure are Si tetrahedra of the type $Si\text{-}(Si_xO_yN_z)$ in which the distribution of atoms for all possible $x + y + z = 4$ is statistical for any given atom ratio.

The use of silicon nitride films in semiconductor technology has prompted a number of investigations concerning their electrical and chemical characteristics (1, 2). The optical properties of this material, on the other hand, are relatively unknown. This is due in part to the fact that the spectral region where these layers absorb light strongly is in the vacuum ultraviolet, and this wavelength range is not accessible with conventional measuring equipment. In addition there is no theory for this absorption and thus such data, even if available, would appear to have little analytical value.

Key words: reflection spectra, optical constants, silicon oxynitride, bonding model.

In a recent paper (3) we presented and discussed the optical properties of noncrystalline SiO_x materials for $x = 0 \rightarrow 2$. The data could best be interpreted by assuming the bonding to be of the type $Si\text{-}(Si_yO_{4-y})$ where the four atoms bonded to each Si are determined by statistics for any given atom ratio. We related the presence of Si-Si and Si-O bonds in these materials with certain rather general optical characteristics. In

addition we were able to correlate the presence of like bonds of the dimension of a Si-(Si_4) and Si-(O_4) tetrahedron with more specific optical structure which shows up in the data and which is a prominent and distinguishing feature of the curves for amorphous silicon and quartz, respectively, in bulk. This point of view had not been considered previously.

The present investigation (4) was undertaken in the expectation that the simple concepts outlined above might prove useful in the discussion and comparison of silicon nitride films made under various conditions and having different stoichiometries. By evaluating those optical characteristics particular to Si-N bonds and utilizing our knowledge of the properties of Si-Si and Si-O bonds, we may be able to account for the optical effects which show up in silicon nitride layers containing excess Si (5, 6) or new atom constituents such as oxygen (1). Thus the position of the absorption threshold or the value of the index of refraction could have quantitative significance in characterizing such materials.

To test this approach, the optical properties of silicon nitride must first be documented. This is the main task of the present paper. It is accomplished by analyzing a variety of data including that obtained from reflectance and transmission studies and by utilizing the Kramers-Kronig relations (7) to find a consistent set of optical parameters for the range of photon energies where silicon nitride absorbs strongly. For completeness, photoelectric data were also obtained which enables the electron affinity to be estimated (8).

The material selected for this study is noncrystalline silicon nitride formed on silicon or quartz substrates at 1000°C by reaction of a gaseous mixture of silane and ammonia in the ratio 1 to 40,000 (1). Such layers have a stoichiometry very near to that of crystalline Si_3N_4 yet possess at most only short range atomic ordering (2). Thus we are able to relate the properties we find to a rather localized environment of Si-N bonds. This feature is essential to the discussion of SiO_xN_y materials which we envision as made up of a network of Si atoms tetrahedrally bonded to other Si, N, or O atoms where the distribution of different Si-($Si_xO_yN_z$) tetrahedra for all possible $x + y + z = 4$ is statistically determined for any given atom ratio.[1] We will show that this model (3) is vastly superior in explaining the observed optical properties than the one generally considered (9) which treats such materials as mixtures of Si, Si_3N_4, and SiO_2 compounds. We shall use data obtained on chemical vapor deposited samples of SiO_xN_y prepared as above but with the addition of NO gas (1) to help support this conclusion.

Procedures and Results

The optical properties of any material may be described by the complex frequency dependent dielectric constant $\epsilon = \epsilon_1 + i\epsilon_2$ which in turn is related to the optical constants n and k by $\epsilon_1 = n^2 - k^2$ and $\epsilon_2 = 2nk$ (10). The extinction coefficient k describes the attenuation of the electromagnetic wave as it traverses the material. It is simply related to the absorption coefficient by $\alpha = 4\pi k/\lambda$ where λ is the wavelength of the light in vacuum. The real part of the index of refraction n has particular significance in the region of optical transparency where it describes the propagation velocity of the light wave. These parameters can be evaluated from transmission and reflectance studies which take into account interference effects and the presence of a substrate (11).

In the present study reflectance data were obtained from silicon nitride layers on polished silicon substrates (*i*) in the region 6 to 24 eV where this material is opaque and (*ii*) in the region 1 to 6 eV where these layers are transparent and the position and magnitude of interference minima enable n and hence the reflectance R for silicon nitride to be evaluated.[2] The experimental procedures used here have been described previously (10, 12). The uncertainty in the smooth curve of reflectance shown in Fig. 1 is estimated to be less than 5% in the region 1-10 eV and possibly larger at higher energies. From this curve initial values of n and k were computed in the range 1-24 eV using the Kramers-Kronig relation

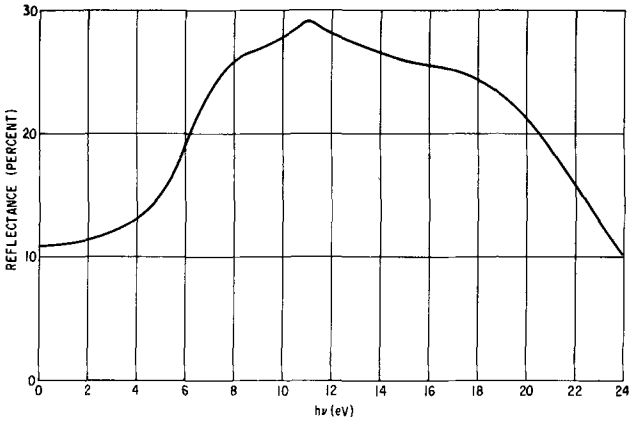

Fig. 1. The spectral dependence of the reflectance of silicon nitride.

$$\theta(\omega_0) = \frac{1}{2\pi}\int_0^\infty \frac{d\ln R(\omega)}{d\omega} \ln\left|\frac{\omega+\omega_0}{\omega-\omega_0}\right| d\omega \quad [1]$$

which connects

$$R = |r|^2 = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \quad \text{and} \quad \tan\theta = \frac{-2k}{n^2 + k^2 - 1} \quad [2]$$

where $r = (n - ik - 1)/(n - ik + 1) = |r|e^{i\theta}$. This procedure is described in more detail elsewhere (13).

Transmission data were obtained in the range 4-8 eV for silicon nitride layers of various thicknesses on quartz substrates to independently and more accurately evaluate k in this energy span. For absorption coefficients greater than 10^3 cm^{-1} these results are reasonably precise (±5%) and are presented in the curve for absorption given in Fig. 4 below. These values were used to correct those obtained above and a second Kramers-Kronig analysis was performed using

$$n(\omega_0) = 1 + \frac{\lambda(\omega_0)}{4\pi^2}\int_0^\infty \frac{d\alpha(\omega)}{d\omega} \ln\left|\frac{\omega+\omega_0}{\omega-\omega_0}\right| d\omega \quad [3]$$

to again compute n (and thus R) for the region 1-24 eV (7). These procedures were repeated until a set of values for n and k were obtained which best agreed with the experimental reflectance and transmission measurements and were consistent with both Kramers-Kronig causality relations. The results for ϵ_1 and ϵ_2 are shown in Fig. 2. More detailed graphs of the index of refraction and absorption coefficient for selected energy ranges are presented in Fig. 3 and 4.

Photoelectric data were obtained for silicon nitride layers on silicon substrates using sealed-off vacuum tubes with LiF windows.[3] The techniques employed here have been described previously (8). The photoelectric yield curve is plotted in Fig. 5.

Transmission and index of refraction data were obtained on a series of films, 6000Å thick, on quartz substrates prepared in the manner previously described but with the addition of various amounts of NO gas to the silane and ammonia mixture (1). This intro-

[1] The numbers x and y used to denote a range of stoichiometry in SiO_x, SiN_x, and SiO_xN_y materials are not related to the integers x, y, and z which describe possible tetrahedra types.

[2] The n and k values of the silicon substrate used in this determination were taken from H. R. Philipp and E. A. Taft, *Phys. Rev.*, 120, 37 (1960).

[3] These samples were exposed to the atmosphere prior to mounting in the tube. The surfaces are thus not uniquely characterized, and the results should be considered approximate.

duces oxygen into the material and forms silicon oxynitride, SiO_xN_y. The photon energy at which the transmission is 10% and the index of refraction for light of wavelength 6000Å are shown in Fig. 6 as a function of the per cent of injected NO gas. The amount of oxygen introduced into the films by this process appears to saturate with increasing NO percentage at a lower value than expected. We do not understand this effect since the "pyrolytic" decomposition of silane and NO gas alone produce layers of SiO_2 which do not absorb within the energy scale of Fig. 6 and have an index of about 1.45. It could be an experimental artifact due to the particular way the gases are introduced in the apparatus employed or to some unknown or premature chemical reaction taking place somewhere in the sample chamber. The situation, however, does not affect the results or the discussion below in any known way.

Discussion

We shall take the point of view that the fundamental bonding unit in materials like SiN_x and SiO_xN_y is the

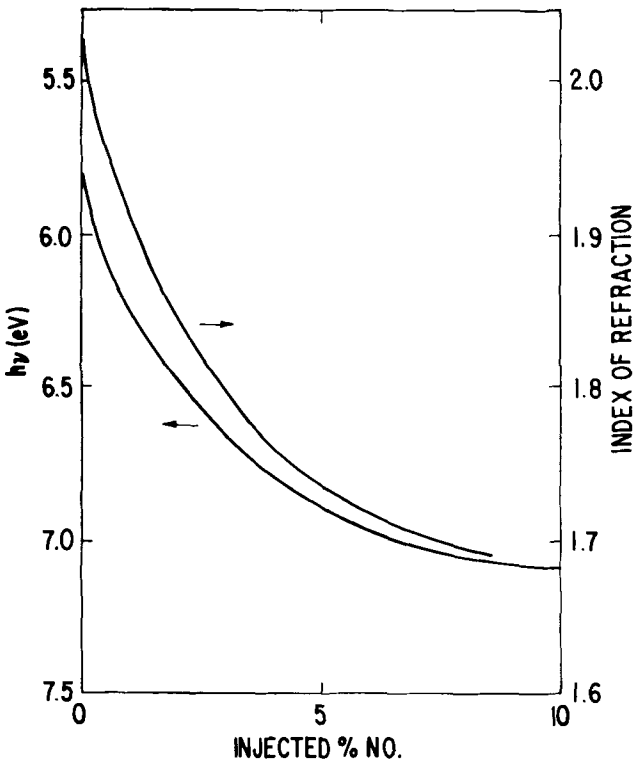

Fig. 6. The index of refraction and the photon energy at which the transmission is 10% for SiO_xN_y films as a function of the per cent of NO gas used in forming the film.

Si tetrahedron and that the atom constituents form bonds with Si on a statistical basis with no dominant rules of selection.[4] That is, for any given atom ratio, the numbers of each kind of atom in the network of Si-($Si_xO_yN_z$) tetrahedra for all possible $x + y + z = 4$ are determined by chance and O-O, N-N, and N-O bonds are assumed not to occur. This is called the random bonding model. The amount of each constituent present in these materials depends on the method of fabrication and in our case on the types of gases present and their pressures, sample temperature, etc. This complicated aspect of the problem is beyond the scope of this discussion. We will make the reasonable assumption, however, that where the amount of silane in the gas mixture is extremely small, there is no excess Si present and we must only consider Si-(O_yN_{4-y}) tetrahedra in this network. In the absence of NO gas in the mixture and for arbitrary silane to ammonia ratios we obviously only consider Si-(Si_yN_{4-y}) tetrahedra.

An entirely different point of view is taken in the analysis of x-ray and electron scattering experiments where these materials are considered to be mixtures of "pure compounds" (9). They claim SiN_x is composed of 10 to 20Å particles of Si and Si_3N_4 and SiO is really a mixture of Si and SiO_2. It should be pointed out, however, that the experimental radial distribution functions from which these results are deduced can be equally well explained using our model (3) provided we make the very reasonable assumption, which is actually inherent in this model, that the individual bond distances are about the same as in the pure materials. The argument is that in such non-ordered systems each scattering event can be considered independently of all others and thus the contribution from one Si-N bond is the same whether this silicon is bonded to other nitrogens as in a Si-(NN_3) tetrahedral grouping or to other silicons as in Si-(NSi_3) or to some random distribution of atoms as in Si-(Si_yN_{4-y}). The radial distribution function counts only the number of atom pairs of each particular kind and in most cases this number would be the same for both the mixture and random bonding model. Differences would actually exist in the radial distribution function calculated for the two models which might distinguish between them, however, this would require a more precise analysis than has been heretofore attempted.

More significantly however, the mixture model fails in several important aspects. It is difficult to cite a mechanism for the growth of such particles especially in materials made at relatively low temperature as in glow discharge deposition apparatus. In addition this model is not able to explain the optical properties and other basic characteristics of these materials. Particles 10-20Å in diameter should exhibit the same optical properties as materials in bulk. Thus the position of infrared bands, the threshold for intrinsic absorption, etc., should essentially stay fixed as the composition is varied since this is the consequence of the existence of these particles. Actually these "markers" and others vary smoothly and continuously with changes in composition (1, 6). The magnitude of these absorptions (or, for example, the value of the dielectric constant) should vary linearly with the amount of each component in the mixture while in reality they are often observed to be grossly nonlinear. We thus conclude that the atom species are blended on a finer scale such that these properties cannot be accounted for by the simple addition of bulk, pure compound characteristics.

We found (3) that data for SiO_x materials could best be interpreted where this blending is on an atomic scale. This result was achieved by postulating there was some reasonable size to a grouping of Si-Si or Si-O bonds which would indeed have the essential optical properties of these bonds in bulk. We calculated the density of such clusters, which had the dimension of a Si-(Si_4) and Si-(O_4) tetrahedra respectively, on the basis of our random bonding scheme and found that the magnitude of the absorption near threshold (and thus its apparent position) and the position and intensity of a prominent absorption peak at much higher energy could be correlated with this density. The same reasoning should apply to SiN_x and SiO_xN_y. We will demonstrate below that data for the latter material shown in Fig. 6 are consistent with the random bonding model and the assumption that a group of Si-N bonds the size of a Si-(N_4) tetrahedra has approximately the optical properties of $SiN_{4/3}$ in bulk. The results of Fig. 6 cannot be explained on the basis of the mixture model.

The optical properties of the tetrahedral bonding arrangements considered in our model are difficult to predict. We can, however, make use of certain sum rules on ϵ_2, which are completely general and valid for any arbitrary system (10) to help clarify various aspects of their expected behavior. The first of these

$$\left(\frac{2\pi^2 N e^2}{m}\right) n_{\text{eff}} = \int_0^{\omega_0} \omega\, \epsilon_2(\omega)\, d\omega \qquad [4]$$

is for n_{eff}, the effective number of electrons per atom or molecule of density N contributing to the optical properties in the energy range to $\hbar\omega_0 = E_0$. Thus according to Eq. [4] the electrons of importance in the bonding of these tetrahedra contribute a definite amount to the integral of $\omega\epsilon_2$ although we cannot off hand specify the energy range involved except for the case where these electrons or bonds are considered in bulk and this equation can be evaluated experimentally.[5] For silicon (3) this integral saturates near

[4] The use of the word tetrahedron or tetrahedral here and below is not meant to imply any particular angle between bonds but simply a coordination number of 4. Such tetrahedra might well be greatly distorted in these materials. We also recognize that the bond energies are different and that the formation of some bonds may be "easier" than others.

[5] In this discussion and elsewhere we consider individual bonds (for example a Si-N bond) to possess "optical properties." We do not mean to imply by this that absorption processes are governed by some particular mechanism or are localized to this degree but rather that through Eq. [4] a definite $\epsilon_2(\omega)$ exists for these bonding electrons. In a similar way a Si tetrahedron can be thought of as having optical properties as do bulk samples which contain many bonds.

4 electrons per atom or 2 electrons per Si-Si bond at 16 eV with most of the contribution occurring in the region 3 to 10 eV. For quartz this integral reaches 8 electrons per SiO_2 molecule or 2 electrons per Si-O bond at ~24 eV with the largest contribution being in the region 12-20 eV. These are the characteristics of electrons in a collection of similar bonds of minimum size corresponding to that of a Si-(Si_4) or Si-(O_4) tetrahedra respectively. Each of these would contribute 8 electrons per tetrahedral unit to the integral of Eq. [4] for energies to ~24 eV. The integrated contribution should also be 8 electrons per unit for mixed tetrahedra, Si-(Si_yO_{4-y}) although the spectral dependence can no longer be precisely specified. A Si-Si bond in a mixed tetrahedron has a higher threshold for absorption (ϵ_2) than a Si-Si bond in Si-(Si_4) and the contribution to n_{eff} occurs mainly in the 4-10 eV range rather than between 3 and 6 eV as in silicon (3). On the other hand, an Si-O bond in a mixed tetrahedra appears to absorb in nearly the same energy span as an Si-O bond in Si-(O_4) although it does not have the sharp features associated with absorption in quartz. Unfortunately, the theoretical framework for any analysis of this behavior is entirely lacking and the most we can present is an empirical picture based on experimental observations.

The second sum rule

$$\epsilon_{0,\text{eff}} = 1 + \left(\frac{2}{n}\right)\int_0^{\omega_0} \omega^{-1}\epsilon_2(\omega)\,d\omega \qquad [5]$$

is for $\epsilon_{0,\text{eff}}$, the contribution to the dielectric constant associated with optical absorption in the energy range to $E_0 = \hbar\omega_0$. This formula describes the effect on ϵ_0 of changes in material density or in the spectral dependence of absorption (possibly associated with variations in composition or methods of preparation, etc.). We shall use Eq. [5] to estimate the composition of the SiO_xN_y material described in Fig. 6. The curve of ϵ_2 for silicon nitride shown in Fig. 2 has a broad maximum near 9 eV and falls off slowly at higher energies decreasing below 1 above 19 eV. The ϵ_2 curve for SiO_2 (3) has a sharp maximum at 10 eV and a similar fall off at higher energies decreasing below 1 above 19 eV. Although the threshold energy for absorption in these materials is different, as will be discussed further below, we note that the main absorption for groupings of both Si-N and Si-O bonds is relegated to the same energy region and has roughly the same spectral shape. If we now make the reasonable assumption that electrons associated with individual Si-N bonds in Si-(O_yN_{4-y}) tetrahedra contribute to an absorption spectrum having these same gross characteristics, which, as mentioned earlier appears to be the case for individual Si-O bonds, then ϵ_2 for SiO_xN_y would depend linearly on the density of Si-O and Si-N bonds present. Thus from Eq. [5] we should have simply $\epsilon_{SiO_xN_y} = f_{SiO_2}\epsilon_{SiO_2} + f_{SiN_{4/3}}\epsilon_{SiN_{4/3}}$ where $f_{SiO_2} + f_{SiN_{4/3}} = 1$ are the equivalent fractions of the material (based on the density of Si-N and Si-O bonds present) which are SiO_2 and $SiN_{4/3}$ respectively. That is, the dielectric constant is a linear function of composition and the index data, $\epsilon_0 = n^2_0$, of Fig. 6 can be used to approximate the composition of our SiO_xN_y material. Knowing this we can calculate the distribution of the five possible tetrahedron types, Si-(O_yN_{4-y}) for y = 0-4, assuming the atoms to be statistically placed.[6]

The absorption of SiO_xN_y should be lower in magnitude than that of $SiN_{4/3}$ in the region of the threshold of absorption in $SiN_{4/3}$, 4.5-5.5 eV, by an amount equal to or greater than the ratio of the density of Si-N bonds in the two materials. This is due to the fact that in SiO_xN_y, Si-N bonds are replaced by Si-O bonds which contribute to absorption only at much higher energy. If absorption processes in these materials are localized to an essentially atomic basis, that is, if the optical characteristics of single Si-N bonds are independent of their environment, then the absorption in SiO_xN_y should be lower than that for $SiN_{4/3}$ by exactly the Si-N bond density ratio. In this case the mixture model would describe these optical properties even though clusters of "pure material" 10-20Å in extent were not present. However we found in our work on SiO_x (3), that absorption processes are not atomically localized but rather extend to a larger unit of the dimension of a silicon tetrahedron and that within this dimension some averaging of possible single bond optical properties takes place. If this is also valid for SiO_xN_y then we would expect that the threshold absorption characteristics of Si-(N_xO_{4-x}) tetrahedra would be progressively shifted to higher energy as the number of oxygen bonds is increased, attaining the characteristics of quartz, with an absorption threshold near 9 eV, when all the bonds are to oxygen as for Si-(O_4) tetrahedra. Thus the absorption in macroscopic SiO_xN_y in the region 4.5-5.5 eV compared to that for $SiN_{4/3}$ would be given by the relative density of Si-(N_4) tetrahedra in the materials and for higher energies would decrease from this ratio as tetrahedra containing oxygen atoms commence their contribution to the optical absorption. At still higher energy, near and above 11 eV, the Si-N bond contribution in all tetrahedra should be closely the same, as discussed previously in connection with Eq. [5]. Since Si-O and Si-N bond absorption are also comparable here, the absorption of all SiO_xN_y materials should be roughly the same at these energies.

We can test the above reasoning using the data of Fig. 6 and 7. We find from Fig. 6 that a SiO_xN_y layer

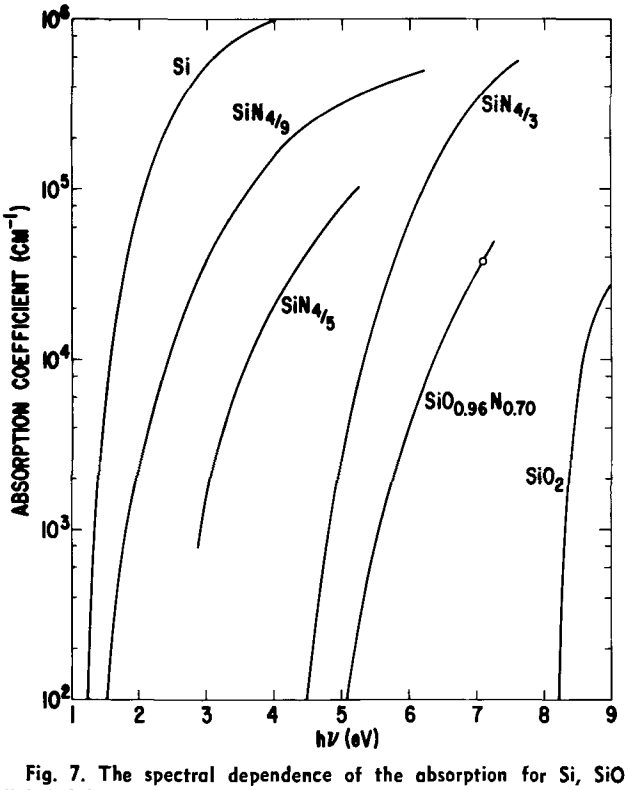

Fig. 7. The spectral dependence of the absorption for Si, SiO (labeled $SiN_{4/9}$), $SiO_{1.5}$ (labeled $SiN_{4/5}$), and SiO_2 obtained from Ref. (3). The basis for relabeling the curves for SiO and $SiO_{1.5}$ is given in the text. The curve for $SiN_{4/3}$ is obtained from Fig. 4. The data point for $SiO_{0.96}N_{0.70}$ and the extension of this curve to lower energies is described in the text.

[6] The ratio of density to formula weight is proportional to the number of atoms corresponding to this formula present in a unit volume of the material. If this quantity determined for $SiN_{4/3}$ and SiO_2 is multiplied by the fraction of the unknown material which is $SiN_{4/3}$ and SiO_2 respectively, as calculated from the dielectric constant, the composition can be determined. Each $SiN_{4/3}$ and each SiO_2 formula unit present contribute 4 Si-N and 4 Si-O bonds respectively to the material. Since these are the only bonds considered here, their probabilities of formation may be found and thus the distribution of tetrahedron types simply calculated.

formed at 10% injected NO has an index of 1.68 ($\epsilon_0 = 2.82$) and an absorption coefficient of 4×10^4 cm^{-1} at 7.09 eV. This point is indicated by the circle in Fig. 7. From the index we estimate[6] the composition to be $SiO_{0.96}N_{0.70}$ and the probability of forming a Si-N bond to be 0.52. Thus the fraction of tetrahedra which are Si-(N_4) is 0.073. This value is slightly smaller than the experimental ratio of absorption at 7.09 eV which, according to Fig. 7, is ~0.1. Unfortunately the data of Fig. 6 are for relatively thin samples. For this large a value of absorption coefficient and for an energy far from threshold (4.5 eV), the experimental ratio should be lower than that calculated since absorption due to Si-N bonds in mixed atom tetrahedra may be contributing. We can extend the curve for $SiO_{0.96}N_{0.70}$ to lower energies by assuming that the ratio of absorption in this material compared to that in $SiN_{4/3}$ is proportionally the same for corresponding values of absorption coefficient as that of SiO compared to Si where for SiO the probability of a Si-Si bond is 0.5. This extrapolation is shown in Fig. 7 and we note that in the region of $\alpha = 10^2$ to 10^3 cm^{-1}, this curve is lower than the one for $SiN_{4/3}$ by the ratio ~0.04. It is this value which should be compared to the calculated one of 0.073. The agreement is very good considering the simplicity of the analysis. We thus conclude that SiO_xN_y is not a simple mixture of SiO_2 and Si_3N_4 particles but rather the atoms are blended on an atomic scale and like bonds of the dimension of a Si-(N_4) tetrahedra have the same optical properties as these bonds in bulk.

In discussing SiN_x we shall assume that Si-Si bonds have the same properties in SiN_x as in SiO_x. That is we assume that for energies below ~5 eV all the absorption is due to the presence of Si-Si bonds and that this absorption is not appreciably influenced by the existence of Si-N compared to Si-O bonds nearby. Thus, neglecting density changes, the absorption curve for $SiN_{4/9}$ should be identical to that of SiO since the probability of a Si-Si bond in each case is ½. The curve for $SiN_{4/5}$ should be identical to that of $SiO_{1.5}$ where the probability of a Si-Si bond is ¼. These curves are drawn in Fig. 7 using the results of (3). It should also be noted that the dielectric constant of SiN_x is not a linear function of the "equivalent" amount of Si and Si_3N_4 present. This is due to the fact that as the number of Si-Si bonds increases not only does the absorption (ϵ_2) increase, but it occurs at lower energy and each of these factors contribute to ϵ_0 according to Eq. [5]. Thus we might expect $\epsilon_{SiN_x} = (1 - 3x/4)^n\epsilon_{Si} + (3x/4)\epsilon_{Si_3N_4}$ where $n \sim 2$, is the number used for SiO_x.

Finally, we can utilize the absorption and photoelectric data to estimate the electron affinity of $SiN_{4/3}$. The photoelectric threshold fixes the valence band relative to the vacuum level and the optical absorption edge corresponds to the valence-conduction band separation. The difference is the electron affinity which for $SiN_{4/3}$ is ~2 eV. However, in the absence of a quantitative theory which assigns a unique threshold energy to the valence band photoemission data and to the optical absorption data, this value is an estimate.

The point of view taken in the above discussion is an obvious oversimplification of the complex factors which control the bonding and optical absorption processes in these materials. It is hoped that this approach has some analytical value in classifying substances like SiN_x and SiO_xN_y. There are a number of other experiments, in addition to those employed here, which would help clarify the bonding in these materials. These include the measurement and analysis of infrared bands for various SiN_x and SiO_xN_y compositions and new work of a more precise nature concerning the measurement and interpretation of x-ray and electron scattering experiments. It should also be emphasized that at the present time there is no theoretical framework for the discussion of these materials. It is further hoped that this paper will stimulate this important and much needed activity.

ABSTRACT

EMF measurements have been made on Cu-Sn, Sb-Sn, and Cu-Sb-Sn molten alloys using molten $SnCl_2$ electrolyte in stirred H-cells. Deviations from the approach to the slope of Raoult's law by emf and vapor pressure data in dilute metallic solutions are discussed. In this case the deviations can be ascribed to a need to correct for reaction between $SnCl_2$ and Cu, although known corrections do not account for similar deviations in all cases. Effects of liquid structuring are discussed in relation to the solution activity equations. A heat of formation of $SnCl_2$ of ~ -81 kcal/mole (as selected elsewhere) is supported. Solute-solute interactions between Sb and Cu have little effect on the tin activity. Possible fine structure in Sb-Sn solutions as suggested by earlier work is not supported.

Many solution theories describe activities, logarithms of activity coefficients, freezing points, heats of mixing, etc., by mathematical-power series involving the solute composition. A single set of constants is assumed to apply over a broad range of solution compositions, and one constant is assumed to be obtainable by extrapolating the measurements to infinite dilution.

Especially for molten alloys (but also for some aqueous electrolytes (1, 2), *e.g.*, divalent sulfates) precise measurements now show that solutions often behave contrary to the assumptions of the theories. For one thing, as pointed out elsewhere (3), in most cases the published activities are not consistent with the constant evaluated at infinite dilution. Also, instead of demonstrating slowly varying behavior, the alloys frequently show sharp changes of behavior; often a two-term power series with one set of constants will apply over a few per cent in composition, and then abruptly (within one tenth of a per cent in composition) a new set of constants will be needed. Furthermore, there can be liquid-phase nucleation problems. Sometimes a phase is observed for many days in metastable equilibrium at a composition beyond its region of true stability.

We use the term "structural complexity" to describe the abruptly changing behavior and metastability. Such complexity has been demonstrated by vapor-pressure studies, calorimetry, emf work, viscosity behavior, solution densities, electrical conductivities, metallography on quenched alloys, and x-ray studies. References to this work can be found elsewhere (3, 4).

In spite of numerous failures, the theories work very well in some cases. When tin is used as the reactive solvent in Sb-Sn (5), Ag-Sn (5, 6), and Au-Sn (5, 6) solutions as measured by emf with molten $SnCl_2$ electrolyte, the calculated activities fall very close to regular solution behavior with its asymptotic approach to the slope of Raoult's law. This relationship holds even though structural complexity is definitely shown in the Au-Sn data (6). For cadmium solutions, using molten salt emf techniques (7-9), the measurements for Ni-Cd, Au-Cd, and Pd-Cd all indicate very nearly the same limiting slope, and this limiting slope can be brought into Raoult's law by assuming corrections for Cd_2^{++} formed by the reaction of Cd^{++} with cadmium (7). Ag-Cd and Cu-Cd behaviors (9) are also perhaps consistent with regular solution theory if other corrections are applied to the data.

In view of the conflicts in detail between the earlier theories and the structural complexity, it becomes important to understand why the older theories worked as well as they did. As discussed earlier (3, 4) part of the answer seems to lie with trends of entropy and enthalpy which pass closely through the complexity; in effect, the complexity often can be treated as a "fine structure" which is imposed on the general thermodynamic trends. Thus, the earlier theories (though simplistic) often can give a good description of the solution behavior although the exact behavior may be quite different (*e.g.*, a constant evaluated as zero at infinite dilution may be far from zero at finite concentrations).

Because so many of the earlier measurements were either imprecise or widely spaced in composition, they cannot answer the question of whether the detailed behavior was approaching Raoult's law asymptotically. Therefore the present detailed emf work with Cu-Sb-Sn alloys was undertaken to examine (*i*) the solvent behavior in two-component alloys and (*ii*) the effect of interactions between solute atoms upon the solvent behavior in three-component systems.

Earlier emf studies with Cu-Sn solutions (10) had shown a shift of relationship between solvent activity and composition at $\sim$0.07 mole fraction of copper, and metallographic studies of very rapidly quenched specimens (11) showed that the shift of behavior was associated with an equilibrium two-liquid region. Thus another purpose (*iii*) was to examine the effect of antimony on the shift of behavior. Regarding the Sb-Sn solutions, the earlier work [(5), as will be plotted later] seemed to indicate structural complexity. Finally, the possibility of important interactions between different kinds of solute atoms in molten alloys has been emphasized recently, *e.g.*, in Ref. (12-14).

Equipment and Procedures

The usual stirred H-cell procedures [*e.g.*, (6-8, 10)] were followed. Reagent grade copper and antimony were used without further purification. Molten reagent grade tin was washed with boiling $SnCl_2$. Reagent grade $SnCl_2$ hydrate was dried, then vaporized in vacuum 3 times (including once in contact with molten tin). The cell volume was used to estimate closely how much $SnCl_2$ was added. Argon was condensed in liquid nitrogen, frozen by evaporative cooling, then distilled

into the H-cell. Tin and $SnCl_2$ were melted together in the cell before solute was added. The H-cell had three legs: (*i*) tin reference, (*ii*) weighed tin to which weighed copper would be added, and (*iii*) weighed tin to which weighed antimony and then weighed copper would be added. All solute additions were introduced *in situ* from sidearms on the cell.

Results and Comments

Table I gives the results of the emf measurements. Figure 1 shows a simple activity-mole fraction plot, based on a calculation of activity using $n = 2$ in $\Delta F = -nF\mathcal{E}$, and on mole fractions from the metals added.

Figure 2 uses the more sensitive plot of $(\log \gamma_{Sn})/N_{Cu}$ *vs.* N_{Cu}. Linearity on this plot corresponds with the equation

$$\log \gamma_{Sn} = \alpha_1 N_{Cu} + \alpha_2 N_{Cu}^2 \quad [1]$$

α_1 is zero only if the intercept is (0,0). As calculated then, the intercept is nonzero. [Elliott and Lemons (6)

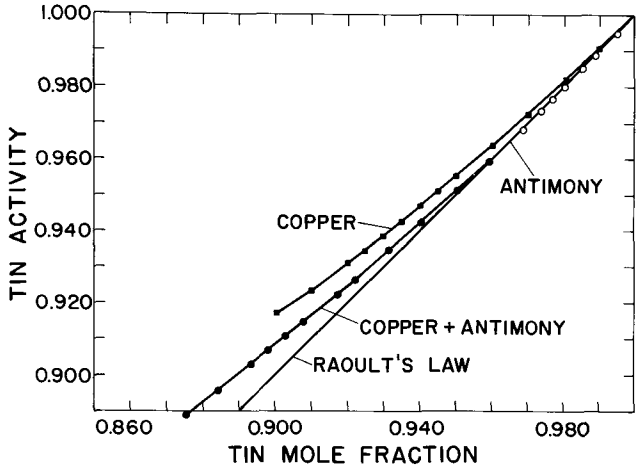

Fig. 1. Tin "activity-mole fraction" relationships for Cu-Sn, Sb-Sn, and Cu-Sb-Sn molten alloys. (See text about calculations.)

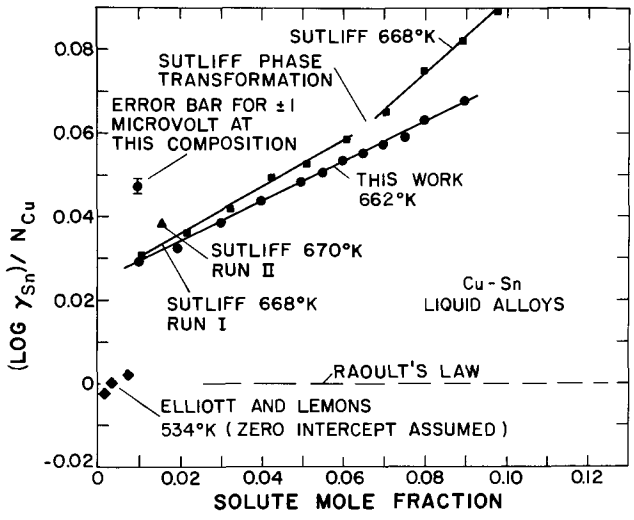

Fig. 2. γ-function plot for Cu-Sn molten alloys. (See text about calculations.)

were not justified in assuming that their limiting slope lay on Raoult's law.] Agreement with Sutliff *et al.* (10) is excellent in the most dilute solutions, but there are small differences in the slope of the line, and finally, the phase change observed by Sutliff *et al.* is not observed in the present results. (The error bar for ± 1 μV is shown in Fig. 2 for the composition indicated. By the right end of the figure, $\pm$ 1 μV is smaller than the data points.)

Figure 3 shows the present Cu-Sn, Sb-Sn, and Cu-Sb-Sn data with the latter system plotted in two ways, *i.e.*, $(\log \gamma_{Sn})/(N_{Cu} + N_{Sb})$ or $(\log \gamma_{Sn})/N_{Cu}$ *vs.* the solute mole fraction. The latter plot superimposes the Cu-Sn and Cu-Sb-Sn data.

Discussion

Superposition of the Cu-Sn and Cu-Sb-Sn plots in Fig. 3 shows that the tin activity is not strongly influenced by mixed solute-solute interactions. This behavior was not necessarily to be expected in view of the mixed solute interactions in three-component alloys, as already mentioned (12-14).

The large bias subtracted in Run 2 appears not to have affected the measurements significantly. Although any large bias is undesirable, the worst uncertainty arises from the bias if a temperature coefficient is taken. Fortunately in this case it was not necessary to take a temperature coefficient.

We do not have thermodynamic data for an accurate calculation of the reactions Cu + 1/2 $SnCl_2$ =

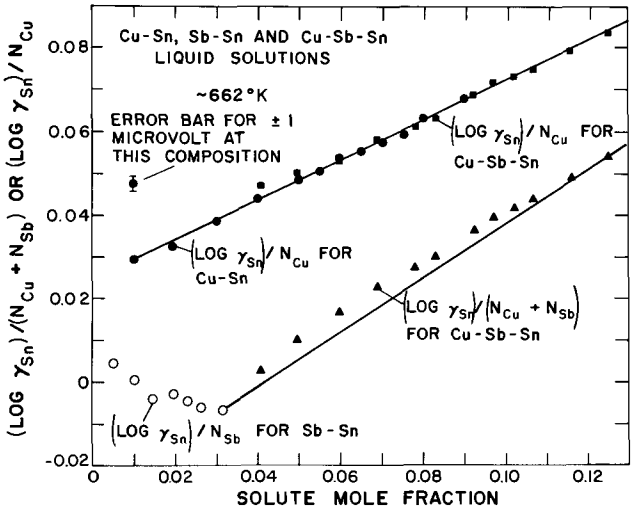

Fig. 3. γ-function plots for Cu-Sn and Cu-Sb-Sn molten alloys. (See text about calculations.)

CuCl + 1/2 Sn and 1/3 Sb + 1/2 $SnCl_2$ = 1/3 $SbCl_3$ + 1/2 Sn. We can, however, roughly predict the extent of these reactions using data from Brewer *et al.* (15).

For the Sb, the exchange reaction should be trivial. $\Delta H°_{298}$ data for the formation of CuCl and $SnCl_2$ are given as −32.6 and −81.1 kcal/mole, and one can use 9.8 and 29 eu for $(\Delta F - \Delta H°_{298})/T$ in the salt melt. Then by assuming unit activity coefficients in the melts, one would predict about 0.025 for the mole fraction distribution ratio of the copper between the molten salt and the alloy.

The distribution ratio would lead to ~2.5% removal of the alloy copper, and it would produce a similar dilution of the $SnCl_2$. These dilution effects would lead one to anticipate about a 5% apparent deviation from the limiting Raoult's law slope. In fact, this apparent intercept is $(\log \gamma_{Sn})/N_{Cu} \approx 0.025$, or the deviation is (0.025) (2.303) (100) ≈ 5.8%.

Thus one can, in this case, account for the whole deviation from the apparent limiting Raoult's law slope as being due to reaction between copper and $SnCl_2$. Such a reaction would also account for the difference in slope between our data and Sutliff's; the proportions of Sn and $SnCl_2$ were not identical in the two cases. (This is a very sensitive plot, and the absolute agreement between our data and Sutliff's is good. For example, at $N_{Cu} = 0.01$ the difference is ~1 μV.)

With reservations one can turn this argument around the other way also. Accepting as a tentative generalization for tin solutions that the tin activities closely approach a Raoult's law slope at these dilutions (in spite of the structuring), and accepting the unit activity coefficients as not in gross error, then Brewer's choice of −81.1 kcal/mole for $SnCl_2$ seems good (15). This value did need confirmation (and still needs further confirmation); it was a value which was included in the original paper (15) which offered estimates and values from meager data in order to present a comprehensive whole; it was not certain enough, however, to include in the tables in "Thermodynamics" (16) which were limited to well-established values.

The plot of $(\log \gamma_{Sn})/(N_{Cu} + N_{Sb})$ is not applicable in this case (Fig. 3) because only the Cu is being extracted into the $SnCl_2$. The Sb is necessary on the abscissa however.

In this case we did not see the phase transformation observed by Sutliff *et al.* at $N_{Cu} \approx 0.07$ and seen (11) in metallographic studies of very rapidly quenched alloys at $N_{Cu} \approx 0.07$. Nucleation of the second phase can be difficult, and liquid metastability can be persistent, as was shown by Sutliff *et al.* We do not consider that there is any contradiction between our results and those of the others.

This phase metastability clouds the issue of the effect of the antimony on the Cu-Sn phase transformation. We did not see the transformation with Sb present, but we do not know if the dilute phase was extended stably or metastably with the added Sb.

Figure 4 compares the present Sb-Sn data with those of Yanko, Drake, and Hovorka (5). The rise at the left of this plot in the earlier data suggested the possibility of fine structure in the Sb-Sn system, and their data at other temperatures showed the same trends. Our results, however, seem to rule out fine structure in this case; there is no indication of a change of behavior of a different slope where the lines of earlier data were lost.

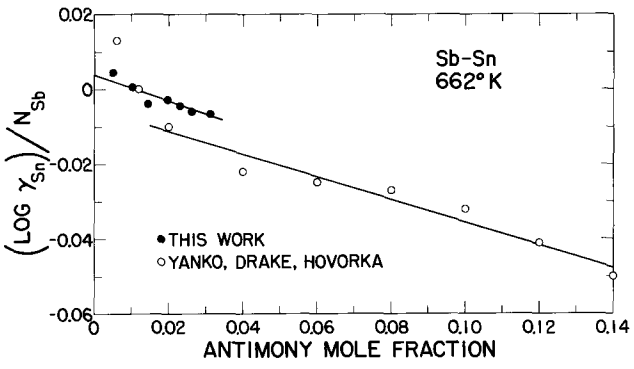

Fig. 4. Comparison of the present and earlier data for Sb-Sn solution emf's. No fine structure is indicated for $N_{Sb} < 0.02$ in the present case.

Summary

In spite of other evidence for structural complexity, the molten Cu-Sn solutions appear to lie very close to regular solution behavior. By comparison with other work, extensive metastability in Cu-Sn solutions is demonstrated. Sb-Sn solutions showed no structural complexity. Interactions between Sb and Cu atoms do not influence the solvent tin activity.

Oxygen Diffusion in Liquid Gallium and Indium

K. A. Klinedinst and D. A. Stevenson*

Department of Materials Science, Stanford University, Stanford, California 94305

ABSTRACT

A potentiostatic electrochemical technique was used to determine the diffusion coefficients of oxygen in liquid Ga and In, for temperatures between 750° and 950°C. The oxygen diffused radially outward in cylindrical samples contained in the bottoms of yttria-doped thoria and calcia-stabilized zirconia electrolyte tubes. The experimental results are expressed by the following equations

$$D_O(\text{Ga}) = (3.68 \pm 0.42)(10^{-3}) \exp\left(\frac{-8.37 \pm 0.25}{RT}\right) \text{cm}^2/\text{sec}$$

$$D_O(\text{In}) = (8.22 \pm 1.87)(10^{-4}) \exp\left(\frac{-12.6 \pm 0.5}{RT}\right) \text{cm}^2/\text{sec}$$

The large observed difference between the magnitudes of $D_O(\text{Ga})$ and $D_O(\text{In})$ is not predicted by current theories of impurity diffusion.

Relatively few investigations of the diffusion of oxygen in liquid metals have been reported in the literature, particularly in systems in which the oxygen solubility is low. There is, however, both fundamental and practical interest in such systems. There is interest in diffusion phenomena as a basis for models concerning the structure and transport properties of liquids. Furthermore, in the use of liquid metals as coolant materials or as solvents in the growth of semiconducting thin films by liquid epitaxial methods, the role of oxygen in the melt is important. In the present study, the diffusion coefficients of oxygen in liquid Ga and in liquid In were determined using a potentiostatic electrochemical technique.

Studies of the diffusion coefficients of oxygen in both solid and liquid metals have been reported in which potentiostatic techniques were employed with calcia-stabilized ziconia (CSZ) as the solid oxide electrolyte. Rickert and Steiner (1) reported measurements of the diffusion coefficient of oxygen in solid silver, and Pastorek and Rapp (2) reported measurements of the diffusion of oxygen in solid copper. In both of these studies, a linear cell geometry was used. Rickert and El Miligy (3) determined the diffusion coefficients of oxygen in liquid silver and copper, using a cylindrical cell geometry. The metals used in all of these studies possess relatively high oxygen solubilities and form oxides with relatively high decomposition pressures. As a consequence, the ranges of oxygen chemical potential encountered in the diffusion studies were within the electrolytic domain of CSZ [ZrO_2 containing 7.5 weight per cent (w/o) CaO] (4).

The metals Ga and In form quite stable oxides, and in particular the decomposition pressures of β-Ga_2O_3 at temperatures of interest in this study are close to the lower electrolytic domain boundary for the CSZ electrolyte (5). Therefore, a sufficiently broad range of oxygen activity for a study of the diffusion of oxygen in liquid Ga would involve oxygen partial pressures outside of the electrolytic domain of CSZ. As a consequence, yttria-doped thoria (YDT) (ThO_2 containing 7.0 w/o Y_2O_3), whose electrolytic domain encompasses much lower oxygen partial pressures than does that of CSZ (4), was used as the electrolyte in this work. However, CSZ was used in some of the experiments with liquid In samples.

Experimental

The electrochemical cell used in this work, shown in Fig. 1, was similar to that described in a previous article (5). Vacuum-tight YDT and CSZ tubes, containing 7.0 w/o Y_3O_3 and 7.5 w/o CaO, respectively, were obtained from the Zirconium Corporation of America. The tubes were about 46 cm long and were closed on one end. The outer diameter of the tubes was about 0.95 cm, and the wall thickness was about 0.045 cm. The inner diameter of the tubes varied from 0.689 to 0.722 cm. The tubes were always helium leak-checked before and after every experiment. Gallium and indium of 99.999% purity were purchased from Eagle-Picher Industries, Incorporated, and Cominco American, respectively. The liquid metal was melted in the bottom of the electrolyte tube and formed a cylindrical column about 10 cm high. A porous platinum electrode (made from Englehard unfluxed platinum paste, No. 6926) extended from the bottom of the electrolyte tube to a height of about 10 cm, to coincide with the height of the column of liquid metal. Electrical contact with the

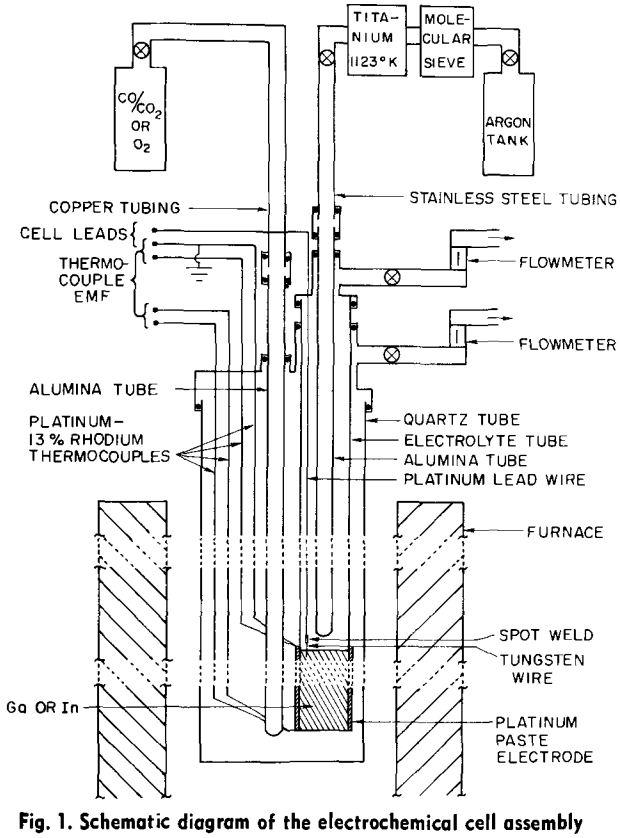

Fig. 1. Schematic diagram of the electrochemical cell assembly

* Electrochemical Society Active Member.

Key words: oxygen diffusion, impurity diffusion in liquid metals, gallium, indium.

liquid metal was made using a short piece of tungsten wire spot-welded to the platinum lead wire.

Two platinum-13% rhodium thermocouples were attached to the extremities of the platinum electrode and were used to determine the sample temperature and the temperature gradient along the column of liquid metal. The cell was heated with a Marshall resistance-heated furnace, 61 cm long with a 5 cm bore. Temperature control of ±1°C was achieved using a Barber-Colman Model 357A Digiset null balance controller. The thermocouple potentials were measured using a Leeds and Northrup K-3 potentiometer and a Leeds and Northrup 9834 null detector. External shunt resistors were used to adjust the furnace temperature profile to produce a temperature gradient of about 1°C along the length of the liquid metal sample with the hotter region on top in order to eliminate possible thermal convection (6). The platinum side of one of the two thermocouples was used to carry the cell current while the other thermocouple was being used to measure the cell temperature.

Argon gas, purified by passing through a column of activated Linde 4A molecular sieve and a column of titanium metal sponge heated to 850°C, was slowly flowed through an alumina tube and over the surface of the liquid metal (to prevent contamination of the metal by gaseous oxygen). Using an oxygen gauge with a YDT electrolyte and porous platinum electrodes, the oxygen content of the argon was determined to be about 10^{-25} atm.

In most experiments, the reference oxygen partial pressures were established with a high purity CO-CO_2 gas mixture, prepared by Liquid Carbonic, Incorporated. The CO-CO_2 mixture was flowed through an alumina tube and over the porous platinum electrode at a rate of 5-10 cc/min. The ratio of the partial pressure of CO_2 to that of CO, determined by I_2O_5 analysis of several different samples of the gas mixture, was 12.50. In some experiments, pure oxygen was used as the reference gas as described below. The oxygen, obtained from Liquid Carbonic, Incorporated, was maintained at a pressure of one atmosphere. It was purified by passing through an Englehard Deoxo gas purifier and a column of activated Linde 4A molecular sieve.

A schematic diagram of the electrical circuit used in the potentiostatic measurements is given in Fig. 2. Constant voltages were provided by the output of a Lambda Model LA50-03B regulated power supply. The output voltage could be instantaneously changed by the use of a calibrated decade resistor wired into the output circuit of the power supply. Voltages were accurately measured with the K-3 potentiometer and null detector. Currents were measured using a Keithley 602 electrometer and were recorded as a function of time with a Hewlett-Packard Model 7101B strip chart recorder.

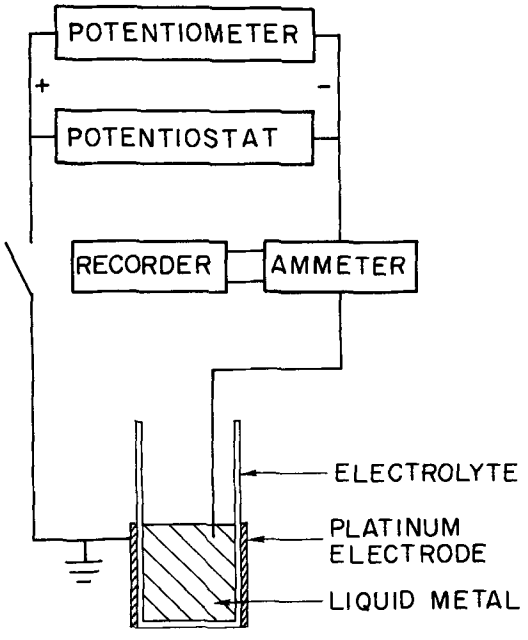

Fig. 2. Schematic diagram of the circuit for potentiostatic measurements.

In a typical experiment, a weighed amount of solid gallium or indium was placed in the bottom of an electrolyte tube. The cell was then assembled in the furnace, and the tube was alternately evacuated and filled with the purified argon gas. The cell temperature was slowly raised to between 850° and 900°C. With the reference gas flowing over the platinum electrode and the argon flowing over the surface of the liquid metal, an emf was applied to the cell so that the oxygen activity in the metal was reduced to a value several orders of magnitude lower than that corresponding to the equilibrium between the metal and its most stable oxide (in order to insure that any residual oxide was dissolved). This deoxygenation was continued for at least 12 hr and until the cell current had reached a value of about 10^{-5}A.

The cell temperature was then adjusted to the desired value and an emf was applied to the cell, corresponding to an oxygen activity in the metal slightly lower than that at which the most stable oxide of the metal forms. After the cell had equilibrated at this temperature and applied emf value, the emf was instantaneously changed to a value corresponding to an oxygen activity in the metal between 10^{-2} and 10^{-4} times the equilibrium value. Oxygen then diffused out of the metal, and the diffusion-limited current was measured and recorded as a function of time. An analysis of the time dependence of the current, for long times, resulted in the determination of D_O in the metal at the cell temperature. An equilibration time of at least 3 hr was allowed between consecutive out-diffusion runs.

Out-diffusion experiments, with either gallium or indium as the liquid metal, were performed using YDT as the electrolyte with the CO-CO_2 reference gas mixture. In addition, some experiments were performed, with indium as the liquid metal, in which CSZ was the electrolyte and either the CO-CO_2 mixture or pure O_2 served to fix the reference oxygen partial pressure. The CO-CO_2 reference gas mixture was used with the YDT electrolyte, rather than a metal-metal oxide mixture, in order to avoid possible errors resulting from anodic polarization.

Calculations

Values of the oxygen partial pressures in equilibrium with the CO-CO_2 gas mixture, $p(O_2,CO\text{-}CO_2)$, were calculated from the data of Wicks and Block (7) and are listed in Table I for temperatures between 750° and 950°C. The authors have previously determined the oxygen partial pressures in equilibrium with Ga and In and their most stable oxides, $p(O_2,Ga\text{-}\beta\text{-}Ga_2O_3)$ and $p(O_2,In\text{-}In_2O_3,In_2O)$, respectively (5, 8). These values are also listed in the table.

The Nernst equation expresses the relationship between the emf applied to the electrochemical cell, the reference oxygen partial pressure, and the activity of atomic oxygen in the liquid metal

Table I. Equilibrium oxygen partial pressures

T(°C)	log[p(O₂, CO-CO₂) (atm)]	log[p(O₂, Ga-β-Ga₂O₃) (atm)]	log[p(O₂, In-In₂O₃,In₂O) (atm)]
750	−17.53	−25.75	−20.14
800	−16.19	−24.02	−18.67
850	−14.96	−22.48	−17.58
900	−13.84	−21.10	−16.70
950	−12.81	−19.79	−15.82

$$\text{emf} = \frac{RT}{2F} \ln \frac{p(O_2,\text{ref})^{1/2}}{a_O(M)} \quad [1]$$

Here, $p(O_{2,ref})$ is the reference oxygen partial pressure [$p(O_2,CO\text{-}CO_2)$ or 1.00 atm, corresponding to the $CO\text{-}CO_2$ gas mixture and pure O_2, respectively], $a_O(M)$ is the activity of atomic oxygen in the liquid metal M, R is the ideal gas constant, $\mathbf{F}$ is the Faraday constant, and T is the absolute temperature. In the limiting case of a saturated solution of O in Ga or In, the following identities hold

$$a_O(Ga)_{satn} = p(O_2,Ga\text{-}\beta\text{-}Ga_2O_3)^{1/2} \quad [2a]$$

$$a_O(In)_{satn} = p(O_2,In\text{-}In_2O_3,In_2O)^{1/2} \quad [2b]$$

Radial diffusion in a cylindrical sample can be treated as if the sample were of infinite length if the ratio of the sample length to its radius is large enough to cause the distortions in the diffusion flux *vs.* time curve (resulting from end effects) to be negligible. It was assumed that this was the case in the present work, since the sample length was about thirty times larger than the sample radius.

The mathematical solution of the diffusion equation for radial diffusion in an infinitely long cylinder has been reviewed by Rickert and El Miligy (3). The diffusion equation in cylindrical coordinates

$$\frac{\partial C}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(rD_O\frac{\partial C}{\partial r}\right) \quad [3]$$

must be solved for the following potentiostatic boundary conditions

$$\begin{aligned} C &= C_o \quad 0 < r < a \quad \text{for } t = 0 \\ C &= 0 \qquad r = a \qquad \text{for } t > 0 \end{aligned} \quad [4]$$

Here, C is the concentration of dissolved oxygen, D_O is the diffusion coefficient of oxygen in the liquid metal, C_o is the initial concentration of dissolved oxygen (assumed to be uniform), r is the radial coordinate, a is the sample radius, and t is the time.

For sufficiently long times, the solution of the diffusion equation can be expressed as (3, 9)

$$\frac{M_t}{M_\infty} = 1 - \frac{4}{\alpha_1^2}\exp\left(-\frac{\alpha_1^2 D_O t}{a^2}\right) \quad [5]$$

where M_t is the amount of oxygen that has diffused out of the cylinder in time t and is given by

$$M_t = \frac{1}{2F}\int_o^t I dt \quad [6]$$

M_∞ is the amount of oxygen that has diffused out of the cylinder in the limit of infinite time (equal to the total amount of dissolved oxygen) and α_1 is the first root of the Bessel function of zero order (having the numerical value, 2.405), and I is the cell current.

Differentiation of Eq. [5] with respect to t results in the following expression for I as a function of t

$$I = \frac{8F D_O M_\infty}{a^2}\exp\left(\frac{-\alpha_1^2 D_O t}{a^2}\right) \quad [7]$$

Thus the value of D_O can be calculated from the slope of a plot of log I *vs.* t. It should be noted that the cylindrical cell geometry allows the determination of D_O without a prior knowledge of the initial equilibrium concentration of oxygen in the liquid metal (*i.e.*, without knowing the activity coefficient for dissolved oxygen as a function of temperature).

An important test of the above solution may be achieved by using a series of potential changes to initiate the out-diffusion process. Assuming that the step change in potential is large enough to approximate the second boundary condition, the calculated value of D_O should be independent of the actual magnitude of the potential change. If the calculated D_O values appear to be functions of the magnitude of the potential step (for sufficiently large steps), then it is probably safe to conclude that the I *vs.* t curve is at least partly determined by some process other than the diffusion of oxygen in the liquid metal.

Results and Discussion

Potentiostatic experiments, in which the YDT electrolyte was used and the $CO\text{-}CO_2$ mixture served as the reference gas, were performed on samples of liquid Ga, for temperatures between 750° and 950°C. For sufficiently long times, the plots of log I *vs.* t were linear to a good approximation. A typical log I *vs.* t plot is shown in Fig. 3. Values of $D_O(Ga)$, calculated from the slopes of such plots, were independent of the size of the potential step used to initiate the out-diffusion process (for steps corresponding to out-diffusion interfacial activities between 5×10^{-2} and 5×10^{-3} times the equilibrium activities).

The initial equilibrium activities used were usually slightly smaller than the saturation values as given by Eq. [2a] and Table I. However, as expected for diffusion of a very dilute solute, changes in the initial oxygen activities were found not to affect the calculated $D_O(Ga)$ values.

Assuming that the temperature dependence of $D_O(Ga)$ can be expressed by an equation of the form

$$D_O(M) = A\exp(-E/RT) \quad [8]$$

a least-squares analysis of the data resulted in the following analytical representation for the diffusion coefficient of oxygen in liquid Ga

$$D_O(Ga) = (3.68 \pm 0.42)(10^{-3}) \exp\left(\frac{-8.37 \pm 0.25}{RT}\right) \text{cm}^2/\text{sec} \quad [9]$$

$$1023 < T < 1223\ K$$

The indicated uncertainties correspond to two standard deviations, and the activation energy is given in units of kcal/mole.

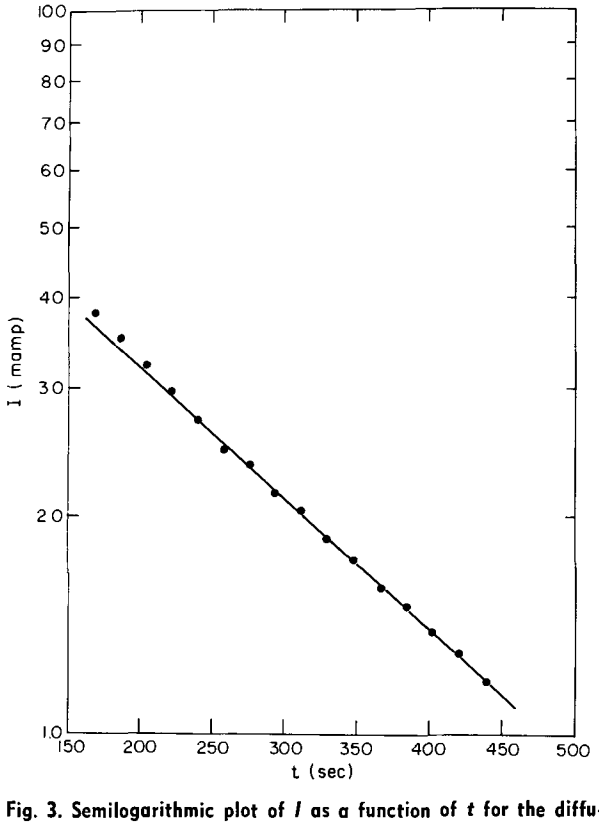

Fig. 3. Semilogarithmic plot of I as a function of t for the diffusion of oxygen in liquid gallium at 850°C.

Similar potentiostatic experiments were performed on samples of liquid In, using the YDT electrolyte and the CO-CO_2 reference gas mixture. The equilibrium activities used were slightly smaller than the saturation values given by Eq. [2b] and Table I. As in the case of diffusion in liquid Ga, the plots of log I *vs.* t were linear for long enough times. A typical log I *vs.* t plot is shown in Fig. 4. As seen from the figure, the slopes of these plots and the derived values of $D_O(In)$ were much smaller than the corresponding quantities for diffusion in liquid Ga.

Additional experiments were performed with liquid In, using CSZ as the electrolyte and either CO-CO_2 or O_2 as the reference gas. The resulting values of $D_O(In)$ were in agreement with the values obtained in the experiments with YDT as the electrolyte.

In all of the experiments with liquid In, $D_O(In)$ values were found to be independent of the magnitude of the potential step used to initiate out-diffusion, for steps corresponding to out-diffusion interfacial oxygen activities between 5×10^{-2} and 5×10^{-3} times the initial equilibrium activities.

The temperature dependence of $D_O(In)$ can be represented by the following expression obtained from a least-squares analysis of the experimental values

$$D_O(In) = (8.22 \pm 1.87)(10^{-4}) \exp\left(\frac{-12.6 \pm 0.5}{RT}\right) \text{cm}^2/\text{sec} \quad [10]$$

$$1023 < T < 1223\ K$$

The indicated uncertainties correspond to two standard deviations, and the activation energy is expressed in units of kcal/mole. The larger uncertainties in $D_O(In)$, as compared with $D_O(Ga)$, resulted primarily from the difficulties encountered in obtaining the diffusion coefficient from the much smaller slopes of the log I *vs.* t plots.

In Fig. 5, $D_O(Ga)$ and $D_O(In)$ are plotted semilogarithmically as a function of $1/T$. The points shown are those given by Eq. [9] and [10], and the error bars indicate two standard deviations. The figure shows clearly the large difference between the rates of diffusion of oxygen in liquid Ga and in liquid In. This result is not predicted by any of the current theories of impurity diffusion in liquid metals.

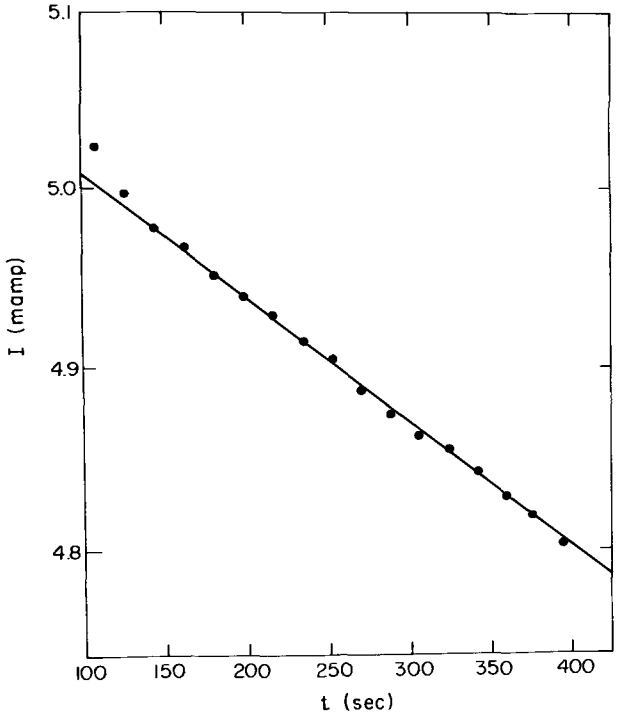

Fig. 4. Semilogarithmic plot of I as a function of t for the diffusion of oxygen in liquid indium at 850°C.

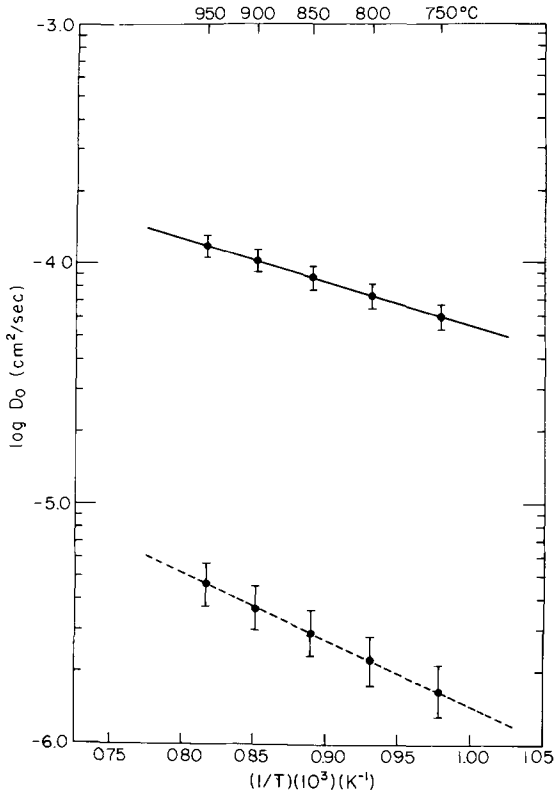

Fig. 5. Diffusion coefficients of oxygen in liquid metals as a function of temperature, plotted as log D_O *vs.* $1/T$. ———, O diffusion in Ga; - - - -, O diffusion in In.

The most important theories of diffusion have recently been critically reviewed (10). What emerged from this review was the fact that almost all of the theories assume that the diffusing atoms and solvent atoms can be treated as noninteracting hard spheres. This assumption may be acceptable for the derivation of self-diffusion coefficients. However, these theories should not be expected to accurately estimate diffusion coefficients in systems such as Ga-O and In-O, where strong interatomic potentials are present (as evidenced by the formation of quite stable oxides).

The factors leading to the large difference between the measured diffusion coefficients of oxygen in Ga and In are not known. However, some insight might be gained by investigating the diffusion of oxygen in liquid Ga-In alloys, as a function of temperature and composition. To the best of our knowledge, the diffusion of an impurity atom in a binary metallic alloy system has never been studied by an electrochemical technique, as a function of alloy composition. In a recent investigation, it was found that the Ga-In system is nearly regular (11). Also, heats of mixing have been shown to be small (amounting to about 275 cal/mole for an equimolar mixture) (12, 13). The relative thermochemical simplicity of this system should increase the chances of such a study producing useful insights into the nature of impurity diffusion in liquid metals.

In order to successfully observe diffusion-limited currents in potentiostatic experiments, it is necessary to use an electrolyte with a sufficiently low internal resistivity. Since CSZ has often been used in such experiments, a comparison of the ionic conductivity of YDT with that of CSZ was sought. Such a comparison has been made by other investigators (14), using samples they prepared containing the same amounts of Y_2O_3 and CaO as those used in this work. It was shown that the ionic conductivity of CSZ is only about three or four times that of YDT, for tem-

peratures between 800° and 1000°C. This fact, and the fact that the D_O(In) values obtained in this work using both CSZ and YDT as the electrolyte were in agreement, indicates that YDT can be safely used as a replacement for CSZ in such measurements.

However, it was found in the course of our experiments that most of the YDT tubes obtained from the Zirconium Corporation of America could not be used. The internal resistivity of the tubes was much higher than expected, as evidenced by the fact that the magnitude of I, for a particular value of t, was roughly proportional to the emf applied to the cell. Further, the log I *vs.* t plots were not linear for these tubes.

In an effort to explain these observations, electron microscope and electron microprobe analyses of the high resistivity YDT tubes were carried out. It was found that the tube surfaces were partially covered with needle-shaped crystallites of Y_2O_3, indicating that a partial segregation of the electrolyte constituents had occurred, probably during the firing process. Since the ionic conductivity of the oxide electrolytes varies significantly with the concentration of the dopant, such segregation would be expected to result in conductivities lower than those observed in the absence of segregation.

Summary

A potentiostatic electrochemical technique was used to determine the diffusion coefficients of oxygen in liquid Ga and In, for temperatures between 750° and 950°C. The oxygen diffused radially outward in cylindrical samples contained in the bottoms of YDT and CSZ electrolyte tubes. The experimental results can be expressed by the following equations

$$D_O(\text{Ga}) = (3.68 \pm 0.42)(10^{-3}) \exp\left(\frac{-8.37 \pm 0.25}{RT}\right) \text{cm}^2/\text{sec}$$

$$D_O(\text{In}) = (8.22 \pm 1.87)(10^{-4}) \exp\left(\frac{-12.6 \pm 0.5}{RT}\right) \text{cm}^2/\text{sec}$$

$$1023 < T < 1223\ K$$

The large observed difference between the magnitudes of D_O(Ga) and D_O(In) is not predicted by current theories of impurity diffusion. A study of the diffusion of oxygen in liquid Ga-In alloys, as a function of alloy composition and temperature, might lead to some insight into the nature of oxygen impurity diffusion in liquid metals.

Brief Communications

Residual Chlorine in O_2:HCl Grown SiO_2

Ronald L. Meek*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Workers in a number of laboratories (1-4) have found that inclusion of small amounts of chlorine-bearing species (Cl_2, HCl, or C_2HCl_3) in the oxidizing ambient (O_2 or H_2O) used for thermal oxidation of silicon results in improved oxide properties. In particular, sodium, or other positive fixed charge, appears to be reduced, and, perhaps more important, the stability of the oxide to bias-temperature stress aging is improved. In order to understand these effects as well as effects on the oxidation kinetics it is useful to know the amount and distribution of chlorine incorporated into the oxide. In this note, results of direct measurement of the chlorine distribution by He^+ ion scattering are reported.

For these experiments 1000Å thick silica films were grown at 1100°C in 1% HCl in O_2 on <111> phosphorus-doped 10 ohm-cm silicon wafers which had been precleaned using a procedure involving NH_4OH and H_2O_2 (5). For control purposes, oxides were also grown at 1100°C in pure dry oxygen.

The chlorine distribution in the oxide was determined by measuring the energy spectrum of backscattered 2 MeV He^+ ions. The Rutherford backscattering technique (6-8) for chemical analysis is now widely used and here only a brief discussion will be necessary.

* Electrochemical Society Active Member.
Key words: silicon oxidation, silica, ion scattering, chlorine in silica.

For energetic ions undergoing Rutherford scattering from a target atom the scattering yield per unit solid angle is given by

$$\frac{dn}{d\Omega} = \frac{n_o N b^2}{16} \sin^{-4}\left(\frac{\theta_c}{2}\right) \quad [1]$$

where

$$b = \frac{Z_1 Z_2 e^2}{\frac{1}{2}\left(\frac{M_1 M_2}{M_1 + M_2}\right) V^2} \quad [2]$$

Z_1 and Z_2 are the atomic numbers of incident particle and target atom, M_1 and M_2 are the respective masses, and θ_c is the center of mass-scattering angle. e is the electronic charge, V is the velocity of the incident ion, n_o is the number of incident ions, and N is the number of target atoms cm^{-2}. The center of mass and laboratory scattering angles are related by

$$\sin(\theta_c - \theta_L) = \frac{M_1}{M_2} \sin\theta_L \quad [3]$$

Since the scattering is elastic, ions scattered from a target atom of given mass at a given θ_L have a characteristic energy, E, given by

$$\frac{E}{E_o} = \frac{M_1^2}{(M_1 + M_2)^2} \left\{ \cos\theta_L + \left(\frac{M_2^2}{M_1^2} - \sin^2\theta_L\right)^{1/2} \right\}^2 \quad [4]$$

where E_o is the ion energy before the scattering event.

For scattering from target atoms of given mass distributed in a substrate, the energy scale may be converted to a depth scale by use of the kinematic energy loss and the specific energy loss rate in the material; namely

$$\Delta t = \Delta E \left\{ \left(\frac{dE}{dx}\right)_{E_{in}} \left(\frac{E_{out}}{E_{in}}\right) + \left(\frac{dE}{dx}\right)_{E_{out}} \frac{1}{|\cos\theta_L|} \right\}^{-1} \quad [5]$$

which relates the energy shift ΔE to thickness increment Δt.

In these experiments a beam of 2 MeV He^+ ions collimated to ~0.05° through two Ta collimators 1 mm in diameter about 2m apart was used. The backscattered He ions were detected at $\theta_L = 177°$ in a 50 mm^2 surface-barrier detector having an energy resolution of 16 keV. This energy resolution corresponds to a depth resolution of about 200Å. Secondary electron suppression and pile-up rejection electronics were used. Samples were surrounded by a baffle cooled to liquid nitrogen temperature and were mounted in a two-axis goniometer. The scattering chamber was maintained at 10^{-6} Torr and the He ion fluence was typically 10^{16} cm^{-2}.

Typical backscattered ion spectra from an as-grown oxide, oriented with the crystal silicon substrate in a random and a <110> axial channeling direction, are shown in Fig. 1. The arrows labeled O and Si denote the energy of ions scattered from oxygen and silicon at the surface. The arrows labeled Cl denote the range of energies for ions scattered from chlorine in the oxide film. For this sample the total chlorine concentration is 5.4 $(10)^{14}$ cm^{-2}, and varies from sample to sample in the range 5-7 $(10)^{14}$ cm^{-2}. Spectra from control wafers show only a few isolated counts in the energy region corresponding to scattering from chlorine.

The oxide thickness, 1000Å, can be checked using the width of the silicon and oxygen peaks corresponding to scattering from the oxide and in this way accurately position the end points for the depth scale corresponding to chlorine in the oxide. Thus we can invert the

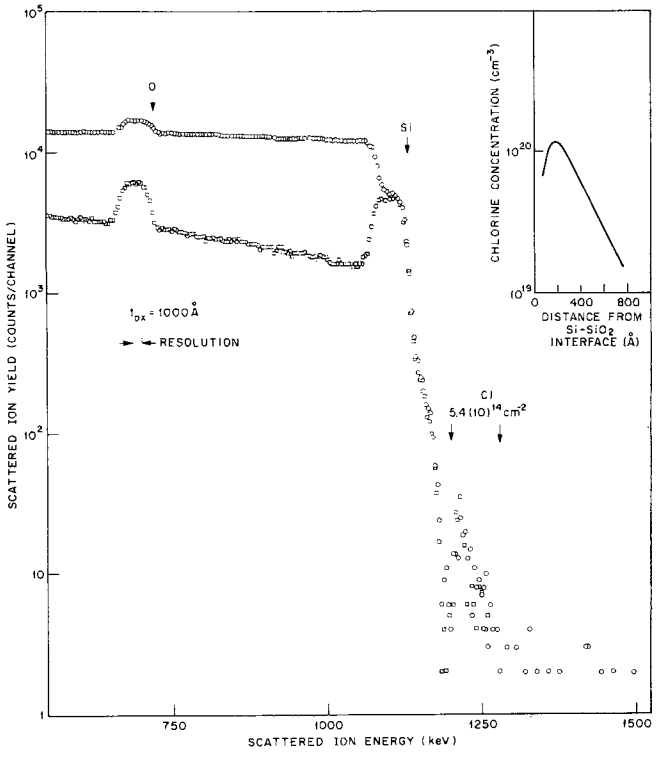

Fig. 1. Backscattered ion spectrum for 2 MeV He ions scattered from a O_2:HCl grown silicon dioxide film on silicon. Ion yield (as counts per channel) vs. ion energy.

observed scattered ion yield from chlorine to a volume distribution for chlorine in the oxide. In doing this one must be cognizant of the fact that chlorine has two abundant isotopes, ^{35}Cl (75.5%) and ^{37}Cl (24.5%). Scattered ions from the two at the same depth are separated in energy by 32 keV. The chlorine concentration in the oxide is given in the insert to Fig. 1. The distribution is always found to be peaked at about 200 ± 100Å from the silicon-silica interface at a level of about 10^{20} cm^{-3}, and drops below 10^{19} cm^{-3} at 500-800Å from the interface. It should also be noted that impurities heavier than chlorine are absent in both pure O_2 and O_2:HCl oxides. The sensitivity for detection of heavier species is about 10^{13} cm^{-2} for mass numbers near Cu, and about 10^{12} cm^{-2} for mass numbers near Au.

If a given wafer is annealed at 1100°C in argon to improve MOS properties, no change in the chlorine distribution is observed. Also, oxides have been bias-temperature stressed at 200° and 300°C with a voltage on the field plate (Al or Au) corresponding to $\pm 10^6$ Vcm^{-1}. Again no shift in the chlorine distribution is observed. However, it does appear that bombardment with 10^{14} cm^{-2} 1 keV Ar^+ can shift the chlorine since in that case we find all of both chlorine isotopes within 200Å of the silicon-silica interface. This latter observation is of significance to the interpretation of impurity profiles in insulating films which are obtained by progressively sputtering away the film since several impurity species, apparently including Cl, are known to become mobilized.

Finally, it is noted that Kriegler (9) recently found from radiotracer Na^{22} studies that the ions in HCl oxides still migrated to the vicinity of the silicon-silicon dioxide interface, but had no effect on the surface potential, presumably because they became neutralized through some interaction with the chlorine containing species. In fact, after drifting to the interface, the Na^{22} distribution was found to be peaked at 200Å from the interface, dropping off by an order of magnitude at the interface and about 500Å from the interface.

Procedure for Polishing PbS and $PbS_{1-x}Se_x$

G. A. Ferrante, M. C. Lavine, T. C. Harman, and J. P. Donnelly

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

For the fabrication of quality p-n junction diodes in PbS and $PbS_{1-x}Se_x$, an etchant which leaves a smooth, undamaged, film-free surface is necessary. The etchant procedures (1-4) previously reported in the literature were found to either badly pit the surface or to leave an insoluble film. Using the etchant technique described below, smooth, damage-free clean surfaces have been obtained, and high quality photodiodes in PbS and $PbS_{0.58}Se_{0.42}$ have been fabricated (5).

Key words: PbS, $PbS_{1-x}Se_x$, polishing, etching, IV-VI compounds.

The PbS and $PbS_{1-x}Se_x$ crystals used in these experiments were grown by the Bridgman method. Both p and n-type crystals, appropriately annealed in either a chalcogenide or metal -rich atmosphere, were used. For example, the p-type PbS crystals were annealed in a sulfur-rich PbS atmosphere for 7 days at 700°C and an additional 7 days at 500°C. They had a p-type

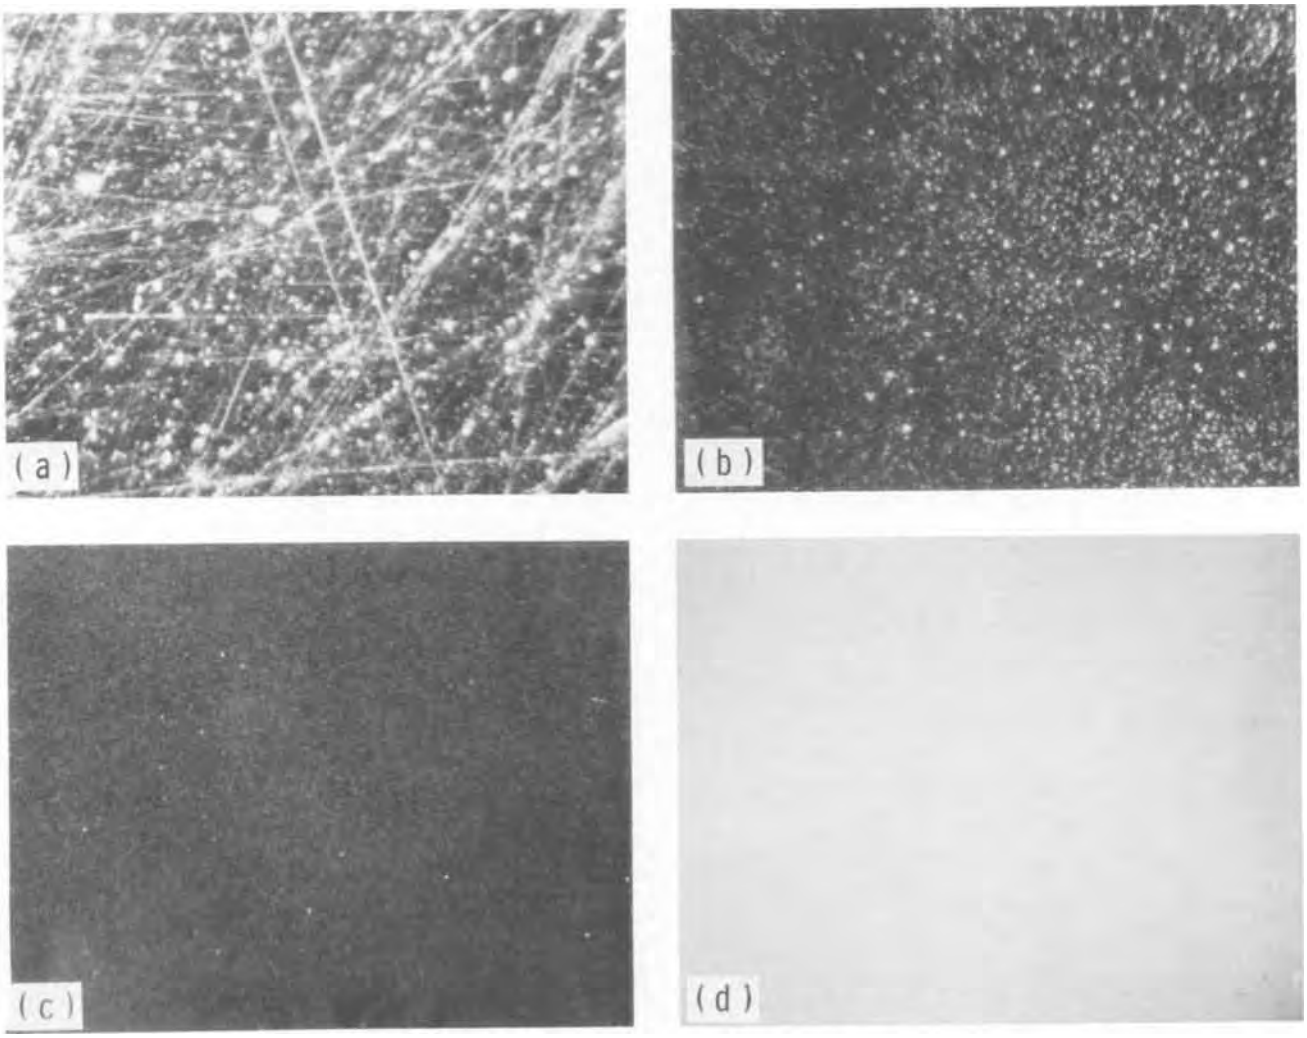

Fig. 1. PbS sample: (a) after lapping with 0.1 μm grit, showing scratches and particles, dark field, 300×; (b) after etching for 15 min in aqua regia at 40°C and rinsing in distilled water showing sulfur particles in film, dark field, 300×; (c) after rinsing in CS_2, CCL_4, and absolute CH_3OH, dark field, 300×; and (d) as in (c), bright field, 300×. Results for PbS_xSe_{1-x} are similar.

carrier concentration of 3×10^{18} cm^{-3} and a mobility of 9000 cm^2/V-sec at 77°K. The etch-pit density of these crystals was about $10^7/cm^2$.

Slices were cut using a 5 mil wire saw. Both unoriented and (100) oriented slices were used. After slicing, approximately 25 μm was removed from each side of the sample by polishing with 2 μm grit. An additional 5 μm was then removed by using 0.1 μm alumina.

Each sample was then etched in a solution of aqua regia (3 parts HCl, 1 part HNO_3) heated to between 35° and 45°C. During etching the aqua regia was vigorously agitated using a Teflon-coated magnetic stirring bar. The sample being etched was held close to the stirring bar but away from the center of rotation using a pair of Teflon-coated tweezers. The agitation close to the sample was found important to minimize film formation. The etch rate was found to be 7 μm per minute at 35°C and 10 μm per minute at 45°C. About 150 μm was removed from each side of the sample during etching. This appears to be more than sufficient to remove any surface damage introduced by lapping and sawing. On removal from the aqua regia the sample was rinsed in a stream of distilled water to dislodge any film formed during etching. The sample was then rinsed in carbon disulfide for $\approx$30 sec to remove any residual sulfur film or specks that were left on the surface. Following the carbon disulfide rinse the sample was further rinsed sequentially in carbon tetrachloride, methanol, and finally deionized water. The surface of each sample was then examined under a metallurgical microscope. If necessary, the above procedure was repeated. Dislocation etch measurements indicate that no additional bulk strain was introduced by holding the samples with the Teflon tweezers.

Figure 1 is a series of photomicrographs showing the surface of a p-type PbS sample after lapping, after etching for 15 min at 40°C in aqua regia, and after cleaning in carbon disulfide, carbon tetrachloride, and absolute methanol. As can be seen, the final surface is polished with a roughness of the order of 0.1 μm. Similar results have been obtained on n-type material. These surfaces have been found suitable for fabricating shallow p-n junction diodes by ion implantation (5).

Leak Rates in Sealed Cells

H. A. Frank* and A. A. Uchiyama*

Jet Propulsion Laboratory, Pasadena, California 91103

ABSTRACT

Water vapor loss rates were determined from simulated and imperfectly sealed alkaline cells in the vacuum environment. The observed rates were found to be in agreement with a semi-empirical equation employed in vacuum technology. Results thereby give support for using this equation for the prediction of loss rates of battery gases and vapors to the aerospace environment. On this basis it was shown how the equation can be applied to the solution of many heretofore unresolved questions regarding leaks in batteries. Among these are the maximum permissible leak size consistent with a given cell life or conversely the maximum life consistent with a given leak size. It was also shown that loss rates of these cells in the terrestrial environment are several orders of magnitude less than the corresponding loss rates in the aerospace environment.

At the present time there is no reliable method for establishing whether a sealed cell is sufficiently leak tight such that it can operate unattended and effectively for a prescribed period of time (1). The phenolphthalein leak test (2) is purely qualitative and gives no indication whatsoever of the magnitude of the leak or its effect on cell life. The vacuum-type "helium" leak test and the "rate of pressure rise" test (3) do give some measure of the size of a leak but, as above, neither of these tests indicate what effect the leak will have on cell life. What is clearly needed to resolve this problem are two additional sets of information. The first is the relationship between leak size, as measured by one of the above or other techniques, and loss rate of leakable components. The second is the relationship between the loss of these components and the cell's electrical characteristics.

The lack of this type of information is explained by the apparent lack of a need for it in the past. This, in turn, is attributed to the fact that leaks have not heretofore represented the primary limitation to cell life. Rather, the life of these cells has been limited by the prior occurrence of degrading chemical and electrochemical phenomena such as dendrite growth, passivation, slumping, and separator degradation.

During the past several years progress has been made in delaying the onset and also reducing the severity of degradative phenomena in sealed cells. As a result it is now quite possible that the life of some of these cells may now very well be limited by leaks rather than the other phenomena. In this regard some models of the nickel-cadmium cell have been shown to exhibit satisfactory electrochemical performance for over ten years. On this basis then, the leakage studies take on renewed importance in that they may very well determine the degree of improvement that may be obtained in ultimate life expectancy and the reliability of a cell, especially during the latter stages of its electrochemical life. This information is needed in many applications of sealed cells, such as in aerospace applications, wherein reliability and life are of prime concern.

* Electrochemical Society Active Member.

Key words: leaks, sealed cells.

This paper deals with the former of the above leakage problems, which is the loss rate of the leakable gases and vapors and primarily for the condition of the aerospace or vacuum environment. The primary objective is to test the applicability of a previously developed mass-transfer equation for the prediction of loss rates under these conditions. Having established this point it will then be possible to determine the cumulative loss of each component based on the known or measured leak size as indicated above. The major emphasis is on a test of the equation for the transport of water vapor in that: (*a*) this compound is one of the key leakable components in this type of cell, (*b*) the transport of water vapor has not heretofore received much study under the conditions as described herein, and (c) the equation has already been shown to be applicable to the transport of other leakable gases, H_2 and O_2, under similar conditions as described herein.

The equation of concern was originally derived by Guthrie and Wakerling in 1949 and was later modified by Ochert and Steckelmacher in 1951 (4, 5). As shown below, it gives the mass flow or leak rate, Q, of a gas through a small hole with a diameter D and length L. The gas pressure on one side of the hole is given by P and the pressure on the other side is zero or a hard vacuum. The terms k_1 through k_4 are constants dependent on temperature and the physical properties of the gas including viscosity and molecular weight

$$QL = k_1D^4P^2 + k_2D^3P + k_3D^2 \ln (1 + k_4DP) \quad [1]$$

Heretofore, Eq. [1] has been used primarily for its intended application which has been in the study of leaks in high vacuum systems. Therein it has proved useful in design of variable and fixed leaks for calibration purposes and for estimating leak rates of gases, including H_2 and O_2, other than those for which a leak has been calibrated.

The following section describes experimental studies aimed at confirming the applicability of Eq. [1] for the prediction of water vapor leak rates from alkaline cells to the vacuum environment. The studies were carried out in simulated alkaline cells and over a wide range of the indicated parameters, including hole

length and diameter as well as electrolyte concentration and temperature, both of which affect water vapor pressure.

Experimental

A schematic diagram of the simulated cell assemblies is given in Fig. 1. These consisted of small glass containers each of which was equipped with a fill tube, a leak assembly, and two vent pipes which communicated with an adjacent cold trap and vacuum manifold line through a three-way stopcock. One of these tubes was used for degassing the electrolyte and the other for transmitting the water vapor which passed through the leak assembly. The leak assemblies consisted of 1.0 cm sections of 0.635 cm diameter stainless steel tubes of which one end was attached to the glass container by a Kovar seal and the other end was sealed off with stainless steel disks of various thicknesses and with holes of accurately known size in their centers. The disks and their holes were prepared either by machining a disk from stainless sheet stock and then laser drilling a hole in its center or by slicing segments of special tubing which had been drawn previously on small diameter wires. The former method was employed for thin disks with small holes and the latter method was employed for thicker disks and somewhat larger holes. In either case the disks were electron beam-welded to the tubes and the complete assemblies were helium leak checked after temporarily blocking off the holes.

The first step in a leak rate determination consisted of connecting the assembly to the manifold of a vacuum system and then partially filling the container with KOH solution of known concentration. The solution was then degassed in the frozen state by placing a Dewar of liquid nitrogen around the container followed by turning the three-way valve to open the degas tube to the vacuum. The Dewar was then removed and the solution allowed to melt; on reaching room temperature, the complete assembly was removed and accurately weighed on an analytical balance. The assembly was then reinstalled on the vacuum system and a run was initiated by turning the three-way valve to open the leak assembly to the vacuum. After a given period of time, which was accurately measured with a stop watch, the run was terminated by removing the assembly from the vacuum and weighing it once again on an analytical balance. Water loss rate was then calculated on the basis of the observed weight loss and the elapsed time. Time under test was selected to be sufficient to obtain a measurable and accurate weight loss of at least 50 mg but yet not so long as to cause a change in the KOH concentration of more than a small fraction of 1%. On this basis the test times ranged from several minutes for the larger sized holes to several hours for the smaller sized holes. The *pH* of water condensed in the adjacent cold trap was measured periodically to insure that there was no KOH entrainment in the evolved vapors. The runs at low and high temperature were carried out in a similar manner to the above but in a bell jar vacuum assembly located in an environmental chamber.

Test Results

Table I gives a summary of the experimentally determined water loss rates in terms of grams/hour for the indicated values of the parameters. Also shown therein are the corresponding theoretical water loss rates, in the same units, obtained by substituting the appropriate values in Eq. [1]. Figures 2 through 5 give graphical representations of these rates as a function of each of the parameters. The water loss rates in these figures are expressed in terms of grams/year to facilitate subsequent battery life estimates. The effect of hole length on loss rate is given in Fig. 2 for the case of a hole diameter of 0.015 cm and with 30% KOH at 20°C. The effect of electrolyte concentration on loss rate is given in Fig. 3 for the case of hole length and diameter of 0.254 cm and 0.015 cm, respectively, and at 20°C. The effect of temperature on loss rate is given in Fig. 4 for the case of hole length and diameter of 0.254 cm and 0.015 cm, respectively, and with 30% KOH. The effect of hole diameter on loss rate is given in Fig. 5 for the case of hole length of 0.025 cm and with 30% KOH at 20°C. The *pH* of condensed vapor samples was found to be in the range of 6 to 7 so that there was little if any KOH entrainment.

Discussion

Examination of Fig. 2 through 5 reveals good correspondence between the experimentally determined

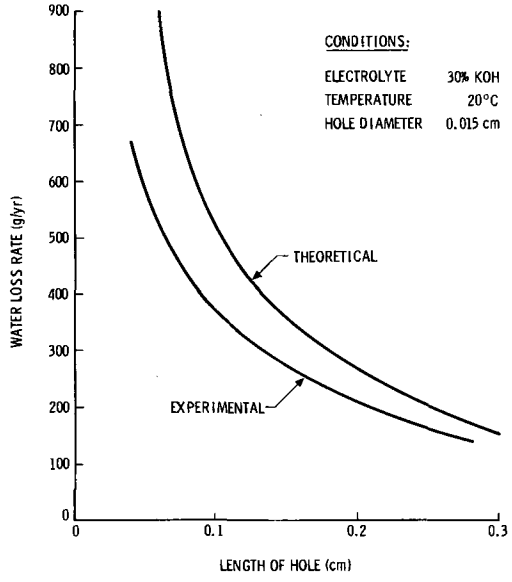

Fig. 2. Effect of hole length on water vapor loss rate

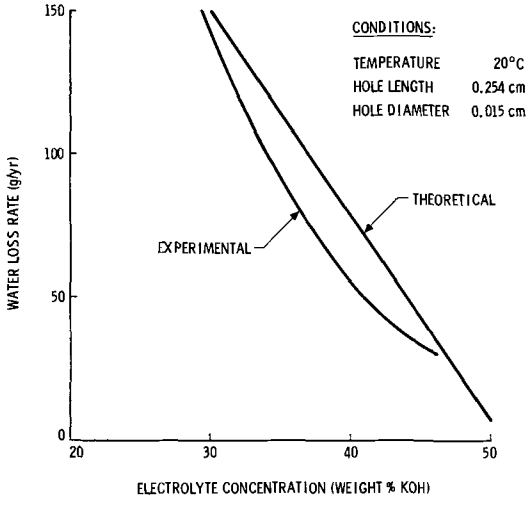

Fig. 3. Effect of electrolyte concentration on water vapor loss rate

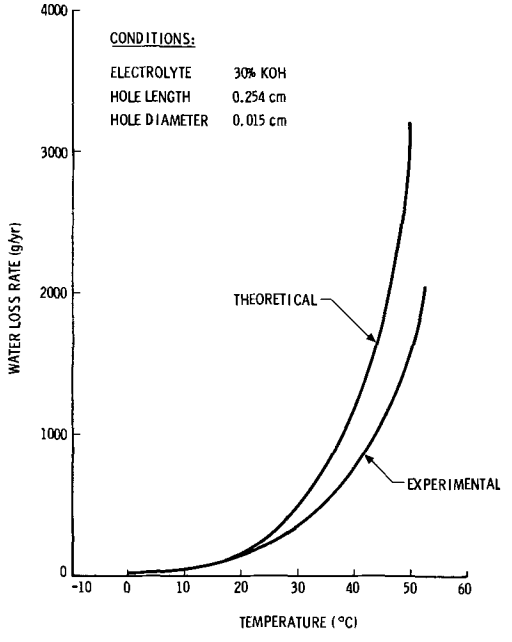

Fig. 4. Effect of temperature on water vapor loss rate

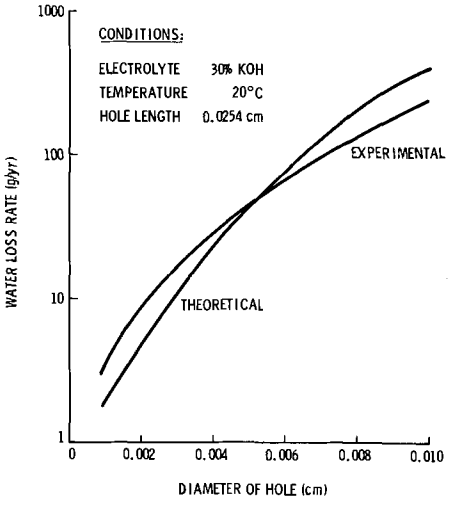

Fig. 5. Effect of hole diameter on water vapor loss rate

water loss rates and those predicted by Eq. [1]. Values of the experimental and theoretical rates are noted to correspond within a factor of two, and usually much less, over the complete range of each parameter. Figure 2 indicates that the experimental water loss rate is inversely proportional to length of the hole in accord with Eq. [1] and there is good agreement in the actual magnitude of the experimental and theoretical water loss rates especially for hole lengths greater than 0.1 cm. Figure 3 reveals that the loss rate declines in an essentially linear manner with increase in KOH concentration. This trend is in accord with theory in that vapor pressure is known to decrease in an essentially linear manner with KOH concentration in this range (6) and furthermore that loss rate is proportional to the first power of pressure under these conditions. The latter follows from the fact that under the given conditions the flow is of the molecular type and the rate is primarily dependent on the second term in Eq. [1] (5). There is also good agreement in the magnitude of the experimental and theoretical water loss rates over the indicated range of KOH concentration. Figure 4 reveals that the loss rate increases sharply with increase in temperature. This is in accord with theory in that vapor pressure, and hence loss rate, is known to be an exponential function of temperature. Good agreement is noted in the magnitude of the experimental and theoretical water loss rates, at least at temperatures below 30°C. Figure 5 reveals that the loss rate also increases sharply with increase in hole diameter. Detailed examination of this curve indicates that the loss rate is approximately proportional to the third power of diameter. This trend is in accord with theory in that molecular flow again predominates under these conditions and the rate is therefore primarily dependent on the magnitude of the second term in Eq. [1] (5). With much larger diameter holes the flow will be of the viscous type and the rate will be primarily dependent on the magnitude of the first term in Eq. [1]. Under these conditions the rate will be proportional to the fourth power of the diameter.

Having established applicability of Eq. [1] to the prediction of instantaneous water loss rates, it will now be applied to the problem of determining cumulative water loss of imperfectly sealed cells as a function of time in the aerospace environment. This problem is quite straightforward and involves integration of the instantaneous rates, taking into account the variation in rate with time due to the changing electrolyte concentration and hence vapor pressure driving force. The process is most conveniently carried out by integrating the losses over assumed short intervals of time wherein concentration and vapor pressure, and hence loss rate, remain relatively constant.

As an example of the above the cumulative water loss of a 20 A-hr aerospace Ni-Cd cell was calculated for each of three different assumed leak sizes. The leaks were assumed to consist of small holes located in the cell's stainless steel cover with assumed thickness of 0.076 cm (0.030 in). To simplify the numerical calculations it was decided to define the leak size in terms of the hole diameter rather than the more commonly employed helium leak rate. Either of these characteristics would have been sufficient, however, in that they are mutually dependent for a given hole length as shown by Eq. [1]. The diameters which were selected for this example were 0.001, 0.003, and 0.010 cm (10, 30, and 100μ respectively). On the basis of Eq. [1] the corresponding helium leak rates are calculated to be 1.3×10^{-3}, 6.6×10^{-2}, and 6.6 cm^3 atm He/sec, respectively. Initial electrolyte content was arbitrarily taken as 80 cm^3 of 30% KOH. This electrolyte level may perhaps be somewhat high for cells of this type, but is at least within a workable range. Results shown in Fig. 6 reveal a marked difference in the cumulative losses for the relatively narrow range of hole diameters. For example, the time required for loss of 20g of water is noted to increase from 2.0×10^{-1} yr to 3.5×10^{2} yr as the diameter is decreased from 100 to 10μ. Although not shown in Fig. 6 it was also determined that the corresponding time for a loss of 20g with a 1.0μ hole is 4.0×10^{5} yr. By way of this example, it has thus been shown how Eq. [1] can be applied to the determination

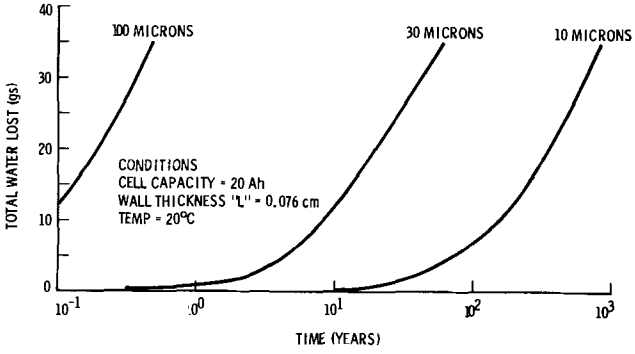

Fig. 6. Predicted cumulative water loss of a typical 20 A-hr aerospace Ni-Cd cell in the space environment.

of cumulative losses over a wide range of leak sizes and operating conditions.

The cumulative loss results, such as above, are directly applicable to the problem of predicting maximum permissible life of a cell with a known leak size or conversely the maximum leak size for a given cell life. All that is necessary to know, as described above, is the relationship between cumulative loss and cell performance. This latter relationship may, as shown in a subsequent paper (7), be derived analytically but is best obtained by experimental data on actual cells. Figure 7 presents such data for an actual Ni-Cd cell which is similar to the one described in the above example. Capacity of this cell was 20 A-hr, as in the above example, and its electrolyte consisted of 66 cm^3 of 33.8% KOH, which is not too different than in the above example. Wall thickness, 0.076 cm, was the same in both examples. Curve A gives the initial discharge characteristics of this cell in the as-received condition. Curves B, C, and D give the discharge characteristics after having removed the indicated amounts of water by venting the cell and exposing it to vacuum. Results indicate a gradual decline in capacity with water loss to about 20g as shown by curve C, where the cell can deliver about 75% of its initial capacity. Thereafter, the results indicate a sharp decline in capacity with water loss to about 28g as shown by curve D, where the cell has essentially lost all of its capacity. Based on these performance results in Fig. 7 and the cumulative loss results in Fig. 6, it is now possible to arrive at quantitative estimates to the above questions. For example, if it is known that this cell has a 30μ hole in its case it can be shown by Fig. 6 and 7 that its maximum life will be approximately 12 years in a space environment if it is to deliver at least 75% of its initial capacity. Alternatively, it could be stated that the maximum permissible leak size would be 30μ if the cell is expected to retain at least 75% of its capacity for 12 years. By way of this example it has been shown

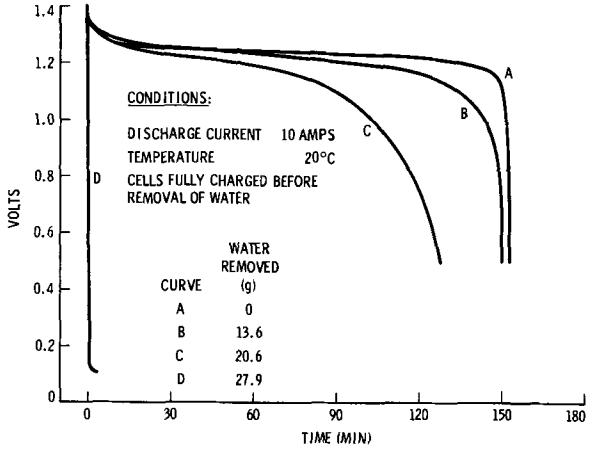

Fig. 7. Effect of water loss on output of typical 20 A-hr aerospace type Ni-Cd cell.

how the previously developed relationships may be employed to determine maximum cell leak size consistent with a specified performance level and life.

The above life estimates apply only to the indicated 20 A-hr Ni-Cd cell. Extrapolation of the procedures to the solution of life estimates for other types and sizes of cells is possible. These extrapolations must consider the pertinent differences in these cells which affect loss rate, *i.e.*, cell dimensions and initial electrolyte content and concentration.

Finally, it is worthwhile to briefly examine the analogous expression to Eq. [1] which describes the rate of water loss to the terrestrial rather than the space environment. This will give some basis for judging the severity of leaks in aerospace cells which may be subjected to long periods of storage before use or in cells which are intended for commercial or industrial use. The pertinent equation, which accounts for the inhibiting effects of air, is given (8)

$$QL = k_5 A P_t (P_1 - P_2/P_m) \qquad [2]$$

In Eq. [2] the terms Q and L again refer to the water loss rate and length of leakage path as in Eq. [1], P_t represents the total system pressure which in this case is 1.0 atm, and P_1 represents the vapor pressure of water inside the cell which can, of course, be determined with known temperature and electrolyte concentration. P_2 represents the vapor pressure of water in the surrounding air which can be determined with the known temperature and relative humidity. P_m is the logarithmic mean pressure of the water vapor which can be determined directly with known values of P_1 and P_2. Finally, the factor k_5 is a constant which can be determined from known values of the diffusion coefficient of water in air, the gas constant, and the temperature.

The magnitudes of the leak sizes predicted by Eq. [2] are found to be appreciably lower than those predicted by Eq. [1] for the same size leakage path. For example, the predicted water loss rate from a cell with 30% KOH at 20°C and with hole diameter of 100μ and length of 0.1 cm is calculated to be 4.6×10^{-2} g/yr to the terrestrial environment with 0% relative humidity and $1.0 \times 10^{+2}$ g/yr, or over three orders of magnitude more, to the aerospace environment. In actual practice the rate predicted by Eq. [2] may be somewhat high due to the existence of normally higher relative humidity than the above and also the impediment to flow that will most likely result from carbonate formation in the hole. On this basis, then, it may be concluded that water loss rates in the terrestrial environment are several orders of magnitude less than those in the space environment and hence maximum permissible leak sizes or operating lives of imperfectly sealed cells will be appreciably higher in the terrestrial than the space environment.

Conclusions

It has been shown that a previously developed mass transfer equation is applicable to the problem of predicting loss rates of leakable gases and vapors from imperfectly sealed alkaline cells in the vacuum environment. Experimental confirmation of this point was demonstrated for the case of water vapor loss from simulated alkaline cells in a vacuum chamber. On this basis it was shown how the equation can be used to obtain quantitative estimates to many heretofore unresolvable questions regarding maximum permissible leak size and life of such cells in the aerospace environment. Finally, it was shown that the loss rate from a cell with a given size leak will be several orders of magnitude less in the terrestrial environment than in the aerospace environment.

The Electrochemistry of Iron in 1M Lithium Hydroxide Solution at 22° and 200°C

Digby D. Macdonald[1] and D. Owen

Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited, Pinawa, Manitoba, Canada

ABSTRACT

The electrochemical behavior of iron in 1M LiOH solution at 22° and 200°C has been investigated using cyclic voltammetry, galvanostatic charging, and steady-state polarization techniques. At 22°C the data are consistent with the initial formation of Fe_3O_4 and $Fe(OH)_2$ on the surface followed by the oxidation of iron to γ-Fe_2O_3 or $Fe(OH)_3$. The anodic behavior of iron at 200°C can be explained by the following processes

$$Fe + 3\,OH^- \rightarrow HFeO_2^- + H_2O + 2e^- \quad [1]$$

$$3Fe + 8\,OH^- \rightarrow Fe_3O_4 + 4H_2O + 8e^- \quad [2]$$

$$3HFeO_2^- \rightarrow Fe_3O_4 + H_2O + OH^- + 2e^- \quad [3]$$

$$Li^+ + HFeO_2^- \rightarrow LiFeO_2 + H^+ + e^- \quad [4]$$

where process [1] accounts for active dissolution of iron, [2] for the direct formation of the base oxide layer from the metal, and [3] and [4] for the nucleation and growth of the "upper-layer" oxide crystals.

The behavior of iron and carbon steel in hydroxide solutions at temperatures greater than 100°C is of practical interest to the electrical energy producing industries, since many of the nuclear and fossil fueled power stations employ dilute hydroxide solutions as heat transport media. Lithium hydroxide is the most commonly used alkalizing agent in nuclear reactors, since lithium gives rise to fewer radiation problems than other alkali ions. The use of lithium hydroxide has also been suggested by Bloom (1) as a means of avoiding boiler pitting due to localized concentration of the feed water alkali. This alkalizing agent is of fundamental interest, since a number of studies (1-4) have suggested that the corrosion mechanism of mild steel in LiOH solution at elevated temperatures is distinctly different from that in NaOH under the same conditions.

The present study was undertaken to define more clearly the electrochemical behavior of iron and carbon steel in lithium hydroxide solution at 22° and 200°C. The electrochemical techniques used include cyclic voltammetry, which is a convenient method of "mapping" the general behavior of solid electrodes (5-9), and the more conventional potentiostatic and galvanostatic methods for studying active to passive transitions. The electrochemical studies were supplemented by detailed examination of the oxide films formed on iron and carbon steel surfaces using scanning electron microscopy.

Experimental

Electrochemical studies.—The high-temperature electrochemical cell used for polarization studies of iron

[1] Present address: Department of Chemistry, Victoria University of Wellington, Wellington, New Zealand.

Key words: electrochemistry, autoclave, corrosion, lithium hydroxide, iron.

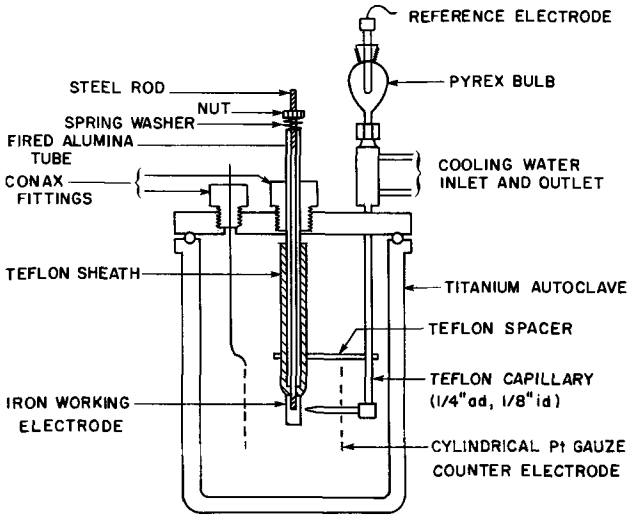

Fig. 1. High-temperature electrochemical cell

in 1M LiOH at 22° and 200°C is shown in Fig. 1. The pressure vessel was constructed from titanium and used without a liner. Analysis of the autoclave contents by atomic absorption spectroscopy after polarization runs lasting up to 10 days failed to detect any titanium in solution (*i.e.* < 0.5 ppm). The working electrode was insulated from the autoclave body by a fired alumina tube. In order to avoid contamination of the solution by aluminate ions, direct contact between the alumina tube and the alkali solution was prevented by a Teflon sleeve. The working electrode assembly was made pressure tight by compressing the spring washers at the top of the alumina tube.

The autoclave was heated by an a-c furnace coupled to an automatic controller which allowed temperature to be regulated to ± 1°C. Since the working electrode was grounded via the potentiostat, it was necessary to isolate the autoclave and furnace from ground and from the rest of the system.

The reference electrode assembly used is shown in Fig. 2. A porous asbestos plug was employed to maintain electrolyte contact between the autoclave contents and the external reference electrode which was maintained at room temperature. By carefully adjusting the compression nut the rate of flow of solution across the pressure drop (~ 250 psig at 200°C) could be reduced to less than 1 ml/week. Initial experiments showed that interruption of the electrolyte column frequently occurred and resulted in the loss of potentiostatic control. The interruptions were attributed to vapor bubble formation in the Teflon capillary, especially at the low pressure side of the system. This

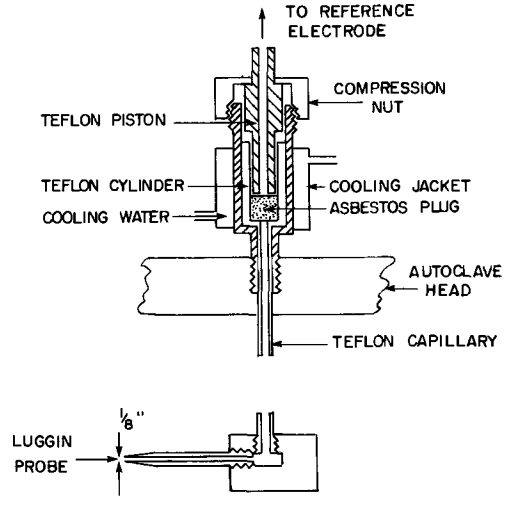

Fig. 2. High-temperature reference electrode bridge

problem was eliminated by cooling the asbestos plug and by inserting asbestos string into the Teflon capillary to act as a wick. The tip of the Luggin probe was held 1 mm from the surface of the working electrode by a Teflon spacer. All potential measurements were made with reference to a $Hg/Hg_2SO_4/K_2SO_4$ (sat.) electrode. This reference electrode was chosen in preference to the more conventional calomel system to eliminate possible diffusion of chloride ions into the autoclave. Chloride ions are known to affect the electrochemical behavior of metals in hydroxide solutions at elevated temperatures (10, 11).

Potentiostatic and cyclic voltammetry studies were performed using an electronic potentiostat coupled to a motor potentiometer. Potentials were measured with a high impedance electrometer and the polarization curves were recorded on an x-y recorder. Galvanostatic experiments were performed using a d-c constant current power supply.

Corrosion studies.—A series of experiments were performed in which 2.54 cm diameter carbon steel disks were rotated in 1M lithium hydroxide solution at 200°C for one to four days. The apparatus consisted of an autoclave and heater assembly similar to that described in the previous section. The autoclave head was fitted with a pressure-tight gland and stirrer connected via a belt-pulley arrangement to a constant speed motor. The disk was rotated at 43.5 rad sec^{-1} (415 rpm) in all experiments. This velocity corresponds to a maximum Reynold's number (Eq. [A] of ~ 7×10^3

$$Re = \frac{\omega r^2}{\nu} \qquad [A]$$

where ω is the rotational velocity, ν the kinematic viscosity (taken as 1×10^{-2} cm^2 sec^{-1}), and r is the radius of the disk. This value is well below the lower limit for transition to turbulent flow (12) and the corrosion process occurs in the laminar flow regime.

In order to eliminate possible precipitation of corrosion products on the metal surface during cool-down, the solution was removed from the autoclave at 200°C via a cooling coil. The disks were then rotated in the vapor space for a brief time to remove any adhering liquid. After cooling, the disks were removed and examined using scanning electron microscopy. Surface charging effects were alleviated by evaporating a film of gold onto the corroded surface prior to microscopic examination.

Materials.—Iron electrodes, 0.635 cm in diameter and 1.27 cm long, were machined from commercially pure material. Spectrographic analysis revealed the following impurities in ppm: C 20, Cu 75, Mn 18, and Ni 80. The area exposed to solution (2.85 cm^2) was polished on a lathe with No. 600 grit silicon carbide paper. The iron electrodes were degreased with acetone immediately before exposure to the solution. A number of experiments were performed with vacuum annealed electrodes (670°C for 24 hr) which were etch-cleaned in 5M HNO_3 before polarization. Unless otherwise noted the electrochemical work reported here refers to the abraded electrodes.

Carbon steel disks, 2.54 cm in diameter and 0.635 cm thick, were machined from commercially available material. Spectrographic analysis revealed the following major constituents (besides iron) in weight per cent: C 0.3, Ni 0.09, Cr 0.1, Sn 0.015, Mo 0.1, Al 0.034, Cu 0.11, Mn 0.75, and Si 0.33. The surface was abraded as described above and washed with acetone and distilled water immediately before commencing an experiment.

Lithium hydroxide solutions were prepared from reagent grade lithium hydroxide monohydrate and doubly distilled water. The alkalinity of each solution was checked by titrating to neutrality with standard hydrochloric acid. All solutions were purged *in situ* with pure nitrogen (99.999%) or hydrogen (99.99%)

gas before the start of each experiment. No specific effects of either gas were noted.

Results

General.—At room temperature (22° ± 1°C) an iron electrode in contact with 1M LiOH spontaneously adopted a corrosion potential of −750 to −800 mV *vs.* the $Hg/Hg_2SO_4/K_2SO_4$ (sat.) reference electrode used in this work. During heat-up (~ 3°C/min) the potential at first changed slowly until the temperature reached ~ 100°C, and then rapidly to −1420 ± 10 mV at ~ 125°C. No further change in potential with temperature was noted during the rest of the heat-up period. The electrode maintained this potential for a certain time and then changed to a stable corrosion potential of −1250 mV. The time taken from the end of the heat-up period until the electrode adopted the stable corrosion potential was found to be highly dependent on the previous history of the autoclave. If the interior walls of the autoclave were freshly sand-blasted this transition frequently took several days to occur. However, if the autoclave walls were covered with a layer of iron oxide from previous runs the transition would occur in a few minutes.

A scanning electron micrograph of the oxide film formed on carbon steel in 1M LiOH at 200°C for 24 hr is shown in Fig. 3. The film is similar to that reported previously by others (13, 14) and consists of two layers: a base layer with little apparent structure at a magnification of 1200X and an upper layer of octahedral crystals. The highly developed crystallographic faces suggest growth from solution as suggested by Castle and Mann (15) and Moore and Jones (16). Similar films were formed on iron electrodes exposed to the same oxidizing conditions and at the stable corrosion potential of ~1250 mV. Further, the morphology of the oxide film did not depend on whether or not the solution was removed from the autoclave prior to cooling. This discounts the possibility that deposition of corrosion products during cool-down contributes to the observed morphology. If the corroding surface was removed from the solution before the potential decayed from −1420 to −1250 mV, only a single layer film was formed which was similar to the base layer shown in Fig. 3. High magnification showed that this layer consisted of small (< 200Å) cubic particles separated by deep channels extending well below the surface. Field *et al.* (17) found that the base layer formed on carbon steel surfaces in 15% NaOH at 315°C had a porosity of 10-15% and that the oxide grains ranged in size from 250 to 5000Å.

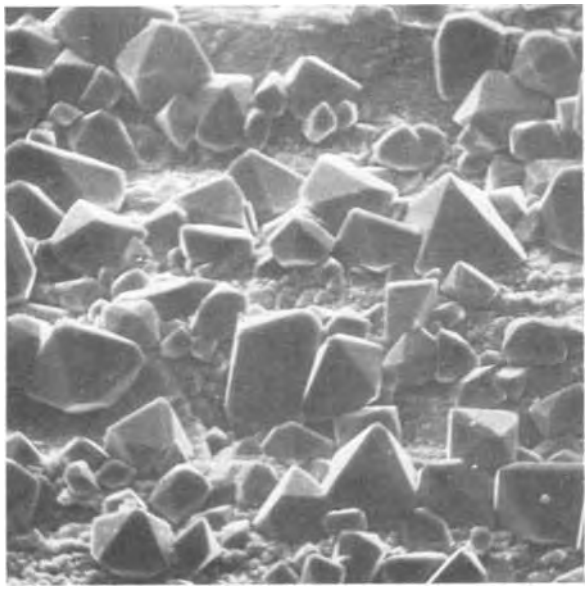

Fig. 3. Oxide film formed at −1250 mV on carbon steel in 1M LiOH at 200°C for 24 hr (×900).

Electrochemistry. — *Cyclic voltammetry.* — Cyclic voltammetry traces for iron electrodes in 1M LiOH at 22° and 200°C are shown in Fig. 4 and 5, respectively. In both cases the potentials at which peaks occur on the anodic and cathodic sweeps were highly reproducible. However, the current passed at any given potential was not very reproducible from run to run and particularly so for the low temperature experiments. It was found that reproducibility improved by first briefly holding the potential of the electrode well into the hydrogen evolution region in order to reduce oxides which form spontaneously on the metal surface. A similar procedure was used by Asakura and Nobe (18) in a recent potential sweep study of iron in 1M KOH at room temperature. In the present work at 22°C the electrode was held at −1800 mV for 10 min prior to sweeping the potential of the electrode to oxygen evolution and back. At 200°C the electrode was held at −1700 mV for 2 min prior to sweeping; the shorter time and lower potential being dictated by the greatly increased rate of hydrogen evolution at the higher temperature. The sweep behavior was not affected by further increasing the potential cathodically nor by holding the potential for longer times.

Double layer capacities (C_{dl}) for metal electrodes in aqueous solutions are usually less than 100 $\mu F/cm^2$ (19). Thus, for an area (A) of 2.85 cm^2 and a sweep rate of 0.0139 V/sec (*i.e.*, 50 V/hr) the nonfaradaic contribution $[C_{dl}A(dE/dt)]$ to the total current should not exceed 4×10^{-6}A. This is several orders

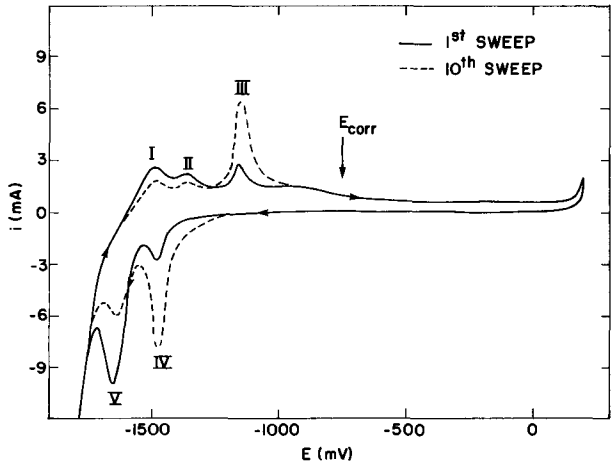

Fig. 4. Cyclic voltammetry of iron in 1M LiOH at 22°C, dE/dt = 50 V/hr.

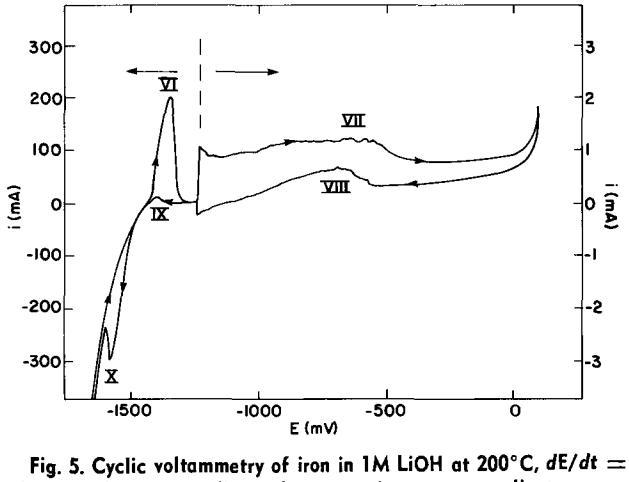

Fig. 5. Cyclic voltammetry of iron in 1M LiOH at 200°C, dE/dt = 50 V/hr. The arrows indicate the appropriate current ordinates.

of magnitude less than the observed current (Fig. 4) and can be ignored. Thus the observed current arises almost entirely from charge transfer for processes which occur at the metal surface.

As seen in Fig. 4, iron exhibits five clearly defined peaks on cyclic sweeping between hydrogen evolution and oxygen evolution at 22°C. Three peaks (I, II, and III) occur on anodic sweeping and two (IV and V) on the reverse cathodic sweep. The current/voltage traces show that on repetitive sweeping the charge consumed at peaks I, II, and V decreases while that consumed at peaks III and IV increases. Further, if the sweep is reversed after each anodic peak (Fig. 6) then both peaks I and II result in a single reduction process at −1650 mV (*i.e.*, peak V). However, if the sweep is reversed after peak III both peaks IV and V occur on the cathodic sweep. Annealed electrodes gave similar results, except peak I was greatly reduced in size relative to peak II and peaks II and V showed little variation on repetitive sweeping.

The cyclic voltammetry behavior of iron in 1M LiOH at 200°C is illustrated in Fig. 5. These experiments tended to be more reproducible than those at 22°C. This probably reflects enhancement of rate processes due to the higher temperature. The electrochemical behavior of iron at 200°C is markedly different from that at 22°C. At 200°C a single, large peak (VI) occurs at −1360 mV on anodic sweeping followed by a broad peak (VII) from −1250 to −500 mV which is characterized by erratic current fluctuations. On the reverse sweep from oxygen evolution the current/voltage trace tends to follow the anodic sweep, including a region of current fluctuations (VIII) and a small anodic "loop" (IX) close to the potential at which peak VI occurs. Further cathodic sweeping results in a large reduction peak (X) at −1600 mV. If the anodic sweep is reversed immediately after peak VI the reduction peak (X) still occurred at −1600 mV. Multiple sweeps resulted in a slight decrease in peak current (< 10%) for peaks VI and X on the second and third sweeps. Further cycling produced super-imposable traces. Finally, the existence of anodic peaks on the reverse sweep (*i.e.*, peaks VIII and IX) are indicative of reactivation processes involving charge transfer reactions which produce ionic products. It is interesting to note that Bignold (6) could find no evidence for similar processes on iron in 0.1-10M NaOH at temperatures between 200° and 250°C.

Cyclic voltammetry studies were carried out at 22° and 200°C using sweep rates of 20, 50, 60, and 150 V/hr. At both temperatures the peak currents were found to increase markedly with sweep rate as has been observed for other systems at 25°C (9, 18). Unfortunately, the peak currents were not sufficiently reproducible at room temperature to allow a quantitative determination of the functional dependence of peak current on sweep rate. At 200°C, however, reproducibility was sufficiently good that this functional dependence could be ascertained and it was found that the peak currents for peaks VI and X were proportional to the square root of the sweep rate. The same functional dependence has also been observed during room temperature studies of iron in 1M KOH (18) and polycrystalline lead in sodium hydroxide solution (9) and indicates that the charge transfer process is mass transport controlled, probably through the diffusion of hydroxyl ions to the metal surface. Finally, it was found that at both 22° and 200°C the potential differences between conjugate oxidation/reduction peaks increased significantly with sweep rate. This indicates that the charge transfer processes occurring on the electrode surface are not very reversible (20).

Galvanostatic charging studies.—Anodic and cathodic charging curves for iron in 1M LiOH at 22° and 200°C are shown in Fig. 7 and 8, respectively. Initial surface treatment consisted of polarizing the electrode cath-

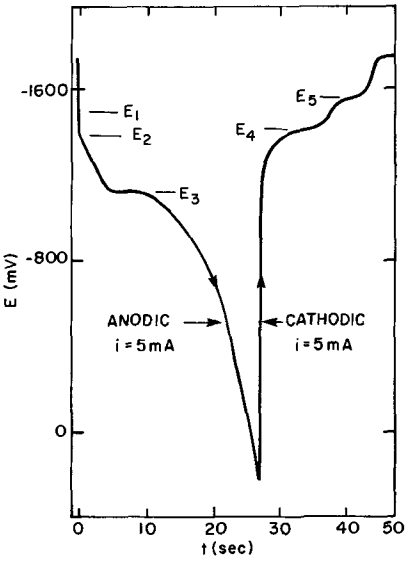

Fig. 7. Galvanostatic charging curve for iron in 1M LiOH at 22°C and at a current of 5 mA. The electrode was polarized cathodically at 5 mA for 2 min prior to anodic charging.

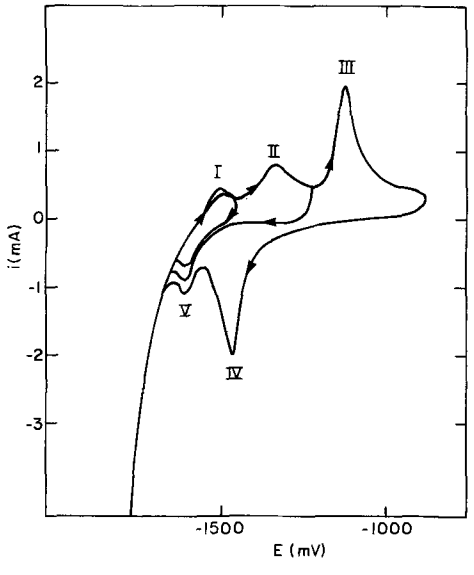

Fig. 6. Cyclic voltammetry of iron in 1M LiOH at 22°C, dE/dt = 50 V/hr. The sweeps were reversed at −1450, −1230, and −880 mV.

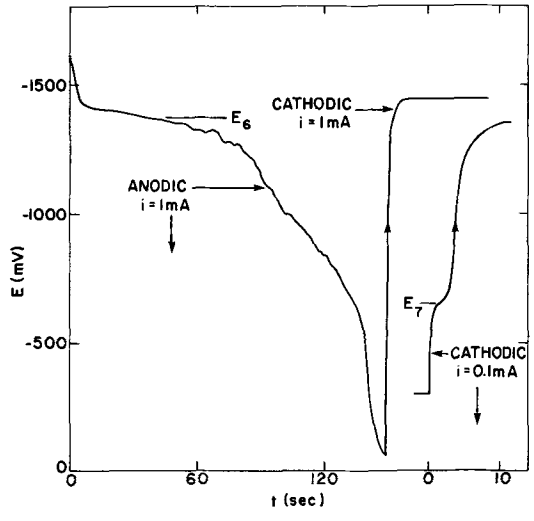

Fig. 8. Galvanostatic charging curves for iron in 1M LiOH at 200°C. The electrode was polarized cathodically at 100 mA for 2 min prior to anodic charging.

odically until the potential remained constant. The current was then reversed and the potential recorded as a function of time. When the potential had reached a preselected value (usually at oxygen evolution) the current was again reversed and the potential recorded on the cathodic sweep. In a few experiments the sequence described above was repeated over a number of cycles (usually five).

Two clearly defined potential arrests were observed on both anodic (E_2 and E_3) and cathodic (E_4 and E_5) sweeps at 22°C (Fig. 7). Improved time resolution indicated the existence of an additional arrest (E_1) at about −1500 mV during anodic polarization. The potentials at which the arrests occur on galvanostatic charging are close to the peak potentials observed in the cyclic voltammetry studies (Fig. 4). This suggests that both the potential arrests and current peaks reflect the same electrochemical processes at the metal surface. Additional support for this hypothesis is gained from cyclic charging studies in which it was found that the charge consumed during the arrests at E_3 and E_4 increased, while that at E_5 decreased, on successive cycling. This is precisely the behavior of the corresponding peaks in cyclic voltammetry (Fig. 4).

The galvanostatic charging curves for iron in 1M LiOH at 200°C are illustrated in Fig. 8. On anodic polarization the potential changes rapidly to −1420 ± 10 mV followed by an arrest (E_6) which extends to about −1300 mV. The latter stages of this arrest are characterized by the onset of erratic potential fluctuations. These potential fluctuations continued as the potential of the electrode drifted to −600 mV. The potential then changed rapidly to oxygen evolution. On cathodic polarization from oxygen evolution the potential changed rapidly to −1450 mV with a brief arrest (E_7) at −650 mV. This arrest is shown more clearly by a cathodic transient at 0.1 mA obtained by first polarizing the electrode anodically at this current for 2 min. Again, there is a close correspondence between the galvanostatic charging behavior and cyclic voltammetry. Thus, the arrest E_6 observed on anodic charging occurs at the same potential as peak VI during the anodic sweep shown in Fig. 5. Further, the region of potential instability shown in Fig. 8 corresponds closely with the region of current instability exhibited during cyclic voltammetry. This is expected in view of the interdependence of current and potential.

Steady-state polarization studies.—Galvanostatic and potentiostatic polarization curves for iron in 1M LiOH at 200°C are presented in Fig. 9. Polarization experiments from the stable corrosion potential at −1250 mV were carried out as follows: the electrode was first held potentiostatically at −1700 mV for 10 min to reduce any oxide on the metal surface and to provide a reproducible initial state. The potentiostat was then turned off and the potential allowed to decay for a preselected time before determining the current/voltage curve for the electrode. The potential first decayed rapidly to −1420 ± 10 mV and held this value for a time which depended on the previous history of the autoclave as described earlier. This was followed by a rapid decay to −1250 mV. The polarization curves were obtained by increasing the current (galvanostatic) or potential (potentiostatic) in increments of 0.05 mA or 50 mV, respectively, every 2 min. In both experiments it was found that the potential and current, respectively, changed only very slightly after 2 min at each setting. Thus, the polarization experiments were performed under very nearly steady-state conditions. Potentiostatic polarizations were carried out 1, 19, and 47 hr after cathodic pretreatment of the electrode. No reproducible dependence of the current/voltage curves on the time between initial cathodic treatment and the start of polarization was noted (Fig. 9). Galvanostatic polarization from −1250 mV was performed 1 hr after cathodic pretreatment of the electrode. Both the potentiostatic and galvanostatic polarization experiments initiated at −1250 mV exhibit a typical active to passive transition at −600 mV, *i.e.*, the same potential as the small arrest (E_7) on cathodic charging. Further, the active region exhibited considerable fluctuations in current and potential and this phenomenon became more pronounced as the potential approached −600 mV. This is precisely the potential region where similar fluctuations are exhibited in cyclic voltammetry and anodic charging studies.

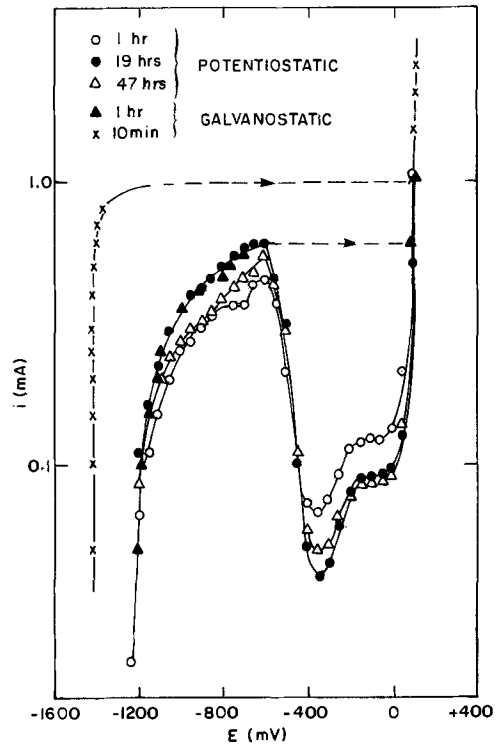

Fig. 9. Steady-state galvanostatic and potentiostatic polarization curves for iron in 1M LiOH at 200°C.

Galvanostatic polarization from the metastable corrosion potential of −1420 ± 10 mV was carried out 10 min after cathodic pretreatment of the electrode. The potential at first changed very slowly until the current was increased to 1 mA. At this point the potential drifted rapidly to oxygen evolution. An attempt was made to obtain a potentiostatic polarization curve from −1420 mV. However, at any potential between −1420 and −1250 mV the current decreased continuously to very small values and no steady-state potentiostatic curve could be obtained in this region.

Discussion

Room temperature study.—A number of previous studies on the behavior of iron in alkaline solution at room temperature have been reported (18, 21-26). Attempts have been made to identify the surface oxides using x-ray and electron diffraction (22-25) and electrochemical methods (18, 21, 26), principally by comparing potential arrests obtained on galvanostatic charging with equilibrium potentials calculated from thermodynamic data (27). These studies have reported the existence of $Fe(OH)_2$, Fe_3O_4, γ-Fe_2O_3, and γ-$Fe_2O_3 \cdot H_2O$ on iron surfaces which have been exposed to highly alkaline solutions.

The cyclic voltammetry and galvanostatic charging studies reported here show that two charge transfer processes occur on iron in 1M LiOH at 22°C between hydrogen and oxygen evolution. Further, the dependence of peak potential on sweep rate, and the large potential differences between the anodic and cathodic peaks, suggests that the charge transfer processes are

quite irreversible and significant overpotentials are required to oxidize or reduce the compounds on the metal surface. Since overpotentials are not included in equilibrium potentials calculated from thermodynamic data there is every reason to expect that experimentally observed potential arrests in charging studies or current peaks in cyclic voltammetry will differ from the calculated values. However, the overpotential ($E - E_o$), where E_o is the equilibrium potential, is positive and negative for anodic and cathodic processes, respectively. Thus, the conjugate oxidation/reduction processes must satisfy the following inequality

$$E_a > E_o > E_c \qquad [B]$$

where E_a and E_c are the potentials at which the potential arrests or current peaks occur on oxidation and reduction.

The first charge transfer process, which gives rise to peaks I and V, is probably the oxidation of iron to $Fe(OH)_2$

$$Fe + 2\,OH^- = Fe(OH)_2 + 2e^- \qquad [1]$$

The equilibrium potential for this reaction at pH = 4 is −1490 mV which satisfies inequality [B] since E_a and E_c are −1470 and −1650 mV, respectively. The $Fe(OH)_2$ is then oxidized to magnetite (reaction [2]) resulting in peak II

$$3Fe(OH)_2 + 2\,OH^- = Fe_3O_4 + 4H_2O + 2e^- \qquad [2]$$

The equilibrium potential for this reaction is −1640 mV which suggests that considerable overpotential is required for the forward process, *i.e.*, reaction [2] represents a highly irreversible process. The above scheme accounts for the similar response of peaks I and II (consecutive reactions) to repetitive sweeping and is consistent with previous findings that $Fe(OH)_2$ (26) or both $Fe(OH)_2$ and Fe_3O_4 (22) are the initial oxidation products formed on iron in alkaline solution at room temperature.

The third charge transfer process results in peaks III and IV at −1150 mV (E_a) and −1480 mV (E_c), respectively. Further, the charge consumed at these peaks increased on repetitive sweeping, while that consumed at peaks I, II, and III decreased. This indicates that the products initially formed on the surface at peaks I and II are not major precursors for the oxidation which takes place at peak III, *i.e.*, the charge transfer processes responsible for peaks I and II and for peak III occur in parallel and not consecutively as is apparently the case for peaks I and II. Thus, it is reasonable to conclude that peak III arises from the direct oxidation of metallic iron. Electron diffraction (23-25) studies have indicated that γ-Fe_2O_3 forms spontaneously on iron in alkaline solution. The equilibrium potential for reaction [3]

$$2Fe + 6\,OH^- = \gamma\text{-}Fe_2O_3 + 3H_2O + 6e^- \qquad [3]$$

was calculated from the free energy data of Wicks and Block (28) and found to be 1450 mV. This value barely satisfies Eq. [B]. However, reactions [1]-[3] all consume hydroxyl ions. Thus, the concentration of OH^- close to the electrode surface will be less than in the bulk solution and the equilibrium potential for reaction [3] will become more positive by 59 mV/pH unit (27). Alternatively, peaks III and IV may be due to the formation of ferric hydroxide, $Fe(OH)_3$, at the metal surface

$$Fe + 3\,OH^- = Fe(OH)_3 + 3e^- \qquad [4]$$

Reaction [4] has an equilibrium potential at pH = 14 of −1380 mV (27) which therefore satisfies Eq. [B]. The ferric hydroxide may then transform to γ-Fe_2O_3 during or prior to electron diffraction examination (29)

$$2Fe(OH)_3 = \gamma\text{-}Fe_2O_3 + 3H_2O \qquad [5]$$

Since no crystalline phase of ferric hydroxide appears to exist (30), it would not be detected on the electrode surface by diffraction techniques.

High-temperature study.—The electrochemical studies reported here on the behavior of iron in 1M LiOH at 200°C demonstrate that iron will adopt one of two corrosion potentials depending on the previous history of the autoclave. With a "clean" autoclave the iron electrode adopts a corrosion potential of −1420 ± 10 mV. However as soon as the autoclave walls become covered with iron oxide the corrosion potential drops suddenly to −1250 mV. The galvanostatic and potentiostatic polarization studies reported in this work show that iron corrodes in an active mode at both corrosion potentials. The sudden drop in potential from −1420 to −1250 mV appears to coincide with the nucleation and growth of octahedral crystals on the base oxide layer on the metal surface.

Thermodynamic calculations (31) show that the stable ionic species in alkaline solutions at 200°C is the dihypoferrite ion, $HFeO_2^-$, and it seems reasonable to assume that the anodic reactions in the active corrosion states at −1420 and −1250 mV involve this species. Further, previous studies (4, 17, 32) have shown that the oxide formed on iron and carbon steel under similar conditions is magnetite, Fe_3O_4, with the possible inclusion of a small amount of $LiFeO_2$ (4). We have found that both Fe_3O_4 and $LiFeO_2$ crystals nucleate and grow on platinum in 1M LiOH at 285°C in the presence of a corroding carbon steel surface (33). These crystals were found to have a similar morphology to the crystals which form the "upper layer" on the corroded steel surface. Accordingly, the following set of reactions is proposed to account for the anodic and corrosion behavior of iron and carbon steel in 1M LiOH solution at elevated temperatures

$$Fe + 3\,OH^- \rightarrow HFeO_2^- + H_2O + 2e^- \qquad [6]$$

$$3Fe + 8\,OH^- \rightarrow Fe_3O_4 + 4H_2O + 8e^- \qquad [7]$$

$$3HFeO_2^- \rightarrow Fe_3O_4 + H_2O + OH^- + 2e^- \qquad [8]$$

$$Li^+ + HFeO_2^- \rightarrow LiFeO_2 + H^+ + e^- \qquad [9]$$

Townsend (31) has recently shown that as the potential of iron is increased anodically it becomes thermodynamically possible for reactions [6], [7], and [8] to occur in the order listed above.

On galvanostatic polarization from −1420 mV iron first dissolves as the ion $HFeO_2^-$ with the concurrent formation of magnetite on the surface by the direct oxidation of the metal according to reaction [7]. The oxide layer produced corresponds to the base film observed by scanning electron microscopy. The proposed origin of the layer is consistent with the previous observation (13, 17) that the film is formed by the metal/oxide interface receding into the metal phase. Marker experiments (13, 17) have shown that this oxide layer is formed with zero volume change from the original metal. Since the number of iron atoms per unit volume is less in magnetite than in metallic iron the excess iron must leave the oxide. This occurs by dissolution of iron through pores in the oxide layer according to reaction [6]. Further galvanostatic polarization from −1420 mV (Fig. 9) causes increased blocking of the metal surface by magnetite and the potential of the electrode shifts slightly in the anodic direction. At a total current of about 1 mA reactions [6] and [7] are no longer able to consume the charge being forced across the interface and the potential shifts rapidly to oxygen evolution at + 100 mV. The gradual blocking of the freely corroding surface by magnetite is supported by the potential behavior of the electrode during arrest E_6 on anodic charge (Fig. 8). Thus, at the start of the arrest (−1430 mV) the potential increases smoothly but as the amount of charge passed increases the potential becomes unstable. Since the potential is determined partly by the

current density due to reaction [6], fluctuation in the area available for free dissolution due to the increasing formation of magnetite on the surface would produce the observed fluctuations in potential.

The processes described above also account for the active dissolution behavior on polarizing the electrode from the stable corrosion potential of −1250 mV. However, the electrode surface is now essentially covered with magnetite and free dissolution of metal is restricted to intergranular pores in the base oxide film. Thus, the potential fluctuations exhibited on anodic charging (Fig. 8) from −1430 to −1250 mV continue to −600 mV and the erratic current fluctuations observed on potentiostatic polarization (Fig. 9) occur over the same range of potential. Since the porosity of the base film is now quite low [10-15% (17)], the current density due to free dissolution will be high. This leads to the concentration overpotential effects exhibited by both the potentiostatic and galvanostatic curves above a total current of 0.1 mA (Fig. 9). Further polarization results in an active to passive transition at −600 mV after which the potential on galvanostatic polarization drifts rapidly to oxygen evolution and the current on potentiostatic polarization drops sharply to less than 0.1 mA. Although no clearly defined potential arrest occurs at −600 mV on anodic charging (Fig. 8), a small one does exist at −650 mV on cathodic charging from the passive state at 0.1 mA. The amount of charge passed during this arrest is small and probably much less than is required to convert all of the oxide on the metal surface to another oxidation state. However, in order to passivate the electrode it would only be necessary to produce an oxide [possibly α-Fe_2O_3 or a lithium iron spinel oxide (4)] impervious to free dissolution at the base of the pores and the amount of charge required would be small. It is interesting to note that the total charge consumed on oxidizing the electrode is considerably greater than that required to reduce it back to the original potential (Fig. 8). The difference in charge is accounted for by dissolution since the product of this process (reaction [6]) diffuses away from the electrode surface and will not be reduced on cathodic polarization.

The shift in corrosion potential from −1420 to −1250 mV, which appears to coincide with nucleation and growth of the octahedral crystals on the base layer, can be accounted for by electrocrystallization of $HFeO_2^-$ to form Fe_3O_4 and $LiFeO_2$ (*i.e.*, reactions [8] and [9], respectively) exerting partial control over the corrosion potential. Evidence for the nucleating and growth of these crystals from solution has been assembled by Castle *et al.* (15, 34). Additional evidence has been obtained in this laboratory (33) including the observation of growth steps (Fig. 10) on the faces of crystals grown on iron and carbon steel in 1M LiOH at 200°C. The potential dependence of the origin of the octahedral crystals was illustrated experimentally by potentiostating an iron electrode at −1400 mV for 24 hr at 200°C. Examination of the surface did not reveal any "upper layer" oxide crystals even though the conditions chosen were such that nucleation would have occurred in a few minutes on open circuit. Instead, a single layer of oxide was formed and was considerably thicker than the base layer produced on free corrosion. However, the potential was controlled slightly anodic to the metastable corrosion potential at −1420 ± 10 mV and a small anodic current (~ 0.02 mA) was passed for the duration of the experiment. The increased thickness of the oxide layer probably results from the partial consumption of this charge by reaction [7].

Finally, we have observed that if the corrosion tests are performed in a "clean" autoclave a single layer oxide film is first produced but as soon as the autoclave walls become covered with corrosion products then octahedral crystals nucleate on the base oxide

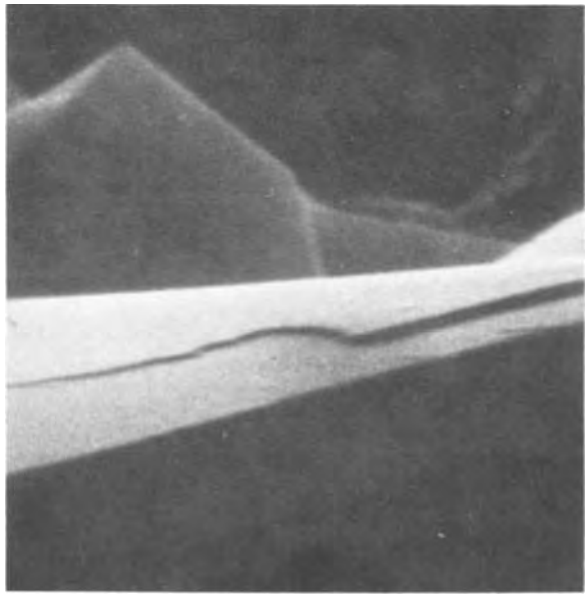

Fig. 10. Growth step on the face of an "upper layer" octahedral crystal grown on carbon steel in 1M LiOH at 200°C for 24 hr (×18,000).

layer and the corrosion potential shifts from −1420 to −1250 mV. This suggests the existence of a source/sink relationship between the corroding electrode and the autoclave walls. Thus, when a freshly cleaned autoclave is used the flux of $HFeO_2^-$ from the electrode to the autoclave walls is sufficiently large that the concentration of this species at the base layer/solution interface does not exceed the value necessary to nucleate the octahedral crystals. However, when the autoclave walls become covered with corrosion products the sink for $HFeO_2^-$ no longer exists and the concentration of this species in the bulk solution quickly increases to the value necessary for nucleation on the corroding surface. However, iron metal is thermodynamically less stable than magnetite (and most likely $LiFeO_2$) so the concentration of $HFeO_2^-$ derived from reaction [6] at the electrode surface will be greater than the equilibrium values for reactions [8] and [9]. At this point the nucleation and growth of the octahedral crystals on the corroding surface becomes thermodynamically possible.

Manuscript submitted April 24, 1972; revised manuscript received Sept. 18, 1972.

Measurement of Zincate Permeation in a Polyethylene Battery Separator with Controlled External Hydrodynamic Conditions

Mitchell Litt, Leonard Nanis,* and Joseph L.-P. Chen[1]

Department of Chemical Engineering, School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

A rotating disk geometry has been used to characterize solution-side transport resistance in measurements of zincate permeation in Ag-Zn battery separator material. The apparent diffusivity of zincate was 1.2×10^{-7} cm^2 sec^{-1} at 25°C in a polyethylene, acrylic acid grafted and divinylbenzene cross-linked membrane, and was independent of zincate concentration up to 0.57M ZnO in 40% KOH. In the temperature range 11°-27°C, the activation energy for diffusion of zincate in the membrane is 6.1 kcal/mol.

The alkaline silver-zinc secondary battery is of considerable interest for space and other applications because of its potentially high energy output per unit weight and volume. Broader application of this battery has been limited because of limited cycle life. Development of a battery separator which will improve the performance and life of alkaline cells has been and continues to be the focus of concerted efforts in polymer science, in both formulation and production of new materials.

The characterization of separator performance includes the important factor of permeability of the membrane to electrolyte ion constituents. The permeability, in turn, reflects the diffusivity of ionic species through the membrane matrix and any interaction between permeant and membrane. In conjunction with measurements such as electrical conductivity and porosity determination, the effective ionic diffusivity can ultimately be used to correlate membrane microstructure and battery performance. Measurement of membrane permeability requires knowledge of permeant ion concentration at both sides of the membrane in the membrane phase, as well as the flux through the membrane, from which effective diffusivity can be calculated from knowledge of membrane thickness. Unfortunately, these membrane concentrations are not available from direct measurement, and concentration in the bulk solution on either side of the membrane are used, requiring an accounting of transport resistance effects caused by depletion of diffusant in a solution-side boundary layer adjacent to the membrane surface. For the usual two-compartment arrangement, the membrane is properly considered as a transport resistance in series with two solution-side film resistances. Clearly, the ideal situation is one in which the solution-side resistances are negligible in comparison with the diffusion rate control provided by the membrane. Unless this is known *a priori*, however, considerable error may be introduced by neglecting the boundary layer resistances, particularly in the very viscous solutions characteristic of battery electrolytes. Furthermore, as the goal of more permeable separator materials is approached, the effect of boundary layer resistances becomes increasingly important.

Techniques for the measurement of the diffusion of electrolyte constituents through membranes have been discussed by Harris, Dirkse, and Lander in separate chapters of a compilation of screening methods for alkaline silver-zinc battery separators (1). Each of the three methods for diffusion measurements considers essentially a two-compartment cell separated by the membrane. Two of the three arrangements provided for rapid stirring on the dilute side with no stirring in the concentrated solution compartment, while the third method provided for no stirring whatever. The lack of definition of the mass transport conditions in the liquid immediately adjacent to the membrane is undesirable, since the truly fundamental parameter of importance is the apparent diffusivity of a particular ion in the separator. Stirring, *per se*, cannot be assumed to remove the liquid resistances, unless repeated runs at several stirring rates show no effect

on ion flux. A classical technique in chemical engineering to determine such parameters is the Wilson plot (2), which is usually found in the heat transfer literature. An application of this method to membrane permeability was made by Leonard and Bluemle (3) for artificial kidney dialysis membranes. Their data showed that even with rapid stirring in aqueous solution, the boundary layer resistances were not negligible. To our knowledge, no application of this technique to battery membranes has been made. The method requires quite lengthy determinations, since repeated runs at many stirring rates must be made. Furthermore, in order to properly characterize membrane behavior, the apparent diffusivity should be measured over a temperature range in order to obtain an estimate for the activation energy. By comparison of such membrane results with the free liquid diffusivity and activation energy, valuable insights may be derived concerning the nature of ion-membrane chemical interaction, if any.

A second approach, which has been used in the present investigation, is to adopt a configuration for the permeation cell in which the boundary layer resistances are known *a priori* or measured in a separate experiment. The membrane permeability can then be calculated by subtracting the solution-side resistances from the over-all resistance which includes the membrane. The geometry used here is that of a membrane which rotates at a fixed speed while simultaneously serving as a divider between two compartments. For this rotating disk geometry, the film resistance may be computed from a knowledge of the membrane disk radius, the rotational speed, and the solution viscosity. In addition, the free liquid diffusivity of the ion should be known. Using such an apparatus, we have investigated the permeation of zincate ion in 40% KOH solution through a polyethylene membrane. The membrane material, designated as SWRI-GX, was manufactured by the Southwest Research Institute for the Jet Propulsion Laboratory. It is polyethylene, grafted with acrylic acid, and cross-linked with divinylbenzene.

Experimental

Permeation cell.—The apparatus has been adopted from that used by Litt and Smith (4) to study sodium chloride permeation through ion-exchange membranes. In a preliminary study, Smith (5), using a "membrane" of solid benzoic acid, showed that the rotating membrane seal conformed quite closely to the prediction of mass transfer theory for this geometry, after making suitable allowance for edge effects. The technique was successful in separating boundary layer from membrane resistances and in determining interactions between membrane and diffusant from temperature determinations.

For the present study of zincate ion permeation in polyethylene, the two-compartment cell with rotating membrane used by Smith and Litt (4) was modified slightly for compatibility with concentrated caustic solutions. The apparatus is shown in cross section in Fig. 1. The membrane support is machined of polymethyl methacrylate (Lucite) with a removable center section (B and B') which holds the membrane (A). A Lucite ring (C) screws flush against the surface of B to clamp the membrane tightly, so that the exposed diameter of membrane is exactly 1 in. An "O" ring seals the membrane against leaks. An aluminum ring gear (D), machined from a standard timing belt gear, is glued with epoxy to the outer surface of the membrane holder. The gear was first coated with Kymar, an alkali-impervious vinylidene fluoride resin, to protect the gear in case of leaks.

The membrane holder seals to the faces of the Lucite support (E) with neoprene "O" rings (F). During runs, the "O" rings are lubricated with Dow Corning FS1281 lubricant to provide smooth rotation. Dow Corning 111 lubricant was used as sealer for the plastic components. Pressure of the rotating membrane against the "O" rings is provided by a fixed ring (G). Two Lucite chambers with volumes of 259 (H) and 295 (J) ml, respectively, form the solution compartments, which are held to the center support (E) with flanges and gaskets. Each compartment is internally jacketed (not shown) for temperature control of the bulk electrolyte by water pumped from a constant temperature bath. A separate jacket adjacent to the "O" ring seal was used to maintain constant temperature and to remove frictional heat in the vicinity of the membrane (not shown). Each electrolyte compartment was also provided with a nylon stirrer (K) to maintain bulk concentration constant when taking samples and adding electrolyte. The main rotor assembly was turned by a variable speed 0-3600 Servotek motor and Boston gear 25:1 speed reducer coupled to the ring gear (D) by a timing belt. With this apparatus, speeds up to 25 rpm could be maintained with smooth operation, with temperatures maintained constant to ±0.5°C. Chromel-Alumel thermocouples were used to monitor temperature, using a Keithley Model 160 digital voltmeter.

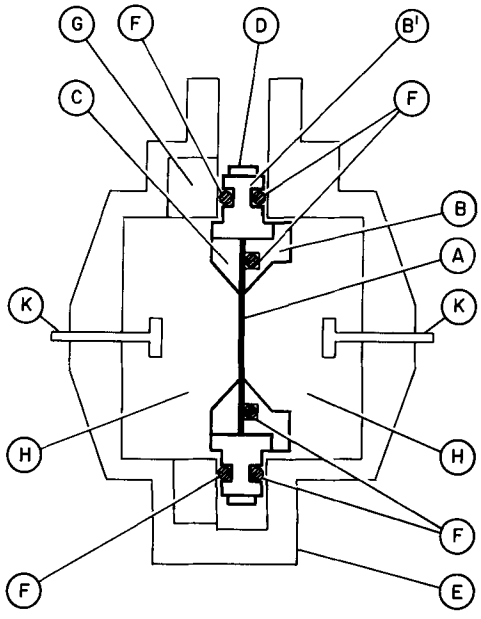

Fig. 1. Schematic arrangement of rotating permeation cell

Procedure.—Membranes were presoaked in 40% KOH solution for 24 hr prior to use. After clamping of the membrane in the holder (B), both chambers were filled with 40% KOH, and the membrane was set to rotate at a speed of 21.5 rpm. An impulse response technique for step changes in the concentrated solution compartment was used to decrease the number of separate runs needed to evaluate a given membrane. The permeation of zincate into the dilute compartment was monitored by analysis of discrete samples removed at regular intervals. At the start of a typical run, a step change of zinc concentration was introduced into the concentrated compartment (H, henceforth called compartment 1) by withdrawing a 100 ml sample of solution and simultaneously replacing the same volume of 0.8M ZnO in 40% KOH. The stirrers (K) were activated for 1 min to promote uniform mixing.

For a given concentration in compartment 1, permeation was allowed to proceed for 30 min. Samples of 1 ml were taken from compartment 2 at 2-min intervals (started from zero time) in the first 6 min and and then at intervals of 5 min for the rest of the run. One milliliter of 40% KOH was replaced for each sample removed from compartment 2 to maintain a constant chamber volume. At the end of 30 min, a second concentration step in compartment 1 was accomplished by removal of a 100 ml volume rapidly followed by replacement with another 100 ml volume of 0.8M ZnO-40% KOH to provide a second step rapid change. A third step was similarly accomplished.

Samples (1 ml) were also taken from compartment 1 in order to monitor the step change of concentration. For each temperature studied, permeabilities were examined for the three zincate concentration steps in a single run, provided that no leakage had occurred and that the continuously monitored temperature was in control within ±0.5°C from the set value. The absence of leaks was verified at the end of a run by the absence of coloration in compartment 2 following the addition of a few drops of methylene blue to side 1. The step changes in side 1 and resulting changes in compartment 2 are shown in Fig. 2 for a typical run at 21.5°C.

Zincate analysis.—A Varian AA-120 atomic absorption spectrophotometer was used for analysis of zinc concentration. For calibration with known concentrations and for use with actual samples, a neutralization procedure was followed to prevent attack of the titanium burner slit by hot alkali. The 1 ml samples were added to 19 ml of 2.4% nitric acid and were well mixed, neutralizing the alkali and reducing the viscosity of the resulting solution, thus avoiding attack and clogging of the AA-120 burner slit. The 20-fold dilution of the zinc was still well within the sensitivity of the analysis. To further reduce analytical error, at least three aliquots of the diluted sample were sprayed into the machine consecutively, with the absorption signal monitored continuously on a strip-chart recorder. The average value of the three readings was then used to determine Zn concentration by comparison with a standard calibration curve. A new calibration was prepared for each series of determinations to compensate for changes in lamp and flame conditions. Calibration curves of absorption *vs.* concentration were linear, facilitating interpolation.

Measurement of membrane thickness.—The wet membrane thickness is of importance in determining the steady-state concentration gradient and thus the permeation flux. A simple microscope method was used to determine the thickness of a wet, swollen membrane without actual contact. A piece of optically flat glass marked with black ink on both sides was used to calibrate the microscope height measurement. By focusing the microscope on the bottom and top surfaces of the glass plate, a scale reading was measured corresponding to the thickness of the glass plate (measured by micrometer to 0.0001 in.). At a magnification of 262.5, ten scale divisions of the height adjustment corresponded to 0.001 in. The dry membrane thickness was measured by micrometer to be 0.0011 in. To measure the thickness of the wet membrane, the microscope was focused alternately on the top surface of the supporting glass plate and on the top surface of the wet membrane placed on the glass plate. The scale difference so obtained indicated that the wet (40% KOH) thickness of the wet membrane was 0.00204 in. at 25°C. The polyethylene GX material is reported to have a typical wet thickness of 0.0014 in. when measured by contacting methods which may cause compression of the wet membrane. Accordingly, the present computations of diffusivity are based on the optically determined wet thickness as a truly representative parameter.

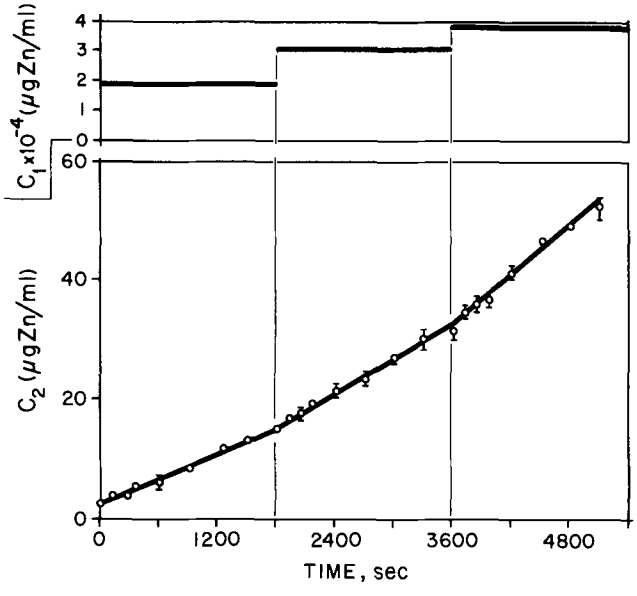

Fig. 2. Concentration *vs.* time for permeation at 21.5°C

In order to determine any effect of zincate concentration on wet thickness, measurements were made on membranes soaked for at least 24 hr at 25°C in 0.2M ZnO-40% KOH, 0.4M ZnO-40% KOH, and 0.6M ZnO-40% KOH. No change in the thickness of the membrane was detected over this concentration range. This result is fortunate, since it implies that there will be no unequal expansion of a membrane which has a concentration gradient of zincate ion during active permeation in the apparatus. Also, the thickness of both the dry and the wet membrane does not measurably change with temperature, as determined at 16°, 25°, and 28°C.

Results

In general, if two well-mixed chambers with the concentration of a permeant species in the first compartment much greater than that in the second compartment are separated by a membrane, the concentration of permeant in the second chamber will increase with time. After an initial unsteady-state period during which the concentration gradient within the membrane is established, a steady-state, or rather, pseudosteady-state period will ensue and last as long as the concentration in the first chamber is much greater than that in the second. This was found to be the case in all runs, as indicated by a linear increase of side 2 zincate concentration with time. Therefore, depletion of side 1 is of no concern. The maximum concentration of zincate in side 2 at the end of a run is still three orders of magnitude less than the concentration in side 1, so that virtually constant boundary conditions at either side of the membrane are assured. Thus, the rate of change of zincate in the second chamber (side 2) is given by

$$\frac{V_2 dc_2}{dt} = KA(c_1 - c_2) \qquad [1]$$

where c_1 = zincate concentration, mol cm^{-3}, in chamber with volume V_1 (side 1); c_2 = zincate concentration, mol cm^{-3}, in chamber with volume V_2 (side 2); K = over-all permeability, including resistance of membrane and boundary layers on either side, cm sec^{-1}; and A = membrane area, cm^2. The factor K includes the effective diffusivity and wet thickness plus similar terms for the solution resistances. No detailed information is needed for the actual zincate concentration just at the membrane surfaces. Since the flux is identical through each region, *i.e.*, boundary layer in side 1, membrane and side 2 boundary layer, Eq. [1] considers the net driving force as the concentration difference ($c_1 - c_2$) across the three transport resistance regions in series. Equation [1] may be further simplified, because $c_2 << c_1$ at all times and for all experiments reported here. Also, dc_2/dt is essentially constant, so that Eq. [1] becomes, solving for K

$$K = \frac{V_2 \dfrac{dc_2}{dt}}{Ac_{10}} \qquad [2]$$

where c_{10} is the concentration in compartment 1 after introduction of the step, and dc_2/dt is obtained as the slope of a regression line fitted to the data, after correcting for the volume changes involved in taking samples. Correlation coefficients for the slopes were all better than 0.99, indicating excellent fit. Values of K for the three different temperatures and concentrations

of zincate are given in Table I. A separate membrane sample was used for each temperature.

Calculation of membrane permeability.—The overall coefficient K in Eq. [2] is related to the membrane permeability by the relation

$$1/K = 1/K_m + 1/K_{b1} + 1/K_{b2} \quad [3]$$

where K_m is the membrane permeability and K_b is the mass transfer coefficient in the boundary layer on either side of the membrane.

The rotating disk system has permitted theoretical prediction of the mass transfer coefficient, K_b, in the fluid adjacent to the membrane, if the dimensions of the system, rotational speed of the disk, and fluid properties are known (5). The mass transfer correlation is given in terms of the dimensionless Reynolds, Sherwood, and Schmidt numbers as

$$Sh = 0.544\ Re^{1/2}\ Sc^{1/3} \quad [4]$$

where $Sh = K_b r/D$; $Re = r^2\omega/\nu$; $Sc = \nu/D$; K_b = mass transfer coefficient through the boundary layer, cm sec^{-1}; r = radius, cm; D = diffusivity of zincate in liquid, cm² sec^{-1}; ω = rotational speed, sec^{-1}; and ν = kinematic viscosity, cm² sec^{-1}.

The numerical coefficient 0.544 in Eq. [4] differs slightly from that for a rotating disk in an infinite medium (0.662) because of edge effects, and is based on the work of Smith (5).

In order to precalculate the mass transfer coefficient, K_b, for zincate in the boundary layer, the following property values were used. The density and viscosity of the KOH-H_2O system at temperatures of 25° and 75°C have been reported by Klochko and Godneva (6). Dirkse (7) has reported the density and viscosity of saturated solutions of ZnO in aqueous KOH at 25°C. Using these sparse data for the properties of ZnO/KOH-H_2O solutions, and assuming that the density and viscosity vary linearly with the content of zinc in the aqueous KOH solution and, further, that they do not change very much in the temperature range of 11°-27°C, it is possible to apply Eq. [4]. For obtaining K_b from the Sherwood number, the value of 5.3 × 10^{-6} cm² sec^{-1} for the diffusivity of zincate ion was used as found by Lu (8) using a rotating disk method with 0.25M ZnO-23.4% KOH at 23°C. The value 5.1 × 10^{-6} cm² sec^{-1} at 25°C is used for the present calculation of the mass transfer coefficient by adjusting Lu's result for the viscosity of the 40% KOH solution. For the temperature range 11°-27°C and for the three zincate step concentrations up to 0.57M ZnO in 40% KOH, solution density was essentially constant, ranging from 1.42 to 1.45 g cm^{-3} depending on temperature and zincate concentration. Likewise, the kinematic viscosity was estimated to range from 0.0307 cm² sec^{-1} at 17°C for 0.27M ZnO in 40% KOH to 0.0344 cm² sec^{-1} at 0.57M ZnO in 40% KOH. Because Eq. [4] involves fractional powers of the Schmidt and Reynolds numbers, the variations in properties such as viscosity and density over the range of temperature and zincate concentrations studied are not greatly significant. Accordingly, the term $Re^{1/2}$ varies from 10.7 (at 11°C, 0.27M ZnO) to 10.2 (at 27°C, 0.57M ZnO). The term $Sc^{1/3}$ varies from 18.4 to 19.0 in the same range. At the rotational speed of 21.5 rpm, the Sherwood number varies even less in this range, from 107 to 105, and the side 1 mass transfer coefficient is taken for all computations as an average value of 4.27 × 10^{-4} cm sec^{-1}. The mass transfer coefficients in side 2 do not vary because the concentration of zinc is so small that the transport properties of 40% KOH were used to compute a value of 4.5 × 10^{-4} cm sec^{-1} for K_{b2}. Although the approximations used here are rough, they are justified given the sparsity of property data, since the values of the solution-side coefficients are roughly twenty times greater than the over-all permeability, so that small errors in K_{b1} and K_{b2} will not greatly influence the calculated values of K_m.

Calculation of membrane permeability.—The permeation coefficient of the membrane can be calculated from the measured over-all permeation coefficient and the mass transfer coefficients (K_{b1} and K_{b2}) through the boundary layers by using Eq. [3]. In the present study, the correction for the liquid boundary layers is a non-negligible 10%. The effective diffusivity can be calculated, therefore, by multiplying the membrane permeation coefficient by the wet membrane thickness. It is understood that the resulting values of effective diffusivity include not only the actual diffusivity of permeant in the membrane matrix, but also any effect of distribution or partition coefficient between the free solution phase concentration and the membrane phase concentration. If such an effect is large, one might expect to find a large dependence of K_m on zincate concentration. Average values of the effective diffusion coefficients for each temperature are shown in the last column of Table I to be on the order of 10^{-7} cm² sec^{-1}. The diffusivity of zincate ion in the membrane is less than the free liquid diffusivity by a factor of about twenty.

Although there is considerable scatter in the results, which is most probably due to using a different membrane sample for each temperature, it is clear that diffusivity of zincate in the membrane increases with increasing temperature, but appears to be independent of zincate concentration over the range used. From the data, the best value of diffusivity activation energy is 6 ± 3 kcal/mol (p = 0.05). Because of the wide confidence interval, no definite statement can be made about permeant-membrane interaction, since the value straddles the range for free liquid diffusivities, and more definite statements will have to await compilation of additional data. If it can be assumed that no permeant-membrane interaction takes place, the reduction in diffusivity can be attributed to reduced area for permeation, or to average pore lengths being increased due to tortuosity in the membrane, or both. A tortuosity factor of 2 would indicate a ten-fold reduction in free permeation cross section, which is of the same order of magnitude reported by Smith (5) for polyethylene and ion exchange membranes. There are no independent data on tortuosity or pore size for the membrane used in this study with which to compare these results. Such data would be extremely useful and will be obtained in future studies.

Summary and Discussion

Effective diffusion coefficients of zincate ion through an acrylic acid grafted and divinylbenzene cross-linked polyethylene membrane in 40% KOH solution were determined as a function of temperature with various zincate concentration gradients across the membrane by using an impulse-response technique on a rotating disk system. This technique permits determination of the diffusion coefficient in a suitably short time on the order of 30 min once the equipment is assembled. Extremely useful features of the method are (*i*) the abil-

ity to precalculate the solution-side transfer resistance, (*ii*) the capability of studying concentration effects for the same membrane, and (*iii*) the capability of studying the same membrane at various temperatures. These features are helpful in characterizing the quality of battery separator material.

There is a scarcity of polyethylene membrane permeation data against which to compare the present results. Lander (1) has determined the permeation rate of zincate ion in 45% KOH solution through a low density polyethylene membrane grafted with acrylic acid at room temperature by using a stationary diffusion cell. From the data, an average permeation coefficient of 2.4×10^{-6} cm sec^{-1} is calculated. This value is about ten times smaller than the present results but is not strictly comparable, since (*i*) the material studied by Lander was cross-linked first and then grafted, and (*ii*) no stirring was provided on side 1. A closer comparison may be made with data obtained by Adams and Harlowe (9) for the typical SWRI produced GX polyethylene used in the present study. They used an arrangement similar to that of Lander (1) but included stirring for both side 1 and side 2 (10). Using the wet thickness reported by Adams and Harlowe (1.4 mil) with their measured (25°C) permeation rate of 2.39×10^{-6} mol cm^{-2} sec^{-1}, the effective diffusivity is 2.2×10^{-8} cm^2 sec^{-1}. Using their permeation rate with the present optically determined wet thickness (2.04 mil), the effective diffusivity is 3.2×10^{-8} cm^2 sec^{-1}, about one-fourth of that reported here, interpolating from the data in Table I for 25°C. This discrepancy may be due partly to solution-side resistances which could not be completely eliminated in the apparatus of Adams and Harlowe. It is unlikely to account for the entire difference, since such a large solution-side resistance in their study would imply a large (1 cm) film thickness, which is improbable given that some stirring is reported to have taken place. The remaining difference is no doubt due to variations in material, even if prepared in a similar manner. Adams and Harlowe report large differences in zincate permeability with small changes in amount of grafting and cross-linking agents, so that differences of the order of magnitude noted would not be unusual.

It is clear, however, that attention should be directed to improved characterization of the solution-side resistances. The presently used disk arrangement has, in addition to known values of K_{b1} and K_{b2}, the advantage of uniform accessibility or constant boundary layer thickness (constant K) over the entire membrane surface (5). Other types of flow cells may also be used to predetermine K_b based on known mass transport geometries such as unidirectional flow in a flat channel past a flat plate (11). Local variations in K_b such as the greater-than-average value at the leading (upstream) edge of a sheet membrane are a minor penalty compared with the great advantage of predictability of K_b.

Phase Equilibria in Lithium-Chalcogen Systems

III. Lithium-Tellurium

P. T. Cunningham, S. A. Johnson, and E. J. Cairns*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The equilibrium phase diagram of the lithium-tellurium phase system has been investigated. Eutectic points occur at 179.9°C and greater than 99.0 atomic per cent (a/o) lithium, 448.5°C and 35.7 a/o lithium, and 423.1°C and 10.5 a/o lithium. Two intermediate phases, Li_2Te and $LiTe_3$, are present having melting points of 1204.5° and 459.9°C, respectively.

The interest in lithium-chalcogen phase equilibria resulting from development work on high-specific-power, high-specific-energy secondary cells has been outlined in the two previous papers of this series (1, 2). The lithium/tellurium couple is not usually considered as a candidate for such cells because of the weight of tellurium, but the possible use of tellurium as an additive to selenium or sulfur cathodes (3) and the desirability of completing study of the phase equilibria in the lithium-chalcogen series led us to investigate this system.

The lithium-tellurium phase diagram has not been previously reported. The intermediate phase Li_2Te has been prepared in liquid ammonia (4) and by directly combining stoichiometric quantities of the elements in a BeO crucible at 950°C (5). Li_2Te has an antifluorite

* Electrochemical Society Active Member.
Key words: lithium, tellurium, phase equilibria, cathode.

structure with a lattice constant of 6.517 (4). The free energy of formation of Li_2Te at 798°K has been determined by emf measurements to be −77.9 kcal/mol (6).

Experimental

Materials.—The tellurium used was a special high-purity semiconductor grade (99.999+%) obtained from American Smelting and Refining Company, South Plainfield, New Jersey. The lithium was high-purity reactor grade (99.98%) obtained from the Foote Mineral Company, Philadelphia, Pennsylvania. Both elements were used without further purification. Li_2Te was prepared in 1-10g batches using the method previously described for Li_2Se (1) except that the lithium was placed in a tungsten crucible and the final reaction temperature was 650°C. The Li_2Te obtained was generally a light gray color but a large amount was also formed as light yellow translucent crystals. The x-ray powder patterns produced by this material were very sharp and agreed with previously reported data for Li_2Te (4). $LiTe_3$, an intermediate phase found in this study, was prepared in a purified-helium-atmosphere glove box (7) by direct addition of stoichiometric amounts of lithium to molten tellurium contained in a tungsten crucible. The reaction is quite violent and lithium must be added in very small quantities. Samples of various compositions used in subsequent experiments were prepared by mixing Li_2Te with the appropriate terminal phase. Samples were contained in quartz, tungsten, niobium, and graphite depending on the sample composition and maximum temperature of the experiment.

Apparatus and Procedures.—Most of the data were obtained using thermal analysis (heating and cooling curves) and differential thermal analysis (DTA). The apparatus and the procedures used for calibration and data collection have been previously described (1).

A platinum-wound resistance furnace was used in determining the melting point of Li_2Te. The sample was placed in a tungsten crucible and could be observed at temperature with a small telescope and suitable optics. The temperature was measured with a calibrated optical pyrometer at the instant when the sample was observed to melt.

Chemical analysis of selected samples was used to verify composition. In most cases, lithium was analyzed by flame photometry and tellurium was obtained by difference. Check analyses, in which tellurium was also determined by standard gravimetric methods, confirmed the accuracy of this procedure (±5% of the lithium weight). X-ray diffraction powder photographs were obtained for a number of samples of various compositions and thermal histories using a 114.6 mm Debye-Scherrer camera with CuKα radiation. Density measurements were made on samples of $LiTe_3$ using a Beckman Model 930 air-comparison pycnometer operated inside a helium-atmosphere glove box.

Results and Discussion

The presence of the intermediate phase $LiTe_3$, which had been tentatively reported by Foster *et al.* (8), has been confirmed. X-ray powder patterns obtained on a sample of $LiTe_3$ prepared by direct combination of the elements are consistent with a body-centered-cubic structure with a lattice constant of 6.162Å. The strongest lines of the Li_2Te pattern appeared very faintly in the pattern produced by the $LiTe_3$ sample and chemical analysis showed the lithium content to be 26.3 ± 1.0 a/o. The density of the sample, as measured with the air-comparison pycnometer, was found to be 5.29 ± 0.25 g/cm^3, which is in good agreement with the calculated density of $LiTe_3$ (5.531 g/cm^3) based on the x-ray data. Powder patterns were obtained for a number of other samples having a variety of compositions and thermal histories. In all cases, the observed lines could be fully explained by Li_2Te, $LiTe_3$ and the terminal phases.

Thermal analysis results are presented in Table I. The tellurium-rich samples had a strong tendency to undercool and vigorous stirring was required to obtain reproducible results for the heating and cooling curves. Composition changes in the sample due to vaporization losses from the open sample crucibles did not appear to be a problem. Chemical analysis of numerous samples indicated that the over-all compositions listed in Table I are accurate to ±0.5 a/o. The DTA temperatures tabulated were all taken from the intersection of the base-line extension and the leading slope of the peak on the heating cycle. Accurate determination of the liquidus crossings was generally not possible from the DTA curves.

The thermal data for samples of over-all composition on the lithium-rich side of Li_2Te indicate a eutectic point at 179.9° ± 0.1°C and more than 99.0 a/o lithium. This temperature is 0.6°C below the lithium melting point and well outside the estimated uncertainty of these measurements. Thermal effects were observed using DTA at 812° ± 5.0°C for three samples with composition between 91 and 80 a/o lithium. It is tentatively suggested that these effects are due to a monotectic reaction taking place at 812°C but the possibility that they are caused by a tellurium-niobium corrosion product has not been ruled out.

The melting point of Li_2Te was observed to be 1208°C using DTA and 1201°C in the resistance furnace with visual observation of melting. The agreement of the two methods is considered satisfactory considering the difficulties associated with accurate high-temperature measurements. The melting point of Li_2Te is taken to be 1204.5° ± 7°C.

Thermal effects observed for samples of over-all composition between Li_2Te and tellurium appear to be completely consistent with the phase relations shown in Fig. 1. The eutectic point between Li_2Te and $LiTe_3$ occurs at 448.5° ± 1.2°C and 35.7 ± 1.0 a/o lithium whereas the eutectic point between $LiTe_3$ and tellurium occurs at 423.1° ± 0.7°C and 10.5 ± 1.0 a/o lithium. The melting point of $LiTe_3$ is found to be 459.9° ± 0.7°C and that of tellurium 449.8° ± 0.3°C.

The stable intermediate phase $LiTe_3$ contrasts sharply with the extensive miscibility gaps observed for the chalcogen-rich regions of the lithium-sulfur

[a] The methods used were heating or cooling curves, (TA), where the temperatures reported are those of thermal arrests or breaks; and differential thermal analysis (DTA), where reported temperatures are those of the intersection.
[b] These temperatures are inaccurate because of rapid heating and are reported for completeness only.
[c] Very weak effects.

(2) and lithium-selenium (1) systems. This trend is similar to that observed for the sodium-chalcogen systems for which a miscibility gap on the sulfur-rich side of the sodium-sulfur system (9) gives way to a peritectically melting $NaSe_3$ phase for the sodium-selenium system (10) and finally to the eutectic form with the congruently melting $NaTe_3$ in the sodium-tellurium system (10). The existence of other stable chalcogen-rich phases in the sodium series confuses the analogy somewhat. That the decreasing tendency for the formation of polymeric species with increasing atomic number in the chalcogens is a significant factor in the trends pointed out above is an interesting possibility. The use of additives that inhibit polymer formation to the cathode of lithium-selenium and lithium-sulfur cells may eliminate the immiscibility and thereby improve mass transfer in the cathodes of these cells.

Acknowledgments

The authors wish to acknowledge Dr. C. E. Johnson and Dr. M. S. Foster who initiated this work and carried out early experiments. X-ray analysis was performed by Mr. R. Shablaske and chemical analyses were carried out by Mr. Z. Tomczuk and Mrs. R. Hanna. The encouragement and support of Dr. R. C. Vogel and Dr. A. D. Tevebaugh is appreciated. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript received Oct. 16, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Ion Selectivity and Diffusion Potentials in Corrosion Layers

$PbSO_4$ Films on Pb in H_2SO_4

P. Ruetschi*

Leclanché S.A., Yverdon, Switzerland

ABSTRACT

The behavior of $PbSO_4$ corrosion layers on Pb in H_2SO_4 solutions is shown to resemble that of perm-selective $PbSO_4$ precipitation membranes, prepared by interdiffusion of Pb^{+2} ions and SO_4^{-2} ions into cellophane foil. Diffusion potentials in these precipitation membranes follow, over a wide pH-range, the equation

$$\Delta\psi_d = (RT/F) \ln (a_{H+1})/(a_{H+2})$$

and can reach values of several hundred mV. The lower limit of that electrode potential range where PbO (and/or α-PbO_2) forms in the interior of the corrosion film, underneath a perm-selective $PbSO_4$ layer, that is, -0.4V (or $+0.5$V) *vs.* Hg/Hg_2SO_4, can be predicted theoretically in a proper manner by taking into account the diffusion potential in the film.

Diffusion Potentials

Anodic corrosion films on Pb in aqueous H_2SO_4 exhibit, when formed within a certain potential range, a characteristic multi-phase structure. Such films then consist in their exterior part (against the solution) of a layer of $PbSO_4$ and in their interior part of tetragonal PbO and/or α-PbO_2 (1-10). The limits of the electrode potential range where PbO, and/or α-PbO_2, is found to be present underneath a protecting $PbSO_4$ layer have been fairly well established experimentally by means of x-ray and electron diffraction. PbO occurs above -0.40V and α-PbO_2 above $+0.50$V *vs.* Hg/Hg_2SO_4 (that is above $+0.25$ and $+1.15$V *vs.* STP H_2, respectively). These limits depend somewhat on H_2SO_4 concentration, temperature, and length of anodizing treatment. Basic lead sulfates may be present along with tetr. PbO. Below -0.40V *vs.* Hg/Hg_2SO_4 the anodic deposit is no longer multi-phased, but consists largely of $PbSO_4$. Above $+0.50$V *vs.* Hg/Hg_2SO_4, the interior part is composed of mixed material PbO-α-PbO_2, above 1.1V of α-PbO_2. Above 1.1V the exterior part consists of β-PbO_2 instead of $PbSO_4$.

Electrode potential measurements during (interrupted) anodization (11, 12) and during depassivation, or cathodic stripping, (3, 4, 6-8, 10, 13, 14) have also been used in the past to obtain diagnostic information on the types of corrosion products present in anodic films on Pb. For meaningful studies of this sort it is imperative to exclude carefully any oxygen from the cell, to work with highly purified solutions, and to employ voltage recording equipment of very large input impedance (4, 13). As discussed in this paper, the interpretation of any experimentally observed potential arrests in galvanostatic or depassivation studies, or of current peaks in potentiodynamic experiments (15) and their correct assignment to specific corrosion products, requires the consideration of possible membrane diffusion potentials existing in the corrosion film.

PbO is thermodynamically stable only above a certain pH, the stability limit depending on the concentration of SO_4^{-2} ions (4, 16). The presence of PbO in the interior of corrosion films means that it is protected against the H_2SO_4 solution by a layer of $PbSO_4$, practically impermeable to H_2SO_4. As the $PbSO_4$ film builds up in thickness, the following equilibria successively determine the *p*H in the interior of the film (16).

$$\begin{aligned}
H_2SO_4 &= SO_4^{-2} + 2H^+ \\
Pb^{+2} + SO_4^{-2} &= PbSO_4 \\
\log a_{Pb^{+2}} + \log a_{SO_4^{-2}} &= -7.8 \\
PbSO_4 + 2H_2O &= HPbO_2^- + 3H^+ + SO_4^{-2} \\
\log a_{HPbO_2^-} + \log a_{SO_4^{-2}} &= -36.0 + 3\,pH \\
pH &= 12.0 + (1/3) \log a_{HPbO_2^-} + (1/3) \log a_{SO_4^{-2}}
\end{aligned} \qquad [1]$$

$$\begin{aligned}
2Pb^{+2} + SO_4^{-2} + H_2O &= PbO\,PbSO_4 + 2H^+ \\
2 \log a_{Pb^{+2}} + \log a_{SO_4^{-2}} &= 1.0 - 2\,pH \\
PbO\,PbSO_4 + 3H_2O &= 2HPbO_2^- + 4H^+ + SO_4^{-2} \\
2 \log a_{HPbO_2^-} + \log a_{SO_4^{-2}} &= -55.2 + 4\,pH \\
pH &= 13.8 + (1/2) \log a_{HPbO_2^-} + (1/4) \log a_{SO_4^{-2}}
\end{aligned} \qquad [2]$$

$$\begin{aligned}
4Pb^{+2} + SO_4^{-2} + 4H_2O &= 3PbO\,PbSO_4\,H_2O + 6H^+ \\
4 \log a_{Pb^{+2}} + \log a_{SO_4} &= 21.2 - 6\,pH \\
3PbO\,PbSO_4\,H_2O + 4H_2O &= 4HPbO_2^- + 6H^+ + SO_4^{-2} \\
4 \log a_{HPbO_2^-} + \log a_{SO_4^{-2}} &= -91.2 + 6\,pH \\
pH &= 15.2 + (2/3) \log a_{HPbO_2^-} + (1/6) \log a_{SO_4^{-2}}
\end{aligned} \qquad [3]$$

$$\begin{aligned}
5Pb^{+2} + 7H_2O &= 5PbO\,2H_2O + 10\,H^+ \\
\log a_{Pb^{+2}} &= 12.6 - 2\,pH \\
5PbO\,2H_2O + 3H_2O &= 5HPbO_2^- + 5H^+ \\
\log a_{HPbO_2^-} &= -15.5 + 1\,pH \\
pH &= 15.5 + \log a_{HPbO_2^-}
\end{aligned} \qquad [4]$$

Individual $PbSO_4$ crystals in the outer layer have dimensions in the order of 0.1 to 10 μm, (6, 7, 9, 10, 14, 17-21). The layers become impermeable to SO_4^{-2} and HSO_4^- when they have reached a thickness of 1 to several μm. The pores are then practically closed. The same behavior is observed with AgCl films on Ag (22). Further corrosion of Pb then occurs by dissociation of H_2O underneath the $PbSO_4$ layer, precipitation of the anodically generated Pb^{+2} in form of PbO, and migration of the H^+ ions away from the electrode interface. The potential-determining couple Pb/PbO is thus exposed to a basic environment.

Under these conditions one would theoretically expect the existence of a considerable diffusion potential across the outer $PbSO_4$ layer, this latter exhibiting the characteristics of a precipitation membrane with pronounced ion selectivity (23). It appears that diffusion

* Electrochemical Society Active Member.

Key words: anodization, corrosion, diffusion potential, lead-acid battery, lead.

potentials in corrosion films have received little attention hitherto.

Generally, membrane potentials due to concentration differences between opposite sides may, at vanishing matrix charge and vanishing current, be expressed by (24)

$$\Delta\psi_d = -(RT/F) \int_1^2 \sum_n (t_i/Z_i)\, d \ln a_i \qquad [5]$$

where

t_i = transport number
Z_i = valency
a_i = activity of ions of type i

Equation [5] follows from the condition of equilibrium for those ions i for which the membrane is permeable. If the completely formed $PbSO_4$ membrane becomes essentially nonpermeable to SO_4^{-2}, HSO_4^-, and Pb^{+2} ions, so that the diffusion potential ψ_d arises entirely from the H^+, or OH^- ion concentration difference, one derives with $(a_{H+}) \cdot (a_{OH-}) = \text{const}$

$$\Delta\psi_d = (RT/F) \ln (a_{H+})_1/(a_{H+})_2 \qquad [6]$$

At 25°C the diffusion potential amounts thus to 59.16 mV per unit of pH difference.

In the interior of a corrosion film containing PbO, the pH can be expected to reach a value of 9.34, corresponding to equal activities of Pb^{+2} and $HPbO_2^-$ (25, 26). With a pH of 0 in the H_2SO_4 bulk solution, the diffusion potential would then amount to 553 mV (Fig. 1).

When the electrode potential of the Pb/PbO interface in the interior of the film, exposed to the local pH of 9.34, is being measured experimentally by means of a Hg/Hg_2SO_4 reference electrode, located, *e.g.*, in 0.1M H_2SO_4 bulk solution of pH 1, the diffusion potential is included in the measured value. For an experimentally measured potential of, *e.g.*, −0.500V, the actual, local potential for the Pb/PbO interface in the interior of the corrosion layer would be −0.993V *vs.* Hg/Hg_2SO_4.

Measurements with $BaSO_4$ and $PbSO_4$ Precipitation Membranes

In the light of the foregoing, it appeared of interest to simulate corrosion film behavior on lead with artificially prepared precipitation membranes.

Huber (22) had been able to separate corrosion films of Al_2O_3 on Al, and of AgCl on Ag, from the substrate and to measure Donnan equilibrium potentials of such isolated anodic membranes, inserted between two electrolyte compartments of different concentration. However, such measurements are difficult to carry out experimentally. Easier to handle are precipitation membranes in cellophane, as studied by Hirsch-Ayalon (27), and Honig and Hengst (28). These authors found $BaSO_4$ membranes to be highly ion-selective, being nonpermeable for Ba^{+2}, SO_4^{-2} and HSO_4^- ions, but permeable for H^+, OH^-, and H_2O. The two-compartment cell used in the present study (Fig. 2) consisted of 2 precisely machined Teflon blocks, clamped together by 8 threaded bolts. The electrolyte cavity in each block had a volume of 50 cm^3, the horizontal connecting bore had a diameter of 15 mm. The cellophane membrane, du Pont 193 PUDO, (thickness 12 μm) was sealed tightly between the two compartments by means of a Neoprene O-ring.

The precipitation membranes were formed by filling compartment I with 0.1M H_2SO_4, compartment II with 0.1M $Ba(ClO_4)_2$ for $BaSO_4$ membranes, and with 0.1M $Pb(ClO_4)_2$ for $PbSO_4$ membranes. A minimum time of 24 hr was allowed to complete the precipitation in the membrane. Thereafter the forming solutions were carefully removed through suction by means of evacuation pipes, and the solutions to be studied were then introduced into the cell. After insertion of the reference electrodes, which had previously been equilibrated during at least 24 hr with the corresponding solutions, the potentials were read and the measurements continued for several hours. Reference electrodes were Hg/Hg_2SO_4 in H_2SO_4 solutions, and Hg/HgO in sat. $Ba(OH)_2$ solutions (29). In those experiments where the pH was varied systematically by dilution, a H^+/H_2 reference was employed.

Figures 3 and 4 show electron micrographs of a $PbSO_4$ membrane. To prepare the membrane for electron microscopy, it was washed quickly in distilled water, dried in air, coated on the side to be studied with a carbon film, then shadowed with chromium (Balzers high-vacuum equipment).

The carbon layer was reinforced with paraffin and the cellophane subsequently dissolved with Schweizer's reagent during 24 hr. After watering, the paraffin-reinforced carbon layer was collected onto a copper screen carrier, whereupon the paraffin was removed by chloroform vapor extraction. Pictures were taken with a Siemens electron microscope at 60 kV.

From Fig. 3, showing the side exposed originally to the $Pb(ClO_4)_2$ solution, it is apparent that the $PbSO_4$ crystals resemble in morphology those found in corrosion films (20, 21). They exhibit primarily the diamond-shaped basal pinacoid. The humps in the sur-

face are due to $PbSO_4$ crystals which had developed just below the surface in the cellophane membrane. On the H_2SO_4-side (Fig. 4) the $PbSO_4$ crystals are much larger and the cellophane surface appears smooth. This indicates that SO_4^{-2} ions diffuse more rapidly than Pb^{+2} ions during formation of the precipitation membrane.

Figure 5 refers to results obtained with a $BaSO_4$ membrane. For this series of measurements compartment I was filled with 0.1M H_2SO_4, equipped with a Hg/Hg_2SO_4 reference, compartment II was filled with successively diluted solutions of H_2SO_4, and finally with increasingly concentrated solutions of $Ba(OH)_2$, and was equipped with a H^+/H_2 reference electrode.

The measured potential difference (curve A) between the two electrodes remained invariant at $-0.735V \pm 5$ mV, irrespective of the pH in compartment II. Theoretically, the H^+/H_2 potential should have decreased by 59.16 mV per pH unit, as indicated by the line B. The pH dependence of the H^+/H_2 electrode was therefore exactly compensated by the pH dependence of the diffusion potential in the membrane, the latter following Eq. [6] over a very wide pH range. Similar results were obtained with $PbSO_4$ membranes for the pH range 0-5.

In the presence of foreign ions, such as ClO_4^- or K^+, the measured potential difference is no longer independent of pH in compartment II. The results of Fig. 6 were obtained by again filling compartment I with 0.1M H_2SO_4. In compartment II the pH was varied systematically by diluting 1M $HClO_4$ with 0.1M $Ba(ClO_4)_2$ or by diluting $Ba(OH)_2$ sat. + 0.1M $Ba(ClO_4)_2$ with 0.1M $Ba(ClO_4)_2$. The diffusion potential is decreased in proportion to the relative importance of the transport number of ClO_4^-.

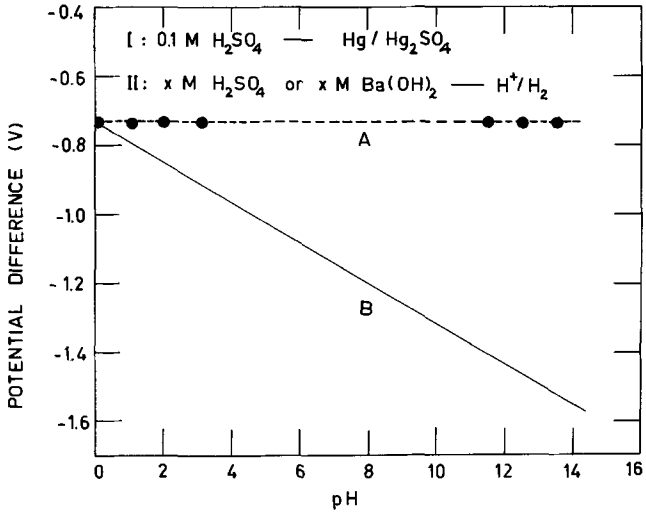

Fig. 5. Electrode potential of a H^+/H_2 electrode in solutions of varying pH (compartment II) against a Hg/Hg_2SO_4 electrode in 0.1M H_2SO_4 (compartment I). $BaSO_4$-membrane.

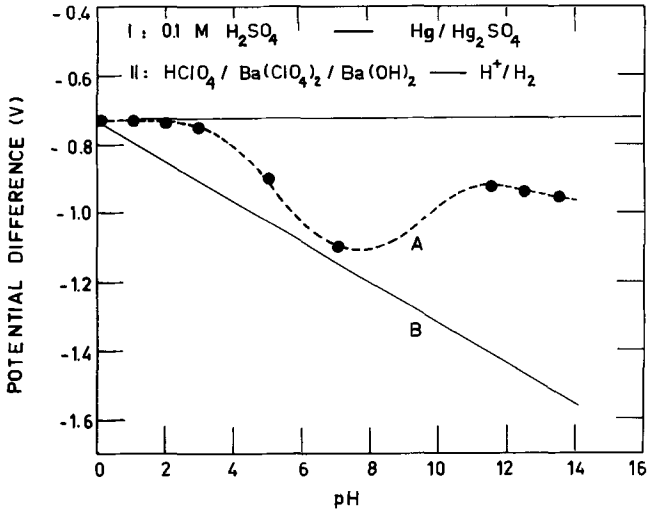

Fig. 6. Electrode potential of a H^+/H_2 electrode in solutions of varying pH containing ClO_4^- anions (compartment II) against a Hg/Hg_2SO_4 electrode in 0.1M H_2SO_4 (compartment I). $BaSO_4$-membrane.

Figure 7 illustrates the influence of K^+ ions on the membrane potential. Here, compartment I was filled with $Ba(OH)_2$ sat. and was equipped with a Hg/HgO reference electrode (29). The pH in compartment II was varied by diluting 1M H_2SO_4 + 0.1M K_2SO_4 with 0.1M K_2SO_4 or by diluting 1M KOH + 0.1M K_2SO_4 with 0.1M K_2SO_4. As in the case of the ClO_4^- anion, the influence of the transference number of the K^+ cation is most pronounced around pH 7 where the concentrations of H^+ or OH^- ions are smallest.

In conclusion, one can state that $BaSO_4$ and $PbSO_4$ precipitation membranes are highly selective, being nonpermeable for SO_4^{-2}, HSO_4^-, and Ba^{+2}, or Pb^{+2}, but being permeable for H^+, OH^-, and at least partly permeable for ClO_4^- and K^+.

The results confirm that very large diffusion potentials (over 700 mV) can indeed exist over prolonged time periods (several days or weeks) in precipitation membranes. An analog behavior can be expected for $PbSO_4$ corrosion films on Pb.

In order to carry the analogy to a corroding electrode as far as possible, the cell of Fig. 2 was used to mea-

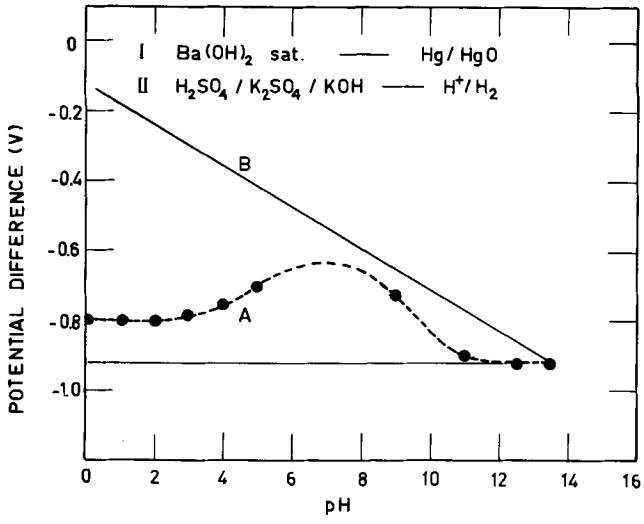

Fig. 7. Electrode potential of a H^+/H_2 electrode in solutions of different pH containing K^+ cations (compartment II) against a Hg/HgO electrode in $Ba(OH)_2$ sat. solution (compartment I). $BaSO_4$-membrane.

sure directly the potential difference of the following system

Pb/PbO	$Ba(OH)_2$ sat. + PbO sat. pH 13.2	$PbSO_4$ – $BaSO_4$ membrane	H_2SO_4 0.1M pH 1	Hg_2SO_4/Hg

The pH of a sat. $Ba(OH)_2$ solution (pH ~ 13.2) is of course considerably higher than the value expected in the interior of corrosion films containing PbO(pH 9.34). However, the $Ba(OH)_2$ sat. + PbO sat. electrolyte provided the desirable conductivity for reproducible measurements and contained, as required for the build-up of a maximum diffusion potential, beside OH^- only nonpermeating ions. The effect of the increased pH on the Pb/PbO potential was compensated by a correspondingly larger diffusion potential in the membrane. Indeed, the measured voltage of the above system, −0.49V, was very close to the experimental value for the depassivation plateau at −0.50V of a corroding Pb electrode in 0.1M H_2SO_4 (4). Using Eq. [6] for the diffusion potential, (13.2 − 1) × 59.16 mV, one calculates theoretically for the above system, with the value of 0.676V for the Hg/Hg_2SO_4 electrode in 0.1M H_2SO_4 *vs.* STP H_2 (4), and with the standard potential of 0.260V for Pb/PbO the following voltage

$$E = 0.260 - (13.2 \times 0.05916) + (13.2 - 1) \times 0.05916 - 0.676 = -0.48V$$

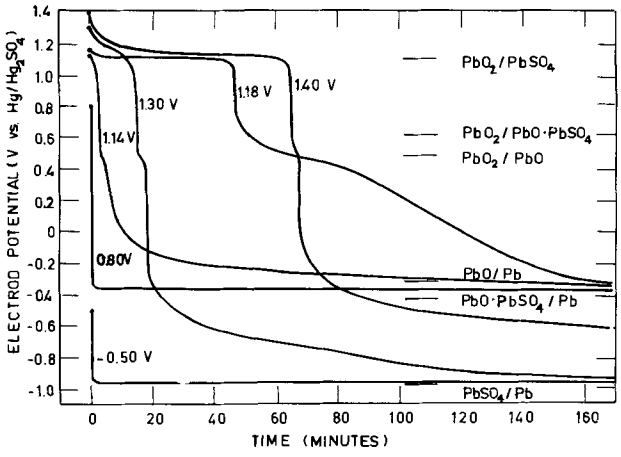

Fig. 8. Self-depassivation of lead electrodes after potentiostatic anodization at different potentials (−0.5, +0.8, +1.14, +1.18, +1.30, and +1.40V *vs.* Hg/Hg_2SO_4) for 24 hr in 4.2M H_2SO_4.

Interpretation of Depassivation Potential Plateaus

Lead electrodes, anodized in H_2SO_4 at different constant potentials and then put on open circuit, show during depassivation on open circuit at least 4 characteristic plateaus (3, 4, 7-9, 14). Typical voltage-time curves on open circuit are reproduced from Ref. (4) in Fig. 8.

Taking into account the diffusion potential in the corrosion film, these plateaus may now be interpreted and assigned to electrochemical processes in an unambiguous manner. The interpretation given earlier (4) must be qualified as being valid only in the absence of diffusion potentials.

Plateau potentials may be computed theoretically by calculating the reversible potential of the presumed potential-determining couple (*e.g.*, PbO/Pb) at the local pH in the interior of the film, using the proper pH-potential-dependence, and then adding the diffusion potential in the $PbSO_4$ film (this is the product of the pH difference across the film with 59.16 mV).

In order to express the potential against the Hg/Hg_2SO_4 electrode one must subtract the potential difference between the STP H_2 electrode at pH 0 and the Hg/Hg_2SO_4 electrode in the corresponding H_2SO_4 solution. For 4.2M H_2SO_4, pH 0.48, this amounts to 0.620V (4).

Table I presents calculations made on this basis for experiments in 4.20M H_2SO_4. The formulation of Bode and Voss (16) was retained for the basic sulfates and for hydrated lead oxide. Using PbO instead of 5 PbO ·

Table I.

Plateau	Experimental plateau potential *vs.* Hg/Hg_2SO_4 (V)	Electrode reaction [see Ref. (4), Table II]	pH at potential determining site	Film diffusion potential (V)	Calculated plateau potential *vs.* Hg/Hg_2SO_4 (V)
I	1.12	$PbO_2 + SO_4^{-2} + 4H^+ + 2e^- = PbSO_4 + 2H_2O$ $E = 1.685 - 0.1182\ pH + 0.0295 \log a_{SO_4^{-2}}$	−0.48 (4.2M H_2SO_4)	0	1.120

III	−0.38	$5PbO{\cdot}2H_2O + 10H^+ + 10e^- = 5Pb + 7H_2O$ $E = 0.260 - 0.0591\ pH$	9.34**	0.586	−0.332
		$PbO{\cdot}PbSO_4 + 2H^+ + 4e^- = 2Pb + SO_4^{-2} + H_2O$ $E = -0.099 - 0.0295\ pH - 0.0148 \log a_{SO_4^{-2}}$	6.35* ($\log a_{SO_4^{-2}} = -3.9$)	0.405	−0.443
IV	−0.96	$PbSO_4 + 2e^- = Pb + SO_4^{-2}$ $E = -0.356 - 0.0295 \log a_{SO_4^{-2}}$	−0.48 (4.2M H_2SO_4)	0	−0.970

* Equilibrium value for coexistence of $PbSO_4$ and $PbO{\cdot}PbSO_4$, at a sulfate activity corresponding to the solubility product of $PbSO_4$ ($a_{SO_4^{-2}} = a_{Pb^{+2}} = 10^{-3.9}$).

** Equilibrium value for PbO ($a_{Pb^{+2}} = a_{HPbO_2^-}$).

$2H_2O$ the calculated values remain practically unchanged.

Excellent agreement exists between observed and calculated plateau potentials. During depassivation of an electrode with PbO_2 film, the following stages are successively reached. First a sulfate layer starts to form on the PbO_2 film by a self-discharge mechanism described earlier (4, 30, 31), while the electrode potential is determined by the $PbO_2/PbSO_4$ couple. As the sulfate layer increases in thickness, the pH in the interior rises abruptly due to hindered H_2SO_4 diffusion. The self-discharge of PbO_2 proceeding rapidly at this point, the electrode passes then quickly through the sequence of potential-determining couples: (*i*) $PbO_2/PbO \cdot PbSO_4$, (*ii*) $PbO_2/3PbO \cdot PbSO_4 \cdot H_2O$, (*iii*) PbO_2/PbO. (In Table I only the first and the last of the plateau potentials are calculated since the second falls in-between the two others). At the potential of the PbO/Pb couple it can remain for a considerable time, depending only on the diffusion of H_2SO_4 into the film. Finally, when the PbO is (completely) sulfated, the potential decreases to the value of the $PbSO_4/Pb$ couple. In Fig. 8 it is apparent that for thin-corrosion films (1.30 and 1.40V) the amount of $PbSO_4$ formed during self-discharge is insufficient to protect properly the region of high pH in the interior, and the plateau at −0.4V is absent. Although some α-PbO_2 is apparently formed in the film, as predicted theoretically, at potentials as low as +0.5V *vs.* Hg/Hg_2SO_4 (8), it does not seem to be potential-determining, possibly because sufficient PbO remains in contact with the underlying Pb at all times.

It had been pointed out by different authors (3, 6-8, 12, 14) that the depassivation plateau at −0.4V *vs.* Hg/Hg_2SO_4 (+0.25V *vs.* H_2) coincides with the value one would expect theoretically for Pb/PbO at pH of about 0. However, at this low pH, PbO is unstable, and at a high pH its theoretical potential is lower than the experimentally observed value. This dilemma had led earlier to the suggestion that the plateau at −0.4V was due to the PbO_2/PbO couple in alkaline solution (4). Now, taking account of the diffusion potential in the film, the coincidence of the experimental plateau with the hypothetical Pb/PbO potential at pH 0 is readily explained.

Since, for the couple

$$PbO + 2H^+ + 2e^- = Pb + H_2O \qquad [7]$$

$$E = 0.260 - 0.05916\,pH^1 \text{ (vs. STP } H_2)$$

and for the diffusion potential in the film, when the pH in the solution is 0

$$\Delta\psi_d = +0.05916\,pH^1 \qquad [8]$$

the externally measured value becomes

$$E_{exp} = E + \Delta\psi_d = 0.260\text{V (vs. STP } H_2) \qquad [9]$$

corresponding to the Pb/PbO value at pH 0.

It is to be noted that the cancellation of the pH dependence of the potential-determining couple is only complete if the potential of this latter varies with 0.05916V per pH unit (as *e.g.* in [7]). For potential-determining couples with different pH-dependence, (see Table I), the experimentally measured potential cannot then be expected to be close to the standard potential.

Cathodic Stripping

During cathodic stripping of corrosion films on Pb, one observes characteristic potential plateaus (4), corresponding to those obtained during self-depassivation. The plateaus are, however, displaced in the cathodic direction. The plateau at −0.4V, *e.g.*, due to the PbO/Pb couple may thus be found at −0.8V *vs.* Hg/Hg_2SO_4. Using the data of Ref. (4) and the present theory on diffusion potentials in corrosion films, the multi-phase structure of the films, after potentiostatic anodization in 4.2M H_2SO_4 during 24 hr, can be represented schematically as shown in Fig. 9. This illustration differs from an earlier model (4), in that α-PbO_2 may now be expected to be present in the film only above +0.5V *vs.* Hg/Hg_2SO_4 and that below this voltage the inner layer consists essentially of PbO, in agreement with (8) and (9).

Interpretation of Potentiodynamic Studies

The diffusion potential in the corrosion film is also of importance for the assignment of current peaks to specific electrode couples during linear anodic and cathodic potential sweep. In fact, a reduction peak, observed at −0.8V *vs.* Hg/Hg_2SO_4, that is slightly above the $PbSO_4/Pb$ peak (15), should, on the basis of the present theory, be attributed to the reduction of PbO to Pb at pH 9.34 and not to the reduction of α-PbO_2 to PbO.

Implications with Respect to Lead-Acid Storage Battery Technology

Plate formation.—Unformed, cured battery plates, made with a paste of PbO, Pb, and H_2SO_4, show in 1M H_2SO_4 a potential of about −0.6V *vs.* Hg/Hg_2SO_4. This means that the potential is about 350 mV above the theoretical value for the $Pb/PbSO_4$ couple. Upon formation at low current the potential of the negative plates may remain for a considerable length of time above the expected value (−0.97V *vs.* Hg/Hg_2SO_4) while the potential of the positive plates may stay several hundred mV below the value of the $PbO_2/PbSO_4$ couple, (+1.1V *vs.* Hg/Hg_2SO_4). This behavior, which is illustrated in Fig. 10, may readily be explained by the fact that the interior of the plates stays, during the initial hours of formation, in an alkaline condition, due to the presence of PbO (pH 9.34). A surface film of $PbSO_4$ prevents the acid from penetrating into the plate. In this way Pb in the negative plate and PbO_2 in the positive plate are formed under alkaline conditions, where the potential is higher, or lower, respectively. For the same reason, a high proportion of α-PbO_2 is found in the positive plate (13, 30-35).

From Table I it may be seen that 5 PbO · 2 H_2O could theoretically be oxidized to PbO_2 already at 0.478V *vs.* Hg/Hg_2SO_4, and 5 PbO · 2 H_2O could be reduced to Pb already at −0.332V *vs.* Hg/Hg_2SO_4. In a solution of pH 9.34 the formation voltage is only 0.81V. In acid solution one has at $a_{SO_4^{-2}} = 1$ and pH 0 a formation volt-

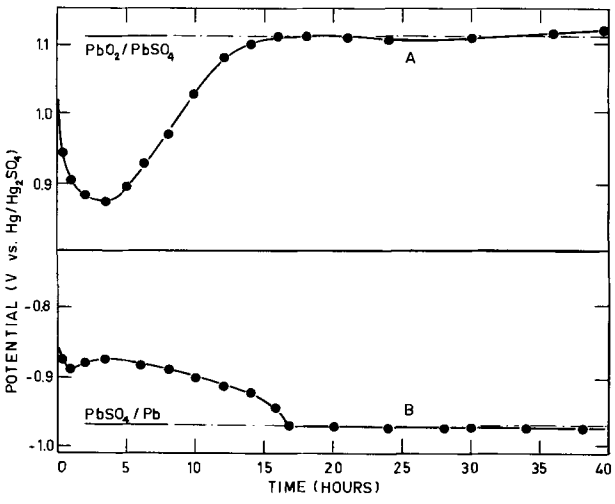

Fig. 10. Potential of positive (A) and negative (B) storage battery plates (12 A-hr) during initial, very low-rate formation (200 mA) in 2.2M H_2SO_4.

age of

$$2\,PbSO_4 + 2H_2O = Pb + PbO_2 + 2H_2SO_4$$

$$E = 2.041V$$

since the energy of the sulfation process

$$PbO + H_2SO_4 = PbSO_4 + H_2O \quad \Delta G = -28\ \text{kcal}$$

$$\Delta E = 0.61V$$

must be added to each electrode.

Grid corrosion on open circuit.—If positive storage battery plates are stored in a partly or completely discharged condition, a relatively high *p*H can develop underneath the $PbSO_4$ films on the grids. Self-discharge of positive plates due to reaction between PbO_2 in the active material and Pb in the grid (30, 31) is then highly accelerated. It should be noted that the present discussion has been limited to Sb-free grids. On Pb-Sb alloys, the sulfate films are probably less dense, due to the higher solubility of the basic Sb-sulfates. The $PbSO_4$ layers may then be less permselective, the diffusion potentials possibly somewhat decreased, and α-PbO_2 would be able to form even at lower potentials than +0.5V *vs.* Hg/Hg_2SO_4. It would be of interest to measure experimentally diffusion potentials in mixed $PbSO_4$ — $(SbO)_2 \cdot SO_4$ precipitation membranes.

The Anodic Oxidation of Several Rare Earth Metals in Sodium Aluminate Solution

Leonard Gruss* and Thomas Mackus

Pitman-Dunn Laboratories, Frankford Arsenal, Philadelphia, Pennsylvania 19137

ABSTRACT

Samarium, europium, gadolinium, yttrium, dysprosium, holmium, erbium, and ytterbium metal rods (99.9% pure) were anodized in a 0.1*N* solution of sodium aluminate (15°C) at constant current density of 0.16 A/cm^2. Anodic barrier film effects and dielectric breakdown (sparking) were observed with all of the metal-electrolyte combinations investigated. Powder x-ray diffraction patterns and diffuse reflectance spectra in the near u.v. to visible range were obtained for the anodic oxidation products. The anodic spark reaction process produced perovskite structured coatings on the lower atomic number samarium, europium, and gadolinium metals. Mixtures of perovskite and garnet structured coatings were produced on the higher atomic number dysprosium, holmium, erbium, and ytterbium metals including yttrium.

A variety of aluminate compounds having different structures are formed when the rare earth sesquioxides and/or Y_2O_3 react with Al_2O_3. The two most common varieties are the perovskite (1:1) and garnet (3:5) structures. Many ABO_3 compounds containing the rare earths and small trivalent ions such as aluminum have been the subject of intensive and detailed studies. The ABO_3 compounds containing lanthanum closely resemble an ideal perovskite structure but those compounds containing smaller rare earths form a distorted perovskite. Keith and Roy (1) studied the 1:1 aluminates of lanthanum through samarium and classified them as perovskites with $LaAlO_3$ being nearly cubic. Goldschmidt *et al.* (2) first prepared $YAlO_3$ and considered it to have the perovskite structure. However, on the basis of substantial differences in optical and powder x-ray diffraction data, Keith and Roy (1) classified this compound as having a distorted perovskite structure. Geller and Bala (3) and Bertaut and Forrat (4) carried out an extensive investigation of the ABO_3 rare earth compounds. They considered all these compounds to be of the perovskite type having an orthorhombic distorted structure.

Yoder and Keith (5) unexpectedly synthesized the first rare earth aluminate (3:5) garnet. They investigated the extent of the substitution of $Y^{+3} + Al^{+3}$ for $Mn^{+2} + Si^{+4}$ in the garnet $Mn_3Al_2(SiO_4)_3$. A garnet having a formula $Y_3Al_2(AlO_4)_3$ was produced corresponding to complete substitution of the Y^{+3} and Al^{+3} ion. In terms of molar composition the formula $Y_3Al_2(AlO_4)_3$ corresponds to $3Y_2O_3 \cdot 5Al_2O_3$. Bertaut and Forrat (4) prepared aluminum garnets only with rare earths smaller than samarium but no studies were made with europium compounds. They showed that gadolinium, dysprosium, yttrium, and erbium garnets can be produced. Warshaw and Roy (6) and Schneider *et al.* (7) agree that aluminum garnets can be formed with the smallest rare earths between thulium and lutetium but no aluminum garnets are formed with europium and gadolinium. $NdAlO_3$ to $DyAlO_3$, $YAlO_3$, $TbAlO_3$ (8) single crystals were prepared from various flux compositions in some cases by slow cooling and in others by evaporation of the flux at constant temperatures. It is noted that $YbAlO_3$ thus prepared (8) coexists with the garnet phase, $Yb_3Al_5O_{12}$. The usual procedure for the preparation of polycrystalline aluminum perovskites or garnets involves firing a rare earth oxide with aluminum oxide at temperatures over 1000°C. This investigation was undertaken to study the preparation, structure, and composition of rare earth aluminates by the anodic spark reaction of rare earth metals in sodium aluminate solution.

The phenomena of anodic sparking has been observed by many investigators and was described in detail in the work of Guntherschulze and Betz (9). The effect appears when the voltage across an anodic barrier film is raised to a point where film thickness can no longer increase uniformly and any small increase in voltage results in a large increase in current. The excess current is carried by scintillations, hence, dielectric breakdown. The anodic spark reaction has been utilized for the protection of light metals, *i.e.*, magnesium by the HAE (10) and Cr-22 (11) processes. In the HAE and Cr-22 process, a hard adherent layer containing a mixture of refractory magnesium compounds is deposited on the magnesium surface. The solution in the HAE process which contains OH^-, PO_4^{-3}, F^-, AlO_2^-, and MnO_4^{-2} ions produces an alkaline coating whereas the Cr-22 solution which contains CrO_4^{-2}, HPO_4^{-2}, and F^- ions produces a nonalkaline coating. Cadmium niobate (12) was prepared by anodic sparking of cadmium in potassium niobate solution. Anodic spark reactions were made with a variety of metals (13) in sodium aluminate, sodium tungstate, and sodium silicate solutions. The principal spark reaction products were α-Al_2O_3 and spinels, *i.e.*, $MgAl_2O_4$ with aluminate solutions, monoclinic WO_3 with tungstate solutions, and crystalline silicates or metals dispersed in amorphous material with silicate solutions. Cadmium sulfide was also synthesized by the anodic spark reaction of cadmium in $Na_2S \cdot 9H_2O$ solutions (14).

Although many studies have been made with the rare earths, electrochemical studies of the rare earth metals have been limited. In 1963, Greene and Lee (15) studied the electrochemical characteristics of the rare earth metals in dilute phosphoric acid solution up to 4V in the noble direction. He found anodic polarization curves of the rare earth metals to be typical of metals which form oxide barrier films at their interfaces, *i.e.*, aluminum, zirconium, and tantalum. Most recently, Heller *et al.* (16-18) studied cathodic and solution electroluminescence of trivalent rare earth ions. Solutions of inorganic cations in phosphorus oxychloride electroluminesce when a direct current is passed through the liquids. The electroluminescence originates at the surface of the cathode.

Experimental

The rare earth metals in rod form were mounted in tight-fitting Teflon sleeves. These sleeves serve to mask the anode at the air-electrolyte interface and to fix the area for anodization. Prior to anodization the

Key words: rare earth metals, rare earth aluminates, anodic oxidation, anodic spark reaction.

metals were polished with a series of silicon carbide abrasive papers down to a 3/0 emery and finally with microcut polishing paper (GRIT=600 soft) and washed with absolute ethanol. Samarium, europium, gadolinium, yttrium, dysprosium, holmium, erbium, and ytterbium metal rods (99.9% pure) were anodized in a 0.1*N* solution of reagent grade sodium aluminate. A current density of 0.16 A/cm^2 was employed in all reactions. The reaction cell was thermostated at 14.5° ± 0.5°C. The cell was equipped with a magnetic stirrer and a platinum cathode whose area was at least equal to the anode surface area in all experiments.

The voltages were monitored by an Electronic Measurements constant current power supply and a Hewlett-Packard 410c voltmeter and recorded on a Speedomax strip chart recorder.

The analyses of the anodic spark reaction products were performed on the insoluble material which was ejected from the anode surface during the spark reaction. X-ray diffraction patterns were obtained on all samples using a Debye-Scherrer 114.59 mm camera (Norelco) and a Norelco basic x-ray diffraction unit employing nickel filtered copper K_α radiation. The results of powder x-ray diffraction analysis on the anodic products are shown in Table I.

Diffuse reflectance spectra between 220-700 mμ were obtained for the anodic spark products using a Cary Model 14 Spectrophotometer equipped with a Model 1411 diffuse reflectance (ring collector) accessory.

Results

Anodic barrier film effects and dielectric breakdown were observed with all of the rare earth metal-electrolyte combinations investigated. The composite voltage-time curves for the anodic reactions of seven rare earth metals and yttrium, in sodium aluminate solution, are shown in Fig. 1. The curves of Sm, Gd, Y, Dy, Ho, and Er are typical of metals which form oxide-barrier films at their interfaces, *i.e.*, Al, Ta, and Zr. Steeply rising slopes are evident occurring within the first 15-20 sec of anodization corresponding to the growth of thin transparent insulating films. In the regions of the steeply rising slope up to the point of dielectric breakdown yttrium apparently divides the curves (except europium) of the low and high atomic number rare earth metals.

Most studies were made with erbium metal and in the initial stages of the anodic reaction up to 20V, the very rapid rise of voltage is accompanied by a film which exhibits a sequence of interference colors corresponding to increases in thickness. As the anodic film increases in thickness the 20V film which is gray-white has the tendency to become cloudy although an iridescence can be seen at 500V.

Yb and Eu have the tendency of deviating from the trends which exist with the other rare earths, *i.e.*, atomic volumes, melting points, densities, etc. A similar effect was noted with the voltage-time curves. The curves are somewhat typical of valve metals except that a much longer period of time was required to achieve dielectric breakdown. An unusual effect was noted with europium in the $NaAlO_2$ solution. Europium being very reactive, reacted to form a bulky lime-green coating during polishing, water rinsing, and during immersion in the $NaAlO_2$ solution just prior to anodization. As current was passed through the cell, the voltage rose slowly with time. This was followed by a rapid rise in voltage to about 75V. At this point, a shoulder formed representing a slow rise in voltage with time. At about 100V an anodic reaction occurred which is somewhat typical of those metals which form oxide-barrier films at their interfaces. Although europium is very reactive in sodium aluminate solution it appears to undergo two anodic reactions evidently forming two separate barrier films. The final spark reaction coating formed on the europium surface prevents reaction of the europium metal with either water or sodium aluminate solution.

Table I. The anodic spark reaction products of the rare earth metals when anodized in sodium aluminate solution

Metal	Products
Samarium	$SmAlO_3$
Europium	$EuAlO_3$
Gadolinium	$GdAlO_3$
Yttrium	$YAlO_3$
	$Y_3Al_5O_{12}$
Dysprosium	$DyAlO_3$
	$Dy_3Al_5O_{12}$
Holmium	$HoAlO_3$
	$Ho_3Al_5O_{12}$
Erbium	$ErAlO_3$
	$Er_3Al_5O_{12}$
Ytterbium	$YbAlO_3$
	$Yb_3Al_5O_{12}$

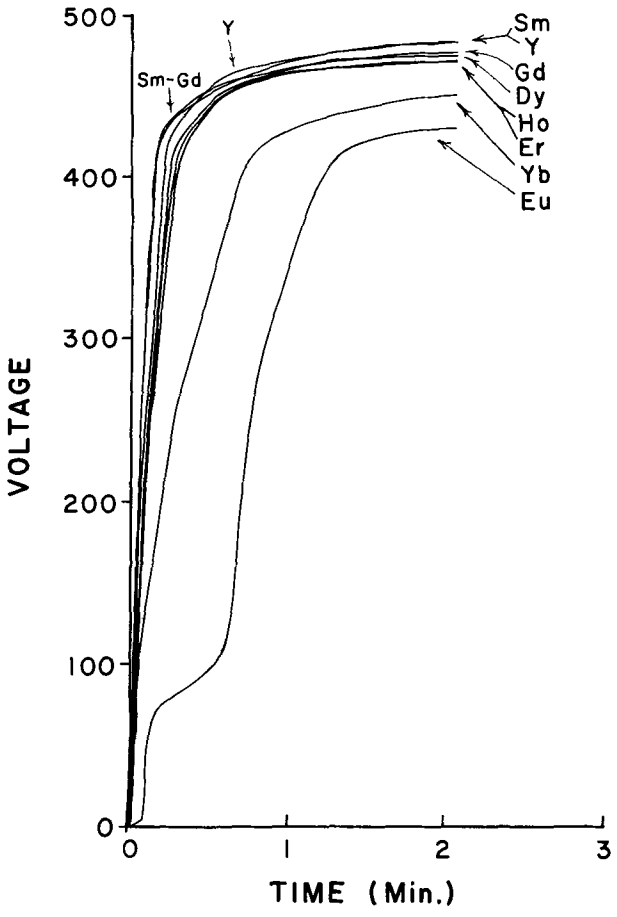

Fig. 1. The composite voltage-time curves for a variety of rare earth metals and yttrium anodized in 0.1*N* $NaAlO_2$ solution.

Electroluminescence was observed with all of the metal-electrolyte combinations investigated except with europium. The electroluminescence appeared over the entire anodic film at voltages below the spark potential and was present with spark discharges at 400V. The color of the electroluminescence varied from one rare earth metal to another but no color variations were noted with increases in voltage.

The appearance of sparking was noted with all of the rare earth metals including yttrium. The sparks were as described by Guntherschulze (9) increasing in size and becoming less mobile as the voltage increased toward the maximum. The potentials at initial and highly energetic sparking and the final potentials are given in Table II. The final potentials were obtained from the constant current density experiments performed manually after 30 min of anodization. The voltages at which highly energetic sparking became apparent for each rare earth metal were taken at the base of the knee of the curve at the point of deviation from linearity. Since small highly mobile scintillations precede the highly energetic sparks the change in slope

Table II. The potentials for initial and highly energetic sparking and the final anodization potentials for rare earth metals anodized in sodium aluminate solution

Metal	Potential (volts)		
	Initial sparking	Highly energetic sparking	Final
Samarium	271	423	555
Europium	203	385	502
Gadolinium	263	423	550
Yttrium	251	422	555
Dysprosium	250	415	543
Holmium	220	413	543
Erbium	183	412	550
Ytterbium	175	407	555

prior to the knee of the curve was taken as the point where scintillations begin.

The very strong adherent anode coatings display striking colors characteristic of the individual rare earth cations under the influence of visible light. The colors are best described in Table III. These coatings were very hard and had the appearance of fired ceramics.

The anodic spark reaction process produced perovskite coatings (see Table I) on the lower atomic number samarium, europium, and gadolinium metals. Mixtures of perovskite and garnet coatings were produced on the higher atomic number rare earth metals including yttrium. These results show the component(s) of the spark reaction products are derived from the anion constituent of the electrolyte. It is possible that noncrystalline compounds may also be present but are unaccounted for by x-ray diffraction analysis. In some patterns, *i.e.*, ytterbium products, a few extraneous and weak lines were present. Since only a few lines are left unaccounted for, it is very difficult to assign them to a definite compound. These lines, however, do not correspond to ytterbium sesquioxide.

Diffuse reflectance spectra in the near uv to visible range were obtained for the spark reaction products. The reflectance spectra for europium, holmium, and ytterbium products are shown in Fig. 2. In these regions of the spectrum the sharp absorption peaks characteristic of the rare earth ion were observed. These peaks are intra f-f transitions of predominantly electric dipole character (19) resulting from spin-orbit interactions and to a lesser extent due to the extent of the crystalline field. For the samarium, europium, and gadolinium products the spectra contained slightly displaced peaks from the corresponding peaks of similar sesquioxides. In addition, in the region of strong optical absorption only a single absorption edge was observed for the perovskite products, indicative of a single compound. The spectra for yttrium, dysprosium, holmium, erbium, and ytterbium products in addition to the slightly shifted peaks contained some extra peaks when compared to the corresponding sesquioxides. The observed spectra in the region of strong optical absorption for the perovskite-garnet products is suggestive of the existence of two absorption peaks as is found in a mechanical mixture. This data apparently confirms the results of the x-ray diffraction study that single compounds exist in the anodic products of the lower atomic number rare earth metals and mixtures exist in the anodic products of the higher atomic number rare earth metals when these metals are anodized in sodium aluminate solutions. In addition, many of the peak intensities of the perovskite and perovskite-garnet products increase and/or decrease from similar peaks found in the sesquioxides.

Table III. Color description of the anodic coatings deposited on the rare earth metals by the anodic spark process

Metal	Color
Samarium	Dark tan-brown
Europium	Light yellow-green tint
Gadolinium	Light tan
Yttrium	Tan
Dysprosium	Light tan
Holmium	Salmon
Erbium	Pink (orange-purple tints)
Ytterbium	Yellow (with pale green)

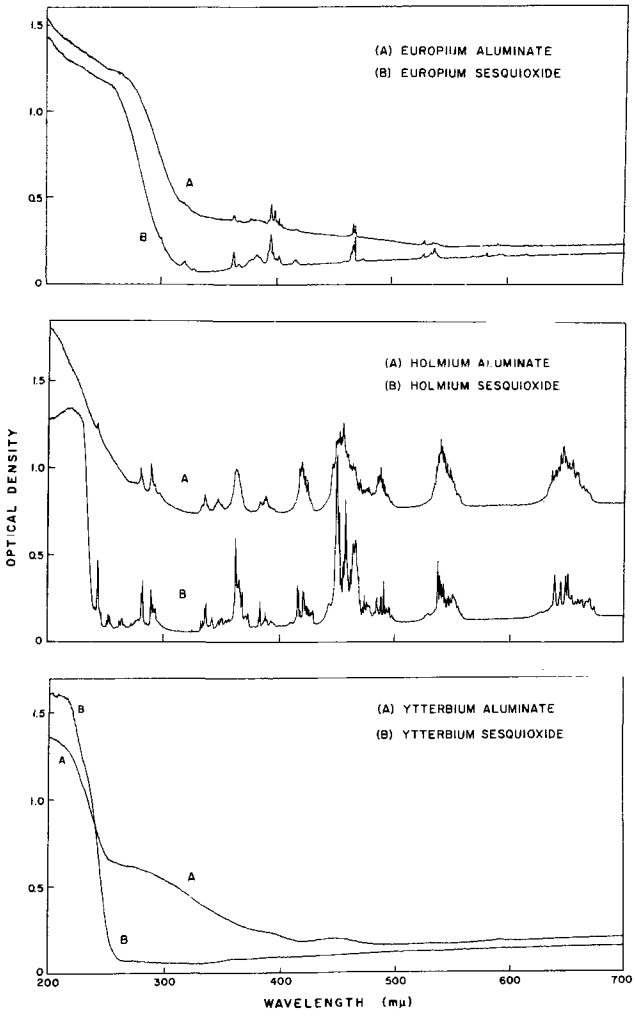

Fig. 2. Comparison of the diffuse reflectance spectra of the spark reaction products of europium, holmium, and ytterbium metals with the reflectance spectra of the sesquioxides of these metals, respectively.

Discussion

When a rare earth ion such as Yb^{+3} is added to a rare earth sesquioxide lattice, *i.e.*, Er_2O_3, no interactions take place between the erbium and ytterbium cations in the solid solutions (20). The electrostatic field generated by the Yb^{+3} ion in the erbium oxide lattice has no effect on the erbium ion. In other words, the erbium ion when in the ground state is completely independent of the ytterbium ion. However, when Al^{+3} is added to a rare earth sesquioxide lattice the tightly bound f electron levels are no longer shielded from the changes in the electrostatic field produced by the addition of Al^{+3} to the rare earth oxide lattice. This was observed in the diffuse reflectance spectra of the rare earth aluminates where the f-f transition absorption peaks were shifted. In addition, there are variations in the occupancy of the levels as indicated by the increases and/or decreases in some of the peak intensities. Where mixtures occurred as with perovskite-garnet products the extra peaks as mentioned under results are merely the absorption peaks of two compounds some of which are superimposed upon each other and others are shifted when compared to the rare earth oxide absorption peaks.

We note in Table II that both the initial spark potential and highly energetic spark potentials decrease with a decrease in size of the rare earth metal atom. Europium is an exception but the general trend is ap-

parent. This decrease in the spark potentials from Sm to Yb is similar to the decreasing values for the standard oxidation potentials of the rare earths described by the equation (21)

$$RE(s) \rightleftarrows RE^{+3}(aq) + 3e^-$$

The high values of the standard oxidation potentials which are in accord with their electropositive character places yttrium metal between gadolinium and dysprosium metals. The values of both the initial and highly energetic spark potentials also place yttrium metal between gadolinium and dysprosium. The chemistries of the rare earths (22) in the +3 oxidation state are nearly identical although slight quantitative differences exist varying systematically from lanthanum through lutetium with yttrium being placed approximately between dysprosium and holmium.

X-ray diffraction analyses showed that the anode metal was found chemically combined in the crystalline spark reaction products forming stable perovskite or perovskite-garnet rare earth compounds (Table I). This was true with all rare earth metals studied. Anodization studies of erbium metal at a voltage (150V) below the spark potential revealed the existence of two coatings. The outer coating was a white opaque glassy material identified by x-ray diffraction to be β-$Al_2O_3 \cdot 3H_2O$. The inner portion of the anode coating is pink erbium oxide produced by oxidation of the erbium anode. Continuation of anodization into the sparking region produces a series of glassy pink beads at each spark site in the white coating. These pinkish beads were identified by x-ray diffraction as the products given in Table I for erbium. Further continuation of sparking (30 min) produces on the anode surface the final pinkish colored products described in Table III.

The growth mechanism which apparently accounts for the compositions of the anodic coatings formed in sodium aluminate solution is similar to that reported by McNeill and Gruss (23) who studied anodic film growth by anion deposition in sodium aluminate solution. The present study showed that erbium metal and presumably the other rare earth metals and yttrium form a film of oxide of the anode metal prior to the deposition of the anion constituent. The metal oxide film is apparently the anodic barrier film which is common to anodes such as Al, Ta, and Zr which exhibit strong tendencies to form such barrier films in most electrolytes. This, of course, is followed by accumulation and precipitation of the anion constituent on the anode surface that is β-$Al_2O_3 \cdot 3H_2O$. At this point it is uncertain whether the barrier film remains as the metal oxide initially formed or has been modified by the deposition of the anion constituent. Upon precipitation of the anion constituent on the anode surface sparking induces the interaction of the metal oxide film and the precipitated anion constituent. It is uncertain whether the metal-oxidation and/or anion deposition reactions continue when sparking commences. However, since spark reaction products are ejected from the anode surface followed by healing at the site of ejection, it is believed that both reactions continue. In addition to the reactions described, there are undoubtedly other anodic phenomena occurring simultaneously at the anode.

The crystalline spark products obtained from the anodic reactions of Sm, Eu, Gd, Y, Dy, Ho, Er, and Yb metals in 0.1*N* sodium aluminate solution are quite similar to the solid solutions produced by Schneider *et al.* (7). In the study of Schneider *et al.* equimolar amounts of Sm_2O_3, Eu_2O_3, Gd_2O_3, Y_2O_3, Dy_2O_3, Ho_2O_3, Er_2O_3, and Yb_2O_3 were respectively mixed with Al_2O_3, pressed into pellets, and fired in an atmosphere using a program controlled furnace at 1650°C for 6 hr. Equilibrium was attained when x-ray patterns of a specimen showed no change with successive heat-treatments. Perovskite structures of $SmAlO_3$, $EuAlO_3$, and $GdAlO_3$ were produced for equimolar compositions heated to 1650°C for 6 hr. These results were also obtained by Geller and Bala (3). Perovskite and garnet mixtures having the general formulas of $(RE)AlO_3$ and $(RE)_3Al_5O_{12}$ (RE = rare earth) respectively were produced for dysprosium, holmium, yttrium, and erbium. Only garnets were produced with ytterbium. Most of these mixtures also contained an unknown or c-type oxide. Garton and Wanklyn (8) in their work with the rare earth aluminates reported that $YbAlO_3$ prepared coexisted with the garnet phase which is comparable to our results (see Table I).

The lattice parameter of the $Yb_3Al_5O_{12}$ garnet which we prepared by the anodic spark reaction was calculated to be 11.8962Å. This value is in agreement with the trend demonstrated by Bertaut and Forrat (4) showing decreasing lattice parameter values in going from gadolinium to erbium.

Manuscript submitted Sept. 5, 1972; revised manuscript received Oct. 27, 1972. This was Paper 15 presented at the Houston, Texas, Meeting of the Society, May 7-11, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

pH Optimization Studies on a Basic Ammoniacal Citrate Ni-Fe Plating Solution for Use in Plated Wire Memory Production

R. L. Barauskas* and A. E. Guttensohn

GTE Automatic Electric Laboratories Incorporated, Northlake, Illinois 60164

ABSTRACT

Plated wire was produced from a basic ammoniacal citrate Ni-Fe plating solution. The solution pH and solution aging characteristics were investigated *vs.* plated wire material, device, and memory properties. An optimum operating range of this solution was found to be between pH = 8.4 and 8.6. A group of equations was developed which accurately predicted both the device and the memory characteristics of the plated wire from only the materials data and solution pH.

The electrodeposition of zero magnetostrictive Ni-Fe alloys for plated wire memory applications has been successfully accomplished with either acid or basic Ni-Fe electrolyte solutions (1, 2). Both solution types were also tried in our laboratories. A preference was found after extensive experimentation with both. The basic ammoniacal citrate solution was found more acceptable for the following reasons: (*i*) The evaporation rate of deionized water from the Ni-Fe baths was lower for the basic bath which was operated between 18°-24°C than for the acid sulfate baths which were operated between 45°-50°C. The advantage of the lower evaporation rate is that the concentration level of the various ionic species present in the bath is more stable with time. (*ii*) After a two-day "age in" the oxidation of Fe^{++} to Fe^{+++} in the basic solution is complete. In the case of the acid sulfate solutions, the oxidation aging is a continuing process which necessitates daily bath analysis and appropriate additions. After two days only pH adjustments have to be made to the basic solution. This is accomplished by additions of NH_4OH. The Ni and Fe levels in the basic solution are monitored every two weeks and maintained by additions of nickel and iron(III) citrate. By using this technique we were able to maintain a bath for two and one-half years. (*iii*) No stress relievers were necessary. (*iv*) Bath analysis and maintenance are simpler which result in lower costs for bath upkeep.

In the process of working with the basic bath as described in Stephen's patent (2), it was found that concentration changes and Ni-Fe ratio changes were required in order to produce zero magnetostrictive films with our plating line (3). The 5 to 1 Ni-Fe ratio which Stephen proposes had to be changed to 9 to 1 because of our solution flow rates and cell currents. Also the suggested pH range of 9.2-9.25 at our operating conditions and the new concentration levels produced some undesirable plated wire device and memory properties. Therefore, it became of interest to characterize fully, for the conditions of use, the basic ammoniacal citrate Ni-Fe plating solution in terms of the material, device, and memory properties of the plated wire. The characterization led to a new and more stable pH operating range and the development of a group of equations which allowed us to predict the device and memory properties of the annealed plated wire from only the materials and pH data. Results from these equations were spot checked with an off-line memory tester. Agreement was close enough to allow us to eliminate an on-line memory test screening station and replace it with a few simple off-line materials tests. A very simple on-line device test setup which displayed e_{out} *vs.* I_w (see Fig. 1) was also used to aid in wire screening. By using these equations and the on-line device test setup we were able to screen out wires or wire lots which were unworthy of any off-line memory testing.

* Electrochemical Society Active Member.
Key words: electrodeposition, alloys permalloy, Ni-Fe films, plated wire, pH.

Experimental Procedure

The basic plating line setup uses Lexan and Lucite plating cells with various exposure lengths and solution flow rates. Our plating line consisted of the following steps (3): an anodic electroclean solution (Enbond 160) operated at 70°C and 6.5 A/dm²; a 5% H_2SO_4 solution operated at 65°C; an anodic electropolish solution consisting of 2 to 1 parts by volume phosphoric acid to glycerin operated at 55°C and 8 A/dm²; a 50% methanol water rinse operated at room temperature; a pyrophosphate dip consisting of 540 g/liter of Unichrome S-13 in water operated at pH = 9, and room ambient; a cathodic pyrophosphate copper strike consisting of 540 g/liter of Unichrome S-12 in water operated at pH = 9, room ambient and 20 A/dm²; a cathodic bright acid sulfate copper plate consisting of 655g $CuSO_4 \cdot 5H_2O$, 107 ml conc H_2SO_4, 15 ml UBAC No. 1 brightener, enough HCl to make the total chloride ion concentration 30 mg/liter, and deionized water to make the total volume 3000 ml, operated at room ambient and 50 A/dm²; an anodic etch consisting of 2 to 1 parts by volume phosphoric acid to water operated at room ambient and 40 A/dm²; four identical NiFe plating cells operated between 18°-20°C with a flow rate of 1.5-2 liters/min and a current density of 10 A/dm²; a deionized water rinse cell; an on-line annealer which was operated between 225°-325°C with a nitrogen gas atmosphere; and a limited on-line device test station. All plating cells were followed by a water rinse cell except electropolish, pyrophosphate, and NiFe cells. The specifics on the geometry of each of our plating cells is proprietary.

Seven plated wire lots, each containing 120 pieces of 9-in. long plated wire, were made at seven different values within the pH range of 8.23-9.61 of the basic ammoniacal citrate NiFe plating solution. The resultant NiFe plate was then evaluated for material, device, and memory characteristics (see Fig. 1). In all, twenty-two characteristics were evaluated. The materials characteristics included H_c, H_k, skew, dispersion, hysteresis of the Belson trace, film thickness as calculated from the hard axis sense voltage output for a sinusoidal drive field large enough to completely saturate the film in the hard axis direction, and alloy composition in terms of torsional strain sensitivity. The device characteristics included output, uniformity of output as σ/output, where σ is the standard deviation of sampled outputs from a 9-in. long piece of plated wire, time duration of the output, initial switching, intermediate switching, final switching, output symmetry, switching symmetry, I_{Hc}, maximum

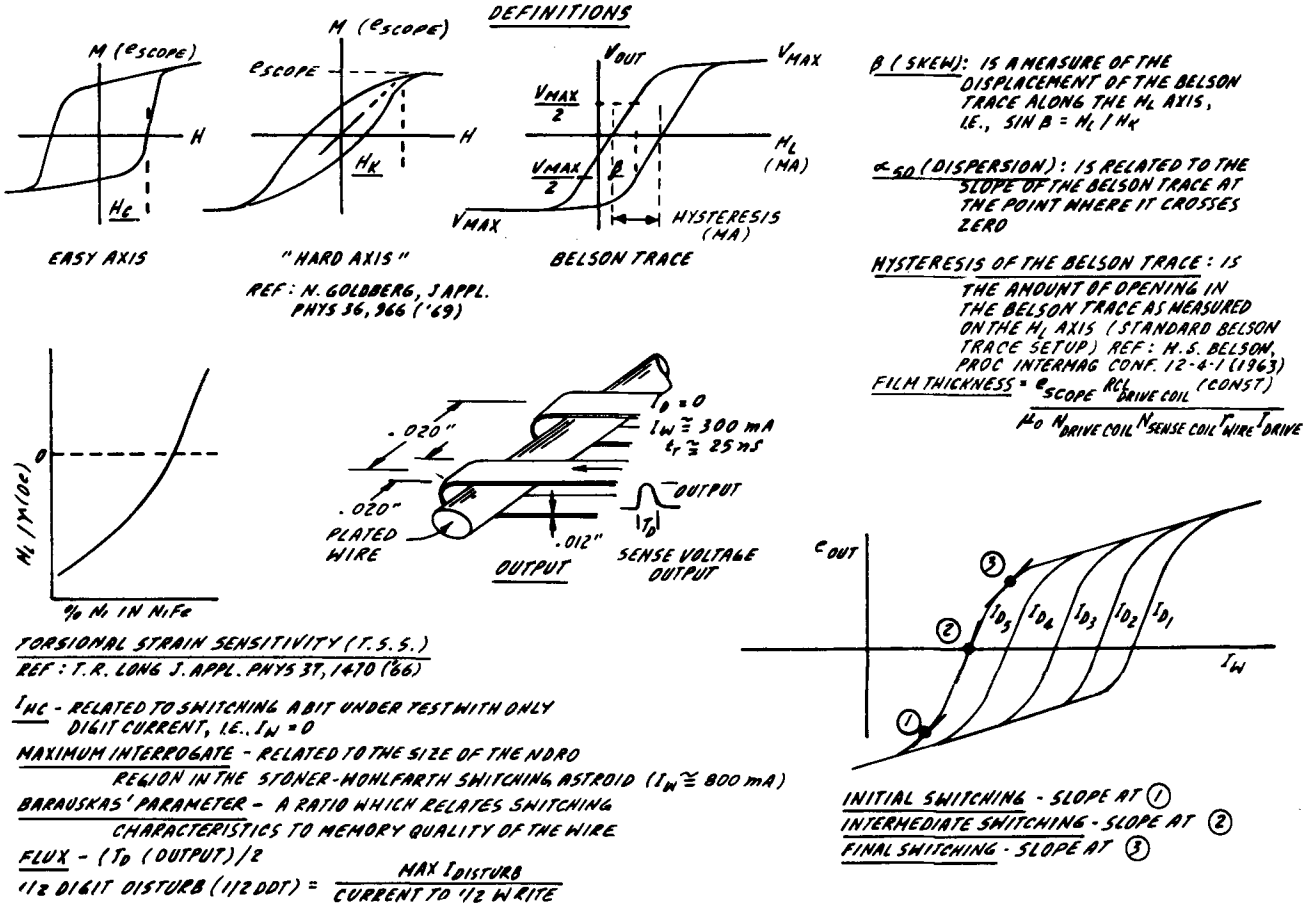

Fig. 1. Definition of terms

interrogate, flux, flux/film thickness, output, film thickness, and Barauskas' parameter. Barauskas' parameter is a quotient of two digit currents. The numerator is the digit current which when combined with a word current of 600 mA causes the output from the plated wire to be reduced by ½ of its fully switched value. The denominator is the digit current which when combined with zero word current produces 0.9 of the fully switched output value. It was verified that wires with smaller Barauskas' parameter values had a better chance of passing the half-digit disturb creep related memory test than those with larger values. The single memory characteristic which was tested was half-digit disturb. Previous work showed that some characteristics, even though they varied significantly, produced little or no effect on the memory quality of the wire. These characteristics are termed noncritical. The remaining characteristics were critical and are referred to as such: skew, dispersion, H_k, uniformity of output, I_{Hc}, maximum interrogate, initial switching, Barauskas' parameter, and half-digit disturb. These were further broken down into three groups of three with the last three characteristics being the most critical to the functioning of the wire as a memory element, the middle three being less critical, and the first three being the least critical.

The ammoniacal citrate plating solution (Ni/Fe = 9) contained the following; Part 1: 900g of $NiCO_3$, 1504g of $(NH_4)_2HC_6H_5O_7$ (ammonium citrate), and 1250g of $HOC(CH_2CO_2H)_2CO_2H \cdot H_2O$ (citric acid monohydrate) diluted to 11 liters with deionized water; Part 2: 49.5g of iron dust, 223.3g of $(NH_4)_2HC_6H_5O_7$ (ammonium citrate), and 191.6g of $HOC(CH_2CO_2H)_2CO_2H \cdot H_2O$ (citric acid monohydrate) diluted to 5.5 liters with deionized water.

Results and Discussion

The aging mechanism of this ammoniacal citrate nickel-iron plating solution was investigated. Upon mixing, all iron is in the ferrous (Fe^{++}) state and oxidation to the ferric (Fe^{+++}) state starts immediately (see Fig. 2). When the solution is brought up in pH by additions of NH_4OH this oxidation takes place more rapidly. Data in Fig. 2 were taken immediately after the NH_4OH addition. As the $2Fe^{++} + H_2O + \frac{1}{2} O_2 \rightarrow 2Fe^{+++} + 2(OH)^-$ reaction neared completion, both film thickness and output increased and the magnetic properties approached those characteristic of wires plated from a used or aged ammoniacal citrate nickel-iron plating solution. The Fe^{++} was monitored hourly by titration. The reaction took two days to reach completion. Wires were taken hourly and materials tested. It was found that as Fe^{++} decreased, both output and thickness increased. The rate of Fe^{++} oxidation to Fe^{+++} when the solution was agitated (about 1.5 liters/min flow) was an order of

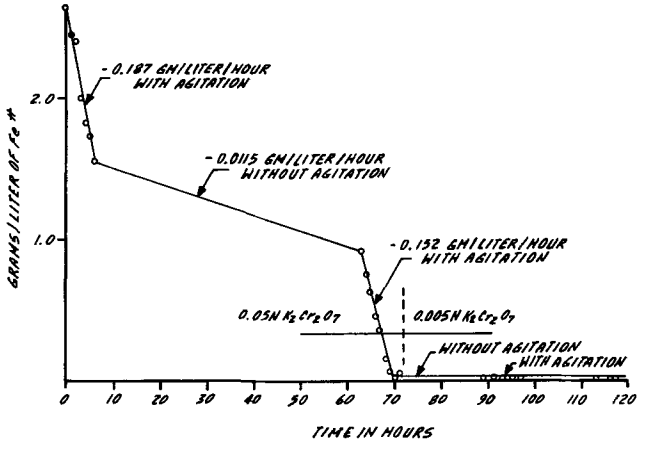

Fig. 2. Grams/liter of Fe^{++} vs. time for ammoniacal citrate nickel-iron plating solution. Solution temperature +16°. Fe^{++} determined by the dichromate method.

magnitude greater than that for the nonagitated state (see Fig. 2). The increased oxidation rate is due to the larger surface area of solution exposed to the atmosphere when the solution is agitated. The iron plates out from some Fe^{+++} complex rather than from a complex of Fe^{++}. The effective magnetic thickness tells us when the solution is ready for plating. When the effective magnetic plating thickness reaches 0.8 μm at standard operating conditions, the solution is then producing wire characteristic of an aged solution. This oxidation aging process can be avoided by using ferric citrate.

The efficiency study of the ammoniacal citrate nickel-iron plating bath was done under the following conditions: nickel to iron ratio was 9, the nickel-iron solution temperature was 17°C, the pH of the solution was 9.2, the cathode was the beryllium copper wire, the current density was 9.873 A/dm^2, the anode was a platinum helix, the flow rate of the solution was 1.6 liters/min, four 1-inch cells were used, the wire speed was 3 in./min, and the annealing temperature was 225°C.

Thickness measurements were made using a B-H loop tracer which measures integrated voltage output from the film *vs.* drive field (see Fig. 1). From these film thickness measurements we were able to determine efficiency of the plating solution.

The resulting efficiency of the basic ammoniacal citrate NiFe solution was calculated to be 30.6%.

In making plated wire it was found that in order for the wire to work as a memory element, the materials and device parameters had to assume certain values. Thus we were able to predict good memory properties with a high probability using just materials and device testing results. Barauskas' parameter correlates highly with the half-digit disturb test (95% confidence level). If Barauskas' parameter was 40 or less, there was then a high confidence that the wire had good memory properties (passing, or nearly so).

An arbitrary value of 100 or less for Barauskas' parameter, (anything over 100 was failing), was used to define testworthy wire. These testworthy wires were found to have predictable properties, while untestworthy wires (those which failed Barauskas' parameter) were found to have nonpredictable properties and were not worth device and/or off-line memory testing.

We then constructed a matrix of materials, device, and memory parameters using 49 lots of wire, including both testworthy and untestworthy wires. Using regression analyses between highly correlating parameters, we defined values of all other parameters in terms of just passing Barauskas' parameter with a value of 100 or less (testworthy wires) and having a value of 40 or less for Barauskas' parameter (memory value). The results are given in Table I.

To get the most out of our data, we developed equations to predict device and memory characteristics from materials data. Since the extensive device and off-line memory tests are time consuming, wire lots can be screened for this testing by the quick materials and on-line device tests. The one qualification that had to be imposed was that only testworthy wires (with Barauskas' parameter less than 100) could be used to predict device and memory values with any accuracy using the developed equations. From these equations one can tell that a wire is untestworthy, but one cannot characterize it, so that in this case the equations can be used to screen but cannot be used to predict values. The testworthy wires followed the equations closely.

The development of the equations was straightforward, but assessing their worth was time consuming. Initially, we had the 28 testworthy lots in a matrix and ran correlations among the device, materials, and memory characteristics. After making sure that the correlation was linear by running a scatter diagram, we picked the highest correlation between a materials and memory/device characteristic and ran a regression analysis for the particular materials and memory device characteristic. We picked the next highest correlation and repeated the procedure until we had all of the device and memory parameters in terms of material parameters. We then compared values for the device and memory characteristics using the developed equations and the actual values obtained when they were tested. Most of the equations were found to be unsatisfactory. The highest correlating parameters were fairly close. Our hope to keep the equations simple was gone. We then ran a multiple regression with each device and memory parameter against all five of the materials parameters to get equations of the form: $y = a_1x_1 + a_2x_2 \ldots + a_nx_n + b$. These were found to be quite satisfactory except in one case, half-digit disturb. We did a multiple regression analysis for half-digit disturb in terms of both materials and device parameters. The equation which resulted was found to be useful. Therefore, if one had only materials parameters, one could calculate the device parameters and then use these values in the equation for half-digit disturb.

The last refinement of the equations was the addition of a process parameter, namely NiFe solution pH, to the matrix. This refinement came after we had seen that lots run at pH's significantly different from 8.5 (our operating pH) were not as close in their calculated to actual values as those run at a pH of 8.5. To make these equations useful for the range of pH's studied we ran multiple regressions with each memory and device parameter against all five materials parameters and pH (for the half-digit disturb materials parameters, pH and device parameters were included). Upon comparing the multiple regressions, we found that for some device and memory characteristics, adding pH to the equation did not produce an increase

Table I. Regression analyses

(Refer to Fig. 1)

Parameter	Testworthy wire value	Memory value
Initial switching	≧0.74	≧0.95
Maximum interrogate	≧560 mA	≧830 mA
Hysteresis	≦20 mA	≦11 mA
H_k	≦7.4 oe	≦5.7 oe

wires produced from this basic ammoniacal citrate bath, it is difficult to say anything quantitative about radial or circumferential compositional gradients in our wires. However, others have found that the first roughly 1200-1500Å of plate is very iron rich, usually 40-60% instead of 20% Fe (4, 5). If these gradients do in fact exist in our wires (6), we feel that they could be eliminated by changes in the NiFe solution flow pattern around the wire and/or by the superposition of an a-c current on the d-c NiFe plating current (7).

Conclusion

The usual 9.2-9.25 pH range for the basic ammoniacal citrate Ni-Fe plating solution has been found

less acceptable for producing memory quality plated wire than the 8.39-8.5 pH range (solution Ni Fe = 9).

For this particular plating solution a group of equations was developed which accurately predicted the resultant device and memory characteristics of annealed plated wire from the materials and pH data alone. This approach proved to be a valuable time saver prior to off-line memory testing as it served as a very effective screener of good, bad, and marginal quality memory wires. Studies to note changes in the developed equations brought about by wire aging and a combined a-c to d-c plating current had been planned but to date have not been accomplished.

Acknowledgments

The authors wish to acknowledge the help of E. P. Bulan, all of the members of the plated wire efforts at our laboratories, and especially Doctors R. F. Janninck and M. E. Dempsey for their suggestions and encouragements during the course of this study. Also special thanks to Hernando Corredor for drawing the figures.

Anodic Oxidation of N,N,N'-Triphenyl-o-Phenylenediamine

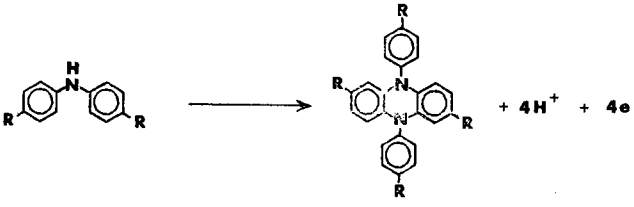
Peter Berkenkotter[1] and Robert F. Nelson*

Department of Chemistry, University of Idaho, Moscow, Idaho 83843

ABSTRACT

The anodic oxidation of N,N,N'-triphenyl-o-phenylenediamine in acetonitrile at platinum leads to 5,10-dihydro-5,10-diphenylphenazine in near quantitative yields *via* an intramolecular cyclization reaction. This reaction is the key intermediate step in the formation of dihydrophenazines from substituted diphenylamines. Selection rules are presented for these reactions defining the structural requirements and electrolysis conditions necessary.

The oxidative cyclization process of certain substituted diphenylamines to form the corresponding dihydrophenazines has been known for some time. This reaction was first effected chemically by Wieland using either permanganate or lead dioxide (1, 2). Recently, a number of investigators have studied the electrochemical oxidation of a series of substituted diphenylamines and have found that in some cases this same pathway is followed. This possibility was first suggested by Němec and co-workers (3) for di-*p*-tolylamine and later verified for a number of 4,4'-disubstituted diphenylamine derivatives (4). Subsequent studies of Cauquis and co-workers have further established the validity of this process in diphenylamine systems (5, 6). Thus, there is little doubt that the over-all process is as shown below



The detailed mechanism is still somewhat in doubt; this communication is intended to identify the intermediate in this remarkable reaction and provide a set of selection rules for formation of dihydrophenazines.

Experimental

The N,N,N'-triphenyl-o-phenylenediamine (TPOPD) was prepared by the method of Welzel (7), mp 94.5°-95° (lit. 93°). Acetonitrile (MeCN) was purified by drying for several days over CaH_2, followed by distillation twice from P_4O_{10}; for the distillations, only the middle 60% fraction was retained. The tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium hydroxide and perchloric acid, followed by recrystallization four times from water. The instrumentation and electrodes used were standard and all potentials reported are *vs.* an aqueous SCE. An authentic sample of 5,10-dihydro-5,10-diphenylphenazine (DPPZ) was donated by Professor Henry Gilman.

Preparative electrolysis of TPOPD.—The TPOPD (84 mg) was dissolved in MeCN/0.1F TEAP (200 ml) in a commercial two-compartment Sargent electrolysis vessel; the working electrode was a platinum gauze and the auxiliary a carbon rod. At a cell potential of +1.3V the electrode process yielded an n-value of 4.1 ± 0.1 Faradays/mole of TPOPD. The oxidation process required roughly 40 min for completion (1% of initial current) and was followed by re-reduction at −0.7V to convert the product to the neutral form and electrolyze away protons generated in the coupling reaction. The solvent was evaporated, (room temperature) and the residue was extracted with benzene. This was combined with a small amount of product scraped off the working electrode and the whole was chromatographed on Woelm neutral alumina with benzene and recrystallized from benzene/petroleum ether, mp 286°-287° [lit. 283°-285° (8)]. Cyclic voltammetric curves established the absence of any parent material following electrolysis and the isolated yield was 74 mg (88%).

Results and Discussion

In Fig. 1, cyclic voltammetric curves are shown for a millimolar solution of TPOPD before and after exhaustive electrolysis. There is some distortion of the TPOPD curves at different scan rates due to adsorption

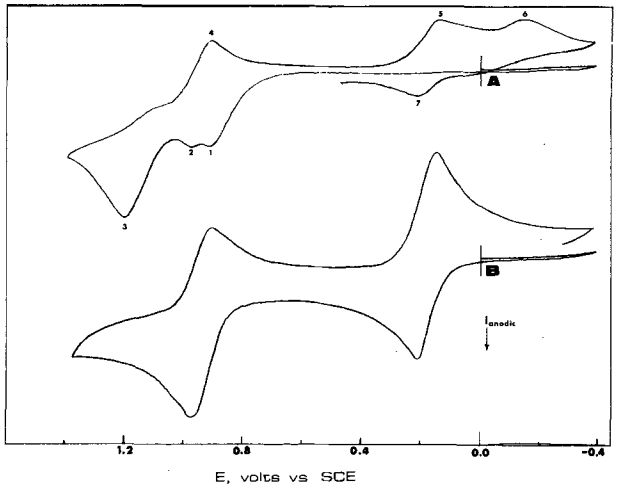


Fig. 1. Curve A: Cyclic voltammogram of 1.2 X 10^{-3}F TPOPD in MeCN/TEAP Pt button working electrode, scan rate = 0.5 V/sec. Curve B: Cyclic voltammogram of the same solution following controlled-potential exhaustive electrolysis at +1.3V, scan rate = 0.1 V/sec.

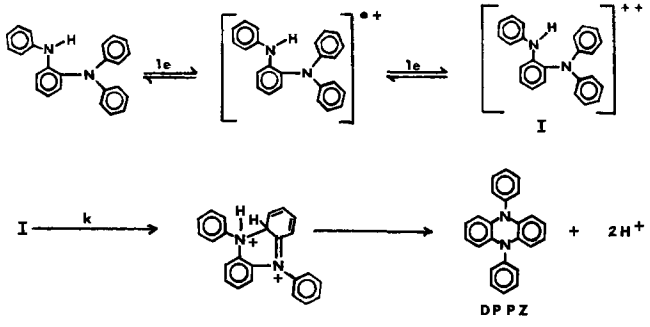
Key words: diphenylamines, dihydrophenazines, N,N,N'-triphenyl-o-phenylenediamine, anodic cyclization.

of the various species involved, but the data shown are representative. Wave 1 is the primary oxidation of the parent TPOPD to the cation radical; the radical is moderately stable. At a sweep rate of 2 V/sec and a reversal potential of +1.0V this wave is completely reversible. Waves 2, 4, 5, and 7 are due to the DPPZ, as can be seen in curve B, a scan of the solution following exhaustive electrolysis; curve B is identical to the cyclic voltammogram of an authentic sample of DPPZ. Wave 3 is most likely the TPOPD cation-dication wave (its height decreases markedly with decreasing scan rate), although this must be considered as speculative. Wave 6 is due to the reduction of protons released in the coupling reaction.

Chronoamperometric data confirm the coulometric n-value of four electrons per TPOPD molecule. Although some details of the oxidation process have not been delineated, the mechanism can be depicted as the following



Note that the cyclization is depicted as occurring in the dication state; however, in Fig. 1, curve A it can be seen that some DPPZ is present following the initial oxidation process, *i.e.*, following generation of the cation radical. If the cyclization reaction does take place through the dication, then the possibility of rapid disproportionation of the cation radical to parent and dication must be considered. This is not unlikely, since the parent-cation and cation-dication waves are only separated by about 250 mV. Another possibility is cyclization of the cation radical and subsequent oxidation of this species to generate the DPPZ. Both of these mechanisms are tenable, but it would be difficult indeed to distinguish between them at this time. It is also possible, as shown, that some oxidation of the TPOPD cation occurs at the potential where DPPZ shows up in curve A; upon formation of the dication there would be an immediate cyclization to the DPPZ. Chemical intuition suggests a cyclization from the dication, but all of the above pathways must be considered plausible at this time.

This cyclization reaction going through a TPOPD-like intermediate is not at all general for all diphenylamines; in fact, there are several stringent structural limitations to its facilitation. As can be seen, TPOPD could be generated from diphenylamine (DPA) by N-*ortho* intermolecular coupling. However, previous studies of the electrolytic oxidation of DPA in MeCN have not cited the formation of DPPZ (4, 9,10), although in the presence of bases some N-ring coupling has been cited (10). It could be argued that since DPPZ is not obtained from DPA under standard electrolytic conditions the cyclization reaction of TPOPD to DPPZ cannot strictly be analogized to the formation of substituted DPPZ's from the corresponding diphenylamines. However, inspection of the reaction pathway shows that the substituent positions are relatively remote from the cyclization site and so their effect would only be upon the rate of cyclization. In addition, it is difficult to propose another likely intermediate in place of substituted TPOPD's for the diphenylamine systems; an intermediate is almost a certainty, since it is not likely that the diphenylamine-dihydrophenazine pathway would go by a single concerted reaction. Further spectroscopic studies are under way to search for TPOPD-type intermediates in anodic oxidations of 4,4'-disubstituted DPA's in order to obtain quantitative kinetic data.

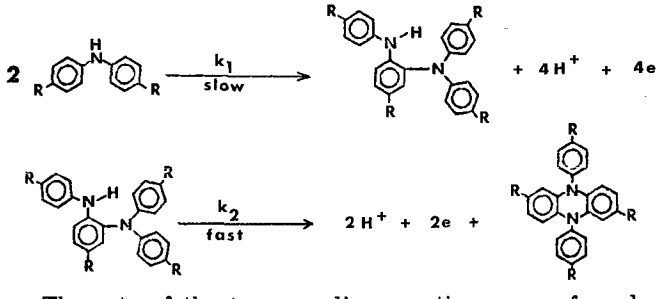
Interestingly, this reaction does not occur with 2-aminodiphenylamine (N-phenyl-o-phenylenediamine) (9, 11), although it has been noted for a series of polyfluorinated 2-aminodiphenylamines (12, 13). It was noted in these latter systems that a necessary condition for cyclization was a fluorine *ortho* to the NH group in the ring not containing the amino function (12); the dihydrophenazine derivatives were oxidized on to the corresponding phenazines since the nitrogens were not protected. It seems to be generally true that the nitrogens must be heavily substituted as in TPOPD in order to prevent decomposition of the dihydrophenazines once they are formed.

An extensive study of substituted diphenylamines (4) has revealed that the following selection rules apply to the formation of the dihydrophenazines by electrolytic oxidation of substituted diphenylamines in MeCN:

1. Both *para* ring positions must be substituted.
2. The *para* substituent must not eliminate; if this occurs *para-para* benzidines form (as with 4,4'-dibromodiphenylamine).
3. The *para* substituent must be strongly electron donating, neutral, or weakly electron withdrawing; substituents such as nitro and cyano inhibit formation of the corresponding dihydrophenazine.
4. The amine nitrogen must not be alkylated or arylated.
5. The yields in these reactions on a preparative scale are increased substantially by electrolyzing at low current densities.

These points will be considered more fully in a later publication (14), but they are presented here to provide background information for consideration of the decomposition pathway of TPOPD.

The reaction pathway for 4,4'-disubstituted diphenylamines, then, is as shown below



The rate of the two coupling reactions are inferred from electrochemical data on TPOPD and substituted diphenylamines. According to this scheme, these systems should exhibit second-order kinetics and the rate constants should be easily measurable (the "fast" rate constant in the second reaction is actually quite slow, estimated at about 1-10 sec^{-1} from cyclic voltammograms for TPOPD).

The system is obviously complex, but it is unique in that two discrete steps are involved and both reactions are slow compared to many electrochemical processes.

Electrochemical Behavior of Blood Coagulation Factors

Prothrombin and Thrombin

L. Duic,*[1] S. Srinivasan,* and P. N. Sawyer

Electrochemical and Biophysical Laboratories of the Vascular Surgical Services, Department of Surgery, State University of New York, Downstate Medical Center, Brooklyn, New York 11203

ABSTRACT

Cyclic voltammetry was used to investigate the electrochemical behavior of prothrombin (blood coagulation Factor II) and thrombin, its product in the blood coagulation sequence. The results show that these proteins undergo adsorption and charge transfer reactions at the platinum electrode-sodium chloride solution interface. The electrochemical conversion of prothrombin to thrombin at constant anodic potentials was attempted. Preliminary results indicate the possibility of intermediate electrochemical steps in the over-all blood coagulation reaction.

Heart disease is the number one killer in the United States. The heart attack is the end result; thrombosis is the real cause of the heart attack. Thrombosis may be defined as the formation of a solid or semisolid mass from constituents of blood anywhere within the heart or blood vessels during life (1). A mass formed from the constituents of blood *in vitro* or within the cardiovascular system after death is a clot (1). The thrombosis reaction is catalyzed (*i*) at a site of injury in blood vessels, (*ii*) in atherosclerotic vessels, or (*iii*) in vascular and heart valve prostheses.

The evidence accumulated within the last two decades suggests that thrombosis at the blood vessel wall or prosthetic material-blood involves intermediate steps which are electrochemical in origin (2-8). The data published to date have shown the importance of the surface charge (and/or potential across the solid-electrolyte interface) of blood vessel wall as well as of prosthetic materials in inhibiting or catalyzing blood clotting and/or thrombosis. Positively charged surfaces initiate thrombosis, while clean uniformly negatively charged surfaces inhibit thrombosis. In addition, a number of papers have been published describing the effect of electrolysis of blood and plasma in both *in vitro* and *in vivo* systems. While the work of our group and of several other workers gives evidence for the accelerated coagulation of electrolyzed plasma or blood (7-13), there are other authors who have presented work which gives somewhat conflicting results (14-16). Blood as well as plasma are far too complex systems to investigate the electrochemical phenomena taking place in the over-all thrombosis reaction, or in general in blood coagulation.

The International Committee on Blood Clotting Factors has recognized thirteen blood coagulation factors, most of which are involved in the over-all blood coagulation sequence (17). They are designated by Roman numerals from I to XIII. The most common synonyms for these factors are given in Table I. The final step in the coagulation sequence is the conversion of fibrinogen to fibrin. The cellular elements (erythrocytes, leukocytes, and platelets) are linked by this fibrous structure in a blood clot or thrombus deposit. The fibrinogen-fibrin conversion reaction is catalyzed by the enzyme thrombin. Thrombin, in turn, is formed from the blood coagulation factor prothrombin. There are two distinctive mechanisms by which the prothrombin-thrombin conversion occurs. In the intrinsic mechanism, only the constituents of blood are involved. The extrinsic mechanism occurs outside the vascular tree and requires tissue factors. The two pathways (18) are represented in Table II.

Since the prothrombin-thrombin conversion is an essential step in the over-all blood coagulation sequence, the electrochemical behavior of both these factors was determined in the present study. Prothrombin was first isolated from bovine prothrombin

Table I. Roman numeral designation and most common synonyms for blood coagulation factors (1)

Roman numeral designation	Most common synomym
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium ions
Factor V	Proaccelerin
Factor VI	Not assigned
Factor VII	Proconvertion
Factor VIII	Antihemophilic factor
Factor IX	Christmas factor
Factor X	Stuart factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin stabilizing factor

by Seegers *et al.* (19). The concentration of prothrombin in bovine plasma is 0.1-0.15 mg/ml. Human and bovine prothrombin are similar in most respects. The molecular weight of purified prothrombin is 68,000-68,500. The main contaminants in prothrombin preparations are Factors VII, IX, and X. These activities can be removed by chromatography on DEAE cellulose. The molecular weight of bovine prothrombin complex (*i.e.*, prothrombin containing Factors VII, IX, and X activities) is 70,500. Bovine prothrombin complex is ellipsoidal, of length 119Å, and width 34Å. It contains 526 amino-acid residues. The amino-acid composition of bovine prothrombin is given in Table III. The molecular weight of the amino-acid fraction in bovine prothrombin is 58,800. Subtracting this value from the molecular weight of purified thrombin, a value of about 8000 is arrived at for the molecular weight of the carbohydrate fraction in prothrombin. This represents about 11.2% by weight. It is made up as follows: galactose 3.03%, mannose 1.53%, fucose 0.09%, hexosamine 2.3%, and sialic acid 4.2%. In 8 molar urea, 8 moles of disulfide were found per mole of bovine prothrombin. The N-terminal amino acid in prothrombin is alanine. Two C-terminal amino acids, tyrosine and glycine, were found in nonchromatographed and on IRC-chromatrographed bovine prothrombin complex.

Thrombin can be obtained from prothrombin in different ways. Its molecular weight is 33,700. The length of the molecule is 84Å and its width is 30Å. Its amino-acid composition is listed in Table III. Bovine thrombin contains 258 amino-acid residues, corresponding to a molecular weight for this fraction of 28,400. There are 2.15 moles of disulfide per mole of thrombin. It has two N-terminal amino acids, isoleucine and threonine. The total carbohydrate content of thrombin, 9.68%, is made up as follows: galactose 2.34%, mannose 1.17%, fucose 0.07%, hexosamine 2.2%, and sialic acid 3.9%. The physicochemical evidence indicates that thrombin has

Table III. Amino-acid composition of bovine prothrombin and thrombin (1)

Tryptophan	1.8	1.5

half the molecular weight of prothrombin. It has been hypothesized that the other half of prothrombin is composed of autoprothrombin III (inactive Factor X). More recent investigations suggest that prothrombin might be a dimer of two thrombin molecules (17).

One method of obtaining information concerning the possible participation of electrochemical reactions in thrombosis is to determine the electrochemical behavior of blood coagulation factors at metal-solution interfaces. These relatively simple studies on the individual factors should indicate whether they are subject to electrosorption, and whether they undergo charge transfer processes. Electrosorption of some blood proteins and their structural subunits (amino acids and peptides) have been previously investigated (20-22). Electrochemical polymerization of fibrinogen (Factor I) yields a product quite similar to the enzymatically produced fibrin (23).

Cyclic voltammetry appears to be a convenient screening technique to give at least a qualitative picture of the electrochemical behavior of proteins. In the present work, the electrochemical activities of prothrombin and thrombin were ascertained from such studies on a platinum electrode in 0.154*N* sodium chloride solutions containing one of these proteins. The biological activity of the electrochemically treated product, particularly with prothrombin, was determined. In addition, the possibility of electrochemical conversion of prothrombin to a thrombin-like product was investigated.

Cyclic Voltammetric Studies on Prothrombin and Thrombin

Experimental

It is well known that siliconization greatly enhances the clotting times of blood in glass tubes. Hageman factor (Factor XII) is activated in unsiliconized glassware. It is not certain whether prothrombin is activated in unsiliconized glassware. For this reason, experiments were carried out in both siliconized and nonsiliconized three-compartment glass cells. Siliconization was carried out using standard procedures with General Electric Dri-Film No. 9987. A smooth platinum wire, 1 cm^2 of geometric area, served as the test electrode. The test electrode was placed in the central compartment. In the side compartments, separated from the central one by closed stopcocks, the Pt-counter and reference electrodes (SCE) were placed. The physiological concentration of sodium chloride (0.154*N* NaCl) was used as the supporting electrolyte. All the experiments were carried out in an open air atmosphere so as to avoid denaturation of proteins which occurs in an inert atmosphere.

Voltammetric studies were carried out with a three-electrode potentiostatic circuit, using a Wenking Model 61R potentiostat and Elron Model CHF-1 signal generator which provides potential variation for cyclic single and multiple scans with a choice of different scan rates (from 10^{-2} to 10^2 V/sec). The potential of the test electrode was checked using a Keithley electro-

meter (610B). Voltammograms were recorded for lower scan rates in a Hewlett Packard Model 7001AM X-Y recorder, and for higher scan rates on a Tektronix oscilloscope Model 564 with plug in units Model No. 3A3 for the horizontal and 2A63 for the vertical axes.

Bovine prothrombin (obtained from "Sigma"[2]) was studied at two concentrations (0.1 and 1 unit/ml). Three concentrations of bovine thrombin (obtained from "Upjohn") were investigated (1, 10, and 100 NIH units/ml).[3]

Results and Discussion

Adsorption and charge transfer reactions of prothrombin.—Voltammograms were first recorded in the supporting electrolyte. The change in transient was recorded immediately after introducing the desired amount of protein. Figure 1 shows the immediate change in *I-V* transient after prothrombin was introduced into the supporting electrolyte making the bulk concentration of prothrombin 0.1 unit/ml.[4] Hydrogen peaks are suppressed, the current in the platinum oxide formation region is lowered, and the area representing platinum oxide reduction is reduced. Experiments were repeated at least three times and the reproducibility in current at any potential is within 10%. This is also the case with peak potentials. The change in voltammogram can be attributed to the blocking of the electrode surface by adsorption of added species, reducing the electrode area available for the hydrogen adsorption and desorption processes and for platinum oxide formation. During subsequent cycling, a further decrease in the area representing oxide reduction was recorded. This behavior was observed at both concentrations, 0.1 and 1 unit/ml. At the higher concentration (1 unit/ml), however, a further change in the voltammogram was observed with continuous cycling. In saline solution containing no prothrombin, there was no change in the shape of the voltammogram with repeated cycling over long periods of time (> 48 hr). Thus, the changes observed in the voltammogram when prothrombin is present in solutions do indeed correspond to processes other than electrode surface processes. The voltammogram recorded after 10 min of continuous cycling at 50 mV/sec shows the development of new peaks. There is no trace of a platinum oxide reduction peak, but a new cathodic peak is recorded at more positive potentials (+200 mV *vs.* SCE). There is also a significant change in the hydrogen region. New peaks develop giving rise to much higher peak currents than can be attributed to hydrogen peaks, the difference approaching one order of magnitude after 60 min of cycling. From the values of the peak currents (Fig. 2), it is clear that some Faradaic process is taking place. From the voltammogram recorded at this stage, it appears that at least two electrode reactions are taking place; one at positive and the other at negative potentials.

It was of interest to determine the interdependence of electrode reactions and the potentials at which the electrode reactions are triggered. With continuous cycling in the positive potential region (*vs.* SCE) for an additional 30 min, and then returning to the usual scan, the peak currents showed a slight increase, but without any major change (Fig. 3). By limiting scanning only to the negative potential region, the peak currents displayed an immediate decrease. It therefore appears that the species participating in the electrode reaction at negative potentials is the product of the reaction, the reactant (prothrombin) undergoes in the

[2] According to specifications from the company, the total content of Factors VII, IX, and X is less than 0.01 units per unit of prothrombin.

[3] The amount of prothrombin expressed as 1 unit is the amount of prothrombin present in 1 ml of normal human blood, *i.e.*, the physiological concentration of prothrombin. Concentration units for thrombin cannot be based on physiological concentrations since thrombin is not normally present in blood. Therefore 1 NIH unit of thrombin is not directly comparable to one unit of prothrombin. 1 NIH unit is the amount of thrombin which clots fibrinogen at 37°C in 15 sec. Empirically 1 unit of prothrombin can be compared to 100 NIH units of thrombin (24).

[4] The IUPAC sign convention is followed, *i.e.*, anodic currents are positive, potentials anodic with respect to the potential of the reference electrode are positive, and vice versa. The opposite convention is adopted in most polarographic texts.

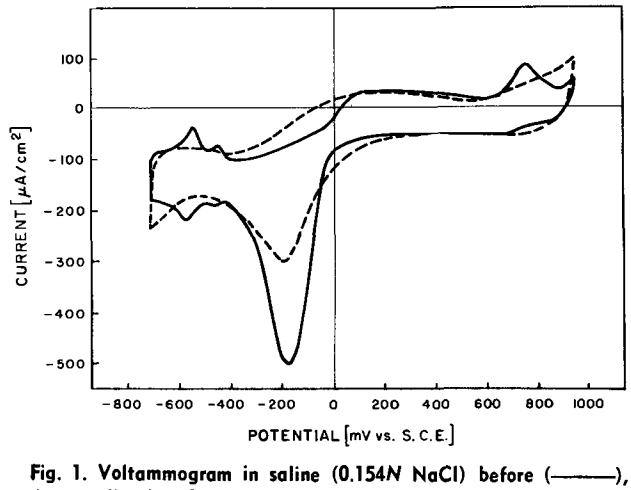

Fig. 1. Voltammogram in saline (0.154*N* NaCl) before (———), and immediately after (- - - -) the addition of prothrombin (0.1 unit /ml) at a scan rate of 50 mV/sec.

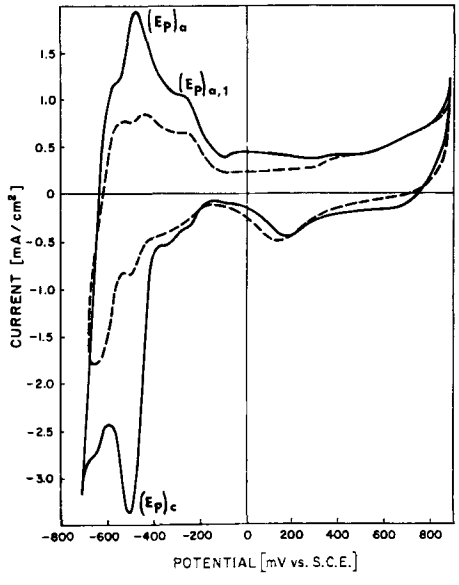

Fig. 2. Voltammogram for prothrombin (1 unit/ml) after prolonged scanning: 10 min (- - - -), 60 min (———) at a scan rate of 50 mV/sec.

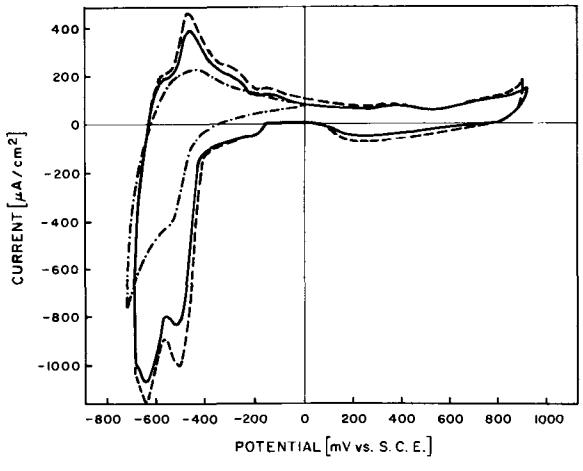

Fig. 3. Effect of limiting potential scan to only positive and to only negative potential range: normal scanning region (———), after 30 min scanning only in anodic (- - - -), and after 30 min scanning only in cathodic (—·—·—·) potential range at a scan rate of 50 mV/sec.

positive potential region where, possibly, an intermediate is formed. Thus the reaction taking place at positive potentials is a necessary step for the electrode reaction at negative potentials.

To evaluate the nature of reactions recorded in voltammograms, the scan rate was altered from 50 mV/sec, which was generally used throughout the study, to lower and higher values in the range from 10 mV/sec to 2 V/sec. Although the difference in potentials of cathodic and anodic peaks (ΔE_p) for lower scan rates is 57 mV (a criterion for the reversible charge transfer), the shift of both peak potentials, $(E_p)c$ and $(E_p)a$, with the change in scan rate, indicates a departure from the reversible behavior, *i.e.*, the degree of irreversibility increases with the increase in scan rate.

The shift of E_p *vs.* logarithm of scan rate (v) gives a slope of 30 mV per tenfold change in scan rate for both cathodic and anodic peaks in the negative potential region (Fig. 4). The criterion for the irreversible charge transfer reaction, $dE_p/d \log v = 30/\alpha n$, thus gives the value $\alpha n = 1$, where α is the charge transfer coefficient and n is the number of electrons participating in the charge transfer reaction (25).

The values of the peak currents also change with the change in scan rate. The ratio of anodic to cathodic peak currents (i_a/i_c) increases with log v (Fig. 5) but never approaches unity. The fact that the ratio i_a/i_c gives lower values at lower scan rates and increases with the increase of scan rate might indicate that a chemical reaction is interfering with charge transfer (26, 27). If it is assumed that the chemical reactions are slow compared to charge transfer reactions, the observed effects on the ratio of peak current at higher scan rates are understandable.

The poorly pronounced post peak $(E_p)a,1$ (Fig. 2) following the anodic charge transfer in the negative potential region shows the behavior expected for a strongly adsorbed reactant, *i.e.*, increases with the increase in scan rate and diminishes at lower scan rates (27). However, additional studies would be necessary for the evaluation of this peak as well as for the other peaks appearing in the voltammogram.

Adsorption and charge transfer reactions of thrombin.—A similar study was undertaken with thrombin. Figure 6 shows that adsorption takes place immediately after the introduction of thrombin into the supporting electrolyte, at concentrations as low as 1 NIH unit/ml. At a first glance, the *I-V* transient resembles that with prothrombin.[5] Studies at low and intermediate concentrations of thrombin (1 and 10 NIH units/ml) showed no significant changes in the voltammograms with continuous cycling. At a high concentration (100 NIH units/ml) continuous cycling resulted in new peaks. Although resembling the shape of the voltammograms recorded for prothrombin, the peaks recorded in the negative potential region are at more negative potentials for the same scan rate than is the case with prothrombin. Only the resultant cathodic peak at positive potential appears to be close to the potential of the peak (200 mV/SCE) with prothrombin (Fig. 7).

The influence of restricting the potential scan only to the cathodic or anodic part is similar to that observed with prothrombin. Figure 8 represents the change in voltammogram after 30 min of scanning in the positive

[5] Cyclic voltammetric studies have been conducted on some other blood coagulation factors as well (fibrinogen, Factors, V, VIII, and IX). The voltammograms, their time responses, variations with scan rates are quite specific for each of the factors investigated.

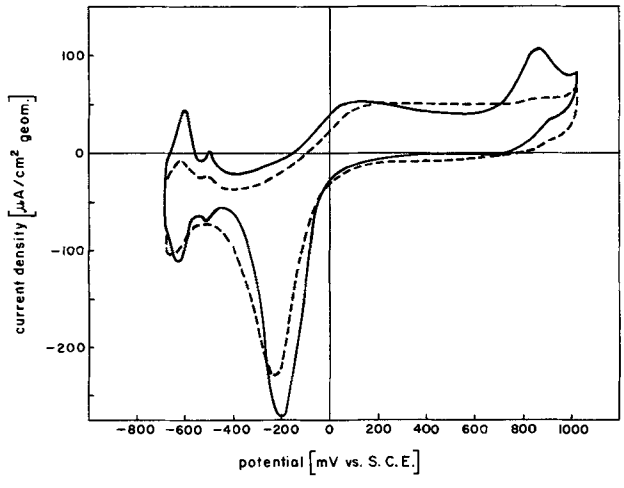

Fig. 6. Voltammogram before (———) and immediately after (- - - -) the addition of thrombin (1 NIH unit/ml) to saline.

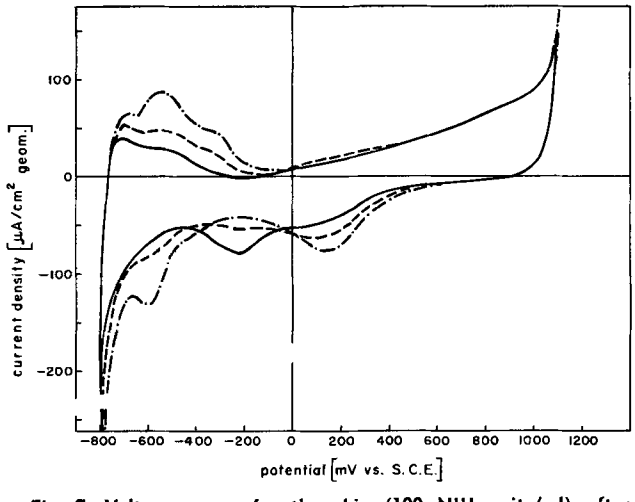

Fig. 7. Voltammogram for thrombin (100 NIH units/ml) after 20 min (———), 60 min (- - - -), and 180 min (—·—·—·) of scanning at a scan rate of 50 mV/sec.

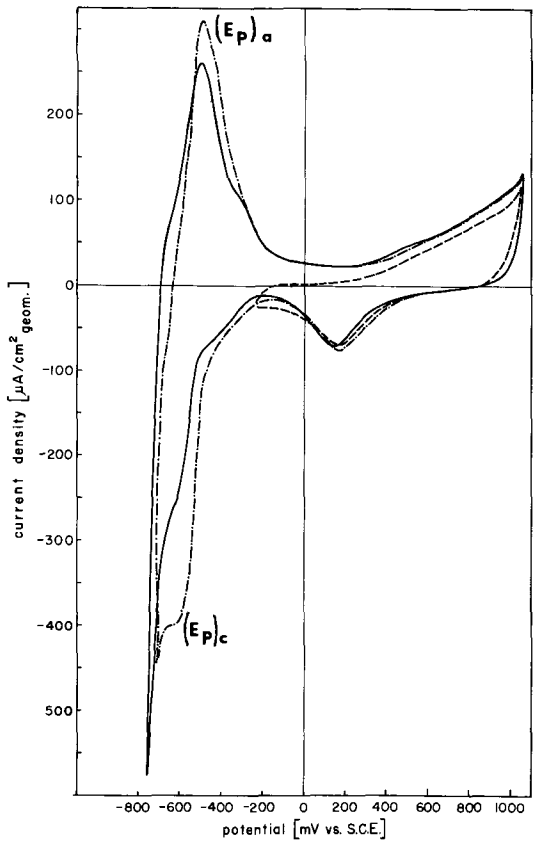

Fig. 8. Effect of scanning in anodic potential region (- - - -) for thrombin (100 NIH units/ml): after 6 hr of scanning over the usual potential range (———), after 30 min scanning in anodic region (—·—·—·).

potential region, the peak currents increase; Figure 9 shows the change during the scan at negative potentials which resulted in a rapid decrease in peak currents.

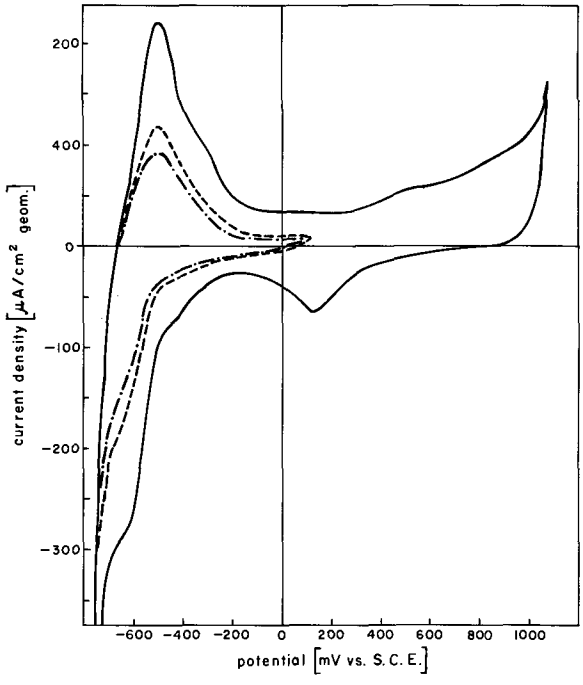

Fig. 9. Effect of scanning at cathodic potentials for thrombin (100 NIH units/ml): after 5 hr of scanning over the usual potential range (———), after 10 min scanning at negative potential range (- - - -), and after 20 min scanning over the negative potential range (—·—·—·).

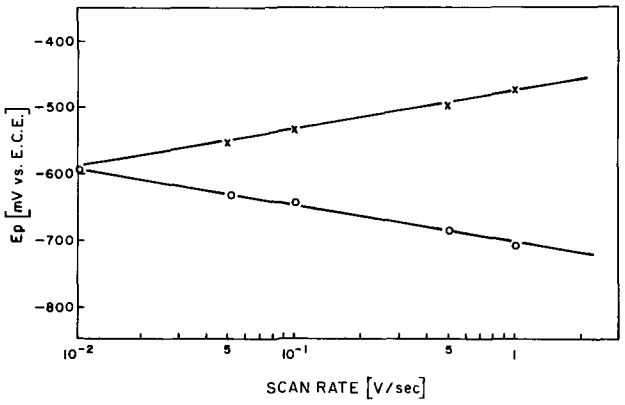

Fig. 10. Peak potential (E_p) as a function of scan rate for the solution containing thrombin (100 NIH units/ml).

The shift of the peak potential (E_p) with the logarithm of scan rate gives a slope of 60 mV per tenfold change in the scan rate (Fig. 10). This gives an αn value of 0.5. Speculating that the charge transfer coefficient α might be of the same value for these two proteins (prothrombin and thrombin), it appears that the number of electrons involved in the charge transfer process in the case of prothrombin is twice the number of electrons involved in case of thrombin.

The ratio of anodic to cathodic peak currents (i_a/i_c), Table IV, shows that the charge transfer reaction is complicated by some chemical reaction. The ratio gives values lower than unity throughout the applied rates of scan, although there is a steady increase with increase in scan rate.

Some conclusions from the cyclic voltammetric studies.—Although the results presented in this work are essentially of qualitative value and additional research is necessary to understand the mechanism of the reactions involving prothrombin and thrombin, the present studies reveal that both proteins take part in adsorption and charge transfer processes. At the lower concentrations, adsorption effects predominate, while at higher concentrations, the rates of charge transfer reactions are significant. The product of the charge transfer reaction at anodic potentials takes part in a further charge transfer reaction at negative potentials.

Some additional studies have been performed in an attempt to obtain information on the possible electrochemical transformation of prothrombin to thrombin.

Electrochemical Conversion of Prothrombin to Thrombin?

One of the simplest methods of determining whether electrochemical activation causes a prothrombin-thrombin conversion is to check whether there is any change in the hematological activity after the electrochemical treatment. After the cyclic voltammetry experiment, the effects of the solution samples on the clotting time of blood were determined. The tests showed a decrease in clotting time and hence a reduction in prothrombin activity but did not reveal significant increases in thrombin activity. The explanation for such a result might be that the conversion of prothrombin into thrombin was in minute quantities and as such could not be detected, or that the conversion was not complete. Biochemical studies on prothrombin show that the first stage of prothrombin conversion yields three different species, one of which plays the

Table IV. Effect of scan rate on the ratio of anodic to cathodic peak currents $(i_p)a/(i_p)c$ with thrombin

5×10^{-2}	0.76
10^{-1}	0.78

role of an inhibitor in the further conversion of two additional species to thrombin (19). In accordance with this, the electrochemical conversion of prothrombin could have stopped at the intermediates and thus did not reach complete conversion to thrombin.

In an alternate study, solutions containing prothrombin were exposed to electrodes maintained at constant anodic potentials. The same cell and supporting electrolyte, as in previous experiments, were used. A platinized platinum electrode was used as the working electrode; its potential was maintained at one of several values from +500 to 1200 mV/SCE. Prothrombin was at a concentration of 0.1 unit/ml, and a fresh solution was prepared for each potential applied. The test on the clotting time of fibrinogen was carried out with the samples of prothrombin that were taken after 15 min of maintaining the electrode at a constant potential. Table V shows a decrease in clotting times of fibrinogen with samples being exposed to higher anodic potentials. The pH of each of the solutions was measured. It was found that the pH decreased with increase of the potential because solutions were not buffered. However, the shorter clotting time obtained for the solutions exposed to higher anodic potentials cannot be attributed to the change in pH, since a lower pH inhibits the clotting activity of thrombin (28). Thus, one may conclude that during electrolysis at constant anodic potentials a product with thrombin-like activity was formed. The formation of this material is increasingly favored at more positive potentials. Since thrombin is the only one of the proteins present that causes clotting, these results indicate that the product formed is thrombin and that electrochemical reactions are involved in the conversion of prothrombin to thrombin. It is necessary to elucidate further the electrochemical path of prothrombin to thrombin conversion by identifying the intermediates or products of the electrochemical reactions.

Acknowledgments

The research this publication is based upon was performed pursuant to contract No. PH 43-68-75 from the National Heart and Lung Institute, National Institute of Health, Public Health Service, Department of Health, Education and Welfare. The authors express their deep gratitude to Dr. Glen Stoner and Miss W. L. Walker of the University of Virginia, Charlottesville, for assistance in the experiments to determine the effect of electrochemically activated prothrombin on the clotting time of fibrinogen. Helpful discussions with and suggestions from Drs. N. Ramasamy and J. S. Keates of our laboratories are gratefully acknowledged.

Electrochemical Behavior of Blood Coagulation Factors

Fibrinogen

N. Ramasamy,* M. Ranganathan,[1] L. Duic,*[2] S. Srinivasan,* and P. N. Sawyer

ABSTRACT

The adsorption and charge transfer reactions of fibrinogen, one of the blood coagulation factors, have been investigated using ellipsometric, potentiodynamic, and steady-state potentiostatic methods. The protein is adsorbed on platinum over a wide potential range (−600 to +800 mV *vs.* SCE) even at very low concentrations. Steady-state potentiostatic studies show that it is involved in anodic and cathodic charge transfer reactions. Adsorption plays a prominent role in the development of potentiokinetic peaks and in their shifts with scan rate variation. The observed charge transfer reactions of this protein throw new light on the correlations between blood compatibility of metallic materials and their spontaneous potentials in blood.

Fibrinogen plays a crucial role in blood clotting and in thrombosis. It is one of the thirteen blood coagulation factors (Table I) recognized by the International Committee on Blood Coagulation Factors (1). Many of the proteins involved in the blood coagulation sequence are activated before they take part in the blood coagulating scheme (2). Fibrinogen is present at a concentration of about 3 mg/ml in blood, while some of the other blood coagulation factors are present only in trace amounts (3). The polymerization of fibrinogen to fibrin is the last of the series of intermediate steps in thrombosis and in blood clotting. The fibrin strands trap blood cells and other particles in blood leading to thrombus formation. The terminal conversion of fibrinogen to fibrin is one of the most fundamental steps in thrombosis. The preceding steps, leading to the formation of the fibrin in the normal intact vascular system, have been elucidated. In the intrinsic pathway (4) the cascade process starts with activation of Hageman factor and involves various other proteins in sequential steps. The fibrinogen-fibrin conversion reaction is catalyzed by the enzyme thrombin. This is not present in circulating blood but is formed from the precursor prothrombin. The prothrombin-thrombin conversion can also take place by the extrinsic pathway (5) without the surface activation of Hageman factor. The two pathways for blood coagulation are represented in Table II. Irrespective of the type of activation, the last two steps of the blood coagulation scheme are the same, *i.e.*, conversion of prothrombin to thrombin and the polymerization of fibrinogen to fibrin by thrombin.

Table I. Roman numeral designation and most common synonyms for blood coagulation factors (1)

Roman numeral designation	Most common synomym
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Tissue thromboplastin
Factor IV	Calcium ions
Factor V	Proaccelerin
Factor VI	Not assigned
Factor VII	Proconvertion
Factor VIII	Antihemophilic factor
Factor IX	Christmas factor
Factor X	Stuart factor
Factor XI	Plasma thromboplastin antecedent
Factor XII	Hageman factor
Factor XIII	Fibrin stabilizing factor

The reactions leading to thrombosis are in general catalyzed by materials used in cardiovascular implants. Metals, alloys, and insulator materials have been used in the fabrication of heart valves and other vascular prostheses (6). The presence of the foreign material provides a new interface with blood, and this can cause or induce thrombus formation. Studies in this laboratory on blood compatibility of prosthetic materials have shown that insulators with a uniform negative surface charge in contact with blood are nonthrombogenic, while those with a positive surface or with a nonuniform surface charge almost invariably induce thrombus formation (7). Metals which register spontaneous negative potentials in normal saline with reference to NHE are thrombo-resistant. Noble metals

that develop positive potentials in blood are thrombogenic (8). When blood or plasma comes in contact with electronic conductors, only two basic reactions can occur, namely, adsorption and charge transfer. Most of the proteins are large molecular weight organic compounds containing multiple functional groups with a number of benzene rings (*e.g.*, tryptophan residues in fibrinogen). They may be expected to be adsorbed on the metal surface over a wide potential range. Since plasma or whole blood contains, in addition to the blood coagulation factors, albumins and globulins it cannot be used to investigate the electroactivity of individual blood proteins. Purified individual blood coagulation factors, dissolved in saline (0.154M NaCl), have been used in some basic investigations.

The blood proteins are very difficult to purify, especially to remove completely the extraneous blood coagulation factors. Even in the purest preparations available, trace amounts of other proteins are present as contaminants. The fibrinogen used for the investigation is free of plasminogen and plasmin but contains trace amounts of fibrin stabilizing factor and Factor VIII. Because of the difficulty of isolation and extreme lability of some of these proteins, (*e.g.*, Factors V, VIII) very little is known about the structural aspects like the amino-acid content, amino-acid sequence, etc. Fibrinogen, however, is a well-characterized protein. It has a molecular weight of 300,000. It is a globular-type protein with about 3% carbohydrate content. Irrespective of the source, *i.e.*, human, bovine, or canine, fibrinogen has similar composition and molecular weight. The molecule contains about 18 amino acids of which glycine, lysine, tyrosine tryptophan, and arginine are a few. A large number of molecules of each of these amino acids are present per molecule of fibrinogen. For example, bovine fibrinogen contains in addition to other amino acids, 60 tryptophan, 55 lysine, and 84 tyrosine residues per molecule. Fibrinogen is believed to exist as a dimer with about 28 disulfide links in the molecule. Human fibrinogen was used in the present work.

Thrombin, generated from its precursor prothrombin through the complex series of conversions acts on fibrinogen, polymerizing it to fibrin. The protein has a proteolytic effect on fibrinogen which is highly specific at four peptide bonds in fibrinogen. The sequence of steps leading to the final formation of a stable fibrin clot and the type and structure of *fibrinopeptides* released during this reaction have been elucidated (9).

The results of ellipsometry at constant potentials, steady-state potentiostatic and potentiodynamic methods employed in an investigation of the adsorption and charge transfer reactions of fibrinogen, are reported in the present communication.

Experimental

Purity and Source of Fibrinogen

Fibrinogen used for these investigations was prepared from human plasma[3] (10) by a modification of glycine precipitation procedure of Kazal *et al.* (11). It is 97% clottable and is free from plasminogen and plasmin but contains trace amounts of fibrin stabilizing Factor VIII. Ultra-centrifugal analysis gives a main peak comprising 95% of total area with apparent sedimentation coefficient of 5.8×10^{-13} and a smaller peak of 5% area with sedimentation coefficient of 3.5×10^{-13}.

Experimental Methods

Ellipsometric studies.—The potential dependent adsorption of fibrinogen was determined using this method. Since fibrinogen is one of the most strongly adsorbed peptides, it is possible to use very small concentrations of the protein. The three concentrations used were 0.07, 0.03, and 0.007 mg/ml of fibrinogen in normal saline (0.154M NaCl). The lowest concentration corresponds to 1/400 of physiologic concentration of the protein in normal human blood.

Experiments were carried out with a Rudolph Model No. 436-200E ellipsometer which uses the mercury green line as the source and has the quarter wave plate after metallic reflection. The angle of incidence was adjusted for 75° and the azimuth of the retardation plate was fixed at 135°. Only orientations of the polarizer and analyzer were varied during measurements. The reflecting surface was a glass slide sputtered with platinum (10,000Å thick) over tantalum oxide base (3000 Å thick). The electrical circuit consisted of a potentiostat, a silver-silver chloride reference electrode, a platinum foil counterelectrode, and the test electrode (the platinum sputtered glass slide). The potential of the electrode was initially set at −500 mV/Ag-AgCl reference electrode. The settings of the polarizer and analyzer were adjusted for minimum transmission and the readings were noted. Two sets of readings were taken in two different zones. These correspond with a blank set before the addition of the protein. The potential was varied in steps of 100 mV from −500 to +500 mV/Ag-AgCl. At each potential the "blank" readings were taken 15 min after impressing the potential. The protein was added and a similar set of readings were taken under similar conditions for each potential setting from −500 to +500 mV/Ag-AgCl. During the period of 15 min, the variation of photointensity was recorded with a Honeywell Recorder (Electronic No. 194). The measurements were made for three concentrations of the protein in solution.

Potentiostatic studies.—In the potentiostatic study, a platinum foil of 1 cm^2 apparent area was used as the test electrode. As in the previous case, the potentials were varied in steps of 100 mV from −800 to +1000 mV/SCE. The steady-state current passing through the system was measured 15 min after impressing the potential. A blank reading was taken with pure saline solution for the entire potential range. The experiment was repeated following addition of protein. Three concentrations of the protein were studied, 0.007, 0.07, and 3 mg/ml in physiologic saline (0.154M). The highest concentration corresponds to the physiologic concentration of the protein in blood. The experiments were carried out in air-saturated solutions because the proteins undergo denaturation during the process of deaeration by bubbling N_2. One experiment was conducted with deaerated saline solution to which fibrinogen was added (concentration of 0.07 mg/ml of the protein).

Potentiodynamic studies.—The equipment for the potentiodynamic study consisted of a potential sweep generator (Elron Model CHF1), a potentiostat (Wenking Model 61TR), and an X-Y recorder (Hewlett-Packard Model 700 AM). Platinum electrodes were used; a calomel reference electrode was employed. The potential range scanned was from −800 to +1050 mV/SCE. The scan rate was varied from 10 to 300 mV/sec. Multiple sweeps were employed; it was observed that the sweeping must be continued for at least an hour to reach a steady state.

Three concentrations of the protein were used, 0.007, 0.07, and 3 mg/ml in saline. At each concentration, the system was swept at a constant rate of 50 mV/sec for an hour, so as to develop a reproducible voltammogram shape. To determine the shift of peak potential with scan rate, the scan rates were varied from the 10-300 mV/sec. At each scan rate, sweeping was continued for the necessary time to obtain a constant shape of the voltammogram. The peak currents and corresponding potentials were noted as a function of scan rate for the two higher concentrations of the protein.

Results

Ellipsometric Studies

Under the conditions of the ellipsometer geometry indicated, the shift in analyzer settings is, to a first

[3] The purified protein was obtained from Dr. Glen Stoner and Miss Louise Walker of the Department of Materials Science at the University of Virginia, Charlottesville.

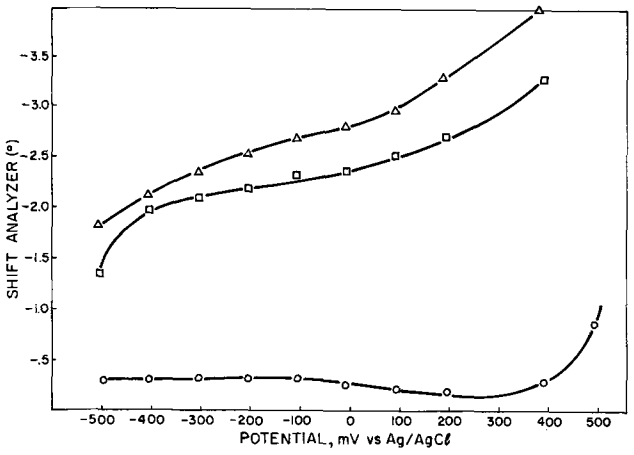

Fig. 1. Change in ellipsometer analyzer setting (a measure of adsorption) as a function of potential for three concentrations of fibrinogen in solutions; 0.07 (▲), 0.03 (□), and 0.007 (○) mg/ml.

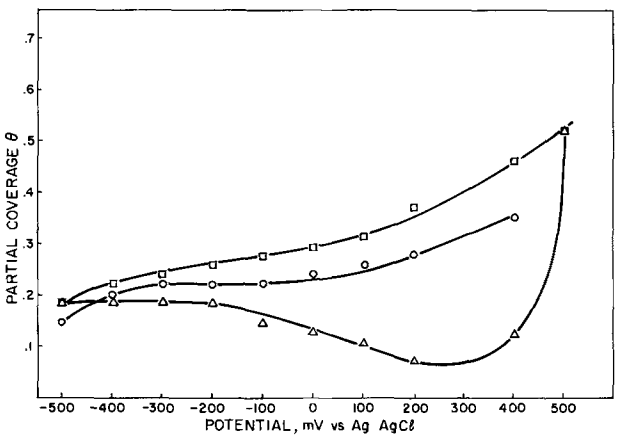

Fig. 2. Coverage-potential relation deduced from ellipsometry for three concentrations of fibrinogen in solution: 0.07 (□), 0.03 (○), and 0.007 (△) mg/ml.

approximation, proportional to the film thickness. Hence the analyzer setting was plotted as a function of potential. The curves for the different concentrations of the protein are shown in Fig. 1.

The plots of the shift of analyzer settings as a function of potential indicate that for all the concentrations of the protein there is an increase of coverage as one passes over from cathodic to anodic potentials. The variation of thickness is not so marked for the lowest concentration. Not only is the variation with potential much less for this concentration but there also appears to be a minimum in the analyzer setting-potential curve.

To obtain more quantitative results, the amplitude and phase changes were deduced from the changes in the polarizer and analyzer settings. For the particular ellipsometer geometry, from a consideration of the Poincare spherical representation, it is seen that the amplitude (Δ) and phase (ψ) are related to the two azimuths by

$$\Delta = 2A - 270 \text{ and } \psi = P \quad [1]$$

The changes in the amplitudes and phases from the corresponding values in pure saline are given by

$$\delta\Delta = \Delta - \Delta_0 = \delta\, 2A \quad [2]$$

$$\delta\psi = \psi - \psi_0 = \delta P \quad [3]$$

where A and P are the analyzer and the polarizer azimuths. The angle of incidence was corrected for refraction at the air-glass and glass-solution interfaces. Knowing the wavelength of light used, the optical constants for platinum, (5461Å and $n = 2.450$ and $k = 3.460$) and the refractive index for fibrinogen, ($n = 1.600$) assuming it to be nonabsorbing (12), the computer was programmed to give a set of Δ's and ψ's for a range of refractive indices of the film for each probable thickness of the film. The fibrinogen molecule is made up of three globules of diameter 50-60Å and has a length of about 500-700Å. Thus, a search for the closest fit of the experimental and computed values of the Δ's and ψ's was made over the thickness range indicated. The closest fit for the Δ's and ψ's gave the refractive index n_f of the film. Assuming the refractive index of the fibrinogen (n_f) to be 1.600 and the refractive index of the surrounding medium, saline (n_s), to be 1.3317 the coverage θ of the protein on the surface was deduced from the empirical relation (13)

$$n_f = \theta n_p + (1 - \theta) n_s \quad [4]$$

The coverage was calculated for each potential for all the concentrations of the protein. The coverage-potential ($\theta - E$) relations, observed for the three different concentrations of protein, are shown in Fig. 2. It is observed that the $\theta - E$ behavior is not very different from the plot of analyzer setting as a function of potential. The essential features are the same.

Potentiostatic Studies

The i-E curves[4] for the three concentrations of fibrinogen in aerated saline are shown in Fig 3-5. The curve of fibrinogen at a concentration of 0.07 mg/ml in deaerated saline is shown in Fig. 6.

Potentiodynamic Studies

The voltammogram[4] on a platinum electrode in normal saline and with the protein in solution at a concentration of 0.007 mg/ml are represented in Fig. 7. The two reversible hydrogen peaks and the platinum oxide reduction peak are clearly visible in normal saline, Fig. 7, curve 1. The addition of fibrinogen completely eliminates the hydrogen peaks developed at the anodic and cathodic scans, Fig. 7 curve 2. The platinum oxide reduction peak, however, is still observable. For the higher concentration of fibrinogen, 0.07 mg/ml (Fig. 8), one clearly sees the distinct de-

[4] The IUPAC sign convention, i.e., anodic currents are positive, potentials anodic with respect to potential of reference electrode are positive, and vice versa, is adopted in this paper.

velopment of a new peak on the anodic scan at about −620 mV/SCE. There is a high current peak on the cathodic scan at about −800 mV/SCE. But this is not properly developed at all sweep rates, perhaps because the currents are so high that the cell resistance limitations come into play. Thus, in some fast scan rates one observes only a flattened portion of the curve in the highly cathodic region of the voltammogram. These voltammograms were recorded at a scan rate of 50 mV/sec. At the physiologic concentration (3 mg/ml) (Fig. 9), the peak on the anodic scan is more pronounced with higher peak current and also there is a small but distinct hump at +20 mV/SCE on the cathodic scan. These two peaks are also visible for

reduction peak and its replacement by a new peak at +100 mV are clearly seen in this case.

Since the potentiodynamic technique is applied to the study of high molecular weight compounds with a number of functional groups, it is worthwhile indicating the specificity and reproducibility of voltammograms observed with some blood proteins. Six blood coagulation factors have been investigated so far, *i.e.*, fibrinogen, prothrombin, thrombin, Factors V, VIII, and IX. The potentials (E_p) at which peaks develop, their peak currents (i_p), the variation of E_p and i_p with scan rates (v), the dependence of i_p/v and $i_p/v^{1/2}$ on concentrations are clearly distinct for each one of the proteins. Hence, it is believed that the method is specific to the type of protein under study. Many replications have been made for each of the proteins, using samples from different lots and the variation in peak current is about 10%, while the shift of peak potential (ΔE_p) with scan rate also shows about the same deviation. From a hematological standpoint even though these proteins are complex molecules, only some specific peptide links are probably involved in the blood coagulation scheme. It is likely that in electrochemical studies as well, only some specific sites are active. These may or may not be the same ones attacked enzymatically. The present studies, however, are not sufficient to localize the active sites in the molecule. The observed activity does not appear to be due to that of contaminants, because these are present in very low concentrations ($\approx$1%), and it is unlikely that they can give rise to the recorded currents.

Discussion

Potential Dependent Adsorption of Fibrinogen on Platinum

The adsorption behavior of the protein and its dependence on potential are revealed by ellipsometric (Fig. 2) and steady-state potentiostatic studies (Fig. 3-6). The coverage-potential curve passes through a minimum at +300 mV/SCE for a concentration of 0.007 mg/ml of the protein. The evidence from this study is not sufficient to indicate any desorption at this potential range for that particular concentration. At higher concentrations the coverage steadily increases with increasing anodic potential. This agrees with the surface excess-potential behavior of fibrinogen in electrocapillary measurements (14).

At low concentrations of the protein in solution, steady-state potentiostatic studies also show that the decrease in current over the entire potential range is probably due to the fact that fibrinogen is adsorbed over a wide potential range from −600 to +800 mV/SCE (Fig. 3). However, one cannot exclude other possible causes such as modification of the double layer structure or interaction of the proteins with the reactants. With increase of concentration, charge transfer reactions seem to take place at highly cathodic and over a wide range of anodic potentials (Fig. 4, 5).

The potentiodynamic investigations also indicate the influence of adsorption on the development of peaks. Unlike with the other methods, the presence of adsorption is not explicitly revealed here. In potentiodynamic studies, the presence of adsorption is shown by the development of pre- or post-peaks in addition to charge transfer peaks. Such peaks are not developed for this protein and thus there is no direct evidence for the presence of adsorption. Some of the quantitative diagnostic criteria to establish the role of adsorption have been applied (15). Two of these are (*i*) the study of the variation of the peak current functions i_p/v and $i_p/v^{1/2}$ (v is the scan rate and i_p is the peak current at that scan rate) with scan rate. If adsorption is present, the former is constant while the latter steadily increases; and (*ii*) determination of concentration dependence. If adsorption is present, i_p/c will increase with decrease of concentration, c, at the same scan rate. The results are shown in Tables III-V. It is seen that for both concentrations investigated, the anodic peak II and the cathodic peak obey both these criteria while the anodic peak I shows an increase of i_p/c with decrease of c.

Charge Transfer Reactions of Fibrinogen at the Platinum-Saline Interface

Information regarding the charge transfer reactions of the protein is obtained from steady-state potentiostatic and potentiodynamic studies. The i-E curves for three concentrations of the protein (Fig. 3-5) indicate that at the lowest concentration, only adsorption reactions predominate over the entire potential range because the currents in the solutions with protein are always less than that in normal saline. But if the concentration of fibrinogen is increased (Fig. 4, fibrinogen concentration of 0.07 mg/ml), distinct changes are observed at cathodic potential (more cathodic than −600 mV/SCE). There is a steep increase of cathodic currents by more than one order of magnitude over the corresponding values for blank saline solution. Ellipsometric study shows that the coverage θ decreases with increase of cathodic potential. The increase of cathodic current at potentials more negative than −700 mV/SCE cannot be explained on the basis of desorption alone. Either the protein is taking part in a direct charge transfer reaction or the hydrogen evolution reaction on the platinum substrate is catalyzed by fibrinogen.

To determine whether the protein is directly involved in an electron transfer reaction across the metal-solution interface at these potentials or hydrogenation of the molecule by the discharged hydrogen occurs, the steady-state potentiostatic studies were carried out in deaerated saline with the addition of fibrinogen. The results are presented in Fig. 6. Even though the behavior of the protein on the anodic side is very different from the one observed for the same concentration in air-saturated solution (Fig. 4), the cathodic currents below −600 mV/SCE are almost identical in pure saline and in saline containing the protein at the same potential. In aerated solutions of saline, the dissolved oxygen in the system causes depolarization and hence the cathodic currents do not increase steeply at the extreme cathodic potential. From the behavior in deaerated saline, it appears that the protein undergoes an electrolytic hydrogenation reaction at the metal-solution interface. This type of electrolytic hydrogenation of organic molecules has been reported earlier (16). This is the first time in which a physiologically important blood protein has been shown to take part in such a type of reaction. From a knowledge of the structure of the fibrinogen molecule, the present findings are not surprising. Even assuming in a crude way that the cathodic process does not lead to decomposition of the molecule as a result of the reduction process, the reaction can be accounted for due to the presence of a large number of tryptophan residues. It is probable that these are hydrogenated. It is also likely that the sulfhydryl groups in the molecule may be hydrogenated. At present, the type of product formed as a result of the reaction is based only on speculation. Detailed amino-acid, N- and C-terminal assays, and gel electrophoresis studies on the reduced product have to be carried out to characterize the product formed at these highly cathodic potentials. At physiologic concentration of the protein, not only at highly cathodic potentials but also at anodic potentials, fibrinogen is involved in electron transfer reactions (Fig. 5). This increase of anodic current from about −100 mV/SCE is visible even at the lower concentration (0.07 mg/ml, Fig. 4) but is more marked at the higher concentration (3 mg/ml) of protein. This indicates that fibrinogen undergoes an anodic charge transfer reaction. This anodic reaction seems to take place over a wide range of potentials from −100 to 900 mV/SCE. It was shown previously that fibrinogen undergoes electropolymerization to fibrin in the region from −200 to +100 mV/SCE (17). This conclusion was arrived at by showing that the electron micrographs of the anodic product and of the enzymatically formed fibrin by addition of thrombin to fibrinogen were quite similar. Also in the potential range investigated, *i.e.*, −200 to +100 mV/SCE, the log current was observed to vary linearly with potential. The present work shows that the electropolymerization reaction probably takes place over a much extended region of anodic potentials up to +900 mV/SCE. At anodic potentials above +900 mV, the anodic current is nearly the same as in pure saline probably due to the influence of the oxide formation reaction and the desorption of the protein at such high potentials.

The results of potentiodynamic studies for the three concentrations of the protein show that it takes part in at least three charge transfer reactions. The complete elimination of the reversible hydrogen peaks, the suppression of the oxide reduction peak at all but the lowest concentration of the protein, and the development of new peaks at distinctly different potentials are seen in Fig. 8 and 9. The figures indicate the shape of the voltammogram at a scan rate of 50 mV/sec. The anodic peak I appears at −620 mV/SCE and anodic peak II at −400 mV/SCE, while the cathodic peak is developed at about 0 mV/SCE. The pronounced anodic peak I at the more cathodic potential masks the next peak (anodic peak II) and it is more easily discernible at faster scan rates. On the anodic scan, at potentials more cathodic to −600 mV/SCE, there is a steep increase of current and the peak at this potential region is not properly developed. At faster scan rates, one observes a truncation over a 100-mV region. It is interesting to note that the position of the peak appears to be exactly at the same potential where the second hydrogen reduction peak is observed for normal saline without protein addition.

In the light of the information obtained from ellipsometric and potentiostatic studies, an examination of the voltammograms indicates the involvement of the protein in electrochemical reactions both at extreme cathodic and over a wide range of anodic potentials. Adsorption effects predominate in the intermediate potentials. But the voltammograms do not explicitly indicate these charge transfer reactions by any pronounced peak or even a hump in the cathodic or anodic scans. The cathodic reaction is, however, indicated by the large increase of current in the highly negative regions. The recording of this in the voltammogram is vitiated by external factors like cell resistance and instrument limitation. The currents from −100 to +1000 mV/SCE in the anodic scan, suggests the occurrence of an anodic charge transfer reaction, although no peaks are visible in this region. The three clearly visible peaks (anodic peaks I and II and cathodic peak) are probably due to reactions of the products of the charge transfer reactions visible in the steady-state potentiostatic measurements. Thus, it appears that the results of the potentiodynamic study complement those from potentiostatic measurements.

The effect of scan rate variation was investigated for the two concentrations of fibrinogen in which the development of peaks is distinct (concentrations 3 and 0.07 mg/ml). Several of the diagnostic criteria developed by Nicholson *et al.* (15) for stationary electrode polarography have been applied to this case, leading to some valuable conclusions regarding the nature of these reactions, the role of adsorption, and reversibil-

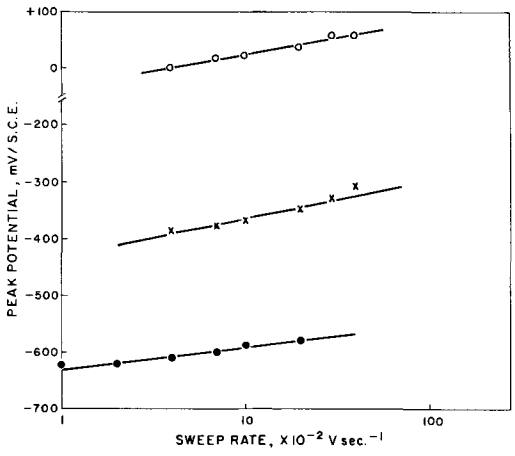

Fig. 11. Peak potentials as a function of scan rate: anodic peak I (●), anodic peak II (X), and cathodic peak (○).

ity. The shifts of peak potential as a function of scan rate for anodic peaks and the cathodic peak are shown in Fig. 11. The anodic peak I has a shift of 30 mV/decade of scan rate, while the second anodic peak and the cathodic peak have a shift of 60 mV for a tenfold increase of scan rate. The variation of the peak potentials with scan rate and the nonoccurrence of corresponding cathodic peaks show that the reactions are probably irreversible. The other criterion of total irreversibility, *i.e.*, the peak current function ($i_p/v^{1/2}$) being independent of the scan rate is not fulfilled by these peaks (Tables III and IV). Normally, the variation of peak potential with scan rate and the current function dependence are both to be considered for determining reversibility of the reaction. It is likely that complications may arise due to the adsorption of the reactant and perhaps the product. The development of pre- or post-peaks which readily characterize adsorption is not clear in this case. Even the anodic peak II cannot be considered as a post-peak as it shows a distinctly different shift of peak potential with scan rate (Fig. 11). As discussed earlier, the application of quantitative methods for determining the presence of adsorption shows the three charge transfer reactions to be also associated with adsorption processes. No attempt is made to calculate the number of electrons involved in the charge transfer reactions indicated by the three peaks due to the complexity of the system.

Correlation Between Electroactivity of Fibrinogen and Blood Compatibility of Materials

It is now necessary to examine the results in the light of some of clinical findings with materials used for cardiovascular prostheses. The observation that fibrinogen is adsorbed on the surface over a wide range of potentials (potentiostatic and ellipsometric study) is fully corroborated with earlier research in the field. Irrespective of the type of material, insulators, or metallic conductors, it is well known that fibrinogen is one of the first proteins to be adsorbed on to the surface (18). Fibrinogen adsorption seems to be the first step even during platelet retention studies in glass bead columns (19). Electrocapillary and capacity data also confirm its strong adsorption as found in the present work (20). The involvement of fibrinogen in anodic and cathodic reactions at the metal-solution interface seems to throw new light on the behavior of metallic prosthetic materials. It is generally known (21) that among metallic materials, noble metals, *i.e.*, those that develop a spontaneous positive potential in saline with respect to the NHE are thrombogenic, while the corrodible base metals are nonthrombogenic. The metallic materials so far experimented with can be classified under three headings, (A), thrombogenic, (B) fairly thromboresistant, and (C) highly thromboresistant. Copper, silver, gold, and platinum belong to class A; stellites and other cobalt-chrome alloys, some types of stainless steels to class B; and pure aluminum and its alloys and magnesium to class C. A cursory examination of their rest potentials in saline shows that class A metals have their spontaneous potentials in the thrombogenic range. If it is assumed that the primary reaction in thrombosis is the formation of a fibrin clot at the interface and the prime material for this fibrin clot formation is fibrinogen, the importance of the potentiostatic studies and their bearing on the data of thrombogenicity of metals becomes clear. The predominantly thrombogenic metals fall in the potential zone in which electropolymerization is most likely to occur. The metals of class B fall in the middle range of potentials where fibrin formation does not appear to occur but only adsorption of the protein predominates. In this region, for some of the materials, kinetic factors may play a role in leading to thrombus formation. Thus, surface roughness, contamination, and similar problems may induce thrombosis as has been observed (22). In the case of metals which belong to class C, their potentials are so highly negative that either there is complete desorption of fibrinogen or it may undergo a cathodic charge transfer reaction. Thus for aluminum the rest potential in saline is −800 mV/SCE. This falls in the zone where the cathodic reduction of fibrinogen possibly takes place. Probably the cathodic product acts as an inhibitor in the over-all thrombosis reaction. It was also observed that blood treated with aluminum powder shows a longer clotting time than controls (23).

To support the above qualitative conclusions on a solid quantitative biological footing, it is necessary to conduct hematological correlations of these findings. It is necessary to compare N-terminal assays of the electrolytically formed fibrin and the naturally formed fibrin. Similarly on the cathodic side, it is necessary to determine the influence of the cathodically formed product on the normal plasma clotting times. Such studies should yield useful information to the clinicians in addition to providing an insight on the mechanism of electropolymerization and fibrinolysis.

Conclusions

Investigations of the electrochemical reactions of one of the most important blood coagulation factors, fibrinogen, by using some of the well-known electrochemical and optical tools yield interesting information. The molecule is adsorbed on the metal surface over a wide potential range even at a very low concentration of the protein. The presence of adsorption is shown by ellipsometric, potentiodynamic, and potentiostatic methods. This confirms the previous observations that this protein adsorbs on most surfaces from plasma solutions.

The results of the potential sweep study are rather interesting. The investigations do not shed any new light on the charge transfer reactions, as revealed by the potentiostatic method, but show the occurrence of at least three charge transfer reactions at different potentials in the anodic and cathodic scans. These seem to be due to the products of the two primary reactions (shown by potentiostatic method) taking part in subsequent charge transfer reactions. All these reactions have significant adsorption contributions and the shift of peak potentials with scan rate leads to a crude guess about the number of electrons in the reactions. However, due to the absence of more sophisticated information, no quantitative conclusions can be drawn from the present results on this and on the type of adsorption.

The material undergoes both anodic and cathodic charge transfer reactions at the metal-solution interface. The cathodic reaction occurs at highly negative potentials beyond −600 mV/SCE, while the anodic reaction seems to take place over a wide potential range. The anodic reaction has been studied earlier and its product shown to be identical electron microscopically to enzymatically formed fibrin by the action of thrombin (17). The present work shows that this reaction takes place over an extended potential region.

The results of the potentiostatic study throws new light on the blood compatibility of metallic prosthetic materials. They explain the previously known fact that the spontaneous potential of the metal in saline is an important criterion in assessing its blood compatibility. The extreme thromboresistant property of metals with highly cathodic potentials in saline seems to be due to the involvement of the protein in some cathodic reaction at the interface and the product of this reaction may have an inhibitory effect on thrombus deposition. Correlative experiments are essential to prove that similar reactions occur in biological systems.

A New Technique for First-Drop Polarography

E. Kirowa-Eisner, N. Tshernikovski, and U. Eisner

Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

ABSTRACT

A new instrument for automatic "first-drop" polarography is described. The advantages of this system are shown in the evaluation of kinetic parameters of an electrode reaction. A detailed description of the operation of the instrument is presented.

It is well known that in spite of the stirring effect caused by the falling of the mercury drops, successive drops grow into a solution whose concentration differs from that to which the first drop at any particular potential is exposed. Depletion of the diffusion layer and accumulation of intermediates near the electrode surface may alter the character of the layer adjacent to the drop and cause a change in the current-time characteristics.

Advantages of first-drop measurements were demonstrated by the Czechoslovak School of Polarography. First-drop measurements were achieved with the use of horizontal or tilted capillaries (1). Other devices were constructed by Hans *et al.* (2) and by Němec (3).

Despite its advantages mainly in kinetic studies of electrochemical processes, the technique has not been generally adopted for routine work by electrochemists.

Key words: polarography, instrumentation, electrode kinetics.

In a recent paper by Kirowa-Eisner and Gileadi (4) a first-drop technique was used for the elucidation of the electroreduction of glycol aldehyde (GA). In these experiments the potential was kept at a less negative value where no electrochemical process took place and was then stepped up to a value corresponding to the plateau just as a drop fell. In this way measurements were conducted on what electrochemically constitutes a first drop.

The present work describes an instrument which enables one to carry out first-drop polarography conveniently and automatically. Its advantages are demonstrated with the use of some electrochemical processes.

Experimental

Polarograms were recorded on a Yokogawa recorder Type 3046. Fast transients were recorded on a Tektronix Type 564 storage oscilloscope. Lifetime of the

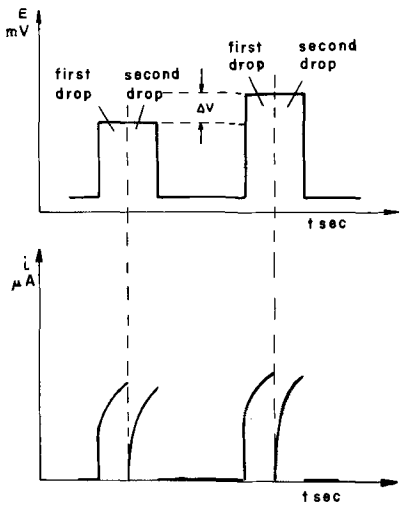

Fig. 1. Potential wave form and respective current of the polarographic unit.

drops was determined by a Radiometer Drop Lifetimer Type DLT1, currents were measured with the aid of a home-made current follower. Cell and electrodes were Radiometer, Copenhagen.

Method of operation of the instrument.—General.— The initial potential is set at some value at which no electrochemical process occurs. The potential is kept at this value for a predetermined number of drops and is then stepped synchronically with the enforced fall of the next drop, to the desired value. The potential is held constant, again for a predetermined number of drops, and then changed back to the initial value. (Fig. 1).

The final potential may be kept at a certain value thus permitting the recording of the current to be repeated as many times as desired.

In a different mode of operation the potential can be kept at the final value indefinitely. The instrument can also operate as a regular staircase generator for polarographic measurements. In that case, its main feature is the fact that the potential does not change during the lifetime of the drop. A delay in the application of the pulse for a predetermined time enables application of the potential toward the end of the drop life. A time sampler constructed in this laboratory connected to the present generator enables the operation of the instrument in a "Tast" mode. This mode of operation and the use of the instrument for solid/electrode voltammetry will be discussed in subsequent papers. The generator also can be used for the construction of electrocapillary curves. Results will be reported later.

Description of the instrument and its operation.—The instrument comprises three main parts: (*i*) central control unit, (*ii*), counter and digital-to-analog converter (D/A), and (*iii*) output stage

The control unit.—The central control unit (CCU) controls the functioning of the instrument. It contains a delay and a trigger unit which synchronizes the operation of the instrument with the lifetime of the drop. The unit is activated by an external pulse obtained from a drop dislodger (in this work the drop life timer manufactured by Radiometer was used). Each drop is counted by one of two counters. One counts a certain predetermined number of drops, m (1-9), to which the initial voltage is applied. The second counts another predetermined number, n (1-9), of drops to which the working voltage is applied. The values of m and n are chosen independently by "4-bit" digital comparators to which the counters are connected.

The comparators control the state of a "flip-flop" circuit. The latter chooses which of the two counters will get the trigger pulses. It also controls the output stage.

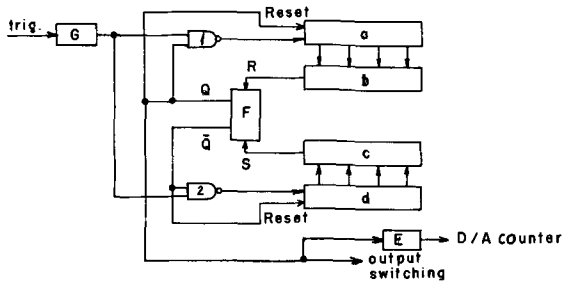

Fig. 2. Block diagram of the control unit. a, Counter n; b, comperator n; c, comperator m; d, counter m; e, delay; f, flip flop; g, delay.

Theory of operation.—At the outset the flip-flop circuit is in its zero state, $Q=0$, $\overline{Q}=1$ (Fig. 2). Gate 1 is open and gate 2 is closed. The trigger pulses will be counted by the m counter until the number in the counter equals m. At this point the m comparator will change the state of the flip-flop, $Q=1$, $\overline{Q}=0$. Gate 2 is then opened, gate 1 is closed, and the m counter is reset to zero. The trigger pulses are counted by the n counter up to a value n. At this point the flip-flop will return to its initial state and the n counter is reset to zero. At the end of each flip-flop cycle a pulse is sent to the D/A counter which is advanced by one. The role of the delay is to ensure that the advance will occur while the output is already at the initial voltage. The flip-flop connects the D/A while the n counter is on and the m counter is off. The D/A is disconnected when the m counter is on and the n counter is off.

The D/A unit (Fig. 3).—The counter is a 9-bit binary counter which is made of an 8-bit counter and a 1-bit counter. This arrangement permits one to obtain 512 pulses with a voltage difference of ΔV between two successive pulses or 256 pulses with a voltage difference of $2\Delta V$. In this work a ΔV of 2.5 mV was chosen. (If a larger potential is desired, ΔV may be increased up to 5 mV in the output stage.) The nine binary outputs of the counter are connected through nine Nand gates to the D/A electronic switches. The second inputs of all the gates are connected to the flip-flop in the control unit.

When the m counter is on, a "zero" appears on this line and all the gates will be in the "high state" which opens all the switches. When the n counter is on, a "1" will appear on the line and the outputs of the gates will depend on the number contained in the 9-bit counter. This number will be translated to an analog current value by the switches and resistor network.

The output stage (Fig. 4).—The output stage comprises two operational amplifiers. The first is fed by two sources: (*i*) The current output from the D/A. This current will be either zero or proportional to the number of measuring cycles passed, depending on the state of the control unit. (*ii*) A second source supplies the initial voltage which will be applied to the electrodes

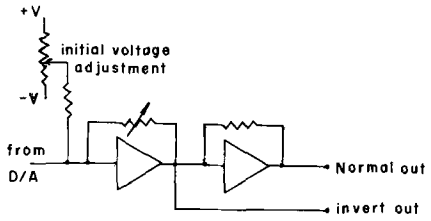

Fig. 4. Block diagram of output stage

in the m state. A second amplifier acts as an inverter enabling one to obtain pulses of reversed polarities.

Results and Discussion

The behavior of the first and subsequent drops are demonstrated for a few cases.

Diffusion-controlled process.—The system selected was Cd^{+2} in KCl.

1. The current at the beginning of the drop life is different in the first drop from that in subsequent drops (Fig. 5). At the end of the drop life (2-4 sec) the currents differ by less than 2%.

2. A "true" first drop is obtained only when three or more drops are released at the potential where no faradaic current flows (Fig. 6).

3. The log i *vs.* log t plot for the first drop is linear with a slope of 0.17 for a time less than 1 sec (drop life about 4 sec) (Fig. 7). This value differs from the slope of 0.19 obtained by others (5). The reason is that under the conditions in our experiment (measurements were carried out at the early stages of drop growth) the spherical correction is smaller and the value of the slope approaches 1/6 as is expected for linear diffusion.

The reproducibility of the current/time curves is excellent (better than 0.1%). Thus a log i/log t plot (during drop growth) is proposed as a method to determine whether or not a process is diffusion controlled. This method is faster and more accurate than the evaluation of the dependence of current on the height of the mercury column or the dependence of current on the drop time (maintaining the same height of mercury column and using different drop times by enforced fall of the drops).

Temperature effect.—As the temperature is lowered the diffusion coefficient decreases, slowing down the equalization of concentrations and one might expect greater differences between the first and subsequent drops than at higher temperatures. This difference, which is not very pronounced, can be seen from Fig. 8.

Analytical aspects.—First-drop polarography for diffusion-controlled processes has no advantage over classical polarography for routine polarographic analysis since calibration curves are generally used.

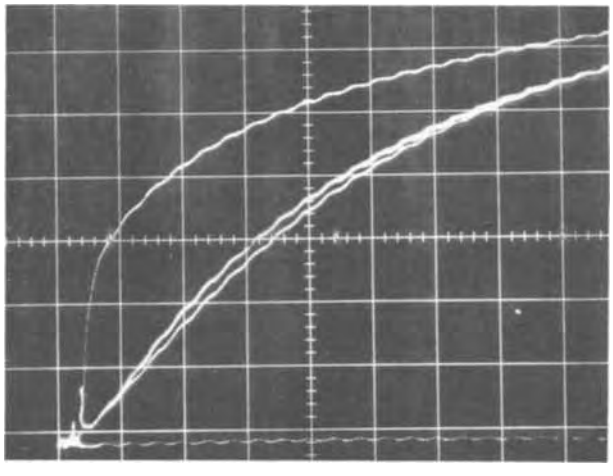

Fig. 5. First, second, and third drop. τ = 4 sec, 3 mM Cd^{++}, 1M KCl, h = 40 cm. X axis = 50 msec/cm, Y axis = 2.1 μA/cm, temperature = 4°C.

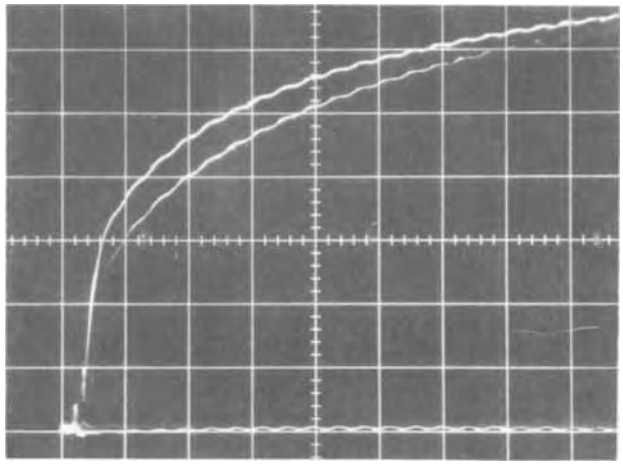

Fig. 6. Effect of the number of the drops at initial potential on the first drop. Upper curve, three drops at initial potential; lower curve, one drop at initial potential; other conditions as for Fig. 5.

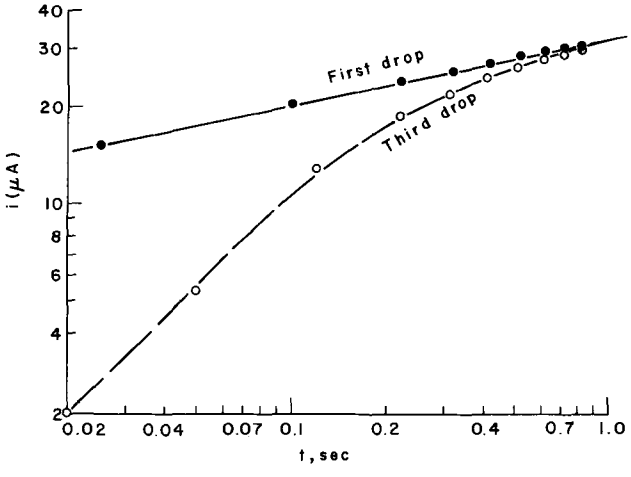

Fig. 7. Log i-log t dependence for first and third drops. 3 mM Cd^{++} in 1M KCl.

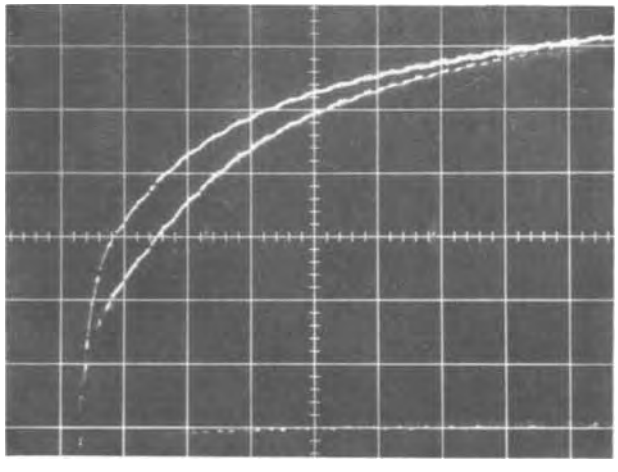

Fig. 8. Same as Fig. 6 but at 25°C and current density (Y axis) 3.1 μA/cm.

Kinetic processes.—The reduction of glycol aldehyde (GA) is presented as an example of a kinetic process. The general reduction scheme is

$$GA_{hydrated} \xrightarrow{k} GA \qquad \text{(base catalyzed process} \quad [1]$$

$$GA + 2e + H_2O \rightarrow AA + 2\,OH^- \qquad \text{(AA acetaldehyde)} \quad [2]$$

The detailed mechanism was studied by Kirowa-Eisner and Gileadi (4).

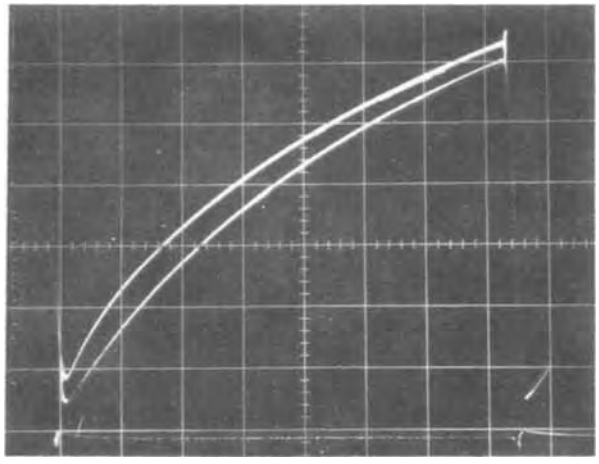

Fig. 9. First drop and second drop current-time curves throughout the drop life (4 sec) for GA. pH = 12.7. (Distortion of the curve at the beginning of the drop life is caused by an external capacitor connected in parallel with the resistor at the output stage for elimination of "noise.")

The curve of the limiting current as a function of pH has a maximum at pH = 12.7.

This pH was chosen for the experiments described below. The supporting electrolyte was $LiClO_4$ and the pH was adjusted by the addition of LiOH. As the potential is applied and the current-time curves are recorded, the accumulation of OH^- near the electrode surface results in an increase in pH which suppresses the limiting current of the subsequent drops. The current for the first drop is higher throughout the drop life (Fig. 9). When the pH of the solution is 11.5, the i-t curves for the first and subsequent drops are essentially the same. Depletion of GA in the vicinity of the electrode causes a decrease in the current, but this is compensated by the increase in pH. Thus the determination of the kinetic parameters of a reaction must be carried out on the first drop.

The rate constant for the chemical step in the reduction of GA was determined by Koutecky's method with the use of i-t curves (4).

The difference in the behavior of i-t curves will be most pronounced for catalytic processes

$$A + e \rightarrow B$$

$$B + c \rightarrow A$$

Accumulation of reaction products which affect the kinetics of the over-all process at the electrode surface will result in a large difference between the i-t curves of first and subsequent drops.

i-E curves.—The calculation of the Tafel slope $(\partial E/\partial \log i)$ for electrochemical processes is essential for the evaluation of the mechanism of the process. First-drop polarography is most convenient in this respect. The potential is stepped automatically in the desired step heights. The potential is constant during the life of the drop as opposed to the case of classical polarography where it changes linearly with time during the drop life. Figure 10 presents a Tafel slope for formaldehyde.

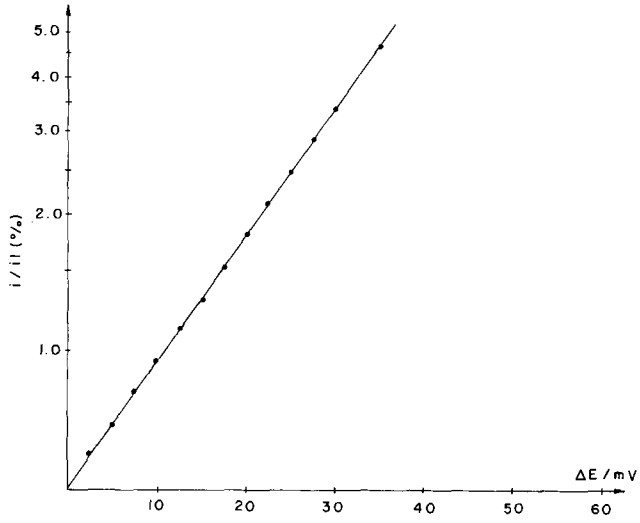

Fig. 10. Tafel plot for formaldehyde

Conclusions

The instrument described herein is a useful and convenient tool for the elucidation of the character of electrode reactions. It enables automatic measurements on first drops, thus avoiding the changes in the current-time curves which stem from depletion of reactants or accumulation of intermediates near the electrode surface. It is, furthermore, most suitable for evaluation of the kinetic parameters of kinetic, catalytic, or adsorption processes. It is versatile, dependable, and simple to operate.

Acknowledgment

The authors thank Mr. Y. Kliger for carrying out the design of the details and building of the instrument.

Electrode Filming in Ring Substituted Anilines

Keith B. Prater*

Department of Chemistry, University of Texas at El Paso, El Paso, Texas 79968

ABSTRACT

The study of the electrode filming behavior of a series of ring substituted anilines has indicated that filming occurs only in those compounds containing several doubly activated ring positions. This leads to the conclusion that the films arise due to multiple ring-ring coupling.

Electrode filming is one of the banes of the electrochemist's existence. All too often, an interesting compound is electrolyzed and found to yield an insoluble material which rapidly coats the electrode and renders it nonconducting. Such filming makes obtaining electrochemical data difficult at best, and usually necessitates the use of very rapid transient methods in which the data are (hopefully) collected before significant filming has occurred. More often, however, the compound is simply set aside and some more well-behaved compound is studied.

It is generally assumed that these films are polymeric materials, but, to the author's knowledge, no one has considered the problem of why some compounds form such films and others do not. This paper reports the results of a survey of the filming properties of a series of ring substituted anilines and suggests that these results are understandable on the basis of the effects of the substituents on the activities of various ring positions.

Experimental

All solutions were prepared from acetonitrile which had been stored over CaH_2 and then triply distilled from P_4O_{10}. The solutions were 0.1*M* in tetraethylammonium perchlorate. The ring substituted anilines were obtained from Eastman-Kodak and were used as received. The N,N-dimethylated anisidines were prepared from the corresponding anisidines by methylation with trimethylphosphate (1). Solutions were *ca.* $10^{-3}M$ in the anilines. The working electrode was a platinum wire and the reference electrode was a silver wire. The potentiostat and voltage scanner were of standard design.

Results and Discussion

The results which were obtained for a series of ring substituted anilines are summarized in Table I. There was little difficulty in separating these compounds into the two categories shown in Table I on the basis of their cyclic voltammograms. Those compounds which were classed as nonfilming exhibited cyclics similar to that of *o*-anisidine as shown in Fig. 1. After stirring the solution, a second cyclic could be obtained which differed in peak height from the first by less than 2% and in peak potential by less than 30 mV.

Those compounds which were classified as filming exhibited behavior similar to that of *m*-aminophenol shown in Fig. 2. The first cyclic on a clean electrode was characterized by a broad, rounded peak and a rapid decrease in current after switching the direction of potential scan. After stirring the solution, the second cyclic yielded a peak height significantly smaller than before and the peak potential was shifted by several hundred millivolts. After wiping the electrode, a third cyclic was obtained. In general, the peak height for this third cyclic was much less than had been observed on the clean electrode, but the peak potential was close to that obtained on the clean electrode. It should be pointed out that examples of less severe filming were also observed.

The obvious observation to be made from Table I is that filming occurs only when the substituent group is electron donating and *meta* to the amine group. An electron donating group *ortho* to the amine does not cause filming, nor does an electron withdrawing group ($-NO_2$) in either position. The difference between these two groups of compounds is that, since electron donating groups (including $-NH_2$) activate the ring

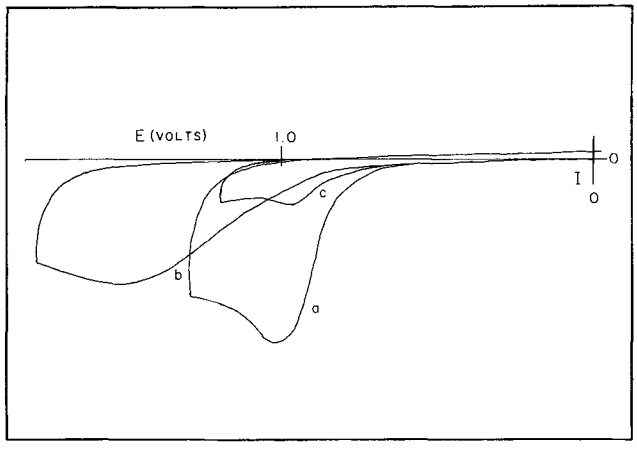

Fig. 2. Cyclic voltammogram of *m*-aminophenol in acetonitrile. a. Clean electrode; b. after stirring solution; c. after wiping electrode.

to electrophilic attack at the positions *ortho* and *para* to the substituent itself, a compound having two electron donating groups *meta* to one another will have three ring positions which are doubly activated (see Fig. 3), whereas, if the two electron donating groups are *ortho* to one another, there are no doubly activated positions. The presence of an electron withdrawing group anywhere on the ring would be expected to decrease the susceptibility toward electrophilic attack.

From these arguments, one would conclude that the mechanism of the formation of the films involves multiple electrophylic attack, probably by electrogenerated cation radicals, on such an activated ring yielding a polymeric material containing units such as is shown in Fig. 4.

In addition to the compounds listed above, the N,N-dimethylated *o*- and *m*-anisidines were investigated. As expected, the *ortho* isomer showed no signs of filming. The *meta* isomer was observed to film, but much less than the corresponding anisidine; less even than *m*-chloroaniline. This result could be taken as evidence that coupling through the amine nitrogen is important in the filming process. Coupling through nitrogen is well known in the oxidation of aniline (2). It hardly seems likely, though, that the amine nitrogen would be further activated by the *meta* substitution of an electron donating group. A more palatable explanation is that the N-methyl groups interfere sterically with attack on the positions *ortho* to the amine group and thus deter polymer formation. This is consistent with the fact that little *ortho-para* or *ortho-ortho* benzidine is formed when N,N-dimethylaniline is oxidized electrolytically (3) even though MO calculations indicate only slight differences between the electron densities at the *ortho* and *para* positions in dimethylaniline (1).

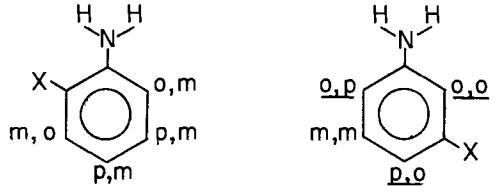

Fig. 3. Activation of the ring by *ortho* and *meta* substitution of electron-donating Group X.

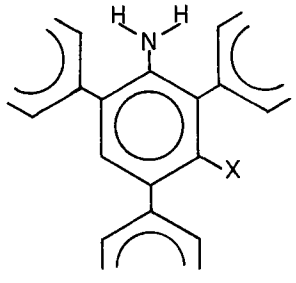

Fig. 4. Supposed polymer unit

Conclusion

This work strongly suggests that electrode filming in ring substituted anilines is due to the formation of polymeric material resulting from multiple electrophilic attack on molecules having several doubly activated ring positions. This immediately suggests several other studies including quantitative correlation of filming with electron densities from MO calculations, tracer studies to prove that the polymers arise due to ring-ring coupling and to measure the extent of this coupling, and the extension of such studies to other types of compounds.

Electroreduction of Vanadium(V) in the Presence and Absence of Chlorite Ion

Ronald L. Birke* and Thomas D. Santa Cruz

Department of Chemistry, University of South Florida, Tampa, Florida 33620

ABSTRACT

Polarographic and voltammetric *i vs. E* curves have been used to study the electroreduction of ammonium metavanadate solutions in 1*F* NH_3, 1*F* NH_4Cl at dropping and hanging drop mercury electrodes. Polarographic experiments were also made in the same media with EDTA added. When chlorite ion is present in these systems, a catalytic current is manifested. In the absence of EDTA, the catalytic current process appears to involve an equilibrium reaction of the product of the electrode reaction. In the presence of EDTA, a normal catalytic current is found. The mechanisms of these processes are discussed and rate constants are measured. The average homogeneous rate constant calculated for the proposed electrode mechanism is 2×10^5 liter/mole-sec without EDTA and 9×10^4 liter/mole-sec in 0.1*F* EDTA.

The electroreduction of vanadium(V) on mercury electrodes in alkaline media has been studied with polarographic methods by several workers (1-3). There has been some confusion in the literature concerning the polarographic behavior of V(V) in ammonia, ammonium chloride media. Lingane (2) found that a $1.58 \times 10^{-3}F$ solution of ammonium metavanadate in 1*F* NH_3, 1*F* NH_4Cl exhibited two closely spaced waves with a 3:1 ratio of wave heights. His interpretation was that the first wave is due to the reduction of V(V)

* Electrochemical Society Active Member.
Key words: electroreduction, vanadium, mercury electrode.

to V(IV) and that the second wave is due to the reduction of V(IV) to V(II). Schmidt and Reilley (4) found that sodium vanadate in 1*F* NH_4Cl, 6*F* NH_3 shows a single wave up to concentrations of about $5 \times 10^{-4}F$ and at higher concentrations a double wave appears. The first wave is not a function of total [V(V)], whereas the total wave height is directly proportional to this concentration. Their interpretation of the double wave is that the first wave is caused by an inhibited electrode reaction where the product of the initial reduction forms a film of vanadium hydroxide of lower oxidation state on the electrode surface and presents a barrier to further reduction until the potential is made more negative.

Baumann (5) has observed the same inhibition effect with vanadium(V) concentrations above $5 \times 10^{-4}M$ in 1*F* NH_3, 1*F* NH_4Cl medium. It is somewhat surprising that often quoted tables of polarographic half-wave potentials (6) still list the first wave in this system as the V(V) to V(IV) reduction process and give a diffusion current constant for the first wave. Since the ammoniacal medium is convenient for analytical determination of trace quantities of vanadium (7, 8), it is important to emphasize that only the plateau on the second wave corresponds to a diffusion controlled process.

Recently Jedral and Galus (9, 10) studied V(V) in 2-8*F* NH_3 and 0.1*F* $NaClO_4$ solutions. Their slow sweep voltammetric and chronopotentiometric experiments give additional evidence of film formation at higher [V(V)] which inhibits the electroreduction. They propose a mechanism in which V(V) is irreversibly reduced and forms a monolayer of $V(OH)_2$, which is blocking, and at more negative potentials a thick dense film of $V(OH)_2$ can be formed on the monolayer. The formation of the latter film is the process occurring on the second wave or peak of the *i vs. E* curve, and the first peak or wave is due solely to the inhibited irreversible electrode reaction.

We have investigated the voltammetric behavior of the electroreduction of V(V) at concentrations above and below $5 \times 10^{-4}F$ in the 1*F* NH_3, 1*F* NH_4Cl buffer. This treatment was undertaken because it was felt that $V(OH)_3$ may also be involved in the mechanism since $V(OH)_3$ is more insoluble than $V(OH)_2$. In addition, we have studied the polarographic catalytic current produced when chlorite, ClO_2^-, is added to the medium in the presence and absence of ethylenediammine tetraacetic acid (EDTA). Baumann (5) has observed the catalytic process with NO_2^- in the V(V) system in the 1*F* NH_3, 1*F* NH_4Cl buffer. We had previously (11) studied the oxidation kinetics of several ferrous complexes and cuprous amine with ClO_2^- in 1*F* NH_3, 1*F* NH_4Cl by the catalytic current method, and so it was natural to extend the treatment to the vanadium system.

Experimental

The instrumental setup used for polarographic and controlled potential coulometry has been described previously (11). In the present experiments a Hewlett Packard 7100B strip chart with disk integrator was used for integrations. Single and multiple cycle cyclic voltammetry was accomplished using a Wenking 68 FR 0.5 potentiostat, a Chemtrix Model 800 waveform generator, and a Hewlett Packard 7004B X-Y recorder. The electrolysis cell in this work was a Metrohm water-jacketed vessel (EA 874 and 876) with the microburette hanging mercury drop apparatus (E 410). For some experiments, a low resistance amalgamated Pt tip electrode was used to hang a mercury drop extruded from the microburette. A gas train for purifying nitrogen over copper at 350°-400°C was used in all measurements. The reference electrode in every case was a Metrohm saturated calomel electrode, SCE. Experimentally determined residual currents were subtracted from all measured polarographic currents in the catalytic current study.

All reagents used were analytical reagent grade purity. The sodium chlorite was purified by a procedure already described (11). A vanadium(V) stock solution was made up from ammonium metavanadate, NH_4VO_3, by dissolving the salt in 1.0*F* NH_3, 1.0*F* NH_4Cl. The stock solution was standardized by reduction with ferrous solution, oxidation of excess ferrous with persulfate solution, and titration of the V(IV) with $KMnO_4$. Chlorite solutions were made up determinately.

Error limits for slopes of plots are rough estimates and those for rate parameters are the standard deviations for the indicated number of measurements.

Results and Discussion

Polarography and coulometry of NH_4VO_3 in 1F NH_3, 1F NH_4Cl.—In order to interpret the kinetic data for the catalytic current produced by the chlorite oxidation of a vanadium species of lower oxidation state, it is necessary to consider the polarographic reduction of V(V) species in ammoniacal media in the absence of chlorite. The polarographic current-potential curves at concentrations above 0.5 millimolar [V(V)] in ammoniacal buffer exhibit two waves. At 0.50, 1.0, and 2.0 millimolar [V(V)], the ratio of total wave height to the first wave height is 2.0:1, 2.4:1, and 3.0:1, respectively, with $E_{1/2}$ nearly the same for each concentration. Clearly, the changing ratio of the wave heights is not proportional to the number of electrons transferred. If the concentration is increased to around 5 millimolar the current time curves in the potential region from −0.94 to −1.3V *vs.* SCE show a drastic decrease over the drop life indicating an adsorption process.

A controlled potential electrolysis, cpe, at a Hg pool electrode at −1.3V *vs.* SCE showed the number of electrons exchanged as 2.05 and 2.02, indicating a V(V) → V(III) process. Jedral and Galus (9) established that a V(II) electrode product reacts with V(V) in ammoniacal media to produce a V(III) species so that cpe does not establish the product of the electrode reaction Assuming $D = 5 \times 10^{-6}$ cm²/sec Jedral and Galus (9) calculate $n = 3$ in a voltammetric experiment. Calculations of n at −1.4V *vs.* SCE on the polarographic diffusion current plateau are ambiguous because a value of $n = 2.96$ is found for a 1.00 millimolar V(V) using the above value of D whereas a value closer to two is found at lower concentrations. This apparent dependence of n on concentration results because of a nonlinear relationship between i_d and V(V) concentration (5). Thin layer voltammetry (9) in 6*F* NH_3, 0.5*F* $NaClO_4$ indicates that electrode reaction product is a V(II) species. A similar process is most likely occurring in the 1*F* NH_3, 1*F* NH_4Cl buffer.

A number of interesting phenomena occur upon cpe of NH_4VO_3 at a large Hg pool electrode at −1.3V *vs.* SCE. The experiment was performed with a DME placed in the electrolysis cell for recording *i vs. E* curves, and stirring was achieved with a Teflon stirring bar on the Hg pool surface. The solution turns yellowish-brown as electrolysis proceeds and becomes very cloudy indicating colloid formation. An *i vs. E* curve taken with the DME directly after the cpe (Fig. 1) shows a residual current from +1.0V *vs.* SCE where Hg is oxidized to −0.8V *vs.* SCE where hydrogen is reduced. This *i vs. E* behavior appears to be caused by a passivating film on the Hg surface which is rather amazing in its blocking of Hg oxidation. There is some passivation of a DME in the pure supporting electrolyte buffer, but nothing like that when colloidal V(III) is present. The decrease in hydrogen overvoltage is most likely due to a catalytic process involving the reduction of a hydrogen ion located on the film. Both the potential which corresponds to oxidation of Hg and that which corresponds to reduction of hydrogen become more negative with time after reduction.

An additional experiment was performed on the colloidal solution of V(III) obtained by cpe. A solution of 0.625×10^{-2} millimoles of ClO_2^- was added to 2.50×10^{-2} millimoles of V(III). The solution cleared

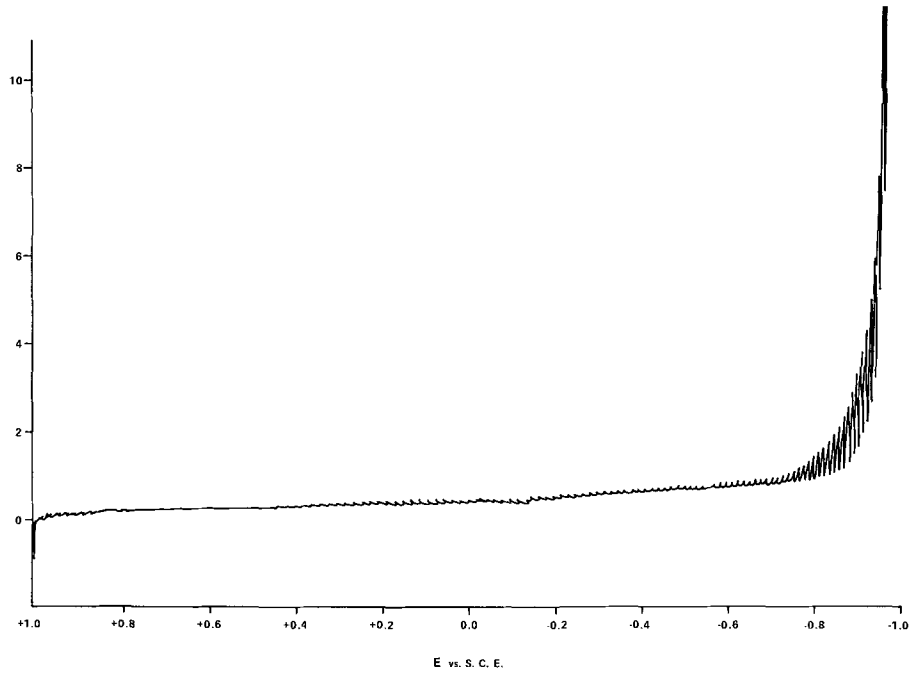

Fig. 1. Polarogram run on 50.0 ml of a 5.00 x $10^{-4}F$ NH_4VO_3 in 1.0F of NH_3, 1.0F NH_4Cl after controlled potential reduction at —1.30V vs. SCE.

up immediately and a polarogram run on this solution was very irreversible, but had an $E_{1/2}$ of —0.68V compared to —1.1V *vs.* SCE for the original 5 × $10^{-4}F$ NH_4VO_3 solution before electrolysis. The positive shift in $E_{1/2}$ after oxidation is evidence of the production of a V(IV) species since V(IV) → V(II) is more reversible than V(V) → V(IV) (9). A calculation using i_d showed that n was approximately 2, which is another indication that a 1:4 ratio of ClO_2^- to V(III) gives a V(IV) species.

Polarography and coulometry of NH_4VO_3 in 0.1F EDTA, 1F NH_3, 1F NH_4Cl.—In the presence of 0.1F EDTA, the *i vs. E* curves of NH_4VO_3 in 1F NH_3, 1F NH_4Cl show a morphology quite different from the curves observed in the pure supporting electrolyte buffer. The polarography of the V(V)-EDTA system was originally investigated by Pecsok and Juvet (18). These workers describe the number of waves in the *i vs. E* curve changing from 2 to 1 as the *p*H is varied from 9.0 to 10.0. Figure 2 shows that the V(V)-EDTA system in 1F NH_3, 1F NH_4Cl has three discernable polarographic waves. The experimental determined *p*H is 9.44. The first wave begins from the potential of Hg oxidation. The second and the third waves are irreversible with $E_{1/2}$ *vs.* SCE of —1.01V and —1.29V respectively. The $E_{1/2}$ of the third wave corresponds to the $E_{1/2}$ found by Pecsok and Juvet (18) for the V(III) to V(II) electrode process. The second wave appears as an irreversible prewave on the polarograms given by Pecsok and Juvet for the V(V)-EDTA system and was not reported by them as a separate wave. These authors, however, do discuss this prewave as the V(IV) to V(III) reduction and the "main wave" as the V(III) to V(II) reduction in the polarogram of V(IV)-EDTA solution at *p*H = 9.54.

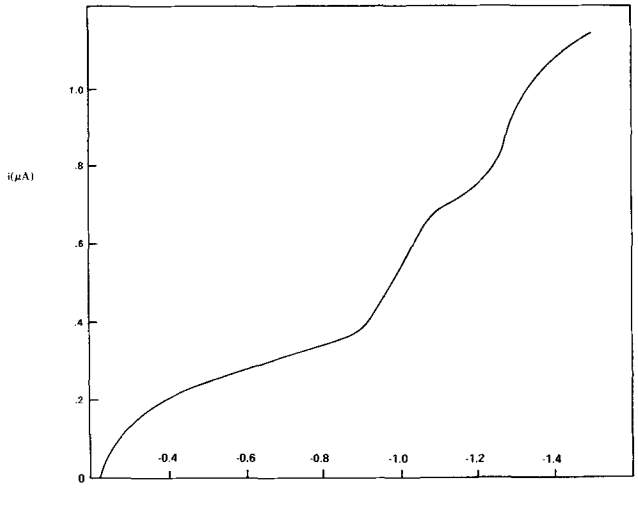

Fig. 2. Polarogram of 1.02 x $10^{-4}F$ NH_4VO_3 in 1.0F NH_3, 1.0F NH_4Cl, and 0.10F EDTA. T = 25°C, m = 1.627 mg/sec.

When the height of the Hg column is raised to 73 cm, a maximum develops on the rising portion of the third wave. The peak of the maximum drops at —1.43V *vs.* SCE and is followed by a sharp dip in the curve which then rises to a current level slightly higher than the peak of the maximum. Addition of Triton X-100 results in complete disappearance of the peak on the third wave but a fourth wave now appears with $E_{1/2}$ at about —1.6V *vs.* SCE. A plot of log *i vs.* log *h*, where *h* is the Hg column height, was obtained over the range of 32.8 to 72.8 cm. In the absence of maximum suppressor, the log-log plot gave coefficients of 0.44, 0.53, and 0.70 for currents on the plateau of waves one to three, respectively. Since $i \propto h^{0.50}$ for pure diffusion control, the plateau currents on the first two waves are close to diffusion controlled. The fact that the coefficient is high for the third wave might be due to the contribution of the maximum current. However when *i vs. h* was studied in the presence of 0.001% Triton X-100 the current was proportional to $h^{0.41}$, $h^{0.43}$, and $h^{0.98}$ for the three waves, respectively. The coefficient in the case of the third wave suggests an adsorption process, however, this may be due to the effect of maximum suppressor.

Coulometry at a large Hg pool electrode was carried out on the V(V)-EDTA system. A blank correction was made on each determination and the electrolysis stopped when the current reached that of the electrolyzed blank. When the potential was controlled at —0.70V *vs.* SCE and 1.936 × 10^{-2} millimoles of V(V) added, the number of coulombs found was 1.968 giving an n = 1.05. On moving the potential to —1.1V *vs.* SCE on the plateau of the second wave, 370 millicoulombs were found for 1.936 × 10^{-3} millimoles of V(V) giving an n = 1.98. Controlled potential reduction at —1.40V vs. SCE was not possible since a catalytic hydrogen wave moved positive during electrolysis and the current did not decay. This wave is most likely the fourth wave which appears when Triton X-100 is added.

At the pH of our buffer the solution composition is a mixture of the VO_2EDTA^{3-} complex and polyvanadates (19). The log formation constants (19, 20) of $VEDTA^{2-}$, $VEDTA^{1-}$, $VOEDTA^{2-}$, and VO_2EDTA^{3-} are 12.7, 25.9, 18.4, and 18.1, respectively, indicating that all vanadium species are complexed. At concentrations of V(V) larger than $10^{-3}F$, the *i vs. t* curves do not show the decrease with time which is present when EDTA is absent. Complexation undoubtedly prevents the inhibited electrode process which occurs when EDTA is not present.

The ratio of the total wave height of the third wave to the second wave is 1.50 ± 1.5% for three concentrations in the range $5 \times 10^{-5}F$ to $2 \times 10^{-4}F$. The coulometry shows that the process occurring on the plateau of the second wave is the reduction of V(V) to V(III), *i.e.*, a two-electron transfer. The ratio of wave heights then indicates that a V(II) species is formed on the third wave. Thus the assignment of stepwise reduction processes V(V) to V(IV), V(IV) to V(III), and V(III) to V(II) can be made for the three waves. The actual species involved in the electrode reactions have not been determined. In fact, the first wave may be due to Hg $EDTA^{2-}$ produced by oxidation of Hg by NH_4VO_3.

Cyclic voltammetry of NH_4VO_3 in 1F NH_3, 1F NH_4Cl. —Figure 3 is a cyclic voltammogram of $1.00 \times 10^{-3}F$ NH_4VO_3 in 1F NH_3, F NH_4Cl. The hanging mercury drop area was 0.0491 cm^2 and the scan rate was 0.0278 V/sec. There are two cathodic peaks at $E^c_{p1} = -1.05V$ and $E^c_{p2} = -1.21V$ and a sharp anodic peak at −0.39V *vs.* SCE. The two cathodic peaks correspond to the two waves in polarographic scans. The sharpness of the second cathodic peak and the anodic peak indicate that a surface film is being electrolyzed in both cases. If the sweep is stopped at −1.0V *vs.* SCE and held for 60 sec and then continued, Fig. 4 is obtained. The peak current on the second cathodic peak is now 22.5 μA as compared with 15.0 μA when the sweep was not stopped. The anodic peak current has also increased from 17.1 to 31.0 μA. The large increase in current can be explained assuming that V(III) hydroxide film is the

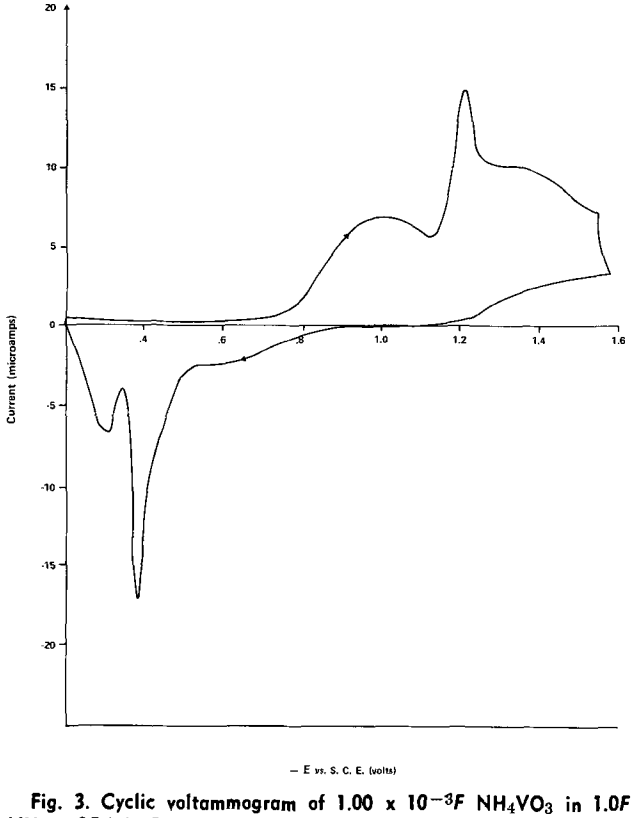

Fig. 3. Cyclic voltammogram of 1.00 x $10^{-3}F$ NH_4VO_3 in 1.0F NH_3, 1.0F NH_4Cl. Scan rate of 0.0278 V/sec and hanging mercury drop area is 0.0491 cm^2.

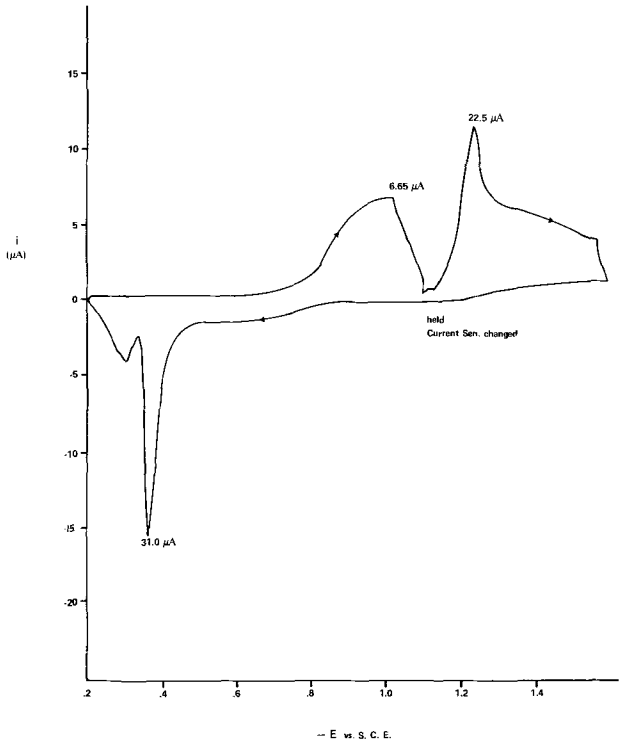

Fig. 4. Cyclic voltammogram of 1.00 x $10^{-3}F$ NH_4VO_3 in 1.0F NH_3, 1.0F NH_4Cl where the scan is held at −1.1V vs. SCE for 60 sec and then continued. Scan rate is 0.0278 V/sec and hanging mercury drop area is 0.0491 cm^2. The current sensitivity was changed after the holding period to 10 μA/in.

reduction product at −1.0V *vs.* SCE. When the sweep is started again the surface quantity of V(III) hydroxide is reduced to V(II) hydroxide giving the sharp cathodic peak. Results of Garrels (12) show that the log solubility product constant is −15.4 for $V(OH)_2$ and −34.4 for $V(OH)_3$ and that at $pH = 9.0$ and a potential of −1.24V *vs.* SCE the $V(OH)_3$ is the stable solid. At a potential of *ca.* −1.3V *vs.* SCE and *pH 9.0*, the $V(OH)_2$ becomes the stable solid. Thus the cyclic voltammetry curves are in agreement with thermodynamics in regard to the formation of surface layers of both (III) and (II) oxidation states. As we shall see, this is only the case at V(V) concentrations larger than $5 \times 10^{-4}F$. The existence of a $V(OH)_3$ species which is blocking is also in agreement with the controlled potential experiment in which a V(III) species passivated a dropping electrode over a large potential region.

The fact that the electrode reaction is inhibited by film formation is confirmed (Fig. 5) by a scan on a single hanging drop from −0.8V to −1.5V *vs.* SCE. The first cathodic peak disappears on the second cathodic scan indicating that the film (which has not been oxidized off) inhibits the electrode reduction in the potential region −0.9V to −1.2V. A very similar curve is obtained if the scan is stopped at −1.1V, held for 10 sec, returned to the initial potential and then rescanned through the second peak. These results indicate that both $V(OH)_2$ and $V(OH)_3$ are blocking in the potential region −0.9V to −1.2V *vs.* SCE.

Another experiment performed on the hanging drop electrode was to scan the potential from −0.6V *vs.* SCE to −1.1V *vs.* SCE and hold the potential constant for various lengths of time. The scan was then continued and the peak currents on the second wave were plotted as a function of holding time (Fig. 6). A set of such runs was made on an individual drop which was cleaned between each run by cyclic scanning in the anodic direction before the normal cathodic scan. The reproducibility of identical experiments made under these conditions was very good. The curve obtained (Fig. 6) tends to reach a constant value of peak cur-

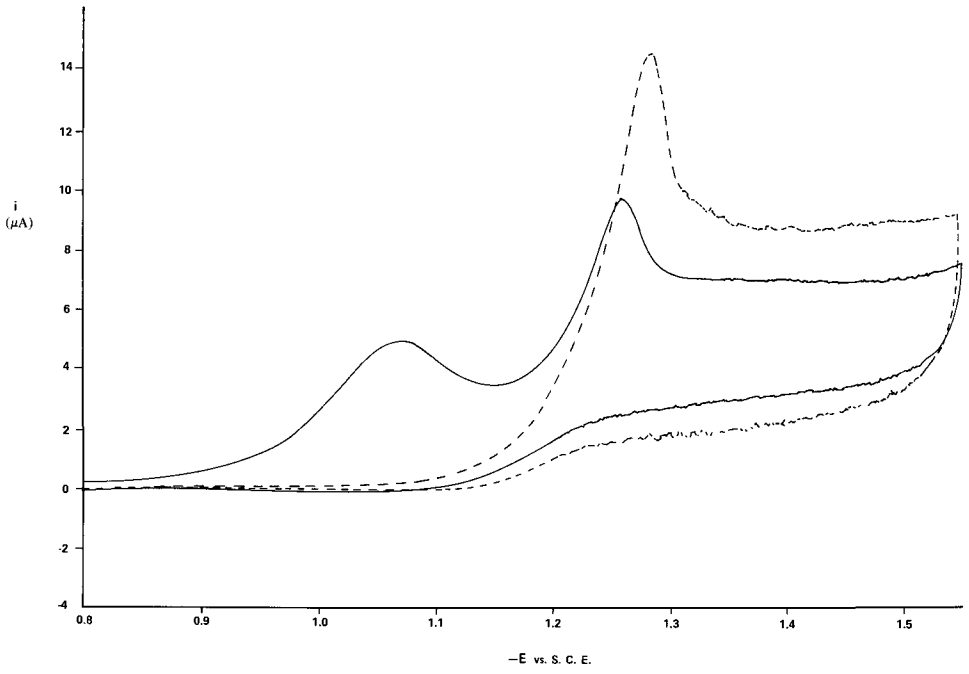

Fig. 5. Effect of repetitive voltammetric scan on 1.00 x $10^{-3}F$ NH_4VO_3 solution in ammoniacal buffer. Hanging drop area is 0.0491 cm^2 and voltage scan rate 0.0149 V/sec.

rent indicating that there is a monolayer of $V(OH)_3$ plated out in agreement with the results of Jedral and Galus (10).

The features of cyclic voltammetry curves change as the concentration of V(V) is lowered. At a concentration of $4.5 \times 10^{-4}F$, there is a single peak at *ca.* —1.2V *vs.* SCE which does not disappear on cyclic scanning but does shift in a cathodic direction on repeated cycles. The peak current is proportional to the 0.55 power of scan rate which is close to the 0.50 value for a diffusion controlled process. At $1.0 \times 10^{-4}F$ V(V) concentration, there is no shift on repeated cycling indicating that at or below this concentration adsorption on the electrode surface is negligible.

Polarographic catalytic current.—In the presence of ClO_2^-, there is a large increase in the polarographic current (in a potential region where the ClO_2^- is not reduced) of a solution of NH_4VO_3 in 1*F* buffer as compared to the current in the absence of ClO_2^-. Under these conditions the limiting current is constant to ±0.5% as a function of mercury column height from 30 to 90 cm. Both of these facts indicate a catalytic current process with a fast regeneration reaction.

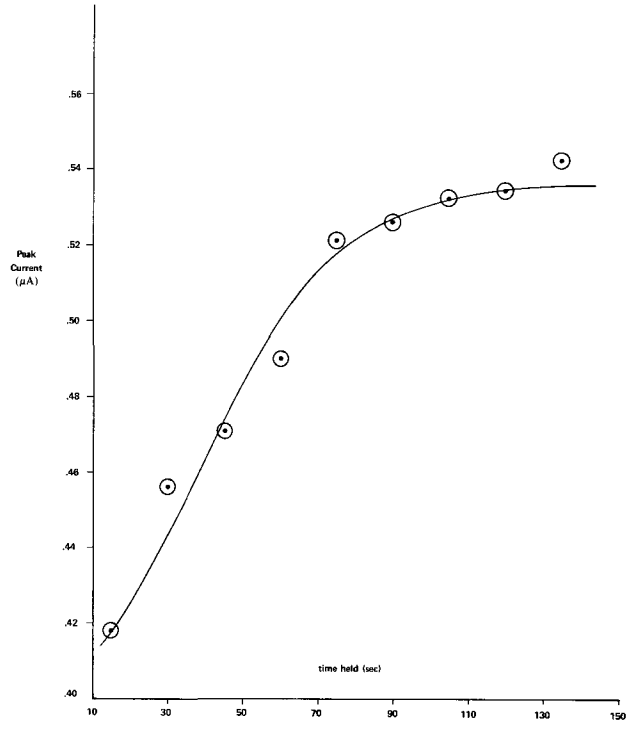

Fig. 6. Peak current as a function of time held at —1.1V *vs.* SCE. NH_4VO_3 is 1.00 x $10^{-3}F$ in ammoniacal buffer, hanging mercury drop area 0.0491 cm^2 and scan rate 0.140 V/sec.

Table I gives data for the instantaneous limiting current as a function of $[ClO_2^-]$. Since $E_{1/2}$ for the ClO_2^- polarographic wave is —1.5V *vs.* SCE, it is necessary to keep $[ClO_2^-]$ values low in order to reduce its reduction current to a minimum in the region of the catalytic wave. The value of $[ClO_2^-]$ was always equal to or less than $10^{-3}F$. A plot of log *i* *vs.* log $[ClO_2^-]$ at a total vanadium concentration of $2.0 \times 10^{-5}F$ has a slope of 0.58 ± 0.08 illustrating reaction which is first order in ClO_2^- since $i \propto [ClO_2^-]^{1/2}$ for this case (13). In addition, the table shows that at $2.00 \times 10^{-5}F$ the values of $i/[ClO_2^-]^{1/2}$ have a 6% deviation from the average value and at $5.00 \times 10^{-5}F$ V(V) there is only a 1.5% deviation from the average value. These data certainly show that *i* is proportional to $[ClO_2^-]^{1/2}$ as is predicted for a catalytic process.

A normal polarographic catalytic process should show values of catalytic limiting current divided by the diffusion current measured in the absence of the catalytic mechanism that are independent of vanadium concentration. This is definitely not the case for this system since values of i/i_d decrease as the total vanadium concentration increases as can be seen in Table II. The diffusion current i_d was measured with mass flow rate $m = 1.63$ mg/sec and drop time $\tau = 7.50$ sec, and it is directly proportional to [V(V)] in the concentration range of interest. The value i^*_d is a value of diffusion current converted to capillary characteristics of the particular catalytic current, *i*. The data in Table II were taken with $[ClO_2^-] = 1.00 \times 10^{-3}M$ and $E = -1.25$V *vs.* SCE. A log-log plot of *i* *vs.*

1.00 x 10^{-4}	4.90	1.07	5.88	1.41	0.812	0.587	8.34

[a] i_d calculated from a calibration curve where m = 1.63 mg/sec, τ = 7.50 sec, E = −1.25V *vs.* SCE.

[V(V)] at [ClO_2^-] = 1.0 × $10^{-3}M$ has a slope significantly less than unity. A slope of one would be expected for a reaction first order in the vanadium species which is oxidized in the catalytic process.

A catalytic current is also found in a V(V) solution of ClO_2^- in 1*F* buffer when 0.1*F* EDTA is added. In this case the values of i/i_d are independent of V(V) concentration as can be seen from Table III. Thus the mechanism of the electrode process in the presence of 0.1*F* EDTA is the normal catalytic process.

It is possible to derive a current expression for a catalytic process which has the properties of the trend in data of Table II. The mechanism upon which this current expression is based is the situation where the product of the electrode reaction dimerizes (14). If it is considered that monomer and dimer are in a mobile equilibrium and both react with ClO_2^-, the current expression (14) for a mechanism with two regeneration reactions, one first order in monomer and ClO_2^-, the other first order in dimer and ClO_2^- is

$$i = n\mathbf{F}qf(a_o)\,[\alpha b^* k_1 D_a]^{1/2}\,H(u) \qquad [1]$$

with

$$f(a_o) = a_o\left[1 + \frac{8D_eKa_o}{3D_a} + \frac{2k_2Ka_o}{3k_1} + \frac{2k_2D_eK^2a_o^2}{k_1D_a}\right]^{1/2}$$

and

$$a_o = \frac{D_a}{4KD_e}\left[\left(1 + \frac{8D_eD_cKc^*}{D_a^2}\right)^{1/2} - 1\right]$$

where n is the number of electrons transferred per species in the electrode reaction, **F** is the Faraday constant, q is the electrode area, α is a stoichiometric coefficient, k_1 and k_2 are the homogeneous rate constants for the monomer species A and the dimer E, respectively. C stands for the electrode reactant and B for chlorite. The lower case letters represent the concentration of species; thus $K = e/a^2$ is the dimerization constant. Starred lower case letters represent bulk concentrations with b^* = [ClO_2^-]; the D_i's are the diffusion coefficients of the i-th species, and a_o is the concentration of A at the electrode surface under limiting current conditions. The factor $H(u)$ in Eq. [1] depends on the deviation from pseudo first-order conditions and a very accurate approximation for this factor (15) is

$$H(u) = \tfrac{1}{2}\left[1 + \left(1 - \frac{1.504\,n_b i}{\alpha n i'_d}\right)^{1/2}\right] \qquad [2]$$

where

$$i'_d = n_b\mathbf{F}qb^*\sqrt{\frac{7D_b}{3\pi\tau}}$$

Table III. Data and rate constant calculations for $VEDTA^{2-}$ oxidation

[V(V)]	$i(\mu A)$	$i_d(\mu A)$	i/i_d	$H(u)$	k
1.02 x 10^{-5}	1.6	0.085	18.8	0.965	7.91 x 10^3
5.10 x 10^{-5}	5.6	0.30	18.6	0.864	9.57 x 10^4
6.12 x 10^{-5}	7.2	0.38	18.9	0.814	11.1 x 10^4
8.16 x 10^{-5}	8.1	0.50	16.2	0.783	8.84 x 10^4

Equation [1] can be put in a more useful form by dividing it through by the diffusion current in the absence of ClO_2^-

$$i_d = n_c\mathbf{F}qc^*\sqrt{\frac{7D_c}{3\pi\tau}}$$

giving

$$\frac{i}{i_d} = \frac{n}{n_c}\,1.160\,(k_1b^*\alpha\tau D_a/D_c)^{1/2}\,(f(a_o)/c^*)H(u) \qquad [3]$$

This equation along with Eq. [2] can be used to calculate rate constants if the values of K and the D_i's are known.

The function $f(a_o)$ takes limiting forms as the value of K goes to zero and to infinity. Thus in the limit as

$$K \to 0, f(a_o) \to \frac{D_c}{D_a}c^*$$

since

$$a_o \to \frac{D_c}{D_a}c^*$$

and as

$$K \to \infty, f(a_o) \to \left(\frac{k_2D_c^2}{k_1\,2D_eD_a}\right)^{1/2}c^*$$

since

$$a_o \to \left(\frac{D_cc^*}{2D_e}\right)^{1/2}$$

Thus, both limiting cases yield i/i_d expressions which are independent of c*. It is only for the case when K is large and $k_1 >> k_2$ that i/i_d is a function of c* and decreases with increasing c*. For this case Eq. [3] becomes

$$\frac{i}{i_d} = \frac{n}{n_c}\,1.160\,\sqrt{k_1b^*\alpha\tau}\left(\frac{8D_c}{9D_eK}\right)^{1/4}\frac{H(u)}{c^{*1/4}} \qquad [4]$$

Equation [4] predicts that if the mechanism is occurring, a log i/i_d *vs.* log c* plot will have a slope of −0.25. Such a plot for the data in Table II gives a slope of −0.37. Since Eq. [4] is an approximation of Eq. [3] for particular conditions which may not exactly hold, the experimental result is considered in good enough agreement with the theory to support the conclusion that the mechanism involves an aggregation (dimerization) equilibrium of the reduced form of the electroactive species.

Mechanism and rate constant calculation.—In order to calculate a rate constant for the ClO_2^- oxidation, the mechanism of the catalytic electrode process must be known. A value of $n_c = 3$ indicating a V(II) species as the product of the electrode reaction in the absence of adsorption is most consistent with the data. An independent value of the diffusion coefficient has not been determined making the calculation of $n_c = 3$ from diffusion current somewhat unsatisfactory. However, the thermodynamic data already cited indicate that at voltages more negative than −1.3V *vs.* SCE a V(II) hydroxy species should be formed. In an earlier paper (14), we concluded that a V(III) species was being oxidized. This conclusion was based on the controlled potential data which showed a two equivalent reduction; however, the reaction between V(II) and V(V) leads to this stoichiometry even if V(II) is formed at the electrode. The oxidation experiment with ClO_2^- shows that a V(IV) species is the product of the homogeneous oxidation so that in the catalytic current Eq. [1], $n = 2$.

The following proposed mechanism for the catalytic process is based on the above conclusions concerning oxidation states and a dimerization equilibrium where only the monomer is oxidized.

$$V(V) + 3e \xrightarrow{k_e} V(II)$$

$$2V(II) \rightleftarrows V_2(II)$$

$$2H_2O + 2V(II) + ClO_2^- \xrightarrow{k_1} 2V(IV) + Cl^- + 4\,OH^-$$

$$V(IV) + 2e \xrightarrow{k_e} V(II)$$

The reactions

$$V(II) + V(IV) \rightarrow 2V(III)$$

$$2V(II) + V(V) \rightarrow 3V(III)$$

will most likely take place outside the reaction layer and therefore are not considered to effect the mechanism. A similar electrode process without dimerization has been proposed for the catalytic reduction of NO_2^- in the same V(V) system (5).

In order to calculate a homogeneous rate constant a value of K for the equilibrium constant must be used. A very rough value of K can be found from the data by finding the smallest value of K necessary to give the c* dependence of Eq. [4]. In this way, a value of $K = 7 \times 10^5$ is found. Also we make the not too unreasonable assumption that $D_a = D_c$ and assume spherical symmetry so that $D_e/D_a = 0.8$. With the above values of K and D_i's, $n_c = 3$, $n = 2$, and $\alpha = 2$, a value for the homogeneous rate constant can be calculated using Eq. [3] and a value of $H(u)$ from Eq. [2]. Since we assume $k_1 >> k_2$ only the first two terms of the $f(a_o)$ function are retained in the calculation. The values of k_1 are given in Table IV along with k values calculated for the usual catalytic mechanism where $f(a_o)/c^* = 1$. The average value of k is $4.0 \pm 2.2 \times 10^4$ liter/mole-sec while the average value of k_1 is found to be $2.2 \pm 1.1 \times 10^5$ liter/mole-sec. The value of 2×10^5 liter/mole-sec of course is only a lower bound to the actual value of the rate constant which depends on $K^{1/4}$.

When the solution is 0.1F in EDTA, there is no need to postulate an aggregation equilibrium involving a lower oxidation state of vanadium since the value of i/i_d is independent of c*. The effect of the EDTA is no doubt to complex the lower oxidation states of the vanadium central ion reducing the hydrolytic and aggregation equilibrium. The catalytic process is found to take place on the third wave which means that it is the V(II)-EDTA species which is being oxidized by the ClO_2^-. Table III gives the data and the values of k calculated. The $[ClO_2^-]$ was 1.00×10^{-3} M, $\tau = 3.64$ sec, and the measurement was made at $E = -1.40$V *vs.* SCE. The average value of the rate constant is $9.4 \pm 0.7 \times 10^4$ liter/mole-sec which shows better precision than in the absence of EDTA.

The fact that the rate constants for homogeneous oxidation of a V(II) species by ClO_2^- are about the same in the presence and absence of EDTA is consistent with the proposed mechanism involving dimerization in the absence of EDTA. The latter rate constant was calculated with an assumed value of K that would only give a lower bound to the true rate constant. However, since both rate constants are found to be very similar, if we assume an identical oxidation step the value of K used in the calculation must be of an order of magnitude close to the true equilibrium constant. Of course, the two rate constants in question can only be approximately compared since they refer to different vanadium species as reactants in the oxidation.

Table IV. Rate constant calculations for V(II) oxidation

c*	b*	i/i_d*	$H(u)$	$f(a_o)/c^*$	k	k_1

$Cr(EDTA)(H_2O)^{2-}$	$1.8 \pm 0.4 \times 10^3$	(16)
$V(II)(OH)_n(NH_3)_y^z$	$2.2 \pm 1.1 \times 10^5$	This work
$VEDTA^{2-}$	$9.4 \pm 0.7 \times 10^4$	This work
$Cu(NH_3)_2^+$	44.0 ± 3.7	(11)

Rate constants for the oxidation of various complexes by ClO_2^- are compared in Table V. The rate constant for the $Cr(NH_3)_5OH^{2+}$ was calculated from the data given in an earlier publication (15). The data for the chromium system in the presence of EDTA has not been presented (16). The rate constant in this case is an order of magnitude smaller than that found in the absence of EDTA. From the table it can be seen that the high spin metal complexes of Fe(II) and Cr(II) which are substitution labile show fast oxidation kinetics. The low spin substitution inert complex $Fe(CN)_6^{4-}$ does not have a catalytic polarographic current with ClO_2^- and uv-vis spectroscopy shows the reaction is very slow. This reaction is thermodynamically favored and it must be concluded that both fast inner-sphere substitution and outer-sphere electron transfer do not operate in this case.

In an earlier paper (11), it was suggested that a general mechanism for ClO_2^- oxidation of metal complexes involved inner-sphere substitution. However, V(II) which shows fast kinetics is a d^3 ion and somewhat substitution inert (17). If inner-sphere substitution were rate controlling V(II) complexes should be oxidized much slower than Cr(II) complexes which is not the case. A possible rate determining step for V(II) oxidation may be an outer-sphere atom transfer of an oxygen atom in a two electron change.

The complexes with rate constants from 10^3-10^5 liter/mole-sec and their oxidation products will have H_2O molecules in their coordination sphere, and it is highly possible that oxidation by ClO_2^- in these cases involves either outer-sphere oxygen atom transfer or O^- ion transfer. Such a mechanism remains to be experimentally verified. However, what has been established is that ClO_2^- shows fast oxidation kinetics with a wide variety of metal complexes of the first transition series.

Thermoelectric Powers and Transported Entropies in Aqueous Hydrochloric Acid

Arthur D. Payton,* Bruce H. Boyd, C. Michael Houck, Edward H. Temple, and Albert H. Zimmerman

Chemistry Department, Willamette University, Salem, Oregon 97301

ABSTRACT

The initial thermoelectric power (TEP) has been determined for hydrogen electrodes in aqueous HCl solutions as a function of molality from 0.002 to 0.6 mol/kg and as a function of temperature for a 10° gradient at mean temperatures of 20°, 25°, and 30°C. For each mean temperature the TEP's are analyzed by fitting the data to an equation with three constants. At rounded molalities, the TEP's that were obtained from the 25° equation have been combined with known values for the heat of transport of HCl in order to determine a single-ion property, the transported entropy of the hydrogen ion. By extrapolation the standard value of this property has been determined as 5.42 ± 0.16 eu, which is in agreement with literature values.

In order to determine the concentration dependence of transported entropies of ions in aqueous electrolytes over a wide range of concentration, we decided to measure initial thermoelectric powers (TEP) as a function of molality from 0.002 to 0.6 mol/kg. In addition, we wanted to determine the concentration dependence of initial TEP's at several mean temperatures, since there is a lack of data on temperature-dependent experiments related to thermal diffusion in solutions. Aqueous HCl with hydrogen electrodes was chosen as the system to be investigated because the electrodes are excellent in terms of reproducibility and because auxiliary data on HCl are readily available. Although we have measured these emf's at mean temperatures of 20°, 25°, and 30°C, we could determine the transported entropy $\overline{\overline{S_i}}$ at 25° only, due to a lack of data for heats of transport at other temperatures.

In an electrolytic solution, $\overline{\overline{S_i}}$ is the entropy carried along by the ion to which the electrodes are reversible. It is made up of the sum of the partial molal entropy S_i and the entropy of transport $\hat{S}_i$. The latter quantity is equal to the heat of transport $\hat{Q}_i$ divided by the Kelvin temperature T. One fascinating aspect of $\overline{\overline{S_i}}$ is that it represents a single-ion property that is not based on an arbitrary convention (1). For example, this is not the case when dealing with individual ionic activity coefficients, ionic heats of transport, and partial molal ionic entropies. For individual ionic heats of transport, the molar heat of transport $\hat{Q}$ is usually split into its ionic contributions using the convention (2) that $\hat{Q}^0_{Cl^-} = 0$ or $\hat{Q}_{Cl^-}\ (m = 0.01) = 0$. The superscript zero on the heat of transport indicates the value at infinite dilution and m the molality. For partial molal ionic entropies S^0 of neutral salts are broken up using the convention that $S^0_{H^+} = 0.0$ (3), −5.5 (4), or −5.1 eu (5), in which the superscript indicates the standard value (1 eu = 43.36 μV **F**/K = 1 cal/K = 4.184 J/K).

It turns out that data of such quality as we obtained for HCl with hydrogen electrodes are not needed in order to calculate transported entropies because the concentration dependence of the heat of transport is not known that precisely. However, the initial TEP's themselves should prove valuable in elucidating the concentration dependence of related quantities in thermocells.

For aqueous HCl the heat of transport may be obtained from the Soret coefficient by means of the formula (2)

$$\hat{Q}_{HCl} = 2\sigma RT^2\,[1 + (\partial \ln \gamma_\pm / \partial \ln m)] \qquad [1]$$

in which $\gamma_\pm$ is the mean molal ionic activity coefficient, $R = 8.31434$ J K^{-1}mol^{-1}, $T = 298.15$K, and 1 cal = 4.184 J. The expression $[1 + \partial \ln \gamma_\pm / \partial \ln m]$ is usually called the "thermodynamic term." The Soret coefficient σ is defined as $(-1/m)(\delta m/\delta T)$ at the steady state (Soret equilibrium) (1). This convention makes σ algebraically positive for the normal Soret effect (salts diffusing thermally from hot to cold) and avoids the attendant confusion in comparisons of values of Soret coefficients. In place of Eq. [1], Breck, Cadenhead, and Hammerli (6) measured $\hat{Q}$ directly by obtaining both the initial and final thermoelectric powers of an aqueous HCl thermocell with quinhydrone electrodes, before thermal diffusion had commenced, and at the steady state, respectively. They used the formula

$$\mathbf{F}(\epsilon_0 - \epsilon_\infty) = \tfrac{1}{2}(\hat{S}_Q - \hat{S}_{H_2Q}) + (t_{Cl^-})(\hat{Q}_{HCl}/T) \qquad [2]$$

in which t_{Cl^-} is the transference number, and $(\epsilon_0 - \epsilon_\infty)$ is the difference between the initial and final thermo-

* Electrochemical Society Active Member.

Key words: entropy of transport, heat of transport, hydrogen electrodes, single-ion property, Soret coefficient, temperature gradient, thermal diffusion.

electric powers. They assumed that one-half the difference of entropies of transport between quinone (Q) and hydroquinone (H_2Q) is small and estimated its value to be 0.05 eu at all molalities.

By use of Eq. [3] we corrected all observed emf's so that the hydrogen pressure in both the hot and cold electrode compartments was 760 Torr (= 1 atm = 101325 N/m^2). The barometric-pressure- and vapor-pressure-correction factor was given by

$$k = \frac{RT_U}{2F} \ln \frac{BP - P_U + \Delta P_U}{760} - \frac{RT_L}{2F} \ln \frac{BP - P_L + \Delta P_L}{760} \quad [3]$$

in which R = 8.31434 J/mol K, $\mathbf{F}$ = 96487 C/equiv, BP is the barometric pressure in Torr, and T_U and T_L are the upper and lower temperatures. Here P_U and P_L are the vapor pressures of pure water and ΔP_U and ΔP_L are the solvent vapor-pressure lowerings at the upper and lower temperatures, respectively. At m = 0.1 mol/kg, this correction was approximately −200, −265, and −350 μV for runs at 15°/25°, 20°/30°, and 25°/35°C, respectively. This correction was added to the emf before division by the temperature difference ΔT to obtain the TEP. For the vapor pressure of pure water, we used the constants given in Lange's Handbook (7) for Antoine's equation

$$\log P \text{ (in Torr)} = 8.10765 - \frac{1750.286}{(T - 38.15)} \quad [4a]$$

At 25°C, the fractional vapor-pressure lowering was calculated by

$$(\Delta P/P) = 10^{-4}m(272.144 + 271.016m - 225.760m^2) \quad [4b]$$

derived from vapor-pressure lowering data given in Ref. (8). At 25°C and the highest molality (*ca.* 0.6m) valid for Eq. [4b], the fractional vapor-pressure lowering was calculated to be 0.021. This increased the value of k by 5.2 μV, compared with the value obtained from Eq. [3] by neglecting ΔP_U and ΔP_L. This correction, although small, was not ignored.

In our calculation of the TEP, we have considered neither the increase in hydrogen pressure due to the depth of the bubblers below the surface of the solution nor the nonideality of hydrogen gas, mentioned by Hills and Ives (9).

We found the function $\sqrt{m}/(1 + \sqrt{m})$ suitable for the abscissa of graphs of our results. At nine rounded values of this function we determined $\bar{\bar{S}}_{H^+}$ from our values of the TEP and from Breck, Cadenhead, and Hammerli's (6) values of $\hat{Q}_{HCl}$ using the formula

$$\bar{\bar{S}}_{H^+} = \tfrac{1}{2}S^0_{H_2} - \bar{\bar{S}}_e + (t_{Cl^-})(\hat{Q}_{HCl}/T) - \mathbf{F}(TEP) \quad [5]$$

in which $S^0_{H_2}$ = 31.21 eu, the standard value of the entropy of hydrogen gas (3), and $\bar{\bar{S}}_e$ (Pt) = 0.104 eu (10), the transported entropy of the electron in the nonisothermal part of the platinum. After we corrected these values for the mass-action term, using Eq. [6]

$$\bar{\bar{S}}_{H^+} \text{ (mod 1)} = \bar{\bar{S}}_{H^+} + R \ln m \quad [6]$$

they still showed a trend. However, we obtained nearly constant values by including the mean molal ionic activity coefficient and its temperature derivative, according to Eq. [7]

$$\bar{\bar{S}}_{H^+} \text{ (mod 2)} = \bar{\bar{S}}_{H^+} \text{ (mod 1)} + R \ln \gamma_{\pm} + RT \frac{\partial \ln \gamma_{\pm}}{\partial T} \quad [7]$$

as has been derived by deBethune and Daley (11) [cf. Eq. 10 of Ref. (11)].

We also determined the concentration dependence of the TEP at mean temperatures of 20°, 25°, and 30° by fitting the data to an equation of the form

$$Y = A - B\sqrt{m}/(1 + \sqrt{m}) + Cm \quad [8]$$

in which Y is defined by Eq. [9a]

$$Y = TEP - (R/\mathbf{F}) \ln m \quad [9a]$$

Here TEP is $(1/\Delta T)$ times the observed emf corrected for barometric pressure and vapor pressure according to Eq. [9b]

$$TEP = \frac{\text{emf(obs)} + k}{\Delta T} \quad [9b]$$

Other workers (1, 6) have used Eq. [8] without the Cm term in their critical evaluation of the nonideal behavior. Preliminary graphs of the TEP *vs.* log m were not sensitive enough to evaluate our data, although at lower molalities the data approached the limiting slope of $(R/\mathbf{F})\ln 10$.

Experimental

Electrical apparatus.—To measure the emf's, a L&N Type K-3 potentiometer was used with the revised circuit for measurement of high-resistance emf's. In this circuit the Ayrton shunt of the potentiometer is shorted out and the unknown emf is put in series with the detector. For null detection a Boonton sensitive d-c meter No. 95A (input resistance 10 megohm) was used. Standardization was accomplished with the normal circuit and a guarded constant voltage supply (Dynage Model No. 505A) and a plug-in standard cell (Dynage Model No. LVB-1).

Temperatures.—Temperatures were measured at 20°, 25°, and 30° by means of a Brooklyn Thermometer Company thermometer graduated in 0.01° (range 19°-34°). Since some of the temperatures were outside this range, a 2- or 4-junction copper-constantan thermocouple was used to determine the other temperature (20°/30° = 1615 μV *vs.* a 4-junction table (12) value of 1628 μV). We used 803 μV for the 2-junction thermocouple for 15°/25°, 811.5 μV for 20°/30°, and 819 μV for 25°/35°. The two water thermostats were regulated by Bronwell thermoregulator-circulators, which maintained the temperatures to ±0.01°.

The bath temperatures were always within ±0.1° of 15°, 20°, 25°, 30°, or 35°C. Although the mean temperature for a run was known to 0.01°, it could vary by up to 0.1° from the values 20°, 25°, or 30°. Antoine's equation (Eq. [4a]) was used in the temperature range 14.9°-35.1° for the vapor pressure of pure water. Use of Eq. [4a] avoided the need for five different sets of constants for linear interpolation within 0.1° of the five bath temperatures. A deviation of 0.10° from 25.00° for the mean temperature would cause TEP or Y to change by 0.2 μV/K, which is well within our experimental error of ±2 μV/K. This change was calculated from the temperature derivative of the TEP as given in the next section (dY/dT = 2 μV/K).

For one of the 20°/30° runs, the temperature of the solution in the hot side of the cell was found to be less than 0.01° lower than the bath temperature. Since ambient temperature was *ca.* 25°C, density instability causing convection in the solution would have reduced the solution temperature even farther below that of the bath. Therefore, the effect of convection was neglected, and we equate our bath temperature to that of the solution.

One run was performed using a 6° temperature difference, instead of 10°. The result of this run was not significantly different from our usual 10° runs, although the precision was not as good. Use of a temperature difference, which is less than 10° in order to avoid errors due to the temperature dependence of the TEP, is probably unnecessary (13). Thus we identify our TEP as the true TEP at the mean temperature of the run.

Electrodes.—Each hydrogen electrode was constructed by welding a 1 cm^2 (0.002 in. thick) piece of platinum to a length (*ca.* 80 cm) of No. 27 platinum wire with an oxygen-gas flame. The length of wire was then sealed in a 3-mm OD, soft glass tubing. This length of external wire allowed us to be certain that the temperature gradient of the metallic connector was in platinum, rather than in the copper part of the lead that was connected to the potentiometer. Platinum black was deposited on the electrode by reduction of a 2% platinic chloride solution that contained 0.02% lead acetate (9). The electrolysis was carried out for a few minutes at a current density of 80 mA/cm^2, until the deposit appeared uniformly black. It was not necessary to reverse the current periodically as some authors recommend.

Chemicals.—Ultra-pure (99.9998% pure, Airco) hydrogen gas was further purified by a "de-oxo" cartridge (J. T. Baker Company), which was attached directly to the regulator. The gas was then bubbled through deionized water to saturate it with water vapor before it entered the solution in the cell. Reagent grade HCl was used to make stock solutions, which were then diluted to the desired concentrations with deionized water. Titrations were carried out on the solution that was removed from the cell following a successful run, when the concentration was above 0.02*N*. For more dilute solutions the concentration was taken as that calculated from dilution of the standardized stock solution. One run was performed using HCl purified by distilling the constant-boiling azeotrope, but the result of the run was not noticeably different from the other runs.

Cell and bubblers.—The cell was W shaped, with each compartment being 35 mm diam by 40 cm tall. The compartments were connected with 12-mm OD Pyrex tubing to which was sealed a side arm and Teflon stopcock. The solutions in the compartments could then be drawn together by gentle suction, thus avoiding the stopcock. The design of an H-shaped cell (14) had been discarded because of the possibility of convection in the solution causing an error in the temperature difference. Treating our cell as a conductivity cell, we determined the cell constant to be 200 cm^{-1}. Two electrodes and a bubbler tube were inserted into a rubber stopper, which was sealed into the 34-mm diam end of a 34/45 standard taper joint. Apiezon W was used for the sealing of the electrodes, bubbler tube, and stopper. One of these assembled female joints was placed on top of each side of the W-shaped cell. The solution was never allowed to come in contact with the lightly greased joint (Apiezon N), since the grease was on the outside.

Procedure.—To remove oxygen, prepurified nitrogen was bubbled through the saturator and cell solution for 15 min, with the solution in each cell half separated. Then hydrogen was bubbled for another 15 min, before the solutions were drawn together. Usually the emf became steady within 15-30 min after the solutions were drawn together. The emf was then recorded. In some of the runs this waiting period had to be extended to 1-2 hr until "things settled down." The nonsteady results could usually be explained as being caused by an empty saturator, not waiting long enough for equilibration of the electrodes in the solution, or an extra gas-escape hole. Freshly platinized electrodes sometimes caused erratic results. For concentrations above 0.05*N* the electrodes had to be presoaked in a solution of that concentration for 20 hr before the run. At concentrations below 0.05*N* the electrodes were merely placed in deionized water prior to use in the cell. With each pair of electrodes, two readings were taken, first with the current in the forward direction and then in the reverse direction. The more dilute the solution was, the larger was the difference between forward and reverse readings. This is due to the resistance of the solution being comparable to the input impedance of the null detector (15). To eliminate any asymmetry in the electrodes, bubblers, or solution, the bubblers were disconnected, the cell physically reversed, and bubbling started again. Four readings were again taken, making a total of eight in all. A slight difference in concentration between the solutions in each cell compartment would show up as a large difference in emf: a 0.1% difference in molalities causing an estimated 50 μV difference in the two emf readings. It was found very important to have only one escape outlet in the stopper for the hydrogen gas. Atmospheric gases outside the cell tended to flow in through any other opening and thus change the partial pressure of hydrogen above the solution. If the single escape hole were covered temporarily, this could also be observed as a change in the emf of the thermocell.

Results and Discussion

Thermoelectric powers.—In all runs the polarity of the thermocell was such that the hot electrode was positive, except for the three most dilute runs at 15°/25°. Our results are summarized in Fig. 1, in which curves are shown for the function $Y = TEP - (R/F) \ln m$ at mean temperatures of 20° (lower curve), 25° (middle), and 30° (upper). Each of our actual data points is represented by a rectangle. The width of each rectangle is twice as large as the estimated error of ±0.1 in the molality function $100\sqrt{m}/(1 + \sqrt{m})$, whereas the height of the rectangle approximates the estimated error of ±2 $\mu V/K$ (0.046 eu). Approximately 10% of our runs were not within our estimated limits of precision and were not retained in the final data analysis. The curve shown for each set of rectangles was fitted by nonlinear least squares to an equation of the form of Eq. [8]. The constants are given in Table I. From the three values for the A constant at the three mean temperatures, we determined the temperature coefficient of Y° (the limiting value at infinite dilution) to be 2.19 $\mu V/K^2$.

Transported entropies at 25°C.—We used Eq. [5] to calculate the transported entropy of the hydrogen ion $\bar{\bar{S}}_{H^+}$ at nine rounded values of the molality function $100\sqrt{m}/(1 + \sqrt{m})$. Details of this calculation are found in columns 1 to 5 of Table II.

The transported entropy of the counter ion $\bar{\bar{S}}_{Cl^-}$ may also be calculated, if one first determines $\gamma_\pm$, S_{HCl}, and $\bar{\bar{S}}_{HCl}$ at the nine molalities. The mean molal ionic activity coefficients were calculated by Eq. [10] from Harned and Owen (17)

Table I. Results and constants based on the three-constant equation (Eq. [8]) for Y as a function of molality

Mean temperature, °C	Molality range, mol/kg	n, number of runs	Standard error,[a] $\mu V/K$	A	B	C
20	0.0016-0.61	50	1.01	510.33 ± 0.39[b]	88.02 ± 3.16	14.76 ± 2.64

Table III. Constants for determination of mean molal ionic activity coefficients and molarity of HCl using Eq. [10] and [11]

Mean temperature, °C	$-\mathfrak{S}^{\mu}$	A'[a]	B[b]	D[b]	a[b]	b[b]
20	0.5033	1.414	0.1312	0.0063	0.9982	0.01805
25	0.5075_5	1.418_5	0.1292	0.0061	0.9972	0.01817
30	0.5129_5	1.423	0.1272	0.0060	0.9958	0.01822

[a] Determined by averaging values from Ref. (17) and from Ref. (23) (with $\mathring{a}$ = 4.33Å).
[b] From Ref. (17).

$$\log \gamma_{\pm} = \frac{-\mathfrak{S}\sqrt{c}}{1 + A'\sqrt{c}} + Bc + Dc^2 - \log(1 + 0.03604m) \quad [10]$$

The molarity c is given by

$$c/m = a - bm \quad [11]$$

The constants for Eq. [10] and [11] are shown in Table III. Comparison of the values for $\gamma_{\pm}$ determined from Eq. [10] with literature values (18) at ten rounded molalities in the range 0.001-1.0 mol/kg yielded an excellent average error of 0.0005. After calculating $\gamma_{\pm}$, we next obtained the partial molal entropy of HCl at the nine rounded values of the molality function by a formula similar to that of Haase, Hoch, and Schönert (19)

$$S_{HCl} = S^0_{HCl} - 2R \ln m - 2R \ln \gamma_{\pm(25)} - \frac{2RT[\gamma_{\pm(30)} - \gamma_{\pm(20)}]}{10\,\gamma_{\pm(25)}} \quad [12]$$

in which T = 298.15K and S^0_{HCl} = 13.17 eu (3). By use of Eq. [13]

$$\bar{\bar{S}}_{H^+} + \bar{\bar{S}}_{Cl^-} = \bar{\bar{S}}_{HCl} = S_{HCl} + (\hat{Q}_{HCl}/T) \quad [13]$$

we obtained $\bar{\bar{S}}_{Cl^-}$. The results of these calculations are given in columns 7, 8, and 9 of Table II.

Earlier, it was suspected (6, 11) that the transported entropies, after correction for the mass-action term (R ln m), would vary only slightly with molality. Since our results did not confirm this, we added two additional (negative) terms to $\bar{\bar{S}}_{H^+}$ (mod 1) to obtain the quantity $\bar{\bar{S}}_{H^+}$ (mod 2), according to Eq. [7]. Column 13 of Table II shows the results of a similar calculation to obtain $\bar{\bar{S}}_{Cl^-}$ (mod 2). These values are not as nearly

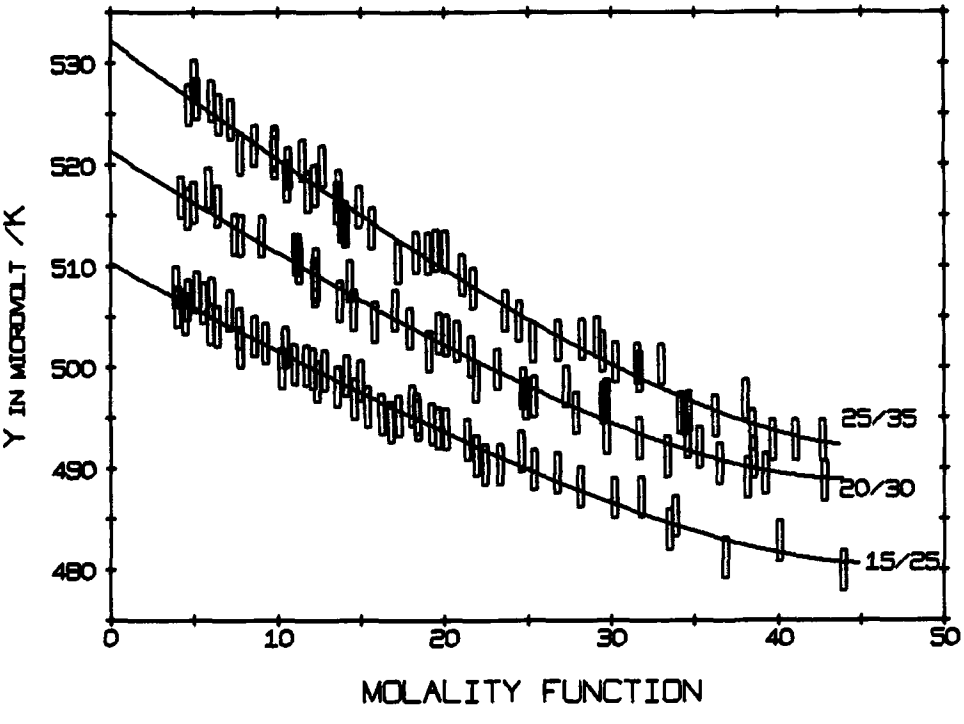

Fig. 1. Function $Y = TEP - (R/F)$ ln m vs. the molality function, $100\sqrt{m}/(1 + \sqrt{m})$. The three curves have been fitted by least-squares analysis according to Eq. [8] with values of constants from Table I. The mean temperatures are: 20° (lower curve), 25° (middle), and 30°C (upper curve).

constant as those for $\bar{\bar{S}}_{H^+}$ (mod 2) in column 11.

Error analysis for transported entropies.—The dominant contribution to the error in both $\bar{\bar{S}}_{H^+}$ and $\bar{\bar{S}}_{H^+}$ (mod 1), calculated from Eq. [5] and [6], respectively, comes from the third term on the right-hand side of Eq. [5], *viz.*, $(t_{Cl^-})(\hat{Q}_{HCl}/T)$. This contribution was determined from Eq. [2]. An error of ±5 μV/K for $(\epsilon_0 - \epsilon_\infty)$ in Eq. [2] corresponds to ±0.69 eu in the entropy of transport of HCl, or ±210 cal/mol in $\hat{Q}_{HCl}$ (6). Our estimate of ±2 μV/K in the TEP yields an additional contribution of ±0.046 eu for the error in both $\bar{\bar{S}}_{H^+}$ and $\bar{\bar{S}}_{H^+}$ (mod 1). Thus the total error comes out to be ±0.16 eu for both transported entropies.

In calculating S_{HCl} at 25°C we used the mean molal ionic activity coeffiecient $\gamma_\pm$ at 20°, 25°, and 30°. An error of ±0.002 in $\gamma_\pm$ leads to ±0.4 eu for the error in S_{HCl}, calculated by Eq. [12]. This error then contributes to the error in both $\bar{\bar{S}}_{Cl^-}$ and $\bar{\bar{S}}_{Cl^-}$ (mod 1).

Although we calculated $\bar{\bar{S}}_{Cl^-}$ (mod 1) from Eq. [12] and [13], we estimated its error from an equation analogous to Eq. [6]. An error of ±2 μV/K in the TEP leads to ±0.046 eu for the error in **F** (*TEP*). The final significant term in the error of $\bar{\bar{S}}_{Cl^-}$ (mod 1) is $(t_{H^+})(\hat{Q}_{HCl}/T)$, although it does not appear explicitly in our calculation of $\bar{\bar{S}}_{Cl^-}$ (mod 1). Because of the occurrence of this term, rather than $(t_{Cl^-})(\hat{Q}_{HCl}/T)$ as in Eq. [6], this term contributes ±0.63 eu to the error in both $\bar{\bar{S}}_{Cl^-}$ and $\bar{\bar{S}}_{Cl^-}$ (mod 1). For these quantities the total error is then ±1.08 eu.

This error may be contrasted with a slightly smaller value of ±0.9 eu for the error in $\bar{\bar{S}}_{Cl^-}$ (mod 2), resulting from the three sources just mentioned. However, this time, the error contribution from the terms in the activity coefficients is only ±0.2 eu instead of ±0.4 eu. The smaller value results from cancellation of terms in going from $\bar{\bar{S}}_{Cl^-}$ (mod 1) to $\bar{\bar{S}}_{Cl^-}$ (mod 2).

Comparison of results with other values.—From extrapolations to infinite dilution of $\bar{\bar{S}}_{H^+}$ (mod 1) and $\bar{\bar{S}}_{H^+}$ (mod 2) of Table II, we determined $\bar{\bar{S}}^0_{H^+}$ as 5.42 ± 0.16 eu. This value compares well with the value of 5.12 eu of Breck, Cadenhead, and Hammerli (6), which was determined using quinhydrone electrodes in aqueous HCl. Our result for $\bar{\bar{S}}^0_{H^+}$ is in agreement with the value 5.27 eu of deBethune and Daley (11), which was determined from thermocells with calomel electrodes.

By extrapolation of $\bar{\bar{S}}_{Cl^-}$ (mod 1) and $\bar{\bar{S}}_{Cl^-}$ (mod 2) of Table II to infinite dilution, we found $\bar{\bar{S}}^0_{Cl^-}$ to be 18.6 ± 1.0 eu. This is in excellent agreement with the value 18.69 eu for $\bar{\bar{S}}^0_{Cl^-}$, as determined by deBethune and Daley (11) using calomel electrodes. It also compares well with the value 19.1 eu of Haase, Hoch, and Schönert (19), obtained using silver-silver chloride electrodes. Our values are also in agreement with those of Agar (1) and Temkin and Khoroshin (10).

A comparison may also be made of our TEP with the work of Goyan (20). He measured the initial emf of a hydrogen-electrode thermocell containing 0.01*M* HCl, and obtained 1.41 mV for ΔT = 9.90K. For this result the two temperatures were centered at 25°C and the warm electrode was positive. We used a typical value of $k = -264$ μV in Eq. [9b] and obtained *TEP* = 115.8 μV/K for Goyan's result. Our value of 115.77 μV/K, calculated from Eq. [8] for 20°/30°C and for m = 0.01003 mol/kg, is in excellent agreement with this value.

At m = 0.1003 mol/kg, our values of Y calculated from Eq. [8] and the constants from Table I are 490.66, 498.94, and 505.78 μV/K at mean temperatures of 20°, 25°, and 30°C, respectively. From these values dY/dT is calculated to be +1.656 and +1.368 μV/K². These temperature derivatives compare favorably with those of Fales and Mudge (21), as calculated by deBethune, Licht, and Swendeman (22). Their value for the temperature derivative of the TEP of a thermocell at m = 0.1003 mol/kg and 25°, using hydrogen electrodes and a saturated KCl salt bridge, was 1.287 μV/K². Considering the different experimental conditions and that our bridge was 0.1*m* HCl, while Fales and Mudge used a saturated KCl salt bridge, this is excellent agreement indeed.

SYMBOLS

A	intercept in Eq. [8] for Y as a function of molality
A'	constant in first term of Eq. [10]
a	constant in first term of Eq. [11], for the molarity to molality ratio
$\mathring{a}$	mean distance of approach for HCl (= 4.33 angstroms)
B	coefficient of the $\sqrt{m}/(1+\sqrt{m})$-term in Eq. [8]
B	constant in linear term of Eq. [10]
b	constant in linear term of Eq. [11]
BP	barometric pressure (corrected to 0°C), Torr, (1 atm = 760 Torr = 101325 newton meter^{-2})
C	coefficient in linear term of Eq. [8]
c	molarity, mols of solute per liter of solution
D	constant in quadratic term of Eq. [10]
emf(obs)	the observed electromotive force of a thermocell, μV
F	Faraday constant, 96487 coulomb/equiv
k	correction factor for barometric and vapor pressure, μV, calculated from Eq. [3], used in Eq. [9b]
m	molality, mols of solute per kilogram of solvent
Molality Function	$= 100\sqrt{m}/(1+\sqrt{m})$
N	normality, mols of H^+ ions per liter of solution
P_U, P_L	vapor pressure of pure water at temperatures T_U and T_L, respectively
$\hat{Q}_i$	heat of transport of a salt or ion, cal/mol, defined by Eq. [2] (1 cal = 4.184 Joule)
R	gas constant, 8.31434 J mol^{-1} K^{-1}, 1.987175 eu mol^{-1}
S_i	molal entropy, partial molal entropy of a salt or ion, eu mol^{-1}, cal mol^{-1} K^{-1}
S^0_i	standard value of S_i
$\bar{\bar{S}}_i$	transported entropy of an ion or salt, eu mol^{-1}
$\bar{\bar{S}}^0_i$	transported entropy of an ion in the hypothetical standard state with m = 1 mol/kg
$\hat{S}_i$	entropy of transport of a salt, eu mol^{-1}
$\bar{\bar{S}}_i$(mod 1), $\bar{\bar{S}}_i$(mod 2)	"modified" transported entropies of an ion, eu mol^{-1}, defined by Eq. [6] and [7], respectively
T	Kelvin temperature, K
t_i	Hittorf transference (transport) number of an ion
T_U, T_L	upper and lower thermostat temperatures, °C
TEP	initial thermoelectric power, μV/K, defined by Eq. [9b]
Y	thermoelectric power corrected for the mass-action term, defined by Eq. [9a], μV/K
Y^0	the value of Y at infinite dilution, μV/K
$\gamma_{\pm(25)}$	mean molal ionic activity coefficient at 25°C
ΔP	solvent vapor pressure lowering, in Eq. [4b]
ΔP_U, ΔP_L	solvent vapor pressure lowering at T_U and T_L, respectively, Torr
ΔT	temperature difference between thermostats, K
ϵ_0, ϵ_∞	initial and final thermoelectric power of a thermocell, respectively, μV/K
σ	Soret coefficient, K^{-1}, $= (-1/m)(\delta m/\delta T)$ at the steady state (= Soret equilibrium)
$\mathfrak{S}$	constant in first term of Eq. [10]

Acknowledgment

We are indebted to Professor J. N. Agar of the University of Cambridge for his numerous suggestions and helpful discussions during the course of the project. We are also indebted to Professor A. J. deBethune of Boston College for his critical review of the manuscript and for suggesting the comparison of our result for dY/dT with that of Fales and Mudge. We gratefully acknowledge support from several sources: two grants from Research Corporation, a grant from the Petroleum Research Fund of the American Chemical Society, and several undergraduate-research-participation grants to Willamette University from the National Science Foundation. Finally, we are thankful for the work of earlier students on the project: Norman P. Hunter, James E. Price, Kenneth D. Rost, Richard W. Harper, and Robert W. Smith.

Manuscript received March 13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Technical Notes

Kinetics of Anodic Oxide Growth on Sodium Tungsten Bronzes

Jean-Paul Randin*

Hydro Quebec Institute of Research, Varennes, Province of Quebec, Canada

Sodium tungsten bronzes have been proposed as electrocatalysts for the oxygen reduction reaction. Their electrocatalytic activity has been the subject of numerous studies (1-8) but the oxide-growth kinetics on this material have not been reported. This aspect of the electrochemical stability of the bronzes is of crucial importance if the material is to be used in a practical device such as a fuel cell or a battery. In such devices, high anodic transients may arise in the course of utilization which can give rise to anodic oxide growth, and hence change the initial properties of the electrocatalyst. The present note reports on the oxide-growth kinetics on sodium tungsten bronzes.

Experimental

The sodium tungsten bronzes were prepared by electrolyses of fused mixtures of sodium tungstate and tungsten trioxide in an alumina crucible (Coors). Analytical reagent grade Na_2WO_4 and H_2WO_4 (Baker Company) were used without further purification. Both reagents were previously dried at 200°C. Gold wires, 99.99% purity, were used as anode and cathode in the crystal preparation where no platinum was included. A platinum sheet, 99.99% purity, was used as anode in electrolyses in which platinum incorporation was sought. The concentration of platinum in the melt was therefore maintained by anodic dissolution of the metal. Galvanostatic depositions were performed at 720°-800°C with current densities between 20 and 50 $mA \cdot cm^{-2}$, applied current being altered appropriately during the growth. Large clusters of adherent crystals were obtained at the cathode. The cleaning procedure consisted of alternate boiling in dilute sodium hydroxide and triply distilled water.

The sodium content in the cubic tungsten bronzes was determined by x-ray measurements of the lattice parameters using Brown and Banks relation between the lattice parameter and the sodium content (9). The value of x in the cubic Na_xWO_3 varied from 0.58 to 0.88 as the melt composition was changed from 10 to 50 mole per cent (m/o) WO_3.

Crystals of sodium tungsten bronze were mounted in electrodes by compression moulding within a Kel-F holder, according to the method described by Yohe *et al.* (10). The apparent surface area of the electrodes used in the present study were about 0.2 cm^2 each. All

* Electrochemical Society Active Member.

Key words: sodium tungsten bronze, oxide growth, anodic oxide.

data are given with respect to the apparent surface area of the electrode. Prior to the electrochemical measurements, the bronze electrode was mechanically polished using different grades of alumina (Buehler Limited) down to 0.3μ.

An all-glass, three-compartment cell was used for the galvanostatic charging experiments. The a-c impedance of the electrode-electrolyte interface was measured in a cell of the type described by Tench and Yeager (11). This cell has three compartments, which contain the sodium tungsten bronze electrode and a Hg pool counterelectrode (internal counterelectrode used only for the a-c impedance measurements) spectroscopic grade graphite auxiliary counterelectrode (external counterelectrode), and the Hg/Hg_2SO_4 reference electrode, respectively.

All the potentials have been measured with respect to a Hg/Hg_2SO_4 reference electrode but all the results reported in the present study are given in V *vs.* NHE.

Helium was used to deaerate the solutions and to maintain an inert atmosphere inside the cells. The gas was purified by passing it through a train, which included a BTS catalyst (BASF, Ludwigshafen-am-Rhein, Germany) maintained at 180°C to remove oxygen and CO, and Linde Type 3A and 13X molecular sieves to remove other impurities.

The 1*N* sulfuric acid solutions were prepared by diluting H_2SO_4 Ultrex (J. T. Baker Chemical) in deionized and doubly distilled water, both distillations being over alkaline permanganate.

Constant current d-c power supply (Hewlett-Packard, Model 6177B) was used for the charging curves. The measurements of the equivalent series capacitances and resistances were carried out at 23°C with an a-c Wheatstone bridge and a d-c polarization circuit. The bridge was checked with standard resistance and capacitance components and found to contribute a negligible error in the experimental conditions used in this study. The a-c voltage applied to the cell did not exceed a few millivolts.

Results

The general behavior of sodium tungsten bronze during galvanostatic anodic charging is shown in Fig. 1. In order to improve the reproducibility of the results, galvanostatic charging curves were recorded after mechanical polishing and cathodic prepolarization at 13 mA · cm^{-2} for 200 sec. An arrest is obtained below 1V *vs.* NHE, the detailed analysis of which will be presented in a future publication. At about 2.3V *vs.* NHE, oxygen evolution is visible at the surface of the electrode. At low charging currents (typically 5 mA/cm^{-2}), this potential remains almost constant over a long period of time. When the charging current was greater than 5 mA · cm^{-2}, the voltage increased rapidly following a period during which it remained constant at about 2.3V. This transition time is shorter the higher the applied current density. At a still higher current density, a voltage buildup as high as 40V is reached during anodization, which is an indication that some electrically limiting layer is formed on the surface.

The repetition of the anodic charging experiment at high current density, preceded by a short prereduction at 13 mA · cm^{-2} for 200 sec, gives rise to a curve slightly different from the first one performed on a fresh electrode surface. The irreproducibility between the first galvanostatic charging curve and the following one may mean that the reduction of the layer formed at high anodic current has not been removed or reduced up to the initial state.

The rotation of the electrode has no significant effect on the potential-time measurements. The electrode was rotated at low speed (1000 rpm) to help remove the oxygen bubbles from the bronzes surface.

The relations between the electrode potential and the time during anodization at different constant current densities are reported in Fig. 2. A logarithmic growth law is indicated.

The impedance measurements of the sodium tungsten bronze/electrolyte interface have been made on an electrode previously anodized for 1 hr at 21 mA · cm^{-2}. Capacitance values between 4 and 6 $\mu f \cdot cm^{-2}$ have been recorded at potentials between 2.7 and 1.0V *vs.* NHE. The capacitance values increase as the potential decreases, whereas the series resistance decreases with the applied potential. The Mott-Schottky plot calculated from a typical capacitance curve obtained in going from high anodic potentials towards more cathodic potentials is reported in Fig. 3. Two linear regions are indicated, which suggest a change in the surface composition at potentials close to 1V. This change occurs only on highly anodized electrode surfaces. The same measurements performed on a nonoxidized surface give only one straight line, whose intersection with the potential axis gives the same flatband potential as that observed at low potentials on the anodized electrode.

The linear section in the most anodic potential region of the Mott-Schottky plot gives a flatband potential of about 0V *vs.* NHE and a slope of 1.22×10^{-2} $\mu f^{-2} \cdot cm^4 \cdot V^{-1}$, from which a n_D value of 2.6×10^{20} carriers · cm^{-3} is calculated. The x value in Na_xWO_3 deduced from the latter donor concentration is 0.015 assuming that: (*i*) the donors are all sodium

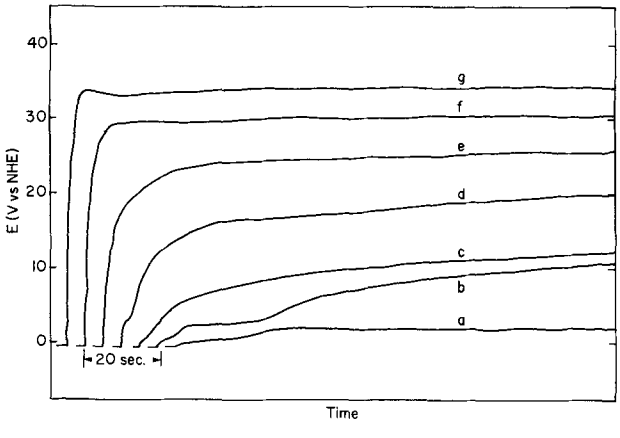

Fig. 1. Effect of current density on anodic charging curves for a sodium tungsten bronze ($x = 0.65$) electrode in helium saturated 1*N* H_2SO_4 at 23°C. Fig. 3. Mott-Schottky plot for the sodium tungsten bronze ($x = 0.65$) following anodic oxidation at 21 mA · cm^{-2} for 1 hr in helium saturated 1N H_2SO_4 at 23°C. A-C impedance measurements for the determination of capacitance values performed at 1000 Hz.

atoms and that (*ii*) the dielectric constant, ϵ, of the bronze is 50. The only available data from which the dielectric constant of sodium tungsten bronze can be estimated is found in a paper by Kir'iashkina *et al.* (12), who quote a value for the ratio ϵ/ρ as 6.95 for WO_3. From the density, ρ, for WO_3 with the cubic tungsten bronze structure being about 7.2 g · cm^{-3}, it can be deduced that $\epsilon \simeq 50$.

The small linear section in the less anodic potential regions of the Mott-Schottky plot gives a flatband potential of 0.6V *vs.* NHE and a slope of 2.5×10^{-2} $\mu f^{-2} \cdot cm^4 \cdot V^{-1}$, which corresponds to a n_D value of 1.25×10^{20} carriers · cm^{-3} and a x value (in Na_xWO_3) of 0.007, with the same assumptions as previously.

The effect of the x value in Na_xWO_3, ranging from 0.58 to 0.88, and the platinum concentration from 2 up to 1200 ppm, has been studied. No significant effect of these two parameters has been found on the general shape of the galvanostatic charging curves. The effect of the x value and the platinum concentration on the oxide growth-kinetics (curve E *vs.* log time) has been found to be within the experimental errors of the measurements.

Discussion

The increase in voltage up to about 40V for high applied currents, the logarithmic-growth law, and the a-c impedance measurements suggest that the electrically limiting layer formed on the bronze surface is most likely an oxide. A similar oxide growth has been observed on valve metals, including tungsten (13-14).

A logarithmic law is generally observed for the oxide growth of both semiconducting and conducting oxides. The rate of growth of a semiconducting oxide is expressed by the following equation (15-16)

$$L = \frac{\epsilon kT}{4\pi \rho e^2 L_1} \ln Kt \qquad [1]$$

where L is the thickness of the oxide, t is the time, ϵ is the dielectric constant, ρ is the density of trapped electrons (or holes) in the oxide; e is the electronic charge, L_1 the thickness of the total space charge, K is a constant $= B/c \exp(-e\psi/kT) \exp(e\chi^\circ/kT) \exp(e C_1/kT)$, in which B and c are constants, ψ is the work function of the metal being oxidized, χ is the applied voltage across the metal-oxide interface, χ° is the potential drop that would hypothetically exist if the oxide thickness were zero, and $C_1 = -4\pi \rho e^2 L_1/\epsilon$.

The rate of growth of a conducting oxide may be expressed by the following equation (15)

$$L = \frac{RT}{b} \ln t + \frac{RT}{b} \ln \frac{RTA}{b} - \frac{\Delta G^*_o}{b} + \frac{cFE}{b} \qquad [2]$$

where A, b, c are constants, ΔG^*_o is the standard free energy of activation for the oxide growth, R, the gas constant, T, the temperature, and E, the electric field. At constant field, the growth follows a logarithmic law.

A direct proportionality between thickness and potential has been frequently observed [see, for example, Ref. (17, 18)], particularly with the valve metals (15). Assuming such a dependence in the case under study, Fig. 2 shows that the anodic oxide growth on sodium tungsten bronze follows a logarithmic law. The a-c impedance measurements from which linear Mott-Schottky plots have been calculated suggest the presence of a semiconducting oxide, rather than a conducting one.

The exact nature of the oxide grown at the surface of the sodium tungsten bronze during anodization is not known. However, some interesting features of the present work may be outlined even though the following discussion is somewhat speculative.

It has been mentioned above that the repetition of the anodic charging experiment at high current density, preceded by a reduction period gives rise to a curve different from the first one measured on a freshly polished electrode surface. This behavior suggests an irreversible change of the electrode surface after anodization. The analysis of the arrest measured at low potentials also suggests a change in the surface composition after prolonged anodization of the electrode (19). The change in surface behavior has also been noticed by McHardy (8) and attributed to a sodium depletion reaction. The same author (8) confirmed by ion-probe analysis of an aged crystal that sodium was lost from the bronze surface. The sodium depletion reaction may be written as

$$Na_xWO_3 \rightarrow Na_yWO_3 + (x - y)Na^+ + (x - y)e^- \qquad [3]$$

The first process taking place during anodization of the sodium tungsten bronze electrode is believed to be the sodium depletion of the surface layer. Reaction [3] is confirmed by the a-c impedance measurements which give a very small value of y in Na_yWO_3, *i.e.*, smaller than 0.02.

In the calculations of the x values of the surface layer from the a-c impedance measurements, it has been assumed that the only donor is the sodium atoms. This assumption is justified at x values greater than 0.25 since bronzes with such a composition are known to have one free electron per metal atom in the host lattice (20). A different mechanism of conduction is operative below 0.25, however. For a single crystal of sodium tungsten bronze of composition $Na_{0.025}$ WO_3 semiconductor-type behavior has been established (21). The equivalent x values, calculated from the a-c measurements using the assumption that the only donor is the sodium atoms, give very low values. Moreover, the calculations have been made using the capacitance values with respect to the apparent surface area of the bronze electrode. If the ratio of the true to the apparent area (not measured) could be taken into account the equivalent x values would drop still further by the square of this ratio (probably at least 25 times). At the very low values of x calculated from the a-c impedance data the sodium atom is most likely not the only donor.

A second possible oxide growth reaction on the sodium tungsten bronze whose surface has previously

been depleted in sodium may be as follows

$$WO_3 + z\,H_2O \rightleftharpoons WO_{(3+z)} + 2z\,H^+ + 2z\,e^- \quad [4]$$

A negative ionic charge carrier is injected into the surface layer of the oxide with adjustment of the electron concentration. The oxide growth on sodium tungsten bronze is therefore analogous to the change of valence observed in the surface region of nickel or silver oxide electrodes on anodic charging (22-24).

Following the preceding discussion, it can be assumed that the a-c impedance measurements are carried out on a bronze electrode whose surface layer is almost completely depleted of sodium. These impedance measurements (Fig. 3) suggest that the surface composition changes with the applied potential since both the slope and the potential at the intersection with the y-axis change with the applied potential. The linear section of the Mott-Schottky plot in the low potential region is observed only over a small range of potential (0.2V) and the capacitance values in this potential range are too high (16-35 μf per apparent cm^2) to be associated only with a space-charge capacitance. The data calculated from the low potential section of the Mott-Schottky plot, therefore, should be interpreted very carefully. In particular the flatband potential determined from the intersection of the potential axis with the extrapolated Mott-Schottky plot shifts from about 0 to 0.6V *vs.* NHE in going from the high to the low potential region. This fact is difficult to explain solely by a change in the oxide stoichiometry according to Reaction [4]. On the contrary, the change in carrier concentration from 2 to 1 $\times$ 10^{20} cm^{-3} observed in going from highly anodic potentials to cathodic potentials can be attributed to a variation of the stoichiometry of the oxide. At high anodic potentials the oxide is less stoichiometric (oxygen-excess, *i.e.*, high values of z) and consequently, has a higher carrier concentration. On reaching less anodic potentials, the oxide becomes more stoichiometric (small values of z) and has a lower donor concentration.

The growth rate of the oxide has not been found to depend significantly on the x value, even if the density of trapped electrons in the oxide is contained in Eq. [1]. This may be attributed to the fact that the oxide growth (Reaction [4]) occurs on a sodium depleted surface layer. In these conditions, the composition of the oxide formed at the bronze surface is not believed to depend significantly on the bulk composition.

Acknowledgments
