Electrical Conductivity for Aluminum Cell Electrolyte between 950°-1025°C by Regression Equation

G. Choudhary

Department of Chemistry, Alabama A. & M. University, Normal, Alabama 35762

The electrical conductivity of molten cryolitic systems is of considerable importance to the aluminum industry. The electrolyte of aluminum reduction cells consists of a molten mixture of cryolite and alumina with occasional additions of salts such as CaF_2, MgF_2, LiF, NaCl, and Li_3AlF_6 to the system. The object of this note is to correlate the effect of the components and the temperature of the cryolitic systems with a view to predicting the electrical conductivity of the electrolyte under the situations normally encountered

Key words: electrical conductivity, cryolitic systems, aluminum extraction, regression equation.

been depleted in sodium may be as follows

$$WO_3 + z\,H_2O \rightleftharpoons WO_{(3+z)} + 2z\,H^+ + 2z\,e^- \quad [4]$$

A negative ionic charge carrier is injected into the surface layer of the oxide with adjustment of the electron concentration. The oxide growth on sodium tungsten bronze is therefore analogous to the change of valence observed in the surface region of nickel or silver oxide electrodes on anodic charging (22-24).

Following the preceding discussion, it can be assumed that the a-c impedance measurements are carried out on a bronze electrode whose surface layer is almost completely depleted of sodium. These impedance measurements (Fig. 3) suggest that the surface composition changes with the applied potential since both the slope and the potential at the intersection with the y-axis change with the applied potential. The linear section of the Mott-Schottky plot in the low potential region is observed only over a small range of potential (0.2V) and the capacitance values in this potential range are too high (16-35 μf per apparent cm^2) to be associated only with a space-charge capacitance. The data calculated from the low potential section of the Mott-Schottky plot, therefore, should be interpreted very carefully. In particular the flatband potential determined from the intersection of the potential axis with the extrapolated Mott-Schottky plot shifts from about 0 to 0.6V *vs.* NHE in going from the high to the low potential region. This fact is difficult to explain solely by a change in the oxide stoichiometry according to Reaction [4]. On the contrary, the change in carrier concentration from 2 to 1 $\times$ 10^{20} cm^{-3} observed in going from highly anodic potentials to cathodic potentials can be attributed to a variation of the stoichiometry of the oxide. At high anodic potentials the oxide is less stoichiometric (oxygen-excess, *i.e.*, high values of z) and consequently, has a higher carrier concentration. On reaching less anodic potentials, the oxide becomes more stoichiometric (small values of z) and has a lower donor concentration.

The growth rate of the oxide has not been found to depend significantly on the x value, even if the density of trapped electrons in the oxide is contained in Eq. [1]. This may be attributed to the fact that the oxide growth (Reaction [4]) occurs on a sodium depleted surface layer. In these conditions, the composition of the oxide formed at the bronze surface is not believed to depend significantly on the bulk composition.

in the aluminum industry, *i.e.*, salt additions 0-10 weight per cent (w/o); weight ratio of NaF/AlF_3 1.1-1.5, and the temperature range 950°-1025°C.

Experimental investigations of the specific electrical conductivity of molten cryolite with additives have been carried out by numerous observers in the last three decades. The author feels that due to the development of more sophisticated methodology of measurements, only the data from the investigations during the last 15 years are sufficiently reliable to be cited. Table I summarizes the references for preferred specific conductivity-temperature diagrams as selected from such investigations. During the choice of these data, particular emphasis has been placed on cells, electrode material, design of measuring bridges, and the technique of measurement. The results of these preferred conductivity-temperature diagrams have also been examined from the point of view of validity, consistency, and accuracy.

The temperature dependence of the electrical conductivity of molten salts of predominantly ionic character has been given by Bloom and Heymann (11) in the form of a basic Arrhenius type of equation

$$k = A_k \exp(-E/RT) \quad [1]$$

where k = specific conductivity, $ohm^{-1}\ cm^{-1}$; A_k = coefficient related to the chemical composition of the melt; E = activation energy of conductance; T = temperature of the melt, in °K; R = universal gas constant, 8.3143 J $mol^{-1}\ K^{-1}$ = 1.987 cal $mol^{-1}\ K^{-1}$.

Morrissey (12) suggested that the coefficients in conductivity-temperature Eq. [1] can be rearranged to render it advantageous to practical cryolitic systems. The parameters required for computing the coefficients can be chosen from the ones commonly encountered in systems of alumina reduction cells. In the present work, the contemplated condition has been met by development of an equation in the form

$$\ln k = A_0 + A_1X_1 + A_2X_2 + A_3X_3 + A_4X_4 + A_5X_5 + A_6X_6 + A_7X_7 + A_8/T \quad [2]$$

where A_0, A_1, A_2, etc. are constants and X's are X_1 = w/o Al_2O_3; X_2 = w/o CaF_2; X_3 = w/o MgF_2; X_4 = w/o LiF; X_5 = w/o Li_3AlF_6; X_6 = w/o NaCl; X_7 = bath-weight ratio: NaF/AlF_3; T = bath temperature, K. The expression of composition in weight per cent and ratio of weights has been chosen because these measures are in conformity with the normal practices in industry.

The unknown constants of Eq [2] were determined by a multiple "least squares" regression program performed by an 1130 IBM computer. A total of 305 electrical conductivity values, covering the composition range normally used in cells for aluminum production, as extracted from the preferred conductivity-temperature diagrams from the references given in Table I, and some taken from the direct measurements of Richards (13) in a 10 kA aluminum reduction cell, yielded the coefficients for the equation as given in the following electrical conductivity equation

$$\ln k = 2.0156 - 0.0207X_1 - 0.0050X_2 - 0.0166X_3 + 0.0178X_4 + 0.0077X_5 + 0.0063X_6 + 0.4349X_7 - 2068.4/T \quad [3]$$

The regression program yielded the square of the multiple correlation coefficient (R^2) of 0.3744 which predicts the error in correlation, thus indicating that

Table II. Comparison of the calculated electrical conductivities of cryolitic bath vs. the observed values
(References for $k_{obs.}$ are shown in parenthesis)

Bath additives, w/o						NaF/AlF_3		$k_{obs.}$,	$k_{calc.}$ from Eq. [3],	
Al_2O_3	CaF_2	MgF_2	LiF	Li_3AlF_6	NaCl	weight ratio	Temp, °C	$ohm^{-1}\ cm^{-1}$	$ohm^{-1}\ cm^{-1}$	% error

			10.0			1.35	1000	3.14 (9)	3.18	+1.2
			2.0			1.35	1000	2.80 (9)	2.75	−1.6

37.4% of the variation in the dependent variable (ln k) is due to the influence of the independent variables. The value of R (0.6119) indicates a fair closeness to a good fit (14) to the "least squares" plane. The mean deviation from the observed values of the electrical conductivity is 0.1144 ohm^{-1} cm^{-1} which is 4% of the accepted value (15) of 2.82 ohm^{-1} cm^{-1} for pure cryolite ($3NaF \cdot AlF_3$) at 1000°C. Table II shows a comparison of some 36 representative electrical conductivity values as calculated from Eq. [3] with those observed by different investigators, from the total population of 305 experimental points used to develop Eq. [3].

Since the electrical conductivity equation covers a broad range of compositions of practical cryolitic systems, it can be recommended for use in alumina reduction cells within the ranges of temperature and chemical composition specified above and illustrated in Table II.

Acknowledgments

This work was done in the Reduction Research Division of Reynolds Metals Company, Sheffield, Alabama.

I wish to thank Mr. W. E. Watts and Dr. N. E. Richards of the Reduction Research Division of Reynolds Metals Company for programming the computations and for assistance while revising the manuscript, respectively. Permission of Reynolds Metals Company to publish this work is gratefully acknowledged.

Manuscript submitted Aug. 3, 1971; revised manuscript received Nov. 16, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Polarographic Behavior of MoO_3 in Butyrolactone Solutions

Luigi Campanella and Gianfranco Pistoia

Instituto di Chimica Analitica and Instituto di Chimica Fisica, Universtà, Rome, Italy

Molybdenum trioxide has been shown (1) to be a suitable positive electrode in a nonaqueous secondary battery based on butyrolactone (BL) as solvent

$$Li/LiAlCl_4 - BL/MoO_3, C \qquad [1]$$

The reduction of MoO_3 in a cell [1] is more complicated than the simple reduction to lower oxides (Mo_2O_5, MoO_2), as evidenced by thermodynamic considerations, and the electrolyte seems able to participate in some way in the process occurring at the positive electrode.

With the aims of elucidating some aspects of these processes, a polarographic study of the cathodic behavior of MoO_3 dissolved in some BL solutions has been performed. Furthermore, through coulometric analysis the number of electrons involved in the reduction process has been determined, by means of which the cathodic efficiency of cell [1] can be calculated.

Experimental

Apparatus.—Polarographic curves have been obtained with an AMEL Model 461 polarograph using a stationary Pt working electrode *vs.* a saturated calomel electrode (SCE), connected to the working electrode half cell by means of a KNO_3 agar bridge, suitably probe shaped in order to reduce the ohmic drop due to the solution. The potential scanning rate (from 0 to negative values) was 0.1 V/min. All the polarographic curves were reproducible within about 5%.

Key words: nonaqueous batteries, MoO_3, lithium.

Techniques.—The saturated solutions of MoO_3 in butyrolactone were prepared by equilibrating an excess of MoO_3 in stirred BL and then by filtering under vacuum. The concentration of MoO_3 was determined by spectrophotometric analysis for molybdenum and was of the order of $10^{-4}M$. The solvent used for the equilibration also contained the supporting electrolyte. Four different electrolytes at concentration $10^{-2}M$ were employed: $LiAlCl_4$, $NaBF_4$, $LiClO_4$, LiCl. Their influences on the solubility of MoO_3 was small. The solutions to be polarographed were deoxygenated with pure N_2. All the manipulations and measurements were performed in a dry box under a dry argon atmosphere, so that the water content can be reasonably assumed not higher than 10 ppm.

Materials.—BL was purified by fractional-vacuum distillation. In this way, according to Foley and Bogar (2), a product containing less than 10 ppm organic impurities and water can be obtained. Commercial high purity $NaBF_4$ and LiCl were dried under vacuum without further purification. Dry $LiClO_4$ was obtained by melting under vacuum the anhydrous commercial product. $LiAlCl_4$ was prepared according to the method described by Rao (3).

Results and Discussion

The reduction behavior of MoO_3 is affected by the supporting electrolyte, the number of involved electrons alone being always the same. In fact, by coulometric analysis, all the reduction processes are found

to involve two electrons, that is, reduction proceeds from Mo(VI) to Mo(IV). The cathodic efficiency was calculated to be 66% for cell [1] at 1 mA/cm^2 current density of discharge (1).

In $LiAlCl_4$ and $NaBF_4$ a quasi reversible ($\alpha = 0.9$) reduction wave was only observed with $E_{1/2} = -1.04$V (*vs.* SCE). The adopted reversibility criteria were based on the logarithmic analysis, on the values of the temperature coefficient of the wave height (di_d/dT, where i_d is limiting current, and T is temperature) and half-wave potential ($dE_{1/2}/dT$), and on ($E_{3/4} - E_{1/4}$) values.

In LiCl two waves were observed, the first of which was irreversible, having $E_{1/2} = -0.32$V (*vs.* SCE) and the second quasi reversible ($\alpha = 0.9$) with $E_{1/2} = -1.02$V (*vs.* SCE).

In $LiClO_4$ one wave is observed characterized by $\alpha = 0.5$ and $E_{1/2} = -0.36$V (*vs.* SCE).

The experimental results can be explained by considering the possibility that molybdenum is made complex by the anion of the supporting electrolyte. So when $LiClO_4$ is used as the supporting electrolyte, the reduction wave of free molybdenum is observed, whereas when $LiAlCl_4$ and $NaBF_4$ are used only the complex molybdenum wave is recorded. In LiCl, both the reductions, *i.e.*, of complex and free molybdenum, were evidenced.

The fact that the reduction is reversible for the complex and irreversible for the free molybdenum accounts for the experimental evidence that a Li/$LiClO_4$-BL/MoO_3, C battery cannot be cycled.

Chloride ions are well-known, strong, complexing agents for molybdenum (4). The fact that in $LiAlCl_4$ (and $NaBF_4$) the wave of free molybdenum is not observed while it is still recorded in LiCl is in agreement with the expected greater concentration of Cl^- in the former electrolyte, due to the presence of $AlCl_3$. This assumption is also sustained by the following considerations. Because of the high-charge density of Li^+ and Cl^-, a strong association occurs on LiCl, as shown for instance by the low conductivity of the solutions of LiCl in cyclic esters, such as propylencarbonate (PC) and BL (5, 6). In PC the association constant of LiCl was found to be 557, while $LiClO_4$ is not associated (7). The same behavior is expected in BL which is characterized by a lower dielectric constant. A very low association, if any, must therefore also be foreseen for $LiAlCl_4$ both in PC and BL because of the reduced interaction between Li^+ and the large anion $AlCl_4^-$. Moreover, the equilibrium $AlCl_4^- \rightleftarrows AlCl_3 + Cl^-$ will be present; in PC and BL this equilibrium will be shifted to the right following the fact that the Lewis acid $AlCl_3$ is strongly coordinated by the negative dipole of the solvent (7). This coordination produces ions such as $Al(PC)_n^{3+}$ and $AlCl_4^-$ and this latter can further yield other Cl^- ions. The problem can be analogously discussed in the case of $NaBF_4$, on the basis of the similarity between the anions $AlCl_4^-$ and BF_4^-

Due to the fact that MoO_3 is sparingly soluble in $LiAlCl_4$-BL (5.10^{-4}M at 18°C), a positive electrode based on this oxide would show considerable polarization for discharge current densities of 1-2 mA/cm^2 (1), if it had previously to dissolve and form complexes with the electrolyte. Thus it is probable that MoO_3 discharges initially as such to Mo(IV) (probably in a complex form); by charging, Mo(VI), in a complex and sparingly soluble form, could be generated, and subsequently cycled.

The hypothesis seems to be confirmed by the fact that the micropolarization test previously reported (1) gives a straight line (the cathodic side on the prolongation of the anodic one) without any appreciable hysteresis, only after three or four polarization cycles.

Key words: Fe-Cr alloys, passive films, scanning electron microscopy, transmission electron microscopy, x-ray analysis.

lead to a cessation of pit growth. In both of these investigations the covering films were referred to as being exposed passive film material that originally existed on the metal surface. However, the composition and structure of the films were not described or compared in any way with those of the passive film. It was the purpose of the present investigation to examine such films found over pits in ferritic and austenitic stainless steels by means of transmission electron microscopy (TEM) and scanning electron microscopy (SEM). In addition, the SEM was equipped with an energy dispersive x-ray detector making it possible to obtain a semiquantitative analysis of the chemical composition of the films for elements above 11 in atomic number.

In order to prepare the films for study by the above methods, a technique was used which was similar to that employed by Yahalom and Weisshauss (3) in a recent investigation of pitting in nickel. When pits were allowed to penetrate very thin rolled-sheet specimens, they found that films remained stretched over the resultant holes. These films were amenable to study by TEM.

Experimental

The materials consisted of a series of high purity ferritic Fe-Cr alloys containing approximately 5, 12, and 19 weight per cent (w/o) Cr [analysis given in Ref. (5)] and two commercial austenitic stainless steels, AISI 304 and 316. Annealed thin-sheet specimens of each alloy were electropolished in a perchloric acid-glacial acetic acid solution to obtain regions thin enough for TEM examination.

The samples were then passivated in an N_2 gas-purged, aqueous solution of 3% ammonium tartrate at the potentials shown in Table I. The potentials were chosen to be above the values usually considered to be critical to initiate pitting (4). An NaCl (or NaBr) solution was then introduced yielding the Cl^- (or Br^-) ion concentrations indicated in Table I. Anodic polarization was continued until the specimens were visibly perforated by pitting.

Results and Discussion

When a pit perforated a foil, a film was typically observed to remain over the resultant hole (Fig. 1). On TEM examination the films were often found to consist, not of a single film, but of two overlapping films usually with entrapped particles or corrosion products (Fig. 1). One film (the back surface film) was the passive film which was exposed when the pit penetrated the foil to produce a hole. The other film (the front surface film) had its origin on the surface at which the pit initiated. An example of a pit with the front surface film visible is shown in Fig. 2. From observations of the broken edges of films their individual thicknesses were estimated to be on the order of 50Å.

Electron diffraction patterns from films over pits in the austenitic 304 and 316 alloys consisted of four or five very broad and diffuse rings, suggesting an amorphous structure. Corresponding TEM images at high magnification showed a fine grain-like morphology on the order of 20Å. Front and back surface films did not appear to be significantly different. Images of films from the ferritic alloys were similar to those from the austenitic alloys. However, the ferritic alloy films produced distinct diffraction spots which, in the case of the 12 and 19% alloys, were present together with diffuse rings. The spot patterns were usually quite symmetrical in appearance, suggesting a single-crystal structure. But, on studying dark field images of the films, it was found that the spots were produced by very small crystallites and that different sets of crystallites, crystallographically oriented with respect to one another, were responsible for the different diffraction spots. Similar diffraction patterns were obtained from the passive films on the metal foil surface, indicating that by this measure the passive film and films over pits were the same. It was not possible to determine the crystal structure of the films on the basis of the electron diffraction results because of the limited number of diffraction spots present and relatively large scatter in the measured values. McBee and Kruger (5) have studied passive films produced in 1*N* H_2SO_4 on the same series of ferritic alloys and found that oxides with a spinel structure were present.

Semiquantitative analyses of the compositions of films from the 12% Cr, 304, and 316 alloys were ob-

Table I. Conditions for pitting

Alloy	Halide ion conc.	Anodic polarization potential (mV SCE)
Fe-5% Cr	0.1*N* Cl^-	+300
Fe-12%	0.1*N* Cl^-	+300
Fe-19%	0.2*N* Cl^-	+700
304	0.1*N* Cl^-	+400
316	1.0*N* Cl^-	+425
316	0.3*N* Br^-	+700

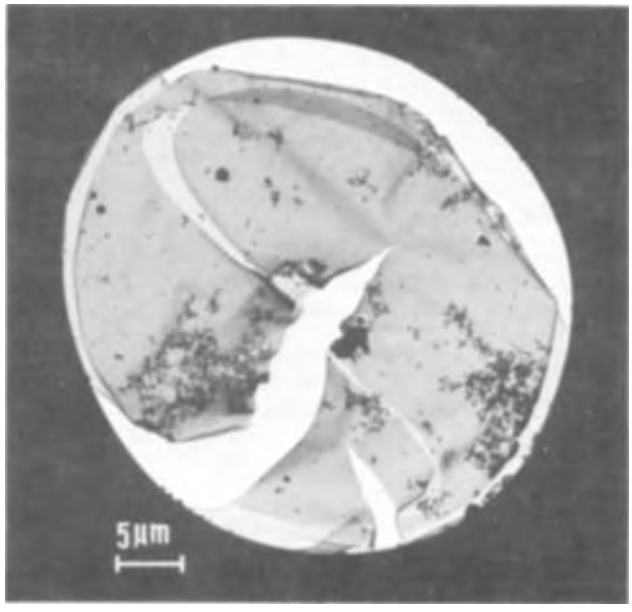

Fig. 1. Transmission electron micrograph of film covering hole left by corrosion pit in 316 stainless steel. Two overlapping films are present. Corroding solution contained 0.3M NaBr.

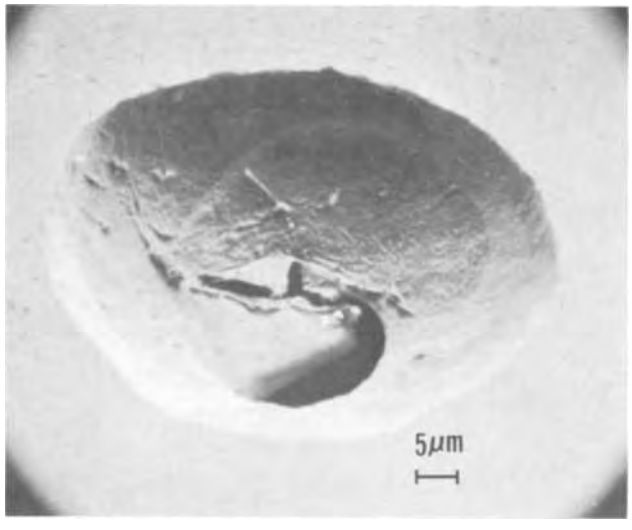

Fig. 2. Scanning electron micrograph of pit in 316 stainless steel corroded in 0.3M NaBr. A film has collapsed to the inside surface of the pit (dark area) and extends across the hole where the pit has penetrated the metal foil.

tained by utilizing energy dispersive x-ray analysis facilities attached to the SEM. To avoid spurious x-ray signals from the metal, the films were cemented to thin tungsten wires and pulled from the foil pits. Films were not successfully extracted from the 5% and 19% Cr alloys. For the films studied, the ratio of Cr to Fe ranged from approximately 2:1 to 5:1 or more, which is considerably larger than the corresponding alloy composition ratio. A large scatter in results did not permit a meaningful quantitative comparison among films from different alloys to be made. Among the other elements found, chlorine was usually detected in films from alloys corroded in solutions containing that element. However, bromine was not detected in films from the 316 stainless steel corroded in a solution containing NaBr. Molybdenum was detected in the 316 films, but nickel was not detected in the 304 or 316 films.

In conclusion, thin films that covered corrosion pits in a series of ferritic Fe-Cr alloys and two commercial stainless steels, 304 and 316, were studied by means of TEM and SEM. Corrosion pits completely penetrated the foils leaving holes that were covered by two overlapping films—one from the entrant opening of the pit and the other exposed when the pit penetrated the back surface of the thin foil sample. The two films appeared comparable in microstructure and produced similar electron diffraction patterns. Since the back surface film did not enter into the pitting process and was the passive film exposed when penetration occurred, these observations indicate that films covering the entrant openings of pits were originally passive film. This is further supported by the fact that electron diffraction results from passive films and films covering pits are similar.

Studies on Ignition Characteristics and Combustion Mechanism of Magnesium in a Chlorine Atmosphere

K. Elguindi and H. Sullivan

Department of Mechanical Engineering, University of Waterloo, Waterloo, Ontario, Canada

and D. R. Spink*

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada

The present study was carried out as a basic investigation of the mechanism and kinetics of the reduction reaction between metal halides and magnesium. Examples of metal halides reduced commercially with magnesium include zirconium tetrachloride, titanium tetrachloride, hafnium tetrachloride, and uranium tetrafluoride. Later studies of the zirconium or titanium tetrachloride-magnesium reaction with magnesium as the fuel burning in an atmosphere of zirconium or titanium tetrachloride are planned.

No data could be found in the literature on the ignition and combustion of magnesium in chlorine or other single halide atmospheres. Extensive data are available (1-5, 9, 10) on magnesium ignition and combustion in several other gases; these investigations were carried out relative to propulsion and aerospace applications.

Although ignition and combustion of magnesium in chlorine differs basically from that of magnesium in other gaseous oxidizers, the fundamental approaches used in carrying out the studies are essentially the same. Theoretical studies and experimental work in combustion laboratories have shown that magnesium burns in the vapor phase under certain oxygen partial pressures when an inert gas is used as a diluent (1). This work is concerned with the fundamental investigation of ignition and combustion of magnesium metal in a chlorine atmosphere.

* Electrochemical Society Active Member.
Key words: combustion, magnesium, chlorine, ignition, reaction, mechanism.

Experimental Techniques and Procedures

Two approaches were employed to carry out the present investigations. In the first tests, attempts were made to ignite magnesium ribbons by passing electrical current though the sample. In these tests combustion could not be sustained. The samples merely heated up until local melting broke the ribbon and interrupted the heating current. It was concluded from these tests that the ignition temperature of magnesium in chlorine atmospheres is above the melting point of magnesium, 650°C. In oxygen atmospheres, magnesium ignites below its melting point (2).

In the second series of tests, induction heating was used to ignite magnesium particles. Induction heating provides predominantly surface heating that emphasizes pre-ignition oxidation as would be found in practice in reduction reactors. Magnesium particles of sizes ranging from 1-5 mm were placed on the surface of a pure calcium oxide bed in a Pyrex glass chamber situated within the work coil of the induction furnace. The gas within the chamber consisted of chlorine or a mixture of chlorine and inert gas (argon or helium).

In addition to visual observations, high speed, colored motion pictures and flame spectra were obtained. Tests were made at pressures up to 1500 Torr with compositions ranging from pure chlorine to almost pure diluent gas.

Ignition temperature measurement.—A Chromel-Alumel thermocouple with a 1/16 in. OD stainless steel

shield was used for the temperature measurements. The temperature was recorded using a 2-channel temperature module, Model 17502A, made by Hewlett Packard Company.

The magnesium sample was mounted on the tip of the thermocouple but supported by a 2.0 cm diameter ceramic disk that was in turn supported by the stainless steel thermocouple shield. The sample and the associated thermocouple were placed in a Pyrex glass tube which was positioned exactly at the center of the work coil of the induction furnace. In these experiments 100% Cl_2 at 500 and 760 Torr were used.

Results and Discussion

Ignition phenomenon of magnesium in chlorine.—In the experiments carried out under different conditions of pressure and concentration of chlorine in the total oxidizing gas mixture, the magnesium particle was observed to ignite only after complete melting as indicated by the formation of a spherical droplet of metal.

In a chlorine atmosphere it was observed that the magnesium formed a thin chloride layer on its surface prior to ignition, similar to the oxide formed in combustion in an oxygen atmosphere. Although the sample was initially cleaned in dilute hydrochloric acid, a very thin oxide layer was always present due to exposure to air. Thus it was concluded that the layer formed on the sample before ignition was a mixture of magnesium oxide and magnesium chloride. However, positive identification by specific analytic techniques has not been undertaken.

Flashing or sparking from the metal surface was observed just before ignition took place for those cases where relatively low pressures of the chlorine-inert gas mixture was used *i.e.*, < 760 Torr total pressure. This phenomenon may be related to a pressure build-up of magnesium vapor beneath the coating on the particle, although in no instance did the vapor pressure of magnesium equal the pressure in the container. Following flashing, the entire sample was almost instantaneously engulfed in flame. As the total pressure was increased (to 1000-1500 Torr), the ignition process became more violent and usually the sample ignited so explosively that unreacted magnesium droplets spattered on the walls of the vessel. This was apparently related to the protective qualities of the coating formed on the sample surface. Just prior to ignition, fissures appeared in the molten coating on the magnesium which likely relates to the surface tension of the coating *vis-à-vis* the vapor pressure of the magnesium. This observation, coupled with the fact that magnesium melts at 650°C and that magnesium chloride melts at 712°C, provided visual evidence that the ignition temperature was greater than either of these temperatures. The high speed, colored movies of the ignition sequence were used for most of the visual observations.

Measurement of ignition temperature.—Ignition occurred above the melting point of both the magnesium and magnesium chloride in all the runs carried out in this part of the work and under all the conditions of the experiments. This was an important observation for it supported an explanation accounting for the failure of the resistance heating tests to provide combustion, namely, that the ignition of magnesium in chlorine took place above the melting point of the magnesium.

Ignition, for the most part, occurred within a temperature range of 850° to 1100°C as indicated below. Several variables seemed to have an important influence on the ignition temperature:

1. Heating rate: the ignition temperature was observed to decrease from approximately 980° to 860°C as the heating rate increased from approximately 50° to 100°C/sec. This is not in agreement with what was concluded by Mellor (2) in his experimental work involving the ignition of magnesium cylinders (2.38 cm diam by 3.8 cm length) and magnesium wafers (3.28 cm diam by 1.59 mm thick) in oxygen atmospheres in an induction furnace in which he stated that any dependence on the heating rate was slight. It is possible that sample size might be responsible for some of these observed differences plus the fact that MgO films are rigid and porous and therefore might be less effective with increasing thickness than an impervious film such as that formed by $MgCl_2$. In the present work where relatively slow heating was employed, occasionally ignition of the sample did not occur below 1000°C. Possibly, at the high heating rates, some temperature lag could have distorted the observed results, but not by more than 40°C (See below). Upon heating the magnesium specimens the thermocouple indicated the melting point of magnesium to be at or slightly below the accepted value of 650°C; the faster the heating rate, the lower the melting point indication. Some samples, after heating to temperatures of approximately 900°C without ignition, exhibited freezing point arrests at exactly 650°C on cooling.

2. Sample size: The ignition temperature increased generally as the sample size decreased. Two sizes, however, were used in these experiments, 3 and 5 mm cubes. The 5 mm size gave an average ignition temperature of 900°C, while the 3 mm size gave an average of 950°C. This, however, seems to be a very small effect under the present experimental conditions. The work of Cassel and Liebman (6), and Mellor's work (2) showed this same effect in more detail over a wide range of sizes in other gases.

3. Total gas pressure: The ignition temperature was found to be somewhat dependent on pressure, increasing from approximately 850° to 980°C with an increase in pressure from 500 to 760 Torr under constant heating rates.

In the ignition runs conducted at high-heat-up rates, it was impossible to detect the ignition temperature within 20°-40°C, and this temperature range combined with an observed melting point lag of approximately 10°C gave an uncertainty of as much as 50°C in the ignition temperature.

Because the ignition temperature could be varied considerably by the heat-up rate, further work was abandoned in this area. The most significant result of this phase of the investigation was that $T_{ign} >> 650$°C.

Effect of ambient pressure.—One of the more interesting factors influencing ignition was the total pressure of chlorine used. A series of experiments were carried out at ambient pressures of 300, 500, 760, and 1000 Torr, all other experimental conditions being held constant. Thus a constant partial pressure ratio of chlorine to argon of 2:1, constant particle size of magnesium (3 mm cubes), and constant heating rates were maintained throughout the experiments.

At comparatively high pressures (760 and 1000 Torr), it took a longer time to ignite the samples than at 500 Torr. Thus, at the higher pressure, higher ignition temperatures could be expected and accordingly were measured at 500 and 760 Torr as reported earlier, *i.e.*, the ignition temperature was 850°C at 500 Torr and 980°C at 760 Torr.

In several experiments, slow heating of the magnesium led to great difficulty in igniting the sample; some samples were held for several minutes at temperatures well above 1000°C without ignition. Under these conditions, the vapor pressure of the magnesium approached the total pressure in the vessel. This was thought to be due to the greater protection offered by a thicker chloride (-oxide) layer formed on the surface of the molten magnesium during the slower heat-up period.

It was shown that an increase of the partial pressure of chlorine up to a certain limit would speed up the ignition process, while an increase in the total pressure at constant chlorine content retarded the ignition process.

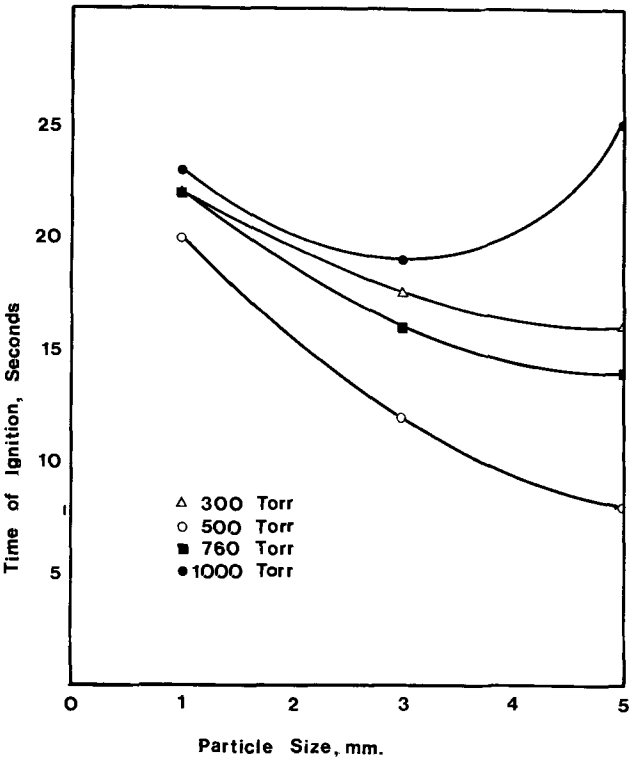

Fig. 1. Variation in time of ignition with particle size and chlorine pressure.

Effect of sample size on the time required for ignition.—Magnesium of 1, 3, and 5 mm sizes were ignited in 100% chlorine at pressures of 300, 500, 760, and 1000 Torr. Each run was repeated three times and the results averaged. Time of ignition was taken from the start of power input to the induction coil to the ignition point. The experimental results are shown in Fig. 1.

From Fig. 1, it can be observed that for the constant pressure experiments, the ignition time for small particles was longer. This could be indicative of a higher ignition temperature on one hand or a slower induction heating of smaller particles with smaller surface area on the other hand.

The sample surface to volume ratio used in the present work were 6, 2, and 1.33 mm^{-1} corresponding to 1, 3, and 5 mm cubes, respectively. Thus, the surface to volume ratio used in this work may be compared to the larger particle sizes that Mellor used in his experiments. Mellor (2) studied the ignition characteristics of magnesium in oxygen and CO_2 gases and found that by merely changing the sample surface area to volume ratio, the ignition temperature reverses its dependence on pressure. The present work does not show this relationship (see Fig. 1), if it is assumed that the observed relationship between time of ignition and ignition temperature is valid.

Spectrographic observations and chemical reaction mechanism.—Spectrography can be used as a tool to investigate the combustion reaction and further, to postulate the reaction mechanism. Emission spectra of the flame of magnesium burning in chlorine gas were recorded at different pressures and chlorine concentrations. Spectra were recorded for flames with 30-100 volume per cent (v/o) Cl_2 in the gaseous oxidizer mixture of chlorine and helium, and 500-1000 Torr total pressure.

Spectral features of MgCl were observed resulting from the $^2\pi$-$^3\Sigma$ transition at 3780, 3775, and 3770Å. Also, the magnesium singlet at 4571.15Å as well as other magnesium lines at 5167 and 5183Å, were recorded.

In addition, other lines and bands were recorded as impurities in the flame. The two Na lines at 5889.95 and 5895.22Å and the Ca line at 4227.73Å were observed. Identification of the atomic and molecular spectra was carried out with the aid of tables (7).

The existence of magnesium lines in the spectrum proved the existence of magnesium atoms in the vapor phase in the flame.

The presence of MgCl in the flame indicates that MgCl in the vapor phase is most probably an intermediate product in the combustion reaction.

From the spectrographic results, the steps of the reaction mechanism have been postulated as follows

$$Mg_{(c)} \rightarrow Mg_{(l)} \rightarrow Mg_{(v)} \quad [1]$$

The following reactions then occur in the vapor phase

$$Mg + Cl_2 \rightarrow MgCl + Cl \quad [2]$$

$$Mg + Cl \rightarrow MgCl \quad [3]$$

$$MgCl + Cl_2 \rightarrow MgCl_2 + Cl \quad [4]$$

$$MgCl + Cl \rightarrow MgCl_2 \quad [5]$$

The dichloride vapor then condenses rapidly and exothermically as follows

$$MgCl_{2(v)} = MgCl_{2(c)} \quad [6]$$

$$\Delta H = -32.7 \text{ kcal (11)}$$

The over-all reaction can thus be written

$$Mg_{(c)} + Cl_2 = MgCl_{2(c)}$$

$$\Delta H = -153.2 \text{ kcal at } 298°K \text{ (11)}$$

Summary and Conclusions

Visual observations, spectroscopy, and high-speed photography were the main tools used in this study. The work may be summarized by the following points.

1. Individual magnesium particles were observed to ignite only after they had melted and formed droplets with a thin protective oxide-chloride coating covering their surface.

2. The ignition temperature of magnesium in chlorine was measured at 760 and at 500 Torr and was found to be in the range of approximately 850°-1100°C depending on the conditions of the experiment.

3. Under most conditions there was flashing from the metal surface just before ignition took place; this could be indicative of point ignition through the protective chloride layer but where the vapor pressure of magnesium was not sufficient to sustain a flame.

4. Up to the point of ignition, heat was continuously supplied to each droplet by the induction furnace. The temperature and vapor pressure of the magnesium metal within the droplet rose gradually until ignition, after which a stable flame was established. Thus magnesium burns in chlorine by a vapor-phase diffusion phenomena in a manner similar to that of magnesium in oxygen as discussed by Coffin (8), Brzustowski and Glassman (1), and Sullivan (10). In all cases in oxygen-containing atmospheres, magnesium ignites before melting occurs which indicates that the oxide-coating on magnesium metal is porous and possibly quite rigid below the melting point of magnesium thereby facilitating diffusion of magnesium vapor from the hot magnesium surface. Magnesium vapor could also escape through faults in the oxide film.

5. Studies of the physical phenomena of combustion of magnesium in chlorine were carried out in the pressure range of 100-1500 Torr. Experimental investigations indicated that magnesium vapor plays the major role in initiating the reaction.

6. A chemical combustion mechanism of magnesium in chlorine was suggested on the basis of the experimental results. Flame spectra revealed that both MgCl bands and magnesium lines were present. The presence of MgCl in the flame suggested that MgCl is an intermediate product in the combustion reaction whereas the presence of magnesium lines indicated the presence of magnesium vapor.

The study carried out in the present work has shed some light on the problem of igniting magnesium in chlorine. It is felt that further studies of the structure of the flame on the basis of flame models in the literature may be important. Except for the ignition temperature measurements carried out in this work, the study was mainly qualitative.

Kinetics and Morphological Development of the Oxide Scale on Iron at 800°C in Oxygen at 2.5×10^{-3} to 3.0×10^{-1} Torr Pressure

A. G. Goursat and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

A thermogravimetric technique was employed to investigate the oxidation of iron in oxygen over the pressure range 2.5×10^{-3}-3.0×10^{-1} Torr at 800°C. The oxidation curves exhibited distinct intervals of linear kinetics followed by transitions to intervals of parabolic kinetics during exposures extending to 125 min. Linear kinetics governed the growth of uniformly thick wustite scales; the linear rate constants showed a proportional dependence on oxygen pressure due to reaction control by a phase boundary reaction involving nondissociative adsorption of oxygen. The sticking coefficient of oxygen on wustite was equal to 0.067. Parabolic kinetics governed growth of wustite-magnetite scales containing magnetite as outermost layers. The values of the parabolic rate constants were independent of oxygen pressure since scale growth was directly dependent on the iron vacancy gradient in wustite established by the oxygen activities at the Fe/FeO and FeO/Fe_3O_4 interfaces.

Several investigations have been carried out to determine the influence of oxygen pressure on the oxidation properties of iron at temperatures in the range 200°-550°C (1-6). The early oxidation stage involves processes for nucleation and growth of magnetite. Growth of hematite on a developed magnetite layer or separation of this layer from the metal leads to a decrease in the oxidation rate. Detailed information is not available, however, on iron oxidation properties at temperatures sufficiently high for formation of wustite as a scale constituent (7-12). Nucleation and growth of wustite occur in the early stage of the reaction at temperatures exceeding 600°C, growth of wustite as a layer being controlled during exposures of short duration by an oxide/gas phase boundary reaction. Growth of a wustite scale at long exposures or the growth of a multilayer scale containing wustite, magnetite, and hematite is associated with diffusional processes. Iron diffuses through wustite and magnetite, while both iron and oxygen may diffuse through hematite (13-15).

Large discrepancies occur among results reported for the influence of oxygen pressure on the form of the oxidation curve obeyed and the magnitudes of the reaction rates at temperatures in the range 600°-1000°C. The results obtained at low pressures appear to be strongly affected by the iron purity and different transport limiting factors depending on the experimental conditions (16). We have therefore systematically investigated the oxidation of high-purity iron in oxygen atmospheres at pressures ranging from 2.5×10^{-3} to 3.0×10^{-1} Torr at 800°C.

Experimental

Iron, 99.999 w/o (weight per cent) pure, was exposed to research-grade oxygen, <25 ppm impurities, in an assembly containing a continuously recording microbalance. Impurity contents of the iron are recorded in Table I.

Iron specimens were prepared by cutting disks, 0.3-1 mm thick, from the received, 1 cm diameter rod. All surfaces of these disks were subjected to abrasion on silicon carbide papers, a wax lap impregnated with 15μ alumina, and a final polish on cloths impregnated with 6 and 1μ diamond pastes using kerosene as lubricant. They were then electropolished in a 5% perchloric acid-glacial acetic acid solution and washed in distilled water and acetone. Finally the specimens were sealed in quartz tubes containing high-purity argon and annealed for 18 hr at 800°C. The metal grain size varied from 0.03 to 0.3 mm which corresponds to ASTM grain size No. 5. Before an oxidation test, an annealed specimen was resubjected to electropolishing and washing.

The thermogravimetric assembly is schematically illustrated in Fig. 1. Weight gains of specimens were determined within ±1 μg by the Cahn R. G. microbalance. The pressures of oxygen at the entrance and exit of the reaction tube were measured by Pirani gauges. These measurements were used to calculate the pressure over the exposed metal specimen assuming a linear gradient. During an experiment, oxygen was leaked from the supply tank and continuously allowed to flow through the reaction tube by means of the open Pyrex tube to the vacuum pump. A specimen was ex-

posed to a vacuum of 3×10^{-6} Torr for 10 min for stabilization of the temperature upon raising the heated furnace around the reaction tube. The temperature was controlled to ±2°C. Up to 3 min were required to establish the constant pressure gradient upon admission of oxygen. A test was terminated by simultaneously lowering the furnace and evacuating the assembly.

Oxidized specimens for microscopic examination were mounted in room-setting epoxy resin and metallographically polished as described above. An ethyl alcohol solution containing 5% concentrated hydrochloric acid was used as an etchant to distinguish wustite from magnetite. Identification of the oxide constituents was carried out by reflection x-ray examinations using Cu-Kα irradiation with a graphite monochrometer and the preferred orientation of wustite in a scale determined by reflecting Mo-Kα x-ray irradiation from the surface of a rotating specimen. Morphological features of the scales were determined by optical and scanning electron microscopy.

Results

The oxidation curves at pressures from 2.5×10^{-3} to 3.0×10^{-1} Torr are shown in Fig. 2 and 3 as weight change (mg O/cm^2) *vs.* time (min) for periods up to 125 min (1 mg O/cm^2 = 7.2μ FeO). The curves of the weight change were constructed using the original dimensions of a specimen. Five runs at 1.2×10^{-1} Torr were reproducible within ±5%. A typical curve exhibited initially a region wherein the reaction rate continually increased, followed by a region of linear reaction behavior and finally by a region of continually decreasing rate. Considering Fig. 2 and 3, the effect of oxygen pressure on reaction behavior is important particularly during the first hour of exposure.

It was found that small wustite crystals developed over a thin base film, their shape and population being dependent on the orientations of the underlying metal grains. These crystals grew laterally and vertically to a uniformly thick layer during the initial period of continually increasing oxidation rate before onset of linear kinetics. An example of the distribution of these crystals is shown in Fig. 4. The composition and structure of the base oxide film have not yet been determined (7).

The metal was covered by a uniformly thick wustite scale during the period of linear reaction kinetics and a subsequent part of the interval described by the continuously decreasing rate. A cross-section of this type of scale is presented in Fig. 5. As illustrated by the micrograph in Fig. 6, quenching of the scales which contained large 10-100μ wustite grains, did not lead by disproportionation to observable amounts of magnetite. Magnetite was also not detected by reflection x-ray examinations nor by scanning electron microscopy observations at a magnification of X1000. These latter observations, as shown by the micrograph in Fig. 7, demonstrated that a scale developed by lateral and vertical growth of wustite platelets.

Wustite grains in the scales also exhibited a preferred texture. Examination of a scale 10μ thick showed a strong preferred orientation of the (311) wustite face parallel to the metal surface. Five thicker scales approximately 50μ thick showed the (110), (100), and (311) faces of wustite lying in decreasing order of parallel orientation with the metal surface.

Fig. 6. Cross section of the etched wustite scale shown in Fig. 5 (X300).

Magnetite was nucleated and it grew to cover the wustite layer in the early period of decreasing oxidation rate which became of shorter duration with increasing oxygen pressure. Using the scanning electron microscope, it was definitely established that the wustite layer was completely covered by magnetite during the first 60 min at pressures in the range 7×10^{-3}-3.3×10^{-2} Torr and within the first 10 min at pressures greater than 0.15 Torr. Figure 8 shows an area from a wustite scale over which magnetite has commenced to grow, while Fig. 9 shows the magnetite crystals in a complete layer at a more advanced stage. Apparently magnetite preferentially formed at ledges on the wustite surface. The grains in a fully developed magnetite layer exhibited ledges and flat surfaces and they appeared to be smaller than the underlying wustite grains. The magnetite layer never did exceed 5% of a scale. This type of scale, as illustrated by the micrograph in Fig. 10, exhibited copious magnetite precipitation in the outermost regions of the underlying wustite layer upon its quenching to room temperature. Nevertheless, hematite was never detected in any of the x-ray diffraction patterns of scales formed to oxygen pressures of 3.0×10^{-1} Torr.

Discussion

The dissociation pressures of wustite, magnetite, and hematite at 800°C are 1.01×10^{-16}, 2.21×10^{-15}, and 3.96×10^{-7} atm, respectively (17, 18). Formation of these oxides is therefore thermodynamically feasible under the experimental conditions chosen. The present results have shown, however, that the two lower oxides only formed under kinetic conditions in oxygen at pressures ranging from 2.5×10^{-3} to 3×10^{-1} Torr for exposures up to 125 min. The oxidation curves exhibited initially an increasing rate followed by a transition to a constant rate which transformed to a decreasing rate. Magnetite nucleated and grew during the early intervals of this latter stage to cover the wustite surface. Although this curve has not been observed before for the oxidation of iron in oxygen, it exhibits the same form as the curve obtained when iron is oxidized in a carbon dioxide atmosphere (19-21).

Charbonnier *et al.* (22) investigated the growth of wustite in the early exposure stages of increasing oxidation rate by employing oxygen pressures ranging from 10^{-6} to 10^{-4} Torr at temperatures in the range 750°-950°C. They were able to demonstrate that wustite crystals expanded over a thin base oxide film, the shape and population of the crystals being dependent upon the metal crystallographic orientation. These crystals had grown to form a uniform layer upon onset of linear kinetics. Our observations confirm these findings and they show that a uniform textured wustite scale subsequently grows during periods of constant and decreasing oxidation rates.

A scale consisting of a wustite or of wustite and magnetite layers grows by means of outward diffusion of iron via vacancies to react with oxygen. It is appropriate, accordingly, to correlate those regions of an oxidation curve exhibiting constant and continuously decreasing reaction rates with mechanisms for linear and parabolic kinetics. The linear kinetics, Fig. 2 and 3, are strongly dependent on oxygen pressure and it can be shown that scale growth is determined by a phase boundary reaction for adsorption and incorporation of oxygen into wustite. On the other hand, the regions of decreasing oxidation rate show a much smaller oxygen pressure dependence. Since this dependence is confined to intermediate times, the decreasing rate at long exposures can be shown to determine the parabolic growth of a scale comprised of wustite and magnetite layers.

Values of the linear oxidation constants, K_L, at pressures in the range $2.5 \times 10^{-3} - 3.3 \times 10^{-2}$ Torr were obtained from the linear sections of the oxidation curves in Fig. 2 and 3. They are plotted *vs.* pressure in Fig. 11. Since they show a proportional dependence on pressure, the expression

$$K_L = \alpha (K_L)_{theor} = \alpha P_{O_2} / (2\pi m k T)^{1/2} \qquad [1]$$

is used to calculate the fraction of impinging oxygen molecules, α, incorporated into wustite. $(K_L)_{theor}$ represents the rate constant assuming that all impinging molecules react, k is Boltzmann's constant, m is the mass of an oxygen molecule, and T is the temperature in °K. The calculated values, Table II, demonstrate that the fraction of impinging molecules adsorbed is only 6.7% and independent of pressure. These results are consistent with the conclusion that the rate-controlling step during linear kinetics involves a non-dissociative oxygen adsorption mechanism.

The oxidation curves have been plotted in parabolic form in Fig. 12. A typical curve exhibits a transition from linear to parabolic kinetics. It is to be noted that the periods for this transition decrease with increasing pressure. Above 1.5×10^{-1} Torr, the transition also occurs at progressively smaller weight gains with increasing pressure presumably due to more rapid nucleation and growth of magnetite. Results are also included for oxidation in dry air in order to show that the rate of parabolic scaling remains pressure independent up to approximately 1 atm. This behavior is

equal to calculated values, within the accuracy of the calculation, using independent iron diffusivity measurements in wustite in the equation derived from the Wagner theory for parabolic scale growth (19, 23). All these values are equal irrespective of oxygen pressure because wustite accounts for at least 95% of the scale thickness. The flux of iron for growth of the scale is then directly related to the iron vacancy concentration gradient in wustite established by the oxygen activities at the Fe/FeO and FeO/Fe_3O_4 interfaces (19, 23).

Conclusions

Iron exposed to oxygen in the pressure range 2.5×10^{-3}-3×10^{-1} Torr exhibits initially an increasing oxidation rate followed by a stage of linear kinetics before onset of parabolic kinetics. The first oxidation stage is associated with the growth of wustite crystals over an oxide base film while linear kinetics govern the growth of a uniformly thick wustite scale. This scale exhibits a textured structure containing the (110), (100), and (311) faces of wustite in the predominant parallel orientations with the metal surface. The magnitude of the linear rate constant was proportionally dependent on pressure due to reaction control by nondissociative oxygen adsorption; the sticking coefficient of oxygen was 0.067. Parabolic kinetics, which were not dependent on oxygen pressure, governed growth of duplex scales containing layers of wustite and magnetite for exposures up to 125 min. Magnetite comprised less than 5% of scale thickness. Values of the parabolic constant at low pressures were equal to those at pressures near 1 atm because the iron flux for scale growth was directly related to the iron vacancy concentration gradient in wustite established by the oxygen activities at the Fe/FeO and FeO/Fe_3O_4 interfaces.

Charge Formation Characteristics of Epoxy Resin Electrets

P. K. C. Pillai and Malti Goel

Indian Institute of Technology, New Delhi-29, India

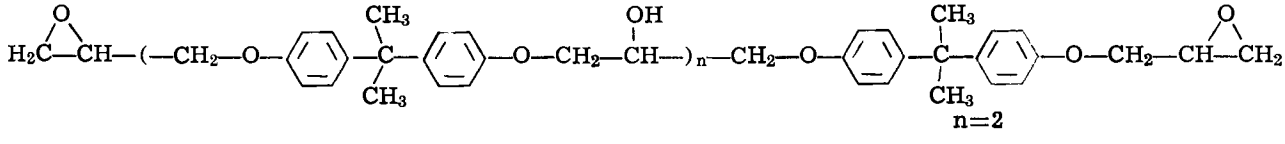
ABSTRACT

Charge storage properties of epoxy resin are investigated in this paper. Thermoelectrets of the resin are prepared by external thermal and electrical treatment and resultant surface charges are measured for one month. Initial heterocharges are observed on both the surfaces of thick sample, but a charge reversal takes place on anode surface depending upon the conditions of polarization such as polarizing field, polarizing temperature, and polarizing time. For thin foil electrets, positive surface charges are observed on both the sides. Permanent charges of both thick and thin electrets are positive, on both the surfaces, suggesting hole conduction in this resin. Optical absorption studies have been used as an experimental tool to detect the changes taking place during polarization.

Epoxidation of olefins was first reported in early 1900. First, epoxy resin from Bisphenol was isolated by Schlack in 1933 in Germany. This is used in casting adhesive. Charge-storage phenomena in epoxy resin which is a mixture of diglycidyl ether of Bisphenol A (DGEBA resin) and polyamine has been investigated by studying its thermoelectret properties. Thermoelectrets are permanently polarized dielectrics, which were first prepared by Equchi (1) from carnauba wax. Most of the work on thermoelectrets has been done on waxes and their mixtures. Recently, some plastic materials were used for electret preparation and studied for their stability (2-6). Resins were used for formation of thermoelectrets for the first time by Mikola (7). Those electrets were found to retain charges and showed peculiar characteristics.

The resin used in present investigation is supplied by Ciba of India Limited. Its electret-forming properties have not been studied so far. Electret effect is investigated, since this resin is widely used for insulation in electrical instruments and as a binder in some electret-forming materials. Molded sheets of epoxy resin were prepared and cut into slabs of 0.1 cm thickness and were used for electret preparation. Thin foils were also developed and used for the investigation. Heterocharges or homocharges are observed depending upon conditions of polarization.

The structure of DGEBA resin is given below



Experimental

Samples with two different thicknesses were used for polarization by thermal and electrical treatment. One was 0.1 cm thick sheet cut from a molded block and another was 0.007 cm thick prepared in thin foil form. Resin was molded in block form by mixing the hardener 7% in volume in DGEBA resin at casting temperature of 60°C. The mixture was put into an aluminum casting and heated to 100°C at the rate of 1°C/hr. It was kept at 100°C for 4-5 hr and later brought down to room temperature at a rate of 1°C/hr. Annealing was done for 15 hr at 120°C. The breakdown voltage of this molded substance was found to be 23 kV/cm at room temperature. A slab of dimensions 1 cm × 1 cm × 0.1 cm was cut and kept in between aluminum electrodes and pressed tightly with the help of screws. The whole assembly was kept inside an electric oven, the temperature of which can be adjusted up to 240°C.

The sample was heated to a desirable temperature and an electric field through a high-voltage stabilizer was applied to it for 2 hr at constant temperature and for another 2 hr during its cooling to room temperature. The electric field was switched off at room temperature and resultant surface charges of thermoelectret so formed, were measured with the help of Keithley solid-state electrometer 610C, which can measure charge down to 10^{-13} coulombs. The charge measurements were then carried out after definite time intervals for approximately 1 month. Electrets were kept short circuited by wrapping in aluminum foil in desiccated conditions between successive measurements. The ultraviolet and visible spectra of polarized and unpolarized foil were taken from Unicam SP500 spectrophotometer.

Results and Discussion

Electrets of 0.1 cm thickness show heterocharges on both sides of the electret surface initially. These charges first decay very rapidly and then regain a constant value after some time, which finally decays slowly to zero. Isothermal surface charge decay of electrets prepared by 10 kV/cm at 140° and 200°C are shown in Fig. 1. Charge reversal is observed on the anode surface in 4 days for an electret prepared at 140°C and in 9 days for an electret prepared at 200°C. The final charges on both the surfaces are positive. Observation of initial heterocharge and its subsequent reversal to homocharge indicates the presence of volume polarization in the polarized samples.

The initial values of surface charges as a function of polarizing field are shown in Fig. 2. At 10 kV/cm maximum charge is observed. As the field strength increases further, the magnitude of charge is reduced.

Key words: epoxy resin, thermoelectret, heterocharge, homocharge.

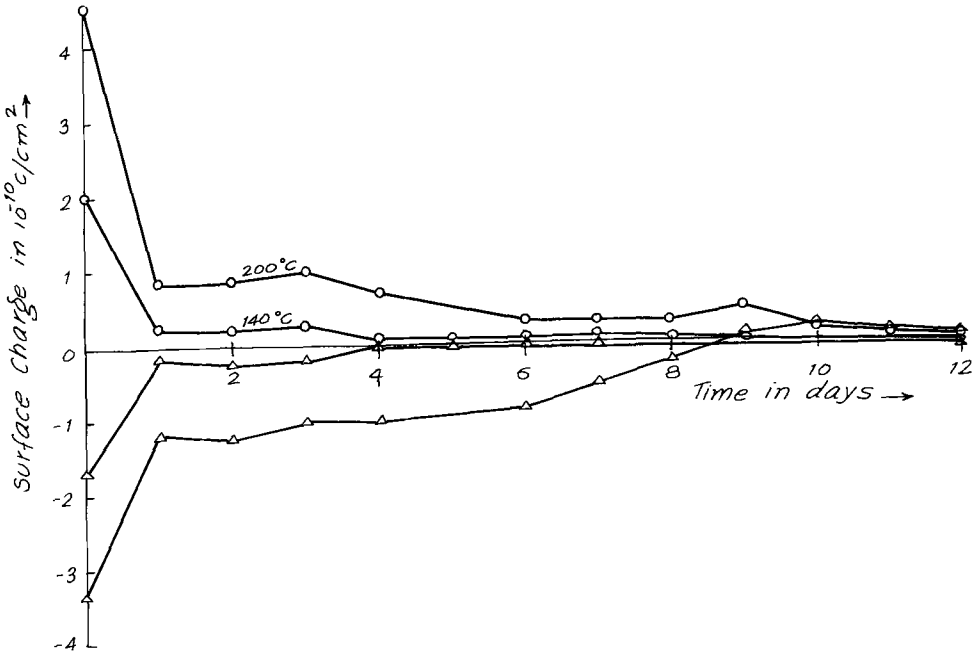


Fig. 1. Surface charge decay of electrets of thickness 0.1 cm prepared at 10 kV/cm at different temperatures in 4 hr polarizing time.

This reduction in initial heterocharge is due to the increased homocharge component at higher fields. The initial charges of electrets prepared at different temperatures is shown in Fig. 3. These surface charges are shown to increase with increasing polarization temperature. The polarizing temperature thus enhances the volume polarization. The electrical resistance of the resin decreases with increasing temperature.

Dependence of surface charge on polarizing time is shown in Fig. 4. The best electret of this material is formed in 4 hr when the sample is prepared at 10 kV/cm. By increasing polarization time, electret properties are found to deteriorate.

In the case of thin foil electrets, positive-surface charges are only observed on both the surfaces, and no charge reversal takes place. The magnitude of positive charge is found to be greater on the anode surface than on the cathode surface. The charges decay initially for 2-3 days, than rebuild up to a high value, again decay slowly, and finally become constant. It is found that the magnitude of surface charge as well as the time taken in acquiring the maximum build-up of charge after polarization depend upon the polarizing field. The initial surface charge as a function of applied voltages for 0.007 cm thick foil polarized at 140°C in 4 hr are shown in Fig. 5. There exists an optimum value of polarization field in this case also, at which maxi-

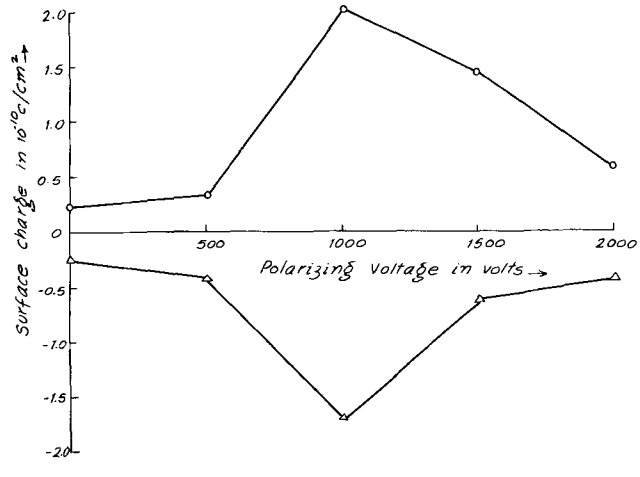

Fig. 2. Surface charge as a function of polarizing voltages prepared at 140°C in 4 hr polarizing time (thickness 0.1 cm).

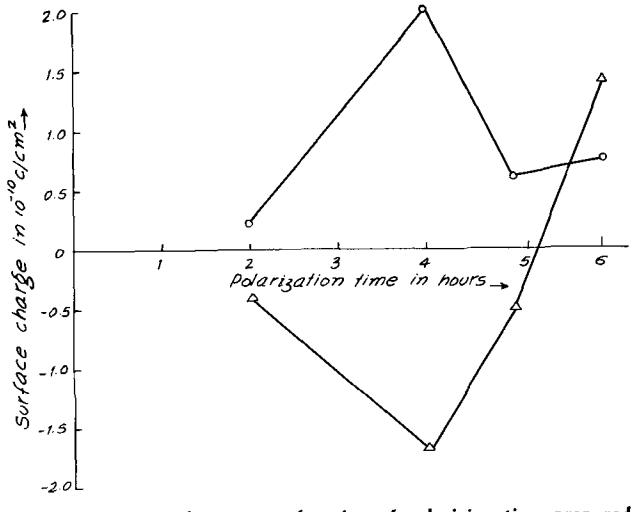

Fig. 4. Surface charge as a function of polarizing time prepared at 10 kV/cm and 140°C (thickness 0.1 cm).

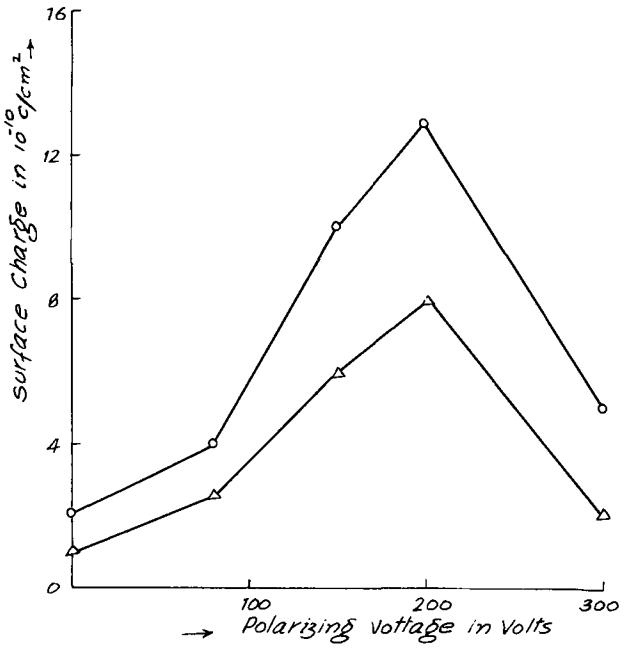

Fig. 5. Surface charge as a function of polarizing voltage prepared at 140°C in 4 hr (thickness 0.007 cm). △, cathode; ○, anode.

mum polarization is obtained. Assuming that the effective surface charge of an electret is given as

$$\sigma_{eff} = \eta - P$$

η is the component due to homocharge formation which may arise because of transfer of charge from electrode-electret gap, molding, and stripping charge.

P is the component due to heterocharge formation, which may be due to dipole alignment, trapping of charge, and interfacial polarization.

The observed surface charge will depend on which of the two components is predominant at a given time. Bisphenol A is a complex molecule and therefore a multiple process of polarization can be expected in this material. In its molecular structure a number of permanent dipoles are present, which orient and align themselves in the direction of applied electric field. In addition space charge trapping and bulk trapping of charge are also taking place (8). Dipole relaxations, ionic and electronic movements are responsible for the charge reversal. Final charges on both the surfaces are positive in this case indicating that holes and positive ions are more predominantly trapped, while in other electret forming plastic materials (6, 9) predominance of electron conduction has been observed.

The optical absorption studies have been carried out in ultraviolet and visible range of spectrum for this resin. The absorption spectra of an unpolarized 0.007 cm thick sample are taken in the wavelength range 200-700 mμ as shown in Fig. 6a. A sample of 0.007 cm thickness is polarized at 140°C by a field strength of 20 kV/cm and its spectral characteristics are shown in Fig. 6c. Absorption spectrum of another sample heated to the polarization temperature of 140°C in the absence of electric field is also shown in Fig. 6b. It is found that an unpolarized sample shows a broad transmission in the wavelength range 300 to 700 mμ. On heating the absorption is increased and in wavelength range 300-340 mμ there is no transmission. This change is contributing to molding and stripping charges observed during surface charge measurements. However, it was found that these surface charges decay quickly. On polarization the absorption is further increased as well as visible opacity of the sample is increased. This increased absorption is due to certain changes taking place in the structure particularly the —OH— group of Bisphenol A. A more quantitative description is yet to be suggested.

Summary and Conclusions

1. Charge storage takes place in epoxy resin when it is heated under electrical stress. This charge is retained approximately for 15 days in thick sample and for 1 month in thin foil.

2. There exists an optimum value of polarization field polarization temperature and polarization time for getting the maximum polarization in case of this epoxy resin.

3. The charge reversal on anode surface takes place from initial heterocharge to final homocharge depending upon conditions of polarization. Permanent heterocharges are only observed on cathode surface.

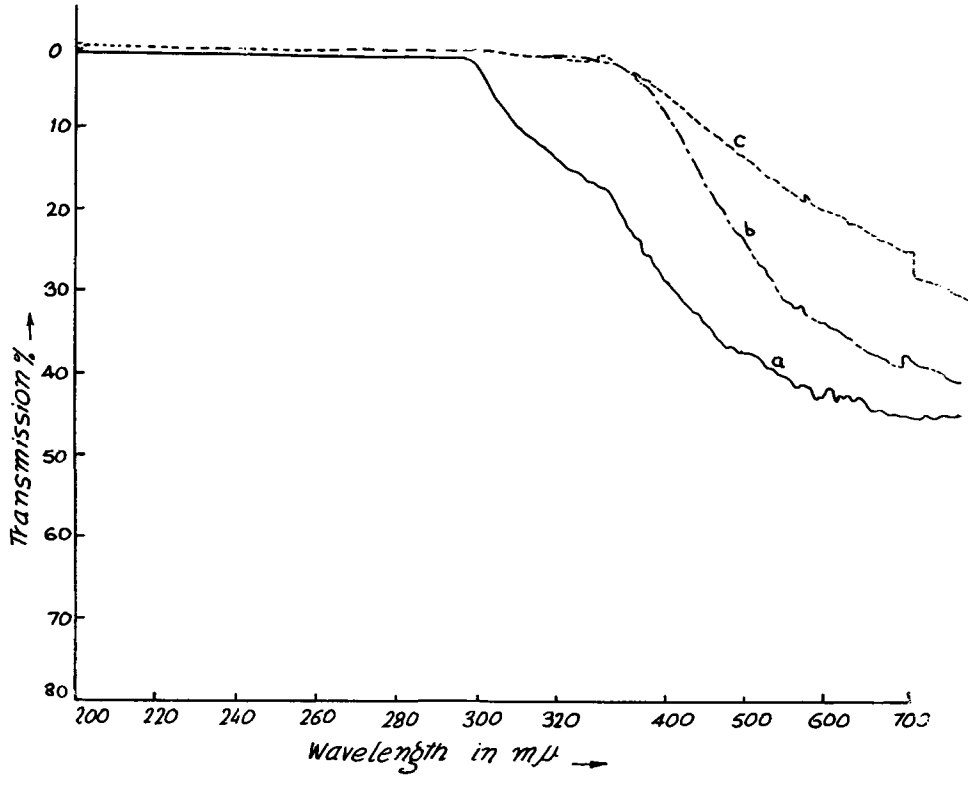

Fig. 6. The ultraviolet and visible absorption spectra of epoxy resin foil of thickness 0.007 cm before and after polarization. a, —— unpolarized; b, —·—·— heated to 140°C; c, - - - - - polarized at 20 kV/cm and 140°C.

4. The final charge of resin electrets is always positive indicating that positive carrier is more predominantly trapped in this resin.
5. The optical studies in the ultraviolet and visible region show the structural changes taking place in the polarized sample.

Transport Numbers of Metal and Oxygen during the Anodic Oxidation of Tantalum

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

An oxide film on a metal surface will thicken only if metal, or oxygen, or both, migrate across it. The relative magnitude of the metal and oxygen migrations can be determined using markers, and the possible results are reviewed for the ideal case of a homogeneous oxide grown to uniform thickness on a plane metal surface. Such experiments require markers that are both inert and immobile; criteria are developed to establish that these requirements have been met. Experimentally, it has been shown that the anodic oxidation of tantalum is a system close to the ideal, and that the radioisotope of a noble gas is a good approximation for the required marker. Radioactive noble gases were implanted by means of a mass separator into thin films of anodic tantalum oxide, and the transport numbers of the tantalum and oxygen measured after thickening by further anodization. The transport numbers were found to be 0.243 and 0.757, respectively, for anodizing conditions of 1 mA/cm^2 at 25°C in 0.1M H_2SO_4. The noble gas concentration profiles were observed to broaden on further anodizing, and this was interpreted as being due to the simultaneous movement of tantalum and oxygen atoms during the charge transfer event.

The oxidation of metals is frequently a rather complex process, and so the fundamentals are best studied in a system that is as simple as possible. The anodic oxidation of tantalum meets this requirement admirably, for it requires little apparatus, can be performed at room temperature, and gives a highly uniform and homogeneous oxide all over the metal surface. Furthermore, the rate of oxidation can be controlled by the applied current, and its extent by the applied voltage.

The anodic oxidation of tantalum has been studied many times, mostly by means of electrical measurements on the current-voltage relationship. These have established the over-all kinetics of the process, and have shown that the current passes through the oxide via the migration of ionic species; they have, however, provided no information on the nature of these species or their migrations. In particular, they have been unable to determine how much of the current is carried by tantalum migrating toward the oxide/electrolyte interface, and how much by oxygen migrating in the opposite direction.

The marker experiments reported here were designed to investigate this problem, using the techniques reported elsewhere (1-3).

Key words: tantalum, anodic oxidation, markers, transport number, oxidation mechanism.

Principle of Marker Experiments

Possible mechanisms for oxide growth.—Under normal conditions, almost all metal surfaces are covered with a thin film of oxide. The oxidation system is one, therefore, in which the two reactants, metal and oxygen, are separated by a layer of their product. If further reaction is to take place, so that the product layer becomes thicker, either metal or oxygen or both must be transported across the existing film. There are then five possibilities.

I. The metal alone migrates, and the reaction to form new oxide occurs only at the oxide/oxygen interface.

II. The oxygen alone migrates, so that the new oxide is formed only at the metal/oxide interface.

III. When both metal and oxygen migrate, these two mechanisms could occur together, so that new oxide would be formed at both interfaces.

IV. When both the metal and oxygen migrate, however, the new oxide does not have to be formed at the interfaces; it could be formed within the existing oxide through the transport of material from each side.

V. Since mechanisms III and IV are not mutually exclusive, the new oxide could be formed both within the existing oxide and at the interfaces.

Other metal and oxygen migrations, not leading to oxide formation, could occur simultaneously with any

of the above. Thus oxygen could be transported to the metal/oxide interface, and there dissolve in the metal instead of combining with it to form new oxide. Similarly, migrating metal atoms could, by crossing the oxide/oxygen interface, be lost to the environment.

Identification of the possible mechanisms.—In the discussion that follows, an ideal oxide is assumed; one that is homogeneous, of uniform thickness, and grown on a plane metal surface. It is also assumed that no oxygen dissolves in the metal and that no metal atoms are lost to the environment.

The five mechanisms can be distinguished if it is possible to identify a particular plane in the oxide parallel to the two interfaces; that is, if the plane can be labeled with a marker. The position of the marker after further oxidation then provides a measure of the fresh oxide laid down on either side of the reference plane. An experiment of this kind is sufficient to distinguish mechanisms I and II, but the remaining possibilities can only be distinguished by labeling a series of reference planes so that the marker takes up a distribution in the oxide. The possible results of such an experiment, assuming that the marker is normally distributed about the middle of the initial oxide, are illustrated in Fig. 1.

For metal migration alone (I), the marker position relative to the metal/oxide interface remains unchanged, since no new oxide is formed between it and the metal surface. Accordingly, the marker becomes deeply buried in the oxide. Similar argument shows that the marker position will remain unchanged relative to the oxide/oxygen interface if oxygen alone moves (II). When both move, so that the new oxide is formed only at the interfaces (III), the marker will be found somewhere in the middle of the final oxide, its exact position depending on the relative amount of oxide formed at each interface. In all three mechanisms, the distribution of the marker about its mean position remains unchanged; it will change only if new oxide is being formed within the marked layer, as in mechanisms IV and V.

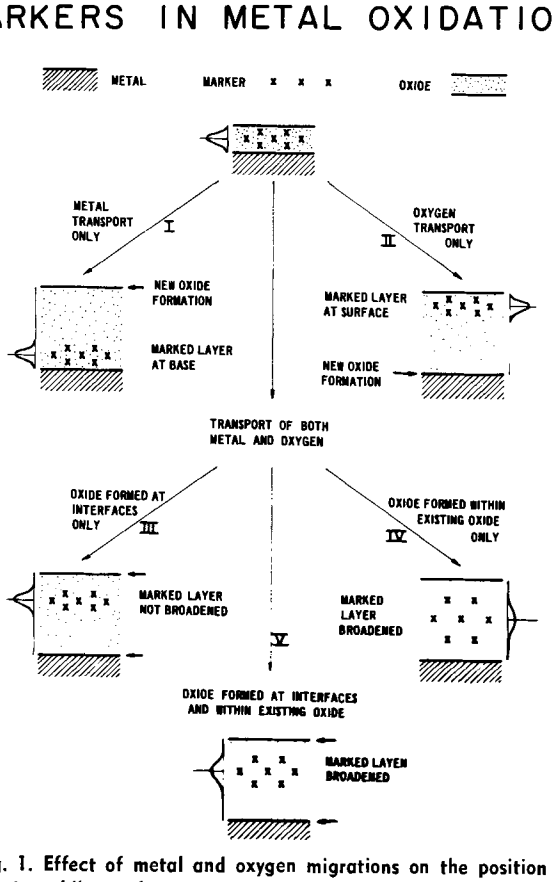

Fig. 1. Effect of metal and oxygen migrations on the position of inert, immobile markers in an oxide film. Roman numerals index the five possible mechanisms discussed in the text, and the resulting marker profiles are shown at the side of each diagram.

In mechanism IV the distribution will broaden, the nature of the broadening depending on where the new oxide is being formed. If the oxide is homogeneous, it is reasonable to assume that the new oxide will be laid down uniformly throughout the existing oxide; the marker would then maintain the same relative position in the oxide, and the same relative profile across it. A combination of III with this form of IV would also lead to profile broadening, but in this case, (V), both the relative position and the relative profile would change as the oxidation progressed.

It must be emphasized at this point that these marker experiments can only determine how much of the new oxide is being formed by metal and/or oxygen migration; they cannot determine how the individual atoms migrate. They cannot distinguish, for example, whether oxygen migrates across the oxide by some process of diffusion, or whether, having crossed the oxide/oxygen interface, it then migrates in one jump to some point at or near the metal/oxide interface. To distinguish between these possibilities, a marker for oxygen itself is required; experiments of this kind have been reported elsewhere [see (4) and the references cited therein].

Criteria for selection of suitable markers.—The first requirement for any marker is that it should not interfere with the oxidation process; that is, it should be inert. Since the mere presence of a marker is enough to perturb the oxide in its immediate vicinity, some interference is inevitable. The best that can be done, therefore, is to reduce the number and size of the markers as much as possible.

The second requirement is that the marker shall be immobile. The position of a marker after oxidation can be interpreted in two ways.

Hypothesis A: The marker is immobile, and its position is determined entirely by the migration of metal and oxygen around it.

Hypothesis B: The marker is not immobile, and its position is determined by its own migration as well as that of the metal and oxygen around it.

If only the position of the marker is known, these hypotheses cannot be distinguished from one another. Since A is a much more rigorous condition than B, the latter is, at first sight, much more likely. And if B is correct, then the relative mobilities of metal and oxygen cannot be determined from the experiment. It is therefore essential that the marker be immobile, and the prime difficulty with any marker experiment lies in establishing this fact.

Evidence for the mobility can be obtained by measuring the marker profile, and by studying the changes in this profile as the oxidation proceeds. The profile must broaden if the marker migrates, due to statistical fluctuations in the distance traveled by individual particles. The absence of such broadening is conclusive proof that the marker is immobile, but its presence is not certain evidence for migration, since the profile could broaden for other reasons; through the formation of new oxide within the existing oxide, for example. If the profile broadens, then, the immobility of the markers is still in doubt.

The doubt can be resolved by noting that any truly inert, immobile marker will behave in exactly the same way as any other truly inert, immobile marker. If two markers are incorporated with exactly the same initial distribution, and they are in fact truly inert and immobile, then (*a*) they will finish up at exactly the same position in the final oxide, and either (*b*) (*i*) their concentration profiles will not broaden at all, or (*ii*) they will broaden by exactly the same amount.

Measurement of transport numbers in anodic oxidation.—To define a measure for the relative migration of metal and oxygen, consider a reference plane in the oxide, parallel to the two interfaces. The formation of

new oxide between this plane and the oxide/electrolyte interface can only occur if metal atoms are transported outward across it; similarly, oxygen atoms must cross in the opposite direction to form new oxide between it and the metal surface. If the total amount of new oxide is proportional to the charge passed during anodization, the amount of new oxide formed on each side of the reference plane is proportional to the fraction of the charge carried by the migrating metal and oxygen atoms. In other words, the fraction of the new oxide formed on either side of the reference plane is proportional to the transport numbers of the metal (t_m) and oxygen (t_o) across it.

The position of an inert, immobile marker in the final oxide is thus determined by the transport numbers of the metal and oxygen across the plane in which it is located. Accordingly, the position of the marker provides a measure of the transport numbers. The preceding discussions can then be recast in terms of transport numbers, so that criterion (*a*) for the immobility of the markers becomes (*a*) the transport numbers measured by the different markers must be exactly the same.

The characteristics of the five mechanisms then become:

I. Metal migration only: $t_m = 1$, $t_o = 0$ for all planes in the oxide film.

II. Oxygen migration only: $t_m = 0$, $t_o = 1$ for all planes in oxide film.

III. Metal and oxygen migration with the new oxide being formed only at the interfaces: $t_m < 1$, $t_o < 1$, with t_m and t_o constant for all planes in the oxide film. This follows since the flux of, say, oxygen atoms crossing the oxygen/oxide interface must equal that arriving at the oxide/metal interface.

IV. Metal and oxygen migration with the new oxide being formed uniformly within the existing oxide: $t_m = 1$, $t_o = 0$ at the metal/oxide interface and $t_m = 0$, $t_o = 1$ at the oxide/oxygen interface. The transport numbers vary monotonically between these limits in such a way that, for a plane at a distance x from the metal/oxide interface

$$(t_m)_x = (h - x)/h$$
$$(t_o)_x = x/h \qquad [1]$$

where h is the oxide thickness.

Suppose that the oxide thickens by an amount Δh, and that x increases by an amount Δx. Then from the definition of transport number

$$(t_o)_x = \Delta x/\Delta h \qquad [2]$$

Combining [1] and [2]

$$(t_o)_x = (x + \Delta x)/(h + \Delta h) = (t_o)_{x+\Delta x} \qquad [3]$$

so that the transport number across the given reference plane remains constant with increasing oxide thickness. The transport numbers observed in a marker experiment would then be determined solely by the position of the marker within the initial oxide, and would remain constant as the oxide thickness increased.

V. Metal and oxygen migration with new oxide being formed both at the interfaces and within the existing oxide: at the metal/oxide interface $t'_m < 1$ and $t'_o < 1$, while at the oxide/oxygen interface $t''_o < 1$ and $t''_m < 1$; within the oxide, $t'_m > t_m > t''_m$ and $t'_o < t_o < t''_o$ in the same way as IV so that

$$(t_m)_x = t'_m - (t'_m - t''_m) \cdot (x/h)$$
$$(t_o)_x = t'_o + (t''_o - t'_o) \cdot (x/h) \qquad [4]$$

A combination of [4] with [2] will show that $(t_o)_{x+\Delta x}$ cannot, except fortuitously, be the same as $(t_o)_x$; that is, the transport numbers across a given plane will vary as anodization proceeds. In this case, therefore, the measured transport numbers would be a function of both the position (x/h) of the marker within the initial oxide, and of the increasing oxide thickness h.

If new oxide is being formed within the existing oxide, the transport numbers of the metal and oxygen must change by equal and opposite amounts at the planes where it is being formed; the rate of formation at plane x is, in fact, proportional to dt_o/dx ($= -dt_m/dx$). When the transport numbers across two neighboring planes are identical, $dt_o/dx = 0$ between them; since no new oxide is being formed, the planes remain the same distance apart. Markers located on two such planes will also remain the same distance apart, and so there will be no broadening of the marker profile. These conditions obtain in mechanisms I, II, and III, since $dt_o/dx = 0$ for all planes within the oxide.

In mechanism IV, however

$$dt_o/dx = 1/h \qquad [5]$$

and in mechanism V

$$dt_o/dx = (t''_o - t'_o)/h \qquad [6]$$

It can then be shown that the breadth of the marker profile will be proportional to h in mechanism IV, and to $h_i + (t''_o - t'_o)(h - h_i)$ in mechanism V, where h_i is the initial thickness of the oxide film.

Transport number measurements using at least two marker species can thus establish whether the markers are immobile, and if so, where the new oxide is being formed. These concepts have been applied experimentally to a study of the anodic oxidation of tantalum.

Marker Experiments in Anodic Oxidation of Tantalum

Ideality of anodic tantalum oxide.—The preceding discussion has been based on the assumption that the oxide is ideal, and so the application of its conclusions to a real system is only as good as the approximation to ideality. For anodic tantalum oxide, the approximation is indeed excellent. All available evidence [see (1) and the references cited therein] suggests that anodic tantalum oxide is very highly homogeneous when formed in dilute aqueous electrolytes. The only irregularities are those resulting from impurities in the underlying tantalum or from fragments of crystalline oxide, but these occupy a minute fraction of the surface area (1, 3). Furthermore, the thickness uniformity is maintained during anodization and the underlying tantalum surface is smoothed (1). No significant amount of tantalum is found in the electrolyte after anodizing (5), and internal friction measurements (6) show that the diffusion of oxygen in tantalum is negligible at room temperature.

Choice of markers.—As already noted, the requirement that the marker be inert cannot be met absolutely; the best that can be done is to use markers that are as small and as few as possible. Obviously, the smallest possible marker is a single atom, and this feature has been provided in both this and previous work (5, 7) by using noble gases. Radioactive isotopes simplify the problem of detection and diminish the number of atoms required; ^{41}Ar, ^{79}Kr, ^{125}Xe, and ^{222}Rn were used as markers in the present experiments. Nevertheless, it is still questionable whether the radioactive noble gases are completely inert.

Apart from ^{222}Rn, obtained from the Radium Chemical Company of New York, the isotopes were all prepared by (n, γ) reactions on the stable precursors. They were then implanted in the oxide by means of a mass separator, whose use for this purpose has been described elsewhere (2, 8). The implantation of a radioisotope is normally accompanied by the implantation of a much larger number of the neighboring stable isotopes (2), and so the total fluence is determined almost exclusively by the latter. Beam current measurements, or counting data in the case of ^{222}Rn, showed that the implanted fluences were about 10^{13} ions/cm^2 for Ar and Kr, 10^{12} ions/cm^2 for Xe, and 10^{11} ions/cm^2 for ^{222}Rn.

The implantations were performed at low energy, so that the noble gas atoms were concentrated in the region immediately adjacent to the oxide surface; thus nearly 99% of the $^{125}Xe^+$ implanted at 5 keV came to rest in the first 80Å of oxide (3). Anodic tantalum oxide has a density of 8.03 (9), and so, assuming it is stoichiometric Ta_2O_5, it can be calculated that each angstrom contains 7.63×10^{14} tantalum and oxygen atoms/cm^2. The implantation of 10^{12} ions/cm^2 of $^{124}Xe^+$ and $^{126}Xe^+$ then produces a maximum concentration of 262 xenon atoms per million matrix atoms, while activity measurements show that the maximum concentration of the radioactive ^{125}Xe is less than 8 atoms per million.

Such concentrations are minute, particularly when compared to the 1700 atoms per million of sulfur impurity incorporated from the 0.1M H_2SO_4 electrolyte (10). The latter has no detectable effect on the properties of the oxide (1), and so it would seem reasonable to suppose that the noble gases would behave likewise. Evidence for this has been presented elsewhere (2), where it has been shown that implantation fluences up to 10^{13} ions/cm^2 have no detectable effect on the anodic oxidation or on the oxide dissolution rate. Since the noble gases are implanted, they must come to rest at the end of a damage trail; no effect that could be attributed to radiation damage has been detected (2). All in all, therefore, radioactive noble gas markers behave as though they were effectively inert.

Previous arguments (5) supporting the immobility of noble gas markers can be summarized as follows. Of all the possible atomic markers, the noble gases are the least likely to exist as charged species in the oxide matrix, and hence are the least likely to move under the influence of the strong electric field present during anodization. The heavier gases, at least, should be very much larger than the tantalum and oxygen atoms surrounding them, and should therefore diffuse more slowly; evidence was presented to show that they did not thermally diffuse in the static oxide. Probabilistic arguments of this kind are, however, unsatisfactory; in particular, no evidence could be cited to support the neutrality of the noble gases within the oxide, and no evidence could be cited to support the absence of diffusion in the growing oxide.

The application of criterion (*a*) to results already obtained with ^{125}Xe (5) and ^{222}Rn (11) tends to support the immobility of these markers. In these experiments, the noble gas atoms were implanted at 5 keV (^{125}Xe) and 6 keV (^{222}Rn) into chemically polished tantalum, which is now known to be covered with a layer of thermal oxide some 30Å thick (12); from the range studies reported elsewhere (3), therefore, half the noble gas was implanted in this oxide and half in the underlying metal. The specimens were then anodized, and the position of the noble gas within the final oxide determined by β-ray spectroscopy (13) for ^{125}Xe and by α-ray spectroscopy (14) for ^{222}Rn. The measured values of t_0 were 0.71 ± 0.03 and $0.74 \pm 0.02_5$, respectively, which agree within experimental error; criterion (*a*) is thus satisfied. No test under criterion (*b*) is possible, since β-ray spectroscopy provides no information at all on the concentration profile, while α-ray spectroscopy is insensitive to small changes. The latter did, however, show that all the ^{222}Rn finished up in approximately the same place, and hence that the ^{222}Rn implanted in the metal behaved in the same way as that implanted in the oxide.

What was required, therefore, was an accurate method for measuring the noble gas concentration profiles, so that both criteria could be used to establish their immobility. Such a method is provided by the sectioning technique discussed in previous papers (1-3).

Experimental Procedure

Data collection.—Tantalum coupons, $3.5 \times 1.0 \times 0.037$ cm^3 were cut from sheet supplied by the Fansteel Metallurgical Company, and a 0.05 cm diameter tantalum wire spot welded on one corner to provide electrical contact. The coupons were cleaned, chemically polished, and dipped in concentrated HF almost saturated with NH_4F to remove any film left by the chemical polish (1, 15). They were then anodized, normally to a thickness of about 880Å, and wrapped in household aluminum foil, leaving the middle 2.0×0.4 cm^2 of one face exposed. Radioactive noble gas ions were implanted into the exposed portion at an energy of 2 keV (^{41}Ar) or 5 keV (^{79}Kr, ^{125}Xe, and ^{222}Rn), and the coupons reanodized to the final thickness, normally 3000Å. All anodizations were performed at 1 mA/cm^2 in 0.1M H_2SO_4 at 25°C, using a constant current apparatus devised by Walker (16). Integrated concentration profiles, as illustrated in Fig. 2, were obtained by means of the procedure elsewhere described (3).

The initial thickness was standardized at 880Å as this was close to the bottom of the continuously measurable range (1). Low implantation energies were chosen to obtain the best compromise between a narrow profile and a complete normal distribution (3); the former enabled small changes in the breadth to be detected, while the latter made for more accurate analysis of the concentration profiles. To make the transport number measurements as precise as possible, it was necessary to anodize to a large final thickness. When the initial thickness was 880Å and the final thickness 3000Å, the noble gas was found with a normally distributed profile at about 2450Å from the metal/oxide interface (Fig. 2).

Analysis of concentration profiles using normal distributions.—The PDP-5 program used to process the counting data in the previous paper (3) was replaced by an improved version written for a CDC G-20 computer. This corrected the N observed counts, $I = 1,2,.....N$, for counter dead time, background, and decay, and expressed the results as percentages, $Y(I)$, of the initial count; it also calculated the corresponding standard error, $EY(I)$, from the square root of the observed counts. The oxide thickness remaining, $X(I)$, was computed in angstroms by interpolation from the calibration in (1); its standard error, $EX(I)$, was taken as 0.067 times the difference between the two "kick" wavelengths (1), rather than 1.8Å as in (3). The quantities $X(I)$, $Y(I)$, $EX(I)$, and $EY(I)$ were then printed

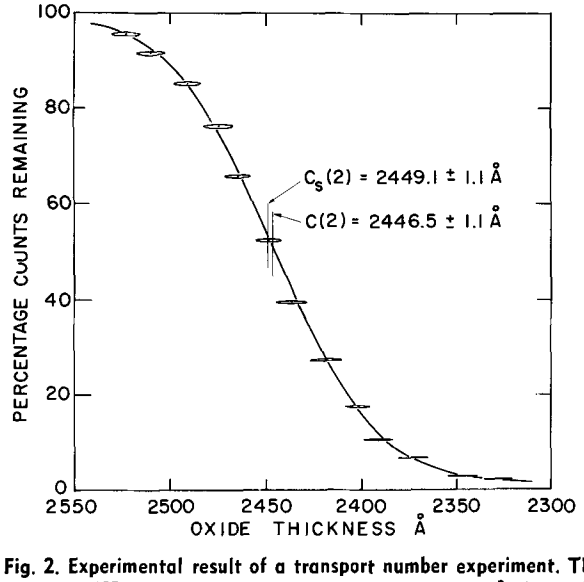

Fig. 2. Experimental result of a transport number experiment. The marker was ^{125}Xe implanted at 5 keV into an oxide 885Å thick, the oxide being subsequently reanodized to 3024Å. On sectioning, the integrated profile shown was obtained; 95% confidence limits have been drawn around each experimental point. The smooth curve is an error function complement, which on differentiation gives the normal distribution describing the concentration profile itself. The significance of C(2) and $C_s(2)$ is discussed in the text.

out, plotted out as in Fig. 2, and punched out on IBM cards for subsequent analysis by the fitting programs.

The purpose of the analysis was to compare the concentration profiles of the noble gases before and after the anodization event. To that end, the experimental data were analyzed for two parameters; one defining the noble gas position, and the other its dispersion about that position. The initial range profiles could be adequately fitted by a normal distribution (3), in which the mode defined the position and the standard deviation the dispersion. Fortunately, the concentration profiles after anodization could also be fitted by a normal distribution, and so the parameters before and after were directly comparable.

The experimental data describe the integrated concentration profile, and so the function least squares fitted (3) was the integrated normal distribution

$$\mathrm{YFIT}(I) = \frac{C(1)}{2} \cdot \mathrm{erfc}\left(\frac{\mathrm{XFIT}(I) - C(2)}{\sqrt{2} \cdot C(3)}\right) + B \qquad [7]$$

where $C(1)$ is a normalizing factor, approximately equal to $Y(1)$; $C(2)$ is the mode of the distribution, and $C(3)$ its standard deviation; $\mathrm{XFIT}(I)$ and $\mathrm{YFIT}(I)$ are the fitted values of $X(I)$ and $Y(I)$, respectively; and B is a background correction.

Since the noble gases were implanted at low energy, the background correction needed was that for the 40 keV neutral tail (3), which has the form

$$B = \frac{C(4)}{2} \cdot \mathrm{erfc}\left(\frac{\mathrm{XFIT}(I) - C(2) - (r_{40} - r)}{\sqrt{2} \cdot \sqrt{(\sigma_{40})^2 + (C(3))^2 - \sigma_i^2)}}\right) \qquad [8]$$

where $C(4)$ is a normalizing factor, similar to $C(1)$; r_{40} is the modal range and σ_{40} is the standard deviation of the noble gas implanted at 40 keV; r is the modal range, and σ_i the standard deviation at the implanted energy.

Values for r_{40}, σ_{40}, r, and σ_i were obtained from the range studies reported in the previous paper (3), and best values for the four parameters $C(1)$, $C(2)$, $C(3)$, and $C(4)$ computed from the fit.

The form of the final concentration profile is determined by the action of the broadening process on the initial profile. Since both initial and final concentration profiles can be analyzed as normal distributions, it follows that the broadening process must also give rise to a normal distribution. Accordingly, the final standard deviation $C(3)$ can be expressed as the sum of components

$$(C(3))^2 = \sigma_i^2 + \sigma_{bn}^2 \qquad [9]$$

where σ_{bn} is the standard deviation associated with the broadening.

Correction for truncation of initial range profiles.— Although the final concentration profiles could all be adequately fitted by a normal distribution, it is nonetheless certain that this cannot be the correct description. As discussed elsewhere (3), the initial range profiles are probably not normal distributions, but can be treated within experimental error as though they are. In any event, they are not complete normal distributions because they are truncated by the oxide surface. Normal broadening of a truncated normal distribution leads , as in Fig. 3, to a final profile that is almost, but not quite, normal; the departure from normality will increase with increased truncation and decrease with increased broadening. Experimentally, the truncation was less and the broadening more than that for the sample illustrated, and so the departure from normality was actually very small. Nevertheless, it was significant for the experimental accuracy achieved here, and therefore had to be taken into account.

The most striking feature of Fig. 3 is that the mode of the fitted normal distribution does not coincide with the mode of the initial distribution. As the broadening increases, it corresponds more and more to the initial

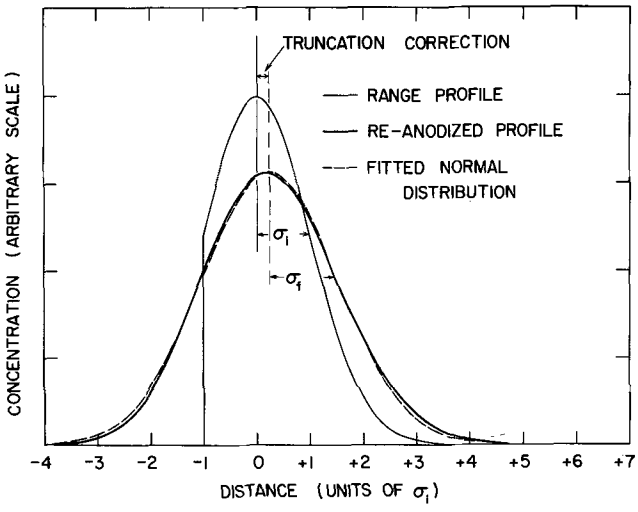

Fig. 3. Relationship between the initial truncated range profile, the same profile broadened after further anodizing, and the corresponding fitted normal distribution. The mode of the fitted normal distribution does not coincide with the mode of the initial profile, and so a truncation correction is required. In the example shown, the standard deviation associated with the broadening, σ_b, was taken equal to σ_i.

mean rather than the mode. The parameter $C(2)$ is therefore in error, and hence $C(3)$ is also in error. An attempt to define the correct mathematical function led to an integral that could not be evaluated analytically, and so the function was simulated numerically by the procedure illustrated in Fig. 4.

The initial concentration profile was divided into elements of equal width, and then simulated by the equivalent histogram shown in the top section of Fig. 4. An initial profile in the form of a line element was assumed to broaden to a normal distribution, and this too was simulated by the equivalent histogram shown in the center section. By summing the broadened histograms for each element in the initial histogram, the final profile could be obtained as illustrated at the bottom of the figure. Despite the crudeness of the ex-

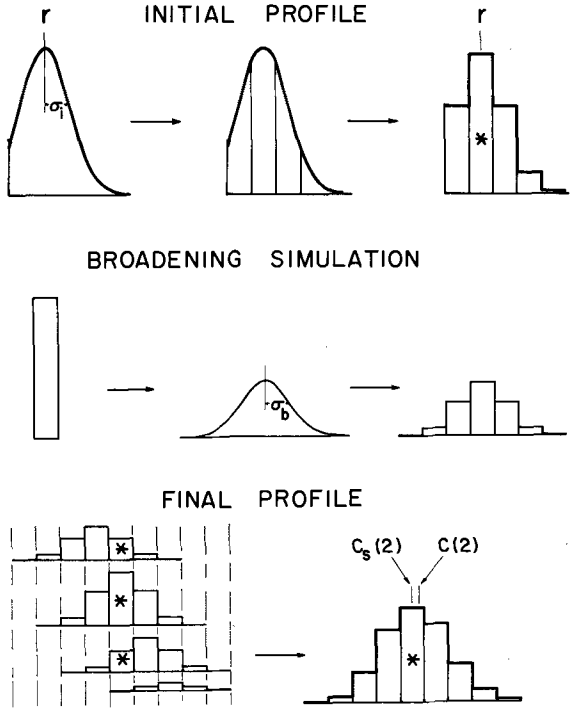

Fig. 4. Simulation of the broadening for a truncated normal distribution. The * indicates the element corresponding to the original mode.

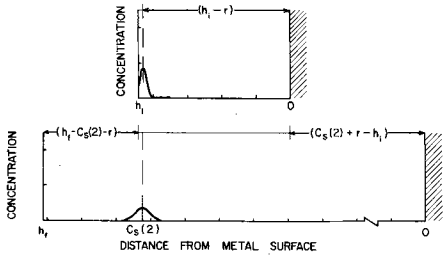

Fig. 5. Diagram illustrating the position of a noble gas marker before (above) and after (below) further anodization, and the quantities required for the calculation of transport number.

ample, the final histogram is obviously close to a normal distribution, and the shift in the mode is readily apparent. For the purpose of computation, the initial profile was split up into elements 1Å wide; the reanodized profile in Fig. 3 is an example of the results, computed with a standard deviation for broadening, σ_b, equal to $\sigma_i = 10$Å.

By summing the elements of the final histogram in succession, starting, in Fig. 4, from the right-hand end, the integrated concentration profile can be obtained. The shape of this is determined by the relative magnitudes of r, σ_i, and σ_b; the first two are known from the range measurements while σ_b is a parameter, $C_s(3)$, that must be fitted. To make a least squares fit through the experimental points, a normalizing factor, $C_s(1)$, is required as before for matching to the $Y(I)$, and a positioning factor, $C_s(2)$, for matching to the $X(I)$. The positioning factor here corresponds exactly to the mode of the initial profile, and so no truncation correction is needed. Finally, a background correction for the neutral tail, involving the adjustable parameter, $C_s(4)$, was made in the same way as before, using a slightly modified version of Eq. [8]. The least squares fitting procedure was then applied to obtain best estimates for $C_s(1)$, $C_s(2)$, $C_s(3)$, and $C_s(4)$, together with their errors. It should be noted that while $C_s(1)$, $C_s(2)$, and $C_s(4)$ are essentially the same as $C(1)$, $C(2)$, and $C(4)$, $C_s(3)$ is not the same as $C(3)$; the former is the standard deviation for the broadening alone, and thus corresponds to σ_{bn} in Eq. [9].

The experimental data were fitted by both the integrated normal distribution and the simulated distribution to see which gave the better fit. No distinction was possible, however, since the fitting probabilities determined from the χ-square test were virtually identical. All fits, except one for ^{222}Rn, were acceptable; that is, $p(\chi^2)_{N-4}$ was greater than 0.025 (3).

Calculation of transport numbers and their errors.—Assuming that the noble gases are ideal markers, the parameter $C_s(2)$ provides a measure of the transport numbers. Writing h_i for the initial oxide thickness and h_f for the final oxide thickness, it can be shown, as in Fig. 5, that the oxide thickness formed outside the marked layer due to tantalum migration is $h_f - C_s(2) - r$. Similarly, the thickness formed underneath the marked layer due to oxygen migration is $C_s(2) + r - h_i$. The transport numbers for the tantalum, t_m, and oxygen, t_o, are therefore

$$t_m = (h_f - C_s(2) - r)/(h_f - h_i)$$
$$t_o = (C_s(2) + r - h_i)/(h_f - h_i) \quad [10]$$

and the standard error in each of these ratios is

$$\epsilon_t = \sqrt{[(C_s(2) + r - h_i)^2 \cdot (\epsilon(h_f))^2 + (h_f - C_s(2) - r)^2 \cdot (\epsilon(h_i))^2 + (h_f - h_i)^2 \cdot (\epsilon(C_s(2) + r))^2]/(h_f - h_i)^2} \quad [11]$$

where

$$\epsilon(h_f) = \sqrt{[(0.00144h_f)^2 + EHF^2]}$$
$$\epsilon(h_i) = \sqrt{[(0.00144h_i)^2 + EHI^2]}$$
$$\epsilon(C_s(2) + r) = \sqrt{[(0.00144C_s(2))^2 + (EC_s(2))^2 + ERA^2]}$$

and EHF is the measured random error in h_f, EHI the measured random error in h_i, $EC_s(2)$ the computed error in $C_s(2)$, and ERA is the computed error in r obtained from previous work (3).

The first term in the errors $\epsilon(h_f)$, $\epsilon(h_i)$, and $\epsilon(C_s(2) + r)$ is, in effect, a systematic error due to uncertainty in the exact value for the refractive index; the factor of 0.00144 is calculated (1) from data by Young. These systematic errors are not independent of one another, but have been treated in the derivation of Eq. [11] as though they are: ϵ_t is therefore somewhat of an overestimate.

Results

Experiments were performed with the radioactive isotopes ^{41}Ar, ^{79}Kr, ^{125}Xe, and ^{222}Rn and the results are listed in Tables I, II, and III. The experiments with radon must be considered less reliable than the others for reasons which are unknown (3).

Error in transport number measurements.—Tables I and II show that the fluctuations in the measured transport numbers are generally consistent with the standard errors calculated from [11].

Variation of transport number with noble gas position in initial oxide.—Mechanisms IV and V require such variation; mechanisms I, II, and III do not. This was studied by implanting 5 keV ^{125}Xe into various thicknesses of initial oxide. Since the xenon was always implanted to the same depth, varying the initial oxide thickness was equivalent to varying its relative position within the oxide. Examination of Tables I and II shows that the transport numbers did not vary significantly with initial position of the noble gas.

Variation of transport number with increasing oxide thickness on reanodization.— Mechanism V predicts such variation while none of the others do. Table I shows that no variation was observed.

Table I. Variation of σ_b and t_o with $(h_f - h_i)$

Anodic tantalum oxide implanted with 5 keV ^{125}Xe (r = 30.0 ± 2.0A, σ_i = 20.2 ± 0.7A) and reanodized at 1 mA/cm² and 25°C in 0.1M H_2SO_4. Data obtained by least squares fit of a truncated normal distribution that had been broadened by the procedure in Fig. 4 using elements 1A wide; fits acceptable if $p(\chi^2)_{N-4} > 0.025$ (3). All thickness measurements have been rounded to the nearest angstrom, which is why they do not sum properly. Standard errors quoted.

[a] Parameters quoted are for 2 keV ^{42}K (3).
[b] Range very small compared to results quoted in (3); measured in same implantation as that used for the reanodization experiments.
[c] Illustrated in Fig. 2.
[d] Specimen originally anodized to 2031Å and then stripped back to 885Å in order to remove the layer containing sulfur species (9).
[e] Range unusually large; reason not known (3).

Variation of profile broadening with increasing oxide thickness on reanodization.—Mechanisms I, II, and III predict no broadening, IV that the breadth of the marker profile will vary as h_f, and V that the increase in the profile breadth will vary as $(h_f - h_i)$.

Table I shows that there is a broadening, but that it is definitely not proportional to h_f. To find out if the increase was proportional to $(h_f - h_i)$, the last eight samples of Table I were fitted to an equation of the form

$$(C(3) - \sigma_i) = c \cdot (h_f - h_i) \qquad [12]$$

where $C(3)$ is used in place of $C_s(3)$ because it is the observed breadth of the profile that is being tested. The proportionality constant, c, was found to be 0.0095 ±0.004, but $p(\chi^2)_7$ was far less than 0.001; the fit was therefore unacceptable. Accordingly, the broadening is not proportional to $(h_f - h_i)$ either.

The same samples were, however, successfully fitted by an equation of the form

$$C_s(3) = \beta \cdot \sqrt{(h_f - h_i)} \qquad [13]$$

with $\beta = 0.835 \pm 0.011$, and $p(\chi^2)_7 = 0.135$; the latter is well above the 0.025 rejection level (3).

Variation of transport number with noble gas used.—If the noble gases are truly immobile, then, by criterion (*a*), the transport numbers measured with the different gases should be identical. The data in Tables II and III, however, suggested that there was a slight variation. To find out whether this variation was significant, the statistical *t* test was applied as follows. Assuming that there were no significant differences between the individual variances for t_o, a pooled estimate for the variance was obtained from

$$S^2_{t_o} = \sum_I [(n_I - 1) \cdot S^2_I] / [\sum_I n_I - 3] = (0.00127)^2 \qquad [14]$$

Table III. Summary of the positioning, t_o, and broadening, β, parameters for the noble gases

Values of t_o are arithmetic means of the data in Table II, quoted with the standard deviation about those means; β and its extrinsic error are obtained from least squares fits of $\sigma_b = \beta \cdot \sqrt{(h_f - h_i)}$ to the same data. All fits were acceptable; i.e., $p(\chi^2)_{N-1} > 0.025$.

Noble gas	t_o	β
^{41}Ar	0.7413 ± 0.0017	1.196 ± 0.013
^{79}Kr	0.7432 ± 0.0011	1.005 ± 0.003
^{125}Xe	0.7461 ± 0.0012	0.821 ± 0.007

where I = Ar, Kr, Xe; n_I are the number of measurements with each gas and S^2_I are the individual variances. Three test values τ were then formed by

$$\tau_{I,J} = (t_{oI} - t_{oJ}) / [S_{t_o} \cdot \sqrt{(1/n_I + 1/n_J)}] \qquad [15]$$

where I, J = Ar, Kr, Xe and I ≠ J. The probability, $p(\tau_{I,J})_F$, of obtaining a value of τ as great or greater than $\tau_{I,J}$ was then computed for $F = n_1 + n_J - 2$ degrees of freedom, and found to be

$$p(\tau_{Ar,Kr})_2 = 0.139$$
$$p(\tau_{Kr,Xe})_5 = 0.020$$
$$p(\tau_{Xe,Ar})_5 = 0.003 \qquad [16]$$

Since both the second and the third probability is less than the acceptance level of 0.05 for a one tailed test, the differences between argon and xenon, and krypton and xenon, are statistically significant.

Variation of profile broadening with noble gas used.—If the noble gases are truly immobile, then, by criterion (*b*), their profiles should either not broaden at all, or they should all broaden equally. Tables II and III show that although they all broaden, they do not do so equally.

Discussion

The results obtained, therefore, are consistent with none of the mechanisms presented earlier, and the noble gases do not meet the criteria for immobile markers. They must therefore be mobile, and the nature of their mobility must be elucidated before the oxidation mechanism can be discussed.

Characteristics of profile broadening.—Two features of the broadening process have been established experimentally. First, the broadening can be described in terms of a normal distribution, and second, the standard deviation for the increase in the profile breadth, σ_b or $C_s(3)$, is proportional to $\sqrt{(h_f - h_i)}$. Since more than one broadening process may occur, σ_b can be expressed in terms of its components by

$$\sigma_b^2 = \sum_{j=1}^{n} \sigma_j^2 \qquad [17]$$

where σ_j is the standard deviation associated with the *j*th process. Because of the squared dependence, the value of σ_b is determined mainly by the magnitude of the largest σ_j, and so this must also vary as $\sqrt{(h_f - h_i)}$.

In fact, the broadening must be due to at least two processes. Measurement of the concentration profiles by means of the sectioning technique involves the removal of thin oxide layers, and inevitably these will not be completely uniform. If nonuniform layers are being removed, the measured profile will be broader than the real one. This type of broadening must occur to some extent, but it is obviously not the dominant process; for if it were, the noble gas profiles would all broaden equally. The nature of the nonuniformities has been studied in a previous paper (1), where it was shown that they are so small as to be effectively negligible for the measurement of concentration profiles. The observed broadening must, therefore, be due to some other process, or group of processes, that depends on the nature of the noble gas itself.

Interpretation of profile broadening.—If the noble gases are mobile, they must be undergoing some form of diffusion. This would account very well for the dependence on $\sqrt{(h_f - h_i)}$, and for the normalcy of the profile broadening. The dependence on $\sqrt{h_f - h_i}$ shows that the diffusion takes place only during anodization, thus confirming that thermal diffusion in the static oxide is negligible (5). Such diffusion could occur in at least three ways, as illustrated in Fig. 6.

(i). The noble gas atoms could be forced to diffuse under the influence of the applied field because they are charged. Since they differ in size and mass, and presumably also in degree of ionization, they may be expected to diffuse at substantially different rates. They would therefore finish up at markedly different positions in the final oxide, and so the transport numbers actually measured would depend on the noble gas used.

As a first approximation, one may assume that noble gas ions diffuse in the same way as the tantalum and oxygen ions. The first question is whether the latter jump from one lattice site to the next, or whether they jump several lattice sites at a time. Evidence presented in the next paper (4) will show that the oxygen ions, at least, jump a distance corresponding to not much more than one interoxygen distance; no evidence is presently available on the migration of the tantalum ions.

The proposed model, then, is that shown schematically at the top of Fig. 6. Here the charge transfer event is the movement of an individual ion from one lattice site to the next as space becomes available, and so the migration of tantalum and/or oxygen ions is balanced by a flow of vacancies in the opposite direction. The concepts of "vacancy" and "lattice site" are rather difficult to define in an amorphous solid such as anodic tantalum oxide, but the usual concepts will serve as a basis for the present discussion.

Some rather simple arguments can be used to predict the profile broadening that would result from such

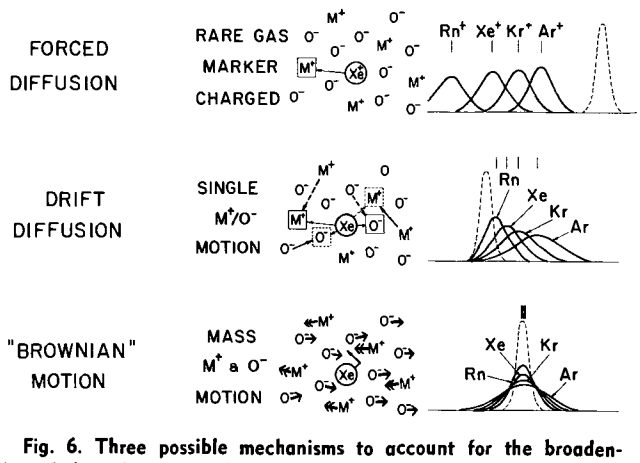

Fig. 6. Three possible mechanisms to account for the broadening of the noble gas profiles on further anodizing. The applied field is such that the metal atoms migrate to the left, oxygen to the right.

diffusion. In discussing the "high field approximation" for the motion of an ion in anodic oxide, Young (17) noted that the most probable jumps would be those in directions close to the axis of the field, and in the forward direction; the probability of a jump in a backward direction, against the field, would be remote. The concentration of the jumps around the forward axis of the field would mean that if the jump distance was a, the average distance jumped along this axis would also be close to a, and hence almost constant from jump to jump. For simplicity, it may be assumed that the jump distance along the axis of the field is constant and equal to a.

Under these conditions, the mean distance diffused by the noble gas atoms will be $a \cdot n$, where n is the mean number of jumps made. The constancy of the transport numbers in Table I requires that the distance diffused, d, be proportional to the thickness added during anodization, so that

$$d = k \cdot (h_f - h_i) = a \cdot n \qquad [18]$$

where k is a constant of proportionality. The root mean square deviation about this mean will be equal to the square root of the sum of the variances in n and a; the latter is of course zero since a has been assumed constant. For a series of uncorrelated jumps, n follows a Poisson distribution with mean and variance both equal to n; if n is large, the Poisson distribution approximates to a normal one. The standard deviation for the normally distributed profile broadening, σ_b, can then be equated with the root mean square deviation in the distance traveled, so that

$$\sigma_b = a \cdot \sqrt{n} \qquad [19]$$

provided n is large. Substituting [18] into [19]

$$\sigma_b = \sqrt{(a \cdot k)} \cdot \sqrt{(h_f - h_i)} \qquad [20]$$

so that σ_b has the observed dependence on $(h_f - h_i)$.

Combining [18] and [19] for two different gases, say argon and xenon, gives

$$d_{Ar} - d_{Xe} = (\sigma^2_{Ar} - \sigma^2_{Xe})/a \qquad [21]$$

since the proposed mechanism requires that a be the same for all gases. The left-hand side of this equation is equivalent to $-(t_o(Ar) - t_o(Xe)) \cdot (h_f - h_i)$; substituting [13] into the right-hand side, and eliminating $(h_f - h_i)$ gives

$$-(t_o(Ar) - t_o(Xe)) = (\beta^2_{Ar} - \beta^2_{Xe})/a \qquad [22]$$

in which the only quantity not determined experimentally is a. When the values listed in Table III are substituted into this equation, a is found to be 160Å, which is an absurd result for the model chosen. To put it another way, if a is to be the expected interatomic distance of about 3Å, Eq. [22] requires that either $|t_o(Ar) - t_o(Xe)|$ be about 0.25, or that β^2_{Ar} be nearly equal to β^2_{Xe}; both possibilities are far outside the experimental error in the results. The noble gases do not therefore move by jumping one interatomic distance at a time.

The possibility remains that they might move more than one interatomic distance at a time; for example, they might actually move 160Å at a time. Given the values for σ_b in Tables I and II, it follows from [19] that n would be considerably less than unity in all cases. Few of the noble gas atoms would therefore move, and they would form a satellite normal distribution 160Å to one side of the original range profile. Similar arguments can be advanced to eliminate other distances.

In deriving [22], it was assumed that the jumps were all in the same direction, and that they were all of equal length. Neither of these assumptions is strictly true, but small departures therefrom will not affect the conclusions reached. Large departures mean that the physical picture of the motion is not as presented;

any other form of forced diffusion seems much less probable. Accordingly, forced diffusion can be eliminated as a possibility.

(*ii*). The noble gas atoms could diffuse via a vacancy mechanism even if they were uncharged. If they are to diffuse at all, they must be capable of jumping into neighboring vacancies, and if they are uncharged, it seems reasonable to suppose they would jump with equal probability in all directions. In making their jumps, however, the noble gas atoms would have to compete for oxygen vacancies with neighboring oxygen ions, and the latter, being charged, would have a marked preference for jumping downfield. The noble gas atoms would therefore tend to jump in the same direction because, as indicated in the middle of Fig. 6, there would be less oxygen competition for the vacancy labeled by the solid square than for that labeled with the pecked square. Similar arguments can be applied to the metal vacancies, and so the net movement of the noble gas atoms would be determined by a combination of the two processes.

The charge transfer event is therefore the same as before, and the noble gas atoms can be regarded as drifting along in the wake of the moving ions, instead of racing with them. Except in the event that the drifts in the two directions are equal, there will be a net motion of the noble gas atoms in one direction or the other. Movement of the different noble gases will depend as before on their size and mass, and so the measured transport numbers will again depend on the noble gas used.

For the drifts in both directions to be equal, the ratio of the probabilities for jumping into tantalum and oxygen vacancies must be equal to the inverse ratio of the corresponding jump distances. Such a cancellation would be highly unlikely for even one gas, and would be impossible for four. The noble gases would almost certainly jump into one kind of vacancy alone, and then only if it was immediately downfield. The mathematics would thus be the same as for forced diffusion, and so the same conclusion applies; it, too, must be rejected.

(*iii*). A third possibility for the diffusion of the noble gas atoms arises if charge is transported through the oxide by the simultaneous movement of a group of atoms. In this model, illustrated at the bottom of Fig. 6, each moving atom carries a fraction of the charge a fraction of a "lattice spacing" in such a way that the total effect is equivalent to one charged atom jumping one "lattice spacing." Both tantalum and oxygen take part in this process, so that the lattice loses its rigidity during the charge transfer event. A noble gas atom situated in the middle of a group of moving tantalum and oxygen atoms must collide with them, and will therefore be subjected to a form of Brownian motion.

True Brownian motion occurs when a particle undergoes a series of displacements, the displacements being of random length and direction. Mathematically, the process can be described as a random walk, whose properties are well known (18). The mean position of such particles remains unchanged, but their dispersion about that mean position increases in proportion to the square root of the time; the concentration profile therefore broadens, and the broadening follows a normal form. Furthermore, it can be shown that the broadening should be approximately proportional to the square root of the reciprocal of the particle radius; that is, the concentration profile of the smallest particles should broaden most. This has been confirmed experimentally for colloidal particles in water (18).

The most familiar illustration of Brownian motion is that discovered by Brown himself; pollen grains suspended in water undergo continual random displacements due to fluctuations in the number of water molecules striking them from each direction. The proposal here, then, is that noble gas atoms embedded in anodic Ta_2O_5 undergo similar displacements during anodization, due to collisions with the moving tantalum and oxygen atoms. At constant current, the increase in the oxide thickness, $(h_f - h_i)$, is directly proportional to the anodization time; since the profile broadening is observed experimentally to be proportional to $\sqrt{(h_f - h_i)}$, it is also proportional to the square root of the time, as required. Furthermore, the profile of the smallest and lightest gas, ^{41}Ar, shows the greatest degree of broadening, again as required.

There is, however, one important difference between ordinary Brownian motion and that postulated here. Water molecules striking the pollen grains have a truly random motion of their own, and so the pollen particles may be expected to behave likewise. In the anodic oxide, however, the motion of the tantalum and oxygen atoms will be largely aligned with the axis of the electric field, the tantalum ions jumping toward the oxide/electrolyte interface, while the oxygen ions jump in the opposite direction. Under these conditions, the noble gas displacements can hardly be random; the inevitable consequence would be a small net motion superimposed on the random component. Once again, therefore, the transport numbers actually measured would depend on the noble gas used.

The magnitude of this net migration is impossible to predict, but since it is a consequence of the broadening process, it would presumably be very small. If so, the differences between the various noble gases would also be very small, as observed experimentally. Calculations based on the data in Table III show that the difference between the argon and xenon positions is 9.6 ± 3.8Å after reanodization by 2000Å, whereas the corresponding difference in the standard deviations is 16.8 ± 0.5Å.

The broadening of the noble gas concentration profiles on further anodizing is therefore attributed to a form of Brownian motion.

Validity of noble gases as inert, immobile markers.—If this Brownian motion hypothesis is true, no markers will be immobile during anodic oxidation of tantalum. All will be subjected to this form of Brownian motion, and so all will have a net migration imposed on their random fluctuations. As the markers get bigger and heavier, the fluctuations will decrease, and hence the magnitude of the net migrations will also decrease. The differences in migration rate will therefore decrease until they are no longer experimentally detectable as differences in the measured transport numbers. At this point, the markers will behave as though they were effectively immobile; but they may by then be so large that they are no longer effectively inert. That is, their geometric interference with the oxidation system may be so great that the final position of the marker depends not on its migration, but on its size. Results by Sachs (19) appear to illustrate this phenomenon experimentally.

In these circumstances, therefore, no truly inert, immobile marker for the system exists. The best that can be done is to find that set of markers that obeys criteria (*a*) and (*b*) most closely. Noble gas markers do obey these criteria rather closely, but it is uncertain, in the absence of comparable information on other possible markers, whether they obey the most closely.

Best estimates for transport numbers.—The data in Table III can be corrected for marker migration by assuming that the distance migrated is directly proportional to the standard deviation for the broadening. It is then possible to extrapolate the β *vs.* t_o data to $\beta = 0$, and hence calculate t_o for a noble gas marker that undergoes no broadening at all; that is, one which undergoes no Brownian motion, and is therefore truly immobile.

Three points are insufficient for a satisfactory least squares fit to a straight line, but graphical extrapolation gave $t_o = 0.757$, with a standard error that may be estimated as about 0.003. This can be taken as the best estimate for the transport number of oxygen in anodic tantalum oxide under the conditions stated;

25°C, 1 mA/cm², 0.1M H_2SO_4 electrolyte, and reanodization to add approximately 2000Å. The transport number of the metal is therefore 0.243 ± 0.003.

Transport mechanism in anodic tantalum oxide.—If the broadening of the marker profiles can be accounted for entirely on the basis of Brownian motion, mechanisms IV and V in Fig. 1 must be eliminated. Since the transport numbers are not 1 and 0, mechanisms I and II must also be eliminated. Accordingly, the transport mechanism is best described by III, in which the new oxide is formed at the metal/oxide and oxide/electrolyte interfaces only.

Conclusions

1. A marker used for measuring transport numbers during the oxidation of a metal must be both immobile and inert. Any inert immobile marker will behave in exactly the same way as any other inert immobile marker.
2. This definition has been used to test the suitability of the radioactive noble gas markers, ^{41}Ar, ^{79}Kr, ^{125}Xe, and ^{22}Rn during the anodic oxidation of tantalum. Although these markers are effectively inert, they are not immobile.
3. Their small mobility has been attributed to a form of Brownian motion resulting from collisions with migrating tantalum and oxygen atoms.
4. This necessarily requires that both tantalum and oxygen migrate during the anodic oxidation, and that these migrations occur simultaneously.
5. The oxide thickens through the formation of new oxide at the metal/oxide and oxide/electrolyte interfaces only.
6. Best estimates for the transport numbers of the tantalum and oxygen are 0.243 ± 0.003 and 0.757 ± 0.003, respectively, for anodizing conditions of 25°C, 1 mA/cm², 0.1M H_2SO_4 electrolyte, and 2000Å thickness of oxide added.

The significance of these conclusions will be discussed in a later paper.

Gallium Arsenide Surface Film Evaluation by Ellipsometry and Its Effect on Schottky Barriers

A. C. Adams* and B. R. Pruniaux

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

To evaluate polishing and cleaning methods for gallium arsenide, the surface film thickness is estimated by ellipsometry. For measurements made at a wavelength of 5461Å, a refractive index of 1.9 is assumed for the film, and an extinction coefficient of 0.304 is assumed for the gallium arsenide. The film thickness is found to be correlated with the cleaning method and a simple and effective cleaning procedure is proposed. The refractive index and the extinction coefficient measured at wavelengths of 4375 and 5461Å for gallium arsenide samples prepared by three commonly used polishing techniques are the same as those of freshly grown epitaxial gallium arsenide. For clean samples the thickness of the surface film increases when the gallium arsenide is exposed to air until a final thickness of about 30Å is reached after a few days. Experimental data describing the behavior of Schottky diodes on differently prepared surfaces are presented. The barrier height increases by 0.07 eV when the thickness of the film increases from 8.5 to 16Å. The reverse bias current-voltage characteristics are explained by existing interfacial layer theories. The annealing of aluminum oxide films on gallium arsenide is also reported.

The use of ellipsometry to study the chemical processing of silicon wafers has been previously described (1, 2). Because the ellipsometric measurements are rapid, nondestructive, and very sensitive to small changes in the sample surface, this technique is ideally suited for studying the surfaces which result after polishing and cleaning of semiconductiors (2). In this paper, we describe the use of ellipsometry to study and evaluate the polishing and cleaning of gallium arsenide. In addition, results on the use of ellipsometry to study thick, nonabsorbing films on gallium arsenide substrates and the behavior of Schottky diodes on differently prepared gallium arsenide surfaces are presented.

Experimental

The experimental data have been obtained with a Gaertner Model L119 ellipsometer. The light source is a 150W xenon arc lamp which is used with a Schoeffel quartz prism monochromator. A photomultiplier is used as the detector. The light source, monochromator, and ellipsometer are mounted on a metal table to reduce vibration and eliminate errors due to misalignment of the components. The measurements are made in a dark, laminar flow clean booth. The dark room is necessary to prevent spurious results due to stray light entering the detector. The clean atmosphere prevents particulate contamination of the samples during the measurements. All ellipsometric measurements have been made at an angle of incidence of 70.00° using radiation with a wavelength of 4375 or 5461Å. At both wavelengths, extinction is measured at two settings of the polarizer and analyzer (zones 1 and 3) (3), and psi and delta are calculated from these settings using the equations for nonideal compensators (4).

The samples are n-type gallium arsenide with a (100) orientation and a carrier concentration of about 1×10^{18} cm^{-3}. The Schottky diode measurements are made on epitaxial gallium arsenide deposited by the arsenic trichloride transport process; the epitaxial layers have a (100) orientation and a carrier concentration near 5×10^{15} cm^{-3}. The Schottky diodes have been formed by evaporating a gold-germanium compound [12 atomic per cent (a/o) Ge] or pure gold at a substrate temperature of 100°C to give a metal film 3000Å thick.

Procedure

The model used to interpret the ellipsometric data assumes that the substrate, which has a complex refractive index, n_2-ik_2, is covered by a nonabsorbing film that is characterized by a real refractive index, n_1, and a thickness, d. It is further assumed that n_1 is independent of the film thickness, and that the substrate-film and film-air interfaces are flat and parallel. There are four variables in this model, n_2, k_2, n_1, and d. Because the ellipsometer measures only two quantities, psi and delta, both of which may be functions of all four variables, it is necessary to independently measure the values for two of these variables before the remaining two can be calculated from the ellipsometric data. We have taken values for k_2 and n_1 from the literature and have calculated the real part of the gallium arsenide refractive index, n_2, and the film thickness, d, from the ellipsometric measurements. For measurements made at a wavelength of 5461Å, the values of k_2 and n_1 are 0.304 and 1.9, respectively. The value of k is taken from the review by Seraphin and Bennett (5) and the recent paper by Lukes (6). The film on a gallium arsenide sample which has been exposed to air is reported to be gallium oxide (7, 8) with a refractive index of 1.9 (9) or 1.8 (10, 11).

The real part of the refractive index of the gallium arsenide, n_2, and the thickness of the film, d, are obtained from the measured values of psi and delta using the curves in Fig. 1. These curves, which show the values of psi and delta for values of n_2 between 4.01 and 4.15 and for values of d between 0 and 50Å, have been calculated using the computer program written by Cox (12). The experimental points are typical data for gallium arsenide samples polished and cleaned using the methods reported in this paper. The errors caused by using $n_1 = 1.90$ and $k_2 = 0.304$ are given in Table I. If the film refractive index is between 1.50 and 2.50 and the gallium arsenide extinction coefficient is between 0.25 and 0.35, the errors caused by assuming $n_1 = 1.90$ and $k_2 = 0.304$ are less than 0.4 and 23% for n_2 and d, respectively. Although this per cent error in d is large, the absolute error in the film thickness is still less than 4.5Å. Furthermore, this is a systematic error so that differences in film thickness can still be precisely measured.

The optical constants of the gallium arsenide surfaces have also been measured at a wavelength of 4375Å. The values of psi and delta measured at 4375Å are corrected for the presence of the surface

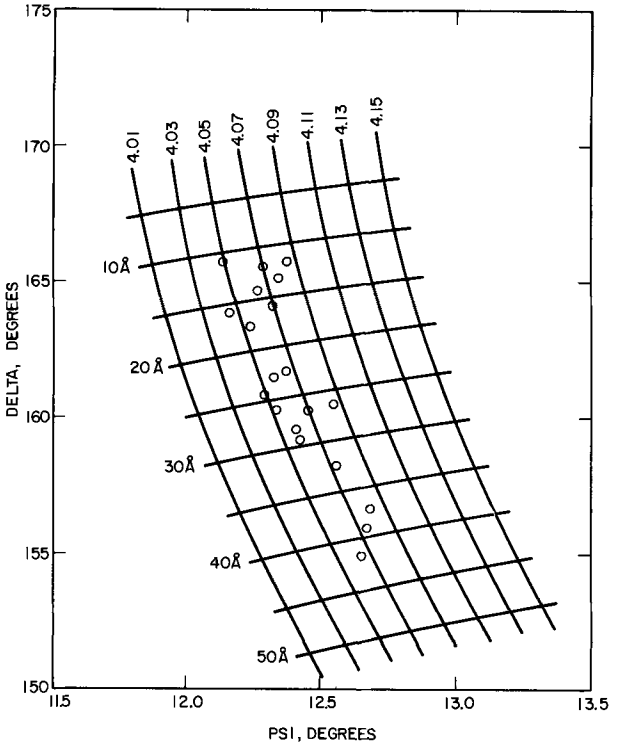

Fig. 1. Delta *vs.* psi for gallium arsenide refractive indices, n_2, from 4.01 to 4.15 and for film thickness, d, from 0 to 50Å. The curves are calculated for $k_2 = 0.304$, $n_1 = 1.90$, $\lambda = 5461$Å, and $\phi = 70.00°$.

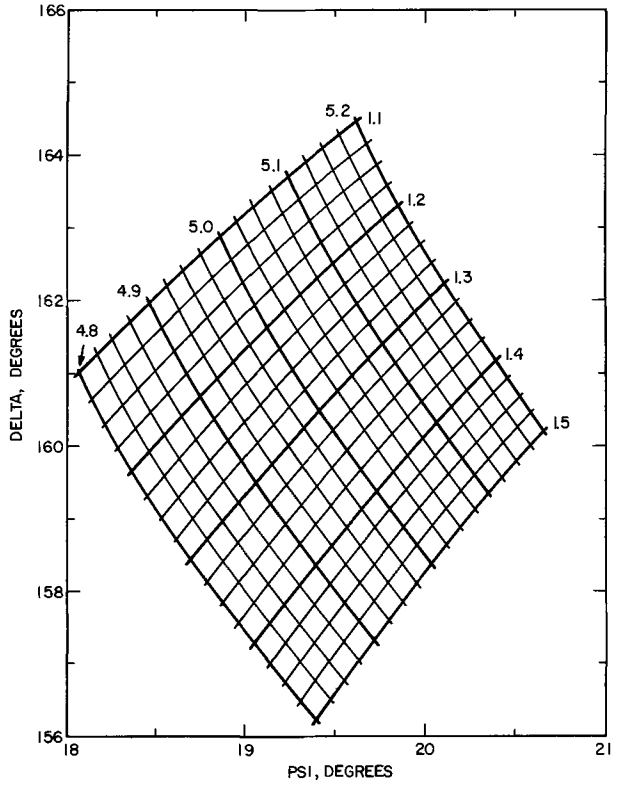

Fig. 2. Delta *vs.* psi for refractive indices, n_2 from 4.8 to 5.2 and for extinction coefficients, k_2, from 1.1 to 1.5. The curves are calculated for a film-free sample ($d = 0$) and $\phi = 70.00°$.

film using exact ellipsometric equations (13). The complex refractive index, n_2-ik_2, at a wavelength of 4375Å is determined from the corrected values of psi and delta using Fig. 2. This figure shows the values of psi and delta that would result from measurements made on clean surfaces with the real part of the refractive index between 4.8 and 5.2 and the imaginary part between 1.1 and 1.5.

The values for n_2 and k_2 obtained from Fig. 2 depend on the correction of the experimental values of psi and delta for the presence of the surface film. The magnitudes of the possible errors in n_2 and k_2 are given in Table II. The calculations presented in Table I indicate a possible error of less than 5Å in the film thickness. An uncertainty of this magnitude in the film thickness may cause an error of about 1% in the value for n_2 and about 10% error in the value for k_2.

Results

Polishing.—Values for d and n_2, which are obtained from Fig. 1, and for n_2 and k_2, which are obtained from Fig. 2, are given in Table III. Data are given for three polishing procedures and for freshly grown epitaxial samples. Each entry is an average of at least four separate experiments. Optical constants are not reported for samples polished by the hydrogen peroxide-ammonium hydroxide process because the computational procedure is not valid for samples with film thicknesses greater than about 50Å.

The values for n_2 and k_2 nearly agree with the values reported in the literature [n_2 equals 4.09 at 5461Å (5); k_2 equals 1.42 at 4375Å (5); n_2 is near a

Table I. Possible errors in n_2 and d caused by assuming values of 1.90 and 0.304 for n_1 and k_2 (calculated for $d = 20$Å, $n_2 = 4.050$, $\lambda = 5461$Å, and $\phi = 70.00°$)

n_1[a]	k_2[a]	n_2	d
1.50	0.304	4.054	17.0
1.75	0.304	4.052	19.0
2.00	0.304	4.049	20.0
2.25	0.304	4.042	19.0
2.50	0.304	4.035	18.0
1.90	0.250	4.041	15.5
1.90	0.275	4.045	17.0
1.90	0.304	4.050	20.0
1.90	0.325	4.054	22.0
1.90	0.350	4.060	23.5

[a] The tabulated values of n_1 and k_2 are used to calculate values for Ψ and Δ. Values for n_2 and d are obtained from the calculated values of Ψ and Δ using Fig. 1 which assumes that n_1 and k_2 are 1.90 and 0.304. The error is obtained by noting the deviation of n_2 and d from 4.050 and 20Å.

Table II. Possible errors in n_2 and k_2 caused by errors in the film thickness

Assumed film thickness, Å	n_2	k_2	Per cent error[a] n_2	k_2
5	4.890	1.52	4.12	26.6
10	4.965	1.42	2.65	18.3
15	5.035	1.31	1.27	9.2
20	5.100	1.20	0.00	0.0
25	5.145	1.08	0.88	10.0

[a] Values of Ψ and Δ were calculated for $n_1 = 1.90$, $d = 20$Å, $n_2 = 5.10$, and $k_2 = 1.20$. Values for n_2 and k_2 were then obtained from Fig. 2 after correcting Ψ and Δ for surface film with the different assumed thicknesses.

Table III. Gallium arsenide refractive index and the film thickness for different polishing techniques

Surface preparation	d[a]	n_2[a]	n_2[b]	k_2[b]
"Syton"-Br_2[c]	23.6	4.066	5.096	1.178
Br_2-methanol[d]	27.3	4.052	5.078	1.223
H_2O_2-NH_4OH[e]	73.6	—	—	—
Epitaxial deposit	11.0	4.050	5.073	1.215

[a] Determined from measurements made at 5461Å using Fig. 1.
[b] Determined from measurements made at 4375Å using Fig. 2.
[c] Syton is produced by the Monsanto Chemical Company; the polishing solution contains 5.7 ml bromine and 100 ml methanol in 1 liter of "Syton." The polishing rate is 10 μm/hr.
[d] Samples are polished with a 0.00916M solution of bromine in methanol. The polishing rate is approximately 1 μm/min.
[e] The samples are polished with a solution containing 1.41 ml of ammonium hydroxide in 1 liter of 30% hydrogen peroxide. The polishing rate is approximately 10 μm/hr.

maximum at 4375Å and is greater than 4.93 (5)]. There is no significant difference in the values of the optical constants for the different surface preparations. This agrees with previous work which reports that the optical constants of gallium arsenide are independent of the polishing technique (14) and that "Syton" polished samples have the same reflectance properties as epitaxially deposited samples (15).

The differences in the film thicknesses for the different polishing procedures should not be considered characteristic of the polishing process since these films can be easily removed by slight changes in the final cleaning. The cleanest surfaces have been observed in freshly grown epitaxial layers which have films that are 8-12Å thick. However, when gallium arsenide is exposed to air, the film thickness increases with time so that these thicknesses are strongly dependent on the time between the epitaxial deposition and the ellipsometric measurement. For our measurements, the epitaxial samples have been exposed to air for less than 10 min. The film that results from the H_2O_2-NH_4OH polish can be easily removed with hydrochloric acid. When the films are removed from the samples polished by the H_2O_2-NH_4OH technique, the optical constants of the resulting surfaces are the same as those reported in Table III. Except for the difference in film thickness, the ellipsometric data show that there are no differences in the surfaces produced by the three polishing methods. Furthermore, the surfaces obtained by these techniques are optically similar to the surface of an epitaxial layer.

Cleaning.—The results from several experiments to determine changes in film thickness when gallium arsenide samples are immersed in various solvents are reported in Table IV. The numbers give the film thickness in angstroms for samples immersed in the given reagent for times from 0 to 24 hr. In general, the film can dissolve giving a decrease in film thickness or the gallium arsenide can react with the reagents to produce a thicker film. The organic solvents listed in Table IV have only slight effects on the film thickness, even when the samples are immersed in the solvents for 24 hr. The film thickness is also only slightly affected when gallium arsenide is immersed in water for 5 min; however, the film thickness increases to about 100Å after 1 hr. This indicates that the gallium arsenide reacts with the water to form an insoluble film on the surface. The original films on the polished gallium arsenide samples partially dissolve in concentrated hydrochloric acid or sulfuric acid. For both reagents, the film thickness is reduced to 12 to 13Å after a 5 min treatment. However, thicker films form when the gallium arsenide remains in the sulfuric acid for 24 hr; consequently, long contact times with sulfuric acid should be avoided. Finally, hydrofluoric acid and phosphoric acid both form a reaction product on the sample surface. In the case of hydrofluoric acid, this reaction is severe since the surfaces often become stained after 1 hr.

Table IV. Film thickness for gallium arsenide samples immersed in different solvents

Reagent	Film thickness, Å 0 min	5 min	1 hr	24 hr
Trichloroethylene	25	36	33	28

Sulfuric acid[a,d]	28	12	27	206
Phosphoric acid[a,d]	30	28	32	42
Hydrofluoric acid[a,d]	17	22	230[c]	—

[a] 30 sec water rinse.
[b] 30 sec methanol rinse.
[c] Surface was stained.
[d] Acids are concentrated reagent grade.

The thicknesses reported in Table IV are calculated by assuming that the film refractive index is 1.90. This assumption is justified if the film is gallium oxide; however, other film compositions are likely for many of the reagents (gallium hydroxide, fluoride, sulfate, or phosphate are obvious possibilities, but many other compositions are also possible). However, as shown in Table I, the error in the film thickness is less than 3Å when the film refractive index is between 1.5 and 2.5. Consequently, it is believed that the thicknesses in Table IV are accurate in spite of the variation in film composition.

The data in Table IV indicate that a suitable cleaning procedure for gallium arsenide consists of rinsing the sample in organic solvents to remove possible organic contamination followed by rinsing in hydrochloric acid and then rinsing in water or preferably methanol. We have found that this procedure gives surfaces with 12-14Å of film. We have also attempted to use this cleaning procedure with hydrofluoric acid substituted for the hydrochloric acid rinse. In this case, the film thickness ranged from 18 to 40Å with most of the films being about 35Å thick. This result is consistent with the data in Table IV which shows that films form on the surface when gallium arsenide is treated with hydrofluoric acid.

We have also examined a sample after it has been heated in vacuum for 1 hr at 420°C at a pressure of 10^{-6} Torr. The film thickness decreased from 27.5 to 23.5Å, indicating that heating in vacuum under these conditions does not produce effective cleaning of the sample.

The film thickness increases when clean gallium arsenide samples are exposed to air. Data from two "Syton" polished samples cleaned with concentrated hydrochloric acid and rinsed with methanol are given in Fig. 3. As in the case of silicon and germanium (1), the thickness is a logarithmic function of time over much of the growth period. The slope of the curve is 7.2Å/decade which compares with 6.8 and 8.1Å/decade for silicon and germanium, respectively (1). After several days, a limiting thickness of about 30Å is reached.

Schottky diodes.—Data from Schottky diode experiments are given in Fig. 4-7. The samples are all n-type epitaxial layers with carriers concentrations of about 5×10^{15} cm^{-3} grown on n^+ substrates with a (100) orientation. The forward current-voltage characteristics for diodes made by evaporating a gold-germanium alloy on two parts of the same sample are shown in Fig. 4. Schottky diodes were made on E599A immediately after the epitaxial deposition; no cleaning

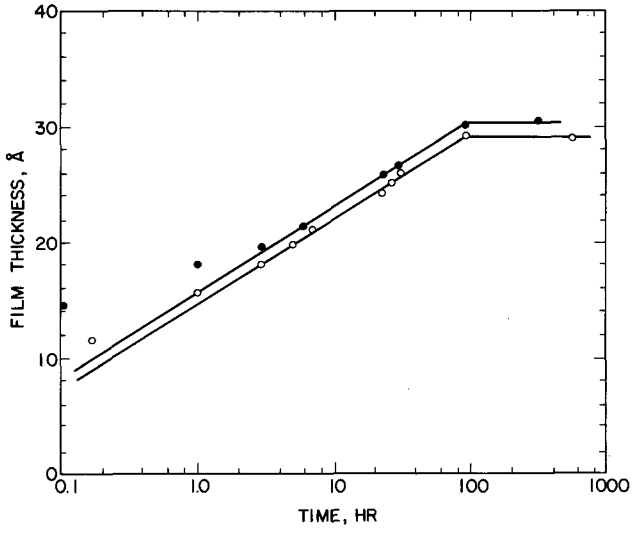

Fig. 3. Film thickness vs. log time for clean gallium arsenide samples exposed to air. The open circles are for the (111) orientation; the closed circles are for the (100) orientation.

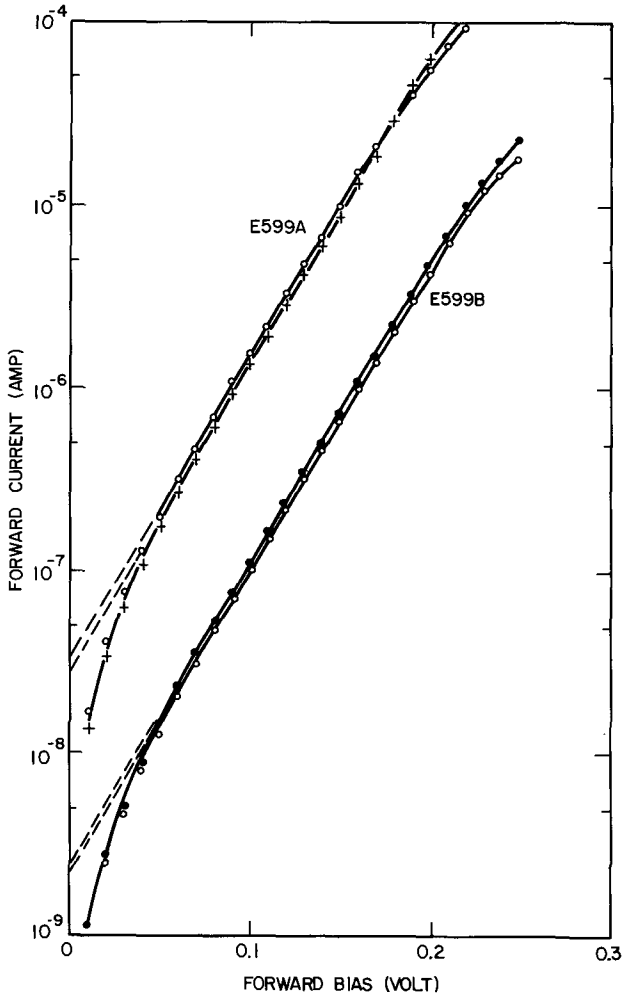

Fig. 4. Forward bias I-V characteristics of Schottky diodes deposited on two differently cleaned gallium arsenide surfaces.

of the sample was performed and a surface film 8.5Å thick was measured by ellipsometry. However, the part of the sample designated E599B was etched in bromine-methanol solution and given a "pre-epitaxy" cleaning before making the diodes, and the remaining surface film was 16Å thick. The curves show data for two diodes on each sample. The forward characteristics for both samples follow the classical thermionic emission law

$$J_f = J_s \exp\left(\frac{qV}{nkT}\right)$$

with the n factor very close to one ($n \approx 1.01$). The electronic barrier height, calculated by extrapolating the current to zero bias, is 0.58 eV for the freshly grown epitaxy and is 0.65 eV for the cleaned sample.

The reverse characteristics given in Fig. 5, are even more interesting. As in the case of the forward bias, the current for the freshly grown surface is about ten times higher than for the treated surface. Also for both samples, log J_r is proportional to the square root to the voltage (Fig. 6), as expected from the interfacial transition layer theory (16, 17). According to this theory, the slopes of the curves in Fig. 6 are given by

$$\text{slope} = \frac{\alpha}{kT}\left(\frac{2eN_D}{\epsilon_s}\right)$$

where N_D is the donor concentration, ϵ_s is the semiconductor dielectric constant, and α is a proportionality constant that depends on the thickness and dielectric constant of the surface film and on the surface states density and dielectric constant of the semiconductor. The values of α, obtained from the slopes of

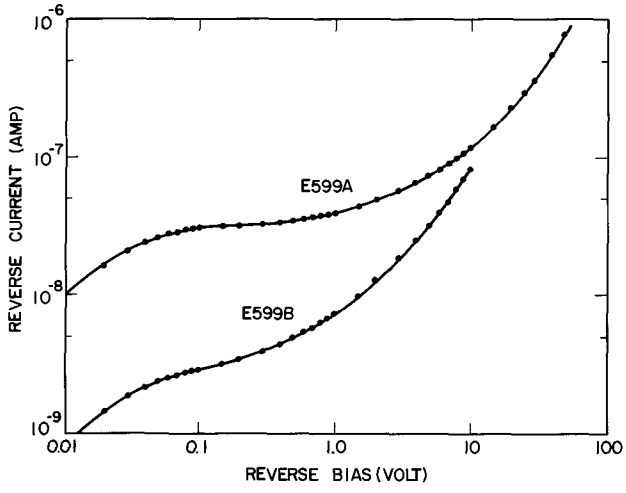

Fig. 5. Reverse bias I-V characteristics of the same Schottky diodes as in Fig. 4.

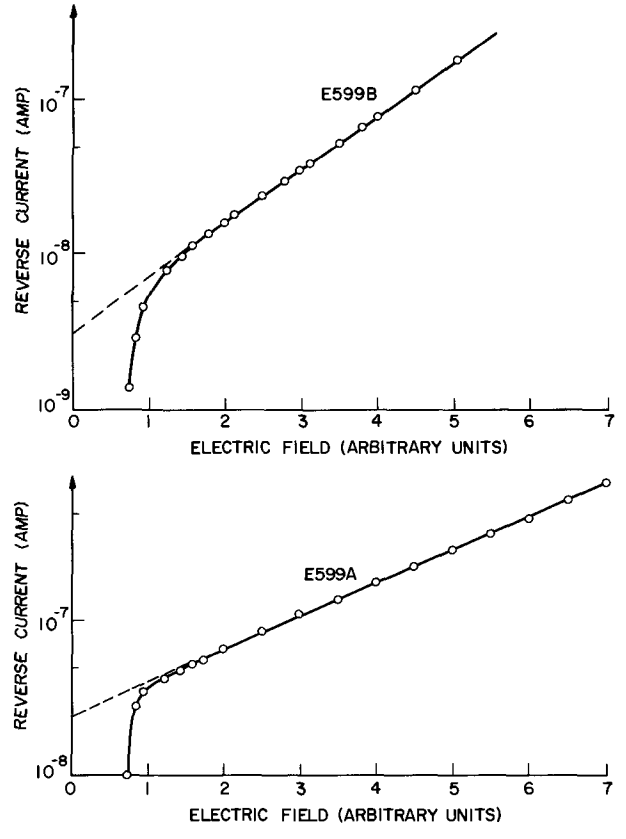

Fig. 6. Log reverse current vs. the square root of the reverse voltage for the same Schottky diodes as in Fig. 4.

the curves in Fig. 6 are 34 and 55Å for E599A and E599B, respectively.

The effects of surface preparation on the reverse characteristics of the Schottky diodes are further illustrated in Fig. 7. This figure shows the reverse current-voltage characteristics for diodes made on six pieces of the same sample; each piece having been subjected to a different cleaning or storage procedure. The particular procedure used, the film thickness as determined by ellipsometry, and the proportionality constant, α, are listed in Table V. The reported film thicknesses are average values for samples which have been given the same treatments as listed in Table V. As the film thickness increases, the value of α increases and the reverse current decreases. The reverse current reaches a minimum for samples 4 and 5 with film thicknesses of 35-45Å and with values of α near 55Å. A further increase in film thickness causes the reverse current to increase and α cannot be measured be-

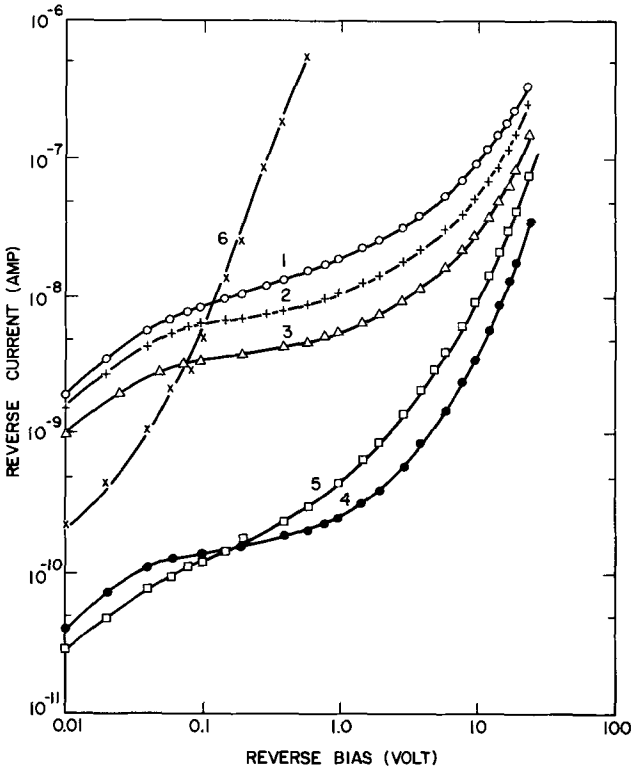

Fig. 7. Reverse bias I-V characteristics of Schottky diodes on parts of the same sample cleaned by different procedures.

cause log J_r is no longer proportional to the square root of the voltage.

These experiments indicate that the electronic barrier height is a function of the thickness of the interfacial film between the metal and the semiconductor. This subject will be discussed in another paper. These experiments also indicate a correlation between the film thickness and the reverse bias proportionality constant, α.

According to the interfacial layer theory (17), the proportionality factor is related to the film thickness by

$$\alpha = \frac{\epsilon_s}{\epsilon_i/d_i + 2qD_s}$$

where ϵ_i and d_i are the dielectric constant and the thickness of the film, D_s is the density of surface states, and q is the electronic charge. The values of α as a function of d_i are plotted in Fig. 8 using D_s as a parameter and assuming $\epsilon_i = \epsilon_o$. The theory is successful in predicting the magnitude of α and also the variation of α with film thickness. From this curve a mean density of surface states of 5×10^{12} cm^{-2} eV^{-1} is

Table V. Film thickness and proportionality constant, α, for Schottky diodes on gallium arsenide

Sample No.	Surface preparation	Film thickness, Å	Alpha, Å
6	No cleaning	57	Not measureable

2	"Pre-epitaxy" cleaning,[b] stored in hydrogen	12	34
1	"Evaporation" cleaning[d]	11	30

[a] Measurements made on two samples.
[b] Samples are heated in acetone, Cobehn, and then methanol; cleaned with hydrochloric acid and rinsed with methanol; etched with dilute sulfuric acid and rinsed with methanol; stored in methanol.
[c] Cobehn is produced by Cobehn, Incorporated, Fairfield, New Jersey.
[d] Samples are heated in trichlorethylene and then in ethanol; dipped in hydrofluoric acid; dried with nitrogen.

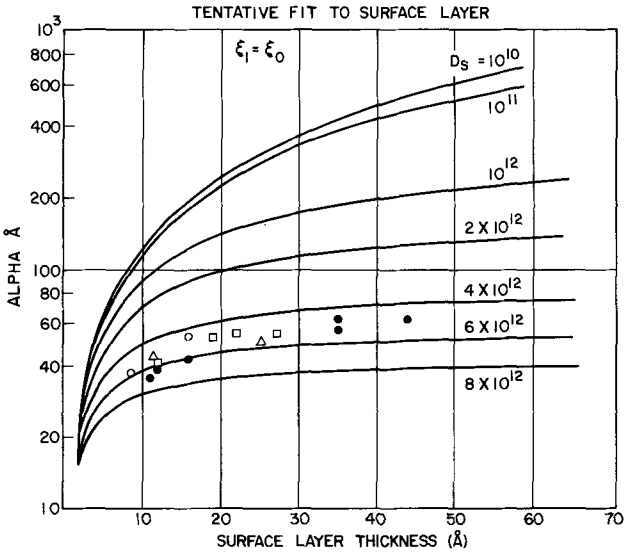

Fig. 8. Comparison between experimental and theoretical values of the reverse bias proportionality factor, α, as a function of film thickness with the surface-states density, D_s, expressed in cm^{-2} eV^{-1}.

deduced. The scatter of the data may be due to different cleaning procedures leaving films of slightly different chemical composition and giving a different dielectric constant and different density of states at the semiconductor surface. Still, these results strongly support the interfacial layer theory.

Thick films.—The use of ellipsometry to measure the thickness and refractive index of thick transparent films is well established (18). The method is based on the fact that for a given substrate psi and delta are determined by the refractive index and thickness of the film. Plots of delta *vs.* psi for films of constant refractive index and increasing thickness are given in Fig. 9. The curves are the loci of points generated by increasing the film thickness while keeping the film refractive index constant. Curves are shown for refractive indices between 1.1 and 3.5; curves of constant phase shift, δ, are shown as dashed lines. The phase shift is related to the film thickness by

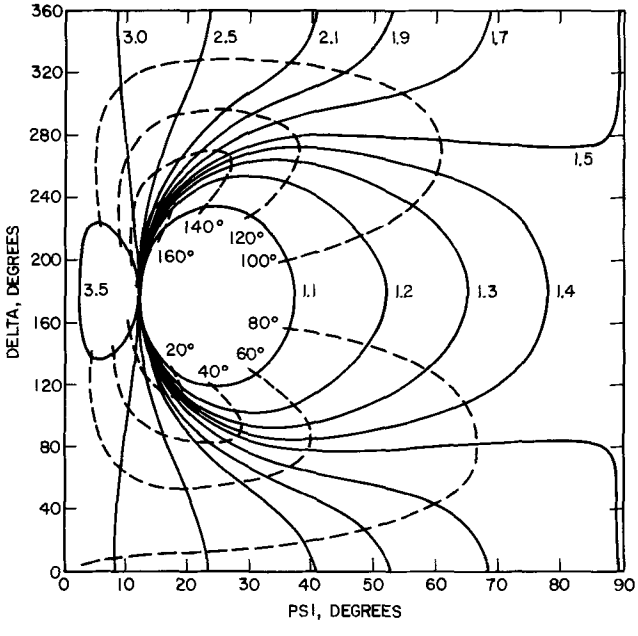

Fig. 9. Delta *vs.* psi for transparent films with refractive indices, n_1, between 1.1 and 3.5 on gallium arsenide substrates. The curves are calculated for $n_2 = 4.050$, $k_2 = 0.304$, $\lambda = 5461$Å, and $\phi = 70.00°$.

$$\delta = \frac{360}{\lambda} d(n_1^2 - \sin^2 \phi)^{1/2}$$

where λ is the vacuum wavelength of the incident light, d is the film thickness, n_1 is the film refractive index, and ϕ is the angle of incidence. The curves in Fig. 9 are quite similar to the curves given by Zaininger and Revesz (19). The differences are due to the slightly different values used for the optical constants of the gallium arsenide substrate.

The curves for all values of the film refractive index pass through a common origin. Consequently, the refractive index of the film cannot be determined if the film thickness is such as to give a value of δ near 0° or 180°. The most accurate values for the film refractive index are obtained when δ is near 90°.

We have made measurements to determine the thickness and refractive index of aluminum oxide films formed by the reactive evaporation of aluminum in a water vapor atmosphere (20) onto gallium arsenide substrates. The results for annealed samples are given in Table VI. The values of δ are all near 90°, thus we expect high precision in the values for the film thickness and the refractive index. The thicknesses as measured by the Talysurf and the ellipsometer fall within the uncertainty of the Talysurf measurement for samples which have been annealed. The refractive indices of the annealed samples increase with annealing time and annealing temperature. This is the expected trend if the films are losing water during the annealing. The reported refractive indices at 5892Å for $Al_2O_3 \cdot 3H_2O$, $Al_2O_3 \cdot H_2O$, and Al_2O_3 are 1.58, 1.62, and 1.77, respectively (21). The slightly anomalous values for the refractive index and the thickness of unannealed samples are not completely understood. The freshly deposited films may contain small amounts of elemental aluminum which cause the film to be absorbing. Since our analysis of the data assumes that the film is nonabsorbing, the reported values for the refractive index and the thickness will be in error if free aluminum is present. The aluminum may be converted to aluminum oxide by reaction with water during the annealing.

Discussion and Summary

The ellipsometric data from the polished samples have been interpreted in terms of a simple optical model in which the values for the real part of the refractive index of the gallium arsenide and the thickness of the surface film are obtained by assuming that the film refractive index is 1.9 and that the complex part of the gallium arsenide refractive index is 0.304. The optical constants at a wavelength of 4375Å have been calculated by correcting the ellipsometric data at this wavelength for the presence of the surface film. The values of these optical constants have been used to investigate the polishing of the gallium arsenide. The ellipsometric technique is expected to be sensitive to variations in the gallium arsenide surfaces because the light penetrates only a very small distance into the sample. Thus the optical constants are measured for gallium arsenide at or near the surface rather than for the bulk gallium arsenide. The penetration depth can be defined as

$$D = \lambda/4\pi k_2$$

where λ is the vacuum wavelength of light and k_2 is the imaginary part of the gallium arsenide refractive index (22). The penetration depth will be smallest when the imaginary part of the complex refractive index is at a maximum. For gallium arsenide, a maximum occurs near 3900Å (5). The penetration depths, calculated using the optical constants in Table III, are 1430 and 290Å for wavelengths of 5461 and 4375Å, respectively. The optical constants reported in Table III show no significant variation with different polishing techniques, indicating that the surfaces are the same for the three different surface preparations, at least for penetration depths of 300Å. This similarity is not surprising since the three polishing methods are all based on the chemical etching of the surface. If a mechanical polishing technique had been used, differences in the optical properties of the surface might be observed (23, 24).

The optical constants reported in Table III are in good agreement with the values reported in the literature (5, 7, 11). However, the value of n_2 at 5461Å is higher than the value reported by Zaininger and Revesz ($n_2 = 3.923$) who also used ellipsometric measurements (19). The difference may result because of different surface preparations on different crystallographic orientations. Zaininger and Revesz made measurements on the (110) orientation; they state that the $(\bar{1}\bar{1}\bar{1})$ and (100) orientations give slightly different results, but no data are reported. This possible difference should be studied in more detail.

Cleaning techniques have been evaluated by measuring the thickness of the surface film. On this basis, the cleanest surface observed has about 8Å of film. This is nearly the same thickness that is reported for etched gallium arsenide (19) and probably represents between one and two monolayers of oxide. This film slowly grows due to air oxidation and reaches a maximum thickness of 30Å.

Alfano has also evaluated the cleaning of gallium arsenide by ellipsometry (25). However, he used the value of delta as a measure of the cleaning rather than actually calculating the film thickness. It is impossible to compare his data with ours because his angle of incidence is not specified.

The Schottky diode measurements indicate that the reverse current-voltage characteristics are very sensitive to surface preparation. In addition, there is a correlation between the thickness of the film that remains after the different surface treatments and the alpha factor obtained from the slope of log J_r *vs.* the square root of the voltage. Such a correlation is predicted by the interfacial transition layer model (16, 17).

Finally, the use of ellipsometry to measure the thickness and the refractive index of deposited transparent films on gallium arsenide substrates has been demonstrated. High precision in these measurements can be obtained by suitably choosing the thickness and the angle of incidence so that the phase shift, δ, is near 90°. This technique should be particularly useful in the future for studying the properties of insulating films on gallium arsenide.

The Effect of Dislocation Density on the Diffusion of Gold in Thin Silicon Slices

F. A. Huntley[1] and A. F. W. Willoughby

Engineering Materials Laboratories, The University, Southampton, United Kingdom

ABSTRACT

The effect of dislocation density on the diffusion of gold in thin silicon slices has been investigated. Precision grinding together with γ-scintillation counting was used to measure concentration profiles of ^{198}Au diffused, over a temperature range 900°-1200°C, into thin slices of both high-and low-dislocation density silicon crystals. U-shaped gold concentration profiles as observed by previous workers were obtained in all cases. Significant differences were observed between diffusion profiles in slices which had different initial dislocation content, but had undergone identical diffusion processing. This effect of dislocation density on gold diffusion is strong evidence to support the dissociative mechanism for gold diffusion in silicon. The differences between diffusion profiles in high- and low-dislocation density material are interpreted by means of a model in which vacancy generation occurs at climbing grown-in dislocations, but it is concluded that this may not be the only process determining the rate of gold uptake in thin slices.

Considerable interest has been shown in recent years in the diffusion of gold in silicon. This interest has arisen both from the needs of silicon device technology, and from the general scientific need to try to fill the many gaps in our knowledge of point defects and impurity diffusion in silicon.

Evidence that gold diffuses in silicon by the dissociative mechanism, first developed by Frank and Turnbull (1) for copper diffusion in germanium, was provided by the studies of Wilcox and LaChappelle (2). The dissociative mechanism involves the fast interstitial diffusion of the element in question accompanied by the transition of interstitial atoms into substitutional sites by annihilating lattice vacancies. Since this should cause the vacancy concentration to drop and hence may cause vacancy generation at dislocations and other lattice defects, the evidence that the diffusion of copper in germanium is highly sensitive to the dislocation density (1) is perhaps the strongest evidence in support of the dissociative mechanism in this case. However, unambiguous evidence on this point has not yet been published for gold diffusion in silicon, although there is evidence that gold diffusion causes vacancy generation at grown-in dislocations (3, 4). A study of the effect of dislocation density on gold diffusion in silicon is thus an essential experiment to test the validity of the dissociative mechanism for this system, and offers the possibility of gathering information about lattice vacancies in silicon.

There are two previous reports, by Yoshida and Saito (5) and Lambert (16), of experiments to determine the effect of dislocation density on gold diffusion in silicon. In neither of these studies were gold concentration profiles measured. Yoshida and Saito (5) measured average diffused gold concentration in slices of silicon crystals grown by four different techniques which they called float zoned (FZ), float-zoned defect free (FZDF), pulled (CZ), and pulled-defect free (CZDF). Small differences were seen between central concentrations of gold, which was diffused into slices of the four different materials for the same times and at the same temperatures. However, differences were also seen between central concentrations of gold, in slices of the same material but of different thicknesses, diffused for the same time at the same temperature. This suggests that the gold profiles in the central parts of at least some of the specimens used to determine

[1] Present address: Institut für Physik, Max-Planck-Institut für Metallforschung, 7 Stuttgart 1, Azenbergstr. 12, Germany.
Key words: dislocation density, vacancy generation, nonequilibrium dissociative diffusion.

the gold concentrations were not flat, as had been assumed on the basis of the work of Martin *et al.* (7) and Sprokel and Fairfield (8). Differences in the gold concentrations, due to the different defect structures of the specimens, might therefore have been masked by apparent concentration differences due to concentration gradients. Lambert (6) has obtained a limited number of results from experiments similar to those to be described here. However, as in the work of Yoshida and Saito, only average gold concentrations were measured, by counting large parts of the specimens after neutron activation.

The experiments reported here are an attempt to determine the effect of initial dislocation density on profiles of gold diffused into silicon, and were designed to test the results of a previously published theory (9) in which vacancy generation during gold diffusion was assumed to take place at jogs on climbing dislocations.

Methods

Disk-shaped slices of between 400 and 480 μm thick and 2.5 cm in diameter were cut from two silicon crystals. Both crystals were N-type, phosphorous-doped, (111) orientation, and of resistivity between 6 and 10 ohm-cm. One crystal had been grown by the float-zone process and had a fairly high dislocation density (EPD $\simeq 10^4$ cm^{-2}). The other crystal was of the Mon-X type (Monsanto Chemicals Limited) and had been grown by a process that yields crystals with a low oxygen content (as for FZ crystals) but with a near zero density of grown-in dislocations as measured by etch-pit techniques, and x-ray topography. The FZ slices were lapped flat on both sides, and then polished on one face with a combined chemical/mechanical polish. In order to preserve their initial perfection the slices of Mon-X crystals were not lapped after sawing, but were heavily etched, removing about 25 μm from each face. One face was then polished by a combined chemical/mechanical tehnique. X-ray topographs of such as-polished slices indicated that the perfection of the starting crystal had been well preserved.

A thin film diffusion source of ^{198}Au, a few hundred Angstroms thick, was vacuum evaporated on the unpolished face of the slices. The ^{198}Au was obtained by the thermal neutron activation of spectroscopically pure metallic gold (the irradiation was carried out at the Isotope Production Unit, A.E.R.E., Harwell). For diffusion, the slices were taken directly from the evaporator and placed horizontally on a flat quartz boat, with the gold-evaporated side underneath, and diffused in a horizontal, open-tube furnace. After diffusion, the slices were quenched by removing them rapidly from the furnace into a quartz transfer tube. A flow of dry nitrogen was maintained over the slices during diffusion and quenching.

As a precaution against possible edge effects, a disk of about 1 cm diameter was cut from the center of each slice for the determination of the gold concentration profile. This disk was mounted on the plug of a microgrinding jig for the lapping of the polished face of the specimen. This face was aligned parallel to the lapping surface by an optical interference technique by using the micrometer adjustments on the jig feet. Successive sections of between 1 and 20 μm thick were then lapped from the specimen, starting at the polished front face, and proceeding through the specimen, towards the rear face on which the gold diffusion source had been evaporated. The grindings were collected and assayed for ^{198}Au using γ-scintillation counting. Careful cleaning of the jig and specimen was necessary between the cutting of each section in order to prevent cross contamination. The thicknesses of the removed layers were measured directly to an accuracy of $\pm$ 0.25 μm using an inductance probe, taking the back surface of the grinding jig plug as a reference surface for each measurement.

In order to determine the specific activity of the ^{198}Au, a known weight of the gold from each irradiation was dissolved in aqua regia. The specific activity was calculated from the scintillation count-rates of suitably diluted aliquots of this solution.

The gold concentration in each section was then computed from the section thickness, the specimen area, the scintillation counter data and the specific activity of the ^{198}Au. Concentration profiles were then plotted from these data.

The only data in which large errors are suspected are those obtained within 50 μm of the rear (gold-deposited) surface of each slice, where concentrations apparently exceeded the maximum solubility limit. The high concentrations are thought to be largely an artifact of the sectioning technique. When the remaining specimen had a thickness of only about 50 μm the mechanical lapping process began to cause chipping round the periphery of the slice. Consequent contamination of the removed section with part of the evaporated gold film from the rear of the slice apparently caused erroneously high gold concentrations to be measured.

Results

In order to make a comparison of gold diffusion in thin slices of different dislocation content, slices of both FZ and Mon-X crystals (high- and low-dislocation density respectively) were gold diffused for approximately 10, 40, 100, and 400 min at each of four temperatures, 900°, 1000°, 1100°, and 1200°C. The families of concentration profiles are shown in Fig. 1 to 8. Both before and after diffusion the defect structure of the slices was investigated using both x-ray topography, and infrared microscopy following copper decoration. Figure 9 shows an x-ray topograph of a FZ slice after gold diffusion, revealing a density of $\rho \simeq 3 \times 10^4$ cm^{-2} of dislocations fairly uniformly dis-

tributed in the slice, and showing no evidence of gross climb of the grown in dislocations, such as helix formation, etc. No difference was obvious between topographs of FZ slices taken before and after gold diffusion. X-ray topographs of the Mon-X slices both before and after gold diffusion were featureless. However, Sirtl etching of the Mon-X slices before gold diffusion revealed roughly spiral striations of etch-pits. After copper diffusion (15 min at 1000°C) both topography and infrared microscopy revealed copper precipitates with the same striated distribution as the etch-pits (Fig. 10). Similar results have been presented by de Kock (10), who suggested that the cause of the etch-pits and the sites of nucleation of the copper precipitates were vacancy clusters, perhaps stabilized by complexing with oxygen atoms. After gold diffusion, changes in the form of the copper precipitates were observed, as discussed below.

The form of the thin slice profiles.—Despite differences in the profiles for the two types of material which are discussed below, the profiles shown in Fig. 1 to 8 are all U-shaped and are similar to those seen by previous workers (7, 8) and to the theoretical profiles obtained in our earlier work (9). This over-all U shape has been discussed in a previous paper by the present authors (11), in which it was pointed out that the rise, or "tip-up" in gold concentration at the surface towards which the gold was diffused, as well as that on which the gold was deposited, had been observed under a variety of conditions (7, 8, 12-14). Earlier work of the authors (11) has shown that, while rapid surface diffusion of gold on silicon certainly does take place on polished or lapped silicon surfaces, surface diffusion is likely to be only a contributory cause of this front surface "tip-up" phenomenon in oxidized silicon slices. Assuming that gold diffuses by the dissociative mechanism, the following three types of process could lead to a "tip-up":

(*i*) A near surface effect over a region much less than 1 μm from the surface. In this group are surface reactions, absorption effects, interface effects (at Si/SiO_2 interface). Concentrations of gold, in "tip-up" regions in this category, may exceed the solid solubility limit.

(*ii*) A bulk effect extending a few tens of microns from the surface, caused by vacancy diffusion from the surface in regions saturated with interstitial gold. Gold concentrations in these cases should not exceed the solid solubility limit.

(*iii*) A bulk effect in regions not saturated with interstitial gold, caused by the true dissociative diffusion of vacancies and gold from the crystal surface. In this case the gold would be transported to the front surface solely by surface diffusion. Concentrations of gold in the "tip-up" regions caused by this effect should not exceed the solid solubility limit.

In the present investigation unoxidized slices were used and it is thus impossible to rule out conclusively mechanism (*iii*), as a contributory cause of the "tip-up" extending over tens of microns. Whether (*iii*) or (*ii*) is dominant depends on whether interstitial diffusion produces saturation before or after surface diffusion produces an effective source on the front surface. The data available at present is inadequate to make a clear conclusion on this point. In the case of profiles obtained for diffusion in thick (1 cm) silicon specimens, however, which also show a "tip-up" near the

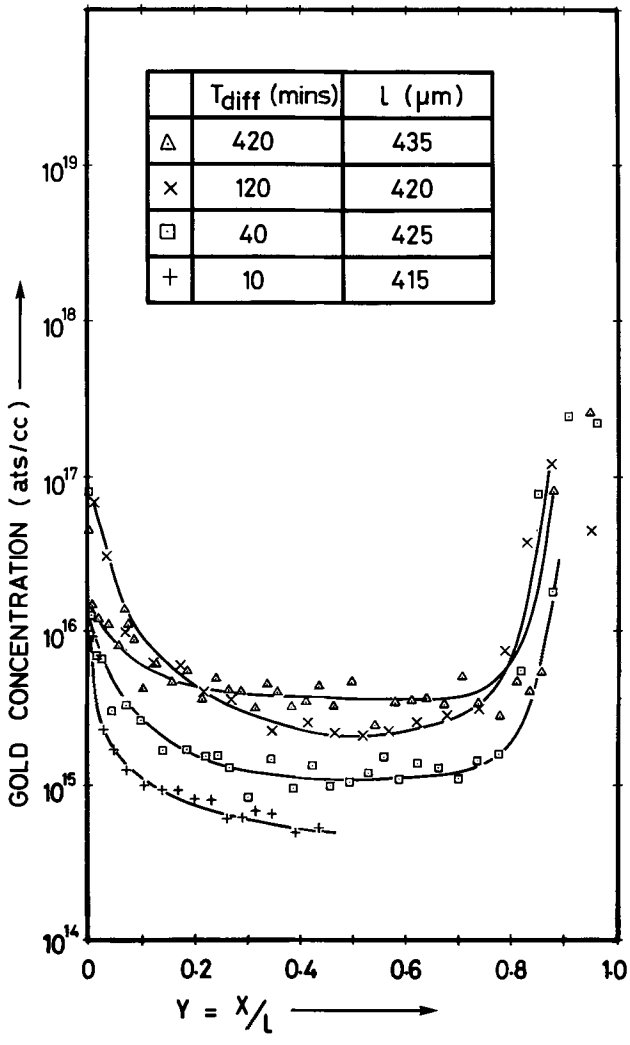

Fig. 4. Concentration profiles of gold diffused into Mon-X silicon slices at 1000°C.

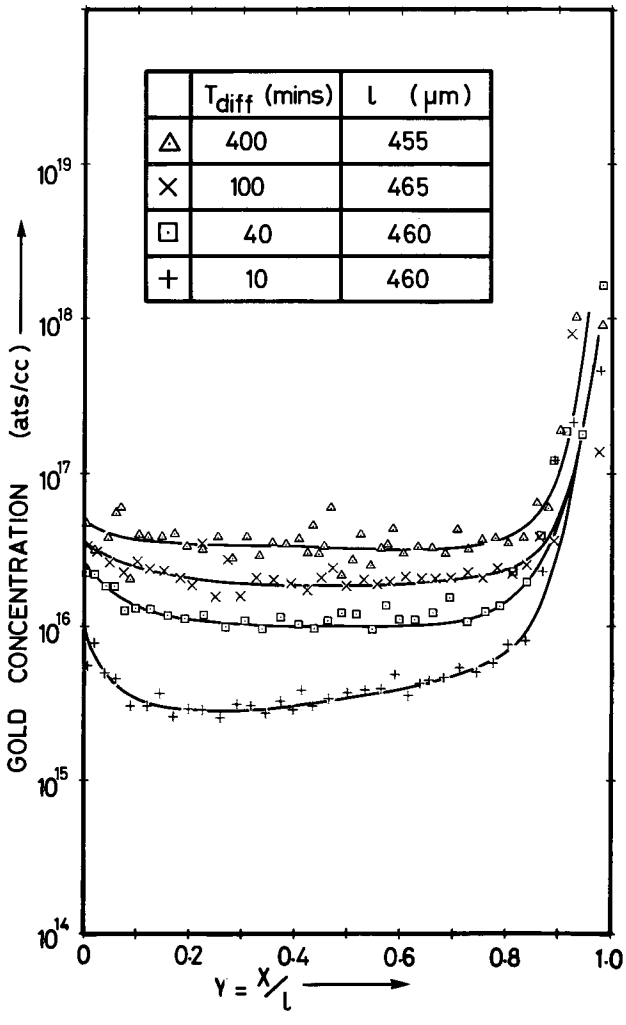

Fig. 5. Concentration profiles of gold diffused into FZ silicon slices at 1100°C.

front surface (15), the rise is thought to be due primarily to surface diffusion, since the conditions used make it unlikely that full saturation with interstitial gold occurred.

The effect of dislocation density on the profile shape.—Although an over-all U-shape of the profiles was found in all cases, there were noticeable differences in the profile shapes for the two types of crystal. The Mon-X profiles were consistently more rounded than the FZ profiles, which had very flat central regions, as may be seen by comparing, for example, Fig. 5 and 6.

These differences can be explained qualitatively on the dissociative diffusion model assuming that, in most cases, the slices are saturated with interstitial gold more rapidly than with the vacancies, and hence that the gold concentration is controlled primarily by the vacancy concentration. (This assumption is obviously not good in all cases, and will be discussed further below.) If vacancy generation from climbing dislocations occurs in the center of the FZ slices, the vacancies diffusing from the surface will make a smaller relative contribution to the total vacancy concentration in this material than in the low dislocation density Mon-X material [cf. Fig. 1 and 2 in Ref. (9)]. Thus the deeper vacancy diffusion profiles in the Mon-X slices will lead, on this model, to more rounded gold diffusion profiles than in the FZ slices.

The second feature of the profiles worthy of note is that some of the profiles for the shortest diffusion times (10 min) are not flat, but show a gradient away from the diffusion source. Again assuming that interstitial gold diffusion is more rapid than vacancy diffusion, this can be understood if the diffusion time is too short to enable $C_i \rightarrow C_i'$ throughout the whole sample. This enables an estimate to be made for D_1 if

$$\sqrt{D_1 \cdot t} \simeq l \quad \text{(the slice thickness)}$$

For $t = 10$ min, $l = 450$ μm, a value of $D_1 = 3 \times 10^{-6}$ cm²/sec is obtained, which agrees well with that determined experimentally by Wilcox and LaChappelle (2) over the temperature range 900°-1200°C, and thus reinforces this interpretation. The fact that the concentration gradient in the central region was predominantly seen only in the FZ specimens can be explained by the interstitial to substitutional gold reaction not proceeding so fast towards the substitutional species in the Mon-X, as in the FZ material, due to the lower vacancy generation rate in the more perfect crystal. The rate of conversion of interstitial to substitutional gold might thus be expected to be slower in the Mon-X material, and saturation with interstitial gold to occur faster than in the FZ material, thus removing the gradient.

Effect of dislocation density on central gold concentrations.—Figure 11 compares gold concentration profiles in slices of Mon-X and float-zoned crystals, diffused at 900°, 1000°, and 1100°C for 40 min. At all three temperatures the central concentration in the float-zoned slices was higher than in the Mon-X slices. Lambert (6) has recently observed an effect of the same direction and similar magnitude for diffusion at 835°C, and although average gold concentrations in parts of the slices were measured, rather than concentration profiles, as in the present work, these results are strong confirmation of the present trends. These consistently observed effects of dislocation density, the first direct studies of this parameter to be re-

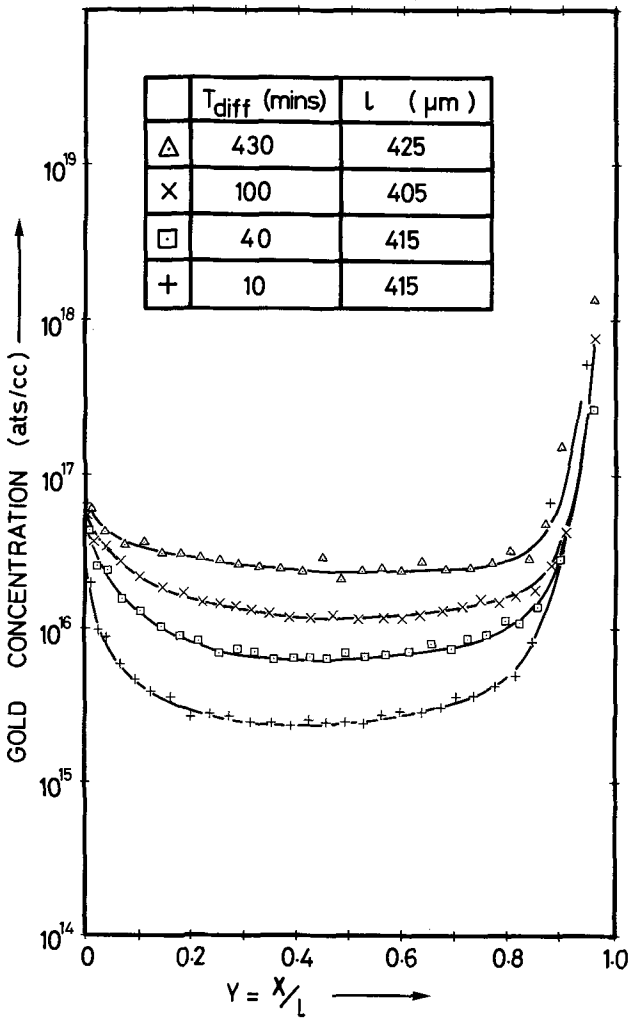

Fig. 6. Concentration profiles of gold diffused into Mon-X silicon slices at 1100°C.

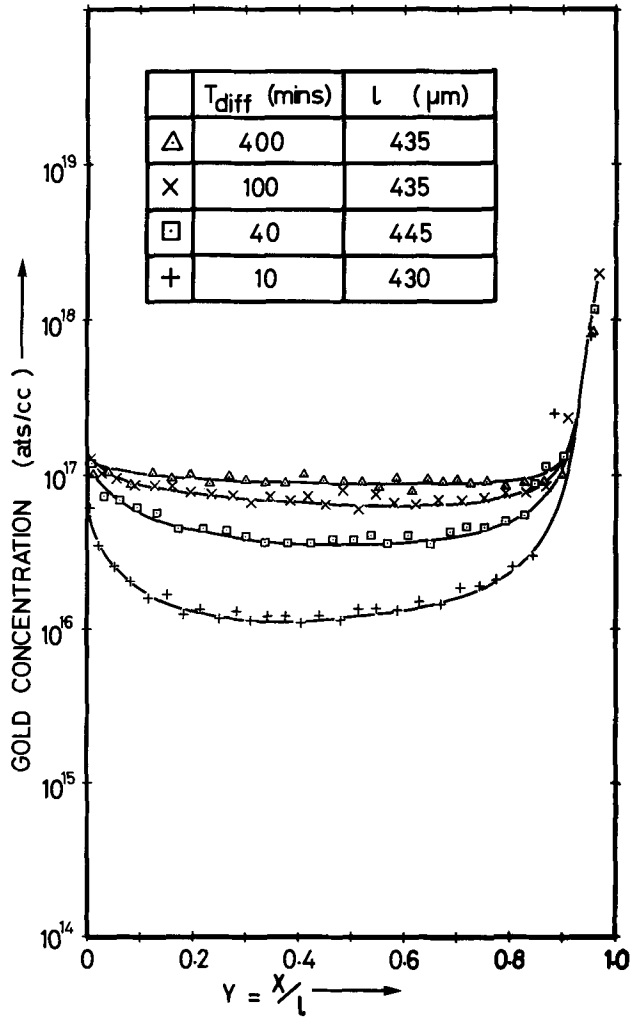

Fig. 7. Concentration profiles of gold diffused into FZ silicon slices at 1200°C.

ported, confirm qualitatively the predictions of the previously described dislocation climb model (9). The results provide strong evidence of the involvement of dislocations in gold diffusion in silicon, and strongly support the contention that gold diffuses in silicon by the dissociative mechanism.

Central gold concentration time dependence.—The central gold concentrations in slices of the two types of material, over the temperature range 900°-1200°C, are plotted as a function of time from 10 to 400 min in Fig. 12. As discussed above, the concentration in the float-zoned material was higher than in the Mon-X material in all cases, except for the two longer diffusion times at 1200°C. In these latter cases the solubility limit was apparently being approached, showing a saturation effect as seen in Fig. 7 and 8. The solubility limit is not likely to be a function of the dislocation density.

Two lines, labelled K and G, having the same slope as two families of theoretical solutions [in the regime unaffected by approach to the solubility limit or to zero concentration (9)], are also shown in Fig. 12 to allow comparison with the observed time dependences. The curve labelled K was obtained using the previously published dislocation climb model (9) which, assuming again that interstitial saturation occurred rapidly compared with vacancy diffusion, led to the following expression for the time dependence of the central gold concentration

$$C_s = C_s' \{1 - \exp(-2Kt)\}^{1/2} \qquad [1]$$

[The notation of this expression has been changed from the nondimensional form used in the earlier work (9) to the dimensional form used by Lambert (6), for ease of comparison.] The parameter K has the units (time)$^{-1}$ and is a function of the dislocation density of the crystal as

$$K = \frac{D^{sd}{}_{1v} \cdot L_j \cdot \rho}{b^2 \cdot (C_s' + C_v')} \qquad [2]$$

where $D^{sd}{}_{1v}$ is the self-diffusion coefficient by a vacancy mechanism, L_j is the jog line density on the dislocations, ρ is the dislocation density, b is the dislocation Burgers vector magnitude, and C_s' and C_v' are the solubility limits of substitutional gold and vacancies respectively.

The previous theoretical work (9) showed that the time dependence of the central concentration under conditions of zero generation rate would be quite different from Eq. [1]. As discussed below however, it is extremely unlikely that the Mon-X material contained absolutely zero vacancy generating defects, and its behavior would thus be expected to conform to Eq. [1], as observed.

The curve labelled G was obtained on the empirical model of Sturge (16) which assumed that vacancy generating sources in the bulk obeyed first-order kinetics, unlike dislocations. This gave a time dependence of the form

$$C_s = C_s' \{1 - \exp(-g't)\} \qquad [3]$$

Comparing the experimental and theoretical curves in Fig. 12 it can be seen that the experimental curves have gradients which lie closer to that of the K curve than to that of the G curve, as do those of Lambert (6) and Sprokel and Fairfield (8) shown in Fig. 13,

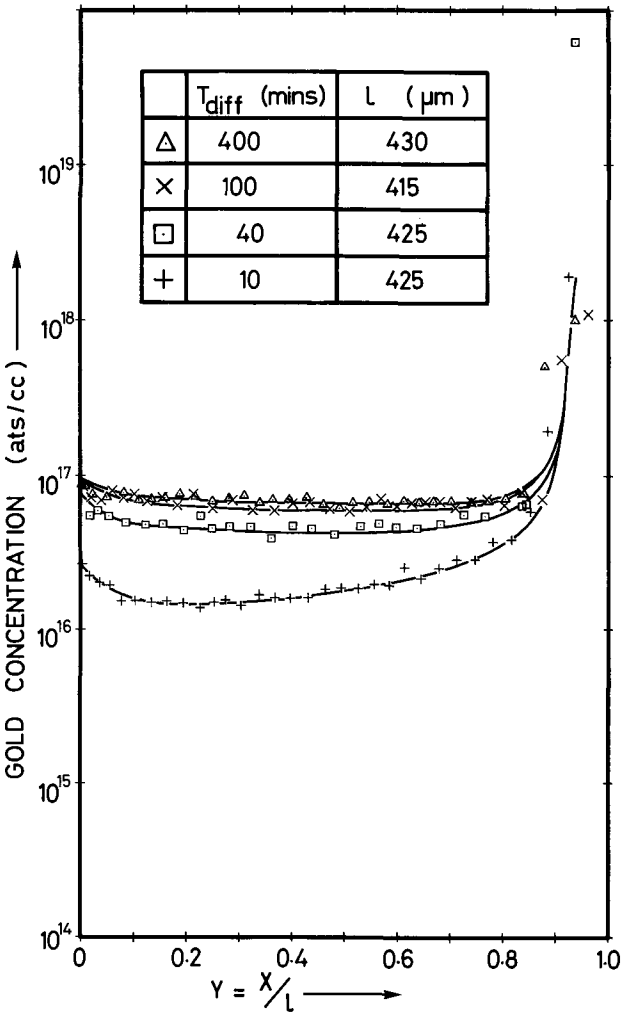

Fig. 8. Concentration profiles of gold diffused into Mon-X silicon slices at 1200°C.

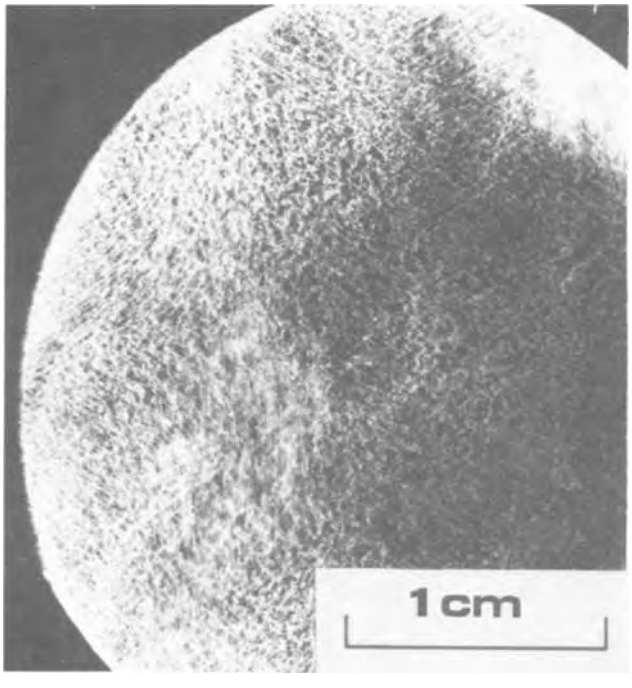

Fig. 9. Transmission x-ray topograph (220 reflection) of an as-polished FZ silicon slice.

thus supporting the vacancy generation model proposed in the earlier work (9). The range of values shown for the results obtained in this work at the

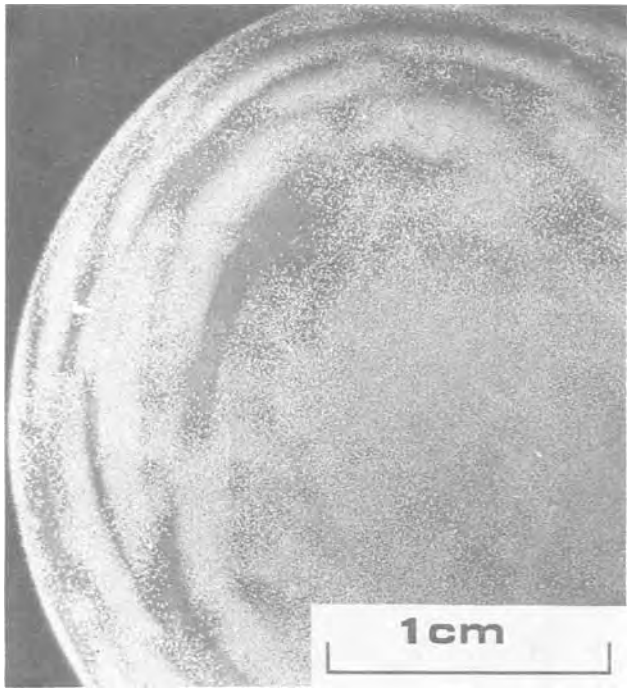

Fig. 10. Transmission x-ray topograph (220 reflection) of an Mon-X silicon slice after copper decoration (15 min diffusion at 1000°C).

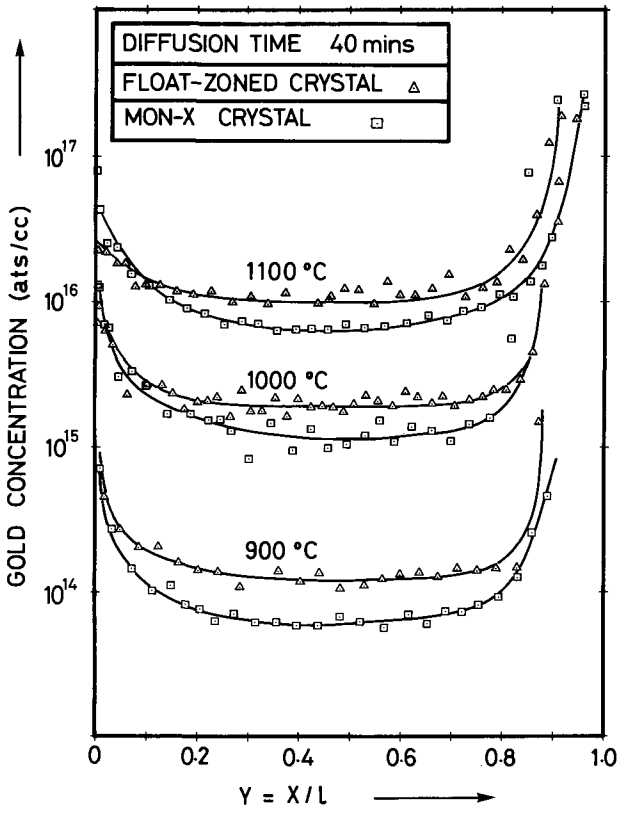

Fig. 11. Concentration profiles of gold diffused into slices of both FZ and Mon-X silicon, at 900°, 1000°, and 1100°C.

shortest diffusion time, indicates the presence of concentration gradients in the central region. At very short diffusion times the slope of the central concentration curve can be expected to increase due to local equilibrium not being established in the $I + V \rightleftharpoons S$ reaction. It can be shown (28) that if the rate of increase of the central concentration is limited by the reaction rate of the $I \rightarrow S$ transition, the slope of the central concentration VS time curve should approach

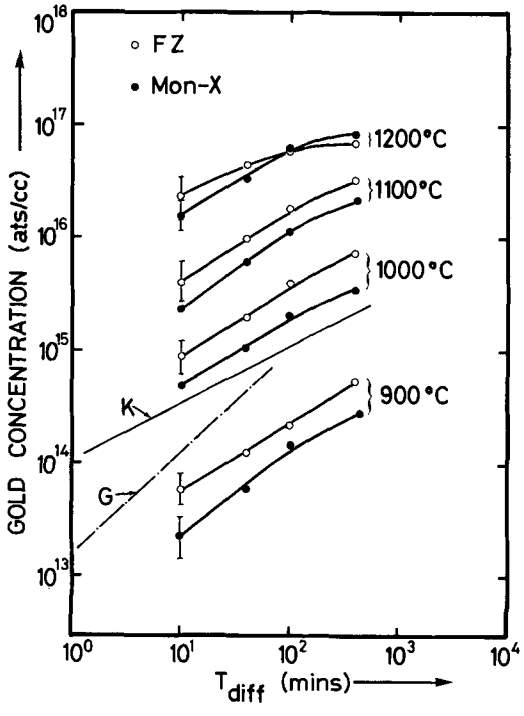

Fig. 12. Gold concentration at the center of diffused slices as a function of time, temperature, and material type.

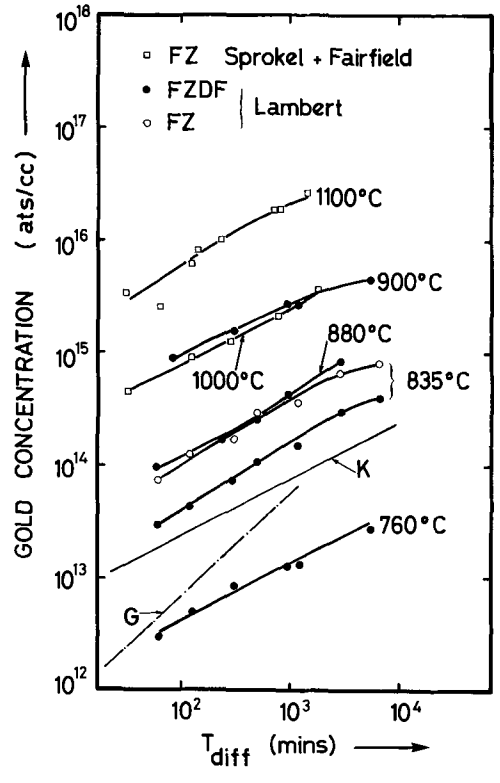

Fig. 13. Central concentration time dependence as determined by Lambert (6) and Sprokel and Fairfield (8).

that of the G curve. This might cause concentrations in slices diffused for short times to be low in general, as well as containing concentration gradients as explained above.

Quantitative test of dislocation climb model.—Substituting the measured dependence of C_s on time into Eq. [1], together with gold solubility limits (18) for C_s', enables values of K for each temperature and material type to be calculated which are shown in Fig. 14.

At a given temperature, Eq. [2] shows that K should be directly proportional to the dislocation density (assuming similar distributions of Burgers vectors, and jog densities in both materials). Figure 14 shows that the K values for the FZ material are a factor of 2 to 6 greater than those for the Mon-X material. The ratio of K values thus implies a similar ratio between the dislocation densities, *i.e.*, much smaller than the ratio of dislocation densities of 10^4:~1 observed by x-ray topography before and after gold diffusion. This difference between the central concentrations found in the high- and low-dislocation density materials was thus consistently smaller for all diffusion temperatures than that anticipated from the measured dislocation density difference. It is to be expected, however, that a large proportion of grown-in dislocations do not act as efficient vacancy generators due to interactions with impurities initiated during the high temperature crystal growth process. This was confirmed by the x-ray topography study which revealed ltitle evidence of gross dislocation climb after gold diffusion.

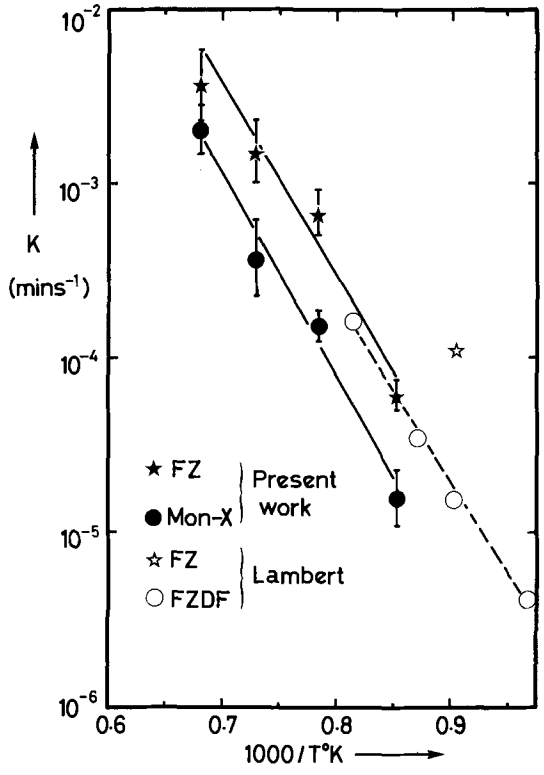

Fig. 14. Temperature dependence of vacancy generation parameter K, as a function of material type.

While the ratio of K values for the two types of material can be thus closely related to the differences in dislocation density, the absolute magnitude of the K values calculated are more difficult to explain, as pointed out (9), and discussed (19, 20), previously. Substituting the measured values of K in Eq. [2] lead to values of jog spacing of less than 10Å which is much smaller than might be expected using simple calculations of jog activation energies, albeit in this nonequilibrium situation. Although the value of $D^{sd}{}_{1v}$ used in this calculation is subject to much uncertainty, the true value cannot be higher than the self-diffusion coefficient measured by tracer methods; and the jog line density calculated using a lower value would be even more unreasonable. It therefore remains to explain a high apparent vacancy generation rate in all samples, upon which the effect of grown-in dislocations is apparently superimposed. Possible explanations of this apparently high background generation rate are discussed further below.

Temperature dependence of thin slice diffusion.—Figure 14 shows the calculated values of K plotted against temperature for both types of material used in this work and that of Lambert (6). Both material types indicate a distinct activation energy of about 2.11 eV

in the temperature range of the measurements, although there appears to be a discrepancy between the absolute values of K determined in this work, and by Lambert (6). If reliable values of the activation energy for self-diffusion by a vacancy mechanism were available [there is considerable doubt as to whether the dominant self-diffusion process in silicon is a monovacancy mechanism (21)] these measured activation energies could be used to test the model further, by calculating jog formation energies. At present it is sufficient to note that the activation of the vacancy generation process appears to be well established [by both the current work and that of Lambert (6)] at about 2.11 eV, and that this is not inconsistent with a dislocation climb process.

Discussion

In this work small but significant differences in the diffusion behavior of gold have been found between two silicon crystals having different dislocation content. It must first be discussed whether these differences in diffusion behavior are associated with the differences in dislocation content, or whether other differences, such as concentrations of trace elements (or even of original gold content) could have been responsible. While alternative explanations seem unlikely even on a theoretical basis, perhaps the strongest argument against such alternatives is the remarkable agreement between the present work and that of Lambert (6) since it is extremely unlikely that both studies would have used crystals with identical trace element concentrations.

Perhaps the most severe handicap in interpreting the results of this work has been the lack of data concerning self-diffusion mechanisms and the properties of native defects in silicon. It has been seen that, even for qualitative explanations of dislocation density effects, the relative diffusion rates of vacancies and interstitial gold atoms really need to be known. It must be pointed out, therefore, that the more quantitative explanations suggested in this paper are very tentative, and await firm data on vacancy diffusion and concentrations for conclusive tests of the models.

With these reservations it can be concluded that the positive effects of dislocation density afford strong evidence in favor of the dissociative mechanism for gold diffusion in silicon. It has been seen, however, that certain quantitative correlations with a dislocation climb model are not fully satisfactory. It is possible that the climb model assumed previously (9) is not appropriate to this particular nonequilibrium situation. Even with the assumption that it is appropriate, an explanation is needed for the apparent high vacancy generation rate.

The possibility that vacancy generation at dislocations in the bulk is only a secondary rate-determining process cannot be ruled out, and the primary process might be one of a number of other processes, *e.g.*, vacancy diffusion from bulk sources, interstitial-substitutional gold transition etc. The time-dependence behavior would appear to rule out the latter interpretation, but all alternatives cannot be dismissed.

Since the rapid penetration of the dissociative impurity cannot be ascribed to dislocation-pipe diffusion [the necessary flux per dislocation appears to be unreasonably high, see Frank and Turnbull (1)] it seems unlikely that the measured dislocation-density effect is due to pipe diffusion. Further, a much more dramatic difference than has been observed would be expected between the diffusion profiles in the two materials, if dislocation pipe diffusion played a significant role. While it has been concluded from this work that there must be a significant concentration of vacancy generation sources in the Mon-X material, there is certainly no dislocation network running through the whole specimen thickness as in the FZ material. Since there can, therefore, be no pipe diffusion in the Mon-X material, if pipe diffusion does take place in the FZ specimens a stronger asymmetry in the FZ profiles would be expected, as well as a greater difference in absolute magnitude of the diffusion profiles in the two materials. Such an effect was not observed, and hence dislocation pipe diffusion can be dismissed.

The only comprehensive interpretation in terms of dislocations alone must assume the presence of a large density of dislocations which were not detected by x-ray topography. As discussed above, there was some indirect evidence for defects in the Mon-X material, which have been suggested to be vacancy clusters (10), formed perhaps during the post-growth cooling of low dislocation density silicon crystals (22) due to the lack of vacancy sinks in the bulk.

It has been proposed that, during the high-temperature anneals, vacancy clusters collapse to form extrinsic stacking faults surrounded by sessile dislocation loops. Such defects have been reported (23-26) in silicon which has been diffused with gold or platinum. In each case it has been proposed that the observed loops, up to a few hundred microns in diameter, have arisen as a result of the growth of similar, but much smaller loops. Diffraction contrast studies, and double crystal topographs of the stacking faults indicate that they are extrinsic (23, 26), *i.e.*, will grow if they emit vacancies. The growth of such loops is therefore consistent with the demand for vacancies caused by dissociative diffusion.

It thus seems possible that the effect of initial dislocation density is apparently so small because significant vacancy generation takes place at dislocation loops, as described above. In addition to the direct evidence obtained by Iizuka (23), the present copper decoration studies also imply that copper precipitation nucleation sites are influenced by gold diffusion and are thus involved in the gold diffusion process. The copper precipitates observed in Mon-X slices before gold diffusion were in the form of complete, or partial six-point stars, as have been previously observed by other workers [for example Dale (27), and by Fiermans and Vennik (28-30)]. An example of the complete star shape can be seen in Fig. 15 (labelled 1). In fact Fig. 15 is a micrograph of precipitates in gold diffused Mon-X. The other two precipitates (labelled 2 and 3) in this figure are examples of types found only after gold diffusion, and which have a more shadowy planar form than the star precipitates. The precipitate labelled 2 would appear to be a derivative of the star form, while the precipitate labelled 3 appears to be more like a hexagonal loop. This evidence

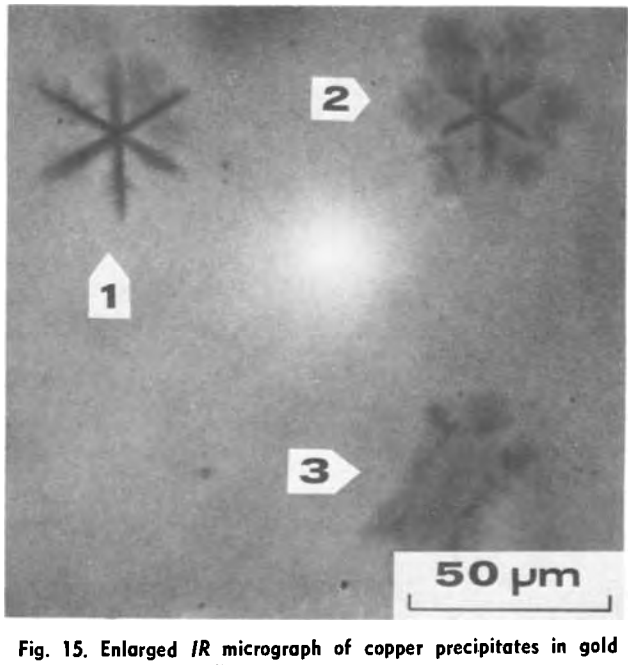

Fig. 15. Enlarged *IR* micrograph of copper precipitates in gold diffused Mon-X silicon slice.

is, however, highly indirect, as there is no evidence that the geometry of the observed copper precipitates bears any fixed relationship to the structure of the nucleating defect.

Against this dislocation loop model it must be pointed out that no evidence for such loops was seen in float-zoned material, and since the equivalent dislocation density in the loops must be greater than the grown-in density it seems surprising that no loops were seen by x-ray topography after gold diffusion. At present, therefore, vacancy generation at climbing dislocations cannot be conclusively established as the only rate-determining process. Detailed explanation awaits more data on intrinsic defects in silicon and on the interaction of impurities with dislocations and point defects.

Conclusions

1. The dislocation density of thin silicon slices affects both the profile shape and the concentration of gold diffused from one face.
2. This small but significant effect of dislocation density on gold diffusion is strong evidence to support the dissociative mechanism for gold diffusion in silicon.
3. The differences between diffusion profiles in high and low dislocation density material are satisfactorily explained by a model in which vacancy generation occurs at climbing dislocations.
4. Vacancy generation at climbing grown-in dislocations is not the only process determining the rate of gold uptake in the thin slices studied in this work. Other processes, such as the growth of diffusion-induced loops, are suggested to account for the results.

Acknowledgments

This work was carried out under a C.V.D. contract and is published by permission of the Ministry of Defence (Navy Department), whose financial support is gratefully acknowledged. Thanks are also due to Dr. J. L. Lambert of A.E.G.-Telefunken, Frankfurt a.M., for a preprint of his results. We further wish to thank S. R. C. for a grant to one of us (F.A.H.) and Professor R. L. Bell for provision of laboratory facilities. We are most grateful to Dr. J. D. Filby, (R. R. E. Malvern) for the x-ray topographs presented in this work, and also for helpful discussions throughout this project. Thanks are also expressed to Dr. R. F. Peart (Plessey Company, Caswell) for assistance with design of the precision grinding jig.

Conduction Mechanisms in Very Thin Silicon Nitride Films

Juan H. Sanchez-Lassise

and J. R. Yeargan

Department of Electrical Engineering, University of Arkansas, Fayetteville, Arkansas 72701

ABSTRACT

The steady-state d-c conduction properties of silicon nitride films in the range of 50-100Å are reported. The nitride films were formed by vapor deposition on degenerate silicon substrates using the silane-ammonia reaction. The temperature, thickness, and field dependence of current indicates that a transition in current mechanisms occurs at a film thickness of approximately 80Å. Below this film thickness, the current is characterized by low temperature dependence and large thickness dependence. At film thickness above this value, the current is proportional to $\exp[\beta V^{1/2}]$.

Due to their importance in the semiconductor industry, the electrical and physical properties of thin-film insulators have received considerable attention in the literature. Extensive studies have been made concerning the electrical characteristics (mostly conduction properties) of these insulators. Previous works have established that current in thin insulating films is due to either a thermal or a tunneling mechanism which can be further divided into a bulk-limited, or an electrode-limited process.

In the case where the insulator is very thin, *i.e.*, less than 50Å, several authors have found direct tunneling to be the dominant conduction mechanism either for MIM (1, 2) or MIS (3, 4) devices. For films above 200-300Å thick, it has been found (5, 6) that the conduction mechanism is a Poole-Frenkel emission at high fields and temperatures. However, the range of thicknesses between 50 and 200Å has not received much attention in the literature. At some thickness in this range, a transition from a bulk-controlled to an electrode-controlled mechanism occurs. The purpose of this work has been to study this transition in a vapor-deposited film of silicon nitride.

Experimental Procedure

The silicon nitride films were deposited by chemical vapor deposition techniques (7) on degenerate p- and n-type silicon substrates. The substrates were polished, cleaned, degreased, and etched in concentrated HF prior to deposition of the films. A deposition rate of 40-60Å/min was used with a silane to ammonia ratio of 10-100 cm^3/min in 500 cm^3/min of hydrogen at a temperature of 650°C. After deposition, aluminum dots of 2 mm diameter were deposited on the silicon nitride film at a vacuum of 6×10^{-6} Torr. The devices were completed by depositing aluminum on the opposite face of the substrates.

Current *vs.* voltage measurements were made with a Keithley Model 602 electrometer and a Darcy Model DM-440 digital voltmeter. The thickness of the films was measured by the capacitance method. Current *vs.* temperature measurements were taken by immersing a test fixture with the sample on it into a Dewar flask filled with liquid air (77°K). A Chromel-Alumel thermocouple measured the temperature.

Experimental Results

The current *vs.* voltage characteristics of a MIS sample which is 94Å thick are shown in Fig. 1. The positive and negative signs indicate the potential of the metal relative to the substrate. This plot shows the typical behavior of p- and n-devices thicker than 90Å. The linear characteristic indicates that $\log I \propto \beta V^{1/2}$ where β is a constant. Figure 2 shows a $\log I$ *vs.* $1/T$ plot for a device of 110Å thick which also exhibits this linear behavior on a Schottky plot. Note here the strong temperature dependence of the current at room temperature.

Other workers (5, 6) report that Poole-Frenkel emission is the dominant current mechanism in silicon nitride films at room temperature. However, this type of emission does not show a polarity effect (as in Fig. 1) because it occurs from impurity centers deep within the insulator. This polarity effect, which the Poole-Frenkel model alone cannot explain, is accounted for by noting that there is always a thin layer of SiO_2 on a silicon surface. Optical measurements (7) have shown that on a freshly etched surface of silicon, an oxide layer of 15-20Å thick is formed in about 2 min of exposure to the atmosphere. After the samples used in this work were chemically etched, they were exposed to the atmosphere for about 5 min. Capacitance measurements on devices reported here indicate an oxide thickness varying from 35 to 45Å. This SiO_2 film

Key words: steady state, thin films, silicon nitride.

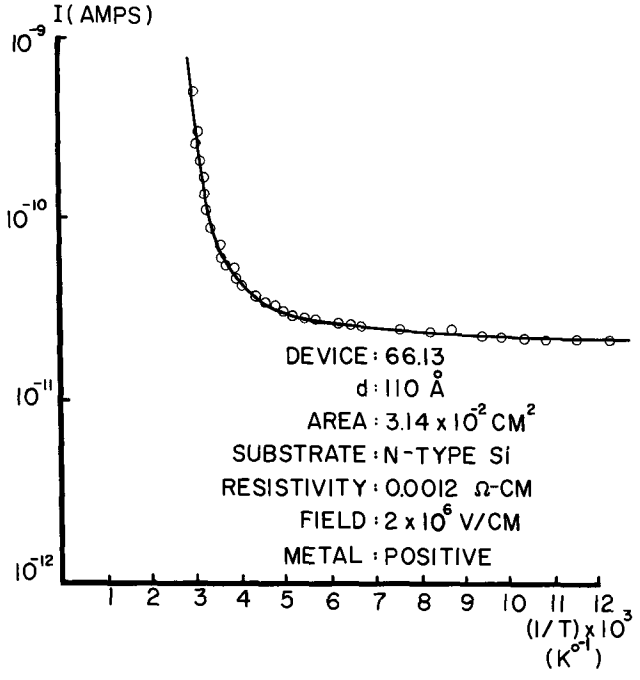

Fig. 2. Current-temperature plot for a n-type substrate device which exhibits linear I-V behavior on a Schottky plot.

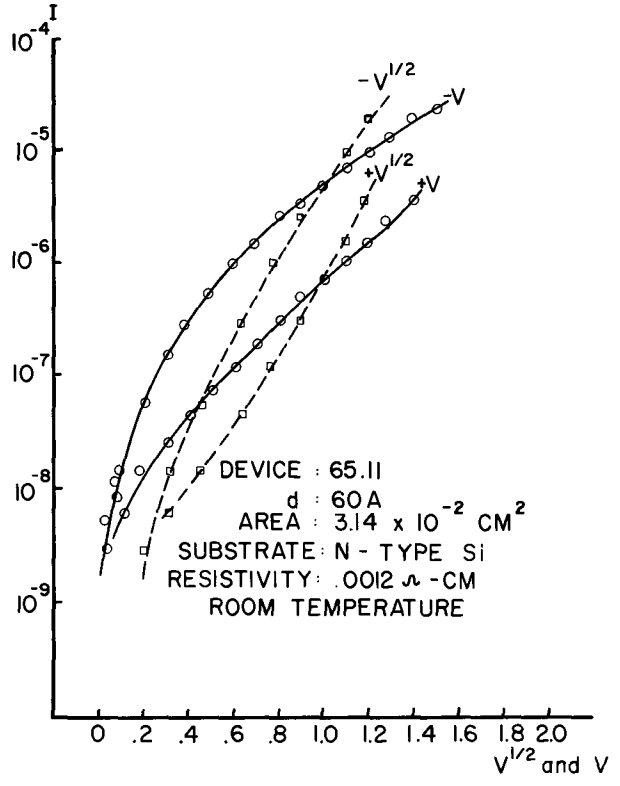

Fig. 3. Log I vs. V and log I vs. V½ curves showing nonlinear characteristics and higher current densities of films below approximately 80Å.

modifies the conduction process from a Poole-Frenkel mechanism to a combination of Poole-Frenkel for the nitride and tunneling through the oxide (9).

Frohman-Bentchkowsky and Lenzlinger (9) studied a similar case with thicker nitride films for which they calculated theoretical current *vs.* voltage characteristics using the two mechanisms mentioned above. Their curves, although for thicker films, are similar to that shown in Fig. 1.

All samples with behavior similar to Fig. 1 exhibit linear behavior up to breakdown. At breakdown, the current shows transient instabilities first, then increases several orders of magnitude. Reducing the field at the onset of the transient behavior prevents the increase in current, but the original characteristics are not recovered.

The current is time dependent, and starts decreasing from the moment the field is applied. A period of 10-15 min is necessary for the current to reach its final value after each increment in voltage. This effect is reduced at liquid-air temperatures.

The samples with film thickness between 60-80Å show different behavior. In Fig. 3, which is typical of this range, conduction starts with a field of the order of 10^3 V/cm, while in devices similar to that of Fig. 1, it starts near 10^6 V/cm. In devices with 60Å films, the current is about three orders of magnitude greater for the same applied field than in devices with 80Å films, as a comparison between Fig. 3 and 4 shows. Such thickness dependence is indicative of a tunneling mechanism (10).

In Fig. 4, the curve corresponding to negative voltages is smooth, while that corresponding to positive voltages shows structures due to the effect of the semiconductor bandgap.

Figure 5 shows the current *vs.* temperature characteristics of an 80Å MIS device. Note here the small variation of current with temperature which is another characteristic of a tunneling mechanism.

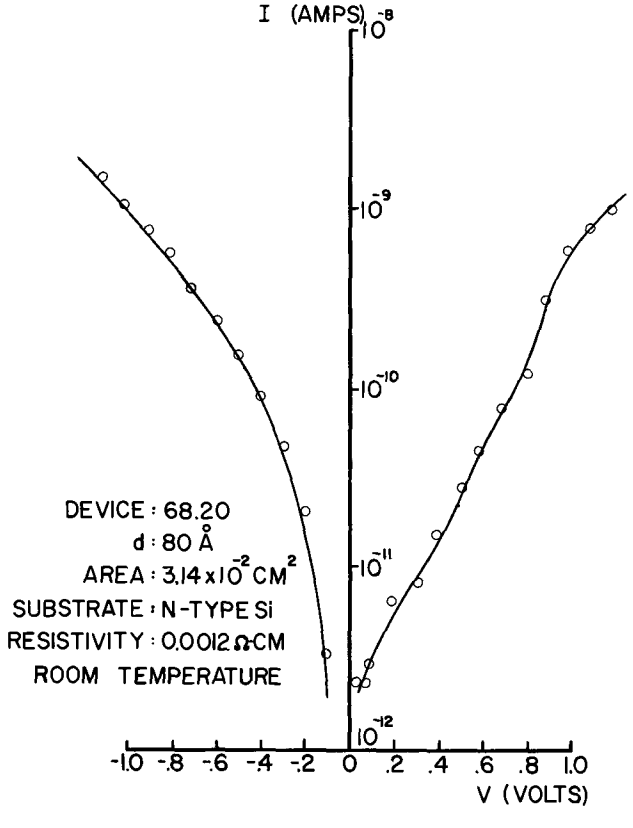

Fig. 4. Current-voltage characteristics of 80Å n-type substrate MIS device which exhibits tunneling.

Conclusion

An analysis of the current *vs.* voltage and temperature characteristics of MNS devices leads us to the conclusion that we have observed a transition of current mechanisms in thin silicon nitride films. For the thicker films, the logarithm of the current is proportional to $\beta V^{1/2}$ over several decades of current, and the current is very temperature dependent at room temperature. This indicates that the emission mechanism is a type of field-assisted, thermal ionization of electrons into the conduction band of the insulator. The polarity effect is due to a thin (40Å) SiO_2 film between the nitride and the semiconductor.

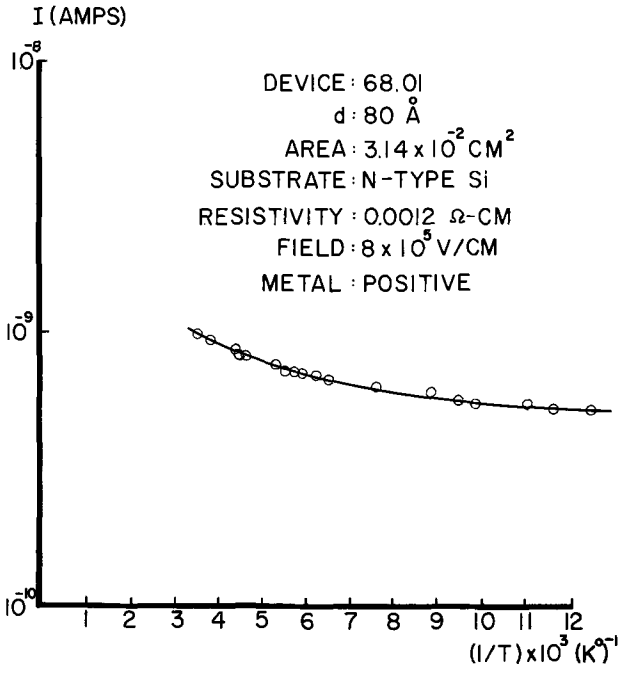

Fig. 5. Current-temperature plot for a n-type substrate device which exhibits tunneling.

At thicknesses below 80Å, the current is due to direct tunneling from metal to semiconductor as shown by the small temperature and large thickness dependence of the current. We were unable to observe both mechanisms on the same device due to the large difference in the field at which both occur.

Transfer of Mobile Ions from Aqueous Solutions to the Silicon Dioxide Surface

S. I. Raider,* L. V. Gregor,* and R. Flitsch

IBM System Products Division, East Fishkill Laboratory, Hopewell Junction, New York 12533

ABSTRACT

The transfer of mobile ions to the SiO_2 surface was investigated by immersing thermally oxidized Si wafers in aqueous solutions containing Na^+ and/or H^+ ions. The number of mobile charges at the SiO_2 surface was determined by electrical measurements on MOS capacitors and the number of Na^+ ions was determined by flame photometry. For deionized H_2O and acid solutions, there is essentially no transfer of mobile charge to the SiO_2 surface. For neutral NaCl solutions, the number of mobile charges transferred is proportional to the Na^+ concentration in solution, and comparable to the number of transferred Na^+ ions. For acidified NaCl solutions, the number of transferred Na^+ ions is comparable to the number of neutral solutions with the same Na^+ concentration; the number of mobile charges is initially much smaller, but slowly increases. These observations are interpreted in terms of the kinetics of cationic adsorption from aqueous solutions at the SiO_2 surface. It is proposed that mobile Na^+ ions are physically or chemically adsorbed directly on an oxide surface, whereas immobile Na ions are adsorbed on an acid-covered oxide surface.

Mobile ions in SiO_2 films can cause semiconductor-device instabilities at concentrations of about 10^{11} singly charged ions/cm^2. This concentration of ions is at, or below, the limit of detection of most available analytical techniques. As a result of the difficulties present in direct identification of the mobile ions, their identities were previously deduced from the nature of the contaminating source. Metal-oxide-semiconductor (MOS) structures were used to study ionic conduction in SiO_2 films. Results from SiO_2 contamination experiments, radiotracer experiments, and electrical measurements were interpreted to show that either alkali ions (1-3) or H^+ ions (4-6) from H_2O, C_2H_5OH (7), and other organics are mobile in SiO_2 films.

In the present investigation, the number of mobile charges transferred to the SiO_2 surface from various contaminating aqueous solutions was determined by electrical measurements on MOS structures and compared with the number of transferred Na^+ ions determined by flame photometry. The mobile ionic species has been identified and experimental results are discussed in terms of adsorption at the SiO_2 surface from the aqueous contaminating solutions.

Experimental

Sample preparation and electrical measurements.— Si wafers (1.25 in. diameter, p-type, 2 ohm-cm, <100>, chem-mech polished) were cleaned in solutions of

* Electrochemical Society Active Member.

Key words: SiO_2 thin films, mobile ions, Na^+ ions, H^+ ions, surface adsorption, MOS, SiO_2-electrolyte interface.

NH_4OH-H_2O_2, HCl-H_2O_2, and HF, then oxidized. An O_2-steam-O_2 oxidation cycle was used at 970°C to grow SiO_2 films 5700Å thick. Some experiments were performed after removing about 200Å of the oxide surface in dilute (1:25) HF and then hydrolyzing in deionized (D.I.) H_2O to form silanol groups. Thinner oxide films were also grown in dry O_2 at 1000°C. Oxides 1000Å thick grown on n-type Si wafers were used for contamination experiments with 1*N* H_2SO_4.

Reagent or electronic grade chemicals were used for contamination experiments. Solutions for contamination of the SiO_2 surfaces were prepared by diluting concentrated solutions with deionized H_2O. Flame photometric analyses showed that the deionized H_2O contained less than 0.3 ppb Na^+ ions. The concentrated HNO_3 and HCl acids each contained about 0.5 ppm Na^+. The starting NaCl or NaOH solutions were prepared by standard volumetric procedures, and Na^+ ion concentrations were determined by flame photometric measurements. Acid or alkali concentrations were determined by acid-base titrations. Contaminating solutions containing both Na^+ and H^+ ions were prepared by combining 45 ml of the Na^+ solution with 5 ml of an acid of appropriate concentration. The solutions were stored in plastic bottles and transferred using only cleaned plastic beakers and plastic graduated cylinders. Contaminations of SiO_2 at elevated temperatures were carried out with Teflon beakers. Quartz beakers were used for the studies in which wafers were ultrasonically agitated during the contamination step.

The SiO_2 surface was contaminated by immersing the wafer, SiO_2 surface up, in a plastic beaker containing 50 ml of the contaminating solution. Generally, this process was carried out at room temperature (22° ± 2°C) for 5 min with no agitation of the solution, but in some experiments, periods of 15 sec, 4 hr, or 4 days were employed. After contamination, the wafers were removed from the beakers and blown dry with warmed, filtered N_2 gas. No H_2O rinse was used after the wafers were contaminated. Control wafers were prepared omitting the contamination step.

Clean Al electrodes (0.05 cm diameter, 5000Å thick) were deposited on the SiO_2 surface through metal masks by electron-gun evaporation. Blanket Al electrodes were deposited on the backside of the Si wafer to improve the electrical contact when testing. The wafers were then annealed at 400°C for 20 min in N_2. In some experiments, Au instead of Al electrodes were evaporated onto the oxide surface.

The electrical MOS measurements to determine the total number of mobile charges per unit area (Q/q) were performed at 250°C with d-c fields of 0.7 MV/cm for biasing. The number (Q/q) was determined from capacitance-voltage measurements (8) by obtaining the difference in flatband voltages before and after biasing MOS structures for 5 min. For $\geq 10^{13}$ mobile charges/cm^2, the charge-time (Q-t) technique (9) was used to make a direct measurement of the total mobile charge when the MOS structures were thermally biased. Four or more MOS structures were examined on each wafer for a particular contamination experiment.

Several lots of oxides were grown over an extended period of time during which the described experiments were conducted. Mobile-charge levels in control samples of these oxides varied from 0.4-2.8 × 10^{11}/cm^2. However, the scatter in this background mobile-charge level for oxides obtained from any particular oxidation lot was generally $<10^{11}$/cm^2. Negligible mobile-ion contamination occurs during Al metallization since thin oxides grown in dry O_2 contained $\leq 5 \times 10^{10}$ mobile charges/cm^2 after Al electrode depositions. Oxides used for a related group of contamination experiments were grown in a single lot. Immersion of the oxide for 5 min in deionized H_2O frequently reduced the mobile charge below that of a nonrinsed control wafer.

Flame photometric determination of Na^+ ions.[1]—The number of Na^+ ions present at an oxide surface was measured by flame photometry. About 200Å of the SiO_2 surface of a wafer was etched away with 15 drops of diluted (1:20) ultrapure (0.5 ppb Na^+)HF. The etch solution was transferred to a clean disposable plastic beaker. The wafer surface was then rinsed with deionized H_2O. The rinse H_2O was also transferred to the disposable beaker, giving a total of about 2 ml of solution. The total number of Na^+ ions was obtained from the solution weight and the Na^+ concentration measured with the flame photometer. The detection limit for Na^+ ions was about 1 ppb by weight or 0.001 μg/ml of solution. When possible, lower Na^+ levels were determined after solvent evaporation to increase the Na^+ concentration of the solution. To facilitate comparisons with the results of electrical measurements, the flame photometric data are expressed as the total number of Na^+ ions per unit area of oxide surface. For example, a weight of 0.1 μg of Na from the wafer surface is equivalent to 3.3 × 10^{14} Na/cm^2.

Results

Total mobile charge transferred to SiO_2 from contaminating aqueous solutions.—Deionized H_2O.—To determine whether deionized H_2O introduces mobile charge to the oxide, wafers were immersed into H_2O for varying times and temperatures, after which the mobile charge was found by C-V measurements. The data from these experiments are given in Table I. These results, which are contrary to those of Hofstein (4) and in agreement with that of Yurash and Deal (10), indicate that SiO_2 immersion into deionized H_2O does not increase the number of mobile charges at SiO_2 surfaces.

Acid solutions.—Both HCl and HNO_3 solutions were used for contamination studies over a wide range of acid concentrations. In Fig. 1, the mobile charge present at the SiO_2 surface after immersion in HCl solutions for 5 min at 22°C is shown as a function of H^+ ion concentration. Similar results were obtained after SiO_2 immersion into HNO_3 solutions and a 1*N* H_2SO_4 solution. Essentially, no mobile charge is transferred to the oxides from these acids despite the large number of H^+ ions present at the oxide surface in solution.

Solutions containing Na^+ ions.—The effects of NaCl contamination of SiO_2 surfaces from neutral aqueous solutions on the total mobile charge for an immersion time of 5 min at 22°C are shown in Fig. 1. The number of mobile charges present at the SiO_2 surface is proportional to the Na^+ ion concentration in the neutral NaCl solutions. Similar results were obtained after SiO_2 immersion into NaCl solutions at 22°C. In Table II, the number of mobile charges present at the oxide surface is given as a function of Na^+ concentration for four different immersion times at 22°C. The rate of adsorption of mobile ions is a function of Na^+ con-

[1] Although flame photometry does not distinguish between Na atoms and Na^+ ions, for convenience we shall refer to the species detected by this technique as the Na^+ ion, since in general the Na present at SiO_2 surfaces is in ionic form.

centration and initially is rapid but decreases with increasing time of immersion. When the temperature of the contaminating NaCl solution was increased from 22° to 70°C, the number of mobile charges transferred to SiO_2 was increased (Table III).

Figure 1 shows that a neutral NaCl solution, with 0.5 ppm of Na^+ ions ($2.2 \times 10^{-5}N$), transferred between 10^{12}-10^{13} mobile charges/cm² to the oxide surfaces after an immersion time of 5 min at 22°C. Concentrated HCl and HNO_3, which also contained 0.5 ppm of Na^+ ions, transferred only about 10^{11} mobile charges/cm² to SiO_2 under the same conditions. This difference indicates that there is a relationship between the concentration of H^+ ions in NaCl solutions and the transfer of mobile charge to the oxide surface. A number of experiments were performed to examine this relationship.

Wafers were contaminated by immersion into acidified (1*N* HCl) NaCl solutions at 22°C for varying periods of time. In Fig. 2 the number of mobile charges present at the oxide surface is plotted as a function of Na^+ concentration for three different immersion times and compared with transfer from neutral NaCl solutions for a 5 min contamination period. During immersion for 5 min no mobile charges were transferred to the oxide from the acidic solutions until the Na^+ ion concentration reached $10^{-2}N$. As the time of wafer immersion is increased, the number of mobile charges transferred to the oxide surface is also increased. After immersing wafers for 4 days in acidified NaCl solutions, the numbers of mobile charges transferred to the oxides appear to be approaching the values obtained with neutral contaminating solutions with the same Na^+ concentrations. These results indicate that in aqueous NaCl contaminating solutions, which are 1*N* with respect to HCl, the rate of mobile charge transfer to the oxide surfaces is decreased in comparison with neutral contaminating solutions.

The number of mobile charges present at the SiO_2 surface after immersion into aqueous NaCl solutions at 22°C was also measured as a function of acid concentration in the solutions. The time of wafer immersion was kept constant at 5 min.

The data from these experiments, which are plotted in Fig. 3, show that as the H^+ ion concentration is decreased, *i.e.*, as the pH is increased, the number of mobile charges transferred to the oxide is increased. Considerable scatter in mobile-charge data was obtained for oxides immersed into NaCl solutions acidified with HCl at concentrations between $10^{-2}N$ and $10^{-5}N$. These results fall between those of $10^{-1}N$ HCl and neutral solutions (D.I. H_2O) and are illustrated as a cross-hatched region in Fig. 3. At pH values greater than 7, solutions of NaOH, rather than NaCl, were used for contamination of the oxides. For Na^+ concentrations of $10^{-5}N$ and above, the number of mobile charges transferred in 5 min was greater for the NaOH solutions than for the neutral NaCl solutions. When the acidified NaCl solutions were ultrasonically agitated, or when the temperatures of the solutions were elevated during the contamination step, the numbers of mobile charges transferred to the oxide increased. Data showing these results are given in Table III.

Some of the room temperature contamination experiments with solutions containing Na^+ and H^+ were repeated with 500Å oxides grown in dry O_2. The results were the same as those obtained for thick oxides.

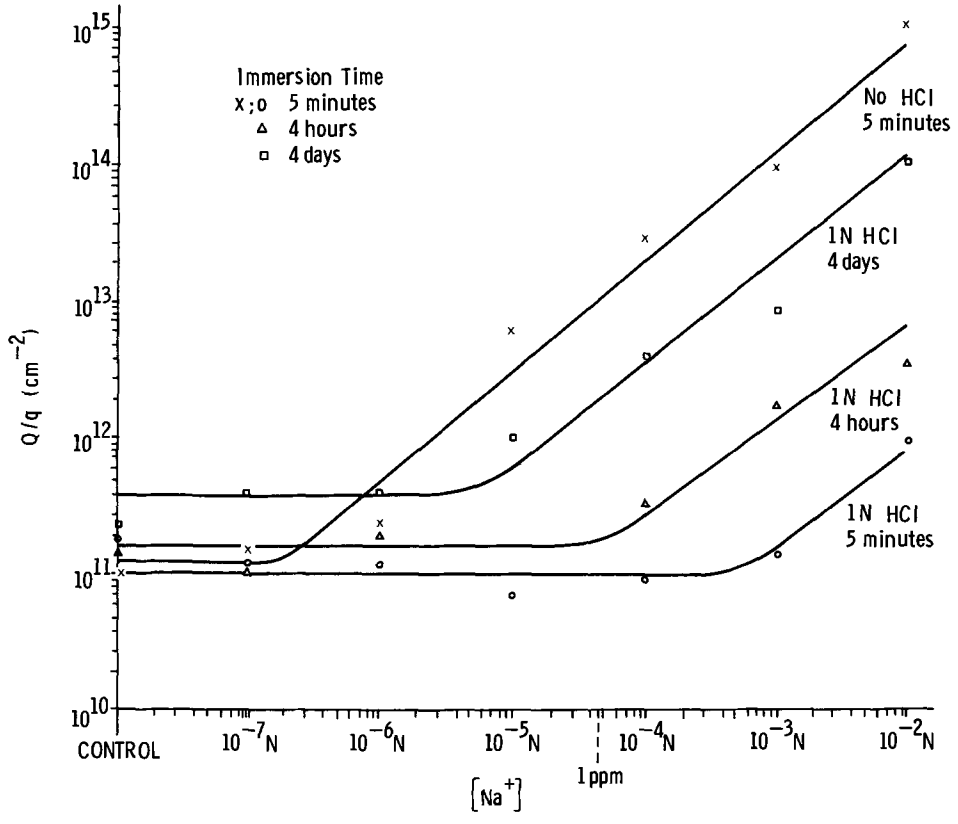

Fig. 2. Total mobile charge at SiO_2 surfaces after immersion in aqueous NaCl solutions, plotted against Na^+ concentration in solution, for neutral solutions (from Fig. 1), and for solutions acidified with 1*N* HCl.

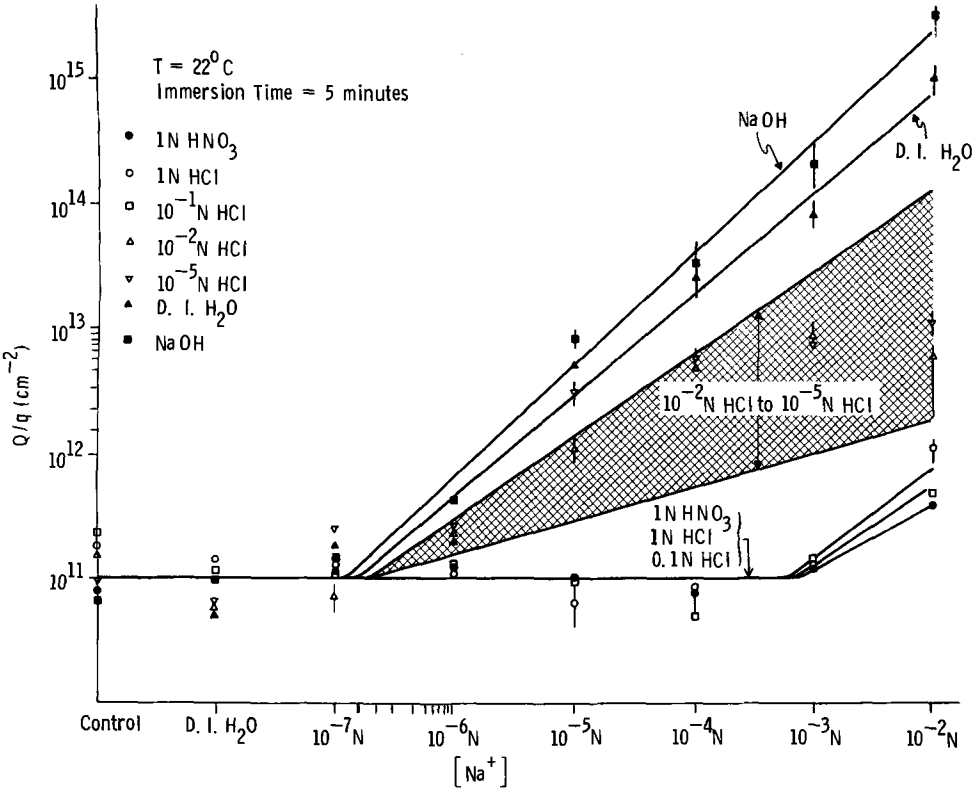

Fig. 3. Total mobile charge at SiO_2 surfaces after immersion in aqueous NaCl solutions, plotted as a function of Na^+, H^+, and OH^- concentrations in solution.

Similar results in reducing mobile charge transfer to the SiO_2 were obtained when 1000Å films (n-Si, <100>, 2 ohm-cm, oxidized in dry O_2) were contaminated by NaCl solutions acidified with 1*N* H_2SO_4. The same effect of acid in reducing mobile ion transfer to SiO_2 was obtained using Au rather than Al electrodes.

Additional experiments were performed to determine whether the SiO_2 surface could be pretreated with acid to prevent transfer of mobile charge. Immersion of the wafers in acidic solutions was followed either by immersion in neutral NaCl solutions, or by evaporation of NaCl onto the oxide surface. In both cases the acid treatments did not prevent mobile-charge transfer to the oxide surfaces. Annealing the oxides in forming gas (H_2:N_2 = 1:9) at 400°C for 20 min prior to immersion into neutral NaCl solutions also failed to reduce the number of mobile charges transferred to the oxides. The reduction in the rate at which mobile charges are transferred to SiO_2 from aqueous solution clearly requires both H^+ and Na^+ ions to be present in the same solution. The removal of mobile charges from SiO_2 surfaces intentionally contaminated with Na^+ ions was also studied. Initially, wafers were immersed into neutral $10^{-2}N$ NaCl solutions for 5 min at 22°C. After drying the wafers with warmed N_2 gas, these contaminated oxides were then

immersed into 50 ml of ultrasonically agitated solutions containing different concentrations of HNO_3. Mobile-charge drift data, shown in Table IV, indicate that a $0.1N$ HNO_3 solution was the most effective for removal of mobile charge from the SiO_2 surface. Similar results of experiments using HCl are also given in Table IV.

Total number of Na^+ ions present at the SiO_2 surface after immersion in contaminating aqueous solutions.— Flame photometry was used to determine the number of Na^+ ions[1] present at oxide surfaces which had been (*i*) immersed into neutral NaCl solutions, (*ii*) immersed into acidified ($1N$ HNO_3) NaCl solutions, or (*iii*) immersed into acidified ($1N$ HNO_3) NaCl solutions and subsequently metalized with Al. In all cases the immersion time was 5 min at 22°C. The results of these analyses are given in Table V where they are compared with results from electrical measurements of mobile charge present on the oxide after the same treatment. For SiO_2 surfaces immersed in neutral NaCl solutions, the total number of Na^+ ions determined by flame photometry is comparable to the number of mobile charges found electrically. However, there is no agreement between these two measurements when the contaminating solution is acidified. In this case, the electrical measurements show that mobile charges were not transferred to the oxide, whereas the flame photometric analysis indicated that Na^+ ions were present at the oxide surface. After Al deposition, the total number of Na^+ ions measured by flame photometry decreased by a small amount but remained orders of magnitude larger than the number of mobile charges found electrically. This decrease in total Na^+ ions after Al deposition was the result of scattering of Na^+ ions by the Al evaporated onto the oxides. In order to avoid the scattering of Na^+ ions, control wafers for flame photometric analyses had to be metalized in the absence of oxides contaminated with NaCl. (Control wafers for electrical measurements of mobile charge were metalized in the presence of oxides contaminated with NaCl. This did not affect the mobile charge level.)

Discussion

The mobile ions transferred to SiO_2 from the different aqueous solutions are identified in the first part of this discussion. In the second part, the effects of H^+ (or OH^-) ions in solution on mobile ion adsorption onto SiO_2 surfaces are considered. A qualitative model is proposed which distinguishes between the mobile and immobile Na transferred to SiO_2 surfaces from aqueous solutions.

Identification of mobile ions transferred to SiO_2.— Negligible mobile charge is transferred to SiO_2 when it is immersed in Na-free solutions containing varying concentrations of HCl (Fig. 1) or HNO_3, or in solutions of $1N$ H_2SO_4, a less volatile acid than HCl or HNO_3. Similar results were obtained with other inorganic [H_2O (10), NH_4OH (11)] or organic [ethanol (7), trichloroethylene (10), acetone (11), i-propanol (11)] reagents containing hydrogen but free of alkali ions. In addition, tritium incorporated in tritiated steam-grown oxides does not drift in an electric field (12). Thus it appears that H in SiO_2 is immobile at typical applied fields used for oxide stability studies.

Appreciable quantities of mobile charge are transferred to SiO_2 from neutral aqueous NaCl (or NaI) solutions. The number of mobile charges is proportional to the Na^+ ion concentrations in these solutions and is approximately equal to the number of transferred Na^+ ions (measured by flame photometry). The polarity (Al+) of the applied bias used to stress the MOS capacitors is consistent with cationic drift. Since the solvent, H_2O, does not transfer mobile charge to the SiO_2, these results show that the transferred mobile charges are Na^+ ions. The difference between Na and H transport in SiO_2 in response to an electric field may be related to a difference in polarizability of the bonds formed. However, when comparing the mobility of Na and H in the present work, it must be kept in mind that no direct evidence was obtained for the presence of H^+ ions on an SiO_2 surface after acidic solution contamination and MOS capacitor fabrication.

Experimental data are given in Fig. 3 for the number of mobile ions present at the SiO_2 surface after immersion into contaminating solutions containing both Na^+ and H^+ ions. Under those conditions in which some charge transfer to SiO_2 is observed, the number of mobile ions increases with an increase in concentration of Na^+ ions and a decrease in concentration of the acid. The mobile ions transferred from the acidified solutions are apparently Na^+ rather than H^+ ions.

The flame photometry results show that the number of Na^+ ions transferred from acidic ($1N$ HNO_3) NaCl solutions to SiO_2 is similar to the number transferred from neutral NaCl solutions (Table V). However, the MOS measurements show that relatively few mobile ions are transferred to SiO_2 from these acidic solutions. Thus Na^+ ions present at the Al/SiO_2 interface can be either mobile or immobile when an MOS capacitor

is stressed in an electric field at an elevated temperature.

Adsorption at the SiO_2 surface.—To explain the behavior of Na^+ ions at the SiO_2 surface, we propose that these ions are mobile if in solution they are adsorbed directly on this surface, but are immobile if they are separated from the surface by a layer of adsorbed acid molecules.

A SiO_2 surface provides approximately 10^{15} sites/cm^2 for cation adsorption. The surface of an untreated thermally grown film consists of siloxane (Si-O-Si) groups, and adsorbed Na^+ ions deposited on such a surface by evaporation are mobile (2). If a thermally grown film is etched with HF and then immersed into H_2O the surface consists of silanol (SiOH) groups. Our experiments show that Na^+ ions transferred to this surface from neutral aqueous solutions are mobile. Thus Na^+ ions adsorbed directly on the SiO_2 surface are mobile whether they are physically adsorbed at siloxane sites or chemically bound (SiO^-Na^+) at silanol sites. This conclusion is consistent with our observation that Na^+ ions are mobile on the surface obtained when a thermally grown SiO_2 film is immersed directly in H_2O without prior etching in HF; in this case the relative numbers of siloxane and silanol groups are not well established.

For contamination of the SiO_2 surface by neutral aqueous NaCl solutions, identifying the mobile-charge carriers as directly adsorbed Na^+ ions permits a straightforward interpretation of the observed dependence of the number of mobile charges on the immersion time (Table II) and on the Na^+ ion concentration in solution (Table II and Fig. 1). The increase in mobile charge with time is due to the increase in the number of adsorbed Na^+ ions as this number approaches the equilibrium value determined by the concentration of Na^+ ions in solution. The rate of approach to equilibrium, which increases with increasing temperature (Table III), is probably determined by the rates at which Na^+ ions diffuse through the solution and are adsorbed and desorbed at the oxide surface. After any fixed immersion time, the number of adsorbed Na^+ ions increases with increasing Na^+ ion concentration in solution and causes a corresponding increase in the number of mobile charges.

Strong acids in alkali-free aqueous solutions modify SiO_2 surfaces by inhibiting dissociation of silanol groups and by becoming contact adsorbed (13) at the siloxane or silanol oxygen atoms, *i.e.*, at the cationic adsorption sites. Anions from solution are subsequently adsorbed to form a layer of acid molecules hydrogen-bonded to the SiO_2 surface. A 1:1 complex between SiO_2 (in solution) and HCl has been reported by Sadek (14).

If a SiO_2 surface is immersed in an aqueous solution containing both H^+ and Na^+ ions, the two types of ions will compete for the cationic adsorption sites. Because of their higher mobility in H_2O, the H^+ ions tend to be more rapidly adsorbed than the Na^+ ions. Electrokinetic and H^+ ion adsorption studies on quartz and other oxides have indicated that H^+ ions are potential-determining (13); they rapidly modify surface charge and become contact absorbed on an oxide surface in the presence of Na^+ or other cations (13, 16, 17).

For contaminating solutions with sufficiently large H^+:Na^+ ion ratios, the number of mobile charges transferred to the SiO_2 surface is initially very small (Fig. 2) even though the number of adsorbed Na^+ ions is appreciable (Table V). This observation can be explained by assuming that in this case H^+ ions are initially adsorbed on practically all the adsorption sites on the SiO_2 surface, an acid layer which completely covers the surface is then formed by adsorption of anions from the solution, and Na^+ ions from the solution are adsorbed on the acid layer. Finally, the model assumes that the order of anion and Na^+ ion adsorption from solution is retained during MOS capacitor fabrication and that Na^+ ions adsorbed on a layer of anions are immobile, so that they cannot be detected by MOS drift measurements.

The proposed immobility of Na^+ ions adsorbed on an acid layer probably results because the drift of these ions toward the SiO_2 surface in an electric field is sterically hindered by the adjacent sheet of large anions. Alternatively, the Na^+ ions might be trapped either in the metal deposited to form the MOS structure or at the metal-oxide interface, since the flame photometric data indicate that Na scattering and entrapment occur during metal deposition. However it is not apparent how this explanation could account for the proposed difference in mobility between Na^+ ions adsorbed on an intermediate acid layer and those adsorbed directly on the SiO_2 surface. Furthermore, Na^+ ions from acid solutions are immobile in MOS structures made with Au electrodes. Since this element is less likely than Al to react with SiO_2, this observation suggests that the metal layer does not play a critical role in immobilizing the Na^+ ions.

Even for contaminating solutions that are sufficiently acidic to make the initial transfer of mobile charge to the SiO_2 surface very small, the number of mobile charges increases appreciably with increasing immersion time (Fig. 2). According to our model, this observation shows that at equilibrium an appreciable fraction of the adsorption sites on the SiO_2 surface in these solutions is occupied by Na^+ ions. The increase in mobile charge occurs as equilibrium is approached by the desorption of initially adsorbed, immobile H^+ ions and their replacement by Na^+ ions that are mobile because they are adsorbed directly on the SiO_2 surface. This exchange process is strongly accelerated by raising the temperature and by ultrasonic agitation (Table III).

Decreasing the H^+ ion concentration in acidified NaCl contaminating solutions increases the amount of mobile charge transferred to the SiO_2 surface during immersion for 5 min (Fig. 3). This change is due to the increased transfer of directly adsorbed, mobile Na^+ ions which is made possible by decreasing the competition of H^+ ions for the adsorption sites on the SiO_2 surface.

Summary

Alkali-free aqueous solutions containing H^+ ions do not transfer mobile charges to thermally grown SiO_2 films. In oxide contaminations with neutral NaCl solutions, the number of mobile charges transferred to SiO_2 was proportional to the Na^+ ion concentration in the contaminating solution and approximately equal to the total number of Na^+ ions determined by flame photometry. The rate of mobile-charge transfer to SiO_2 was reduced by adding H^+ ions to the contaminating solution and increased by adding OH^- ions. To explain these observations, it is proposed that Na ions are mobile if they are adsorbed from solution directly on the SiO_2 surface but are immobile if they are separated from the surface by a layer of adsorbed acid molecules. The kinetics of competing H^+ and Na^+ ion adsorption and exchange on the oxide surface determine the rate of mobile Na^+ ion transfer to SiO_2.

Striations Due to Compositional Variations in Czochralski-Grown $(Pb_{1-x}Sn_x)_{1-y}Te_y$

J. R. Burke, J. D. Jensen, and Bland Houston

Naval Ordnance Laboratory, Silver Spring, Maryland 20910

ABSTRACT

Compositional striations in $(Pb_{1-x}Sn_x)_{1-y}Te_y$ crystals grown by the Czochralski technique in two different laboratories have been revealed by application of Norr's electroetch. The striations appear as contours which delineate the prevailing growth interface. In crystals from both laboratories, the spacing of the contours is much too large and not sufficiently periodic to be accounted for by rotational effects. The nonrotational origin of the striations was confirmed by the observation that their intensity and spacing were not changed by stopping the rotation during growth. Electron-probe microanalysis studies show that x varies by as much as 0.01 over distances of the order of 100 μm in the direction normal to the striations.

Solid solutions of $(Pb_{1-x}Sn_x)_{1-y}Te_y$ are known to exist in the face-centered cubic structure for $0 \leq x \leq 1$ and for $0.50 \leq y \leq 0.51$ approximately (the exact limits of y depend on x). Each composition thus far investigated is a direct-gap semiconductor with conduction and valence-band extrema at or near the L-points of the Brillouin zone. Considerable interest centers on this system from both a basic and device point of view, because (*i*) the bandgap is a strong function of x, and (*ii*) this gap can be made arbitrarily small by the proper choice of x. In this paper we will present some of the metallurgical properties of single crystals grown by the Czochralski technique, and briefly mention the results of Shubnikov-de Haas experiments which appear to be influenced by this method of growth.

Crystal Growth and Surface Preparation

Most of our studies were carried out on material grown by the Electronic Materials Division of Bell and Howell Company (hereafter referred to as BH) (1). Some material recently grown at our laboratory has also been examined. BH provided either complete as-pulled single crystals, or single crystal slices that had been annealed to alter their properties. The crystals were in general pulled in a <111> direction at 8 mm/hr with a seed rotation rate of 10 rpm. Because of the high vapor pressure of $(Pb_{1-x}Sn_x)_{1-y}Te_y$, B_2O_3 was used to encapsulate the melt. The slices were cut out with a wire saw and lapped to a thickness of about 0.75 mm before annealing.

Key words: striations, crystal growth and characterization, compound semiconductors, $(Pb_{1-x}Sn_x)_{1-y}Te_y$, electropolishing, alloys.

As-pulled crystals of $(Pb_{1-x}Sn_x)_{1-y}Te_y$ are characterized by hole concentrations of the order of 10^{19} cm^{-3} produced by deviations from $y = \frac{1}{2}$. In order to obtain lower hole concentrations, the slices were annealed in evacuated ampoules in the presence of a two-phase ingot with the same x, but with $y < 0.5$. Equilibration with the ingot takes place through the vapor phase. This is a well-established procedure for the lead chalcogenides and the $(Pb_{1-x}Sn_x)_{1-y}Te_y$ alloys (2, 3).

To prepare a specimen for metallographic examination, the following steps were applied to one of its surfaces: (*i*) rough grinding on 600 grit SiC paper with flowing water as a lubricant until about 60 μm of material was removed; (*ii*) fine grinding on nylon cloth with Buehler's 6 μm Metadi diamond paste and Metadi fluid as a lubricant for twice as long as necessary to remove the scratches from step (*i*); (*iii*) polishing on Buehler's Microcloth using ¼ μm diamond paste and Metadi fluid for twice as long as necessary to remove the scratches from step (*ii*); and (*iv*) electropolishing and electroetching using the solution and procedures developed by Norr (4). The electropolishing times varied from about 2-10 min. The striations were formed during this period, and usually 2 min were sufficient for them to be easily observable. This stage was followed by an electroetch for 15 sec to see if pits could be developed.

Although Norr's solution was designed for preparation of PbTe surfaces and is not effective on SnTe, we have found that the electropolishing procedure gives high polishes on $(Pb_{1-x}Sn_x)_{1-y}Te_y$ surfaces for x as large as 0.30, and some polishing for $x = 0.60$. The

polishing action, and the degree to which the striations develop, do not depend strongly on the crystallographic orientation of the surface. The electroetching procedure did not produce etch pits consistently, even on {100} surfaces and for x as small as 0.13.

Results of Etching Studies

$(Pb_{0.70}Sn_{0.30})_{1-y}Te_y$.—Figure 1 shows a prepared (001) plane of a slice cut out of a [111]-grown BH single crystal with $x = 0.30$. The slice is about 0.75 mm thick, and prior to our preparation had been annealed by BH at 583°C for 44 days. A well-defined pattern of striations is apparent. They are always visible to the naked eye in fluorescent room light (note the low magnification in Fig. 1). Since the effectiveness of the electroetching technique decreases with increasing Sn content, it was suspected that the striations are caused by variations in x. This has been confirmed by the results of electron probe microanalysis.

The side of this slice after electroetching is shown in Fig. 2. The normal to the striations makes an angle of about 55° with the [001] direction. Thus the striations lie approximately in {111} planes perpendicular to the [111]-growth direction.

Figure 3 is an interference pattern showing the relief of the surface in Fig. 1. It was formed by placing this surface in contact with a 50% transmitting aluminum coating on an optical flat, and using the Hg 546.0 nm line for illumination. The hills (or valleys) are about 100 μm apart. There is a shift of approximately one fringe between a hill and a valley, corresponding to a height difference of about ¼ μm.

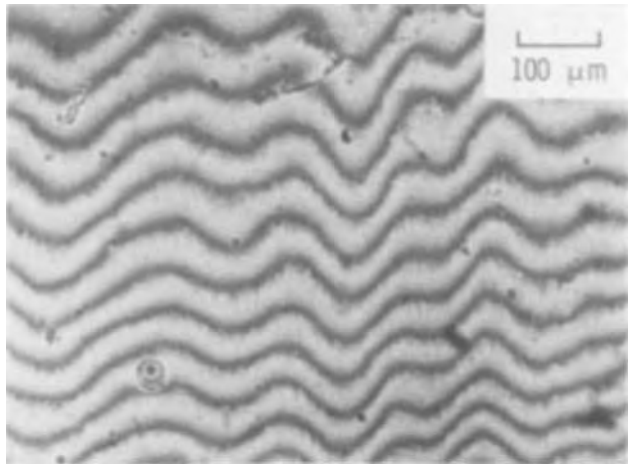

Fig. 3. Interference pattern showing the relief of the surface shown in Fig. 1.

$(Pb_{0.40}Sn_{0.60})_{1-y}Te_y$.—Figure 4 shows a prepared (001) plane of a slice cut out of a [111]-grown BH single crystal with $x = 0.60$. The slice is approximately 0.75 mm thick, and prior to our preparation had been annealed by BH at 500°C for 49 days, 452°C for 17 days, and 405°C for 46 days. In addition to striations, scratches remaining from preparation steps (*i-iii*) are also present. As mentioned above, the electropolishing rate for this material was significantly reduced due to the large amount of tin present. As a consequence the electropolishing time in step (*iv*) was extended to 10 min. Figure 5 is a magnified view of an area near the center of the upper edge of the slice. Figure 6 is an interference pattern obtained by the method described above. The microscope was slightly defocused so that both the striations and the interference pattern could be seen and compared. Higher magnification shows that there is a shift of about four fringes between a hill and valley, which corresponds to a height difference of about 1 μm. This is a factor of 4 greater than the corresponding difference on the $x = 0.30$ slice, but the electropolishing time was also about 5 times longer. This suggests the possibility that the rates of preferential etching are independent of average composition.

Further studies.—Our laboratory has recently initiated a study of the growth of $(Pb_{1-x}Sn_x)_{1-y}Te_y$ crystals by the Czochralski technique. Figure 7 shows a crystal that was pulled at 8 mm/hr using a crucible rotation rate of 10 rpm. It is not single but composed of large single crystal sections. Prior to preparation,

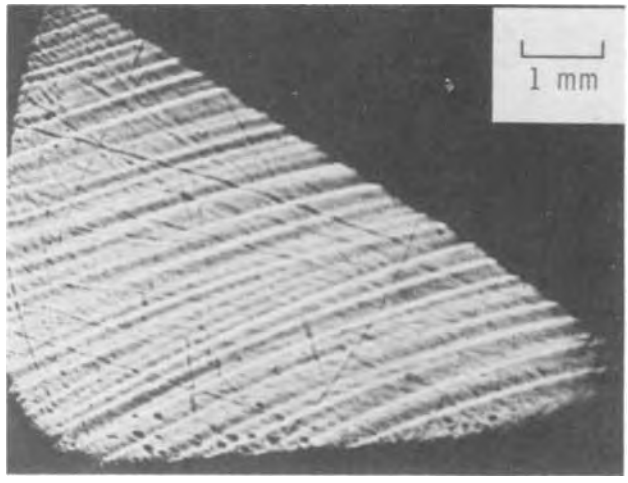

Fig. 4. (001) plane of a single-crystal slice of $(Pb_{0.40}Sn_{0.60})_{1-y}Te_y$ after electroetching.

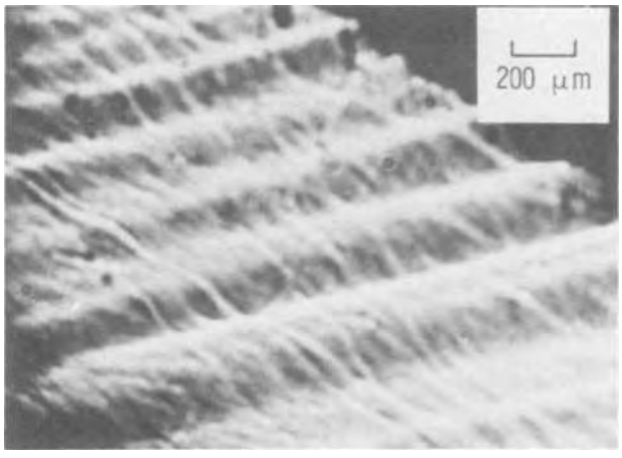

Fig. 5. Magnified view of an area near the center of the upper edge of the surface shown in Fig. 4.

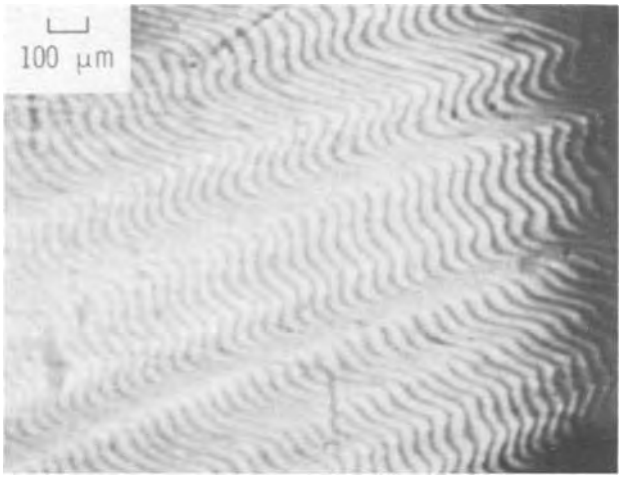

Fig. 6. Interference pattern for part of the surface shown in Fig. 4. Defocusing the microscope slightly revealed both the striations and the interference fringes.

the plane shown was arbitrarily selected by grinding parallel to the growth direction, which is vertical in the figure. The starting composition of the melt was $x = 0.35$, $y = 0.50$. The striations were revealed by the surface preparation previously described. Crystals pulled at the same rate, but with seed rotation instead of crucible rotation, show essentially the same pattern. In addition to the regular striations common to the BH material, there is a superimposed mosaic structure in Fig. 7 near the end of the crystal that was last to grow. This may have been the result of constitutional supercooling caused by an excessive growth rate.

Striations in doped semiconductor crystals pulled from the melt have been studied extensively (6). Both rotational and nonrotational striations are observed. The former are shown to be precisely periodic and caused by rotation of the crystal in a melt in which the temperature gradient is asymmetric, relative to the axis of rotation. Nonrotational striations are known to be caused by destabilizing thermal gradients. The periodicity of rotational striations calculated from the pull rate and rotation rate (6) used to grow our crystals and those of BH is 13 μm, an order of magnitude smaller than the spacing between the observed striations. The nonrotational origin of the striations in our material was confirmed by stopping the rotation during growth. Their intensity and spacing were found to remain unchanged relative to those obtained during rotation.

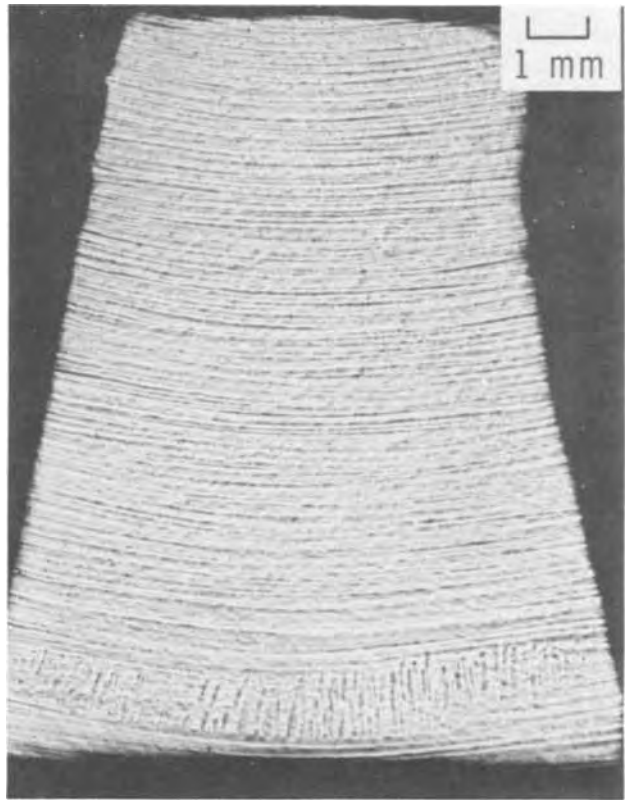

Fig. 7. Electroetched plane of a $(Pb_{1-x}Sn_x)_{1-y}$ Te_y crystal pulled at this laboratory. The plane is parallel to the growth direction, which is vertical in this figure.

Electron-Probe Microanalysis

In order to determine the compositional changes causing the striations, a section of the slice shown in Fig. 1 was submitted to the National Bureau of Standards for electron-probe microanalysis. Figure 8 shows part of this section after microanalysis was completed. The illumination and exposure time were adjusted so that both the striations and the spots made by the electron beam would be visible in the photograph. The spots are due to surface contamination by hydrocarbons broken down by the 20 keV electron beam. It was found that if the beam were scanned over a spot 5 × 4 μm, a target current of 50 nA could be used without damaging the sample. This was checked by repeating measurements at the same point several times. Higher current densities, *e.g.*, 100 nA and a 1μm diameter spot, caused melting.

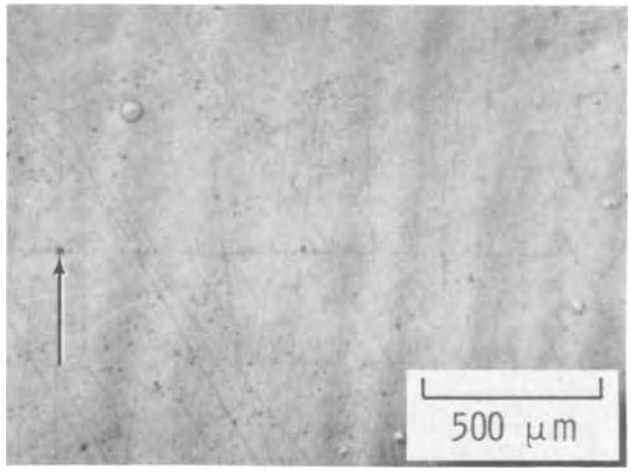

Fig. 8. Section of the surface shown in Fig. 1 that was used for electron-probe microanalysis.

Measurements were made at 20 μm intervals over a distance of 1200 μm beginning at the sixth spot to the right of the large square spot indicated by the arrow. Under microscopic examination, the positions of the spots could be correlated with features of the striations and compared to the results of the microanalysis. Correlation with the microanalysis of a number of detailed features of the striations not apparent in Fig. 8 was possible. As anticipated, it was clear that the hills were associated with excess tin and the valleys with excess lead.

Figure 9 shows the atomic fraction of each element at all the measured points. The x-ray intensities for all three elements were simultaneously measured with a three-spectrometer ARL microprobe having a take-off angle of 52.5°. LiF crystals were used for analysis of Sn L_α and Te L_α lines while an RAP crystal was used for analysis of the Pb M_α (second order) line. These data were then corrected for x-ray absorption, atomic number effects, and secondary fluorescence. Since only relative changes were of interest, the specimen itself was used as a standard for the three elements. The average of all counts for each element was taken as the standard intensity for that element, and the corresponding chemical composition was assumed to be $(Pb_{0.70}Sn_{0.30})_{0.50}Te_{0.50}$. The Pb and Sn concentrations in this formula were determined at BH from Vegard's law which has been verified for this system (5). These compositions were also checked at our laboratory by the same method.

Neglecting for the moment monotonic changes as a function of position, there is a good correlation between the minima in the Pb fraction and the maxima in the Sn fraction. The largest changes in x are about 0.01. The differences between the atomic fractions of Sn in the peaks and valleys are significantly outside the corresponding $\pm 3\sigma$ ranges, and the decrease in the atomic fraction of Sn is in general much larger than

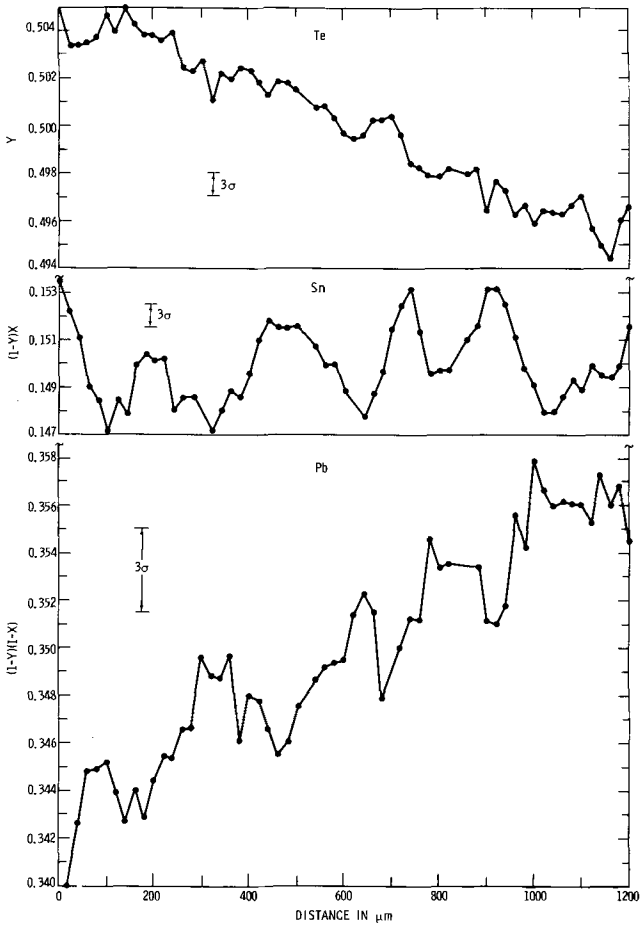

Fig. 9. Atomic fractions of Te, Sn, and Pb as a function of position on the surface shown in Fig. 8.

that forced by the corresponding increase in the atomic fraction of Pb. The fluctuations in the atomic fractions of Pb and Te are comparable to $\pm 3\sigma$. The large σ for Pb is due to the use of the second order M_α line and to a large background. However, the correlation of the Sn and Pb results suggests that the latter are significant.

The monotonic changes in the atomic fractions shown in Fig. 9 were observed in the raw data for the x-ray intensities. They are surprising because this specimen was taken from a slice in which the metal and Te concentrations should have been homogenized by annealing (2, 3). From a linear least squares fit to the Te data, the decrease in y over 1200 μm is 0.01. Although the width of the solidus field has not been established for the alloy $x = 0.30$, this change in y is much larger than the solidus field width for example of the alloy $x = 0.27$ (3). The change in the hole concentration corresponding to a change in y of 0.01 would be about 6×10^{20} cm^{-3} (assuming one carrier per extra atom). To check this, we made Hall coefficient measurements on a sample taken from the microanalyzed specimen. The sample was cut so that it included the spots shown in Fig. 8, and also so that its long dimension lay parallel to the gradient indicated by the microanalysis. Measurements were made at several points along the length of the sample. The results at 300° and 77°K are given in Table I along with the hole concentration $1/R_{77°K}e$. The hole concentration is essentially uniform, and as anticipated, any variation is much less than required if the measured change in the atomic fractions is assumed to come from a change in composition of the alloy phase. Unless there is an error in the electron-probe microanalysis, these measurements suggest that electrically inactive precipitates are present.

Shubnikov-de Haas Measurements

Studies of the Shubnikov-de Haas effect in Czochralski-grown $(Pb_{1-x}Sn_x)_{1-y}Te_y$ alloys (7) suggest that this particular transport phenomenon is very sensitive to the presence of striations. The Shubnikov-de Haas effect, which appears as oscillations in the resistivity as a function of applied magnetic field, is used to study the geometry of the Fermi surface. The number of component frequencies in the oscillations is normally determined by the complexity of this surface. In addition to those frequencies which can be identified with Fermi surface geometry, we have found that extra frequencies are present in each alloy thus far examined. These are the BH alloys with $x = 0.13$, 0.19, and 0.30 (7), and one sample with $x = 0.24$ taken from a crystal grown at our laboratory. Shubnikov-de Haas oscillations observed in nonstriated Bridgman-grown alloys having similar compositions (8) do not exhibit extra frequencies. We believe that variations in carrier concentration are the cause of the extra frequencies in the Czochralski crystals, but a correlation with the detailed nature of the striations has not been established.

Studies of Electret Effects on Polyvinyl Chloride in a Vacuum

P. K. C. Pillai, Kamlesh Jain, and V. K. Jain[1]

Department of Physics, Indian Institute of Technology, New Delhi-29, India

ABSTRACT

Details of an apparatus for the fabrication and measurement of the surface charge of an electret in a vacuum is reported in this paper. The apparatus is useful in the preparation and preservation of the polarized sample under controlled conditions of humidity, temperature, and pressure. The effect of the polarizing field on the formation and characteristics of PVC(SR_{11}) foil electrets under vacuum conditions are investigated systematically. These investigations confirm that a polarizing field is necessary to obtain permanent polarization in electrets. Charge reversal was also obtained at low polarizing fields under vacuum conditions.

The investigation of dielectric properties has provided an important tool for the understanding of the structure of matter. Permanent polarization (1, 2) will occur when the electric field is applied to an insulator at an elevated temperature and has solidified the displaced positive and negative charges in opposite directions. To explain the electret effect more adequately, Pillai and Jain (3, 4) have added the contribution due to the molding and stripping charges to the net effective surface charge calculated by Peich and Handerek (5).

In the study of the electret effect, the measurement of the surface charge is of great importance due to its large number of applications (6). Gubkin *et al.* (7), and later on Pillai and Jain (8), have reviewed the various techniques for the measurement of the charge and they (8) have also developed a simple and accurate induction method for the charge measurement. In 1949 Gross (9, 10) employed the dissectible capacitor method for the polarization and measurement of electrets. Recently Palia (11) has studied electrets under different pressures and found that the charge of the electret decreased as the pressure was reduced from 760 to 10^{-2} Torr.

Extensive studies have been made on electrets of various dielectrics in the form of slabs. But from the practical point of view foil electrets are more important. In this article results obtained from PVC (SR_{11})[2] foil electrets prepared under vacuum conditions have been reported. For this purpose, an apparatus was designed and fabricated in which electrets could be made and the surface charge measured, in vacuum, without removing the sample from the assembly. The apparatus is quite useful for studying the effect of different ambient conditions on the formation and characteristics of electrets.

Key words: dielectrics, electrostatics.

[2] Polyvinyl chloride PVC(SR_{11}) manufactured by Sri Ram Vinyl and Chemical Industries, Kota, India.

Apparatus

The gadget for the polarization and measurement of surface charge of foil electrets was enclosed in a glass chamber as shown in Fig. 1 (point 1). An unpolarized sample was kept in the cavity of a mica holder (point 2, Fig. 1) which was screwed to a brass piece. This assembly was supported with a horizontal glass rod (point 3, Fig. 1). One surface of the sample was in contact with a metallic circular disk (point 4, Fig. 1), 2.5 cm in diameter and of 1 mm thickness, which was supported with a collar (point 5, Fig. 1) and could be moved upward and downward by a rod (point 6, Fig. 1) which passed through a vacuum seal. The vacuum seal was fixed at the center of a 23 cm^2 brass plate of 1 cm thickness. The motion of the lower electrode was restricted to 7 mm in the vertical direction from the horizontal axis of the glass rod (point 3, Fig. 1). The upper electrode (point 7, Fig. 1), of area ½ cm^2, was attached at the end of a movable glass tube (point 8, Fig. 1). The upper portion of the glass tube contained wax and particles of soft iron so that the electrode could be lifted by passing a current through the solenoid. Good contact between the upper electrode and the surface of the dielectric was obtained due to the weight of the electrode system. The sample can be rotated from outside about its horizontal axis without disturbing the vacuum in order to measure the surface charge on both sides of the sample. The rubber tube (point 13, Fig. 1) was connected to the rotary and an oil-diffusion pump, and a vacuum of the order of 10^{-4} Torr was obtained in the glass chamber.

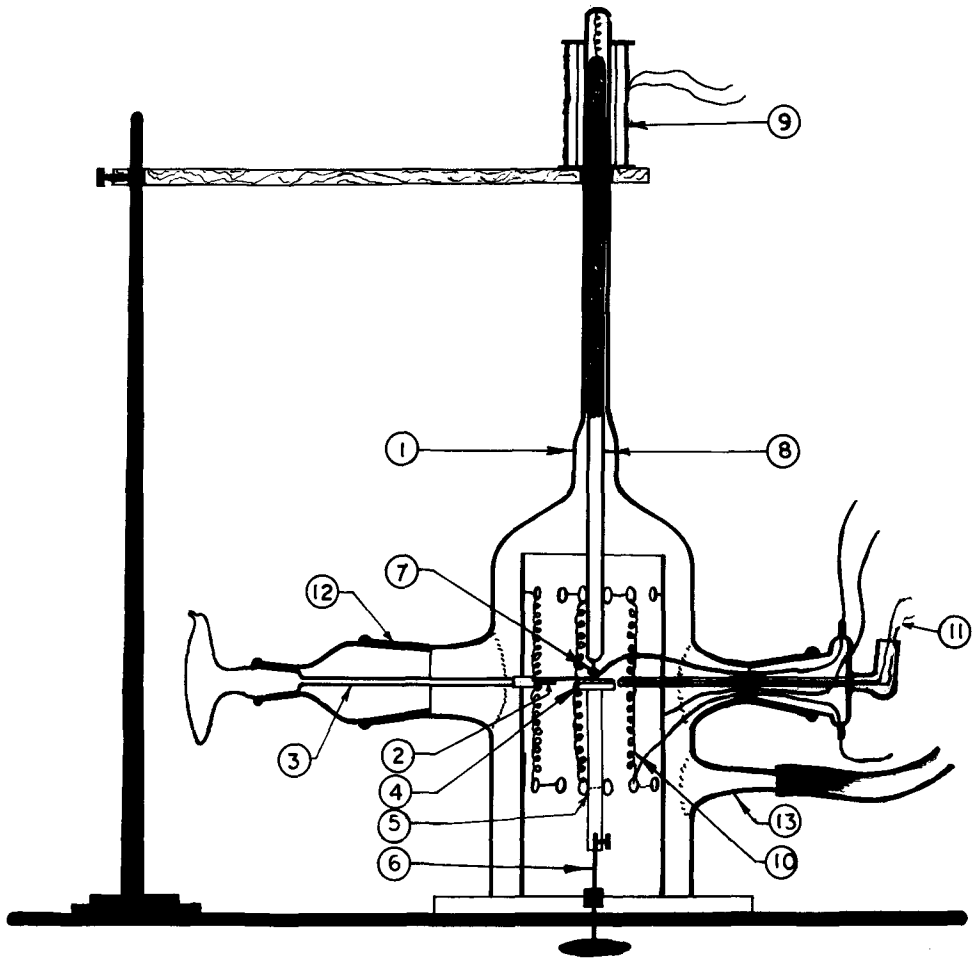

Fig. 1. (1) Glass chomber; (2) mica sheet; (3) glass rod; (4) circular brass disk; (5) collar; (6) vacucm seal; (7) upper brass electrode; (8) glass tube; (9) electromagnetic coil; (10) heating system; (11) Cu-constantan thermocouple; (12) ground joint; and (13) rubber tube.

A glass cylinder with a heating coil was placed inside the glass chamber around the electrodes (point 10, Fig. 1). The tip of the copper-constantan thermocouple (point 11, Fig. 1) was fixed just near the electrodes to measure the temperature. The upper and lower electrodes were used for the polarization as well as for the surface-charge measurements. All the metallic parts of the system were connected to the ground to obtain good electrostatic shielding. The measurements of the surface charge on both sides were taken by the induction technique with the help of an EA810A electrometer amplifier (12) supplied by the Electronic Corporation of India Limited.

Experimental

A solution of polyvinyl chloride (SR_{11}) was made in tetrahydrofuran (Reidal make) and poured in a petri dish with a flat bottom. It was kept in a dust-free chamber at 35°C for about 15 hr to form a thin transparent PVC foil. Samples of size 4 × 4 × 0.04 cm were cut from this foil for polarization studies. Each sample was polarized at 95°C for 3 hr inside the vacuum chamber. After polarization, the samples were kept in the same vacuum chamber throughout the period of investigation. After each measurement, the sample was short-circuited and preserved (13) in the same vacuum chamber for further studies.

Results

In order to see the effect of a polarizing field on the characteristics of foil electrets, especially when it is prepared under vacuum conditions, a series of samples were polarized under different field strengths ranging from 1.25 kV/cm to 2.75 kV/cm. The decay characteristics of these samples were studied for about a month and the results are shown graphically in Fig. 2 and 3.

Another sample was prepared under identical conditions but without the application of the forming field. A relatively smaller amount of charge was obtained on both faces of this sample [Fig. 2 (1A)] which decayed to zero after a few days. This clearly shows that it was merely a surface phenomena due to the close contact between the dielectric and the insulator (14, 15). However, this helps in increasing the magnitude of the initial heterocharge of the samples prepared with polarizing fields. This investigation thus confirms that a

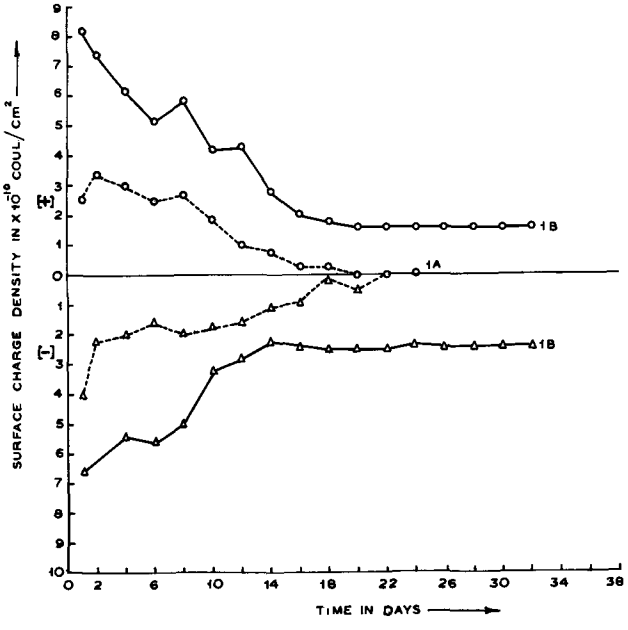

Fig. 2. Surface-charge density plotted as a function of time for PVC(SR_{11}) electret formed in 3 hr polarizing time at a polarizing temperature of 95°C. Curve (A), zero polarizing field; Curve (B), 1.25 kV/cm polarizing field

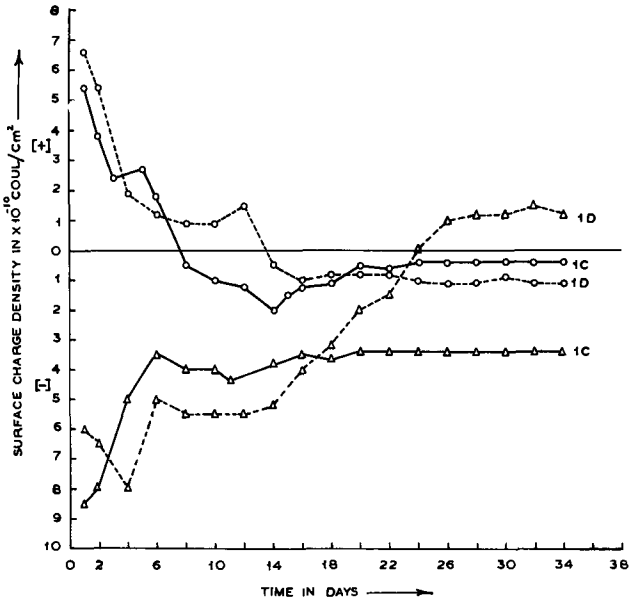

Fig. 3. Surface-charge density plotted as a function of time for PVC(SR_{11}) electret formed in 3 hr polarizing time at a polarizing temperature of 95°C. Curve (C), 2.00 kV/cm polarizing field; Curve (D), 2.75 kV/cm polarizing field

polarizing field is necessary to obtain a permanent polarization.

The samples prepared with 1.25 kV/cm and 2.0 kV/cm [Fig. 2(1B) and 3(1C)] show the presence of the heterocharge on both sides of the sample. But the cathode face of the sample prepared with 2.0 kV/cm [Fig. 3(1C)] shows a reversal from heterocharge to homocharge. By increasing the polarizing field up to 2.75 kV/cm [Fig. 3(1D)] the heterocharge on both faces reverses to a permanent homocharge. The results of this investigation confirm the electret behavior obtained by Gross (9) and Gemant (16) for the reversal from hetero to homocharge.

Discussion

The presence of heterocharge can be explained on the basis of the two-charge theory established by Gross (9) which has been accepted by most of the recent workers in this field. For an electret there are two charge distributions of opposite polarity. One of them is a surface charge, of the same polarity as that of the adjacent forming electrodes, which is generally known as an homocharge. The other is due to the internal polarizations, which produce a net surface charge opposite to that of the forming electrode, and is known as an heterocharge. If a real surface charge predominates over the charge due to volume polarization, the resultant charge will be an homocharge, and vice versa.

Gross (17, 18), and later on Gubkin (19) and Matsionashvili (20), have also given the phenomenological theories to discuss a similar type of results.

It is possible that when a high field is applied in the molten sample, the dipoles are oriented in the direction of the field, and these oriented dipoles in turn attracted the excessive ions of opposite polarity from the bulk of the material, which will be stuck to the surface when the sample is solidified. From the study of thermal degradation of polyvinyl chloride, it was found (21-23) that the weakest C-Cl bond will be ruptured at a higher temperature. This was followed by an abstraction of an hydrogen atom from an adjacent carbon and formation of a double bond in the chain. This will increase the polarizability of the polymer. The difference of polarity reversal on the cathode and anode surfaces might then be explained by the different mobilities of the two types of ions, especially above the glass-transition temperature (80°C) of the material. Above this glass-transition temperature, the conduction in PVC is ionic (24) and these ions in turn will be collected near the surfaces of the sample due to the attraction of the dipoles.

The measured net effective surface charge is the algebraic sum of the heterocharge and homocharge. When the electret is short-circuited the field within the sample becomes negligibly small. And the heterocharge decays only due to thermal motions, while the homocharge remains relatively constant causing the observed reversal in polarity of the net surface charge.

The presence of the homocharge includes two more factors; one is due to the spray of ions from the electrode on the surface of the dielectric, and the other is due to the breakdown of air inside the chamber. It also includes stripping and molding charges (3, 4) as there is close contact between the dielectric and the electrode. But the contribution due to the air breakdown, in this case, must be considerably smaller as the samples were prepared in vacuum conditions.

Acknowledgments

The authors are grateful to Professors K. L. Chopra, S. C. Jain, and M. S. Sodha for the encouragement given to them during the course of this investigation. They are also grateful to Dr. R. K. Jain for experimental help.

Evaluation of $HgCl_2$ as a Transport Agent for ZnO

M. Shiloh and J. Gutman

Soreq Nuclear Research Centre, Yavne, Israel

ABSTRACT

The chemical vapor transport of ZnO by $HgCl_2$ in a closed ampoule was evaluated experimentally and theoretically. A diffusion-controlled mechanism does not explain the experimental results, except for the prediction of the correct order of magnitude, which might indicate that diffusion is an important rate-determining step. The experiments were performed in the temperature range, 1160°-1260°K; a total pressure range, 0.1-3 atm; and with temperature gradients of 70°C and 100°C Above a total pressure of 1.5 atm the measured transport rate increases more slowly (with increasing total pressure) than the calculated rate based on a diffusion mechanism. Computer calculated curves of the relationships between the source and crystallization chamber temperatures, the total pressure, and the partial pressure difference of $ZnCl_2$ in the two chambers, can serve as a guide for future experiments. Single crystals of ZnO, average size 4 × 2 × 2 mm, were grown under the conditions studied in the present work.

In previous studies on the growth of single crystals of ZnO (1), $HgCl_2$ was found to be a promising transport agent. In this system $ZnCl_2$ is responsible for the transport process, in contrast to transport via Zn vapor, which is formed when NH_4Cl is used as a transport agent. The different transport mechanisms of these two agents were taken into account in selecting the one used to grow doped single crystals of ZnO (2).

In the present work the ZnO-$HgCl_2$ system is evaluated by comparing experimental results with calculated thermodynamic quantities, in a closed system. A quantitative evaluation of the growth of ZnO in an open system by the reaction mixture Zn-H_2O, was published recently by Reisman (3).

Experimental

The experimental procedure was similar to that described in a previous publication (1). A set of sealed ampoules, each containing about 5g ZnO and different quantities of $HgCl_2$, were placed in a horizontal tube furnace with the desired temperature gradient between the source chamber and the crystallization chamber.

The ZnO powder (B.D.H. Analar) was calcined at 1000°C before use, in order to eliminate traces of carbonate and hydroxide. The ZnO was heated in the ampoule at 350°C and 10^{-6} mm Hg before sealing. The upper part of the ampoule was cooled with wet cotton to prevent the loss of sublimed $HgCl_2$.

Results and Discussion

The data obtained from two sets of experiments, where the source temperature was the same but the temperature gradients differed (70° and 100°C), are given in Table I.

The average dimensions of the crystals obtained were 4 × 2 × 2 mm. Some of the crystals are shown in Fig. 1.

In order to correlate the results with an assumed diffusion-controlled transport mechanism, the partial pressures of the molecules, which are responsible for the transport effect, have to be computed.

Key words: ZnO single crystals, chemical vapor transport, thermodynamics of the ZnO-$HgCl_2$ system.

Fig. 1. Single crystals of ZnO grown with $HgCl_2$ as a transport agent.

The following equilibrium was assumed for this system

$$ZnO(s) + HgCl_2(g) \overset{K_p}{\rightleftharpoons} ZnCl_2(g) + Hg(g) + \tfrac{1}{2}O_2(g) \quad [1]$$

The function $\Delta F_{(T)}$ for the equilibrium given in Eq. [1] was derived, from available thermodynamic data (5, 6), by combining the individual $\Delta F_{(T)}$ functions given in Table II for the following equilibria

Table I. Transport data of ZnO in closed ampoules with different concentrations of $HgCl_2$

Source chamber	T_1 = 1260°K						T_1 = 1260°K							
Crystallization chamber	T_2 = 1160°K						T_2 = 1190°K							
Diffusion path	ID = 1.0 cm						ID = 1.25 cm							
	Length = 5.0 cm						Length = 3.7 cm							
	Time: 334 hr						Time: 376 hr							
Initial concentration of $HgCl_2$ [mg/cm³]	0.76	1.14	1.52	1.95	2.29	3.56	0.11	0.47	0.79	1.10	1.62	2.31	2.86	3.40
Rate of transport of ZnO ($T_1 \rightarrow T_2$) [mg/h]	2.4	4.8	5.5	5.6	5.9	6.3	2.64	3.05	4.70	5.20	8.43	9.72	9.96	9.95

Table II. Standard free energy of reaction ($\Delta F°_{(T)} = A + B\,T \log T + CT$)

Reaction	$\Delta F°$ in cal A	B	C	Temp. range, °K	Ref.
$ZnO(s) \rightleftharpoons Zn(g) + \frac{1}{2}O_2(g)$	115,400	10.35	−82.36	1170-2000	(6)
$Zn(g) + Cl_2(g) \rightleftharpoons ZnCl_2(g)$	−93,800	−9.44	38.6	1180-1800	(6)
$HgCl_2(g) \rightleftharpoons Hg(g) + Cl_2(g)$	46,500	—	−23.5	630-1500	(5)

$$\begin{aligned} ZnO(s) &\rightleftharpoons Zn(g) + \tfrac{1}{2}O_2(g) \\ Zn(g) + Cl_2(g) &\rightleftharpoons ZnCl_2(g) \\ HgCl_2(g) &\rightleftharpoons Hg(g) + Cl_2(g) \\ \hline ZnO(s) + HgCl_2(g) &\rightleftharpoons ZnCl_2(g) + Hg(g) + \tfrac{1}{2}O_2(g) \end{aligned}$$

The resulting value of $\Delta F_{(T)}$ for reaction [1] is

$$\Delta F_{(T)} = 68{,}100 + 0.91T \log T - 67.26T \text{ [cal/mole]} \quad [2]$$

The equilibrium constant of Eq. [1] can be expressed by

$$K_p = \frac{P_{ZnCl_2}{}^{2.5}}{P_{HgCl_2}} \quad [3]$$

where P_{ZnCl_2} and P_{HgCl_2} are the equilibrium partial pressures of the corresponding halides. The total equilibrium pressure, in a closed system, is given by

$$P_T = P_{HgCl_2} + 2.5P_{ZnCl_2} \quad [4]$$

Using Eq. [2], [3], [4] and the relation

$$\Delta F = -RT \ln K_p \quad [5]$$

one obtains the following relation for P_{ZnCl_2}, P_T, and T

$$\ln \frac{P_{ZnCl_2}{}^{2.5}}{P_T - 2.5P_{ZnCl_2}} = \frac{1}{R}\left[-\frac{68{,}100}{T} - 0.91 \log T + 67.26\right] \quad [6]$$

Assuming a closed ampoule of volume $2V$ (liter) half of which (V) is at T_1 and half at T_2, ($T_1 > T_2$), with an abrupt temperature gradient between them; an expression is derived to relate the initial amount of $HgCl_2$ m (g) placed in the ampoule, to the equilibrium total pressure, and the equilibrium partial pressures of $ZnCl_2$ at T_1 and T_2 (designated P_1 and P_2, respectively). The experimental temperature gradient changed gradually along 10 mm between the two regions.

The initial pressure of $HgCl_2$, P_i, is expressed by

$$P_i = P_{HgCl_2} + P_{ZnCl_2} \quad [7]$$

which, on substitution from Eq. [4] gives

$$P_i = P_T - 1.5P_{ZnCl_2} \quad [8]$$

Using the ideal gas law, inserting the corresponding values of the gas constant (0.082 liter atm), the molecular weight of $HgCl_2$ (271.5) and Eq. [8] for P_i, one obtains

$$m = 3309V\left[\frac{P_T - 1.5P_1}{T_1} + \frac{P_T - 1.5P_2}{T_2}\right] \quad [9]$$

Using a computer program, values of P_{ZnCl_2} at T_1 and T_2 (P_1 and P_2, respectively) were calculated by Eq. [6] for a given set of values of P_T. From these sets of values Fig. 3 and 4 were constructed, using the parameter ΔP_{ZnCl_2} defined as the partial pressure difference of $ZnCl_2$ between the two temperatures ($P_1 - P_2$).

The initial amount of $HgCl_2$, m, is calculated by Eq. [9] for given values of P_T and the corresponding values of P_1 and P_2, calculated by Eq. [6]. The initial concentration of $HgCl_2$ is given by

$$C_i = \frac{m}{2VM} \times 10^3 \left[\frac{\text{micromoles}}{\text{c.c.}}\right] \quad [10]$$

where M is the molecular weight of $HgCl_2$.

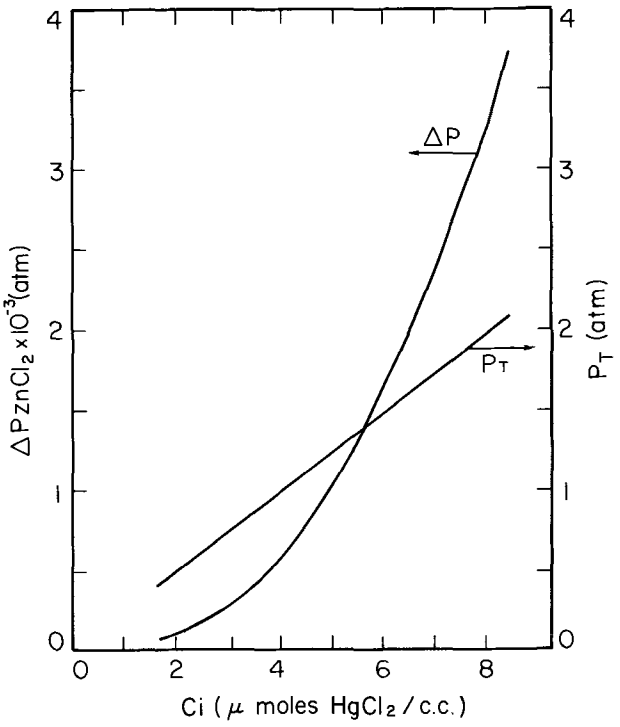

Fig. 2. The partial pressure difference of $ZnCl_2$ and the total pressure as a function of the concentration of $HgCl_2$ in a closed ampoule. $T_1 = 1260°K$; $T_2 = 1200°K$; $V_1 = V_2 = 0.006$ liter (V_1 and V_2 are the volumes of the ampoule at T_1 and T_2, respectively).

For constant values of V, T_1, and T_2 in the range of temperatures and temperature gradients given in Fig. 2-4, the values of ΔP_{ZnCl_2} are small compared with P_1, P_2, or P_T and therefore there is a linear relationship between m, or C_i, and P_T.

Figure 2 shows the effect of increasing the initial concentration, C_i, of $HgCl_2$ (or the initial pressure) with a constant temperature difference between the two chambers of the ampoule (having equal volumes of 6 cm³, $V_1 = V_2$, at T_1 and T_2, respectively). It is seen that ΔP_{ZnCl_2} increases more rapidly than P_T.

Figure 3 shows the dependence of ΔP_{ZnCl_2} on the total pressure and source temperature (T_1), for a constant temperature gradient ($T_1 - T_2 = 100°C$) between the source and crystallization chambers. It is seen that by lowering the source temperature, keeping P_T constant, ΔP_{ZnCl_2} is increased. At the same time ΔP changes more slowly with P_T at lower source temperatures. Figure 4, constructed from the same data, shows the family of curves of ΔP as a function of the source chamber temperature, at various values of P_T. At higher total pressure the maximum value of ΔP shifts to a higher source temperature.

A comparison of the experimental transport rate results with calculated curves, as a function of total pressure, is seen in Fig. 5. For the calculations diffusion-controlled transport was assumed, and the following equation was used (4)

$$R' = \frac{\Delta P_{ZnCl_2}}{P_T}\overline{T}^{0.8}\frac{A}{L}14.65 \text{ (mg ZnO/h)} \quad [11]$$

where $\overline{T}$ is the average temperature between the source and crystallization chambers, A is the cross-section area of the ampoule in the diffusion path, and L is the diffusion-path length. (The data are given in Table I.) In order to eliminate the geometrical factor, the rate values given in Fig. 5 were normalized to 1 cm² cross-section area and 1 cm of diffusion path length

$$R = R'\frac{L}{A} \text{ (mg ZnO/h cm)} \quad [12]$$

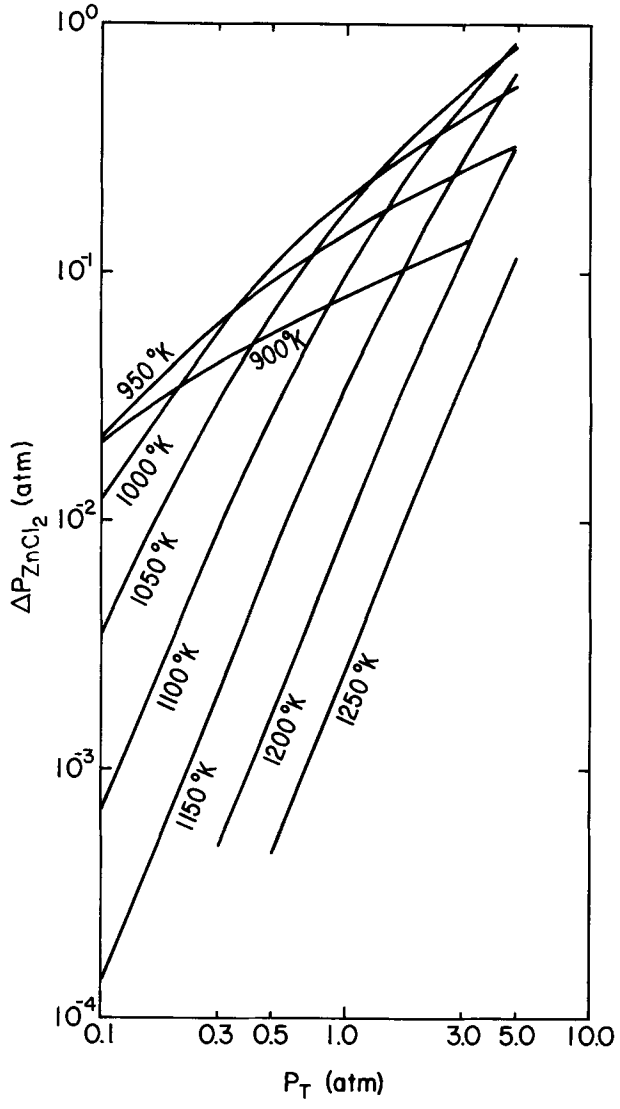

Fig. 3. The partial pressure difference of $ZnCl_2$ as a function of the total pressure at different source temperatures. $V_1 = V_2 = 0.006$ liter; $T_1 - T_2 = 100°C$.

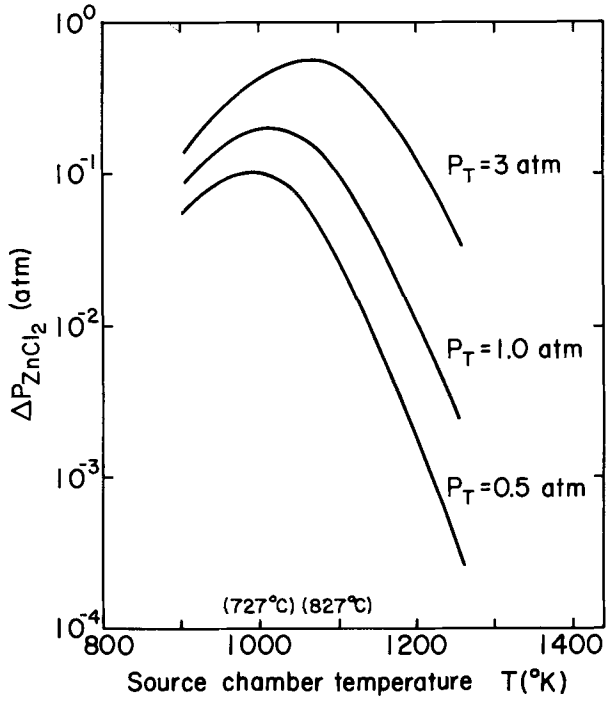

Fig. 4. The partial pressure difference of $ZnCl_2$ as a function of the source temperature, at different total pressures. $V_1 = V_2 = 0.006$ liter; $T_1 - T_2 = 100°C$.

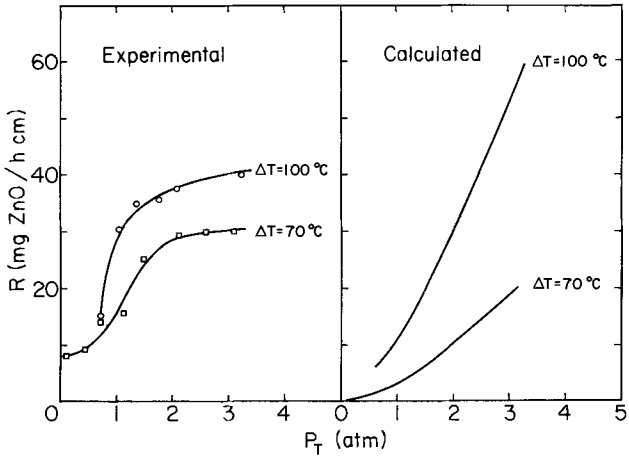

Fig. 5. The transport rate of ZnO as a function of the total pressure. Transport agent, $HgCl_2$; source temperature, 1260°K. (The data are normalized for a transport path of 1 cm^2 cross-sectional area and 1 cm diffusion length).

The calculated curves are in good agreement with the experimental results only in the lower P_T range, below 1.5 atm. A diffusion-controlled transport mechanism and the assumptions made in the derivation (4) of Eq. [4] probably oversimplify the actual mechanism. Figure 3 shows that, with the temperature profiles used in the present work, ΔP (and hence the transport rate) will increase more slowly with P_T only at much higher values of P_T (above the range studied in this work). One should note that the calculated curves are very sensitive to the numerical values of the coefficients in Eq. [2], which were derived from experimental data (5, 6).

The slower change of R at higher pressures might show the heterogeneous reaction to be the rate-determining step at this range.

Figures 2-4, which present the computer calculated values of ΔP_{ZnCl_2} as a function of the various parameters, are very useful as a guide when searching for the appropriate crystal growing conditions. One can estimate the effect of various experimental parameters on ΔP_{ZnCl_2} and hence on decreasing as increasing the growth rate in order to control the nucleation.

The effect of an additional equilibrium, the decomposition of ZnO, was also calculated

$$ZnO(s) \rightleftharpoons Zn(g) + \tfrac{1}{2}O_2(g) \qquad [13]$$

The temperature dependence of the partial pressure of the Zn vapor is given by (7)

$$\log P_{Zn} = \frac{-16{,}173}{T} + 7.24 \qquad [14]$$

From this relation it was found that at the highest temperature used in the present work (1260°K), the partial pressure of Zn is about 10^{-6} atm. This will significantly affect the transport rate of ZnO only at a low total pressure, below 0.1 atm.

Preparation and Properties of II-Ln_2-S_4 Ternary Sulfides

W. M. Yim,* A. K. Fan,[1] and E. J. Stofko

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

Some 50 ternary sulfides of the type II-Ln_2-S_4 were explored, where II = (Zn, Cd, Mg, and Ca) and Ln = (Sc, Y, La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu). The structure of the compounds, if they were formed, was investigated with x-ray diffraction techniques using primarily the materials synthesized in powder form. Single crystals were subsequently grown from the powders for several compounds including $ZnSc_2S_4$ and $CdSc_2S_4$ which were found to have bandgaps of 2.1 and 2.3 eV, respectively, at room temperature. Doping with a variety of impurities provided conducting n-type specimens for both $ZnSc_2S_4$ and $CdSc_2S_4$, and for the latter p-type specimens were also obtained. Weak cathodoluminescence was observed from several compounds including $CaCe_2S_4$ with a green-yellow and $ZnLu_2S_4$ with a blue-green emission color.

Many ternary compounds of the type IIB-III_2-VI_4 (Group IIB element = Zn,Cd,Hg; Group III element = Al,Ga,In; Group VI element = S,Se,) have been synthesized previously (1-3) and some of their electronic properties investigated (4). In contrast, relatively little work has been done on compounds of the similar type II-Ln_2-VI_4 (II = Zn,Cd,Mg,Ca; Ln = Sc, Y, or a rare earth) (5-7). Information is especially lacking regarding the single-crystal growth and the electrical and optical properties of such compounds.

We have explored some 50 II-Ln_2-S_4 compounds which included many of the ternary sulfides involving Ca and Mg, in addition to all of those involving Zn and Cd, with Sc and Y and all but two rare-earth elements (Eu and Pm). The majority of the sulfides was first synthesized in the form of powders, with which we made x-ray determination of the structure and also made visual examination of the luminescence color under cathode-ray excitation. Several compounds, particularly $ZnSc_2S_4$ and $CdSc_2S_4$, were subsequently prepared in the form of single-crystal platelets, on which we measured the optical bandgaps and electrical conductivities. The results show that many of these ternary sulfides have bandgaps in the visible region (*e.g.*, 2.1 and 2.3 eV, respectively, for $ZnSc_2S_4$ and $CdSc_2S_4$), and that electrically conducting specimens could be obtained by doping with suitable impurities.

Materials Preparation

Powders of Zn-Ln_2-S_4, Cd-Ln_2-S_4, Ca-Ln_2-S_4, and Mg-Ln_2-S_4 were synthesized in flowing CS_2 with He carrier gas at temperatures between 1000° and 1200°C, using the apparatus shown schematically in Fig. 1. The general reaction scheme was as follows

$$\begin{matrix} \text{II-S} \\ \text{or} \\ \text{II-CO}_3 \end{matrix} + \begin{matrix} \text{Ln}_2\text{-S}_3 \\ \text{or} \\ \text{Ln}_2\text{-O}_3 \end{matrix} \rightarrow \text{II-Ln}_2\text{-S}_4$$

The carbonates were used for the ternary compounds containing Ca or Mg, and for those containing Zn or Cd the reactant binary sulfides were ZnS or CdS powders. The starting Ln_2-S_3 were obtained by the reaction of corresponding sesquioxides Ln_2-O_3 with CS_2. The stoichiometric proportions of these reactant powders were ground, mixed, and reacted again in CS_2 for total periods ranging generally between 3 and 6 hr until x-ray powder patterns showed the product was a homogeneous, single-phase material, or until no further change occurred in the x-ray patterns upon longer reaction times.

Crystal growth of the II-Ln_2-S_4 compounds was investigated by closed-tube chemical transport at average temperatures of 1000°-1100°C with temperature gradients ranging between 5° and 50°C, using the powders synthesized as above. Single-crystal platelets as large as 5 mm on an edge with thickness ranging up to 200 μm were successfully grown for $ZnSc_2S_4$ and $CdSc_2S_4$, and crystals of smaller sizes were also obtained for $ZnTm_2S_4$ and $ZnLu_2S_4$; while for the remainder of the II-Ln_2-S_4 compounds investigated, only polycrystalline material resulted. Single crystallinity was manifest in the Laue back-reflection patterns with well-defined diffraction spots shown, for example, in Fig. 2 for a (111) $ZnSc_2S_4$ single crystal. It is worthy of note that among the two transport gases used (I_2 and HCl), HCl was found to give crystals of larger dimensions. In general, the crystal growth was made difficult by reactions with quartz of Ca, Mg, as well as the majority of the rare-earth elements. Emission spectrographic analysis showed that the grown

crystals contained sometimes as much as 1000 ppm Si, probably from the quartz growth ampoule used.

Crystal Structure

Tables I-IV list crystal structures determined by x-ray analyses (powder diffraction or Weissenberg techniques) of the majority of the 15 possible compounds in each group of Zn-Ln_2-S_4, Cd-Ln_2-S_4, Ca-Ln_2-S_4, and Mg-Ln_2-S_4, respectively, where Ln = Sc,Y,La,Ce,Pr,Nd,Sm,Gd,Tb,Dy,Ho,Er,Tm,Yb, and Lu. For the first three groups we have attempted to synthesize all the 15 possible combinations, but for the Mg-Ln_2-S_4 group we explored only two possibilities ($MgSc_2S_4$ and MgY_2S_4). Those listed with ? marks denote the case where no stoichiometric compounds were found (in which case x-ray patterns usually showed mixtures of unreacted starting compounds), or the observed structures were too complex to be readily identified. In Ca-Ln_2-S_4 (Ln = Ho through Lu) the crystal structures were not analyzed but were all isomorphous (noncubic), probably with an orthorhombic structure reported previously for these compounds (6). The present lattice constants are generally in good agreement with previous values, as seen in Tables I-III.

The crystal structure data are summarized in Fig. 3, which conveniently shows general relationship between the lattice constants of cubic compounds (spinel or Th_3P_4 type) and the ionic radii of Ln elements (8). While we will not attempt to analyze these data in any quantitative manner, the following generalization emerges from an inspection of Fig. 3. The spinel structure is favored for the Ln elements with small ionic radii—this is true for compounds involving Zn (0.74Å), Cd (0.97Å), and Mg (0.65Å). The Th_3P_4 structure is favored for the Ln elements of large ionic radii, particularly in the compounds containing Ca (0.99Å), while for the Ln of intermediate radii an orthorhombic structure exists. The lattice parameters for the cubic forms as well as for the orthorhombic form, generally decrease with decreasing ionic radii of the Ln elements. This trend holds true whether covalent or metallic radii, instead of the ionic radii, are used.

Optical Bandgap

Optical absorption measurements were made at 300°K with single-crystal platelets, whenever available, using a Cary Model No. 14 double-beam spectrophotometer. The measurements were also made on some of the compounds obtained originally in powder form, after cold-pressing these powders mixed in KBr binder. Although the absorption edges obtained for the KBr-pressed specimens were not sharp, approximate values of the bandgap could be derived from the observed edges. These values ranged from 1.8 eV for $CdEr_2S_4$ to 3.1 eV for $ZnDy_2S_4$, and the largest bandgap value observed for the present II-Ln_2-S_4 compounds was 3.7 eV for $ZnLu_2S_4$, as listed in Tables I, II, and IV.

Somewhat more detailed analyses of the optical absorption data were made on $ZnSc_2S_4$ and $CdSc_2S_4$ with (111)-oriented single-crystal platelets, 25-200 μm thick. The optical absorption coefficient α was calculated, neglecting reflection, as $\alpha = (1/t) \ln (I_0/I)$, where t is the thickness, and I_0 and I are the initial and trans-

Lower graph shows known 3+ ionic radii of Sc, Y, and the rare earths [Ref. (8)]. In the upper graph, dashed lines (- - - -) are used merely for the purpose of grouping together the individual group of II-Ln_2-S_4 having the same Group II element; while the heavy lines connecting data points represent actual variations in the lattice constants of cubic-form (spinel and Th_3P_4 type) II-Ln_2-S_4 sulfides.

mitted intensities, respectively. In all cases, weakly energy-dependent, low-background absorption was subtracted from the measured absorption in calculating the α values.

In Fig. 4 and 5 are shown the dependence of α upon wavelength λ for $ZnSc_2S_4$ and $CdSc_2S_4$ (111) single crystals, respectively, at 300°K. The fundamental absorption edge is seen to occur near 6000Å for the former and near 5300Å for the latter, corresponding to a bandgap of 2.1 eV for $ZnSc_2S_4$ and 2.3 eV for $CdSc_2S_4$. These data are consistent with the observed transparent red to yellow colors of the respective samples.

It is known that the absorption coefficient in the fundamental absorption edge region obeys, in general, a power law of the form $\alpha \propto (h\nu - E_g)^n$, where $h\nu$ is the photon energy and E_g is the bandgap. The exponent n for a direct bandgap is ½ if the electronic transitions are that of the allowed case, and for the forbidden case it is 3/2; for an indirect gap the n is 2 and 3, respectively, for the allowed and forbidden transitions (9). We have attempted to fit the present α to the various power laws; however, the results were inconclusive, although for both $ZnSc_2S_4$ and $CdSc_2S_4$ the direct-bandgap $\alpha \propto (h\nu - E_g)^{1/2}$ relation provided a somewhat better fit for the experimental points than did the other power dependences. It is perhaps worth mentioning in this regard that calculations of the band structure of spinel-type semiconductors have been attempted previously (10); however, only the valence band levels at the Γ points could be deduced with any certainty, leaving lower symmetry points such as X or L uncertain, with the results that unambiguous determination of the type of the fundamental bandgap was not possible.

From the interference fringes obesrved with thin specimens, the refractive index in the wavelength region of 1-2 μm was calculated to be 1.56 for $ZnSc_2S_4$ and 2.39 for $CdSc_2S_4$. Thus the dielectric constant of the former is less than that of the latter, indicating that $ZnSc_2S_4$ is probably more ionic than $CdSc_2S_4$.

Doping Behavior and Electrical Properties

As-grown, undoped II-Ln_2-S_4 compounds investigated were all high resistivity, and consequently their conductivity type could not be determined. Efforts to

[j] The lattice parameters given here are for the Yb_2S_4-type orthorhomic structure, which is the more stable form at low temperatures. The stable form at high temperatures is the MnY_2S_4-type orthorhombic structure, but the lattice parameters are nearly the same as that of the Yb_2S_4-type; see a review article by Flahaut cited in Ref. (6). The only exception is CaY_2S_4 for which the low-temperature form is the Th_3P_4-type cubic. The temperature range of the phase transformation for the above-mentioned compounds is between 900° and 1200°C.
For other abbreviations, see Table I.

dope these materials low resistivity were concentrated on $ZnSc_2S_4$ and $CdSc_2S_4$, since single crystals of relatively large dimensions were readily grown for them.

It is probable that both $ZnSc_2S_4$ and $CdSc_2S_4$ have the normal spinel structure, in which the Group II element (Zn or Cd) occupies the tetrahedral sites and the Group III element (Sc) occupies the octahedral sites. On the basis of valence consideration assuming a simple substitution of elements at various lattice sites, possible p-type dopants are the elements in Groups I, II, IV, and V, and several divalent transition metals; possible n-type dopants are the elements in Groups III and IV, and several trivalent transition metals. In addition, a consideration must be given to the relative size of the doping ion and the host lattice ion to be substituted by it. Of a large number of the possible dopants, we selected 17, and these were incorporated into $ZnSc_2S_4$ and $CdSc_2S_4$ during growth by closed-tube chemical transport in the concentration range 200-5000 ppm, as shown in Table V.

The results of Hall effect measurements[2] on doped crystals in Table V show that Ga, Ag, or Cr doping provided n-type materials for $ZnSc_2S_4$ with carrier concentrations in the 10^{17}-10^{18}/cm^3 range. N-type materials having carrier concentrations of 10^{14}-10^{15}/cm^3 were also obtained for $CdSc_2S_4$ by doping with Ga or Li. To date, p-type material was obtained only for $CdSc_2S_4$ by doping with Cr, which gave a hole concentration of 10^{12}/cm^3. Hall mobilities for both the n-type and p-type materials ranged up to ~40 cm^2/V · sec.

It appears from these results that Ag and Li are interstitial donors since if they are substitutional impurities, they would have acted as acceptors; on the

[2] Ohmic contacts were made with alloys of Zn-In and Cd-In, respectively, for $ZnSc_2S_4$ and $CdSc_2S_4$.

* ppm by weight, determined by emission spectroscopic analysis; "strong" denotes the case of impurity concentration $>10^4$ ppm, and "trace" denotes the case of impurity concentration <1 ppm.

other hand, it appears that Ga is a substitutional donor for the tetrahedral sites. The behavior of Cr is somewhat puzzling in that it acted as an acceptor in $CdSc_2S_4$, but for $ZnSc_2S_4$ it acted as a donor. Halogens apparently do not provide conducting n-type specimens, since all the materials were grown in a halogen atmosphere and they were high resistivity. Group IV elements also appear to be ineffective dopants since as-grown crystals containing a large amount of Si, as well as those crystals intentionally doped with Ge, Sn, and Pb, were all high resistivity. Since Ga doped both $ZnSc_2S_4$ and $CdSc_2S_4$ n-type, we attempted to grow n-type crystals of these compounds from Ga solutions by slowly cooling the melts from about 1200°C. However, only GaS crystals resulted, and thus the solution growth technique appears unsuitable, at least with the Ga solvent.

Observations on Cathodoluminescence

On all powder specimens synthesized without intentional doping, we have made visual examinations of the luminescence color emanating under a cathode-ray excitation. The emission color ranged from a brownish red to a blue, as listed in Tables I-IV. Of the speci-

mens which showed a visible cathodoluminescence, virtually all exhibited less-than bandgap emissions (judging from the emission colors) and thus appeared to involve recombination at deep levels of unknown nature. For $CaCe_2S_4$ and $ZnLu_2S_4$ showing a yellow to green emission which is of practical importance as phosphors, we measured the emission spectral distribution with a 12-kV excitation at room temperature, shown in Fig. 6. The observed cathodoluminescence for both materials was quite weak, and so no quantitative measurements were made to determine the emission efficiency. It would be interesting, however, to try to activate these phosphors with suitable impurity additions, since the emission colors observed were in the visible spectral range.

Acknowledgments

We wish to thank H. L. Pinch and P. N. Yocom for communicating to us their early results on synthesis of several compounds reported in this paper. We are also indebted to J. Gerber for spectral distribution measurements. The research herein reported was made possible by the support of the Advanced Research Projects Agency under Order No. 1034, through the U.S. Army Electronics Command, Fort Monmouth, New Jersey, under Contract No. DAAB07-70-C-0155.

Manuscript submitted June 14, 1972; revised manuscript received Nov. 3, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Silicon Oxynitride Films from the $NO-NH_3-SiH_4$ Reaction

Myron J. Rand* and James F. Roberts

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

Silicon oxynitride films from the $NO-NH_3-SiH_4$ reaction in nitrogen at 850°C are clear, adherent, amorphous dielectrics whose composition may be varied over the entire range between SiO_2 and Si_3N_4 by controlling the NH_3/NO ratio employed. The refractive index is a convenient and accurate measure of the composition. Over much of the nitrogen-rich range, the Si content is about 2% lower than stoichiometric, and the hypothesis is made that one nitrogen in three is bonded to only two other skeletal atoms instead of three, and that some of these nitrogens bear bonded hydrogen. The N-H groups are believed to play a role similar to that of O-H in silicas. Compositions near Si_2ON_2 are highly resistant to ionizing radiation under bias, and are excellent Na^+ barriers at 300°C and 10^6 V/cm. However, they are not better barriers to Na^+ thermal diffusion at 600°C than SiO_2. With appropriate pre- and post-deposition chemical treatments, oxynitride films give low Si surface charge and small nonionic shifts in flatband voltage with bias-temperature aging. Other properties investigated for various compositions include etch rate, i.r. spectrum, film stress, and cathodoluminescence spectra. Films from the $NO-SiH_4$ and $NO-NH_3-SiH_4$ processes are compared.

Silicon oxynitride (SiON), as used here, implies no definite stoichiometry, and means an amorphous polymer of silicon, oxygen, and nitrogen in varying amounts. It is not a mixture or codeposit of SiO_2 and Si_3N_4. Nevertheless these may be considered the extremes of its composition range in the sense that many of the properties of a SiON are consistent with its position along the composition scale between oxide and nitride. SiON films are of interest in device fab-

* Electrochemical Society Active Member.

Key words: silicon oxynitride, thin films, dielectric films, silane, nitric oxide.

rication to the extent that they retain the favorable features of either SiO_2 or Si_3N_4 while minimizing their drawbacks. Among the properties in which the two differ significantly are etch rate, reaction with moisture, resistance to sodium ion drift and diffusion, refractive index, and MIS capacitor behavior (Si surface-state density, charge injection from the contacts, high-field conductivity, dielectric constant, etc.).

In addition to the possibilities for trade-offs in properties, SiON becomes of interest for the case where oxide and nitride are both unsatisfactory but in opposing directions. Two examples have already been reported (1-3). Grown or deposited SiO_2 on Si is under compressive stress, while Si_3N_4 is under even greater tensile stress. It is possible to tailor a SiON film ($SiO_{1.75}N_{0.25}$) which will leave film and substrate stress-free. Another application of the principle is the response to ionizing radiation under electrical bias, where SiO_2 accumulates a positive charge and Si_3N_4 preferentially traps electrons. IGFETS in particular, and bipolar devices to a lesser degree, are thus susceptible to degradation. Si_2ON_2 (*i.e.*, SiON of about 1.77 refractive index) insulating films in MIS structures are insensitive to absorbed doses of 10^7-10^8 rad of ^{60}Co-γ's, and Si_2ON_2-passivated npn transistors require 30 times the radiation dose of those with SiO_2 for the same h_{FE} degradation (3).

The chemical-vapor deposition of SiON films from silane and nitric oxide in nitrogen carrier has already been described (4). The SiON composition is controlled by the reactant ratio, with low NO/SiH_4 ratios giving a deposit richer in nitrogen. NO (which is thermally stable) was chosen because whatever happens during the reaction, probably a free-radical chain mechanism, the nitrogen must go along with oxygen if the N—O bond is not broken, or an active nitrogen moiety must be generated if the bond is broken. In either case some nitrogen should be incorporated into the deposit. But if either N_2O or NO_2 is used as the oxidant, oxygen is liberated upon heating, or can be easily abstracted by attack by silane, silyl radicals, or atomic hydrogen. At any rate, the product of these reactions is essentially SiO_2 only.

The NO-SiH_4 process is not capable of covering the entire range between SiO_2 and Si_3N_4. At $NO/SiH_4 = 1$ the film composition is near $Si_3O_3N_2$; further lowering the reactant ratio results in codeposition of Si, because there is not enough oxidant to combine with all the thermally decomposing silane. There are various ways to reach the nitride-rich SiON composition, most of which involve ammonia and an oxidant competing for the silane. Thermodynamically the oxidation reaction is favored, so that an amount of oxidant so small as to be difficult to control often produces a product with more oxygen than nitrogen. In fact, from the physical properties reported by some investigators for pyrolytic silicon nitride, it is likely that their system contained enough oxygen or moisture to produce a SiON instead. The purest commercially available ammonia, Matheson Gas Products "Ultra High Purity," may require bleeding many liters from the tank before it will yield uncontaminated silicon nitride, as diagnosed by etch rate. We consider that Si_3N_4 deposited at 850°-900°C should have a buffered HF etch rate of 11 ± 2 Å/min at 25°C.

The systems which have been used to produce the full range of SiON film compositions include SiH_4-N_2O-NH_3 (5), SiH_4-CO_2-H_2-NH_3 (6), SiH_4-O_2-NH_3 (6, 7), SiH_4-NO-NH_3 (8), $SiCl_4$-CO_2-NH_3 (9), and rf reactive sputtering in $N_2 + N_2O$ (10), or $N_2 + O_2$ (11) mixtures. In most of these, film composition was not known accurately, although usually it was inferred from refractive index or spectra. Evaluation was mostly concerned with electrical properties. Some products obviously contain excess silicon. Studying these papers it is again evident that NO is the most controllable oxidant, and the work of Brown *et al.* (8) has the most data on the nitride-rich SiON's. Their deposition was at 1000°C, in ammonia at high flow rates, with no carrier gas diluent.

In this paper, SiON films produced by the SiH_4-NO-NH_3 reaction are examined critically, particularly in the nitride-rich region inaccessible to the NO-SiH_4 reaction. Deposition temperature was usually 850°C, in nitrogen ambient with $<8\%$ NH_3 (usually much less). This is a summary report, abstracting and generalizing results, since at this writing about 200 samples have been studied.

Experimental

Depositions were done in a vertical fused silica tube with a bulged section containing a graphite (preferably) or silicon cylindrical pedestal heated inductively at 3 MHz. Substrates were usually 1 in. diameter polished Si wafers of a thickness, type, and resistivity appropriate for the tests to be performed. Reactant gases entered through a jet on the axis of the tube at the top; the coaxial jet was important for thickness uniformity. Film thickness was monitored during growth using the device of Roberts (12).

Tank silane was supplied at 3% in nitrogen, NO as 4% in nitrogen, and ammonia was ultrahigh purity grade (5-9's min.); all were from Matheson Gas Products. Stainless-steel tubing was used throughout. The NO was introduced into the carrier nitrogen stream first and shut off last. The silane and ammonia streams were mixed, and deposition time began with introduction of this mixture into the gas manifold. Total gas flow through the deposition chamber was 1-3 liter/min, a linear velocity of about 3 cm/sec. Reaction appears to be confined to the close vicinity of the heated pedestal, since the reactor remains quite clean for many runs.

SiON film composition was determined using the electron-beam microprobe (13), making twelve analyses per sample; nitrogen was by difference. Refractive index was measured ellipsometrically at 546 nm. Infrared transmission spectra 4000-250 cm^{-1} were taken using high resistivity, thick Si substrates polished on both sides, with a bare substrate in the reference beam. Film-thickness measurements were made by constant angle reflection interference spectra (14), using reference standards measured by ellipsometry and multiple-beam interferometry. Average film stress was measured by deposition on a thin, optically flat, elastic Si beam and observing the curvature interferometrically (15). Cathodoluminescence was investigated in the apparatus described by Mitchell (16), at 7 kV and 1 μA beam current, over the 200-600 nm range. MIS capacitors for studying various electrical properties were made by filament evaporation of 20 mil diameter Al field plates through a mask, and also Al back contacts on the Si. The quasi static technique (17) was used to determine interface-state densities. Procedures in studying sodium ion diffusion strongly influence results of the experiments, and will be described later in the appropriate section.

Results

All SiON films made from SiH_4-NO-NH_3 are clear, smooth, and tightly adherent. Electron diffraction shows no ordering >20Å (estimate).

Composition.—In Fig. 1, which is part of a three-component diagram, electron-microprobe analyses of various SiON films are plotted. All the points are from the SiH_4-NO-NH_3 system, which evidently can produce any composition between SiO_2 and Si_3N_4. In the oxygen-rich end, the points lie on the SiO_2-Si_3N_4 tieline up to a composition of $Si_3O_3N_2$. This happens to be about the limit of the SiH_4-NO process (4), and is also a composition for which some evidence for compound formation has been reported (9). Beyond this point the analyses fall slightly below the tieline, and average ~2% Si low all the way to Si_3N_4. The accuracy of the probe analysis is $\pm 2\%$, but the statistics and distribution of the results suggest a systematic slight

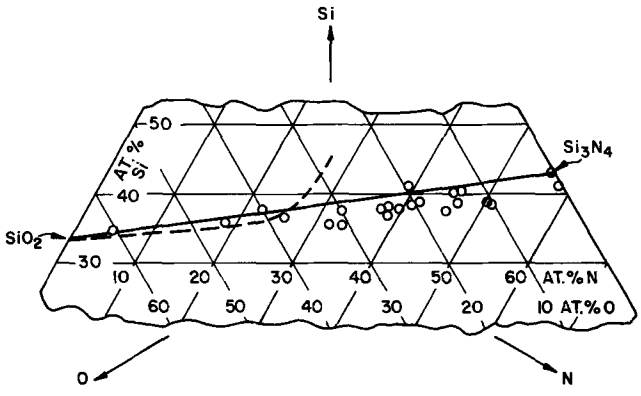

Fig. 1. Microprobe analyses of SiON from the SiH_4-NO-NH_3 reaction. The tieline (solid) represents stoichiometric oxynitride and the dotted line the compositions accessible to the NO-SiH_4 reaction. All the points are analyses of films from the NO-NH_3-SiH_4 reaction.

Si deficiency from the expected oxynitride stoichiometry. It will be shown below that SiON's of apparently the same composition made by the two oxynitride processes do indeed differ in certain properties.

SiON compositions known at this writing to have properties of interest for device applications are located in the ternary diagram in Fig. 2. These have all been reported earlier (1-4).

Preparation of a desired composition.—The concentrations of the three reactants were varied independently in many experiments, but the NH_3/SiH_4 ratio was always >20, to avoid any possibility of Si codeposition. The film-deposition rate depends solely on the SiH_4 concentration (see Fig. 3). The film composition, on the other hand, is governed by the NH_3/NO ratio. In Fig. 4, the refractive index is plotted *vs.* this ratio; note that the abscissa scale is logarithmic. Figures 3 and 4 are both for 850°C deposition, and will probably change somewhat with the deposition equipment used. The silane concentrations used in the runs of Fig. 4 vary over a factor of four. The scatter in the data is much reduced if a given SiH_4 concentration is selected. With all reactant concentrations fixed, the reproducibility of the refractive index has consistently been ±0.01.

The close correlation between the refractive index and composition is shown in Fig. 5, where all the data points are from the SiH_4-NO-NH_3 reaction. The abscissa may be considered the atomic fraction of the oxygen of SiO_2 which has been replaced by nitrogen in proceeding along the SiON composition scale. The NO-SiH_4 process, as shown, follows the same curve

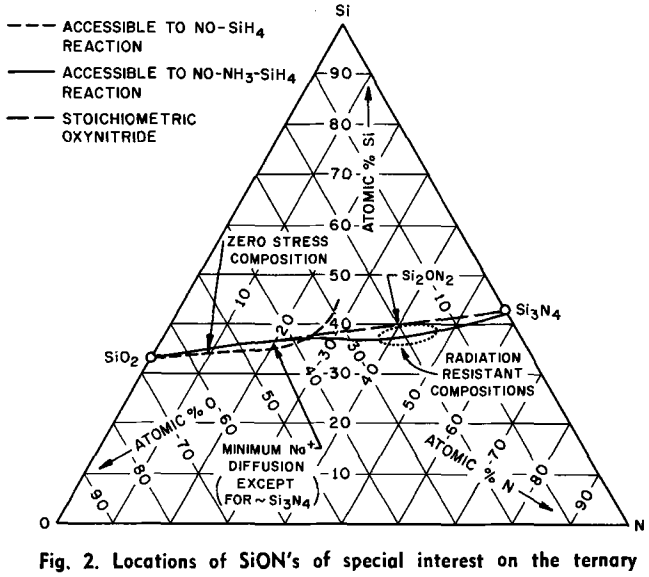

Fig. 2. Locations of SiON's of special interest on the ternary composition diagram.

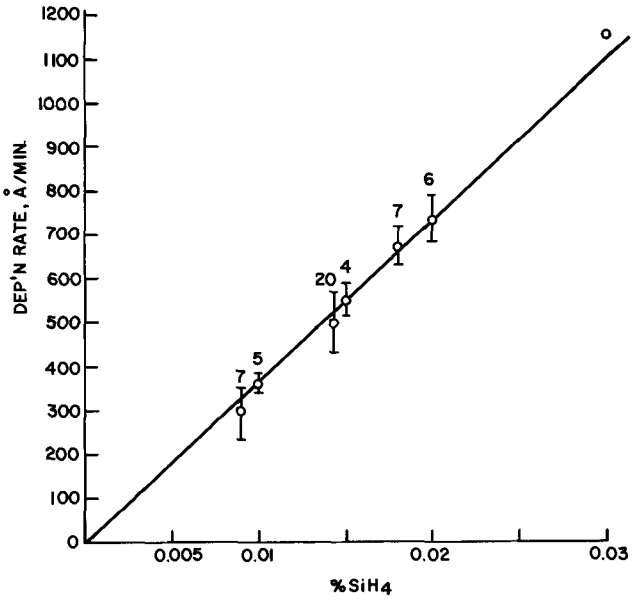

Fig. 3. Dependence of the deposition rate on silane concentration. The number of runs at each concentration is shown. The NH_3:NO ratio varies over a range of 10^3.

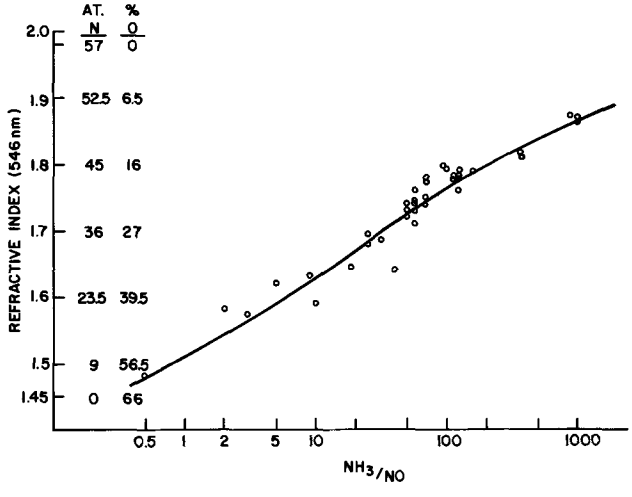

Fig. 4. Control of film composition by the NH_3:NO ratio. Per cent SiH_4 = 0.01-0.04.

until the film becomes Si rich and n shoots up. Although we suspect differences in structure of SiON's of the same analysis made by the two processes, the refractive index is apparently insensitive to any such differences.

Spectrum.—The variation in infrared absorption maximum with film composition is shown in Fig. 6. This is the strongest argument for calling SiON an "inorganic copolymer" rather than a "codeposit" or "mixture," since separate bands for Si-O and Si-N stretching do not appear, but instead only a broadened band in some intermediate position indicative of the composition. This is the result obtained for SiON made by any process, vacuum or pyrolytic. The bending vibration at lower frequency behaves the same way, progressing gradually from the 450 cm^{-1} of SiO_2 to the 485 cm^{-1} of Si_3N_4 as the composition changes.

The curve for the NO-SiH_4 process SiON (Fig. 6) is slightly different, but it lies well outside the uncertainty of the probe analysis. Thus here there is a detectable structural difference between supposedly identical SiON's.

Figure 6 also shows the danger of judging silicon nitride purity by infrared spectrum. The film can have an O/N ratio up to 0.2 and still have an absorption maximum at the same wavelength as pyrolytic Si_3N_4.

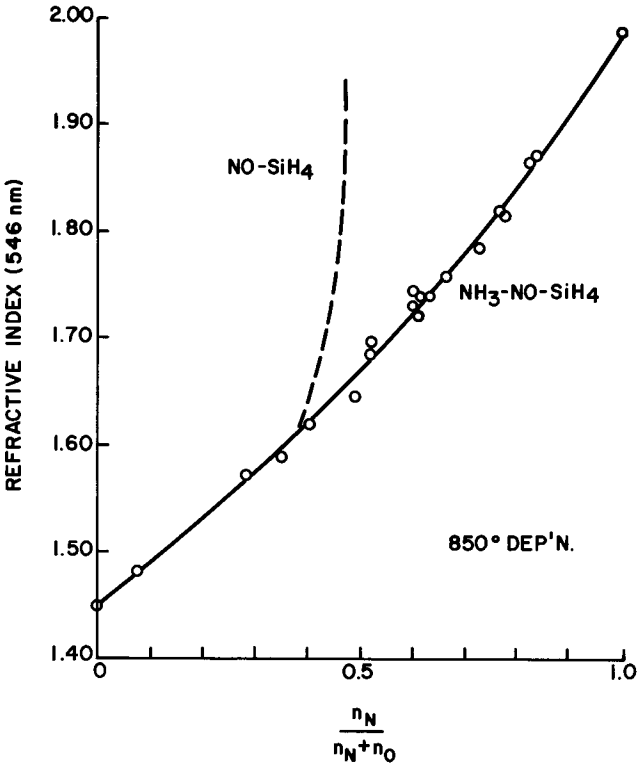

Fig. 5. Refractive index as a function of composition

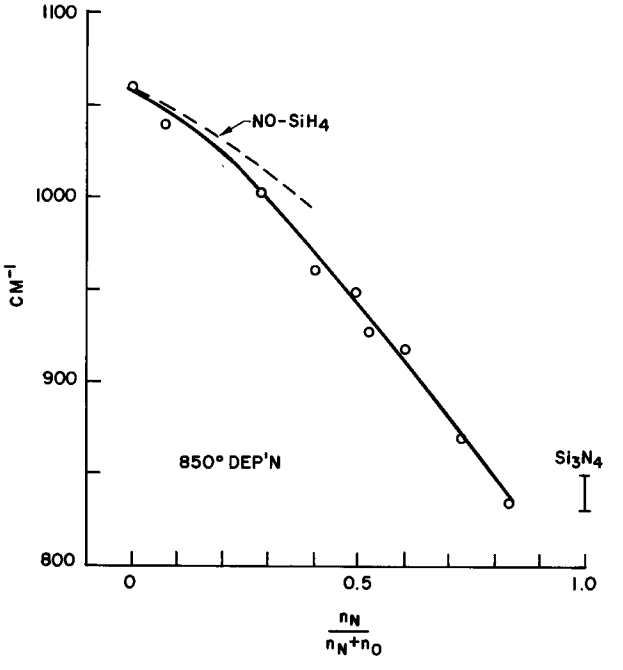

Fig. 6. The infrared absorption maxima of SiON's of various composition.

In addition to the skeletal vibrations given above, all SiH_4-NO-NH_3 SiON's show weak absorption at 3360-3390 cm^{-1}, and weak, very broad absorption at ~1200 cm^{-1}. No absorption at the O-H or Si-H stretching frequencies has been seen.

Etch rate.—Figure 7 shows the variation of buffered HF (7:1) etch rate with SiON composition. The etch rate decreases smoothly over a factor of $\sim 10^2$ from oxide to nitride. Unlike examination by i.r. spectrum, the etch rate is able to detect slight oxygen contamination in Si_3N_4. The difference in etch rate at $n \sim 1.6$ for SiON's from the two processes (more than a factor of two) reinforces the belief that there are fundamental differences between these SiON's. Etch rate is

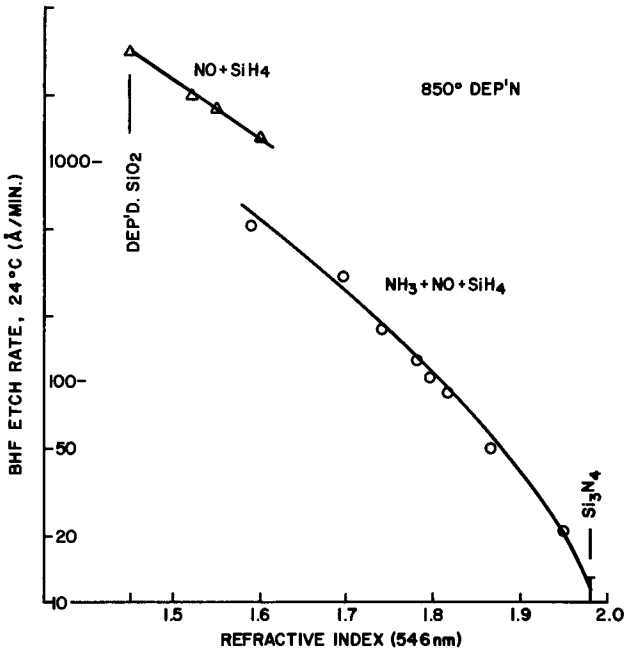

Fig. 7. The buffered HF etch rate of SiON's. Note that the ordinate is logarithmic.

evidently a sensitive indicator of structural strain, as it is with various kinds of SiO_2.

H_3PO_4 (180°C) etch rates have not been determined except at $n = 1.77$, where the rate is 110 Å/min. The rate undoubtedly decreases with increasing oxygen content.

Film stress.—The average stress in films of SiON on Si is shown in Fig. 8. Like Si_3N_4 itself, nitride-rich SiON is under high tension, and there is no drift with time. The failure of the curves for the two processes to join smoothly can only provide further evidence of a fundamental structural difference in the two SiON's. Note also that although NO-SiH_4 process SiON is under much less stress, nevertheless it etches more rapidly (Fig. 7). Mechanical stress, at least in films

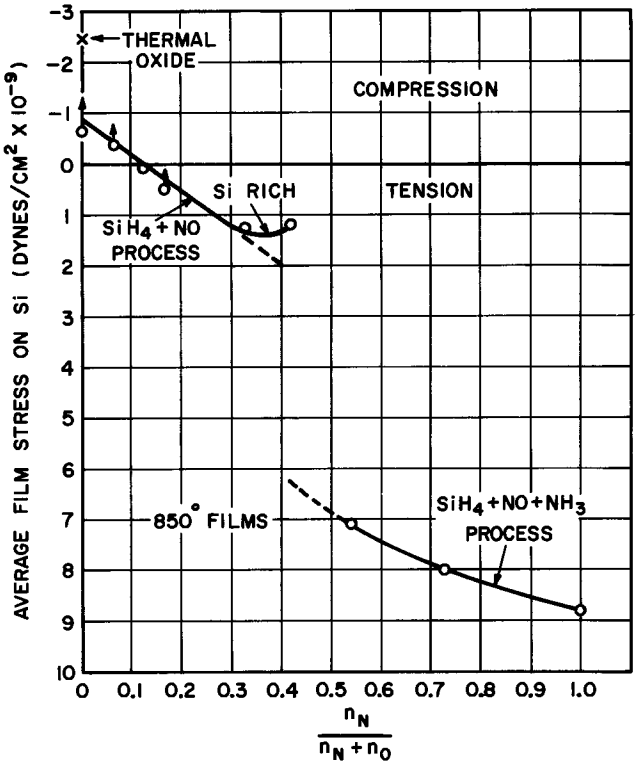

Fig. 8. Average film stress on Si of SiON's from the two processes

deposited at high temperatures, can hardly be a major factor in etch rate, and probably is not a reliable clue to bond strain in the film structure.

Sodium ion diffusion.—NaCl containing $^{22}NaCl$ was evaporated in a vacuum furnace onto the surface of slices coated with 2500-3400Å of SiON. The outer ⅛ in. was covered by Al masks. About a monolayer was deposited and uniformity of deposition was checked by autoradiography. To minimize evaporation losses the slices were paired face to face, horizontally, and diffused for 22 hr at 600°C in forming gas. Excess NaCl was rinsed off, and the back side of the wafers was also etched, although this precaution removed very little of the radioactivity. The samples were etched in steps and the remaining activity of the surfaces measured using a scintillation counter and a Baird-Atomic Model 530 spectrometer, counting the 0.51 MeV annihilation radiation gammas.

With a thin, depletable film source diffusing into a semi-infinite body as a model, and neglecting the absorption of the energetic gammas by the film, the residual activity I as a function of penetration depth x and diffusion time t is written (24)

$$I(x, t) = I_0[1 - \text{erf}(x/2\sqrt{Dt})]$$

where D is the diffusion coefficient (cm²/sec). At $x = 0$, at the surface, $I(0, t) = I_0$. This will be taken to be the initial intensity after diffusion and rinsing off excess.

Then

$$\frac{I}{I_0} = 1 - \text{erf}(x/2\sqrt{Dt})$$

$$= 1 - \text{erf}\, q$$

so that if there is a single diffusion process, and $D \neq f(t, \text{conc.})$, a plot of q *vs.* x gives a straight line passing through the origin of slope $\frac{1}{2}\sqrt{Dt}$, from which $D = x^2/4tq^2$ may be extracted. Note that in this plot a high q corresponds to a low residual activity, *i.e.*, a steep slope indicates a good sodium barrier. Fifty per cent of original activity corresponds to $q = 0.48$, and 10% to $q = 1.16$.

While this model is successful at high temperatures in vitreous silica (25), it is of questionable applicability at <700°C in thermally grown silica. It assumes a single-diffusion mechanism, a completely depletable source, no built-in electrical field, no diffusant reaching the far side of the medium, enough $^{23}Na^+$ or other cationic impurity present to exchange with the $^{22}Na^+$ to preserve over-all electroneutrality, etc. Probably none of these is true, and indeed experimentally a U-shaped sodium profile is found, with anomalously high Na^+ concentration at both film interfaces (26). Little has been reported on sodium diffusion profiles in deposited insulator films; it is not known whether they behave like bulk materials and follow the "residual activity" model outlined above.

Figure 9 is a q *vs.* x plot for SiON's of various compositions, etching and counting until about a third of the original film thickness has been etched away. The plots are not linear, and have a definite tendency to be steeper in the first 200Å, *i.e.*, as with grown silica, there is Na^+ holdup at the surface. These SiON's are not particularly good Na^+ barriers; none is as good as the best SiON ($n \sim 1.58$) from the NO-SiH_4 process, and some are not as good as freshly grown steam oxide. That the best is $n = 1.87$ might be predicted for a sample so close to pure nitride. Next best, however, are those compositions of $n \sim 1.6$, just what was found in the NO-SiH_4 system. Compositions of $n = 1.7$-1.8 are distinctly inferior, indicating no direct correlation between Na^+ barrier properties and nitrogen content or radiation resistance. And $n = 1.48$, which is essentially 850°C deposited oxide, is uniformly permeated with Na^+ throughout its thickness, which is hardly surprising.

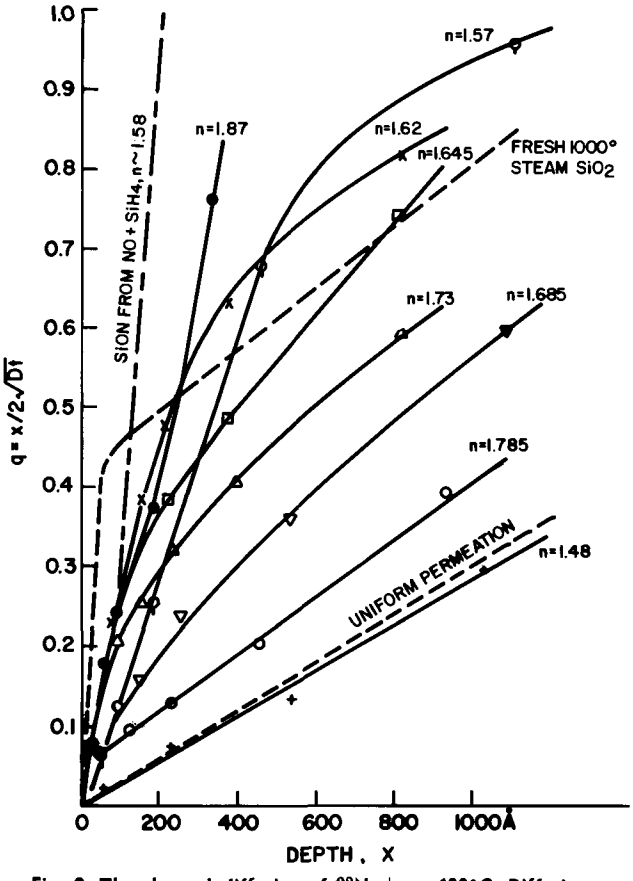

Fig. 9. The thermal diffusion of $^{22}Na^+$ at 600°C. Diffusion was for 22 hr in forming gas.

Autoradiographs of the samples after diffusion often show small "hot spots" surrounded by a depletion zone, or, less often, the exact reverse. The pattern of these spots was usually replicated in the other wafer of the diffusion sandwich; also, the pattern was still present after etching away a third of the film. There is a strong suspicion that there are certain areas of the surface which for some reason attract and tightly hold Na^+. Upon heating to 600°C, nearby Na^+ migrates rapidly over the surface to these sinks, and subsequently diffuses into the film, here as elsewhere.

Sodium ion drift under bias has been investigated mostly for radiation-hard SiON's *i.e.*, $n \sim 1.77$. This is a region of poor resistance to diffusion at 600°C; nevertheless, no unequivocal example of ionic drift under B-T aging at ≤300°C has been found. In other experiments, $^{22}Na^+$ contaminated SiON surfaces were covered by evaporated Al electrodes and attempts were made to drift in the sodium for 2 hr at 160°C and 1.6×10^6 V/cm. After removal of the Al and rinsing the surfaces no radioactivity remained, indicating no penetration into the film. Such tests emphasize a discrepancy between high-temperature diffusion and drift under B-T aging conditions; evidently the diffusion mechanisms can be markedly different.

Radiation resistance; cathodoluminescence spectra.—The remarkable resistance of compositions near Si_2ON_2 ($n \sim 1.77$) to ionizing radiation up to the megarad range has already been reported (2, 3), and will be summarized here only very briefly. The buildup of positive space charge in SiO_2 under irradiation is caused by hole-trapping, while the corresponding electrons, more mobile, drift out under bias. Apparently Si_2ON_2 has an approximate balance of deep traps for both holes and electrons, and an abundance of recombination centers. Under irradiation there is no bias instability at $<3 \times 10^5$ V/cm for negative bias (above which there is negative charge injection by the metal contact) and $<1.5 \times 10^6$ V/cm for positive bias. Interface-state density, after a hydrogen post-

deposition bake, is ~8 × 10^{10}/cm²-eV near midgap and rises only to ~10^{11} after irradiation with bias. Both bipolar and IGFET devices have been fabricated with SiON as the sole insulator, and much improved radiation resistance over devices using SiO_2 has been demonstrated.

Cathodoluminescence spectra have been taken on a series of six samples ranging from deposited oxide through SiON to deposited nitride. In Fig. 10 the light output of the various compositions is shown at two wavelengths: the C peak, 450 nm, which is the major output in SiO_2 films, and the B peak, ~365 nm, which is present in steam-grown oxide but not in dry O_2 oxide (16). The C peak is the strongest seen in deposited oxide (SiH_4 + NO), but it is weaker than in steam oxide, which is in turn weaker than in dry oxide. Figure 10 shows that as soon as nitrogen is introduced into the film the light output drops, and the B peak becomes the major one. Luminescence is at a minimum at $n = 1.77$, the radiation-resistant composition. At a high n it rises again, but silicon nitride gives essentially no signal. One additional findng to be kept in mind in studying Fig. 10 is that the electron-beam radiation annihilates the B peak in a few seconds, and it takes 1 min to sweep the spectrum from 200 to 600 nm.

Electrical properties.—Most of the electrical evaluation of SiON has been on films of $n = 1.72$-1.80, the radiation-resistant composition. In general, there are no surprises; SiON has properties intermediate between those of SiO_2 and Si_3N_4. For example, the 1 MHz dielectric constants for 850°C deposited materials are: SiO_2 ($n = 1.46$), 3.8; SiON ($n = 1.78$), 6.4; Si_3N_4 ($n = 1.98$), 8.0. Again, SiON shows roughly one order of magnitude higher d-c conductivity than SiO_2, but not the high quasi-stable, nonohmic conductivity of Si_3N_4 at > 10^6 V/cm.

For MIS evaluation, 2500-3000Å SiON was deposited on ~5 ohm-cm n- and p-type epitaxial Si layers on <0.01 ohm-cm <111> substrates. When the silicon was cleaned in the conventional way, *i.e.*, with a procedure in which the last steps are HF, water rinse, and spin dry, the fixed charge N_{FC} was 2-3 × 10^{12}/cm², the n-type invariably giving the lower figure. The interface-state density N_{ss} was very high, probably in the high 10^{12}/cm²-eV range.

Because of the persistently high N_{FC}, the aging behavior of SiON on HF treated Si was not studied in detail. The C-V curve is, however, fairly stable, and can be scanned repeatedly to ±2 × 10^6 V/cm with shifts of less than 0.5V, in contrast to the large "hysteresis loops" usually seen with silicon nitride. Holding the sample at 300°C for 24 hr with no bias does not affect the curve.

Deposition of SiON over ~100Å of thermal silica, results in more useful MIS properties. N_{FC} is now ~6 × 10^{11} (on n-type) to 10^{12} (on p-type). N_{ss} is still high, but may be reduced to ~2 × 10^{10}/cm²-eV near midgap by several hours of hydrogen bake at 500°C. These samples of SiON over thin silica have been aged at 300°C and ~1.6 × 10^6 V/cm for 24-64 hr. Slow drifts of V_{FB} of 3-4V in the nonionic direction occurred. Intervening silica layers >100Å do not further reduce N_{FC}. On the few samples of <100> Si tried, N_{FC} was somewhat lower.

The most useful procedure of all for control of SiON MIS properties is treatment of the Si before deposition with a mixture of aqueous ammonia and hydrogen peroxide. This procedure, first used to influence N_{FC} of reactively sputtered SiO_2 (29), works equally well on all CVD insulators we have tried (SiO_2, SiON, Si_3N_4). Its effect is to reduce measured V_{FB}, to an extent apparently determined by the pH of the solution. HNO_3-H_2O_2 has little effect, but NH_4OH-H_2O_2 of pH = 9 reduces N_{FC} by ~2 × 10^{12}. In other words, V_{FB}'s of the order of −20 for 2000Å films can be shifted to zero or even a few volts positive. After the peroxide treatment, N_{ss} is still high, but again a 500°C H_2 bake for several hours reduces it to <10^{11} near midgap, and without effect on the N_{FC} shift. Bias-temperature aging for 24 hr at 300°C and 10^6 V/cm typically produces a slow drift in the nonionic direction of ~3V (ΔN_{FC} ~5 × 10^{11}/cm²) which is proportional to log time. Quite probably a sizable part of this represents the development of higher N_{ss}.

No bias drifts in the ionic direction have been observed on any SiON sample, with the exception of one which had received a 900°C H_2 bake. This latter treatment was abandoned as soon as it was discovered that N_{ss} could be reduced, albeit more slowly, at 500°C without introducing protonic instability.

Representative MIS results are summarized in Fig. 11.

Discussion

The SiH_4-NO-NH_3 system evidently will produce good amorphous insulating films whose composition may be controlled readily and may be varied anywhere between SiO_2 and Si_3N_4. Over the range SiO_2 to about $Si_3O_3N_2$ ($n \sim 1.62$) the even simpler NO-SiH_4 process will serve, and no advantage is known for adding NH_3 to make these compositions. NH_3 is essential for the nitrogen-rich end of the scale. However, microprobe analyses, spectra, etch rates, and stress

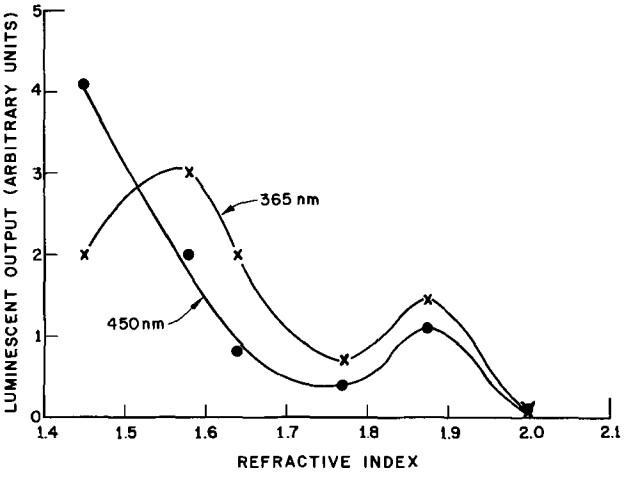

Fig. 10. Cathodoluminescence of SiON's from the SiH_4-NO-NH_3 system; 7 kV electrons.

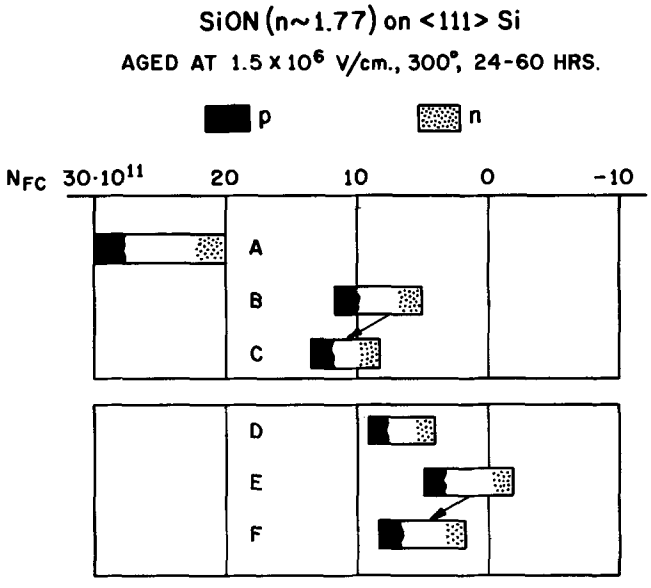

Fig. 11. Summary of typical MIS behavior. A = as deposited on Si with cleaning procedure ending with aqueous HF, rinse, and dry. B = deposited over 100Å of thermal silica. C = B, after negative bias-temperature aging. D = as deposited on Si with cleaning procedure ending with 4% aqueous H_2O_2 + NH_3, pH = 8. E = same, pH = 9. F = E, after negative bias-temperature aging.

determinations all provide evidence that these latter SiON's are not exactly Si^{+4}, O^{-2}, N^{-3} polymers, that their properties reflect this departure, and that there is a significant difference in bonding structure in the products of the two CVD reactions. The discontinuities in the etch rate and film-stress curves are particularly noticeable.

We propose that in SiON's made with ammonia roughly one nitrogen in three is bonded to only two other atoms (Si or O) instead of three. Some or all these "divalent" nitrogens may also have hydrogen atoms attached. This hydrogen would not be detected by the electron probe and would have scarcely any effect on the weight per cent of each component determined.

The probe could hardly distinguish between $Si_{1.85}ON_2$ [38 atomic per cent (a/o) Si] and $Si_{1.85}ON_2H_{0.7}$, but some of their properties may be quite different. The presence of bound hydrogen in pyrolytic silicon nitride was pointed out by Watanabe (18), and a trace of N-H in SiON has also been reported (8). The source of the hydrogen is undoubtedly the ammonia; SiON's from NO-SiH_4 show at the most only traces of OH or NH stretching vibrations in the i.r. spectrum. The refractive index curve is the same for SiON's made with or without ammonia, but sensitivity would be poor because of the low atomic refraction of hydrogen.

The infrared spectrum can detect differences not only in the skeletal vibrations but in the weak 3360-90 cm^{-1} and 1200 cm^{-1} absorptions. These are consistent with the presence of —N(H)—. Marchand *et al.* (19), reporting the spectra of organosilazanes, $R_3SiNHSiR_3$, give 3350-3380 cm^{-1} for ν (NH) and 1176-1179 cm^{-1} for γ (NH). Similarly, when NH_3 adsorbs on SiO_2, new bands at 3400 and 3320 cm^{-1} are attributed to asymmetric and symmetric N-H stretching (20). Pyrolytic Si_3N_4 invariably shows 3330-3350 cm^{-1} and 1200 cm^{-1}, strongest where the most ammonia was used in preparation, with parallel intensity changes, and much diminished by 1100°C baking (21). Si_3N_4 made in a d-c plasma has neither absorption. One note of caution in the picture is that SiO_2 also has a broad, weak absorption at 1200 cm^{-1} (22) which is probably a combination band. Nevertheless, the case remains strong for N-H binding in pyrolytic Si_3N_4 and SiON's made using ammonia. And these groups may well act as efficient electron traps, exactly as the OH sites of hydroxylated silica are believed to do (23).

It is likely that SiON's have some N-O bonding, but this vibration can have a very wide range of frequencies (30), and could easily be either inconspicuous or hidden among the combined Si-O and Si-N absorptions. Finally, the absence of detectable Si-H absorption does not mean no Si-H bonds; thermally grown silicas do not show Si-H in conventional transmission measurements either, but it is present at $\sim 5 \times 10^{19}/cm^3$ (31).

Structure and local stoichiometric anomalies very likely influence diffusion of sodium ion at 600°C also, but speculation on mechanism must await more detailed study; even the case for SiO_2 is not understood at this temperature, since it appears to follow a combination of at least two mechanisms (24). Although SiON is a deposited film, and therefore not formed by the diffusion of charged species through the growing film, the Na^+ profile follows no simple model. Like thermal silica, there is surface holdup, as though there were a surface zone in which the diffusion coefficient was considerably lower. The $n = 1.48$ sample, which is virtually a deposited oxide, is an exception; it is so permeable that after 22 hr the Na^+ is uniformly distributed throughout its thickness. The fact that the $n \sim 1.6$ SiON is the best barrier, regardless of which process is used, is mysterious, especially since that from NO + SiH_4 is much better than that from the process including NH_3.

Concern about the thermal diffusion of Na^+ through SiON becomes academic, however, in the face of its impermeability to bias-aided Na^+ drift at 300°C, a condition of greater pertinence to device operation. At least at $n = 1.7$-1.8, no test has shown any net ionic drift at all, or any penetration of radiosodium. The barrier lowering by the field is more than enough to compensate for the difference in temperatures in the two tests if the same diffusion mechanism were involved. We conclude that two different trapping centers for Na^+ may exist, or that ion charge neutralization phenomena may be quite different with bias-aided drift. At any rate, it seems there is no necessary correlation between a thermal diffusion test and B-T aging behavior of the film on Si; the latter should be a better approximation to real use. We believe that SiON's of substantial nitrogen content are good sodium barriers under conditions pertinent to device testing and operation.

Autoradiograph hot spots are not believed to be decorated pinholes, or areas of different composition, since electron-microprobe analyses (twelve per sample, analyzing a 2μ spot) have never shown such anomalies. SiON MIS capacitors seldom break down or show other evidence of weak spots in the dielectric. Pure Si_3N_4 also shows hot spots, although often they are removed by 100Å or so of etching. Hot spots are sometimes seen even in carefully prepared steam-grown silica. Finally there is the observation that these concentrations of sodium glass etch more slowly than the surrounding film. We think the evidence is best explained by areas of inchoate crystallinity of the film. Sodium ion would accelerate this devitrification.

The cathodoluminescence experiments have added some provocative data to that already known for silica, but the structural features responsible for behavior under irradiation are still unknown. In thermal silica the B peak (365 nm) emanates mostly from the outer part of the film and is destroyed by continued exposure; the larger C peak (450 nm) is concentrated near the Si-SiO_2 interface, its intensity varies inversely with the OH content, it is created by radiation, and is associated with positive space charge buildup (16). We can now add that as soon as nitrogen is introduced (or is it N-H?) the B peak begins to predominate over the C peak, and at the radiation-resistant composition both are at a minimum. While a large number of recombination centers are required for our picture of radiation hardness, this recombination is without luminescence, at least in the 200-600 nm range. Finally, silicon nitride itself gives practically no luminescent signal. An atom-scale model accounting for all these phenomena has yet to be proposed.

The high surface charge observed when SiON is deposited on conventionally cleaned Si is common for vapor-deposited insulators, especially silica, in the absence of special pre- or post-deposition treatments. The difference in N_{FC} with substrate type has been seen also in deposited silica (27) and Al_2O_3 (28); since the V_{FB} difference is several volts as against a work function difference of 0.6V, it is not understood.

The ammoniacal H_2O_2 treatment of the silicon before deposition yields more attractive properties, *i.e.*, low N_{FC} and, with hydrogen baking, $N_{ss} < 10^{11}$. Whatever the mechanism, the treatment acts as though it introduces into the native Si oxide negative charge which survives the 850°C deposition conditions. This oxide, typically ~10Å thick on a freshly cleaned surface, is not significantly thickened by the peroxide treatment; ellipsometer measurements have shown increases of only 2-3Å. Furthermore, the N_{FC} difference between Si types is preserved: both types shift the same amount.

The potential uses of SiON films evolve directly from the properties they possess that other insulators do not. So far SiON of $n \sim 1.76$ is unmatched for resistance to ionizing radiation under bias. The stress-free composition would be useful for unusually thick films, or thinned down or otherwise fragile substrates. SiON deposited on HF cleaned Si, with its stable, high negative V_{FB}, may be useful as insulator in closely spaced diode arrays, as in the Picturephone® camera tube. SiON, $n = 1.7$-1.8, on surface-treated Si, looks promising as a B-T stable, HF etchable, deposited insulator highly resistant to Na^+ drift, with low, and adjustable, surface charge and low fast state densities. Finally, the close adjustment and control of composition available at any stage during deposition permits adjustment of etch rate, and thus the contour of a window. If one wanted a steep-sided or even vertical window, say, for very precise delineation of diffusion or ion implantation, he could use slow-etching, high-nitrogen SiON graded down to silica, and etch with HF. A more common profile, a beveled-edge window for metalization, could be etched out with oxygen-rich SiON over silica, or N-rich SiON graded down into O-rich SiON and using H_3PO_4 etch. Such shapes can be cut with present technology, for example using deposited silica over thermal silica, but an extra operation is usually required, or an extra photoresist step if the profile is terraced. The resistance of oxynitride to Na^+ drift is a further bonus.

Conclusion

Silane, nitric oxide, and ammonia, diluted with nitrogen, react at the surface of a substrate at ~850°C to chemically vapor deposit a clear, adherent, thin-film insulator which is a Si, O, N polymer containing also some H bound to the N. The O:N ratio of this material is readily controllable over the entire range between SiO_2 and Si_3N_4. Its H content is believed to make this oxynitride somewhat different in structure from that from the NO-SiH_4 reaction, and this difference is detectable in several of its properties. Oxynitride composition may be most easily inferred from the refractive index. The composition near Si_2ON_2, $n \sim 1.76$, has been most carefully studied, since this film is radiation hard, a barrier to Na^+ drift under bias, and quite stable to bias-temperature aging as an MIS dielectric. For good characteristics in the latter test the silicon substrate must be pretreated with ammoniacal H_2O_2; then the V_{FB} will be close to zero, and the interface-state density $<10^{11}/cm^2$-eV after hydrogen baking. These treatments do not degrade any of the other properties of the SiON.

Acknowledgments

We acknowledge many helpful discussions with Paul F. Schmidt on the MIS properties of SiON. Much of the sodium drift data are his. The cathodoluminescence measurements were done by J. P. Mitchell of the Whippany, New Jersey, laboratories. Electron-microprobe analyses were done by D. R. Wonsidler.

Preparation of Vacuum-Deposited Films of Rubidium Silver Iodide

John H. Kennedy,* Fred Chen,* and James Hunter

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Vacuum-deposited thin films of $RbAg_4I_5$ have been prepared exhibiting conductivities of 0.25 ohm-cm^{-1} at 25°C and an activation energy of 2.3 kcal/mole. The purest films of $RbAg_4I_5$ were produced when the evaporation source composition was 83-85 mole per cent (m/o) AgI.

Electrolytic cells were prepared of the type $Ag/RbAg_4I_5/Au$ and were studied by cyclic voltammetry with a silver reference electrode and as coulometers. Cells could be cycled electrochemically over 1000 times, but coalescence of $RbAg_4I_5$ films eventually led to loss of e ctrode contact. Degradation was accelerated when the cells were exposed to humid air.

Techniques for vacuum deposition of thin films have advanced greatly in recent years as evidenced by extensive reviews on the subject by Behrndt (1) and Neugebauer (2). Although the characteristics of metallic films such as gold and silver are well known, films of materials which can serve as solid electrolytes have not been extensively investigated. Silver halide thin films have been prepared (3), and a thin-film electrolytic coulometer using AgBr as the electrolyte has been reported (4). It is a natural extension of this work to attempt the preparation of $RbAg_4I_5$ films, although this complex compound owes its stability to its crystal lattice, and therefore, evaporation could lead to decomposition. Takahashi *et al.* (5) have reported the existence of $RbAg_4I_5$ films, but we report here additional details on the preparation and electrochemical properties of $RbAg_4I_5$ thin films.

Experimental

Preparation of $RbAg_4I_5$ evaporation source material.—A RbI (Alfa Inorganics) and AgI powder mixture [83-85 mole per cent (m/o) AgI] was placed in an alumina crucible, and the crucible was placed inside a three-neck flask. AgI was obtained from precipitation by mixing together aqueous solutions of 1M $AgNO_3$ and 1M KI. The three-neck flask was flushed with dry nitrogen gas for several minutes and then evacuated ($<40\mu$ pressure). While under vacuum the mixture was heated at a rate of 10°C/min, until it reached 450°C. The mixture melt had an orange color at 450°C. After heating at 450°C for about 1 hr and after bubbling had stopped, the sample was cooled slowly, and a light yellow solid was obtained. The source material was not removed from the crucible since the same crucible was used during vacuum evaporation. The crucible and source material were stored over silica gel until used.

Preparation of $RbAg_4I_5$ films.—The alumina crucible with the $RbAg_4I_5$ source material was placed inside a tungsten crucible heater. The pressure of the chamber was then lowered to about 1×10^{-6} Torr. The temperature of the sample was increased slowly until it started to melt around 250°C. Ten minutes after the source material had completely melted, the source temperature was increased to 350°C at a rate of 5°C/min. Bubbling by the melt usually stopped within 5 min, and the temperature of the melt was then increased to 500°C. The shutter protecting the substrate from spattering was removed and deposition on the substrate proceeded. The pressure of the chamber during deposition was about 4×10^{-4} Torr, and the average deposition rate was about 1.6×10^3 Å/min.

* Electrochemical Society Active Member.

Key words: rubidium silver iodide, thin films, coulometers, vacuum deposition, solid electrolyte conductivity.

Preparation of thin-film electrolytic cells.—The configuration of the electrolytic cells has already been described in a previous paper (4). A metallic film, usually gold, was deposited first on a clean glass slide. The gold film was about 1000Å thick. The electrolyte film was deposited next with a thickness of 80,000-200,000Å. Finally, another metallic film, about 1000Å thick, was deposited on top of the electrolyte film. If a silver film was used as the second metallic film of the cells, care was taken to ensure that the deposition chamber was perfectly clean before depositing silver, otherwise the deposited silver film was tarnished quite readily by any residual oxidizing gas in the evaporation chamber.

Electrolytic cells with a Ag reference electrode were prepared in the same manner, but instead of using the electrolyte mask of 12 cells per slide, a 6 double-cell electrolyte mask was used. The reference electrode was prepared by electroplating one of the two gold electrodes in the cell with 15 or more monolayers of silver.

Vacuum deposition equipment.—Fairchild Instruments vacuum deposition equipment was used to prepare all thin films. The lowest pressure obtainable with this equipment was 1×10^{-7} Torr. A high nickel content, stainless steel sheet was wrapped around the interior of the bell jar, and a dry ice-acetone trap was installed between the diffusion and mechanical pumps. The substrate was located about 12 in. above the evaporation source material while a stainless steel shutter was placed about 8 in. above the source. A Sloan Technology Corporation Ommi II system, with a deposition monitor and an SCR power controller, was used to monitor (*i*) the initiation of evaporation, (*ii*) the approximate film thickness during deposition, and (*iii*) the rate of deposition.

X-ray diffraction equipment.—X-ray diffraction studies were made with a Philips Electronics x-ray diffraction unit with CuK_α radiation. A Philips 52572 scintillation counter with chart recorder was used for the x-ray diffractometer measurements.

Electrochemical equipment.—A General Radio Incorporated 1650A impedance bridge with a 0.5V rms, 1 kHz a-c signal was used for resistance measurements. A Wavetek voltage-controlled generator was attached to the impedance bridge for resistance measurements at frequencies other than 1 kHz. A Harrison 6112A d-c power supply was used for residual current determinations. A Beckman Instruments Electroscan 30 was used for cyclic voltammetry. A Bissett-Berman Corporation E-Cell Digital Coulometer was used for constant current-charging of cells and for those experiments designated as constant current readouts. A Bissett-Berman Corporation EDR-300 E-Cell Digital Coulometer was used for pulse charge and dis-

charge of cells. The unit was modified to deliver pulses of 1 μcoulomb in place of the normal 100 μcoulombs. Two Hewlett-Packard 412A VTVM's attached to a Hewlett-Packard 7100B strip-chart recorder with 17501 plug-ins were used for measuring the potentials of the cell electrodes *vs.* a reference during the charge and strip cycles.

An Associated Testing Laboratories SW-5101 environmental chamber was used for temperatures other than ambient.

Results and Discussion

Evaporation of AgI and RbI mixtures.—Since $RbAg_4I_5$ owes its stability to crystal-lattice energy, and especially an entropy effect from the random distribution of silver ions, evaporation should lead to a mixture of RbI and AgI. The preparation of $RbAg_4I_5$ films will depend on the ability of RbI and AgI vapors to condense on a substrate in this crystalline form. Obviously, it is imperative that the condensing vapors maintain a stoichiometric ratio of 4AgI:RbI. It is more important to consider the condensation process stoichiometry than the stoichiometry of the source material. Appropriate source composition can be calculated from the vapor pressures of AgI and RbI.

The approximate vapor pressures for RbI and AgI in the temperature range used for vacuum deposition of $RbAg_4I_5$ can be calculated by extrapolating the equation (6)

$$\log_{10} p = (-0.2185\, A/T) + B$$

where T is temperature (°K), and A and B are constants. For RbI between 748° and 1304°C, $A = 38{,}072.3$ and $B = 8.174712$. For AgI between 820° and 1506°C, $A = 37{,}340.1$ and $B = 7.48857$. The calculated vapor pressures for RbI and AgI between the evaporation temperatures of 425° and 550°C are given in Table I.

Assuming ideal behavior for the vapor mixture of both evaporants, a 90-93 m/o of AgI in the AgI + RbI melt is needed in order to obtain an initial vapor pressure ratio of 1:4 (p_{RbI}/p_{AgI}) in the 425°-550°C temperature range. However, with the evaporation of 4AgI for every RbI, the melt would rapidly become richer in AgI, and excess AgI might start depositing on the substrate. When an initial 4AgI:RbI melt composition was used, an initial vapor pressure was obtained which was rich in RbI. The films produced in this way, although containing primarily $RbAg_4I_5$, had very low conductivity. To compromise between an initial excess of RbI, or a later excess of AgI, melt compositions between 83 and 85 m/o AgI were chosen which resulted in a slight initial excess of RbI, but did not lead to a large excess of AgI later in the deposition.

X-ray diffraction data for $RbAg_4I_5$ films are given in Table II. Several features of the $RbAg_4I_5$ films can be noted from the data: (*i*) the tendency for the $RbAg_4I_5$ films to deposit initially on gold along their (110) planes; (*ii*) the preferred orientation along the (110) plane increased with increasing substrate temperature at least up to 70°C; (*iii*) the films reoriented toward their (110) planes by annealing them at 150°C; (*iv*) randomness in orientation increased with increasing film thickness; and (*v*) no diffraction peaks corresponding to RbI, Rb_2AgI_3, and AgI were observed.

Takahashi *et al.* (5) have reported x-ray diffraction results for $RbAg_4I_5$ films deposited on glass between 25° and 152°C. Unfortunately they did not report the intensity, if any was observed, of the peak at 11.3° corresponding to the (110) plane. They did report that x-ray diffraction patterns of films deposited at 101°C or higher showed a peak around 24.5°, and the intensity of this peak increased with increasing substrate temperature. However, this peak can be assigned to Rb_2AgI_3 (5).

Although it has been reported that $RbAg_4I_5$ decomposes slowly into AgI and Rb_2AgI_3 in the presence of humidity at temperatures below 27°C, x-ray diffraction lines corresponding to AgI and Rb_2AgI_3 were not detected for films deposited at 20°C. The detection limit for x-ray diffraction is about 1%, so that traces of AgI and Rb_2AgI_3 could still be present. It is very likely that they were indeed present since electrolytic cells deposited at 20°C usually had resistances 100 times higher than those deposited at 35°C.

Electrochemical characteristics.—The resistances of Ag/$RbAg_4I_5$/Au and Au/$RbAg_4I_5$/Au thin-film cells were found to be frequency dependent as shown in Fig. 1. Some of this frequency dependence and high resistances, compared to pressed powder samples, can be attributed to the existence of silver iodide (or gold iodide) at the interface of the electrode that was on top of the $RbAg_4I_5$ film. During the deposition of $RbAg_4I_5$, some of the AgI in the source boat decomposed liberating iodine gas, and part of the iodine gas might have been trapped at the $RbAg_4I_5$ film surface which could then react with the electrode material forming the iodides. The decomposition of silver halides during evaporation with liberation of halogen gas has also been observed by Vouros (3); and tarnish of the electrode deposited on top of $RbAg_4I_5$ samples has been observed by Breitweiser (7) and Scrosati (8).

The conductivity of our $RbAg_4I_5$ films was determined by using a variation of Takahashi's method. Our cell consisted of 12 equally spaced gold electrodes with a $RbAg_4I_5$ film of known thickness deposited at 40°C on top. A plot of the resistance between two gold electrodes *vs.* electrode separation distance is

shown in Fig. 2. In this way, no effects due to the top surface of the $RbAg_4I_5$ were encountered. The conductivity was calculated from the slope and found to be 0.25 ohm-cm^{-1}. This conductivity value is slightly higher than the value of 0.2 ohm-cm^{-1} reported by Takahashi (5) for films deposited at 25°C and compares closely with the conductivity of polycrystalline $RbAg_4I_5$ of 0.26 ohm-cm^{-1} (9). The measured resistance between two gold electrodes was also

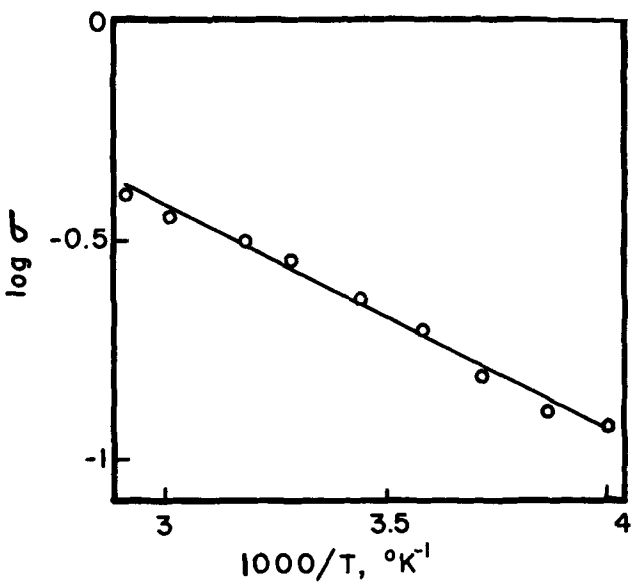

Fig. 3. Temperature dependence of $RbAg_4I_5$ thin-film conductivity determined from slope of Fig. 2.

found to be somewhat frequency dependent. However, by plotting the measured resistances as a function of electrode separation and assuming that the frequency dependency had about the same effect on all measured resistances, the portion of the resistance that was frequency dependent would only affect the intercept and not the slope.

The conductivity of $RbAg_4I_5$ films as a function of temperature is shown in Fig. 3. The activation energy for conduction was 2.3 kcal/mole. This value is about 0.6 kcal/mole higher than the activation energy reported for polycrystalline $RbAg_4I_5$ (9), but only 0.3 kcal/mole higher than the activation energy for Ag^+ tracer diffusion in $RbAg_4I_5$ (10).

Blocking electrode studies with the Ag/$RbAg_4I_5$/Au cells gave residual currents of <1 nA between 0.2 and 0.6V. Assuming that all the residual current was due to electronic current, the electronic conductivity calculated with Wagner's equation (11) was $<4 \times 10^{-10}$ ohm-cm^{-1}. Oxley (12) has reported that the electronic conductivity for polycrystalline $RbAg_4I_5$ to be $<10^{-11}$ ohm-cm^{-1}.

As with pressed powder samples (13), $RbAg_4I_5$ films were found to be sensitive to humidity. The resistance of film cells increased from a few ohms to over 1,000,000 ohms in less than 7 days when exposed to room atmosphere. The increase in cell resistance could be decreased by storing the cells over silica gel between 30° and 35°C. Even so, there was an initial increase of a few ohms during the first couple of days of storage as shown in Fig. 4. This increase in cell resistance can be attributed to coalescence of the $RbAg_4I_5$ film which made it lose contact with the electrode films. Usually, the base electrode film became detached from the glass slide when the $RbAg_4I_5$ film had completely coalesced. The initial film crystallites were less than 4μ in diameter, while some of the coalesced crystals were about 600μ long and 200μ wide with an undefined shape. Figure 5a is a photomicrograph (250X) of a $RbAg_4I_5$ film 150,000Å thick over glass and kept in the normal laboratory environment, taken 3 days after it was deposited, and it shows that coalescence had occurred at several points. Figure 5b is another photomicrograph (250X) which shows complete coalescence for a film 7 days old. As can be observed, the coalesced crystals' grain boundaries are very well defined.

Owens and Argue (13) reported that traces of AgI and Rb_2AgI_3 present in powdered $RbAg_4I_5$ samples can be eliminated by annealing $RbAg_4I_5$ pressed pellets at 160°C for several hours. However, during an-

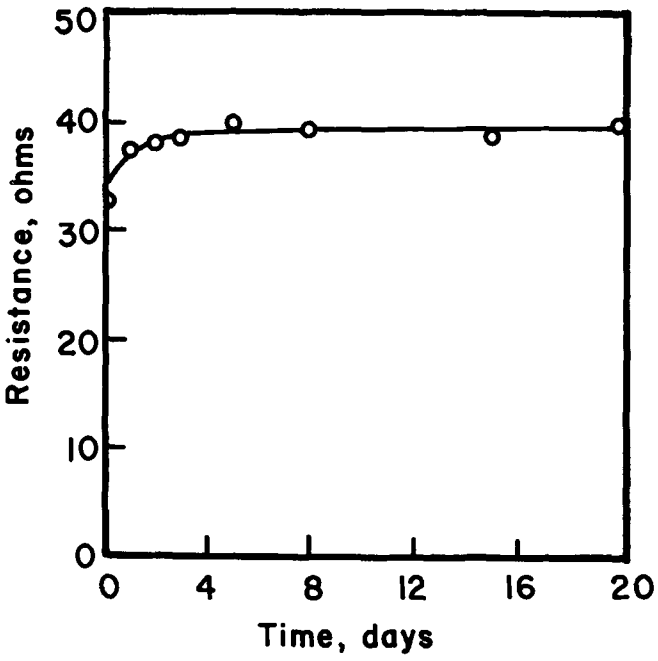

Fig. 4. Dependence of $Au/RbAg_4I_5/Au$ thin-film cell resistance (1 kHz) on storage time.

nealing of film cells at 160°C for several hours the gold electrode lost contact with the glass slide. The loss of contact was probably due to differences in thermal expansion between the gold film, the $RbAg_4I_5$ film, and the glass slide.

Cyclic voltammetry.—Cyclic voltammetry was used to examine the electrode reactions that took place on the gold electrode. The potential of the gold electrode was measured *vs.* a silver reference electrode. In general, one cathodic peak near 0.0V and two small anodic peaks near 0.05 and 0.2V were observed during the forward scan before the final cutoff, Fig. 6. Similar voltammograms were obtained during the succeeding cycles.

An initial applied potential of 0.0V *vs.* the Ag reference electrode caused a cathodic current from Ag^+ reduction since the silver activity at the gold electrode was lower than at the silver electrode. The anodic peak near 0.05V can be attributed to the oxidation of Ag which had been plated on the gold while the current was cathodic. The anodic peak near 0.2V was attributed to the oxidation of some trace impurity such as oxide or sulfide ions at the gold surface.

The final cutoff peak near 0.67V can be attributed to any of the reactions describing the oxidation of gold *vs.* iodide such as

Reaction	Potential calculated from $\Delta G°_f$
$RbAg_4I_5 \rightarrow RbI + 3AgI + Ag^+ + \frac{1}{2}I_2 + e^-$	$E° = 0.729$ *vs.* Ag
$2RbAg_4I_5 + Au \rightarrow Rb_2AgI_3 + 6AgI + Ag^+ + AuI + e^-$	$E° = 0.642$ *vs.* Ag
$RbAg_4I_5 + 4Au \rightarrow RbI + 4Ag^+ + 4AuI + 4e^-$	$E° = 0.665$ *vs.* Ag

It was interesting to note that the final cutoff peak started to rise around 0.45V. This was an important factor in selecting the voltage of 0.45V as the cutoff potential for timing with $RbAg_4I_5$ coulometers. Hull and Pilla (14) reported that iodine started to be liberated in AgI systems with platinum electrodes at 0.46V. During the reverse scan a small cathodic current was observed around 0.2V which can be attributed to reduction of iodine still present at the gold electrode.

Coulometry.—Coulometry of $Ag/RbAg_4I_5/Au$ cells was studied by techniques described previously (4). Accuracy of $RbAg_4I_5$ thin-film cell coulometers was determined for charges of 20-2500 μcoulombs. The results are tabulated in Table III. For constant current readouts, the cutoff voltage was 0.45V. The average error was the average of ten determinations. In general, higher deviations from the average error were observed for the first two determinations. The larger errors for the first few determinations have been attributed to the diffusion of silver along the grain boundaries into the gold electrodes (4).

The use of pulsing techniques during charge and strip cycles did not improve the timing accuracy of the coulometers, Table IIIb, but errors were not greater on initial determinations. A discussion of the pulsing technique has been made in a previous publication (4).

Pulsing techniques were also used to determine the charge storage capabilities of $RbAg_4I_5$ thin-film cells. A charge of 500-1000 μcoulombs was plated on the gold and allowed to stand for several days before stripping. Figure 7 shows that there was rapid loss of about 80 μcoulombs of charge during the first day, and then little additional loss. This can be explained again by the migration of silver into the gold electrode along the gold electrode grain boundaries with the gold electrode eventually becoming saturated. A similar

saturation value was found for AgBr thin-film cells. It was not surprising that the saturation values for both types of thin-film cells were about the same since they had essentially the same type of gold electrode.

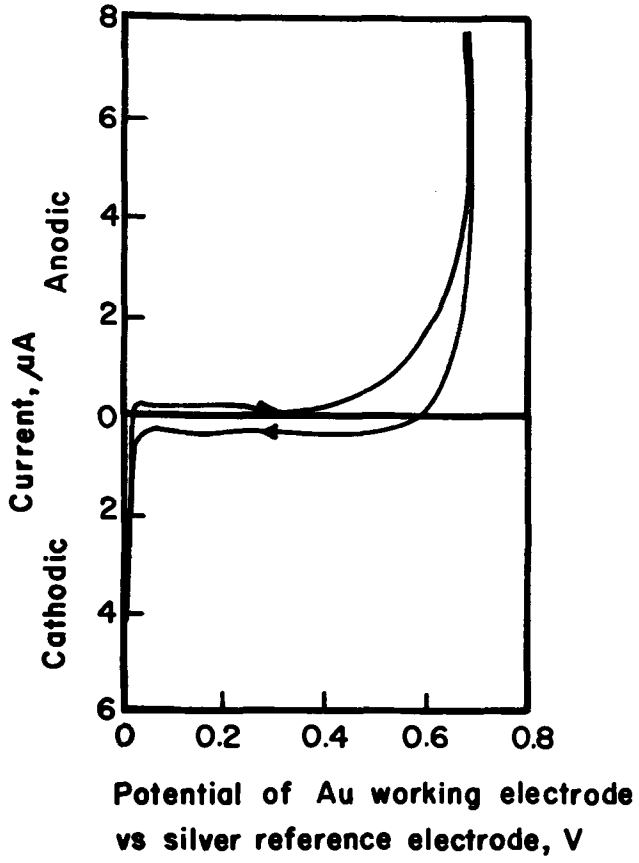

Fig. 6. Cyclic voltammogram of $RbAg_4I_5$ cell. Scan rate, 2 mV/sec

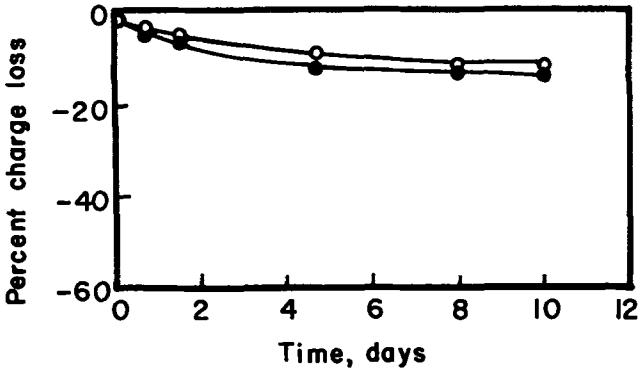

Fig. 7. Charge loss with storage of $RbAg_4I_5$ thin-film coulometers. Initial charge: ●, 500 μcoulombs; ○, 1000 μcoulombs.

Life of the cells was reasonably long considering the close electrode spacing. Some of the cells were cycled continuously with 200 μcoulombs of charge for more than 1000 cycles with no apparent damage. However, the cell life was limited by the coalescence of $RbAg_4I_5$ which can destroy the contact between the gold electrode and the $RbAg_4I_5$ film. Keeping the cells in a dry atmosphere is necessary if the cells are to be used for more than a few days.

The Anodic Dissolution of Copper in Flowing Sodium Chloride Solutions Between 25° and 175°C

A. L. Bacarella and J. C. Griess, Jr.*

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

The anodic dissolution of copper in chloride solutions was studied under laboratory conditions up to 101°C and up to 175°C in a specially designed cell that could be flanged into a pump loop. Under all conditions the anodic polarization curves demonstrated Tafel behavior with slopes equal to 2.3 RT/F. The anodic process was under diffusion control with the primary dissolution product being $CuCl_2^-$; no evidence of solid corrosion products was found at the highest current densities employed. The anodic process was independent of pH and between 0.124 to 1.24M Cl^- depended on the square of the chloride ion concentration. Loop experiments showed that under fixed conditions the current density was proportional to the 0.8 power of flow velocity. A simple kinetic expression based on the Nernst equation and Fick's first law was derived which was in excellent agreement with the experimental results.

Copper and its alloys find extensive use in sea water, and over the years a great wealth of empirical data concerning the corrosion of these materials has accumulated. However there have been relatively few systematic studies of corrosion mechanisms of copper or its alloys in chloride media. Of those that have been reported most were conducted at temperatures below 100°C.

Lal and Thirsk (1) appear to have been the first to demonstrate that the anodic dissolution of copper in sodium chloride solutions exhibits pure concentration polarization and from 17° to 60°C showed that the anodic Tafel slope was equal to 2.3 RT/F. Hurlen (2) also showed the anodic polarization of copper to be under diffusion control. In addition he showed that the potential (E) at constant anodic current varied with chloride concentration according to the relationship

$$\frac{dE}{d \log (Cl^-)} = 2 \left(\frac{2.3\,RT}{F} \right)$$

at chloride concentrations up to about 1M but at higher chloride levels the coefficient was 3 rather than 2. Boden (3) carried out anodic polarizations of copper in sodium chloride solutions from 30° to 140°C. He observed Tafel slopes of approximately 60 mV/decade in the temperature range of 30°-100°C but at higher temperatures the slopes were 140-160 mV/decade. North and Pryor (4) exposed copper specimens to boiling 0.5M NaCl and concluded from their results that Cu_2O formed as a direct anodic corrosion product. More recently Taylor (5) using a ring-disk electrode demonstrated that copper anodically dissolves in 0.5M NaCl only by the generation of soluble cuprous ions over the range of 2.5 to 900 $\mu A/cm^2$. This latter result is consistent with the data of Lal and Thirsk (1) and Hurlen (2) since concentration polarization would not occur if Cu_2O were a direct corrosion product. Thermodynamic considerations at 25°C such as the solubility product of Cu_2O (6), the standard potential for the formation of Cu_2O (15), and the stability constant of the $CuCl_2^-$ complex ion (7) also indicate that in the range of the corrosion potentials of copper in sodium chloride solutions the *in situ* formation of Cu_2O should not occur.

In many distillation-type desalting plants copper alloys are exposed to salt-water solutions well above 100°C, and although their performance is generally satisfactory little is known about their corrosion mechanisms at higher temperatures. While pure copper is seldom used in desalting applications, an understanding of the mechanism of copper corrosion is essential if the mechanism of the corrosion of copper alloys is to be obtained. This paper presents the results of an electrochemical study of the kinetics of the anodic dissolution of copper. The results presented here duplicate to a minor extent the work of Lal and Thirsk (1) and Hurlen (2) but extend the temperature range to 175°C and include studies in flowing streams. In addition our analysis of the data has resulted in the derivation of a simple kinetic expression which is applicable over the entire temperature range.

Experimental

Electrochemical studies were conducted in two different types of cells: conventional laboratory glass cells and a cell mounted in a recirculating pump loop which was constructed of Hastelloy C. In the glass cell temperatures up to atmospheric boiling were investigated and in the loop temperatures were as high as 175°C. Zone-refined copper was used in the laboratory studies whereas standard electrical-conductor grade copper was used in the loop study. In the zone-refined material all metallic impurities were below the level of detection by emission spectrographic analysis. Based on the same method of analysis the electrical-conductor grade copper contained 300 ppm

* Electrochemical Society Active Member.

Key words: copper dissolution kinetics, high-temperature polarization curves, $CuCl_2^-$ ion, anodic concentration polarization, high-temperature polarization cell.

Ag, 90 ppm Fe, and 40 ppm Ni as the major impurities. In the studies described here no detectable difference between the two materials was apparent.

All solutions were prepared from reagent grade chemicals without further purification. In the laboratory studies the chemicals were dissolved in triply distilled water and for the loop studies deionized water with a specific resistivity of $> 10^6$ ohm-cm was the solvent. Again the quality of the solvent made no apparent difference. Solutions were saturated with the appropriate gas by sparging for several hours before use. In these systems the corrosion of copper is proportional to the oxygen concentration, but, since most of our measurements were made at potentials well above the corrosion potential, removal of the last traces of oxygen was not essential.

Both constant current and constant potential polarizations were carried out. All measurements were taken at steady state which was generally achieved within relatively few minutes after changing either the current or potential. An electronic potentiostat designed and built at Oak Ridge National Laboratory and an Anotrol Model 4700 potentiostat were used in these studies. Both instruments also included provisions for galvanostatic operation. In all cases currents were measured as potential drops across precision resistors with Keithley Model 600A battery-operated electrometers, the outputs of which were recorded with Hewlett-Packard Model 7100B dual channel recorders.

Some of the laboratory studies were carried out in a Pyrex glass cell similar to that described by Kelly (8). In these cases temperature control was ± 0.1°C of the specified value. However most of the laboratory experiments were performed in a 3-liter flask which had ground glass necks for admission of a test electrode, a polarizing electrode, a Haber-Luggin capillary probe, a tube for gas entry, a mercury thermoregulator, and a condenser. The condenser was equipped with a water-bubbler trap to prevent back diffusion of atmospheric oxygen. Heat was applied with an electric mantle activated by the mercury thermoregulator through an electronic relay assembly. In this larger flask temperatures were usually within a degree of the specified value. With both cells the potential of the test electrode was measured with reference to a saturated calomel electrode (SCE) in an external compartment at room temperature (~ 29°C) connected to the cell via the Haber-Luggin capillary. The test specimens were cut from 0.65 cm diameter rod stock and were 0.65-0.95 cm long. In both glass cells the electrodes were mounted on conventional Teflon holders and either platinum or graphite served as the polarizing electrode. Gentle stirring was provided by means of a magnetic stirrer in the bottom of the cell.

Polarizations in the Hastelloy C pump loop were carried out in a cell mounted in a bypass line of the loop. Figure 1 is a schematic drawing of the cell which consisted of a 1½-in. diameter schedule 80 titanium pipe with six welded fittings through which the electrodes were inserted. A heavy-walled Teflon tube with a 1-cm diameter flow channel fitted snugly inside the pipe section. The ends of the pipe and the caps (also titanium) were threaded, and flat Teflon gaskets prevented leakage between the liner and the caps. The cell was mounted in the bypass line with flanges (not shown in Fig. 1) attached to the caps.

Figure 2 shows the manner in which a specimen was mounted in the cell. The Teflon liner was drilled and threaded as shown and Teflon seal B was inserted. This seal was permanently bonded to the liner with Chemgrip (Chemplast Inc., Wayne, New Jersey). The specimen was pushed through the opening, and Teflon seal A was then slid over the specimen. Tightening the gland nut sealed the specimen in the vicinity of the junction of the two seals. The four graphite polarizing electrodes were mounted in nearly the same manner. The diameter of the graphite was 0.64 cm, and the ends were shaped so that they could be mounted flush with the inner surface of the Teflon liner. In contrast to the specimen mount, the liner was threaded throughout its thickness as was the graphite. Both the graphite and the lower Teflon seal were permanently bonded to the liner. Threaded into the short length of graphite was a 3-mm diameter copper wire so that the remainder of the assembly was identical to that shown in Fig. 2. During polarizations, the four graphite electrodes were connected in parallel. The reference electrode was in an external vessel and was connected to the cell by a salt bridge as described by Bacarella and Sutton (9). The end of the salt bridge extended into the flow channel and ended a short distance (1-2 mm) from the specimen. At the current densities used no IR corrections were necessary.

The specimens used in the loop were made from 3.2-mm diameter rods which were coated with epoxy cement (Epoxi-Patch, Hysol Division, Dexter Corporation, Olean, New York), and enclosed in a Teflon tube. The end of the rod to be inserted into the cell was ground flat so that the exposed surface area of the specimen was its cross sectional area, 0.08 cm^2. The surface of the test electrode was essentially flush with the Teflon liner.

The loop was constructed of Hastelloy C and a 25 gpm Hastelloy C pump driven by a variable speed motor circulated the solution. In these studies the flow rate of solution past the specimen was either 122 or 244 cm/sec (4 or 8 ft/sec). In all loop tests the solution was 1M NaCl with a *p*H between 6.3 and 7.0. The total volume of solution in the loop was 3.7 liters, and this was refreshed at the rate of 1 l/hr by means of a pulse pump and letdown valve. Loop pressure was maintained at about 200 psig in most cases. Heat was applied to the loop by electric heaters on the pipe

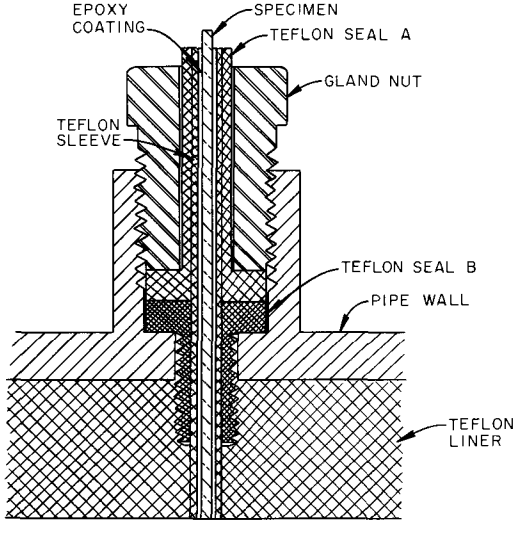

Fig. 2. Method of mounting test specimens in high-temperature polarization cell.

walls and the desired temperature was maintained within ± 2°C by a pneumatic controller operated from a thermocouple upstream from the cell.

In both the loop and laboratory experiments polarization curves were obtained by proceeding stepwise from the open-circuit potential in an anodic direction. However, reversing the polarization sequence retraced the same curve.

Experimental Results

A typical polarization curve for copper in deaerated 1.24M NaCl at 30°C is shown in Fig. 3. The anodic process consists of the oxidation of copper and has a Tafel slope of 60 mV/decade which corresponds to 2.3 *RT/F*. In this particular case the cathodic curve represents primarily the reduction of water to hydrogen, but at low current densities some reduction process which appeared to be diffusion limited can be detected. A future communication will discuss the cathodic behavior of copper in chloride solutions.

Anodic polarization curves obtained with zone-refined copper at different temperatures are shown in Fig. 4. All of these were obtained in 1.24M NaCl using glass equipment under conditions of constant stirring and moderate sparging with H_2 gas. In this figure

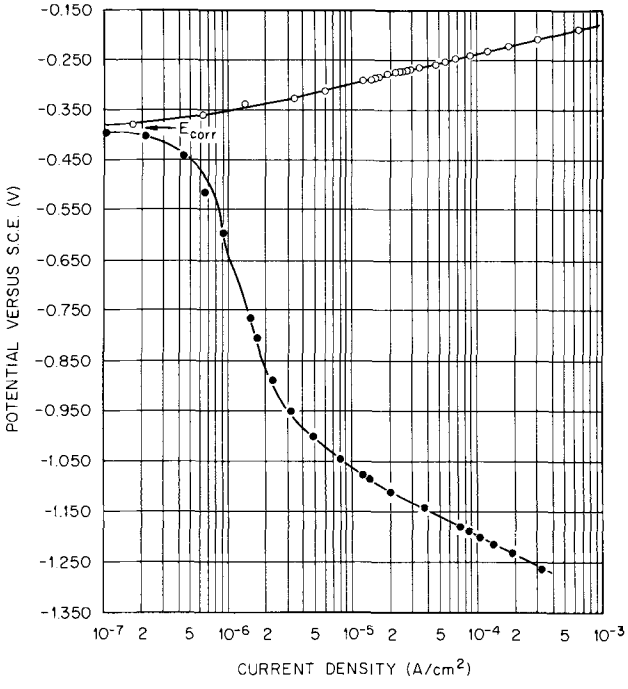

Fig. 3. Electrochemical polarization of copper in deaerated 1.24M NaCl at 30°C, pH = 5.4.

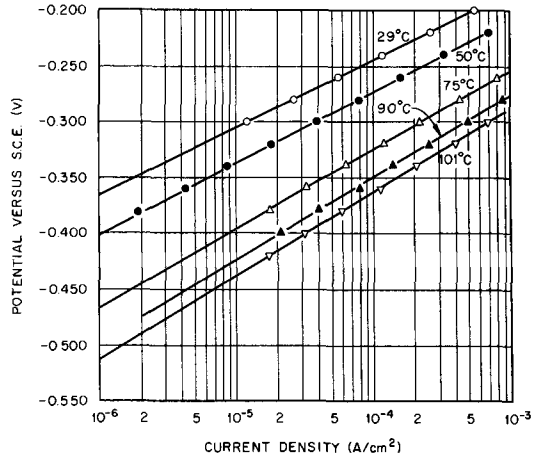

Fig. 4. Anodic polarization of copper in deaerated 1.24M NaCl at different temperatures.

only experimental data in the Tafel region are shown. Polarizations near the corrosion potential were difficult to interpret because contributions from unknown cathodic processes were included. For this reason corrosion potentials at a given temperature were not always reproducible. On the other hand, under constant conditions the polarization curves in the Tafel region were very reproducible and the slopes were equal to 2.3 *RT/F*.

Figure 5 shows anodic polarization curves obtained in 1.24M HCl (*p*H = 0.04) at 29° and 101°C. The dashed lines are those obtained in 1.24M NaCl (from Fig. 4). At 29°C the curve at *p*H = 6.4 is displaced about 13 mV in the anodic direction from the curve at *p*H = 0.04. At a fixed potential an increased dissolution rate in the acid solution might be inferred from these results, but the increase is only apparent and represents the difference in liquid junction potentials ($E_{j2} - E_{j1}$) where E_{j1} is the 1.24M NaCl || sat. KCl junction and E_{j2} is the 1.24M HCl || sat. KCl junction, both at 29°. Using the Henderson equation (10) these junction potentials were estimated to be about 14 mV for E_{j2} and about 1 mV for E_{j1} which accounts for the observed difference between the two curves and shows that the anodic dissolution process is independent of *p*H.

At 101°C the curve obtained at a *p*H of 6.4 is displaced anodically about 28 mV from the one at a *p*H 0.04. At the higher temperature thermal as well as liquid junction potentials existed in both cases. In all experiments described in this report the reference electrode (SCE) was located in a separate vessel at 29°C and was connected to the cell by a salt bridge filled with the particular test solution, so that the temperature of the liquid junction was always constant regardless of the cell temperature. Assuming the anodic dissolution rate to be independent of *p*H at 101°C as it was at 29°C, the difference between the thermal potentials for 1.24M NaCl and 1.24M HCl, both with a thermal gradient of 72°C, is approximately 15 mV. The data presented by Ikeda *et al.* (11) show that thermal potentials are much greater for HCl than for NaCl and most of the 15 mV difference must be due to the thermal potential developed in the 1.24M HCl bridge. Other polarization curves (not shown) were obtained in 1.24M Cl^- at *p*H = 2.8. In these cases the curves were usually within a few millivolts of those obtained in 1.24M NaCl (*p*H = 6.4) under the same conditions indicating that both liquid and thermal junction potentials were less significant than in the 1.24M HCl and within the range of experimental error. Thus in the treatment of the data both junction potentials were ignored except in the 1.24M HCl solution.

Figure 6 shows anodic polarization curves obtained over a greater temperature range in the pump loop. The electrolyte was 1.0M NaCl at a *p*H of 6.3 and the solution flowed past the specimen at either 122 or 244 cm/sec. The procedure consisted of obtaining the

curve at the lowest temperature and the lower flow rate, then disconnecting the cell and increasing the flow rate. After the electrode reached a steady-state open-circuit potential, the curve at the higher flow rate was obtained. The temperature was then raised to the next higher level and the procedure was repeated. Thus all of the curves shown in Fig. 6 were obtained with the same electrode without removing it from the loop. At the highest temperature it was not possible to control the temperature at 8 ft/sec in the existing experimental equipment.

Another specimen was run under conditions identical to the previous run except that the only curve obtained at 244 cm/sec was at 75°C. The agreement between the two specimens was excellent as illustrated in Table I, where the coefficients of the equations for the anodic Tafel lines are shown for both specimens. These values were obtained from least squares analyses of the data points in the Tafel region. At the 95% confidence level all Tafel slopes (A in Table I) were within ± 2% of the reported values. It is evident from the table that the slopes of the Tafel lines are very close to 2.3 RT/F (0.059, 0.069, 0.079, 0.084, and 0.089 V/decade at 25°, 75°, 125°, 150°, and 175°C, respectively).

Although the slopes of the lines at the same temperature were nearly the same at 122 and 244 cm/sec (turbulent flow in both cases), there were slight differences. Hence a determination of the increase in current on going from 122 to 244 cm/sec depends slightly on the potential. At an arbitrarily chosen potential of −0.400V *vs.* SCE the ratios of current at 244 cm/sec to that at 122 cm/sec are 1.5, 1.7, 1.5, and 1.8 at 25°, 75°, 125°, and 150°C, respectively (Fig. 6), and 1.9 for the duplicate specimen at 75°C. The average of these values is 1.7. Since in turbulent flow the Reynolds number (Re) is directly proportional to velocity at a given temperature, the current increased as $Re^{0.8}$.

Other experiments in the loop showed that the reproducibility of the data with regard to the relative positions of the anodic polarization curves at different temperatures was very good, but the absolute values from specimen to specimen varied by as much as 10 to 15 mV. As the data in Fig. 6 clearly indicate the anodic process is diffusion controlled, and slight variations in mounting the specimen in the loop with resultant variation in fluid turbulence probably accounted for the slight differences observed in the curves for different specimens.

The effect of chloride ion concentration on the anodic dissolution current density of copper is shown in Fig. 7. The temperature was either 30° or 101°C, the electrolyte was neutral, deaerated sodium chloride at concentrations of 0.124, 0.372, and 1.24M, and the electrode potential was −0.250V *vs.* SCE. These data were obtained in glass equipment under constant stirring conditions. The slope of the line through the data points, $d \log i/d \log (Cl^-)$, is 2.0 indicating that copper dissolves as the $CuCl_2^-$ ion.

The value of the standard redox potential for the half reaction

$$Cu + 2Cl^- = CuCl_2^- + e$$

is −0.050V *vs.* SCE at 25°C (12), but its temperature coefficient was not available. Similarly activities of the ions involved are not known. In order to determine the temperature coefficient the following experiment was performed at 30° and 101°C. A copper electrode was anodically polarized at a low constant current in deaerated 1.24M NaCl for various lengths of time, and after each interval the open-circuit potential of the copper electrode was measured. From the coulombs of current passed and the volume of solution the con-

centration of $CuCl_2^-$ was calculated. Using the Nernst equation, apparent E^0 values were calculated using concentrations instead of activities. Table II shows the results obtained at both temperatures.

Reasonably constant values of E^0 were obtained, averaging −0.040V *vs.* SCE at 30°C and −0.071V at 101°C. Assuming that the ratio of activity coefficients of $CuCl_2^-$ and Cl^- does not change significantly with temperature, $dE^0/dT = -0.4$ mV/deg; this value was used in all subsequent calculations.

Discussion

Our results, as well as those of other investigators, show that the anodic dissolution of copper in chloride solutions is diffusion rather than activation controlled. The reactions of importance are

$$Cu + 2Cl^- = (CuCl_2^-)_i + e^- \quad [1]$$

and

$$(CuCl_2^-)_i \xrightarrow{\text{rds}} (CuCl_2^-)_s \quad [2]$$

where the subscripts i and s refer to concentrations at the copper-solution interface and bulk solution, respectively. The rate determining step [2] is the diffusion transport of $CuCl_2^-$ from the interface to the bulk solution. The first step [1], the oxidation of Cu to $CuCl_2^-$ is assumed to be in equilibrium for which the Nernst equation

$$E = E^0 + \frac{RT}{\mathbf{F}} \ln \frac{(CuCl_2^-)_i}{(Cl^-)^2} \quad [3]$$

is applicable and from which $(CuCl_2^-)_i$ is obtained

$$(CuCl_2^-)_i = (Cl^-)^2 \exp \frac{\mathbf{F}(E - E^0)}{RT} \quad [4]$$

Substituting $(CuCl_2^-)_i$ into the rate-determining diffusion transport equation (Fick's first law)

$$i = \frac{z\mathbf{F}D\,(CuCl_2^-)_i}{\delta} \quad [5]$$

leads to the rate expression

$$i = \frac{z\mathbf{F}D}{\delta} (Cl^-)^2 \exp \frac{\mathbf{F}(E - E^0)}{RT} \quad [6]$$

In Eq. [6] z, the charge on the species undergoing mass transport $(CuCl_2^-)$, is 1; D is the diffusion coefficient for $CuCl_2^-$ (cm^2/sec); δ is the diffusion layer thickness (cm), and the concentration of $(CuCl_2^-)_i$ is much greater than $(CuCl_2^-)_s$ and is expressed in moles/cm^3. Since the diffusion coefficient is temperature dependent

$$D = D_0 \exp \frac{-\Delta H_D^*}{RT} \quad [7]$$

Equation [6] can be rewritten to include the apparent activation energy for diffusion transport, ΔH_D^*

$$i = \frac{z\mathbf{F}D_0}{\delta} (Cl^-)^2 \exp \frac{-\Delta H_D^*}{RT} \exp \frac{\mathbf{F}(E - E^0)}{RT} \quad [8]$$

In the above expression, E^0, the standard redox potential for Eq. [1] is temperature dependent. Defining overvoltage, η, as $E - E^0$ and expressing Eq. [8] in logarithmic form yields

$$\log i = \log \frac{z\mathbf{F}D_0}{\delta} + 2 \log (Cl^-) - \frac{\Delta H_D^*}{2.3\,RT} + \frac{\mathbf{F}\eta}{2.3\,RT} \quad [9]$$

From this equation the functional dependence of the current ($\log i$) on overvoltage, chloride ion concentration, and temperature is obtained

$$\left(\frac{\partial \log i}{\partial \eta}\right)_{T,Cl^-} = \frac{\mathbf{F}}{2.3\,RT} \quad [10]$$

$$\left(\frac{\partial \log i}{\partial \log (Cl^-)}\right)_{T,\eta} = 2.0 \quad [11]$$

$$-2.3R \left[\frac{\partial \log i}{\partial \frac{1}{T}}\right]_{Cl^-,\eta} = \Delta H^* = \Delta H_D^* - \mathbf{F}\eta \quad [12]$$

The validity of Eq. [10], the inverse Tafel slope, is shown by the data in Fig. 4-6 and Table I up to 175°C. Lal and Thirsk (1) showed a similar result up to 60°C, and Hurlen's data (2) at 25°C were consistent with this relationship. The validity of Eq. [11] is demonstrated by Fig. 7 which agrees with the results of Hurlen (2). Although Lal and Thirsk (1) also investigated the dependence of the anodic process on chloride ion concentration, their concern was with the effect of chloride concentration on the deposition of CuCl on the electrode surface.

Equation [12] relates the temperature dependence of the anodic process to the apparent activation energy of diffusion transport and the electrical work, $\mathbf{F}\eta$. Inherent in Eq. [12] is the assumption that the diffusion layer thickness, δ, is independent of temperature. In the case of the laboratory studies no estimate of the effect of temperature on δ could be made, and δ was assumed to be constant. In the case of the loop experiments the hydrodynamic conditions were better defined and the effect of temperature on δ could be approximated. At either 122 or 244 cm/sec the solution was highly turbulent and for such conditions it has been shown (13) that

$$\delta \propto Re^{-0.9}\,Pr^{-1/3} \quad [13]$$

where Re is the Reynolds number (the product of the diameter of the flow channel and the velocity divided by the kinematic viscosity) and Pr is the Prandtl number (the kinematic viscosity divided by the diffusion coefficient of $CuCl_2^-$ in this case). The average of our data indicated that the current density depended on the 0.8 power of Re which is in reasonable agreement with Eq. [13] since the current density is inversely proportional to δ. The values of all the terms involved in Eq. [13] are known (14) as a function of temperature except the diffusion coefficient for $CuCl_2^-$. Table III shows the values of the Reynolds and Prandtl numbers under the test conditions at 122 cm/sec, and the value of $Re^{-0.9}\,Pr^{-1/3}$ assuming the diffusion coefficient of $CuCl_2^-$ is 10^{-5} cm^2/sec at 25°C and at assumed activation energies of 3.5, 4.5, and 5.5

Table III. Values of Reynolds and Prandtl numbers and the product $(Re^{-0.9}\,Pr^{-1/3})$ using an assumed value of 10^{-5} cm^2/sec for the diffusion coefficient of $CuCl_2^-$ at 25°C and activation energies of 3.5, 4.5, and 5.5 kcal/mole

Temp, °C	Reynolds No.* × 10^{-4}	Prandtl No. × 10^3	$(Re^{-0.9}\,Pr^{-1/3} \times 10^5)$* 3.5 kcal	4.5 kcal	5.5 kcal

* At a velocity of 122 cm/sec.

kcal/mole. Under these conditions δ is not very sensitive to temperature at all of the assumed activation energies but the minimum spread over the temperature range is at an activation energy of 4.5 kcal/mole. Based on the above analysis δ was considered independent of temperature in the treatment of the data obtained from the loop.

Figure 8 is a plot of the log of the dissolution rate (A/cm^2) *vs.* the reciprocal temperature (°K^{-1}) for the data presented in Table I. The upper three curves were obtained at a constant η of −0.450V whereas the lower three were obtained at $\eta = 0$. E^0 is −0.050V *vs.* SCE at 25°C and dE^0/dT, was assumed to be −0.4 mV/deg over the entire temperature range. The current densities were determined from the equations for the Tafel lines, $E = \eta + E^0 = A \log i + B$ with the values of A and B taken from Table I. From the least squares slopes of the upper three curves apparent activation energies of 14.6, 15.4, and 15.0 kcal/mole were calculated for two experiments at 122 cm/sec and the one at 244 cm/sec, respectively. The agreement among these three sets of data is excellent.

It is obvious from Eq. [12] that the above activation energies are composed of the electrical work, $\mathbf{F}\eta$, and the activation energy for diffusion transport of $CuCl_2^-$. The electrical work at $\eta = -0.450$V is equivalent to −10.4 kcal/mole (23.05 kcal/mole·volt × −0.450 volt) which when subtracted from the above values results in apparent activation energies of 4.2, 5.0, and 4.6 kcal/mole for the diffusion process. The same result should be obtained from similar plots at $\eta = 0$, that is at the standard redox potential. The lower three curves shown in Fig. 8 were obtained in this manner, and from the slopes obtained by least squares analyses apparent activation energies of 6.2, 5.1, and 7.0 kcal/mole were obtained. These latter values are subject to greater error than the former values because of the larger extrapolations of the polarization curves. This is reflected in the relatively large scatter of the data points around the lower three curves in Fig. 8.

Figure 9 shows similar plots of the data obtained from the laboratory studies at pH values of 0.04, 2.8, and 6.4 (Fig. 4 and 5). The current densities were determined at $\eta = -0.450$V and $\eta = 0$ in the same way as for the loop data, and δ was assumed to be independent of temperature. At a pH of 0.04 only two temperatures were studied, 30° and 101°C. At 101°C a correction of 15 mV was made because of the thermal potential as previously discussed, and at both temperatures a liquid junction potential correction of 13 mV was applied. A single line is drawn through all the points at each overvoltage. The slope of the top curve ($\eta = -0.450$V) corresponds to an activation energy of 14.7 kcal/mole; subtracting 10.4 kcal/mole ($\mathbf{F}\eta$) results in an activation energy of 4.3 kcal/mole for the diffusion transport of $CuCl_2^-$. The apparent activation energy obtained from the slope of the lower curve ($\eta = 0$) is 4.3 kcal/mole.

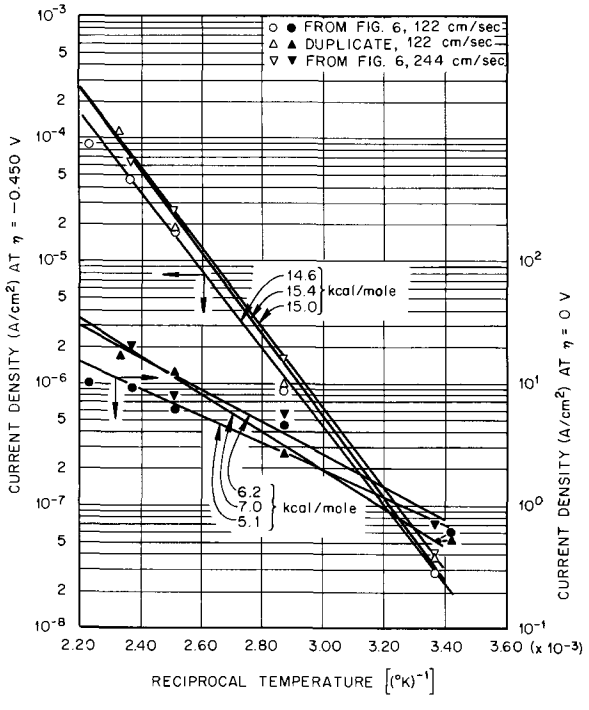

Fig. 8. Arrhenius-type plot showing the temperature dependence of current density at $\eta = -0.450$V and 0V based on data obtained from loop experiments.

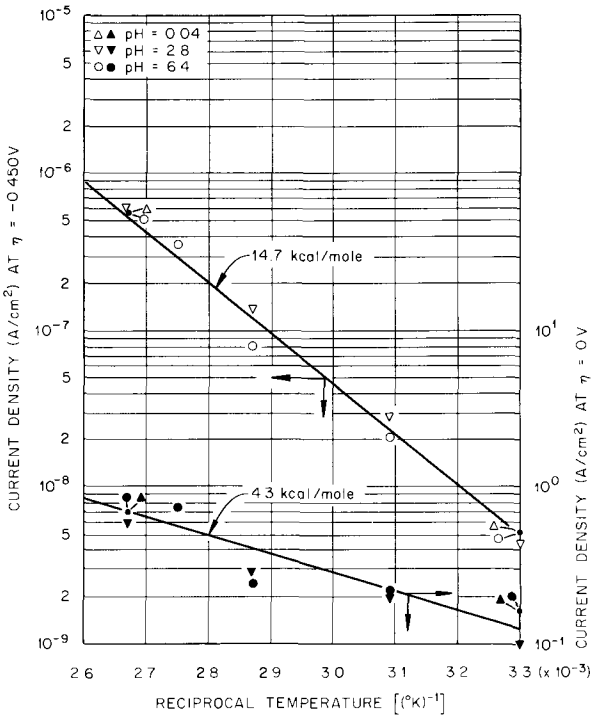

Fig. 9. Arrhenius-type plots showing the temperature dependence of current density at $\eta = -0.450$V and 0V based on data obtained under laboratory conditions.

Figures 8 and 9 show the consistency of the data from the loop and laboratory experiments. At $\eta = -0.450$V the average apparent activation energy for the anodic dissolution of copper (both loop and laboratory data) was 14.9 kcal/mole. Subtracting the electrical work results in an apparent activation energy for diffusion transport of $CuCl_2^-$ of 4.5 kcal/mole which is a reasonable value; a higher average value of 5.7 kcal/mole was obtained at $\eta = 0$, but this value is less reliable because of the large extrapolations involved. Considering the assumptions made, such as the absence of junction potential (except as noted), the constancy of the temperature coefficient of E^0 and the temperature independence of δ, and considering the standard errors inherent in obtaining polarization data, the agreement between the results and the proposed kinetic expressions is excellent.

Although the mechanism postulated above indicates $CuCl_2^-$ as the primary corrosion product, unreported data obtained by us have shown that thin films of Cu_2O developed on copper specimens exposed to flowing deaerated neutral sodium chloride solutions at 100°C and above. A similar observation has been reported in static tests (4). In view of the mechanism postulated the reason for the presence of Cu_2O on the freely corroding copper may be explained as follows.

The standard potential for the reaction

$$Cu_2O + H_2O + 2e = 2Cu + 2\,OH^-$$

is −0.602V *vs.* SCE at 25°C and the temperature coefficient is −0.445 mV/deg (15). Thus at 100°C in

neutral solution the potential of formation of Cu_2O is -0.117V *vs.* SCE. In deaerated sodium chloride solution the corrosion potential is well below this value. Therefore Cu_2O could not be a primary corrosion product under these conditions.

A possible explanation for the presence of Cu_2O is hydrolysis of $CuCl_2^-$ within the diffusion layer. The equilibrium constant for the reaction

$$CuCl_2^- = Cu^+ + 2Cl^-$$

is 2.8×10^{-6} at 25°C (7), and the solubility product of Cu_2O is 1.25×10^{-15} at the same temperature (6). Using Fick's first law (Eq. [5]) and assuming a corrosion rate of 10 miles per year (mpy) it can be shown that Cu_2O should begin to precipitate at a *p*H of about 9.2 in 1M NaCl. In the above calculation δ and D for $CuCl_2^-$ were assumed to be 3×10^{-3} cm and 10^{-5} cm^2/sec, respectively. No evidence of Cu_2O was observed in the polarization experiments at current densities considerably greater than that corresponding to 10 mpy, but this observation was made on an electrode on which the cathodic processes were suppressed. On a freely corroding copper surface both anodic and cathodic processes occur and both $CuCl_2^-$ and OH^- are produced at equivalent concentrations. Using the same assumptions as above and $D_{OH^-} = 5 \times 10^{-5}$ cm^2/sec, it can be shown that at a corrosion rate of 20 mpy the product of Cu^+ and OH^- at the specimen-solution interface would be approximately equal to the solubility product of Cu_2O. Thus even at 25°C the appearance of Cu_2O on corrosion specimens could occur if the corrosion rate is as high as 20 mpy. If either the dissociation constant for $CuCl_2^-$ becomes larger or the solubility product of Cu_2O becomes smaller as the temperature increases, Cu_2O could appear at correspondingly lower corrosion rates. Unfortunately values of both constants are not known at temperatures other than 25°C.

Summary

The anodic dissolution of copper in 1M chloride solution proceeded by the formation of $CuCl_2^-$ at temperatures as high as 175°C, the highest temperature investigated. Anodic polarization curves demonstrated Tafel behavior with slopes equal to 2.3 RT/F. The anodic process was under diffusion rather than activation control, and at chloride concentrations between 0.124 and 1.24M depended on the square of the chloride ion concentration. Within the range of current densities investigated the process was independent of *p*H. At a fixed anodic potential in the Tafel region with other conditions constant, the dissolution rate (current density) increased as about the 0.8 power of the Reynolds number. Using Fick's first law and the Nernst equation a simple kinetic expression was derived which was in agreement with experimental results.

Acknowledgment

The authors would like to acknowledge J. F. Winesette and A. L. Sutton for help in conducting the experiments and to Dr. R. E. Meyer for useful discussion concerning interpretation of the data. This work was sponsored by the Office of Saline Water, United States Department of the Interior and the Atomic Energy Commission under contract with Union Carbide Corporation.

Manuscript received July 14, 1972; revised manuscript received Nov. 8, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

ABSTRACT

Anodic polarization measurements in 1*N* H_2SO_4 and in 1*N* H_2SO_4-0.1*N* NaCl were made on an 11 Cr-12 Ni martensitic stainless steel in the as-rolled, as-quenched, and quenched and tempered conditions. Structural changes on tempering between 100° and 600°C were evaluated by hardness measurements, light metallography, and transmission electron microscopy. The basic shape of the anodic polarization curves was not significantly affected by cold work (75% reduction) or by the carbide precipitation, recovery and recrystallization which occurred on tempering. The critical potential for pitting was unaffected by tempering and chloride addition. The primary passivation potential became more active on tempering above 300°C for 1 hr. A 600°C temper, accompanied by significant recrystallization, resulted in severe transpassive region pitting when the steel was polarized in the presence of Cl^-.

The anodic polarization behavior of austenitic stainless steels has been extensively evaluated by anodic polarization techniques (1-6). The anodic polarization behavior of tempered martensitic stainless steels, on the other hand, has received little attention, although some studies have been made to correlate microstructure and corrosion in quenched and tempered plain carbon steels (7) and quenched and tempered stainless (30% Cr) irons (8). For these two types of alloys, the corrosion rates passed through a maximum as tempering temperature increased, presumably as a result of the development of a critical dispersion of carbide particles.

This paper presents an evaluation of the effects of heat-treatment on the structure and anodic polarization behavior of a low-carbon martensitic stainless steel. Emphasis was placed on the evaluation of the microstructure and fine-structure changes produced by systematically tempering an as-quenched lath martensite to higher temperatures. The structural changes were then correlated with the anodic polarization behavior.

Experimental

The chemical analysis of the vacuum induction-melted martensitic stainless steel used in this investigation is given in Table I. Final heat-treatment was accomplished by annealing a 0.1-in. thick strip at 982°C for 10 min in an air atmosphere and by subsequent air cooling. After annealing, approximately 0.008 in. was removed from each surface by grinding. The strip was then pickled and cold rolled to 0.020 in., a nominal reduction of 75%. All samples were prepared by annealing at 1037°C for ½ hr in an argon atmosphere and then water quenching. Tempering treatments were performed in an argon atmosphere for 1 hr at the specified temperature.

Samples for light microscopy were heat-treated and then mounted in epoxy. The samples were mechanically polished through a 0.3 μm alumina slurry and etched in a solution of 5g $FeCl_3$, 50 ml conc HCl, and 10 ml water to reveal the general microstructure. Electrolytic etching in a 10% oxalic acid solution was used to reveal carbide precipitation. Current densities of approximately 1 A/cm² provided good etching characteristics.

Table I. Composition of the 11 Cr-12 Ni steel in per cent

C	Mn	P	S	Si	Cr	Ni	N
0.015	0.005	0.008	0.002	0.005	11.40	12.28	0.007

Samples for electron microscopy were prethinned electrolytically to about 80 μm in a 20:1 solution of acetic-perchloric acids. The thin foils were prepared by the Bollman technique (9) in a chromic-acetic acid solution. The resultant foils were mounted in copper grids and stored in ethyl alcohol prior to examination in an electron microscope operating at 100 kV.

The diamond pyramid hardness readings were taken on the metallographic samples with a Vickers microhardness machine at an applied load of 300g.

The potentiodynamic polarization experiments were performed using standard equipment and techniques. The potential of the anode was linearly varied by a potentiostat and a motor-driven potentiometer. The potential of the anode was measured against a saturated calomel electrode (SCE) with an electrometer. The current flowing through the cell was measured as a voltage drop across a 100-ohm resistor by a logarithmic converter (dynamic range of 10^6:1). The outputs of the logarithmic converter and electrometer were recorded on an x-y recorder.

The polarization cell was similar to those used by others (10, 11). Two bright platinum sheets (each 29 cm²) served as counterelectrodes and were symmetrically positioned on each side of the sheet sample. The 2 cm² stainless steel samples were abraded through 600 paper, pickled in a 10% conc HCl-2% conc HF (by volume) solution at 60°C, and rinsed in distilled water. The sample was mechanically mounted such that the solution was only in contact with the sample material. Prior to the start of polarization, the solutions were deaerated by bubbling nitrogen gas. The commercial prepurified nitrogen was further purified by passing it through a hot (500°C) copper trap. After 3 hr, the sample was inserted in the electrolyte and bubbling was continued for 10 min. Subsequently, the nitrogen

was bypassed to the cell atmosphere and the potential sweep was initiated.

The solutions were prepared from distilled water and reagent grade H_2SO_4 and NaCl. Solutions of 1*N* H_2SO_4 and 1*N* H_2SO_4-0.1*N* NaCl were used for the polarization studies of each sample. The measurements were made in a constant temperature water bath at 25° ± 0.2°C.

Results

Effect of sweep rate.—The effect of sweep rate variation on the polarization curves was evaluated with samples tempered at 500°C. Results for samples immersed in a solution of 1*N* H_2SO_4-0.1*N* NaCl are shown in Fig. 1. The critical anodic current density, I_c, *i.e.*, the maximum current density attained prior to the start of the formation of a passive film, increased with faster sweep rates. The primary passivation potential, E_{pp}, defined as the potential at the critical anodic current density, was slightly more noble at higher sweep rates. The critical potential, V_c, defined as the potential above which the passive film begins to break down, was more pronounced and distinguishable at lower sweep rates. The transpassive region, where dissolution rate increases with increasing potential, has been attributed to a breakdown of the passive film at very positive potentials. In view of these and other results (12), the 10 mV/min sweep rate was used for all subsequent polarization studies.

Microstructure.—The microstructure of the 11 Cr-12 Ni stainless steel after quenching from 1037°C consisted of lath-type martensitic units which formed parallel to one another in a limited number of orientations. Within the parent austenite grain structure (ASTM grain size of 5), regions consisting of parallel laths of martensite of different orientations formed and could be identified by their etching differences. The martensitic structure is clearly visible in the transmission electron micrograph shown in Fig. 2. The boundaries between the individual martensite plates are well defined and the contrast effects within the plates are due to the high dislocation densities associated with this type of martensite (13). No x-ray or electron diffraction evidence was found for retained austenite in the as-quenched samples.

Tempering treatments below 400°C produced no observable differences in the microstructures of samples etched with either $FeCl_3$-HCl or oxalic acid solutions. The first evidence of carbide precipitation at prior austenite grain boundaries was observed after tempering at 400°C. The former austenite grain boundaries serve as preferred nucleation sites for the precipitation of carbides and localized attack by oxalic acid occurred at these areas. Transmission electron

microscopy showed that two types of carbide distributions were present in the samples tempered at 500°C. Carbides were present at the lath boundaries of the martensite, and as parallel arrays in areas that no longer showed a typical lath structure. Examples of the latter type of carbide distribution are shown in Fig. 3. The strong contrast from the parallel features was the only microstructural evidence obtained for the presence of carbides. Figure 4 shows reduced dislocation densities and some areas where equiaxed

ferrite grains have replaced the laths of the as-quenched martensite after a 600°C temper. Partial recrystallization has obviously occurred.

Hardness measurements.—Tempering above 200°C produced an increase in the hardness of the alloy as shown in Fig. 5. At 300°C, large variations in the microhardness readings were observed, possibly because of the localized nature of the tempering processes discussed in the previous section. Some areas may have experienced carbide precipitation while other areas may have undergone appreciable recovery. As tempering was accelerated by higher temperatures, the structural changes became more uniformly distributed and the variation in the hardness readings decreased. The fact that the hardness increases to a maximum after tempering between 400° and 500°C strongly supports the structural evidence for carbide precipitation presented in the previous section. Recovery and recrystallization processes that lower the dislocation density and replace the fine laths of martensite with a coarser, equiaxed grain structure would tend to lower the hardness, not increase it. This is conclusive evidence that carbide precipitation occurred on tempering.

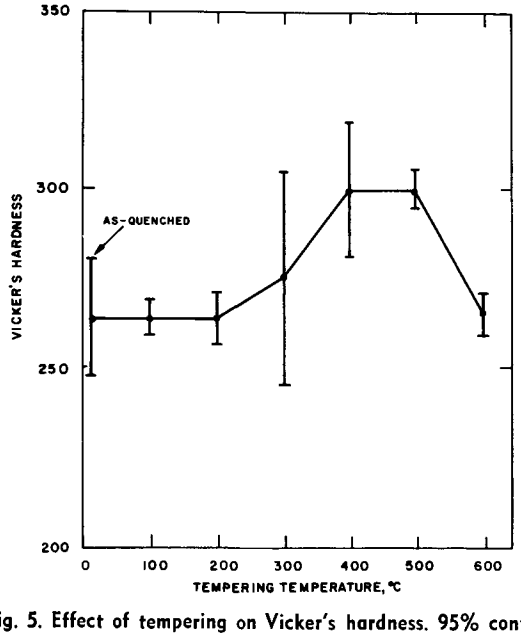

Fig. 5. Effect of tempering on Vicker's hardness. 95% confidence limits on measurements are shown. The as-rolled hardness was 342 ± 6.7.

Table II. Summary of anodic polarization results

Treatment	1N H_2SO_4		1N H_2SO_4-0.1N NaCl	
	I_c, mA/cm²	E_{pp}, V (SCE)	I_c, mA/cm²	E_{pp}, V (SCE)
As-rolled	3.0	−0.30	7.0	−0.26
As-quenched	2.5	−0.30	13.0	−0.28
100°C temper	3.2	−0.30	10.0	−0.26
300°C temper	2.2	−0.30	10.0	−0.28
500°C temper	2.3	−0.32	5.3	−0.26
600°C temper	20.0	−0.34	16.0	−0.30

Anodic polarization measurements.—The numerical data for the polarization studies conducted in 1N H_2SO_4 and 1N H_2SO_4-0.1N NaCl solutions are summarized in Table II. Data obtained from reproducibility experiments showed a limit of error of ±0.01V and ±0.1 mA/cm² for E_{pp} and I_c, respectively.

In the 1N H_2SO_4 solution, the polarization behavior of the as-rolled sample was not significantly different from that of the as-quenched sample. The polarization parameters were virtually identical for the as-quenched sample and the as-rolled sample. Figure 6 shows the polarization curves for the two extreme cases, *i.e.*, as-quenched and quenched and tempered at 600°C. From these two curves it is evident that tempering has no effect on the critical potential when polarization is conducted in 1N H_2SO_4; however, the other two parameters, I_c and E_{pp}, were definitely affected by tempering. It is evident from Fig. 6 and Table II that the primary passivation potential became slightly more active on tempering about 300°C. A significant increase in I_c was noted when the steel was tempered at 600°C where I_c increased almost tenfold.

In all samples, the addition of Cl^- influenced I_c, E_{pp}, and V_c to a greater extent than tempering did. Figures 7 and 8 show the effect of Cl^- additions on the polarization behavior of the as-quenched sample and the quenched and tempered (600°C) sample, respectively. It is obvious that chloride additions increased I_c in untempered samples or samples tempered at temperatures less than 500°C. Chloride additions also ennobled E_{pp}; however, the critical potential V_c was unaffected by chloride additions.

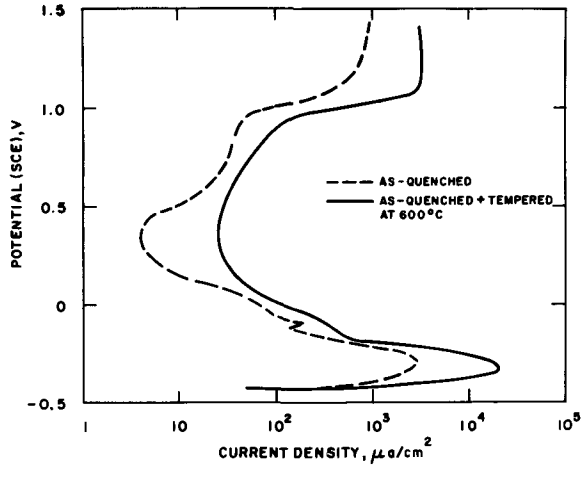

Fig. 6. Polarization curves of as-quenched and quenched and tempered (600°C) samples in 1N H_2SO_4.

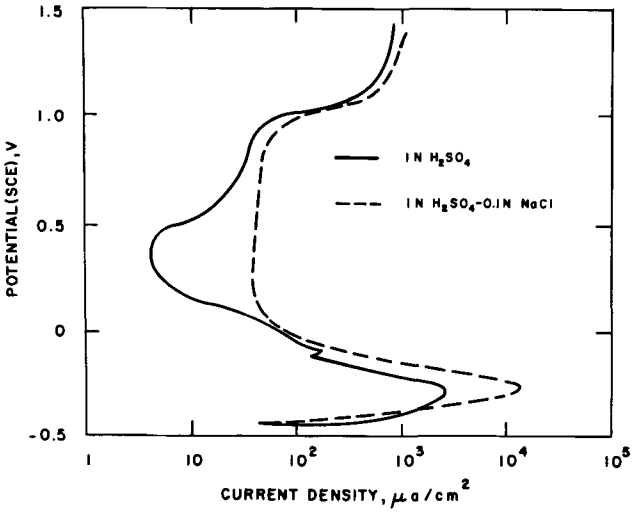

Fig. 7. Polarization curves of as-quenched samples in the presence and absence of Cl^-.

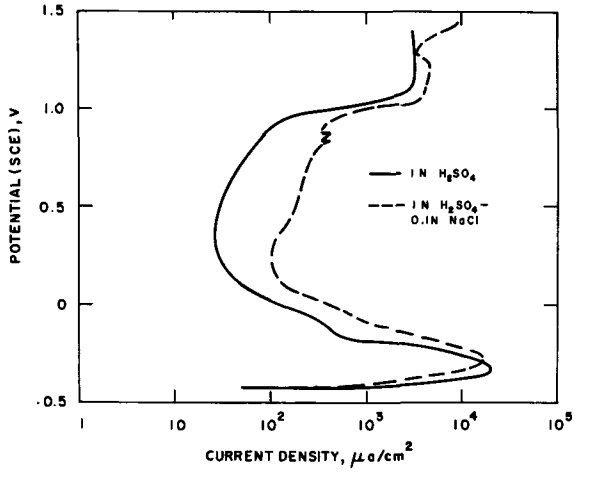

Fig. 8. Polarization curves of samples, tempered at 600°C, in the presence and absence of Cl^-.

Comparison of Fig. 7 and 8 shows that tempering to 600°C did not affect V_c, regardless of which solution was used. The behavior of I_c and E_{pp} (in the presence of Cl^-) was somewhat erratic at intermediate tempering temperatures. Nevertheless, the 600°C sample had the most active value of E_{pp}.

When the 600°C samples were polarized in the 1*N* H_2SO_4-0.1*N* NaCl solution, numerous pits formed in the transpassive region. The pits ranged in size up to 0.5 mm and were randomly distributed on the sample surface. Some pits also formed in the passive region at a potential of approximately 0.8V. Current fluctuations were associated with this pit formation. A repeat of this experiment with a different 600°C sample yielded similar results except that passive region pitting and its associated current fluctuation occurred at 0.4V as opposed to 0.8V mentioned above. The initiation of pitting during polarization in the passive region evidently involves a temporary and localized breakdown of passivity which is not reproducible from sample to sample. A small bridge of metal was observed to span one of pits which formed during polarization in the passive region. Apparently the pit was repassivated before the bridge had time to dissolve. The fact that this bridge remained after polarization suggests that the pit did not serve as a nucleus for future transpassive region pitting. Bond and Lizlovs (14) experienced the same phenomenon in their investigation and associated the repassivated pits with small regions of considerable composition differences from the bulk composition; that after these regions are removed the pits are too small to propagate at the potential in question.

Discussion

The aforementioned results obtained with an 11 Cr-12 Ni stainless steel show that a relationship exists between polarization behavior and microstructural changes caused by tempering. The observed net changes in E_{pp} and particularly I_c are indeed significant because of the excellent reproducibility of these parameters ($\pm$0.01V for E_{pp} and $\pm$0.1 mA/cm^2 for I_c). The parameters E_{pp} and I_c did not vary in a systematic fashion with tempering temperature in the presence of Cl^-. Since the general effect of tempering may have been obscured by the Cl^- addition, the polarization behavior of samples in 1*N* H_2SO_4 will be discussed first.

Some microstructural changes, especially carbide precipitation, were observed in the alloy on tempering above 300°C. Precipitates serve as cathodic sites and have been shown, in general, to enhance corrosion of carbon steel and austenitic stainless steels in aqueous media (1, 3, 15-18). It is reasonable to assume that this induced heterogeneity will cause specific changes in the polarization behavior since microstructural changes affect corrosion behavior and corrosion behavior can be correlated with anodic polarization behavior (1, 3, 4, 14, 19).

The microstructural results have shown that precipitation of carbides began to occur at and above a 300°C temper. The primary passivation potential, however, was not significantly affected until the metal was tempered above 400°C. This precipitation was followed by a change in E_{pp} in the active direction for samples tempered at 500°C. No other parameters exhibited a significant change until tempering was carried out at 600°C. Then the critical anodic current density increased almost tenfold. It was found that the only difference between the 500° and the 600°C samples was the extensive recrystallization occurring at 600°C. The heterogeneity created by recrystallization of varying degrees in adjacent areas may have been responsible for the observed increase in I_c. None of the tempered samples exhibited pitting or a change in the critical potential.

It is interesting to note that the polarization behavior of the as-rolled sample differed little from that of the as-quenched sample in 1*N* H_2SO_4. Perhaps this similarity in behavior is due to the high concentration of dislocations produced by both cold working and the martensite shear-type transformation. Further, Straumanis and Wang (20) have shown that cold working per se does not enhance the corrosion rate of aluminum.

According to Foroulis and Uhlig (18), cold working had little or no effect on the corrosion rate of zone-refined iron in HCl solutions. They concluded that galvanic cells are formed only when cold working causes the precipitation of a second phase, a change in the crystal orientation, or the segregation of impurities at imperfections. The energy imparted to the zone-refined iron by cold working was too small to account thermodynamically for the change in corrosion behavior. In view of these observations, it is not surprising that the polarization characteristics of the stainless steel used in this investigation were hardly affected by cold work because only a minimal amount of carbide precipitation or impurity segregation could have occurred during cold rolling of the sample.

The only pitting experienced in this study occurred on samples which were tempered at 600°C and polarized in the presence of chloride ions. This result suggests that either the recrystallization, which occurred, induced the pitting or a critical size and/or dispersion of carbide particles served as nucleation sites for transpassive and passive region pitting. However, the latter seems unlikely because no carbide particles were observed in the transmission electron micrographs taken of samples tempered at 600°C. The higher temperature

treatments probably resulted in the solution of carbide precipitates.

A Soft X-Ray Study of the Near Surface Composition of Cu30Zn Alloy during Simultaneous Dissolution of Its Components

J. E. Holliday[1] and H. W. Pickering*[,2]

Edgar C. Bain Laboratory for Fundamental Research,
United States Steel Corporation, Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

For certain conditions, alloys composed of metals of different nobility anodically dissolve without noticeable preferential dissolution of the less noble metal (simultaneous dissolution). In principle, an induction period of disproportionate dissolution of the less noble metal should precede simultaneous (nonselective) dissolution. In the present paper, the existence of the induction period is demonstrated by soft x-ray spectroscopy of the alloy surface. Results are presented for anodically polarized Cu-30 atomic per cent Zn in an acidic sulfate solution. Analyses of the Cu $L_{II,III}$, Zn $L_{II,III}$, and oxygen K band spectra of these specimens for several accelerating voltages (corresponding to different depths into the alloy ranging up from 10^2Å) show that the amount of elemental copper in the surface layer increases during an initial period of dissolution. It is concluded that Cu-enrichment of the surface is a necessary condition for simultaneous dissolution of the alloy. A model of simultaneous dissolution is presented which incorporates Cu-enrichment and a diffusion field in a shallow, alloy layer at the surface.

In prior investigations (1-4) it was found that when one component of an alloy undergoes quasi-stationary preferential dissolution in an electrolyte, *i.e.*, when parting of the alloy occurs, the surface and subsurface atom layers enrich in the more noble metal and the surface area greatly increases. Preferential dissolution is expected and is well known to occur in alloys in which the standard potentials, E°, of the components differ greatly (by many times RT/F). Yet for certain conditions simultaneous (nonselective) dissolution[3] of these alloys is the commonly observed stationary mode of dissolution.

In a recent study (5) of brass-acidic sulfate systems it was found that the stationary mode of dissolution (simultaneous or preferential) is mainly determined by the Zn content of the brass and the electrode potential. The boundaries are not sharp. Preferential dissolution more readily occurs at the less noble potentials and in the Zn-rich brasses, and the converse is true for simultaneous dissolution.

In principle, dissolution of brass by the simultaneous mode should be preceded by an induction period of preferential zinc dissolution in view of the difference in nobility of copper and zinc; simultaneous dissolution would then occur when a certain level of enrichment of copper is reached in the surface, and possibly subsurface, atomic layers.

Some data for α-brass [Cu-30 a/o (atomic per cent) Zn] in acidic sulfate solutions are available which support this view. It was found by chemical analysis of the electrolyte that during an induction period a disproportionate amount of Zn dissolves prior to the attainment of steady-state simultaneous dissolution; the "excess" copper on the surface amounts to $\lesssim 10^2$ atom layers (5, 6).

Further studies are needed of alloys undergoing simultaneous dissolution in order to determine the

Key words: alloy dissolution, corrosion, surface enrichment, partial currents.
[3] Simultaneous dissolution is defined as when all components of an alloy dissolve at rates proportional to their mole fraction in the alloy; *e.g.*, the rates of dissolution of Cu and Zn in mol cm^{-2} sec^{-1} from a single-phase Cu-30 a/o Zn alloy would be in the ratio of 7:3 for the formation of divalent Cu and Zn ions.

composition of the surface and the state (metallic or oxidized) and spatial distribution of the residual (more noble) component. In the present paper, a soft x-ray technique is described which enables (*a*) a determination of the composition of the surface region from the first several atom layers to a depth of several hundred atom layers of the alloy and (*b*) the identity and measurement of the relative amounts of oxides on the surface.

The effect of alloy composition and of oxide formation on the shape and wavelength of characteristic soft x-ray emission bands (electron transition from the valence band to vacancies in inner atomic core levels) from the elements, as well as the experimental techniques for measuring these bands, has recently been reviewed (7). When a metal or compound is bombarded with electrons of energy up to 3 kV, soft x-rays originating near the surface are emitted; the depth from which the x-rays come decreases with decreasing electron energy (decreasing accelerating voltage).

For copper and zinc, the L_{II} and L_{III} bands (4s + 3d → 2p transitions) occur in the soft x-ray region (Cu L_{III} at 13.3Å, Zn L_{III} at 12.2Å). The L_{II} band is a (4s + 3d → 2p $J_{1/2}$) transition and the L_{III} band is a (4s + 3d → 2p $J_{3/2}$) transition. The spectra, each consisting of both bands for copper and for zinc, are usually designated Cu $L_{II,III}$ and Zn $L_{II,III}$, respectively.

Since the copper and the zinc emission band intensities from Cu-Zn alloys are a function of alloy composition as shown by Curry and co-workers (8), a variation in composition as a function of distance from the surface of an alloy can be determined from the soft x-ray emission bands by varying the accelerating voltage. This is so since the x-rays come from closer to the surface as one reduces the accelerating voltage. This method differs from that of Curry and co-workers (8) in that their data were obtained at constant voltage in accord with the use of specimens of different bulk composition. In measuring a series of alloys, there will always be the possibility of various instrumental changes from one specimen to another. This can be overcome by comparing the ratio of the peak intensities of the components of binary alloy specimens, *e.g.*, the ratio of the peak intensities of the Cu L_{III} and Zn L_{III} bands of a Cu-Zn alloy.

If a thin oxide is present on the surface, some further change in the Cu L_{III}/Zn L_{III} ratio may occur as a result of a difference in the ratio of the components in the oxide from that in the alloy. The effect of oxide on the intensity ratio is usually easily distinguishable from an alloy composition effect for the following reasons: the structure of the emission band is different for the metallic and ionic states, and the L_{II}/L_{III} intensity ratios are much higher for metal in the oxidized than in the elemental form.

In the present experiments, the Cu L_{III}/Zn L_{III} ratio should increase over that of the undissolved sample if copper accumulates on the surface during dissolution. The Cu L_{III}/Zn L_{III} ratio should increase at a decreasing rate as a function of dissolution time, corresponding to a thickening of the Cu-rich layer at an ever slower rate in the approach to a steady-state thickness; the ratio eventually should level off at a high-value characteristic of the (average) composition of the layer at steady-state simultaneous dissolution; and at all times the ratio should be a decreasing function of the accelerating voltage.

Experimental Procedure

Data were obtained for α-brass containing 30 a/o Zn (Cu30Zn) provided by American Smelting and Refining Company. The alloy was homogenized at 873°K for 60 hr in an evacuated capsule, rolled to 0.015 cm and annealed in vacuum at 873°K for 20 hr. Rectangular specimens were cut with an area of ~7 cm^2, and the specimens were then given a final anneal in vacuum at 873°K.

Surface preparation of the specimens consisted of dry mechanical polishing. Wet polishing was avoided since it was found from the ratio of the Cu L_{III} and Zn L_{III} intensities that the surface was Cu-rich after normal mechanical polishing using aqueous suspensions of alumina; this is described further in the Results section. Specimens to be used in the controlled potential runs, therefore, were only given a dry polish consisting of 600 and 3/0 emery paper, and contact with all liquids prior to anodic dissolution was carefully avoided following the 873°K anneal.

The closed Pyrex cell contained a platinum counter-electrode and a mercury-mercurous sulfate reference electrode. The electrolyte, 1*N* Na_2SO_4-0.01*N* H_2SO_4 of pH 2, was made from reagent grade chemicals and doubly distilled water. Prepurified helium was continuously passed through the electrolyte to remove oxygen. All runs were at room temperature (297°K). All potentials are on the standard hydrogen scale.

The specimen was inserted in the cell at a set potential in the potential region of steady-state, simultaneous dissolution (0.20-0.30V) (5, 6). After dissolution at the control potential, it was withdrawn from the cell, rinsed in distilled water and in methanol, and air-dried. This procedure avoided any redeposition of copper during anodic dissolution. The potential range 0.20-0.27 corresponds approximately to the Tafel region for pure copper in acidic sulfate solution. The specimen was then stored in a desiccator prior to the soft x-ray analyses.

Some changes in composition of the uppermost surface layer are inevitable during drying, exposure to air, and exposure to low pressures in the soft x-ray apparatus. Waters of hydration, hydroxides, and oxides will be removed or undergo changes in structure. As a result, only changes in the amount of the more firmly bound oxygen will be measurable by the soft x-ray technique. It is also possible that between the time the specimen is removed from the cell and then washed, copper ions in the adhering solution may deposit if the open-circuit potential is less noble than the copper potential. This will provide an added increment of copper to the surface, the amount of which is independent of the time of dissolution and, therefore, distinguishable from copper enrichment which occurs during the constant potential dissolution experiment.

Enrichment of copper in the first 10^2 atom layers was examined by the change in ratio of the Cu L_{III} and Zn L_{III} x-ray intensities as a function of accelerating voltage of the incident electrons. The depth from which the emission spectra mainly come is about 100Å at 1.5 kV and increases to several hundred angstroms at the higher accelerating voltages, as roughly estimated from other experiments where metal layers of known thickness and density were examined (9, 10). The intensity distribution of the oxygen K (O K) and Cu $L_{II,III}$ and Zn $L_{II,III}$ band spectra of the anodically dissolved specimens showed with which alloying element the oxygen is bonded, and the intensity of the O K band shows changes in the amount of oxide as a function of dissolution time. The O K, Cu $L_{II,III}$, and Zn $L_{II,III}$ band spectra were measured using a blazed grating analyzer with 3600 grooves/mm in a spectrometer with a 50 cm radius of curvature and a flow proportional counter as detector (11). Undissolved α-brass, zinc, and copper specimens were used as standards. The main source of contamination is the residual vapors, such as hydrocarbons and CO, which may be cracked by the electron beam; some carbon, therefore, may accumulate on the specimen surface. Carbon contamination has been reduced by using ion pumping and a cold finger around the specimen (7). A monolayer or so of carbon on the specimen surface is not expected to affect significantly the metal emission bands, and any influence it may have on oxygen bonding at the specimen surface could be revealed in the oxygen K spectra.

Results

Metal emission spectra.—The single-phase Cu30Zn specimens were dissolved at $E = 0.24$V for times of 0.5, 3, 5, 15, and 60 min. Simultaneous dissolution for this alloy-electrolyte system at $E = 0.24$V is obtained in less than 1 hr and sometimes as early as 10 min, according to chemical analyses of the electrolyte (5). Prior to simultaneous dissolution a disproportionate fraction of Zn^{2+} ions enter the electrolyte; the concomitant copper build-up amounts to $\lesssim 10^2$ atom layers (5, 6). A steady-state current is obtained at or soon after the onset of simultaneous dissolution; both the copper and zinc currents are higher in the initial period (5, 6). The steady-state current at $E = 0.24$V in the present experiments was about 0.05 mA cm^{-2}.

Typical metal emission spectra are shown in Fig. 1. These copper and zinc spectra are from the undissolved (standard) Cu30Zn specimen. For the undissolved Cu30Zn specimens the Cu L_{III}/Zn L_{III} ratio is about 2.6 ($t = 0$ in Fig. 2) at all accelerating voltages, except at the lowest voltage of 1.5 kV for which the ratio is larger. Similarly the Cu L_{III}/Zn L_{III} ratio for the pure elements at $t = 0$ did not vary significantly except at 1.5 kV. One possible explanation for the larger Cu L_{III}/Zn L_{III} ratio at 1.5 kV is the closer proximity of the zinc excitation potential (1.023 kV) to the 1.5 kV accelerating voltage than is the copper excitation potential (0.922 kV).

After anodic dissolution at $E = 0.24$V (time > 0 in Fig. 2) higher Cu L_{III}/Zn L_{III} ratios are obtained. The greatest increase in the ratio as a function of time of dissolution occurs at the lowest voltage corresponding to the shallowest depth of x-ray emission, whereas a rather small change occurs at 4 kV. The ratio eventually levels off and then decreases slightly. The Cu L_{III}/Zn L_{III} ratio was determined at 2, 3, and 4 kV and found to be characteristic of the elemental, rather than oxidized, form of copper. The absolute intensities

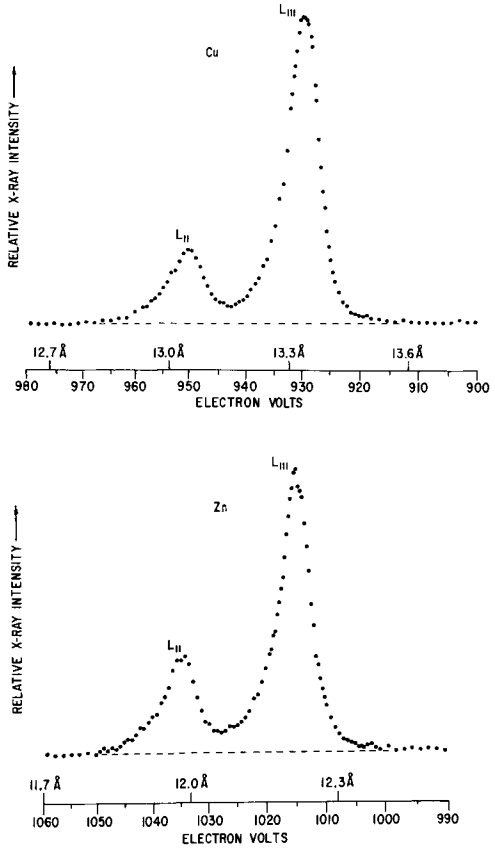

Fig. 1. Cu $L_{II,III}$ and Zn $L_{II,III}$ emission band spectra from an undissolved (standard) Cu30Zn specimen at an accelerating voltage of 4 kV.

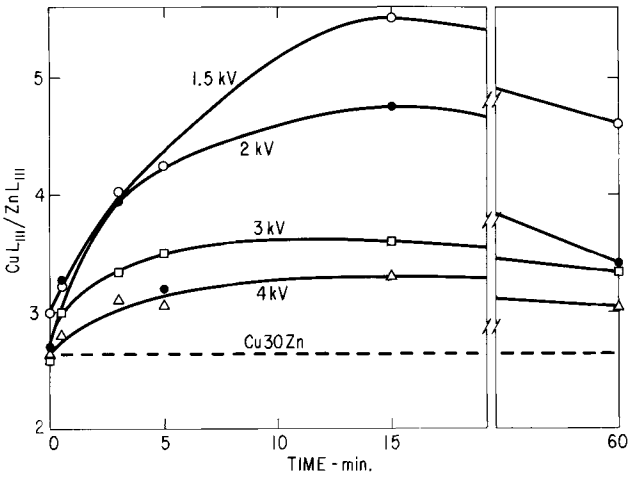

Fig. 2. Cu L_{III}/Zn L_{III} ratio as a function of dissolution time for different accelerating voltages.

of the Cu L_{III} and Zn L_{III} bands go through a maximum as a function of dissolution time; by 1 hr the intensity of the Cu L_{III} band is somewhat higher and that of the Zn L_{III} band somewhat lower than their respective initial values.

Another series of Cu30Zn specimens was dissolved at $E = 0.22$V for times of 5, 15, 40, 60, and 360 min. Simultaneous dissolution is attained after 10^2 min, at this potential according to chemical analysis of the electrolyte (5). The steady-state current at $E = 0.22$V is $\lesssim 5$ μA cm^{-2}. The Cu L_{III}/Zn L_{III} ratios were determined for these specimens at accelerating voltages of 1.5, 2, 3, 4, and 5 kV. A plot of these data is similar to that in Fig. 2. The ratios at the lower voltages were always higher after dissolution and tended to increase and go through maxima prior to leveling off at the longest times of 60 and 360 min.

The surfaces of the specimens polarized at $E = 0.22$ and 0.24V retain their bright, metallic luster. Scanning electron microscopy examinations of similarly polarized Cu30Zn specimens (6) show that a faceted (etched) structure, not unlike that observed for pure metals in the Tafel region (12, 13), develops, *i.e.*, the extent of surface roughening is relatively minor, being comparable to that of a heavily etched pure metal; this is in counterdistinction to the profuse surface roughening which occurs during quasi-stationary preferential dissolution (1-4), and which is expected in principle when diffusion in the alloy is rate controlling (14, 15).

Wet mechanical polishing also causes an increase in the Cu L_{III}/Zn L_{III} ratio of otherwise unreacted specimens. Comparison of the Cu L_{III}/Zn L_{III} ratios as a function of accelerating voltage for a Cu30Zn specimen given a wet (aqueous suspension of alumina) mechanical polish with those for another specimen which was prepared by the aforedescribed dry polishing technique showed that for the wet-polished specimen the copper content was significantly higher in the near-surface region. Comparison of these ratios with those obtained from pure zinc and copper samples showed that the surface of the dry-polished Cu30Zn specimen was characteristic of the bulk alloy composition.

Oxygen emission spectra.—The oxygen K emission band was obtained for the anodically dissolved Cu30Zn specimens described above and in addition for specimens dissolved at $E = 0.23$ and 0.30V (Fig. 3). At $E = 0.22$, 0.23, and 0.24V the O K band is the same as that from pure zinc oxide. The amount of oxide on the surfaces of these anodically dissolved α-brass specimens is small (estimated at a few monolayers), does not increase with dissolution time, and is actually less ($\lesssim 50\%$) than that present on the specimen prior to dissolution. At $E = 0.30$V films are observed to form

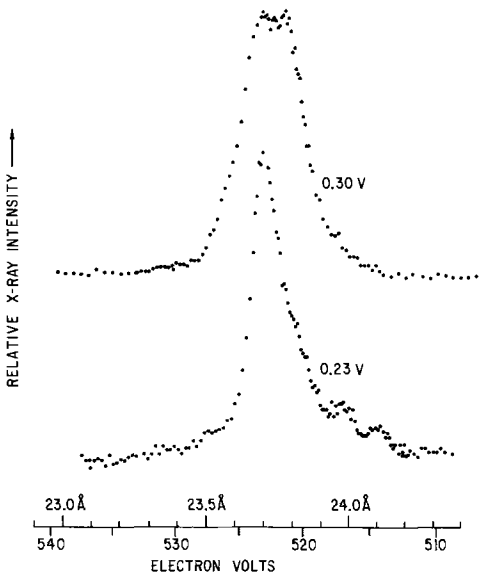

Fig. 3. Oxygen K band spectra for Cu30Zn specimens showing oxygen bonded (a) with zinc atoms after dissolution at $E = 0.23$V (3 kV accelerating voltage) and (b) with copper atoms for $E = 0.30$V (4 kV).

on the specimen during dissolution, in agreement with other studies (5). For these specimens the O K band was that of pure copper oxide, as shown in Fig. 3. This result shows that copper on the surface is converted to copper oxide only at relatively high dissolution potentials. The O K band intensity which indicates oxygen content was much greater on these specimens than on those polarized at the lower potentials.

Discussion

Soft x-ray results.—The Cu $L_{II,III}$, Zn $L_{II,III}$, and O K band spectra of the anodically polarized specimens are all consistent with a build-up during dissolution of the elemental copper content at the surface. This is most directly indicated by the increase after dissolution of the Cu L_{III}/Zn L_{III} ratio (Fig. 2). The O K band spectra and the L_{II}/L_{III} ratios rule out an oxide effect since the former shows that the oxygen content of the surface is less after dissolution at $E = 0.22$ and 0.24V, and the latter are characteristic of copper and zinc in their elemental forms. The slight decrease of the Cu L_{III}/Zn L_{III} ratio observed in the later dissolution periods at the lower accelerating voltages for both the $E = 0.22$ and the 0.24V runs (Fig. 2) is not an expected composition effect, and may be related to area change or to cold work introduced by the surface preparation.

The large increase of the Cu L_{III}/Zn L_{III} ratio during the early dissolution periods at the lower accelerating voltages (Fig. 2) indicates a rather sizable increase of the copper content in the surface region. The depth of the zone of copper enrichment is estimated to be of the order of 10^2Å. The distribution of copper in this zone is unknown. The soft x-ray data are consistent both with a zone where the composition *vs.* distance profile is the same along all normals to the surface, and with a zone involving patches of original alloy and pure copper.

Enrichment model of simultaneous dissolution.—A satisfactory model of simultaneous dissolution must take into account the induction period during which the surface enriches in the more noble metal, and the presence of this enriched layer during simultaneous dissolution. The salient points may be understood without calculations as follows. Let the alloy dissolve at a constant current density, as may be provided by a galvanostatic external circuit. At the start of dissolution of a brass of uniform composition, the rate of preferential zinc dissolution is highest; thereafter the rate decreases as the surface coverage by copper atoms increases.

Let us assume for the moment that interdiffusion of the components in a shallow region of alloy next to the surface does not occur. Then a simplified description of the alternatives is as follows:

(*a*) In the absence of surface diffusion, copper and zinc atoms at kinks alternatively enter the solution without any enrichment of the more noble component.

(*b*) When copper atoms at kinks do not enter the solution, Zn atoms may pass from the uppermost lattice plane into the solution so that this lattice plane attains finally a very loose structure. Furthermore, zinc atoms in the next lattice plane may pass into the solution and so forth. In parallel, sidewise motions of surface copper atoms may occur so that two dimensional patches of copper are formed. Before these patches grow together by supply of copper from underlying lattice planes and form a complete "blocking layer," however, simultaneous passage of zinc and copper atoms into the solution may occur.

Next, let us assume that interdiffusion of the components in a shallow region of alloy next to the surface can occur because of an increase in the vacancy concentration. As in the case of quasi-stationary preferential dissolution (1), vacancies may be formed by zinc dissolution from terrace sites in view of the high overpotential for zinc dissolution. In this event, zinc atoms migrate to the surface from subsurface positions (and copper atoms migrate into the alloy), Fig. 4. Briefly the diffusive flux of zinc to the surface controls the extent of preferential dissolution; this flux is, therefore, inversely proportional to the depth, δ, of the interdiffusion layer. However, since the surface recedes by dissolution of copper and zinc atoms, the interdiffusion depth and flux of zinc to the surface reach steady-state values (the onset of simultaneous dissolution); *i.e.*, the "front" of the interdiffusion layer moves into the alloy at a decreasing rate until this rate equals that at which the surface recedes. The velocity of the front does not decrease further since this would lead to a decrease in the diffusion distance, which would be countered by disproportionate zinc dissolution until the two velocities were again equal. The rates of diffusion and dissolution therefore determine the steady-state thickness of the interdiffusion layer and the time to reach steady-state simultaneous dissolution.

The electrode potential initially assumes a value sufficient for zinc dissolution but below that of cop-

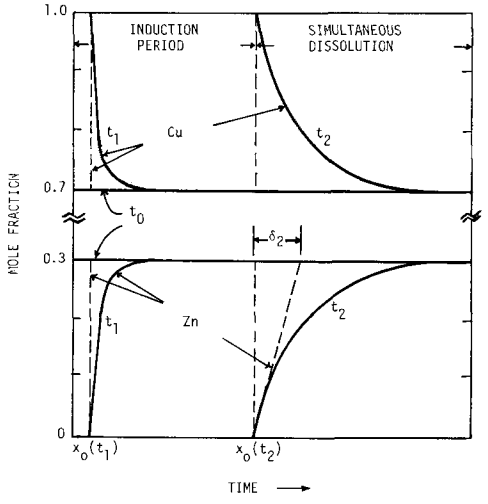

Fig. 4. Schematic illustration of the zinc and copper concentration profiles in the approach to and during simultaneous dissolution. The effective thickness, δ, of the depletion zone increases during the induction period and is constant thereafter (simultaneous dissolution).

per dissolution. However, as the flux of zinc to the surface decreases the potential assumes a more positive value so that anodic dissolution of copper, in addition to that of zinc, becomes thermodynamically possible. The overpotential of copper dissolution is relatively low. Thus copper dissolution is not retarded by some slow step once the electrode potential is only slightly more positive than the copper equilibrium value.

If the specimen is dissolved at a constant potential in the region of copper and zinc dissolution (as in experiments in this paper), instead of at constant current, the aforementioned description needs some modification as follows. At the start of dissolution copper, as well as zinc, dissolves. As in the case of constant current conditions, though, disproportionate zinc dissolution occurs initially because of the difference in nobility of copper and zinc, and decreases as the availability of zinc at the surface decreases until the ratio of Zn/Cu entering the solution becomes equal to the ratio of Zn/Cu in the bulk alloy (simultaneous dissolution).

One may calculate the zinc concentration profile next to the surface, the flux of zinc to the surface, and the depth of interdiffusion when the alloy/electrolyte interface moves at a steady rate in the following way according to Wagner (16). Assume a planar surface, although this is not quite true since faceting of the surface occurs during the induction period, and one-dimensional diffusion normal to the surface. Furthermore assume that the interdiffusion coefficient in the alloy is not extremely low. This latter assumption is realistic only in a shallow surface region, and then only if excess monovacancies and/or divacancies are present by virtue of their formation at the surface.

Let the alloy dissolve with a constant current density, i, in which case the alloy/electrolyte interface recedes at a steady rate. Thus for x equal to the distance from the original position of the interface and x_o equal to the instantaneous position of the interface, one has the following situation (16)

$t = 0$: electrolyte | alloy ($x = 0$)

$t > 0$: electrolyte | alloy ($x = x_o = ut$)

The position of the interface as a function of time is given by

$$x_o = ut = \frac{i}{2\mathbf{F}} V_m t \qquad [1]$$

in which V_m is the molar volume of the alloy and $\mathbf{F}$ is the Faraday constant. The factor 2 is valid for dissolution of copper and zinc as divalent cations.

Since copper is much more noble than zinc, the mole fraction of zinc, N_{Zn}, is assumed to virtually vanish at the surface, $x = x_o$

$$N_{Zn} = 0 \text{ at } x = x_o = ut \qquad [2]$$

For an interdiffusion coefficient independent of composition, D, Fick's second law reads

$$\frac{\partial N_{Zn}}{\partial t} = D \frac{\partial^2 N_{Zn}}{\partial x^2} \text{ at } x > x_o \text{ or } x > ut \qquad [3]$$

Assuming a uniform mole fraction of zinc at $t = 0$, one has

$$N_{Zn} = N_{Zn}^o \text{ at } t = 0,\ x > 0 \qquad [4]$$

Equations [2] through [4] are satisfied by

$$N_{Zn} = N_{Zn}^o \left\{ 1 - \tfrac{1}{2} \exp\left(-\frac{ux - u^2t}{D} \right) \cdot \operatorname{erfc}\left[\frac{x}{2(Dt)^{1/2}} - \frac{ut^{1/2}}{D^{1/2}} \right] - \tfrac{1}{2} \operatorname{erfc} \frac{x}{2(Dt)^{1/2}} \right\} \text{ at } x > ut \qquad [5a]$$

For $t >> Du^{-2}$, *i.e.*, $x_o >> Du^{-1}$, Eq. [5a] becomes

$$N_{Zn} \cong N^o_{Zn}\left[1 - \exp\left(-\frac{ux - u^2t}{D} \right) \right] = N^o_{Zn}\left[1 - \exp\left(-\frac{u(x - x_o)}{D} \right) \right] \text{ at } x > x_o = ut \qquad [5b]$$

According to Eq. [5b] a constant zinc concentration profile moves in the x direction as is illustrated in Fig. 4.

The amount of zinc dissolved per unit area at time t is

$$\frac{n_{Zn}}{A} = \frac{x_o N^o_{Zn}}{V_m} + \frac{1}{V_m} \int_{x_o}^{\infty} (N^o_{Zn} - N_{Zn})\, dx \qquad [6]$$

Substituting Eq. [5b] and [1] into Eq. [6] gives

$$\frac{n_{Zn}}{A} = \frac{ut\, N^o_{Zn}}{V_m} + \frac{N^o_{Zn}}{V_m} \int_{x_o}^{\infty} \exp\left(-\frac{u(x - x_o)}{D} \right) dx = \frac{ut\, N^o_{Zn}}{V_m} + \frac{N^o_{Zn}}{V_m} \cdot \frac{D}{u} \text{ if } x_o >> Du^{-1} \qquad [7]$$

The second term on the right side of Eq. [7] may be called "excess" zinc dissolved, $\Delta n_{Zn}/A$, due to diffusion of zinc to the electrolyte/alloy interface. Thus

$$\frac{\Delta n_{Zn}}{A} = \frac{N^o_{Zn}}{V_m} \cdot \frac{D}{u} \qquad [8]$$

Furthermore, one may define an effective thickness δ of the depletion zone in the alloy

$$\delta = \frac{N^o_{Zn}}{(\partial N_{Zn}/\partial x)_{x=x_o}} = \frac{D}{u} \qquad [9]$$

In the above reported experiments, $i = 5 \times 10^{-5}$ A cm^{-2} at $E = 0.24$V. Hence, for $V_m = 7.1$ cm^3 mol^{-1}, Eq. [1] yields $u = 1.8 \times 10^{-9}$ cm sec^{-1}.

If D is as low as 10^{-16} cm^2 sec^{-1} or even less, and surface roughening does not occur, Eq. [9] yields a value of δ which is of the order of, or less than, an atomic radius. For this condition, the foregoing calculation has no physical significance. One obtains a value of δ from Eq. [9] or $\Delta n_{Zn}/A$ from Eq. [8] which is relevant only if D is much greater than 10^{-16} cm^2 sec^{-1} possibly due to the presence of excess mono- or divacancies (1).

If surface roughening has taken place, the stationary rate of movement of local regions of the interface has to be calculated upon introduction of the true current density in Eq. [1]. Since for a rough surface the true current density is less than the apparent current density (calculated as the quotient of current and the geometrical surface area), lower values of u are obtained. Thus, lower values of D in Eq. [9] yield a value of δ which has physical significance.

Since the situation is complex, the above calculation of the amount of excess zinc dissolved via diffusion to the electrolyte/alloy interface has been presented only in order to show how one may understand qualitatively that zinc initially is dissolved preferentially, and that, thereafter, there is enrichment of copper in an alloy layer next to the surface when (simultaneous) dissolution continues under quasi-stationary conditions.

Conclusions

Soft x-ray data of the surface region of Cu30Zn alloy specimens show an induction period of disproportionate zinc dissolution prior to the attainment of steady-state simultaneous (nonselective) dissolution of the alloy. The Cu $L_{II,III}$, Zn $L_{II,III}$, and oxygen K band spectra indicate the presence of excess elemental copper in the surface region. These spectra show that the copper content and depth of Cu-enrichment increases in the initial period, and that the average

thickness of the layer at steady state is on the order of 10^{-6} cm. Since the polarization conditions are such that steady-state simultaneous dissolution is eventually obtained, it is deduced that a Cu-rich surface layer is a necessary condition for simultaneous dissolution of Cu30Zn. The oxygen K band spectra show that the amount of bound oxygen on the surface decreases during the first dissolution period and then holds constant during subsequent dissolution periods at $E = 0.24$V, and that this oxygen is bound to zinc ions.

These data show the utility of soft x-ray spectroscopy for the investigation of alloying effects which occur very near the surface.

The Cu $L_{II,III}$ and Zn $L_{II,III}$ band spectra show that the usual mechanical polishing methods involving aqueous suspensions of alumina leave the surface of Cu30Zn alloy enriched in copper. Dry mechanical polishing methods are, therefore, recommended for the attainment of a more nearly uniform composition between the bulk and surface.

A model of simultaneous dissolution is presented. It shows how zinc may initially be dissolved preferentially. Then, simultaneous dissolution occurs in the presence of a Cu-rich alloy surface layer.

Acknowledgments

We gratefully acknowledge the contributions of P. J. Byrne who prepared and anodically polarized the specimens, and of W. A. Hester who assisted with the soft x-ray investigations, and the helpful comments of Professor Carl Wagner of the Max-Planck-Institut für Biophysikalische Chemie.

Surface Characterization of Sensitized and Activated Teflon

N. Feldstein* and J. A. Weiner

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

A tin sensitizer solution has been developed which is useful with hydrophobic surfaces. Based on radiochemical tracer adsorption measurements and conventional analytical techniques, a chemical characterization of the surface was made following the sensitization and activation steps. Quantitative results relating to the surface concentrations of active components [tin (II), tin(IV), and palladium] have been established. The surface concentration ratio of tin(II) and tin(IV) was found to be about 3:1. It was also demonstrated that the tin(II)-palladium(II) redox reaction is of low efficiency.

In the plating of dielectric substrates, a pretreatment of the substrate is essential in order to effectively deposit metals by the electroless plating technique. Of the various procedures used commercially in meeting the above requirements, a two-step immersion sequence in acidic stannous chloride solution followed by an acidic palladium chloride solution is commonly used. In general, the first bath is referred to as the "sensitizer" solution while the second solution is the "activator." The net result of this sequence is the formation of finely divided palladium nuclei which initiate the autocatalytic plating process (1, 2). The formation of the palladium metal nuclei has been proposed to be due to a redox reaction (3-5) taking place between the stannous ions adsorbed on the surface and the palladium ions in the activating solution.

The following simplified reactions probably account for some of the chemical and physical changes taking place during the sensitization and activation sequence:

1. Sensitization through stannous adsorption

$$S^* + Sn^{+2}\,(aq) \rightarrow S^* \cdot Sn^{+2}\,(ad)$$

2. Activation through a galvanic replacement

$$S^* \cdot Sn^{+2}\,(ad) + Pd^{+2}\,(aq) \rightarrow S^* \cdot Pd\,(ad) + Sn^{+4}$$

where S* refers to the dielectric substrate, and (ad) refers to an adsorbed state. Although the above process is widely used commercially, little data has been reported as to the efficiency of the reaction and the role of the substrate in such reaction.

In recent publications (6-12) it has been demonstrated that the effectiveness of conventional tin sensitizer solutions ($SnCl_2$/HCl) may be altered through proper bath modification. Specifically, the incorporation of aged stannic chloride solutions was found to provide the improvements in performance. During the aging process, a colloidal compound of tin(IV) was

* Electrochemical Society Active Member.
Key words: sensitizer, electroless plating, tin-113.

formed. The colloidal compound is believed to be β-stannic acid. It was also found (6) that the aged stannic chloride solution may be either added to conventional tin sensitizers or used in a separate step prior to the immersion in conventional tin sensitizers. In either case, identical results were obtained, both with respect to the uniformity of metallic coverage, and by an examination of the resulting surface by contact angle measurements (10). This improvement was of special significance in the case of hydrophobic substrates. Based on the tendency for the interaction between tin(II) and tin(IV), a model has been proposed (11) which accounts for the mechanism of sensitization using the improved sensitizer. In the proposed model (11), it was suggested that the sensitization process is a two-step sequence of adsorption of the aged tin(IV) component, followed by the adsorption of the tin(II) component. The adsorbed tin(IV) component provides a path for the adsorption of tin(II). The new path is based on the chemical interaction of tin(II) and tin(IV) (11). This sequence takes place whether the aged tin(IV) and tin(II) are present together or are used separately.

The choice of Teflon substrates was made in view of its great degree of hydrophobicity (10). It is also believed that the results of the current investigation would be applicable to other hydrophobic substrates (*e.g.*, photoresists) as was demonstrated in the previous work on contact angle measurements (10).

In the current work, analytical examination of the surface under varied conditions was undertaken. This work was carried out to provide verification of the proposed mechanisms (11) and to establish some quantitative values related to the concentrations of active components on the treated surfaces in the course of the sensitization and activation sequence.

Experimental Procedures

Tracer solutions.—Preparation and calibration.—The tracer (tin-113) solution of $SnCl_4$ was obtained from Amersham/Searle Corporation, Chicago, Illinois. The supplier's specification for this material was: chemical form, $SnCl_4$ in 6.3*N* HCl; volume, 2.1 ml; and solids content, 0.181 mg Sn/ml.

The tracer solution (2.1 ml) was transferred to a 100 ml volumetric flask using a freshly prepared 0.51M $SnCl_4$ solution as the transfer agent. After bringing to 100 ml volume, the final concentration was 0.50M $SnCl_4$. No appreciable effect on solution characteristics was encountered due to the slight addition of acid. This solution was allowed to age for about one week before use.

Two milliliters of the $SnCl_4$ tracer stock solution were diluted to 100 ml. Duplicate 2 ml aliquots were removed, placed into individual 1 dram screw-top glass vials and counted in a 2 × 2 in. NaI (Tl) well-type crystal coupled to a multi-channel analyzer. The average count rate of the two standards was adjusted by the appropriate dilution factor to determine the activity of the stock solution. It was found that the activity of the 100 ml tagged stock solution was 6.50×10^6 counts/min/ml. As the stock solution was 0.50M with respect to the tin(IV), the equivalent counts/min/mole of tin(IV) is 1.3×10^{10}.

The tracer (tin-113) solution of $SnCl_2$ was obtained from the same supplier as above. The supplier's specification of this material was: chemical form, $SnCl_2$ in 6*N* HCl; volume, 0.38 ml; and solids content, 1.32 mg Sn/ml.

The tracer solution was transferred to a 25 ml volumetric flask and brought to volume with 0.47M HCl. One milliliter of this stock solution was added to a 50 ml portion of $SnCl_2$/HCl solution for each 0.065 mole/liter $SnCl_2$ present in the 50 ml portion. The hydrochloric acid was held fixed at 0.47 molar.

A technique similar to that described for the tin(IV) tracer calibration was used to determine the activity of the 25 ml stock solution. An activity of 1.17×10^7 counts/min/ml was found. This activity level corresponds to 3.6×10^9 counts/min/mole of tin(II).

Substrate preparation and treatment.—The substrates used throughout the radiochemical measurements were Teflon rods 4 × 0.65 cm. The rods were cleaned in a mild alkaline soap solution, rinsed well in deionized water, and then vapor degreased with Freon TF®. The rods were immersed to a constant depth of 2 cm in a volume of 50 ml of the sensitizer solution. This constant depth immersion was done so that counting rates could be correlated to a solution of known tin-113 activity, which had a height of 2 cm, in order to provide identical counting geometries (area of 4.5 cm^2) in all cases.

Sample counting.—Counting was done on a Packard Model 116 multichannel analyzer in channels 1 through 49 (10 to 490 keV). Background radiations were low and subtracted from the measured values. Each sample was counted for 30 min, and the results are presented on a count/min basis. Prior to counting, the sensitized samples were stored for 24 hr to allow for a complete ingrowth of the In^{113m} daughter from the deposited Sn^{113}, as well as to allow the decay of any co-deposited In^{113m}. Counting of the same samples immediately after the sensitization step showed no In^{113m} peak. The following decay scheme (13) is provided representing the radiochemical characteristics of Sn^{113}.

$$Sn^{113} \xrightarrow[t_{1/2} = 118 \text{ days}]{\text{IT}} Sn^{113m} \xrightarrow[t_{1/2} = 20 \text{ min}]{\text{EC}}$$

$$In^{113m} \xrightarrow[t_{1/2} = 100 \text{ min}]{\text{IT} \cdot \gamma} In^{113}$$

where EC = electron capture: a mode of decay involving capture of an orbital electron by its nucleus; IT = isomeric transition: the decay of a nuclide to an isomeric nuclide by gamma radiation and/or internal conversion electron transition; and γ = gamma radiation of $In^{113m} \rightarrow In^{113}$ with a peak at 392 keV. In all counting experiments, at least two runs were made per composition used. The duplicate runs showed good agreement, well within ±10%.

Chemicals and solution.—All chemicals used throughout were reagent grade; the hydrochloric and nitric acids used were electronic grade. The water used was deionized and then distilled.

Etching and analysis of surface concentrations.—In this phase of the investigation, Teflon spheres were used. The spheres used were 0.094 ± 0.001 in. in diameter and supplied by Orange Products, Inc., Chatham, New Jersey. In all cases 2000 spheres were used, providing a surface area of about 360 cm^2. Following the cleaning procedure described above, these substrates were sensitized and activated in a standard fashion.

For estimating the palladium surface concentration, etching was done in both concentrated HCl and in 1:1 HCl/HNO_3. A colorimetric technique (14) was employed in estimating the reclaimed palladium. In order to estimate the surface chloride concentration following the sensitization step, the sensitized surfaces were etched in concentrated nitric acid, and the chloride was determined by nephelometry.

Results and Discussion

In investigating the interaction between tin(II) and tin(IV), Browne *et al.* (15) studied the kinetics of exchange using a radiochemical tracer technique. The tin(II) and tin(IV) were separated by the selective precipitation of Cs_2SnCl_6 by the addition of a CsCl solution. This technique, however, is applicable only in high concentrations of hydrochloric acid and is not within the range of typical sensitizing solutions. In 10.0F hydrochloric acid, the authors (15) found that the rate of thermal homogeneous exchange reaction (between 0° and 25°C) is given by

$$R = (\text{Sn II})(\text{Sn IV}) \times 4.5 \times 10^{7} \times \exp(-10{,}800/RT) \text{ liter mole}^{-1}\text{ min}^{-1}$$

Furthermore, at 25°C, the rate constants in 9.0, 10.0, and 11.0F hydrochloric acid were found to be 0.38, 0.55, and 0.73 liter mole^{-1} min^{-1}, respectively.

In view of these findings (15), and the lack of knowledge of the exchange rate for solutions having less than 1.0F hydrochloric acid (typical acid concentrations present in sensitizer formulations), the sensitization sequence for the current work was modified to provide additional information. The over-all sensitization process was carried out in two consecutive steps (6, 10), each followed by deionized water rinsing (at room temperature for 1 min): (*i*) immersion in aged stannic chloride solution with added sodium chloride and (*ii*) immersion in conventional sensitizer ($SnCl_2$/HCl). This approach was previously found (6) to give equivalent results in comparison to a sensitization process in which the stannous and stannic components coexist in the same media. By adopting this procedure, the problem of homogenous exchange between tin(II) and tin(IV) was eliminated. The incorporation of sodium chloride was made in view of the further improvement in the wetting of hydrophobic surfaces as demonstrated previously (6, 10).

Table I provides the results of the radiochemical measurements. As stated previously, these values correspond to the average of duplicate runs. In Table IA, the effect is demonstrated of varied concentration of aged stannic chloride on the surface concentration adsorbed. Examination of the results reveals no major variations although the stannic concentration is varied over a five-fold concentration range. Table IA indicates that the adsorbed stannic species (β-stannic acid) was adsorbed onto the Teflon surface to a final surface concentration which was essentially independent of bulk concentration. From the values of Table IA, an average surface activity of 521 counts/min was obtained. This value corresponds to a stannic activity of 4.0×10^{-2} μmole/substrate or 0.89×10^{-2} μmole/cm^2 tin(IV).

Table IB shows the net surface activity after immersion in a fixed stannous chloride/hydrochloric acid solution for substrates which were previously immersed in varied concentrations of aged stannic chloride solutions. Once again, little change is noted as the stannic concentration was varied over a tenfold range. Over this range, an average value of 419 ± 9 counts/min was found.

Based on the average results of Tables IA and IB, there is about a 20% loss in surface activity of tin(IV) following the immersion in stannous chloride/hydrochloric acid solution.

In order to determine the effect(s) associated with varied immersion times in the aged stannic chloride solution, the results of Table IC are provided. From the values of Table IC, it appears that for immersion times of about 1 min or greater in $SnCl_4$ solution, the surface activity of tin(IV) is constant at a value of about 410 counts/min. This value is in excellent agreement with the average results of Table IB (419 ± 9 counts/min).

In Table ID, the net surface activity of tin(IV) is shown following an immersion in acidic stannous chloride solutions of fixed hydrochloric acid content, but variable stannous chloride contents. Over a four-fold concentration range of tin(II), an average value of 381 ± 34 counts/min was obtained, in good agreement with the averages of Tables IB and IC. This result suggests that the fraction of surface material [tin(IV)] desorbed during a 1-min immersion in acidic stannous solution is independent of the stannous content of the solution.

It is interesting to note that a 1-min immersion in a solution containing 0.47M HCl (without $SnCl_2$) resulted in a surface activity [for tin(IV)] of about 200 counts/min. In fact, de-wetting of the Teflon surface takes place in the hydrochloric acid within a few minutes. By contrast, immersion in the same hydrochloric acid media with $SnCl_2$ (*e.g.*, 0.13M) did not produce any de-wetting of the surface after several hours.

In another experiment, the sequence of immersion and timing were identical, but tagged stannous chloride solutions were employed rather than tagged stannic solution. As seen from the results of Table IE, the surface activity of the stannous ion was independent of the bulk concentration used and had an average value of 314 ± 19. This corresponds to a surface concentration of 8.9×10^{-2} μmole/substrate or 2.0×10^{-2} μmole/cm^2 of tin(II). It should also be noted that extended immersion (15 min in the acidic stannous chloride solution) did not change the surface concentration of the adsorbed stannous component. From the average values of Tables IB, IC, and ID, a mean surface activity of 387 ± 29 was found for the tin(IV) after brief immersion (1 min) in acidic tin(II) solutions. From these results, the ratio of tin(IV) to tin(II) was approximately 1:3.

In Fig. 1 the net surface activity for tin(IV) as a function of immersion time in a $SnCl_2$/HCl solution is shown. Although there was an initial decrease in the surface concentration of tin(IV), after about 5 min an equilibrium value was achieved, in the range of 350 ± 25 counts/min/substrate.

This slight desorption of the tin(IV) may be due to either of the following factors operating singly or in combination: (*i*) desorption and/or dissolution of the β-stannic oxide in the acid media (*ii*) desorption due to the replacement of adsorbed stannic component by the stannous ion. Based on the current results it would seem that the possible replacement of adsorbed tin(IV) by tin(II) does not take place to any appreciable extent; instead, the desorption of tin(IV) is

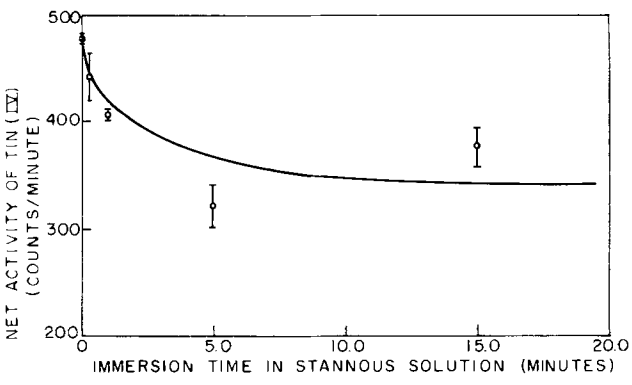

Fig. 1. Surface activity of tin(IV) vs. immersion time in stannous solution.

probably due to the acidic nature of the media and the chloride present. Yet it should be apparent that in a $SnCl_2$/HCl solution an equilibrium state is reached after which no further desorption of the adsorbed tin(IV) component takes place. This stabilization of the surface suggests that either a highly preferred configuration is established comprised of tin(II) and tin(IV), or a subsequent reaction on the surface might have taken place forming a product which is insoluble in the media. In this preferred configuration there is a fixed molar ratio between the stannous and the stannic components. Hence, at equilibrium, which is established (Fig. 1) after about 5.0 min of immersion, the following are the surface concentrations for the tin components

$$\text{Tin(II)} - 20 \times 10^{-3}\ \mu\text{mole/cm}^2$$

$$\text{or } 1.2 \times 10^{16}\ \text{atoms/cm}^2$$

$$\text{Tin(IV)} - 6.0 \times 10^{-3}\ \mu\text{mole/cm}^2$$

$$\text{or } 0.36 \times 10^{16}\ \text{atoms/cm}^2$$

This corresponds to a ratio of about 1 tin(IV) to 3.3 tin(II) existing in the mixed adsorbed layer. This configuration is quite stable and does not seem to change over a period of several hours.

Table II provides a summary of the changes in the surface concentrations of tin(IV) at each stage in the cycle.

Although in the current work the measurements were obtained using the aforementioned technique of consecutive immersion in stannic and stannous solutions, one experiment was conducted using a mixed solution of tin(II) and tin(IV). The solution used was composed of 4.7×10^{-1}M HCl, 1.3×10^{-1}M $SnCl_2$, and $SnCl_4$ varied from 1.5×10^{-3} to 1.5×10^{-1}M. Tagged $SnCl_4$ was incorporated into a 0.5M $SnCl_4$ stock solution which was aged and then used to prepare the mixed tin(II)-tin(IV) solutions.

Radiochemical measurements revealed a surface concentration which was independent of the bulk concentration of tin(IV). The surface concentration found was approximately 4×10^{-3} μmole/cm^2 tin(IV). It is interesting to note that this value agrees fairly well with the surface concentration of tin(IV) found under equilibrium conditions (6×10^{-3} μmole/cm^2) using the two-step sequence. This may indicate that little homogenous exchange between tin(II) and tin(IV) takes place under the conditions employed. This conclusion is consistent with the reported (15) trend of a lower homogenous rate of exchange with decreased acidity. Also, these results reinforce the previous proposal (11) that an identical over-all mechanism takes place regardless of whether the aged stannic component is used with conventional sensitizers or is used as a separate immersion step prior to conventional sensitization.

From the equilibrium concentration data for tin(II) and tin(IV), it would seem that both the adsorbed tin(II) as well as the tin(IV) colloid must be of several monolayers in thickness, since a monolayer is generally 10^{15} atoms/cm^2.

It was also found that the surface activity (tin(II)) of sensitized Teflon was not changed by subsequent immersion in a $PdCl_2$ solution (1.0 g/l $PdCl_2$ + 1.0 ml/l conc HCl). This trend was demonstrated using different types of sensitization [one using combined tin(II) and tin(IV) and the other using tin(IV) followed by tin(II)] procedures. The per cent change in surface activity of tin(II) was below 5%, well within the accepted 90% confidence level.

Analysis for the chloride content following the sensitization sequence revealed a chloride level of less than 3×10^{-2} μmole/cm^2. This upper limit is due to the limitation in the nephelometric method of analysis used. Based on this result, the actual role of the chloride ions in the sensitized film is not understood and requires additional investigation. However, its use in the media has provided improved wetting performance (10).

Etching and analysis of the palladium following the activation step has resulted in surface concentrations in the range of about 2×10^{-3} to 4.5×10^{-3} μmole/cm^2. These values correspond to about 10-25% of the surface concentration of tin(II). It would thus seem that the proposed redox exchange reaction between tin(II) and Pd(II) takes place only to a limited extent. This observation, while it may be puzzling at first, is not surprising since the sensitized surface [composed of tin(IV) and tin(II)] was shown to be a highly preferred configuration which does not change with time. It should be pointed out that the extent of oxidation-reduction observed for the present system does not necessarily apply to other sensitizer media. In fact, Cohen *et al.* (4, 5) have suggested that in conventional sensitizers there is a complete exchange between tin(II) and Pd(II) using Kapton as the substrate. More recently, P. F. J. v.d. Boom *et al.* (16) have shown that no replacement of tin(II) by Pd(II) takes place using soda-lime glass as the substrate.

Conclusions

The present investigation, using radioactive tin-113, has provided quantitative results for the adsorption of aged tin(IV) and tin(II), the findings of which support the proposed model for this system (11). Moreover, it has been demonstrated that prior to the activation step, the surface concentration ratio of tin(II) to tin(IV) is about 3:1. Although the exact surface configuration and bonding is not known, the resulting sensitized film is highly stable, probably due to the chemical interaction of the aged stannic component with the stannous ions. As was found previously (10), the aged stannic component may be used as a distinct immersion step prior to the immersion in conventional sensitizers or be combined with the conventional sensitizer into one solution. In either case, the surface concentration for the aged tin(IV) component was found to be nearly the same.

From a practical consideration of the current system, it has been demonstrated that the surface concentration of active components is fairly independent of variations in immersion times, concentrations of aged tin(IV), and concentrations of tin(II). This permits industrial processes to be operated with wide margins in sensitizer make-up.

It would also seem doubtful whether the redox reaction between tin(II) and palladium(II) does occur. As there has not been a significant decrease in surface activity (using tagged tin(II)) after the activation step, it is possible that either (*i*) the redox reaction does not take place and the palladium is adsorbed in an ionic state, or (*ii*) the redox reaction takes place resulting in tin(IV) which is insoluble in the activator solution. Moreover, if the redox reaction does take place, its efficiency is, at best, 25%.

In view of the wide range of per cent efficiencies reported for the tin(II)/palladium(II) redox reaction, future work in this field should provide greater consideration of the sensitization system and the role played by the substrate. It is believed that future improvements in the sensitization of dielectric substrates

will further result in improved properties of thin films deposited by chemical plating techniques.

The Influence of Anions on the Structure of Porous Anodic Al_2O_3 Films Grown in Alkaline Electrolytes

P. Neufeld and H. O. Ali

Polytechnic of the South Bank, London SE1 OAA, England

ABSTRACT

Porous, anodic Al_2O_3 films have been grown in a variety of alkaline electrolytes. At elevated temperatures film growth beyond the normal barrier thickness and the development of a well-defined pore structure is not uncommon, but only borate solutions have been found to support the growth of films of a thickness comparable to commercial acid anodizing processes.

A transition from porous film growth to electropolishing has been observed in the case of citrate solutions.

The significance of the results is discussed in relation to present theories of acid anodizing.

Some electrolyte solutions such as ammonium tartrate and boric acid-borax mixtures support the growth of thin barrier films of anodic oxide on aluminum. Others, such as sulfuric and chromic acids support the growth of thick, porous films, while electropolishing may occur in others such as phosphoric acid-butyl alcohol (1). The simplest classification of these electrolytes has been in terms of their solvent ability, barrier electrolytes having the least dissolving power on the oxide film. It has long been evident that solubility alone does not explain all the variations of behavior shown by anodized aluminum, and the nature of the anions present has been shown to be important as well as the *p*H. Kissin (2) and Murphy (3) suggested that only di- or trivalent acids would support porous film growth, though evidence for the growth of such films in sulfamic acid ($NH_2\ SO_3H$) is found in the work of La Vecchia (4).

The growth of thick porous Al_2O_3 anodic films has traditionally always been carried out in acid electrolytes. Thus theories of film growth have assigned importance to the role of the hydrogen ion. Hoar and Yahalom (5) suggested that proton entry against the field could reduce the film resistance and lead to increased current flow, Joule heating, and pore initiation. Brock and Wood (6), however, reported heavy hydration and lowering of resistance for films grown in alkaline-tartrate solutions. These ideas may be harmonized to some extent by considering, as did O'Sullivan and Wood (7), that mobile protons in the film would be likely to be included in OH^- ions. Thus structural modifications due to proton entry in acid electrolytes may not substantially differ from those produced by hydroxylation in alkalies.

Recent work by Leach and Neufeld (8) and Neufeld and Ali (9, 10) has shown that thick, porous, anodic films may be grown in hot alkaline solutions containing borate ions. Heating is essential; if the dissolving power of the electrolyte is increased simply by raising the *p*H, pitting attack is induced. Active participation by the anions in the anodizing electrolyte is thus a major factor in the growth of porous films in alkaline electrolytes. The present work describes a study of the effect of a variety of anions in porous anodic Al_2O growth in alkaline solutions at temperatures above ambient.

Key words: aluminum, anodizing, alkaline, anions.

Experimental Techniques

Material.—The material used was 99.99% purity aluminum sheet, about 0.3 mm thick. Flag-shaped specimens were cut, 1 cm^2 in size, with a long narrow "flag pole" which was used for handling and making electrical contact.

The specimens were cleaned and degreased in trichloroethylene vapor. They were then chemically polished in Phosbrite 159 at 105°C, rinsed in distilled water at 65°C, desmutted in 50/50 nitric acid, and then rinsed in cold distilled water.

Electrolytes.—The electrolytes used were prepared from research-grade reagents and distilled water. The various solutions used are tabulated as follows:

Electrolyte	Composition (weight/volume per cent)
Sodium tetra-borate (borax)	5
Ammonia solution (sp gr 0.88)	8.8 (10% by volume)
Sodium meta-silicate	5
Sodium carbonate	5
Potassium sodium tartrate	5
Sodium citrate	2

Anodizing was carried out in a 1 liter Pyrex beaker immersed in a thermostatic water bath which enabled the temperature to be controlled within ±0.5°C.

Electrical control.—The power source used had an automatic switchover from a controlled current to a controlled voltage operation, enabling the anodizing sequence to be as follows:

(*i*) Film growth was started at a constant applied current until a preset cell voltage was reached.

(*ii*) Anodizing was then continued at this constant voltage, the current flow being monitored using a potentiometric recorder.

Microscopy.—For transmission-electron microscopy, very thin oxide films were grown for short times varying from 3 to 60 sec. These films, being fragile, required a special handling technique. Before dissolving away the metal (using 5% iodine methanol solution) the oxide on one side of the specimen was backed with a thin layer of cellulose acetate deposited from a 5% solution in acetone. An abrasive paper (emery paper) was used to make a small window, about 3 mm in diameter, on the other side of the specimen, until the underlying metal was exposed. A special apparatus (11) was used for dissolving away the exposed metal without affecting the plastic backing on the other side of the specimen.

Carbon was then vacuum-deposited onto the exposed oxide surface to provide mechanical support when the plastic was dissolved later.

The doubly supported oxide was then removed from the surrounding metal and placed in a folding electron-microscope grid. The plastic backing was dissolved away by submerging the grid in acetone for about 2 hr. After drying, the specimen was ready for microscopical examination. These thin specimens were also examined by electron diffraction to find out if there were any evidence of crystallinity.

The electron microscope used was an A.E.I. E.M.6.G. Vacuum-deposition was done using an A.E.I. 12 in. vacuum-coating unit.

Results

When the electrolytes were used at room temperature, the current density (for constant voltage anodizing) sharply increased and then dropped to very low values; this indicates the formation of barrier films only. With appropriate *p*H and temperature adjustments, all these electrolytes (except the silicates) were found to support porous film formation; however, only borates allowed the growth of thick anodic films (up to 15μ in an electrolyte of *p*H 10 used at 70°C) (2). The shapes of the current-time curves obtained during anodizing in 5% borax solution (*p*H 10 at 70°C) are generally similar to those recorded during sulfuric and chromic acid anodizing (Fig. 1). This form of current-time curve is diagnostic of porous film growth, following an initial barrier-film formation. Pore formation is confirmed by electron-optical examination of very thin films (Fig. 2). The pore structure showed a development with time in the early stages of growth. The general trend is for a fine structure of many small

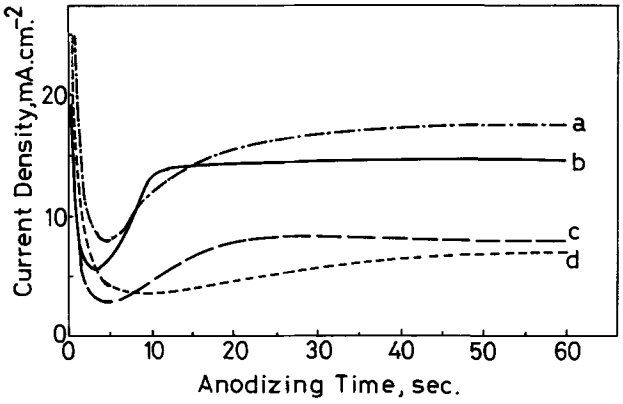

Fig. 1. Current-time curves for different electrolytes. Curves a and c for 5% borax solution (*p*H 10, at 70°C) at 50 and 20V, respectively; b for 15% by volume sulfuric acid at 20°C and 10V; d for 10% chromic acid at 40°C and 30V.

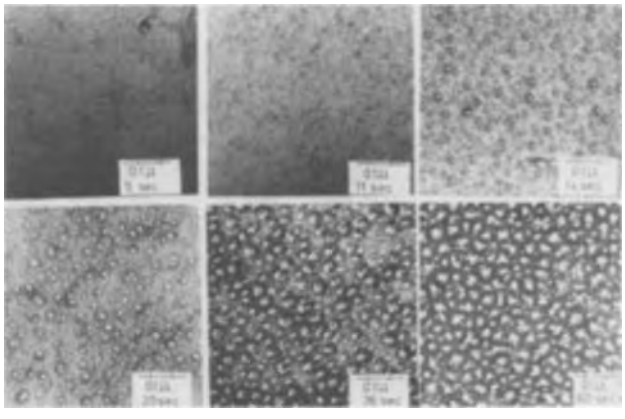

Fig. 2. Transmission electron micrographs of specimens anodized in 5% borax, *p*H 10, at 20V and 70°C.

pores to develop into a coarser one with fewer but larger pores.

The anion in the alkaline electrolyte seems to have very marked effects on both the electrical characteristics during anodic film growth, and the final film structure. Thus on anodizing in a 5% weight/volume sodium metasilicate solution (*p*H 12.5) at 70°C and 50V, only a barrier film was obtained. The current density observed was in the region of 0.3 mA/cm^2 (Fig. 3) which is high for reported leakage currents. When the *p*H was increased to about 13.5 by adding 2 g/liter solid sodium hydroxide, the current density increased to about 0.7 mA/cm^2 (Fig. 3), but the resulting oxide was still mostly a barrier-type film, with very few isolated tiny pores (Fig. 4 III).

When anodizing was carried out in a solution of 5% weight/volume potassium-sodium tartrate + 2 g/liter solid sodium hydroxide (*p*H 12.5) at 70°C and 50V, the current-time curve was indicative of porous film formation. After the initial surge (Fig. 3) the current dropped and then steeply rose to a value of 35 mA/cm^2 within 3 sec. The structure of the film obtained after anodizing for 15 sec showed channels about 15.0-20.0 nm wide (Fig. 4 II). After 1 min of anodizing, pores having diameters of the order 15.0-20.0 nm were more apparent although some channels can still be seen.

The current-time curve obtained during anodizing in the 8.8% weight/volume ammonia solution (*p*H 11.3) at 70°C and 50V (Fig. 3) did not show a rise after the initial drop to a value of 8-10 mA/cm^2. Few irregular pores were initially obtained, but after 10 min of anodizing these were replaced by large and more regular ones (Fig. 4 I).

During anodizing in 5% weight/volume sodium carbonate solution (*p*H 11.7), at 60°C and 50V, the current density dropped to about 50-60 mA/cm^2 (Fig. 3) and

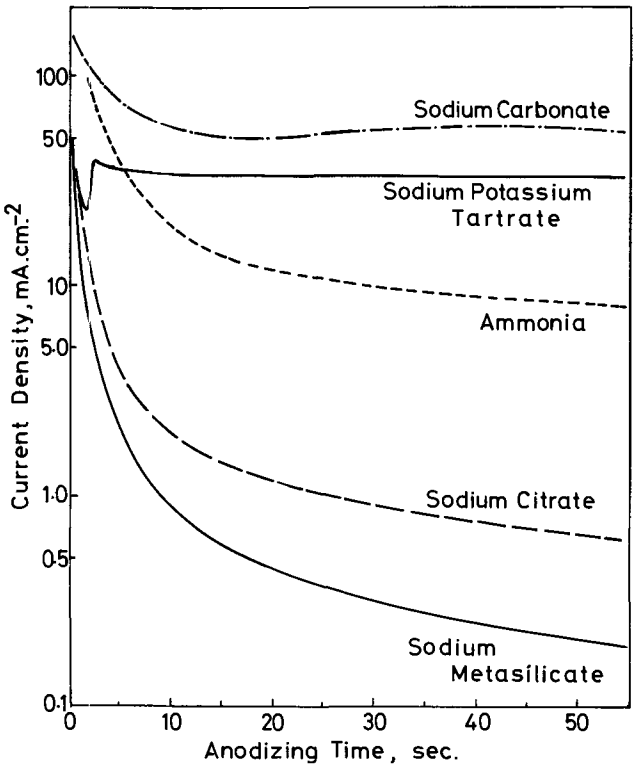

Fig. 3. Effect of anion on current density

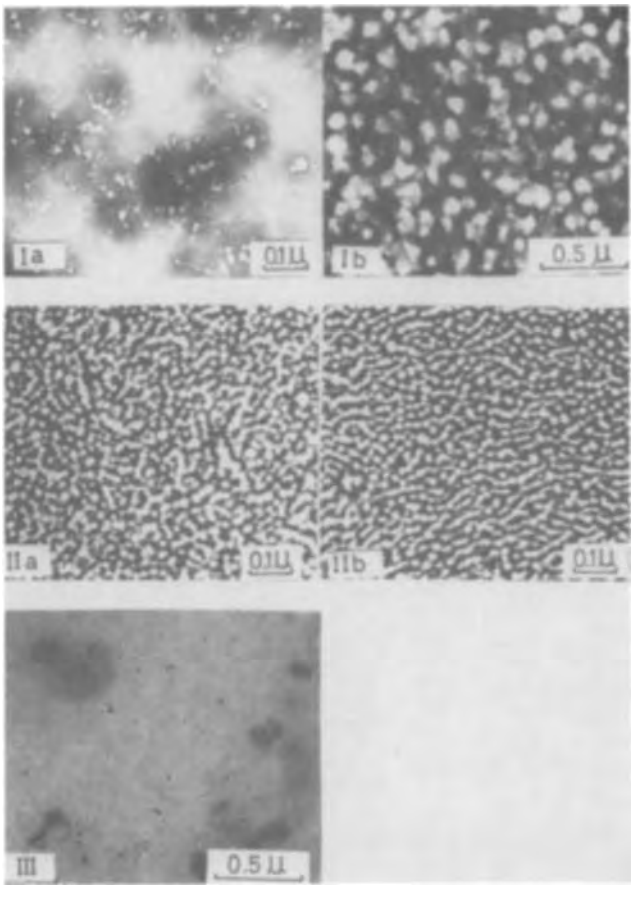

Fig. 4. Electron micrographs of specimens anodized at 50V and 70°C in: I. 10% by volume ammonia solution for (a) 30 sec, (b) 10 min; II. 5% weight/volume sodium potassium tartrate + 0.2% weight/volume sodium hydroxide for (a) 15 sec, (b) 1 min; III. 5% weight/volume sodium metasilicate + 0.2% weight/volume sodium hydroxide for 30 sec.

the resulting structure was porous, with the pores showing large variations in size and distribution (Fig. 5).

On anodizing in a 2% weight/volume sodium citrate solution of pH 8.0, at 70°C and 50V, for 1 min, only a barrier film is formed (Fig. 6), although the current density observed was about 0.6 mA/cm² which is relatively high for nonporous films (Fig. 3). On prolonged anodizing, the current density showed a slow rise to about 0.7 mA/cm² (after 30 min of anodizing) indicating pore formation, which is indeed confirmed by electron microscopy (Fig. 6). On adding 1 g/liter of solid sodium hydroxide to the citrate solution (pH 12.5) a porous structure developed more quickly (Fig. 7b).

With an increasing sodium hydroxide content, which increases the dissolving power of the electrolyte, larger pores were obtained (Fig. 7c). An extreme example was when 10 g/liter sodium hydroxide were added. The current density increased to about 1 A/cm² (Fig. 8), and the specimen was highly polished after anodizing. The stripped oxide showed a cellular structure under the electron microscope (Fig. 7d). The visual contrast was very poor; the significance of this is discussed later. In the case where 2 g/liter sodium hydroxide was added, the film grown for 1 min was similar to that grown for 30 min (Fig. 7e and f), which shows that no considerable thickening had taken place, and probably a terminal thickness had been reached.

All the thin, anodic, oxide films obtained in the alkaline electrolytes were examined by electron diffraction and gave broad diffuse rings; there was no indication of crystallinity.

Discussion

Electrolyte temperature.—It is significant that at normal ambient temperatures no films grown in alka-

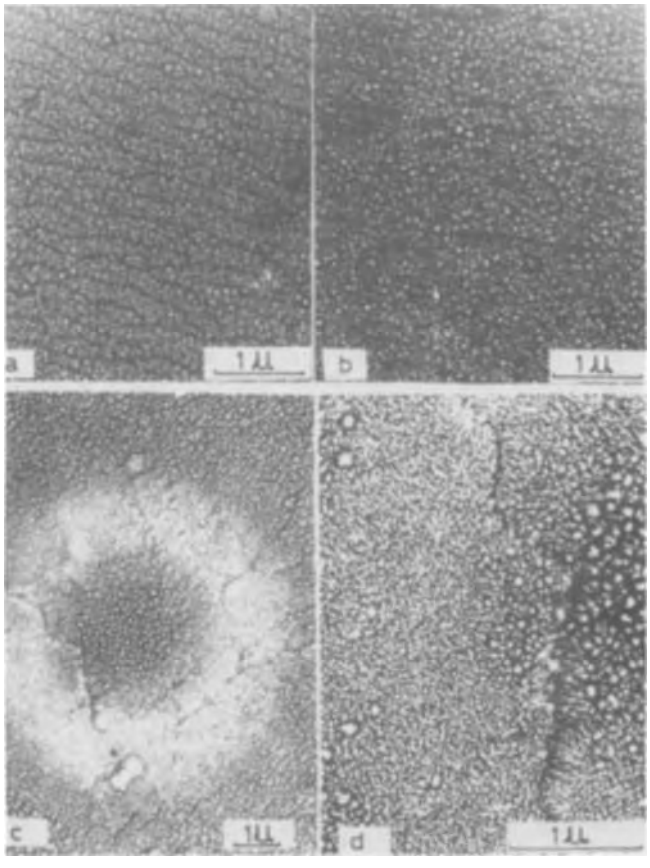

Fig. 5. Electron micrographs of specimens anodized in a 5% weight/volume sodium carbonate solution at 50V and 60°C: (a) anodized for 15 sec; (b) 30 sec; (c) different region in specimen (a); and (d) magnified portion of (c).

line electrolytes have been observed to develop a well-defined pore structure. A faint irregular texture may be observed in most barrier films, but this does not develop further. This implies that preferential dissolution does not occur at surface sites, and hence that the chemical dissolving power due to the OH^- ion concentration is not the controlling factor in pore development.

Pore development is observed when the temperature is raised. This leads to the conclusion that the changes which produce pore formation occur due to adsorption or absorption of ionic species (anions in alkaline solutions) by the oxide film. Electrolytes which operate when cold, such as sulfuric, phosphoric, and oxide acids, are known to incorporate significant concentrations of anions in the oxide (12-14). It must be assumed that under alkaline conditions sufficient modification of film properties by anions can only take place at temperatures above ambient.

Pore initiation.—The results obtained throw further light on the earliest stages of pore formation. All workers are agreed that the initial pore structure is much finer than that which supports continued film thickening. The earliest texture has been described as consisting of micropores (8) or as small, thicker (or more opaque) "islands" (7). Figure 4 (II and III) shows both types of feature to be present on the same specimen. (This is less clearly visible in Fig. 4 III.)

Irregularity in structural modification can only be ascribed to irregularity in the original structure, hence

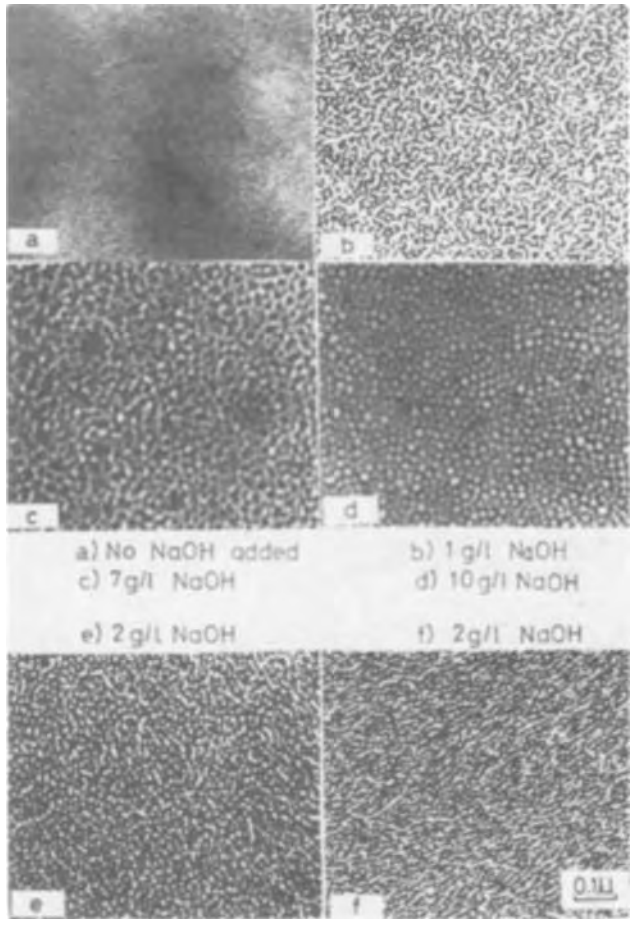

Fig. 7. Electron micrographs of specimens anodized at 50V and 70°C in a sodium citrate solution containing various amounts of NaOH. a, b, c, and d anodized for 1 min, e for 30 sec, and f for 30 min.

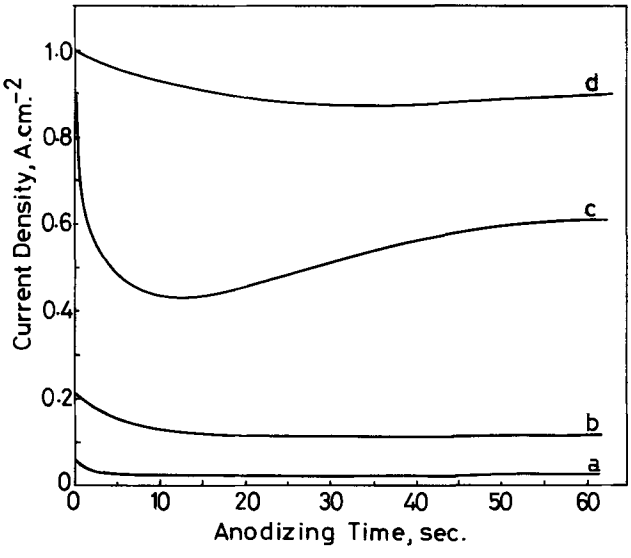

Fig. 8. Effect of sodium hydroxide content on current density. Anodizing carried out in a 2% weight/volume sodium citrate solution containing: (a) 1 g/liter, (b) 4 g/liter, (c) 7 g/liter, and (d) 10 g/liter NaOH, and used at 50V and 70°C.

the initial barrier film cannot be regarded as amorphous but must consist of crystallites. We believe that the less dense regions in electron micrographs of textured barrier films represent regions of hydration or hydroxylation and possibly also penetration by other anions as proposed by Murphy and Michelson (15) and

O'Sullivan *et al.* (16). Where a micrograph shows dense "islands" these may not represent regions of local growth, as proposed by O'Sullivan and Wood (17) but rather crystallites entirely surrounded by modified "grain boundary" regions. Where "pores" are seen, this represents modification only at "triple points," while a structure as seen in Fig. 4 II represents an intermediate stage where modification has extended from triple points along some, but not all, grain boundaries. The crystallite size as revealed by electron micrographs (10) is generally in the range 2.5-5.0 nm which is too small to give well-defined diffraction patterns.

Field-assisted dissolution.—The earliest development of texture in barrier films may be observed even with films which do not develop large pores later on (Fig. 4 II). Thus the effect of anions in modifying the pore structure and film growth is operative on the next stage of pore development which involves the concentration of current through the film in local regions and field-assisted dissolution in these same locations. O'Sullivan and Wood (7) considered a mechanism which would give stoichiometric oxide dissolution at a pore base. This is unnecessary, since under irreversible conditions, oxyanions could not simultaneously be moving into the electrolyte to give dissolution and into the oxide to support further oxidation. Recent tracer measurements by Amsel and Siejka (17) support the view that oxygen in the lattice will not pass into the electrolyte during field-assisted dissolution. This leads to the conclusion that only metal ion dissolution needs to be considered in the mechanism of field-assisted dissolution.

Under acidic conditions a metal ion which has entered the electrolyte will be solvated as a cation and will move away from the interface by diffusion and migration. Under alkaline conditions the metal will be solvated as an anion and migration will oppose diffusion. The concentration of aluminate ions will thus tend to be very high near the surface and will impede further dissolution. Since it has been shown that experimental results favor an interpretation of the influence of anions in terms of modification of oxide properties during field-assisted dissolution, it may be concluded that this effect is produced by adsorption of anions at the pore base. Any adsorption (which would be favored at metal-ion sites on the surface) will displace hydroxyl ions and provide a more favorable environment for dissolving metal to traverse the double layer in the form of cations. All the anions studied, except for silicate, show some development of pore structure; in the latter case there is evidence that a resistant alumino-silicate may form (18). The outstanding effect of the borate ion is not reflected in a particularly high boron content of the anodic film (19), and must be ascribed to adsorption. Borates are well known as corrosion inhibitors for aluminum and it can be assumed that borax inhibits pore-wall dissolution while permitting field-assisted cation escape at the pore base.

Oxygen entry.—During porous film growth, oxyanions must enter the film and migrate under the influence of the field so as to contribute to the formation of new Al_2O_3 at or near the metal-oxide interface; only in this way can growth of oxide in between pore locations be explained. It is likely, in view of the substantial evidence for hydration of the anodic film (20), that OH^- ions would be more mobile than O^{2-} ions (7). In the case of acid electrolytes the oxygen contributing to fresh oxide growth must derive from H_2O molecules (17) and the *p*H of the solution at the pore base would tend to decrease. In alkaline solutions there is an abundance of OH^- ions and the simplest mechanism that can be proposed is one of direct entry of hydroxyl ions into the lattice under the influence of the field. It may be mentioned that the mechanism of field-assisted dissolution proposed by O'Sullivan and Wood (7) can be modified by assuming that a single proton would attach to a surface oxygen anion, which would then become more mobile and re-enter the oxide bulk. This is more likely than the acquiring of a second proton and dispersal into the solution as a water molecule.

Pore angle and terminal thickness.—In the cases where the electrolyte did not support the growth of a very thick porous film (all alkaline electrolytes used except borate), it may be suggested that field-assisted dissolution at the pore base is weak, and that relatively fast chemical dissolution occurs at the pore walls. Thus the terminal thickness is established rapidly. When the pore-wall dissolution is not relatively fast (in the case of borates) long pores and thick, anodic films are obtained.

It has been proposed (21, 22) that chemical dissolution of the pore wall during film thickening leads to a truncated pore structure. The maximum or terminal anodic film thickness is reached when the pore-mouth diameter becomes equal to the diameter of the cell containing it (Fig. 9). This would be expected to occur earlier when the dissolving power of the electrolyte is increased (*e.g.*, when sodium hydroxide is added to a sodium citrate bath). Apparently the terminal thickness is reached after only 30 sec of anodizing, since the film does not thicken enough to obstruct the electron beam even after 30 min of anodizing (Fig. 7e and f). Now consider two adjacent pores in an oxide film which has reached its terminal thickness (Fig. 9). When dissolution is not very severe (*i.e.*, 1 g/liter sodium hydroxide added), the pore would be expected to have a slightly slanting wall (small ϕ Fig. 9a). On increasing the dissolving power of the electrolyte (*i.e.*, add 10 g/liter sodium hydroxide), faster dissolution of the pore wall takes place resulting in a more slanting wall (large ϕ) and a relatively thin film (Fig. 9c).

Electron micrographs (Fig. 7b, c, and d) confirm this effect of increased ϕ and reduced film thickness. When ϕ is relatively small, the wedge-shaped oxide film between two neighboring pores obstructs the elec-

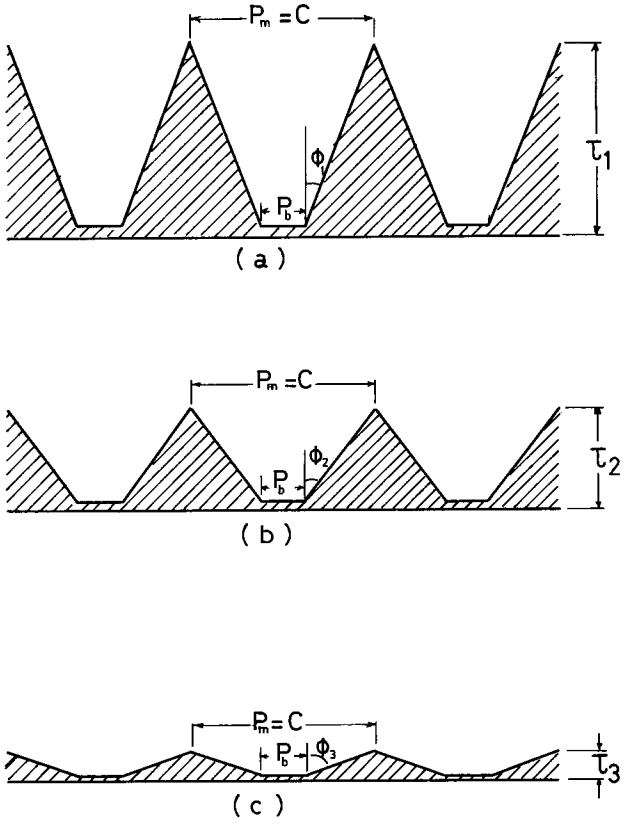

Fig. 9. Film dissolution leading to polishing. P_b, pore base diameter; P_m, pore mouth diameter; C, cell size (diameter); ϕ pore wall slant; τ terminal film thickness.

tron beam substantially. This oxide appears as very dark areas surrounding the light pores, producing a strong contrast. As ϕ increases, the thickness of the oxide wedge decreases, and the contrast drops drastically. This was the case when the sodium hydroxide content in the citrate bath was increased to 10 g/liter. The contrast is essentially due to the difference in thickness of the oxide wedge and that of the barrier film. The thickness of the latter, under the conditions used, was in the region of 5 to 15 nm. Significantly, this extreme barrier film thinning (0.1-0.3 nm/V^{-1}) (19) was reflected in the very high current density (about 1 A/cm^2) which passed during the process (Fig. 8).

It seems likely that the observed electropolishing of aluminum is a form of porous type anodizing, where the angle ϕ approaches 90°.

Conclusions

The results reported support the view derived from Murphy and Michelson (15) that as-formed anodic Al_2O_3 consists of crystallites which become surrounded by hydrated regions. The early stages of pore initiation show features consistent with increased current flow and field-assisted dissolution at these modified regions.

While increasing the pH of alkaline electrolytes does not necessarily produce well-defined, porous, oxide growth, the raising of the electrolyte temperature will induce such growth in electrolytes containing a variety of anions. Thus the action of the anions in supporting and modifying porous film growth is operative on the film properties rather than on dissolved species.

The powerful effect of the anion in altering the morphology and thickness of porous Al_2O_3 films grown in alkaline electrolytes may be tentatively explained in terms of the relative effects of adsorption on the rates of field-assisted dissolution and pore-wall dissolution. Only borate has been found to support film growth beyond a few microns and only metasilicate has been found to inhibit pore formation altogether.

The transition from porous oxide growth to electropolishing has been observed in the case of citrate solutions. The change is not due to a fundamental alteration in film structure, but rather to an increase in pore-wall dissolution at increasing pH.

Acknowledgments

The authors are indebted to Mr. G. Isserlis for the provision of laboratory facilities and for encouraging this study. This paper described part of the work carried out for the Ph.D. degree of the University of London (H.O.A.).

Pulse Electroplating of Silver-Tin Alloys and the Formation of Ag_3Sn

Henry Leidheiser, Jr.* and A. R. P. Ghuman

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Silver-tin alloys were electrodeposited at 50° by pulse plating from a bath containing AgCN 0.020M; $K_2SnO_3 \cdot 3H_2O$ 0.375M; KCN 1.40M; and KOH 1.25M. The major variables studied were pulse cycle and current density. In the current density range of 1.5-3 A/dm^2 with pulse on-times of 5-100 msec and off-times of 50-200 msec, the major constituent in the deposit was the intermetallic compound Ag_3Sn. Several experimental conditions were determined in which the elemental tin and silver contents were small. The Ag_3Sn coatings showed excellent integrity at thicknesses up to 2×10^{-3} cm and were highly ductile. The tarnish resistance of the Ag_3Sn coatings was superior to that of pure silver.

The work reported herein represents a continuing interest in the formation of intermetallic compounds during corrosion and electrodeposition (1-5). Illustrative of this interest a method was given recently for the preparation of Ag_3Sn coatings (5). This method was based on the observation that in stirred solutions the deposit composition was constant over a range of current densities and could be controlled by using spe-

cific silver and tin concentrations. Concentrations of dissolved silver and tin in the plating bath which yielded a 3:1 atomic ratio of silver and tin in the deposit crystallized as Ag_3Sn.

The chief disadvantage of the method was the fact that the deposit tended to become dendritic and noncompact in nature for thicknesses in excess of 1.5×10^{-3} cm. Presumably deposition was occurring near the limiting current density for silver deposition with the consequent difficulty of maintaining a relatively uniform growth rate over the entire surface. It appeared that pulse plating offered a means for circumventing this difficulty. The purpose of this study is therefore to explore pulse plating as a technique for forming useful Ag_3Sn electrodeposits.

Experimental

All deposits were made from a solution containing AgCN, 0.020M; $K_2SnO_3 \cdot 3H_2O$, 0.375M; KOH, 1.25M; and KCN, 1.40M. The bath was stirred during deposition and the temperature of the bath was maintained at 50° by a thermostated water bath. In the majority of cases copper substrates were used, but in several cases steel substrates were used. The counterelectrode was graphite.

The pulsing unit was similar to that developed by Avila and Brown (6). The minimum pulse width obtainable was of the order of 1.5 msec, but the minimum pulse width used in these studies was 5 msec. The current pulses were essentially square wave in character with a very slight decrease in current over the on-time period.

X-ray diffraction examinations of the deposits were made on unstripped coatings using conventional electronic recording of the diffraction lines.

The composition of the deposits was obtained from electron microprobe measurements using both static beam and scanning beam techniques. The data were corrected for absorption and fluorescence effects using a computer program. Inadequacies in the analytical method are apparent from the fact that the sum of the calculated tin and silver contents was always less than 100%, generally being 97-98%.

Results

Effect of pulse cycle.—Important data are summarized in Fig. 1-4 for pulse on-times of 5-100 msec, pulse off-times of 5 to 200 msec, and current densities of 0.8 to 3.25 A/dm². It should be noted that the data are given in terms of the intensity of the strongest line in the x-ray diffraction pattern for the three constituents of interest, silver, tin and Ag_3Sn. Preferred orientation of the constituents was fortunately not a complication as shown by the fact that the relative intensities of the lines for each constituent were always in approximately the same ratios. Changes in the concentration of each constituent can be determined qualitatively as a function of experimental variables, but no conclusions can be drawn from these data alone concerning the relative amounts of each constituent present in the deposit.

The generalizations can be made that at fixed current density, the concentration of elemental silver in

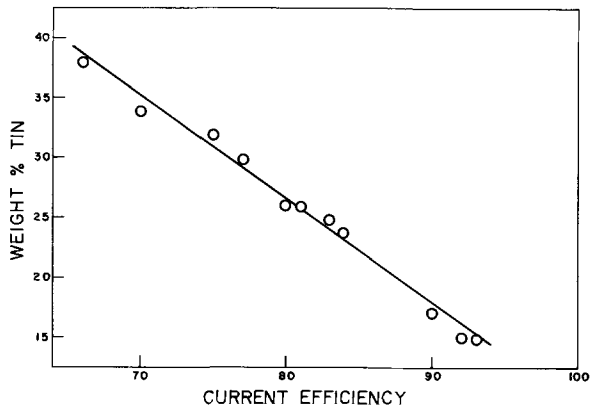

Fig. 5. Current efficiency for the electrodeposition of silver-tin alloys as a function of the composition of the deposit.

the deposit decreases with increase in the on-time and the concentration of elemental tin in the deposit increases with increase in on-time. For fixed on-off cycles, the amount of elemental silver in the deposit decreases with increase in current density and the amount of elemental tin in the deposit increases with increase in current density. The current density required to maximize the amount of Ag_3Sn in the deposit is a function of the on-off cycle utilized.

Current efficiency.—Current efficiencies were calculated from the composition of the deposit as obtained from microprobe measurements and under the assumption that tin was reduced from the tetravalent state and silver from the monovalent state. Representative data from eleven different experiments are plotted in Fig. 5. It will be noted that the current efficiency is a linear function of the weight per cent of tin in the deposit. At the composition corresponding to that of Ag_3Sn [27 weight per cent (w/o) tin] the current efficiency was 80%. The data summarized in Fig. 5 are consistent with the conclusion that silver is deposited in excess of 100% current efficiency and tin is deposited at approximately 15% current efficiency.

Homogeneity of deposits.—The cross sections of many of the deposits were examined by electron microprobe and by scanning microscopy. In the case of compositions approximating Ag_3Sn the composition was uniform throughout the thickness and the distribution of the two metals was homogeneous. X-ray images of a 20μ thick deposit formed at a current density of 2.1 A/dm^2 with an on-time of 100 msec and an off-time of 200 msec are given in Fig. 6a and 6b. This deposit had a composition approximating Ag_3Sn but x-ray diffraction analysis showed the presence of small amounts of elemental silver and elemental tin. Both the silver and the tin x-ray images indicated homogeneity, but the tin x-ray image was much more sensitive to small compositional differences in neighboring regions.

Mechanical properties of the deposits.—Knoop hardness measurements were made on cross sections of eleven deposits. Results are summarized in Fig. 7. The hardness of deposits containing approximately 100% Ag_3Sn were intermediate to those containing excess silver and those containing excess tin.

Deposits generally were made on steel substrates without an intermediate strike of silver. Occasionally such deposits exhibited poor adherence and could be peeled from the substrate with relative ease. The isolated deposit was extremely ductile and could be bent back and forth without fracture.

Deposits could be polished to high luster with no difficulty.

Tarnish resistance.—The tarnish resistance of the electrodeposited coatings relative to that of electrodeposited silver was determined by exposure of metallographically polished and buffed samples to a gaseous environment containing 1% H_2S-1% SO_2-98% air at room temperature. The samples containing Ag_3Sn with minimal amounts of excess silver or tin and those containing excess tin exhibited tarnish resistance superior to that of silver and to the Ag_3Sn deposits containing excess silver. The intermetallic deposit discolored to a yellow or tan while a pure silver electrodeposit became dark blue to black in the same time interval. Quantitative information on the rate of tarnish film growth was not obtained.

Discussion

This study has shown that pulse plating is a very effective technique for the electrodeposition of silver-tin alloys of fixed composition. It is a particularly effective technique for the preparation of high quality Ag_3Sn coatings with minimal amounts of elemental silver and tin. Experimental conditions which lead to the maximum Ag_3Sn content, as determined by x-ray diffraction analysis, are summarized in Table I.

The question arises as to why pulse plating is so effective in forming the intermetallic compound Ag_3Sn. As shown by Girard (7) pulse plating is more effective in maintaining a uniform composition over the thickness of the deposit than is d-c plating. Our microprobe studies confirm that the composition is very uniform over the thickness of the deposit (see Fig. 6a and 6b). Thus, it is to be expected that once the experimental

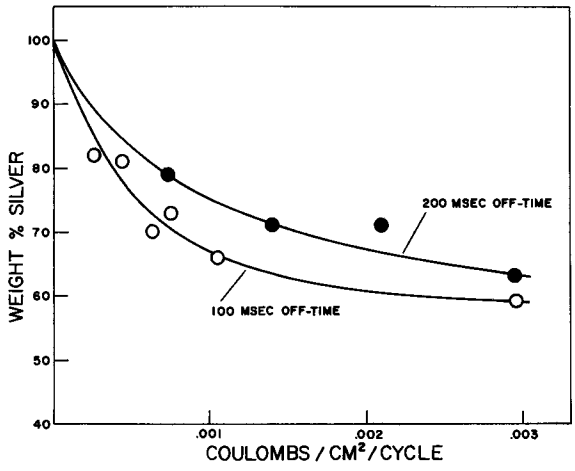

Fig. 8. Composition of the deposit as a function of the coulombs passed during one cycle.

conditions are known for depositing silver and tin in a 3:1 atomic ratio, this composition will be maintained over the thickness of the deposit during the deposition time.

Cheh (8) has calculated the limiting current density for pulse plating as a function of pulse cycle and the ratio of (on-time)/(total pulse cycle time). The majority of our experiments were carried out under conditions where the limiting current density under pulse plating is very similar to that for d-c plating. For example, with an on-time of 50 msec and an off-time of 100 msec, extrapolation of Cheh's curves give a limiting current density under pulse plating not greatly different than that for d-c plating.

Figure 5 indicated that there is a linear relationship between the composition of the deposit and the current efficiency. If the curve is extrapolated to 0% tin in the deposit, the calculated current efficiency for silver deposition is approximately 109%. The most likely explanation for this excess current efficiency is that during the off-time there is a metal replacement reaction between electrodeposited metallic tin and silver ions which diffuse to the surface during the off-time.

The importance of the off-time in controlling the composition of the deposit is demonstrated by Fig. 8. In all cases the weight per cent of silver in the deposit is greater for a 200 msec off-time than for a 100 msec off-time at equivalent coulombs passed during the cycle. Two reasons for this result are proposed. First, the longer off-time allows greater replenishment of silver complex ions in the cathode film. Second, the longer off-time allows greater reaction of metallic tin in the surface of the deposit with ionic silver in the adjoining liquid. The relative magnitude of these two effects is unknown.

Pulse-plated silver-tin alloys, and particularly those with a composition approximating Ag_3Sn, show promise as decorative coatings since the tarnish resistance is greater than that of pure silver. The deposits are ductile, can be polished to high luster and have a pleasing appearance.

Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

Measured limiting currents i_L for the deposition of copper on a platinum rotated disk electrode (RDE) were used to calculate the diffusion coefficients of copper ions in high-purity aqueous copper sulfate and copper fluoborate electrolytes. The diffusion coefficient in a 0.100M $CuSO_4$/1.0M H_2SO_4 electrolyte was found to be $5.23 \pm 0.13 \times 10^{-6}$ cm²/sec, while the diffusion coefficient in a 0.072M $Cu(BF_4)_2$/1.0M HBF_4 electrolyte was found to be $9.88 \pm 0.05 \times 10^{-6}$ cm²/sec. The values of i_L were found to be directly proportional to the square root of the disk rotational rate ω, as predicted by theory. Consistent correlations between the kinetic parameters controlling copper depositions and the concentration of addition agents were found for copper fluoborate electrolytes containing Cubath Hy,[1] thiourea, and gelatin. Generally both the transfer coefficients (α_c) and the exchange current densities (i_o) were found to decrease with increasing concentrations of additives, in accord with the hypothesis that additives retard primary charge transfer and the rate of copper deposition. Anomalous results were obtained at a thiourea concentration of 3.3×10^{-2} g/liter and at a gelatin concentration of 3.2×10^{-2} g/liter.

The purpose of this work was to investigate the deposition of copper from a copper fluoborate/fluoboric acid electrolyte and from fluoborate solutions containing various leveling/brightening agents known to be effective in copper sulfate solutions. Emphasis was placed on obtaining the diffusion coefficient for Cu^{++} ions in the pure solution, and in correlating changes in the kinetic parameters α_c and i_o with the concentration of various additives employed. For comparative purposes the values for $D_{Cu^{++}}$, α_c, and i_o were obtained using a pure copper sulfate/sulfuric acid electrolyte.

Experimental

The apparatus used is depicted schematically in Fig. 1. A time swept cathode/reference potential (2500 mV/min) was generated through a potentiostat circuit consisting of a motor potentiometer (ramp generator), operational amplifier (OA), and electrometer to feed back the reference potential. Cell current was monitored by a current-sensing resistor and continuously recorded on a strip chart recorder along with the potential of the reference electrode. With this equipment the cathode potential could be linearly increased from ~0V *vs.* reference.

The platinum rotated disk cathode[2] was cleaned prior to each experiment by a chromic acid/HCl sequence with multiple rinses. An experimental check of the actual cathode area using published (1) diffusion coefficient data for a $AgNO_3/KNO_3$ electrolyte agreed within 1% with the calculated geometric area. The electrolyte contained 8.379×10^{-4} m/liter of $AgNO_3$ and 0.2 m/liter of KNO_3 and had a kinematic viscosity of 0.874 centistokes measured at 25.0°C.

The reference electrode was fabricated from 99.999% pure OFHC copper wire coiled in a burette containing the test solution and connected to the electrolysis cell by a capillary tube. The capillary was drawn to a tip diameter of ~0.2 mm, and the tip was located in the plane of the RDE as near to the electrode as was possible. The electrolysis cell was immersed in a water bath (not shown on Fig. 1) maintained at 25.0° ± 0.2°C. Nitrogen gas was bubbled through the cell prior to all runs, and a positive nitrogen pressure was maintained over the solution during experiments.

All electrolytes were prepared using triply distilled water. Special care was taken to purify the solutions

by H_2O_2 and carbon treatments and by pre-electrolysis at ~10 mA/cm² for about 15 hr. The Cu^{++} concentration of the fluoborate electrolyte was determined to be 0.072 moles/liter by atomic absorption spectroscopy, and the kinematic viscosity of the electrolyte was 0.876 centistokes at 25.0°C. Titrations with EDTA established the Cu^{++} concentration as 0.100 moles/liter in the sulfate electrolyte, while measurements at 25.0°C resulted in a value of 1.041 centistokes for the kinematic viscosity. The fluoborate solution contained 1.0 moles/liter of fluoboric acid and the sulfate solution contained 1.0 moles/liter of sulfuric acid. All physical properties were measured after the solutions were purified and pre-electrolyzed.

Procedure

Determination of the limiting current for copper deposition was conducted with approximately 450 ml of test solution that had been purged with nitrogen gas for 45 min minimum. After purging, the potential of the RDE was adjusted to +50 mV relative to the reference electrode and held at that value for 60 sec. The cathode potential was then forced to negative values at a sweep rate of 2500 mV/min. Electrolysis was continued until the limiting deposition current was exceeded (as evidenced by the abrupt slope increase of the i-E curve), an operation which required about 30 sec.

The kinetic parameters α_c and i_o were evaluated from that portion of the i-E curve corresponding to the Tafel region ($\eta < -50$ mV) (2). To obtain usable curves for analysis, the plating procedure was modified from that used in determining the limiting currents. Prior to the determination of the i-E relationship for the test solution, the platinum RDE was copper plated at ~2 mA/cm² for 5 min to effectively transform the platinum electrode to a copper electrode. (The potential difference between the copper plated RDE and the copper reference electrode was measured as −3.9 mV). The RDE was then swept to negative potentials at 250 mV/min until a current corresponding to ~0.1 i_L was reached. All kinetic parameter experiments were performed at 900 rpm.

Regressions of i_L on $\omega^{1/2}$ and log i on $-\eta_A$ were performed using a computer CALL/360 STATPACK[3] statistical package.

Results and Discussion

The diffusion coefficient of copper ions.—The diffusion coefficients of Cu^{++} ions in the solutions studied were calculated from the slopes of the i_L *vs.* $\omega^{1/2}$ relationship derived by Levich (3), according to the following equation

$$i_L = 0.62\, n\, \mathbf{F}\, A\, D^{2/3}\, \upsilon^{-1/6}\, C_B\, \omega^{1/2} \qquad [1]$$

A family of curves representing experiments using the 0.072 molar copper fluoborate electrolyte is shown in Fig. 2. Results of the regressions of i_L on $\omega^{1/2}$ along with the values of D_{CU++} calculated from the regression slopes are shown on Fig. 3 and contained in Table I. The regressions included a minimum of five

i_L values at 400, 900, 1600, and 2500 rpm. Rotation rates >2500 rpm produced turbulent fluid flow at the surface of the disk (4). The area of the cathode was taken as 0.453 cm², the concentration of Cu^{++} ions was 0.072 molar in the fluoborate electrolytes and 0.100 molar in the sulfate electrolyte, and n was taken as 2. In both instances the i_L values were directly proportional to $\omega^{1/2}$ and obeyed an equation of the following form:

$$i_L = a + b\, \omega^{1/2}$$

where a and b were positive numbers. The small values of a have no physical significance and are probably due to anomalous experimental effects discussed by Adams (1) and Riddiford (5).

The diffusion coefficient for the Cu^{++} ion in the 0.100M $CuSO_4$/1.0M H_2SO_4 electrolyte was found to be 5.23 ± 0.13 × 10^{-6} cm^2/sec at 25.0°C. Because the deposition of copper from acidified solutions has been repeatedly used in recent years as an indicator reaction for the determination of mass transfer coefficients, comparisons of the value obtained in this work with values obtained by other experimenters was easily accomplished. The diffusion coefficient calculated in this work showed good agreement with reported values obtained in similar $CuSO_4/H_2SO_4$ electrolytes, as shown in Table II.

These results lend credibility to the accuracy of the basic RDE technique employed in this investigation. Bearing in mind that the diffusion coefficient obtained in the copper fluoborate electrolyte was 9.88 ± 0.05 × 10^{-6} cm^2/sec at 25.0°C and that the techniques used for both sulfate and fluoborate electrolytes were identical, one must conclude that the observed difference in diffusivities is a real and accurate effect of the different electrolytes employed. No sound explanation of the cause of the difference in diffusivities can be formulated at this time.

The kinetic parameters governing copper deposition.—The kinetic parameters of deposition can be determined from examination of the current-potential characteristics of the electrolyte, which can be described by the following equation (2)

$$i = i_o \left[\exp \frac{-\alpha_c \eta_A F}{RT} - \exp \frac{\alpha_a \eta_A F}{RT}\right] \quad [2]$$

If η_A is more negative than about 50 mV, the second term in the brackets of Eq. [2] can be neglected, and taking logarithms yields

$$\eta_A = \frac{RT}{\alpha_c F} \ln i_o - \frac{RT}{\alpha_c F} \ln i \quad [3]$$

The kinetic parameters α_c and i_o can be obtained from the slope and intercept, respectively, of a plot of η_A *vs.* ln i. The effect of addition agents on copper deposition should be embodied in the resulting kinetic parameters for the process.

Because of the procedure used in this work, it was more convenient to prepare curves of log i *vs.* $-\eta_A$ for determination of α_c and i_o. The slope of the log i *vs.* $-\eta_A$ curve equals $\alpha_c/0.060$ at 25.0°C, while the intercept at $\eta_A = 0$ yields log i_o directly. Values for $-\eta_A$ could be estimated to ± 1 mV accuracy. Regressions of log i on $-\eta_A$ contained data from 10 duplicate runs for the pure copper sulfate electrolyte, 7 duplicate runs for the pure fluoborate electrolyte and for each concentration of Cubath Hy and thiourea in copper fluoborate, and 5 duplicate runs for gelatin in copper fluoborate. Results are shown on Fig. 4 and 5 and listed in Table III.

The regression analysis performed on the log $i/-\eta_A$ data for the 0.100M $CuSO_4$/1.0M H_2SO_4 solution produced values of 0.35 for α_c and 1.09 mA/cm^2 for i_o. The value for α_c is considerably smaller than the value of 0.59 obtained by Johnson and Turner (2) for a 1.0M $CuSO_4$/1.0M H_2SO_4 solution, the values of 0.47-0.51 obtained by Hayashi and co-workers (9) for a 0.5M $CuSO_4$ solution containing either 0.25M or 1.0M H_2SO_4, and the values of 0.41, 0.45, and 0.49 reported by Radovici and Vass (10) for copper deposition from electrolytes containing 0.05M, 0.25M, and 0.50M $CuSO_4$, respectively, (1.0M H_2SO_4). The exchange current density could not be compared directly with literature values because of differences in the Cu^{++} concen-

tration between published work and this work. However, using the following equation presented by Laitinen (11)

$$i_o = n\,\mathbf{F}\,K_s\,C_{Cu^{++}}{}^{\alpha_c} \qquad [4]$$

where K_s (cm/sec) is the heterogeneous rate constant for the deposition reaction and other symbols have their previously designated meanings, modifications of the i_o value obtained in this work corresponding to the different Cu^{++} concentrations reported in the literature could be made, so that the various values could be compared. Results of this analysis are contained in Table IV. A larger value of α_c would have resulted in closer agreement among published values and the one obtained experimentally from the 0.100M $CuSO_4$ electrolyte.

The values of α_c and i_o derived from the fluoborate electrolytes could not be compared with any published values, for no experimental data have been published. However, no significant difference existed between $\alpha_c = 0.30$ and $i_o = 0.91$ mA/cm² obtained from the additive-free fluoborate electrolyte and the corresponding values from the sulfate electrolyte. Correction of i_o to correspond to a Cu^{++} concentration of 0.100M resulted in a value of 1.02 mA/cm² which is close to the 1.09 mA/cm² obtained from the $CuSO_4$ solution.

Results using additions of Cubath Hy to the pure copper fluoborate electrolyte have been presented in Table III. Generally, they were consistent with what was expected, *i.e.*, increasing concentrations of Cubath Hy produced lower values of α_c and i_o than were obtained with the pure electrolyte. The transfer coefficient was found to be more sensitive to changes in Cubath Hy concentration than was the exchange current density. For example, α_c decreased from 0.30 to 0.25 to 0.18 to 0.15 as the additive concentration increased from 0 to 3.0 to 8.0 to 14 ml/liter, respectively. Because the Cubath Hy additive was proprietary and of unknown composition, no analyses could be formulated.

Table IV. Comparison of modified values of i_o (modified to compensate for different Cu^{++} ion concentrations) from 0.1M $CuSO_4$ with reported values at different Cu^{++} ion concentrations

$CuSO_4$ Molarity	H_2SO_4 Molarity	i_o, mA/cm² Published values (Reference)	i_o, mA/cm² This work	i_o, mA/cm² This work adjusted per Eq. [4]
0.10	1.0	None	1.09	1.09
0.25	0.1	1-2 (12)	1.09	1.50
0.50	1.0	2.5-3.6 (9)	1.09	1.92
1.00	1.0	3.0 (2)	1.09	2.46

The effect of thiourea on copper deposition from the fluoborate electrolyte was less well-behaved than was the effect of Cubath Hy. The transfer coefficient for copper plating remained fairly constant as the concentration of thiourea was increased to 2.28×10^{-3} g/liter; however, at a thiourea concentration of 3.30×10^{-2} g/liter the transfer coefficient changed abruptly to a value of 0.05. On the other hand, the exchange current density was found to decrease to a value of ~0.6 mA/cm² as the thiourea concentration was increased to 2.28×10^{-3} g/liter, and then to abruptly increase to 1.04 mA/cm² at a concentration of 3.30×10^{-2} g/liter. Johnson and Turner (2) saw a similar trend in α_c with increasing thiourea concentrations in a sulfate electrolyte, *i.e.*, α_c decreased from 0.59 to 0.20 with the addition of 3×10^{-2} g/liter of thiourea to the electrolyte. The corresponding exchange current density increased from ~3 mA/cm² (additive-free electrolyte) to ~10 mA/cm² at a thiourea concentration of ~10^{-4} g/liter, and then it gradually decreased with increasing thiourea to the original value at 3×10^{-2} g/liter of thiourea. It is noteworthy that i_o reverted to the original values for both electrolytes at about the same thiourea concentrations. The contrary behaviors at the intermediate concentrations is unexplainable.

It is interesting to note that the concentration of thiourea that resulted in the 0.05 value for α_c was very near that concentration found to produce discontinuous copper electroplates in previously conducted leveling ability experiments (4). It was possible that the cathode efficiency for copper plating in that work was far less than that for the pure copper fluoborate electrolyte (as evidenced by the absence of plated copper from most of the cathode surface). This suggests that thiourea could have complexed cuprous ions as they were formed to prevent complete reduction to metallic copper. Also, it is possible that only a small percentage of the applied overpotential was being utilized to deposit copper, and that much of the applied overpotential could have been used to reduce thiourea to products that "poisoned" the cathode surface to copper deposition

With the addition of 3.2×10^{-2} g/liter of gelatin to the copper fluoborate electrolyte the transfer coefficient increased to 0.37 and the exchange current density decreased to 0.24 mA/cm², compared to values obtained from the pure electrolyte. A similar decrease in the exchange current density had been observed by Johnson and Turner (2). With the addition of 3×10^{-3} g/liter of gelatin to their $CuSO_4$ test solution, they observed a tenfold reduction in i_o from the value of ~3 mA/cm² obtained in their additive-free solution.

Acknowledgments

The authors would like to thank Mr. Robert E. Visco for his continuing interest and valuable suggestions during the course of this work.

ABSTRACT

The adsorption and oxidation of ethanol has been studied in 1*N* H_2SO_4 on bright platinum. Adsorption of two species, one cathodically desorbable, the other nondesorbable, has been found over the potential region 0.05-0.8V. The reaction rate is independent of *p*H at constant overpotential and the reaction is first order in ethanol, at low concentrations, tending toward zero order at high concentrations. The *i-V* curve shows current inhibition above about 0.6V. Possible reaction schemes are discussed in the light of the findings.

The mechanism of the oxidation of ethanol at platinum electrodes has been the subject of attention during recent years (1-4). Probably the most significant studies are those of Rightmire *et al.* (2) and Frumkin (3). Rightmire *et al.* (2) used quasi-steady-state methods (slow potentiodynamic sweeps) coupled with chemical product analysis to investigate the reaction in the potential range up to 0.8V. They proposed a mechanism which involved an electrochemical rate-limiting step preceded by a chemisorption/oxidation step, viz.

$$CH_3 \cdot CH_2 \cdot OH \rightarrow CH_3 \cdot \overset{*}{C}HOH + H^+ + \epsilon$$

and

$$CH_3 \cdot CHOH \rightarrow CH_3 \cdot CHO + H^+ + \epsilon$$

Frumkin (3) carried out similar studies with the addition of experiments in which potential changes, following open-circuit decay from more anodic potentials, were made. Among the products found on analysis were ethane and methane. From these results Frumkin deduced that the initial chemisorption step is rate determining. In addition, slow charging curves demonstrated that the chemisorbed species oxidized at a rate two orders of magnitude lower than did ethanol itself and therefore was regarded as a "poison" rather than an adsorbed intermediate in the over-all reaction. Franklin (4) in his studies showed that the rate was first order in ethanol at concentrations <0.3M but tended toward zero order above this.

In contrast to methanol (5, 6) except where formaldehyde is formed only under unusual conditions (7), and hydrocarbons (8-11) where carbon dioxide and water are formed as sole oxidation products, ethanol (2) and higher alcohols (12) are only partially oxidized to the corresponding aldehydes. It is this fact that makes the reaction an interesting one.

In the present work the studies have been extended to examine the nature of the adsorbate in terms of cathodically desorbable and nondesorbable species in the potential range 0.05-0.9V.

Two distinct species have been identified and their role in the over-all reaction is discussed.

Key words: ethanol, oxidation, adsorbate.

Experimental

Equipment.—The electrochemical cell used has been described previously (13). Potential profiles and potential sweeps were obtained from a pulse generator designed in these laboratories, the signal being fed into a Chemical Electronics 1.6A valve potentiostat. The *i-t* transients were displayed on a Tektronix 502A dual beam oscilloscope and photographed. The oscilloscope was operated in a triggered time-base mode at the beginning of the potential ramp or step of interest.

The *i-t* transient was displayed on the upper beam and the potential ramp or step on the lower beam of the oscilloscope. All measurements were made at 30°C.

Test electrode.—This consisted of a 0.0254 cm diameter platinum wire (Johnson-Matthey) which was first cleaned in hot 1:1 v/v (volume/volume) HNO_3/H_2SO_4 followed by washing with distilled water, and was then annealed in a hydrogen atmosphere at 700°C for 7 hr. The electrode was then sealed into Pyrex glass, a heat sink being used to conduct the heat away from the exposed wire, and the electrode again heated to 450°C in a hydrogen atmosphere for 8 hr, and allowed to cool in hydrogen until required. The exposed geometric area of the electrode was 0.075 cm^2 and the hydrogen deposition charge from 0.4V was 24.2 $\mu C\text{-}cm^{-2}$. This indicated a roughness factor of *ca.* 1.5 if 210 $\mu C\text{-}cm^{-2}$ was taken as the charge for hydrogen deposition (14).

All charges are reported on the basis of the true electrode area based on hydrogen deposition measurements and all potentials are referred to the hydrogen electrode in the same electrolyte. No correction to the potentials was necessary in the presence of ethanol.

Electrolyte.—In all the studies, 1*N* sulfuric acid was used and was prepared by dilution of B.D.H. Aristar grade with triply distilled water. Pre-electrolysis for 48-72 hr at 0.48V was carried out in all experiments, vigorous argon gas stirring was applied during this period. The pre-electrolysis electrode was raised into the gas space. Variation of greater than 10% in the anodic or cathodic charges after 5-min adsorption at 0.4V, with respect to the charges corresponding to adsorption for 10 millisec were rejected. Argon purge gas was Air Products prepurified grade.

Reactants.—Ethanol was B.D.H. Aristar grade and was used without further purification. Ethanol was introduced into the cell through Teflon tubing which had been previously cleaned with 1:1 v/v HNO_3/H_2SO_4 followed by copious washing with triply distilled water and finally dried by purging with argon for two days. The ethanol was introduced into a vessel where it was purged with argon for 1 hr before the required volume was transferred to the cell via the Teflon tubing. A similar procedure was followed for the introduction of the ethanol into the anolyte presaturator. The concentration of ethanol used in the adsorption experiments was 0.1M.

Determination of current/voltage relationships.—A gas/ethanol stirred system was again employed, the results being obtained by setting the potential and then waiting until a steady current was attained before the next potential was set. A constant argon purge was maintained during the determination of the *i-V* curve so that acetaldehyde did not build up to any significant extent and itself become oxidized to acetic acid (2, 15). The *i-V* curve was obtained at four temperatures, and two concentrations at 30°C.

pH effect.—The reference electrode was a bubbling hydrogen electrode placed in the same electrolyte as the anode. The ethanol concentration was 0.1M. The base electrolyte was 1*N* potassium sulfate and the pH monitored using a Pye Dynacap. The pH's studied were 2.0, 3.5, 6.1, 7.4, 9.8, and 11.3. Steady-state *i-V* curves were recorded. Stirring of the anolyte was achieved by means of an argon gas purge.

Concentration effect.—For these determinations 1*N* H_2SO_4 was used. Ethanol concentration was varied from 0.02 to 5M. The results presented were obtained with the aid of cyclic voltammetry, with a sweep rate of 0.048 $V\text{-}sec^{-1}$.

Results

In the pH experiments the current values at constant overpotential showed poor correlation, nevertheless it was clear that $(d \log i/dpH)_\eta \simeq 0$.

Concentration effect.—The variation of the logarithm of the current as a function of the logarithm of the concentration, over the range 0.02-5.0M ethanol, is shown in Fig. 1 for 0.55V, within the approximate Tafel region. It may be seen that the rate starts off first order in ethanol, but approaches zero order as the concentration increases above about 0.5M. This was also observed by Franklin (4). Steady-state measurements also verified this and over the potential range 0.55-0.9V a similar concentration dependence was observed.

Current-potential relationship.—The steady-state *i-V* curves for the oxidation of 1M ethanol on bright platinum at a series of temperatures are shown in Fig. 2 and for comparison 0.1M ethanol at 30°C is also shown. There is a linear Tafel region below about 0.6V followed by the appearance of a passivation region, which occurs below the potential at which significant amounts of chemisorbed oxygen have been detected by optical (16, 17) or electrochemical techniques (18, 19). The oxidation reaction is not therefore inhibited by chemisorbed oxygen in this region in the manner previously reported (10).

Characterization of adsorbate.—The data obtained, using the method described below, enable the coverage of the electrode by adsorbate to be characterized in a number of ways. Thus, the total coverage may be expressed as Q_{ox} (the amount of oxidizable material) or as θ^{org}, in which the adsorbate is defined in terms of the fraction of the electrode it covers. The results, expressed in either way, may be subdivided in terms of adsorbate which can be desorbed at cathodic poten-

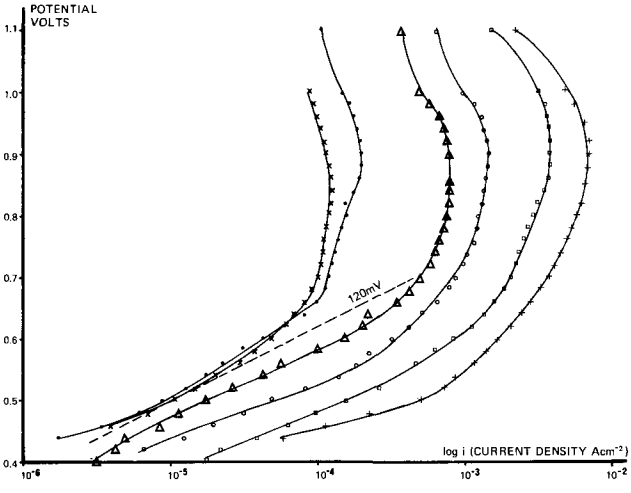

Fig. 2. *i-V* for ethanol oxidation on bright platinum in 1*N* H_2SO_4 at several temperatures. x 0.1M C_2H_5OH, 30°C; ● 1.0M C_2H_5OH, 0°C; △ 1.0M C_2H_5OH, 15°C; ○ 1.0M C_2H_5OH, 30°C; □ 1.0M, C_2H_5OH, 45°C; + 1.0M C_2H_5OH, 60°C.

tials (type I) and that which cannot (type II). Furthermore, by use of Q_{ox}, *i.e.*, θ_{anodic} data, the quantity N_e may be defined, which is the number of electrons required to oxidize the adsorbate expressed on a "per site" basis.

The anodic charge Q_{ox}^{total}, was shown to be independent of the sweep rate over the range 140-1040 V-sec^{-1} for adsorption times 500 millisec to 100 sec at 0.4V. It was noted, however, from the shape of the charging curve that the transient was not identical to the argon blank although the charge under the curves were identical; this is probably attributable to a double layer effect. A sweep rate of 200 V-sec^{-1} was used for routine measurements. Potential sequence shown in Fig. 3A was used to obtain the anodic data. In the estimation of the charge corresponding to electrode coverage, Q_H^{total}, a sweep rate of 250 V-sec^{-1} was employed; no desorption of adsorbed ethanol at this sweep rate being observed. Potential sequence shown in Fig. 3A was again used.

In addition to the total charges, Q^{total}, determined using sequence 3A, the charges corresponding to the oxidation of cathodically nondesorbable material (designated type II) were obtained using potential sequence shown in Fig. 3B. The desorbable material (designated type I) was then obtained by difference. In addition to this, charges corresponding to hydrogen deposition after hydrocarbon adsorption (Q_H^{org}) and subsequent cathodic desorption (Q_H^{nondes}) were obtained (using the same potential sequence).

Figures 4 and 5 show the anodic and cathodic charge data after adsorption to equilibrium coverage. This was typically obtained after 600 sec, although it should be noted that at 0.05 and 0.1V equilibrium coverage may not necessarily have been achieved. The increase in cathodic charge with time, corresponding to type I and type II species at several potentials are shown in Fig. 6. Behavior was similar in the case of the anodic data, closely following the cathodic pattern of adsorption. It may be seen from Fig. 4 and 5 that for potentials below 0.3V type II species predominate, while at 0.3V and above type I species predominate. Type I species release significantly more electrons per site than the type II material.

The charges corresponding to type II observed above 0.7V may indicate the presence of adsorbed oxide due to the nature of the electrode pretreatment used in estimating the electrode coverage data.

Above 0.5-0.6V the electron per site values were observed to fall to fractional values if resolution of the

Discussion

There is little controversy regarding the over-all oxidation mechanism of ethanol. It is agreed by all authors that the major product of the oxidation process is acetaldehyde. Any acetic acid or carbon dioxide reported arise from conditions where significant quantities of acetaldehyde have been allowed to build up and separate studies on the oxidation of acetaldehyde (15) confirm this.

The incidence of ethane or methane as detectable products derived from ethanol arises when the electrode is taken (or decays on open circuit) to potentials where adsorbed hydrogen is present, and on this evidence, Frumkin postulated that the adsorbate consisted partially at least of CH_{ads} fragments, the result of cracking. The data presented here seek to verify the presence of such adsorbed fragments.

Steady-state current-voltage data.—The results shown in Fig. 2 are in accord with Frumkin (3) where the experimental conditions make comparison possible, *i.e.*, the Tafel slopes below 0.6V are similar, 90-110 mV. They disagree, however, with Rightmire (2) who obtained a rectilinear Tafel slope of 110 mV which extended up to about 0.75V. It is perhaps better appreciated now than formerly that nonsteady-state data has little significance and referring to Fig. 6 it will be seen that, over the period of 5 min during which Rightmire's sweeps (0.45-0.95V) were carried out, the amount of adsorbate and the ratio of the two components could change, and Tafel slopes so obtained are dependent on the sweep rate.

pH effects.—Regarding the poor correlation referred to in the results it should be noted that the possibility exists that aldehydic condensation or polymerization of the product, acetaldehyde, can occur which may explain the observed behavior. Conclusions similar to this were made by Liang (4) on the basis of the lack of charge linearity as a function of scanning frequency in solutions of high pH.

Nature of the adsorbate.—It is seen from Fig. 4 and 5 that the total charges for ethanol follow the characteristic bell-shaped isotherm typical of most hydrocarbons. Unusually high coverages of ethanol are measurable, however, at potentials as cathodic as 0.05V, where $\theta_{ethanol} = 0.67$ for an adsorption time of 10 min and is still rising. At this potential $\theta_H = 0.9$ in the absence of ethanol (20). This indicates, in general terms, formation of a much more strongly bound adsorbate than is the case with hydrocarbons. At 0V, however, electrode coverage with ethanol is zero.

Table I. Variation of electrons per site with potential

Potential	Type I species	Type II species
0.05	1.4	1.14
0.1	2.8	1.0
0.2	1.3	1.3
0.3	1.5	0.94
0.5	1.3	0.6
0.6	0.9	0.93

The electron per site values remain reasonably constant for the type II species, releasing $1.1 \pm 0.2e$ per site on oxidation at potentials 0.7V. The type I also remains constant yielding a somewhat higher value at most potentials. At 0.1V, however, a more highly reduced species (type I) is noted at adsorption times >50 sec, releasing *ca.* 2.8*e* per site. This is reflected in Fig. 4 and 5 where it is seen that adsorption maxima (anodic) and minima (cathodic) occur. This suggests that, at 0.1V pre-adsorbed hydrogen affects the mode of adsorption of ethanol.

From Fig. 4 and 5 it may be seen that the two adsorbed species are potential dependent, type II falling to zero coverage at 0.6-0.8V and type I at a slightly higher potential. The *e* values required for the oxidation of adsorbed ethanol, acetaldehyde, and acetic acid are significantly higher than those observed in this work. It is unlikely that these molecules in their uncracked states, contribute significantly to the adsorbate and it is, therefore, likely that the adsorbed species are in part cracked products of the parent molecule. This postulate is necessary to explain the observation that a nondesorbable species occurs, and to explain the higher *e* per site values noted for the type I species.

Kinetics of oxidation.—The following experimental facts need to be explained in any reaction sequence which is considered.

1. The rate of oxidation is substantially independent of pH (with the reference electrode in the same solution).
2. The reaction order with respect to ethanol over the initial concentration range (<0.5M) is first order but approaches zero order as the concentration of ethanol is increased.
3. The slope of the Tafel line progressively increases, except at potentials <0.6V where 90-110 mV is observed.
4. The coverage with adsorbed species decreases as the potential is increased from 0.3 → 0.7V.

Previously, Rightmire (2) proposed a reaction sequence in which the second electron transfer was rate determining although no quantitative analysis was presented, particularly with respect to the effect of pH or concentration. The reaction scheme proposed was

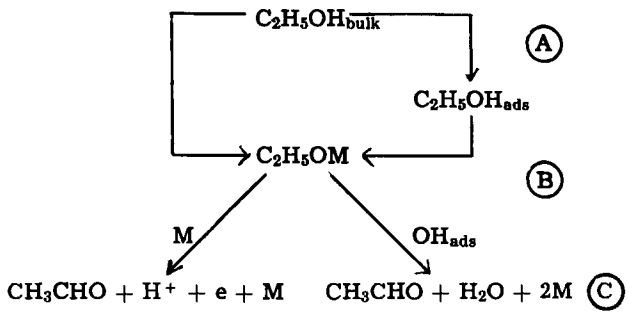
$$C_2H_5OH + M \rightarrow C_2H_5OM + H^+ + e \quad [1]$$

$$C_2H_5OM \rightarrow CH_3CHO + H^+ + e + M \quad [2]$$

Piersma and Gileadi (21) derived kinetic equations assuming that Eq. [1] was in pre-equilibrium, but were

unable to explain the reported experimental facts (4, 22) concerning the effects of concentration and pH.

Reaction schemes as shown below can be envisaged to summarize the possible reaction pathways



where A → B proceeds either directly or via an associative adsorption step.

B → C proceeds either via a second dehydrogenation step or via reaction with OH.

The main mechanistic possibilities are summarized above with the understanding that, as in so many electro-organic reactions, the simultaneous formation of a "poison" can slow any of the above reactions.

Two distinct types of mechanism are suggested.

(*a*) The first type involves dehydrogenation

$$C_2H_5OH + \text{free surface} \rightarrow C_2H_5OM + MH \quad [3]$$

$$MH \xrightarrow{\text{fast}} H^+ + M + e \quad [4]$$

$$C_2H_5OM \rightarrow CH_3CHO + M + H^+ + e \quad [5]$$

where Rightmire has suggested that [5] is rate determining

However, the question arises whether ethanol as reacting species is that to be found in the bulk solution or whether it is physically adsorbed. In the latter case in order to obtain agreement with our experimental results it would be necessary to postulate that such physically adsorbed ethanol, even present at appreciable coverage, is undetectable by the transient methods used here. In addition, it is necessary to explain why the reaction is not diffusion controlled, the rate under all conditions being many times smaller than the limiting current. The rate of this reaction would therefore be determined by the concentration of surface physically adsorbed ethanol and free surface. This mechanism would, however, give the observed parabolic or similar current voltage curve.

The observed first-order concentration in ethanol tending to zero order, which holds over the entire potential range studied here, can only be interpreted on the basis of a Langmuir or a Temkin-Frumkin (23, 24) isotherm applied to the physically adsorbed but undetectable ethanol.

A second mechanism which involves bare metal may be expressed by the following reaction sequence.

$$C_2H_5OH + M \xrightarrow{\text{slow}} C_2H_5OM + H^+ + e \quad [6]$$

$$C_2H_5OM \xrightarrow{\text{fast}} CH_3 \cdot CHO + H^+ + e + M \quad [7]$$

For Eq. [6] the rate equation can be expressed in Langmuir terms, viz.

$$v_{10} = k_{10}C_{C_2H_5OH}(1 - \theta_T)\exp\frac{\beta VF}{RT} \quad [8]$$

where θ_T is the total coverage with adsorbed species, the other terms having their usual significance.

This predicts a Tafel slope of 120 mV, which is close to that observed below 0.7V. This reaction scheme as it stands, however, does not explain all the observed experimental facts, particularly the progressively increasing slope and the observed reaction order. Both these shortcomings can be overcome if a surface poison derived from ethanol is postulated.

The simplest case involves a "poison" produced by an electrochemical mechanism

$$C_2H_5OH \rightleftharpoons \text{"poison"} + H^+ + e \quad [9]$$

$$\text{coverage} = \theta_P$$

In this hypothetical reaction sequence it must be assumed that the rate of removal of "poison" balances its formation in order that a "pseudo steady-state" is attained, the coverage potential dependence of the "poison" resulting in the increasing slope. Consider, therefore

$$\frac{\theta_p}{1 - \theta_T} = k_9 C_{C_2H_5OH}\exp\frac{VF}{RT} \quad [10]$$

If $\theta_T \equiv \theta_p$ then

$$\theta_p = \frac{k_9 C_{C_2H_5OH}\exp\frac{VF}{RT}}{1 + k_9 C_{C_2H_5OH}\exp\frac{VF}{RT}} \quad [11]$$

Substituting for $\theta_T \equiv \theta_p$ in [8] then

$$v_{10} = k_{10}C_{C_2H_5OH}\left[1 - \frac{k_9 C_{C_2H_5OH}\exp\frac{VF}{RT}}{1 + k_9 C_{C_2H_5OH}\exp\frac{VF}{RT}}\right]\exp\frac{\beta VF}{RT} \quad [12]$$

At low coverages with "poison" a Tafel slope of $2RT/F$ is predicted but as the potential increases and coverage with "poison" becomes important the slope observed will increase and eventually in the limit when $k_9 >> 1$ the slope will become $-2RT/F$, *i.e.*, inhibition (25-27) will be observed.

The variation of the rate with pH could be due to the formation of a "poison" which may explain the differences observed by Franklin (4); and in this present work, in passing from acid to alkaline electrolytes.

If the reaction order (25) is defined as $(d \ln i/d \ln C_{C_2H_5OH})_{V,pH}$ then using Eq. [8] and [9] the required reaction order is predicted. This analysis in combination with the experimental results could explain the experimental facts. It must be emphasized, however, that no "poison" has been detected in the adsorption studies, although a similar concept has been suggested by Brummer for formic acid oxidation (28). It is interesting that during experiments to examine time-effects at 0.65V the region where a sharp reduction in the oxidation rate occurred corresponded to the time where coverage with adsorbed ethanol became almost constant (Fig. 7). This suggests that ethanol predominantly undergoes oxidation on free surface [*cf.* Gilman (29)]. It is suggested, therefore, that competition for the active sites will be important.

(*b*) The second mechanism is similar to that widely accepted for a variety of anodic organic oxidations on platinum electrodes (10). Water is oxidized to form a species such as an OH radical which reacts on the surface with associatively adsorbed organic

$$C_2H_5OH_{bulk} \rightarrow C_2H_5OH_{ads} \quad [13]$$

$$H_2O \rightarrow H^+ + e + OH_{ads} \quad [14]$$

$$C_2H_5OH_{ads} + OH_{ads} \rightarrow C_2H_5OM + H_2O \quad [15]$$

$$C_2H_5OM \rightarrow CH_3CHO + H^+ + e + M \quad [16]$$

In the case of ethylene (10) which can be regarded as being strongly adsorbed, negative pressure effects support the hypothesis that increasing coverages with ethylene reduces the over-all reaction rate by reducing

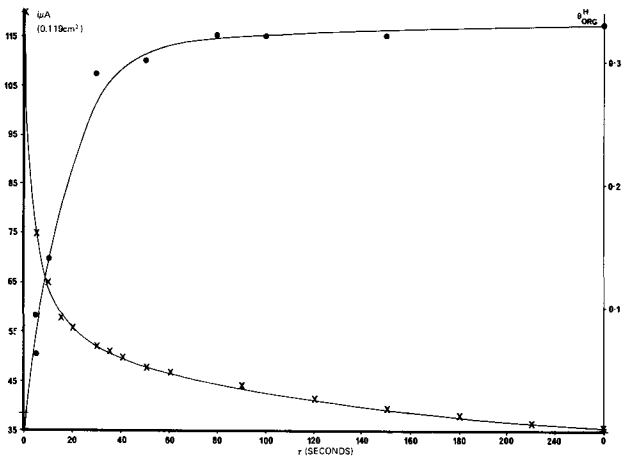


Fig. 7. Variation of ethanol coverage and oxidation current as a function of reaction time.

the coverage of the hydroxyl radicals. For a weakly adsorbed species such inhibition would not play such a dominant role and first-order reaction kinetics in organic at low concentration tending at higher concentrations to zero order would be expected. Such a mechanism then can explain the reaction order in ethanol. The apparent absence of adsorbate at higher potentials where the reaction is proceeding at a considerable rate can be explained on the same grounds as those used by Bockris *et al.* for the hydroxyl radical, namely, that although the concentration is small the rate per adsorbed molecule is extremely high. On this assumption step [14] might be considered to be rate determining and the observed i-V behavior could then be interpreted in terms of ever decreasing amounts of adsorbate. Similar arguments to those postulated by Bockris *et al.* (10) can be invoked to explain the pH effect observed here. One further observation is possibly relevant in considering Eq. [14]; if this mechanism is rate determining then a Tafel slope of $2RT/\mathbf{F}$ would be expected and indeed, if at each potential, the observed current is normalized to unit coverage of organic using the data shown in Fig. 5 a Tafel slope of $2RT/\mathbf{F}$ is obtained up to about 0.7V, beyond which values of θ are too small to be relied upon. This would suggest that OH_{ads} might be involved in the rate determining step. The normalized results are shown in Table II and in Fig. 2.

Another possibility is one in which ethanol is dissociatively chemisorbed and reacts with hydroxyl radicals according to Eq. [15] with Eq. [13] and [14] in pre-equilibrium. This reaction sequence results in a Tafel slope (Langmuir adsorption) at low coverage with hydroxyl species of $RT/2\mathbf{F}$ leading to a limiting slope as the coverage with hydroxyl species increases. This reaction sequence could explain the pH and concentration effects.

Table II. Normalized results

Potential	Deviation factor required to achieve slope of 120 mV	Relative reduction in $\theta^{H}_{ads\ total}$ with potential
0.50	0	0
0.55	1.1	1.18
0.60	1.52	1.57
0.65	2.58	2.46
0.7	4.9	4.0

Conclusions

Ethanol has been shown to adsorb on bright platinum over the potential region 0.05-0.8V, the adsorbate in general comprising a cathodically desorbable and nondesorbable species. These species give N_e values of 1.2 ± 0.3 and 1.1 ± 0.2 between 0.05V and 0.5-0.6V, respectively. A third species, cathodically desorbable, is indicated at long adsorption times at 0.1V and releases 2.8 electrons per site. Above 0.5-0.6V fractional N_e values are noted.

Two distinct mechanisms have been considered, dehydrogenation and reaction involving hydroxyl radicals. No single reaction scheme appears capable of explaining the observed current-voltage behavior although the role of free-surface seems important, indicating the possible formation of a "poison."

The Coexistence of Conductivity and Persistent Electrical Polarization in Polyelectrolyte Membranes

Charles Linder

Montefiore Hospital, Bronx, New York 10467

and Irving F. Miller*,[1]

Polytechnic Institute of Brooklyn, New York 11201

ABSTRACT

Persistent electrical polarization (heterocharged electret formation) and electrical conduction have been found to be compatible in polymer membranes consisting of mixtures of sodium polystyrenesulfonate and various polar polymer matrices. This compatibility is apparently the result of the fact that the mechanisms for these two phenomena are quite different. While the mechanism for conduction is probably electronic in this system, the persistent polarization is probably the result of microscopic displacement of some sodium ions from their fixed sulfonate sites and stabilization of these ions in new sites by interaction with surrounding molecules.

The phenomenon of persistent electrical polarization in materials has been of interest for many years. The phenomenon was first conceived as an electrical analog of a magnet by Heaviside (1) in 1885 and was first experimentally demonstrated by Eguchi (2) in 1922 in studies involving carnauba wax. It has been postulated that such polarization phenomena underlie many biological processes (3-5) and, indeed, the phenomenon has been used in such commercial devices as microphones, electrophotography, electrometers, etc. (6-8).

In spite of the fact that persistent electrical polarization phenomena seem to appear in such a wide variety of places, these phenomena are not too well understood. Since most of the early experimental studies were made with carnauba wax, most of the theoretical work has gone into a phenomenological description of the nature of the process in carnauba wax and the dynamics of its decay (6, 9, 10). As a result of this, most workers in the field still consider the phenomenon to take place essentially in dielectrics of a parallel plate condenser system (11).

Based on our present understanding, two different types of phenomena can be distinguished. When polarization is established by charging electrodes and when the sign of the charge on the surface of the material is the same as the charge on the adjacent electrode, the material is referred to as a homocharged electret. When the charge on the surface is opposite to the charge of the adjacent electrode, the material is referred to as a heterocharged electret (2, 10). Since the rates of formation and decay of homocharged electrets and heterocharged electrets are quite different, it is possible to distinguish between them in the same material.

Studies of homocharged electrets (12-14) indicate that they are formed essentially by absorption of charges by dielectric breakdown of the gas in a space between electrode and dielectric. On the other hand, heterocharged electrets have been shown to involve volume polarization (15) and have been shown to decay by mechanisms of dielectric relaxation (4, 11). In most cases, it is not known whether such heterocharge formation is due to dipole orientation, ion displacement, electron trapping, or some combination of these. Most studies of heterocharged electrets have involved electrical insulators and workers have postulated their formation to involve electron trapping (16) in some cases, or ion displacement of ionic impurities in other cases involving insulating plastics (17). In spite of the fact that a report has appeared in which large amounts of persistent heterocharged polarization was observed in a polyelectrolyte-polyethylene membrane that was a good electrical conductor (19) most workers in the field still state unequivocally that conductivity and electret formation are not compatible and that the electret phenomenon only becomes important when the resistance of the material increases. In fact, however, the incompatibility of electret formation and conductivity has been demonstrated only in insulators and mostly for homocharges.

It is the purpose of this report to present some results on heterocharge formation and conductivity in well-characterized polyelectrolyte-polar polymer membranes in which the polyelectrolyte is incorporated into the polar polymer matrix over a range of concentrations.

Experimental

Polyelectrolyte membranes were prepared with sodium polystyrenesulfonate (PSSNa) in a polar polymer matrix consisting either of poly(vinyl alcohol) (PVA), polyacrylamide (PAC), or polyvinylpyrrolidone (PVP). All polymers used were linear polymers and were purified by standard techniques typically involving dialysis against distilled water.

Membranes were formed by mixing appropriate amounts of the PSSNa and the particular matrix studied in distilled water and casting on a plate of polystyrene, or by pouring into a polystyrene petri dish approximately 44 mm in diameter. The water was then allowed to evaporate in a dust-free environment to form the membrane approximately 0.05 mm thick and the membranes were then preconditioned for 24 hr in a vacuum at 60°C to drive off most of the remaining water. The electrets were formed and characterized in a temperature-controlled vacuum oven able to maintain a controlled temperature to within ±0.2°C in the range 35°-98°C. The electrodes as well as the chamber were machined of naval bronze, and the electrode surfaces were coated with Aquadag (an aqueous carbon suspension from the Anderson Colloids Company) to reduce corrosion of the electrodes and subsequent membrane contamination.

In an experiment, the membrane was placed between the electrodes, the chamber was closed, and a vacuum was established. The chamber was brought to the desired charging temperature and the material was polarized by placing a battery in series with the membrane-electrode system for an arbitrary time, usually 90 min. During the charging cycle and subsequently during the stabilization and discharging cycle, the

current flowing across the membrane was monitored with a model 610-C Keithley Electrometer. After a fixed time of charging, the system was cooled to room temperature at about 5°C per min while maintaining the charging field intact. As in the formation cycle, the membrane current and temperature were recorded throughout.

At room temperature the voltage was removed and the discharge current measured. The discharge current, consisting of free capacitor charge and dielectric absorption not frozen in, decayed exponentially by about 3 orders of magnitude over the 90 min in which the decay current was monitored.

To measure the amount of charge frozen in, the membranes were reheated to 10°C above the temperature of polarization at the rate of 2°C per min. The depolarization current was measured during the heating process and for an additional time required for the current to decay at least 1.5 orders of magnitude from its peak value at the elevated temperature. The measured current integrated over the time of measurement was taken as the amount of frozen polarization per unit area of the membrane. In all depolarization measurements, the currents flowed in the opposite direction from the charging currents, thus indicating heterocharge formation with no sign of homocharge.

The membrane conductivity was calculated from the polarization currents measured at the end of the polarization period before cooling. The reported values are, therefore, for the fully polarized membrane electret. Further details of the experimental techniques utilized may be found in Ref. (20).

All data points presented represent an average of at least 3 separate experiments, with a reproducibility of ±10%.

Results

Figure 1 presents the results obtained for both persistent polarization and conductivity for PSSNa-PVA membranes polarized at 76°C and a charging field of approximately 4.5 kV/cm for 90 min. Although there is a significant difference in the shape of the two curves, the main point to be noted is that both persistent polarization (in this case heterocharge formation) and membrane conductivity increase together. Results for the PSSNa-PVA system were also obtained under a wide variety of other operating conditions of temperature and polarization field. Figure 1 is typical of the results obtained.

Figures 2 and 3 represent typical results obtained for the PSSNa-PAC system and the PSSNa-PVP system, respectively, under the same conditions, namely, 76°C and a field of approximately 4.5 kV/cm for 90 min to achieve polarization. Again, it must be noted that although the shapes of the curves vary considerably, the general trend is that polarization and membrane conductivity increase together.

It might be noted from Fig. 1-3 that there is a significant change in shape for the curves as one increases the PSSNa concentration beyond a mole fraction of about 0.3. A detailed analysis of the shape of these curves has been presented elsewhere (21) and will not be repeated here. However, in summary, what seems to be involved is an indication that the chief mechanism for heterocharge electret formation involves interactions between the polarizable groups on the PSSNa and adjacent molecules. At low concentrations of PSSNa, the predominant interaction is between a PSSNa group and adjacent matrix molecules. At higher concentrations of PSSNa, the predominant interaction involves two or more adjacent PSSNa groups. Since the nature of the interaction between PSSNa and the matrix group is quite different when the matrix is PVA or PAC or PVP, the variation in shape from Fig. 1-3 can be explained on this basis. It may be noted that at higher PSSNa concentrations all three systems approach a common behavior.

An estimate of the stability of the electret presented in Fig. 1-3 can be made by taking the ratio of the total stored charge to the discharging current just prior to

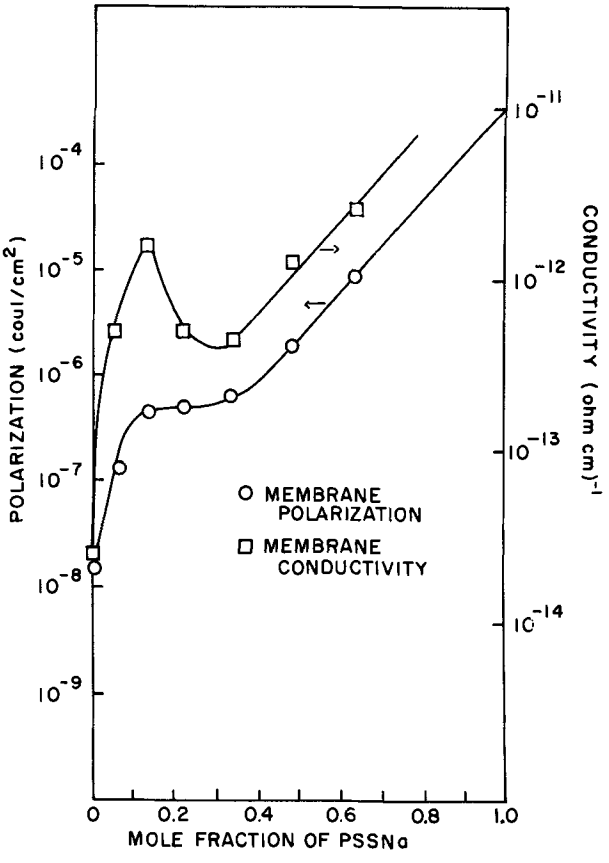

Fig. 1. Membrane polarization and conductivity vs. mole fraction of PSSNa in PVA. Polarization was at 76°C and 4.5 kV/cm for 90 min.

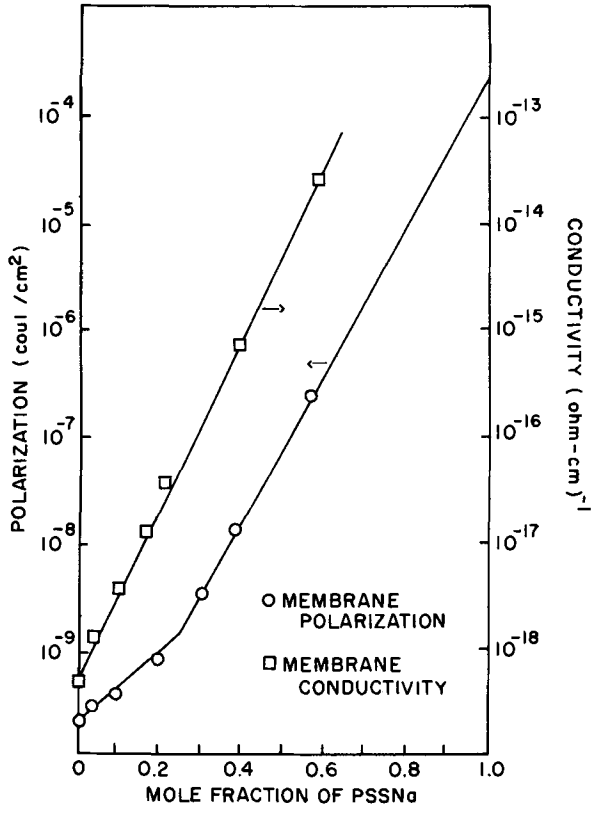

Fig. 2. Membrane polarization and conductivity vs. mole fraction of PSSNa in PAC. Polarization was at 76°C and 4.5 kV/cm for 90 min.

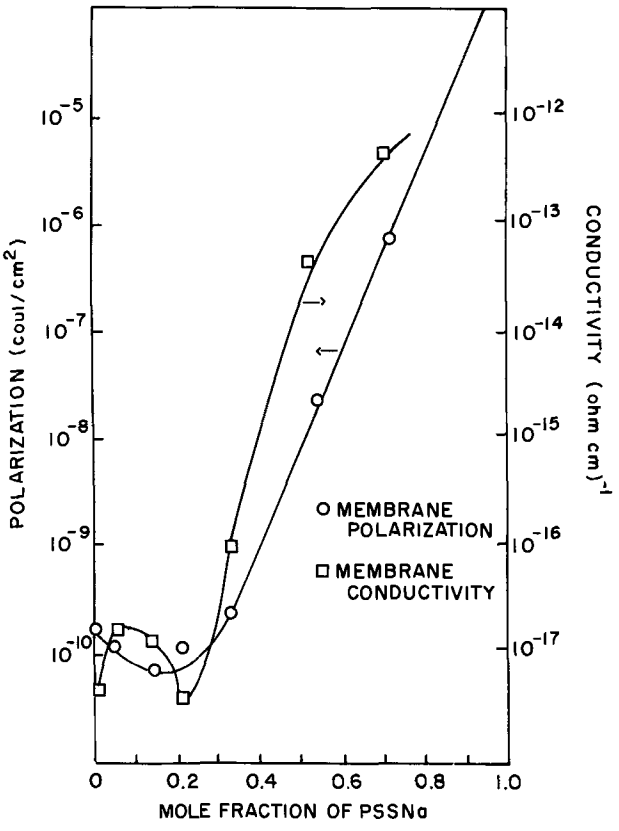

Fig. 3. Membrane polarization and conductivity vs. mole fraction of PSSNa in PVP. Polarization was at 76°C and 4.5 kV/cm for 90 min.

thermal depolarization. Since the discharging current decreases with time, this ratio will be an estimate of the lower limit of the time it would take totally to discharge the electret at room temperature. Estimates of membrane stability calculated in this way are presented in Table I. From Table I it should be noted that an increase in membrane conductivity does not necessarily decrease the apparent stability of the electret and in many cases actually increases the stability. In order to explain such results, one is forced to the conclusion that the mechanism of conduction and persistent polarization must be different. In particular, space charge formation via conduction currents as a mechanism for the persistent polarization observed is essentially ruled out.

Figures 4 and 5 represent results obtained for the amount of persistent polarization and the membrane

conductivity, respectively, for a series of PSSNa-PVA membranes of varying composition at different temperatures between 66° and 94°C. The amount of persistent polarization and the membrane conductivity are both seen to increase substantially as the temperature is increased. The break seen in the curves for both polarization and conductivity correspond to the glass transition temperature of the system, known to be in the neighborhood of 86°C. Above the glass transition temperature, T_g, the free volume for long-range correlation of segmental movement is considerably greater than below T_g and a different mechanism of response to an external force is possible. This change in response mechanism shows up as a change in slope on Fig. 4 and 5. The slope on Fig. 4 and 5 can be thought of as a "heat of polarization" and a "heat of conductivity," respectively, by analogy to the van't Hoff equation, in which a standard "heat of reaction" is determined from the temperature dependence of a chemical equilibrium constant. It should be noted that above T_g there is a strong similarity between the calculated heats for conduction and polarization in PSSNa-PVA membranes. The calculated heats are 24.5 ± 1.4 kcal/mole, and 26.2 ± 1.1 kcal/mole for the conduction and polarization processes, respectively, above T_g. The similarities between the two heats indicate a similarity in the thermal response of the material to the two phenomena. It should be noted that such a similarity does not exist below T_g where the calculated heat for conduction is considerably higher than that for polarization.

Discussion

From the results obtained in this study, it is clear that the nature of the heterocharge in these polyelectrolyte membranes is that of a volume polarization rather than space charge formation. Clearly, space charge formation is incompatible with a conductive membrane system. In addition, it was observed that the position of the peak of the thermal depolarization curve (current *vs.* time) was found to be independent of applied field intensity for a constant heating rate for nearly all the membranes studied. This would be expected for homogeneous volume polarization but not space charge formation (22). Since the membranes were found to obey Ohm's law throughout the voltage range studied, with no rectification, and since all the experiments were performed in vacuum, it is likely that the conduction mechanism is electronic. Therefore, the persistent polarization mechanism must involve a volume polarization in the vacuum independent of the electronic conduction current.

Clearly, different mechanisms must be postulated for the polarization process and the conduction process although each mechanism must be dependent on the same property of the material. If the conduction phenomenon is electronic, the important factors are the concentration of electrons and their mobility (6). Increasing the concentration of PSSNa increases the polarity of the material as characterized by an increase in the dielectric constant. The higher the dielectric constant, the easier it is to ionize electrons from sites or valence bands into other sites further down the field or into the conduction band, respectively. Electron injection from the electrodes is also facilitated if the dielectric is highly polar. Besides increasing the number of electrons participating in the conduction process, an increase in PSSNa concentration also increases the electron mobility. If the conduction process is that of electron hopping, then a higher density of sites (which are postulated to be PSSNa monomer units) would decrease the distance between hops and thus increase mobility. If the process is via a conduction band mechanism, the width of the band is increased at a higher density of polar sites because there is a more efficient overlapping of the electrostatic fields from one site to another.

In the polarization process, on the other hand, the electrostatic units are postulated to be ensembles of sodium sulfonate groups of the PSSNa monomer. Under an electric field these structures would form larger dipole structures in the general direction of the field by ionizing the Na^+ ion to a neighboring site. The higher the concentration of PSSNa, the larger is the dielectric constant and, thus, the easier it would be to ionize the Na^+ ion from its parent sulfonate group. An increase in PSSNa concentration also increases the number of sites available to receive the Na^+ ion and, thus, the stability of the final electret structure. In this model it is presumed that matrix molecules also participate in stabilizing the electret structure. A detailed presentation of this model is presented in Ref. (21). Thus, polarization is characterized by the formation of electrostatic structures with the direction of the applied electric field and which could form additional conductive pathways for electron conductivity. The possibility of polarization producing conductive channels through the membrane could explain why the conductivity of some membranes increases with time (see Fig. 6).

Since both the conduction and polarization process depend on the local electrostatic fields in the same way, and since the concentration of PSSNa as well as the thermal energy content of the system (that is, the temperature) affect these fields, one should also expect that polarization and conductivity increase with PSSNa concentration and the observation that the heat for both of these processes is similar in a given temperature range is to be expected.

Conclusions

Experimental results obtained on a series of PSSNa-polar polymer membranes have demonstrated that persistent polarization (heterocharged electret formation) and electrical conduction are compatible in the same system. This compatibility is apparently the result of the fact that the mechanisms for persistent polarization and electrical conduction are different. Although the mechanism for electrical conduction is probably electronic in this system, the mechanism for heterocharge electret formation probably involves microscopic displacement of some sodium ions from their fixed sulfonate sites and stabilization of these ions in new sites by interaction with surrounding molecules. Historically, persistent polarization and electrical conduction in the same system have been thought to be incompatible. However, this conclusion was formed as a result of studies on simple insulator systems. Clearly, the mechanisms of electrical conduction and charge storage in such simple systems should be differ-

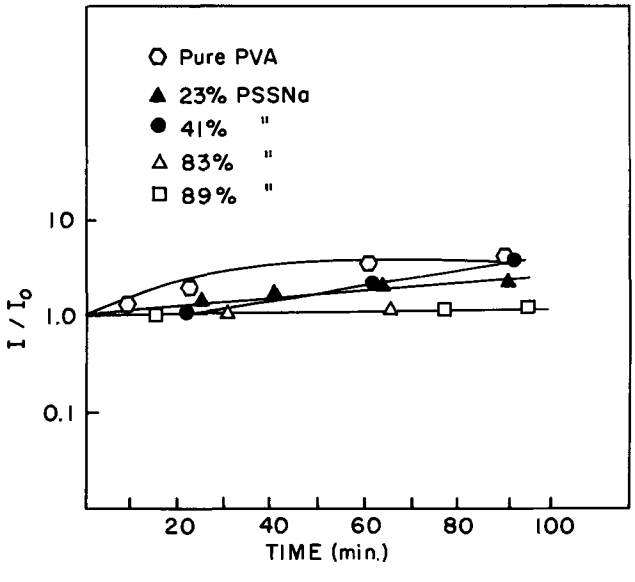

Fig. 6. Relative change in polarization current *vs.* time of polarization for PSSNa-PVA membranes.

ent than the mechanisms for such phenomena in semiconductors, complex biological systems, or the system studied in the work presented herein. The main conclusion of this work, therefore, must lie in the inappropriateness of assuming a basic incompatibility of persistent polarization and conduction, in general, from results obtained on studies only of simple insulator systems.

Acknowledgment

This work is based on part of a thesis submitted by Charles Linder in partial fulfillment of the requirements for the Ph.D. degree in Polymer Chemistry at the Polytechnic Institute of Brooklyn. The work was partially supported by a grant from the National Institutes of Health under grant no. GM-12013.

Manuscript submitted May 4, 1972; revised manuscript received Oct. 16, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Generative and Stabilizing Processes in Tin-Palladium Sols and Palladium Sol Sensitizers

R. L. Cohen and K. W. West

Bell Telephone Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

An extensive study of sol systems produced by the reduction of solvated Pd by Sn^{2+} is presented. We show that the reaction is initiated by the formation of a polynuclear Sn-Pd complex, which is autoreductive, yielding sol particles of a Sn-Pd alloy core with a stabilizing layer of Sn^{2+} ions. The role of the Sn^{2+} stabilizing layer in controlling particle size is discussed in detail. We apply the knowledge of these systems to understand similar processes occurring in commercial Pd sol systems used for sensitizing insulating surfaces for electroless plating. The chemistry of the sensitizing layer generated by these systems has also been studied. The sol sedimentation rate has been studied by centrifugation. Most of the investigation has been carried out via Mössbauer spectroscopy; precise isomer shift parameters for a number of Sn-Pd compounds are reported.

Electroless plating to metalize insulating substrates generally requires a preliminary treatment of the surface to make it catalytic (also called "active" or "sensitive") to initiate the deposition of metal from the electroless bath. An overview of the approaches used has been given by Goldie (1). For many years, the most common preparation process was a two-stage treatment, in which the surface was immersed first in a dilute stannous chloride solution, and then in a dilute palladium chloride solution. We have recently reported (2, 3) a detailed description of the chemical processes and reactions of the two-step process, based on the results of Mössbauer spectroscopy measurements on the tin compounds and complexes formed.

Key words: sensitization, colloids, tin chemistry, palladium chemistry, Mössbauer spectroscopy.

More recently, a number of proprietary systems achieving "sensitization" with only a single-stage treatment have become available. The advantage of the single-stage system goes beyond the elimination of one bath; it makes possible the elimination of intermediate washes, re-racking, and drag-in problems. A number of proprietary[1] single-stage sensitizers are available; all involve tin and palladium. Two of the systems (4, 5) are stated to be Pd sols stabilized by a "protective colloid." These systems are somewhat similar involving mixtures of Sn^{2+} and Pd^{2+} ions, HCl, and water; the concentrations and order of addition are varied. Tetravalent tin may be also added to

[1] The proprietary single-stage sensitizers referred to are the Shipley Corporation 6F sensitizer (4), the MacDermid Corporation Metex PTH 9070 sensitizer (5), and the Dynachem Corporation Activator 101 and 120.

improve wetting of hydrophobic substrates. The evidence is that the palladium colloid coats the substrate in the treatment process, and subsequently is the active agent that nucleates deposition from the electroless bath.

This paper reports the results of measurements by Sn^{119} Mössbauer spectroscopy on the tin components used in the palladium colloid, and an investigation of the colloid formation and stabilization. Special emphasis is placed on the way the colloid-forming reactions determine the properties of the resultant sol. We also discuss the results of Mössbauer measurements on the sensitizing layers themselves. An additional experiment on centrifugation of the commercial sensitizer systems has also been performed to give some idea of the particle size distribution.

The patents describing preparation of two of the one-component systems discuss procedures which are similar in outline, but different in detail. Rather than following analytically each of these "recipes," we have performed a series of experiments which establish the basic chemical stages characterizing the over-all process. The preparation procedures of the individual patents can then be viewed in the light of the findings we present.

This paper deals with a number of very different aspects of the Sn-Pd sol system, and we have modified the normal order of presentation to maintain clarity. We begin with a brief description of the experimental techniques used for the Mössbauer spectroscopy measurements, and a discussion of the interpretation of the spectra obtained. The next section of the paper discusses the formation and identification of a tin-palladium complex which is critical to the colloid formation process. This is followed by a description of the colloid formation as the complex decomposes, and characterization of the components of the colloid from its Mössbauer spectra. In the last third of the paper, the knowledge of the tin-palladium colloid system is used to understand the "recipes" described in the patents for the commercial sol systems and the chemistry of the sensitizing layer deposited on the dielectric. In the last part of the paper, the relation between solution chemistry and particle size in the colloid is also discussed.

Mössbauer Spectroscopy

Experimental techniques and interpretation of spectra.—The experimental techniques used are essentially those discussed in Ref. (2) and (3), and are standard for tin Mössbauer spectroscopy. The source consisted of about 8 mCi of Sn^{119m} in the form of $BaSnO_3$, and was kept at liquid nitrogen temperature.[2] Absorbers were made by freezing the solutions in liquid nitrogen in plastic capsules about 8 mm deep.[3] These capsules were stored and the measurements were made at liquid nitrogen temperatures. A standard transmission-geometry Mössbauer spectrometer was used, with the source being moved by an electromagnetic drive system (8). Data were taken using time-mode up-down multiscaling in a multichannel analyzer, and the figures shown here are traced from the analyzer plotter output. Least squares analysis of the data, and "spectrum stripping" to reveal minor spectral components more clearly, were done as described in the text and figure captions.

Both the systematics and details of the interpretation of Sn^{119} Mössbauer spectra have been extensively discussed in various reviews (9, 10). Only a few different types of tin-containing compounds are involved in this study, and it is possible to identify them, and thus to use the spectra for analysis, by comparison with "standards" of known composition. For convenience, the isomer shifts and quadrupole splittings determined have been listed in Table I. The major features which repeatedly appear, and will be important for the interpretation of the data, are:[4]

1. Sn^{2+} ions, OH^- or Cl^- complexed, give a doublet in the absorption spectrum, centered near +3.6 mm/sec (Fig. 1A).
2. Sn^{4+} ions, bare or complexed, give a broad absorption line (Fig. 1B), near zero velocity.
3. Sn-Pd alloys (11)[5] give a singlet or barely resolved doublet, at about 1.5-2 mm/sec (depending on the Sn-Pd ratio, see Fig. 1C and 1D and Table I).

In all of the results, of course, the spectra are those of the Sn^{119} component of the compound; the chemical state of the palladium can only be inferred from its connection with the tin.

Table I. Isomer shift and quadrupole splitting (in mm/sec) for Sn^{119} in materials studied here

	Material	Isomer shift[a]	Quadrupole splitting[a]
Alloys[b]	$Sn_{0.05}Pd_{0.95}$	1.55	—
	$Sn_{0.09}Pd_{0.91}$	1.53	—
	$Sn_{0.14}Pd_{0.86}$	1.57	—
Intermetallics[f]	Pd_3Sn	1.87	—
	Pd_2Sn	1.62	0.73
	PdSn	2.01	0.62
	$SnO_2 \cdot nH_2O$	0.00	0.55
Frozen solutions	Sn^{2+} in 30% HCl[c]	3.56	1.13
	Sn^{4+} in 30% HCl[c]	0.32	0.43
	Pd(II) · 3Sn(II) complex in 30% HCl	1.42	1.98 ± 0.02
	"PdSn" complex[d]	1.37	2.21 ± 0.05

[a] Quoted with respect to $BaSnO_3$ at 78°K; all absorbers were at 78°K during the measurement. Error ±0.04 mm/sec.
[b] Isomer shift differences among these alloys are significant, but may simply reflect clustering phenomena in these disordered alloys.
[c] These materials contain a number of different complexes; the parameters quoted simply describe a "best fit" of a doublet of the data, and do not characterize any particular complex.
[d] From Ref. (15), extracted as the tetramethylammonium salt. (Isomer shift value converted assuming that the isomer shift of α-tin is 2.00 mm/sec with respect to $BaSnO_3$.)
[e] Obtained by least squares fitting doublets to unresolved broad lines. Estimated accuracy ±0.2 mm/sec, except for Pd(II) · 3Sn(II).
[f] These data are in fair agreement with those of Ref. (11) insofar as it is possible to compare them.

Results and Discussion

Complex formation.—The first part of the experimental work reported here was successful in elucidating the details of the formation of the Pd colloid, and the intermediate reactions. These results are very closely connected with the formation of a Sn-Pd complex. The literature contains a number of reports of tin-palladium complexes, discussing the theoretical and structural chemistry (12, 15),[6] of this system as well as the applications (12, 14, 16). Briefly summarizing, the addition of Sn^{2+} to HCl solutions containing small quantities of Pd^{2+} ions results in the formation of a series of highly colored complexes, which are unstable (14). These are variously reported as being red, brown, yellow-green, and bluish green, depending on the concentration of various species and the solution age. So far as we know, no crystal structure determination on a solid derivative of the Pd-Sn complexes has been performed, and the structures shown in the research articles are either conjectural or based on analogy with similar transition metal complexes.

We investigated the complex by combining two solutions:

[2] The isomer shift of this source with respect to a high-purity $BaSnO_3$ absorber at 78°K was less than 0.01 mm/sec. We are greatly indebted to Dr. P. K. Gallagher of this laboratory for supplying this material.
[3] We have recently discussed the necessity of having glass-forming systems if "frozen solution" Mössbauer spectroscopy experiments are used to characterize the liquid phase (6). In the systems studied here, the presence of 30% (or more) HCl in the solutions served as the glass-forming agent (7). We were able to verify the effectiveness of the glass-forming process both by visual observation of the solutions during freezing and auxiliary experiments with added glycerol as a glass-forming agent.
[4] The major complexing reactions for Sn^{2+} and Sn^{4+} in HCl solutions have been summarized in Ref. (3).
[5] We have also made Sn-Pd alloys and several Pd-Sn intermetallics in our laboratory, and the spectra of these materials are shown in Fig. 1. Values shown in Table I come from measurements on materials made by us.
[6] Baranovskii *et al.* (15) give quadrupole splitting and isomer shift values for a complex which they identify as $(PdCl_2(SnCl_3)_2)^{2-}$, extracted from HCl with hexyl alcohol and as tetramethylammonium salts.

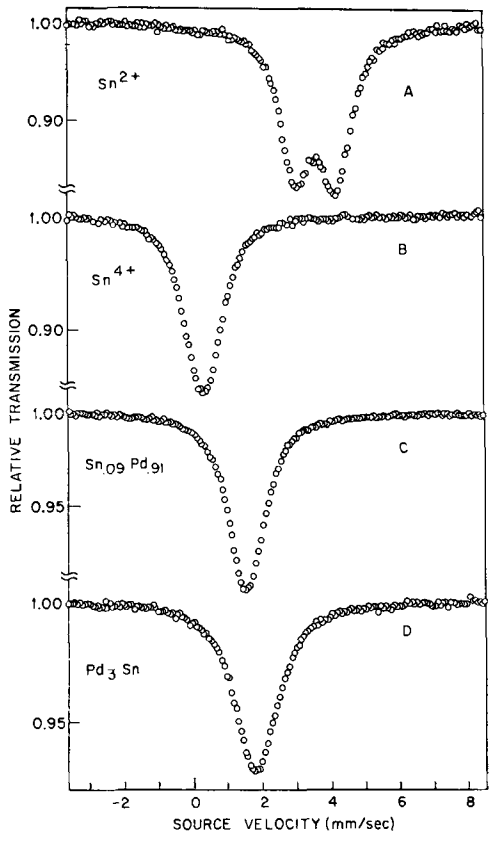

Fig. 1. Mössbauer spectra of pure phases of some tin species encountered in the solutions studied; for comparison with data in other figures. A and B, spectra of Sn^{2+} and Sn^{4+}, respectively, complexed ions dissolved in 4M HCl. C and D, spectra of $Sn_{0.09}Pd_{0.91}$ alloy and Pd_3Sn.

Pd soln.	100 mg	$PdCl_2$ (Fisher)
(11 mM	10 ml	37% HCl (reagent grade)
in Pd^{2+})	20 ml	H_2O (distilled)
Sn soln.	Amount given in text	$SnCl_2$ (purified to remove Sn^{4+})
	1 ml	37% HCl
	2 ml	H_2O (distilled)

The solutions were made slightly above room temperature and cooled to ~0°C (see below); they were maintained under nitrogen gas at all times to prevent oxidation. The Pd solution had a pale orange color; the Sn solution was essentially colorless. These two solutions were combined with rapid stirring, and an intense reddish-brown color formed instantly.

Figure 2A shows the Mössbauer spectrum of a sample of the mixture taken and frozen within 10 sec after combining the Sn and Pd solutions. The most obvious feature of that spectrum is that the doublet characteristic of SnCl complexes (Fig. 1A) is not visible; it has been replaced by another doublet, which our results show arises from the red-brown Sn-Pd complex in HCl. We have explored a range of Sn-Pd ratios and find that for Sn/Pd < 3, all of the tin is immediately complexed to produce the spectrum of Fig. 2A, while for Sn/Pd > 3, additional components which can be identified as arising from SnCl complexes (as in Fig. 1A), appear. Thus each Pd ion complexes three Sn ions, and we conclude that the stoichiometry of the Sn-Pd complex is Pd(II) · 3Sn(II). We abbreviate the dissolved complex as $(Pd\text{-}Sn)_c$ below. This is consistent with the results of Batley and Bailar (12) who suggest $(PdCl)(SnCl_3)_3^{2-}$ for the structure of the complex precipitated (from an HCl-methanol solution) using tetraphenylarsonium chloride.

Colloid generation.—The Pd colloid begins to form immediately after the complex is made, and we found it necessary to cool the Pd solution (as mentioned above) to make the reaction proceed slowly enough to

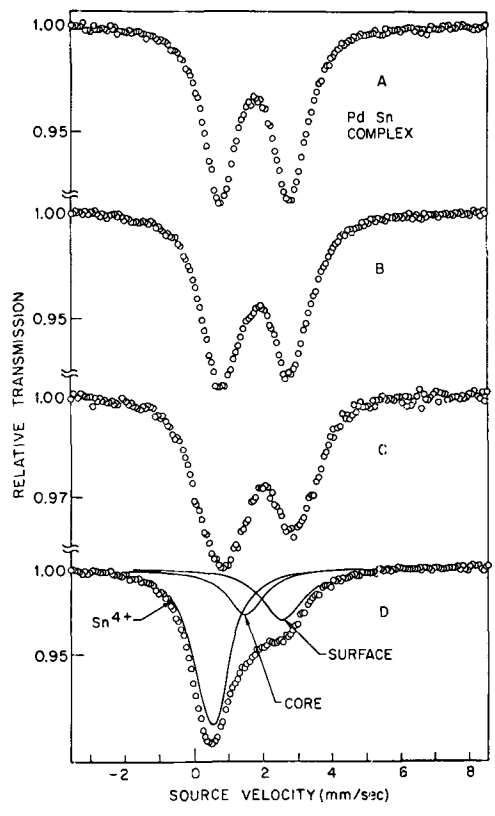

Fig. 2. Spectra of Sn-Pd complex solutions (Sn/Pd ratio 2:1) at (A) 0.2 min, (B) 6 min, (C) 30 min, (D) 120 min after mixing. The doublet in (A) is due to the Sn-Pd complex. This decomposes with time, producing complexed Sn^{4+} due to the redox reaction, Sn-Pd alloy, a small amount of dissolved Sn^{2+}, and a line which we attribute to a protective Sn^{2+} layer surrounding the Pd-Sn sol particles.

be monitored conveniently. As shown in the Mössbauer spectra (Fig. 2), the spectrum of the complex is gradually replaced by three new components. These are identifiable (with the help of subsidiary experiments) as (*a*) dissolved complexed Sn^{4+}, (*b*) the tin protective layer, and (*c*) Sn in Pd-Sn alloy. While it is difficult to resolve the line arising from the alloy from that of the dissolved Sn^{4+}, the colloid can be separated (see below) either by coagulation or centrifugation. It is the spectra of separated materials that allow the identification of the particulate phase as Sn-Pd alloy.

Neglecting for the moment the Sn component in the alloy, this decomposition to produce the Pd colloid would be expected to result from

$$(Pd\text{-}Sn)_c \rightarrow Pd_{metal} + Sn^{4+} + 2Sn^{2+} \qquad [1]$$

During this decomposition process, the red-brown color of the solution changes to a muddy grayish-brown, and then eventually to gray, corresponding to the destruction of the complex. This autoreduction of the Sn-Pd complex is probably the cause for the disappearance of color with time in the use of the Sn-Pd complex test (14) for trace amounts of Pd.

It is instructive to consider four different ratios of Sn/Pd describing the process. For Sn/Pd = 1, the divalent tin is consumed in reducing the palladium, and the spectrum shows only lines attributable to dissolved Sn^{4+} and Sn-Pd alloy. There is no line attributable to stabilizing Sn^{2+} visible in the spectrum, and the sol is in fact unstable and coagulates rapidly.

For Sn/Pd = 2, not all of the Pd is immediately complexed, since the stoichiometry of the complex is Pd:3Sn. As the redox reaction [1] occurs, some Sn^{2+} is returned to the solution, where it is immediately complexed by the remaining Pd. Some Sn^{2+}, however, remains attached to the Pd metal. This Pd metal can

become a nucleus for growth by attaching other Pd metal-tin clusters, and can grow until the Pd core is completely surrounded by Sn^{2+} ions. At this point the growth ceases. This model provides (*i*) a mechanism for particle growth, and (*ii*) a mechanism for terminating the growth and preventing coagulation. Note that if, after the complex-reduction process is complete, the colloidal particles are not completely surrounded by Sn^{2+} ions, they will agglomerate. This process decreases the surface:volume ratio until the amount of Sn^{2+} present is enough to coat the remaining particles.

In the Centrifugation section at the end of the paper we discuss the effects of the amount of available Sn^{2+} in controlling the colloid particle size. The spectra of Fig. 2 show clearly that the complex decomposes completely, leaving (dissolved) Sn^{4+}, a tin-palladium alloy phase, and a third component, which we identify below as the Sn^{2+} stabilizing layer. For the ratio Sn/Pd = 2, there is just enough divalent tin to reduce the Pd and stabilize the colloid; no dissolved Sn^{2+} is observed after the reaction is complete.

For Sn/Pd = 3, all the tin and palladium are immediately complexed; the spectra again show the Sn-Pd alloy phase, Sn^{4+}, and the tin stabilizing layer, but show additional lines, arising from dissolved Sn^{2+}, after the complex has decomposed.

For Sn/Pd > 3, all the Pd is initially complexed, and dissolved Sn^{2+} is observed in the spectrum at all times. Figure 3A shows an example of such a solution, in which a substantial amount of dissolved Sn^{2+} is present after the decomposition is complete.

Visual observations of the color change of the solution show that the decomposition of the complex (as monitored by the disappearance of the red-brown color) is very much slower in tin-rich solutions than in the mixture used for Fig. 2. This has been confirmed by Mössbauer spectroscopy of the frozen solutions.

This probably results from two phenomena. First, the presence of excess dissolved Sn^{2+} forces reaction [1] to the left, increasing the amount of complex at equilibrium. (This residual complex may provide the brownish color in the commercial sol sensitizers.) Second, if large amounts of Sn^{2+} are dissolved, they will immediately coat and passivate fresh sol particles which could otherwise act as nucleation centers for the accretion of additional Pd metal and as catalytic centers for the Pd reduction reaction. At a constant Sn/Pd ratio, the rate of decomposition of the complex was not noticeably affected by increasing the starting concentration by a factor of four over that described above.

We have not been able to determine in detail the chemical mechanism that incorporates the tin in the colloid, but a number of redox reactions involving $(Pd\text{-}Sn)_c \rightarrow (Sn\text{-}Pd)_{alloy} + 2Sn^{4+}$ would be possible.

Composition of solid phase.—One preparation patent (5) states that the Pd colloid is stabilized by a "protective colloid" of Sn^{2+} ions. This picture is supported by the fact that if the solution containing the colloid is allowed to oxidize by contact with air, the particles suddenly coagulate and precipitate just as a Mössbauer spectrum of the frozen bath shows that all the dissolved Sn^{2+} ions in the bath have been oxidized to Sn^{4+}. This coagulation is characteristic of all of the commercial systems. Figure 3 shows spectra taken during this air-oxidation process; lines from the dissolved (Cl^- complexed) Sn^{2+} ions are seen to decrease while the Sn^{4+} line grows in intensity. Just before precipitation, (Fig. 3C), no dissolved Sn^{2+} is visible, but another Sn^{2+} line is visible. We attribute this line to the protective Sn^{2+} layer on the sol particles. This interpretation is supported by the fact that we observe this line only in the colloidal suspensions, and that it disappears just as the colloid coagulates. This, plus the fact that no ionic Sn compound composed of the available ions has a line in the position observed, provides strong evidence that the tin ions involved are at the colloid surface. A likely configuration for such a layer could be for $(SnCl_3)^-$ complexes (which were originally components of the Sn-Pd complex) to be bonded to the Pd-Sn alloy core via Sn-Pd bonds, with the Cl^- ions on the outside.

After coagulation, the supernatant contains only Sn^{4+} ions, while the coagulated solid phase consists of Sn-Pd alloy, plus a small quantity of Sn^{4+} ions. Spectra of these materials are shown in Fig. 4.

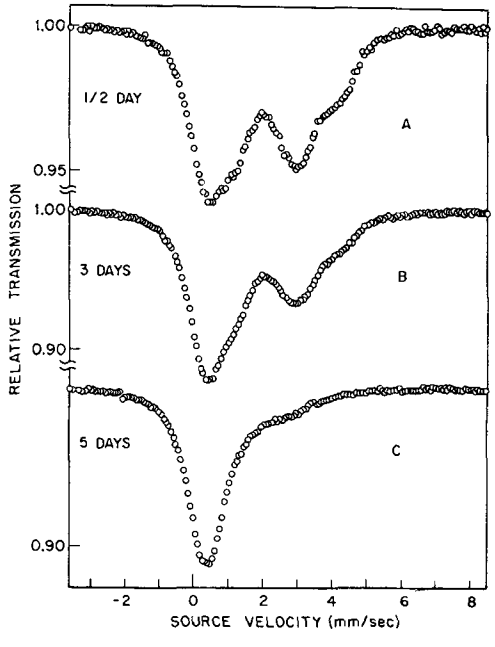

Fig. 3. Spectra showing air oxidation of Sn-Pd sol, made as described in text, but with Sn-Pd ratio of 6:1. The bath was aged at room temperature in an open beaker; (A) ½ day, (B) 3 days, (C) 5 days after Sn-Pd mixing. Initially, most of the Sn^{2+} is complexed in the HCl solution (compare Fig. 1A), and it tends to hide the line originating from the protective Sn^{2+}. As the dissolved Sn^{2+} ions are progressively oxidized, the Sn^{4+} line grows and begins to hide the Sn-Pd alloy line although the latter does remain constant in intensity. Note the line at ~3 mm/sec, due to the Sn protective layer. Coagulation occurred a few hours after sample (C) was taken.

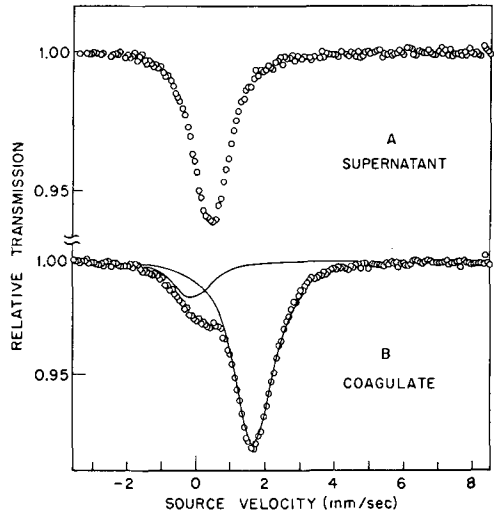

Fig. 4. Spectra of (A) supernatant and (B) coagulated precipitate (washed with H_2O) immediately after coagulation of the colloid following air oxidation of Pd sol used in Fig. 2. Note that no Sn^{2+} ions remain in solution, and that the Sn^{2+} line which we have ascribed to the stabilizing tin layer is no longer present. The Sn^{4+} line visible in the precipitate is characteristic of the $SnO_2 \cdot nH_2O$ family of compounds and results primarily from precipitation during the H_2O wash. Coagulates washed with HCl have relatively little Sn^{4+}.

It is possible to observe the particulate phase much more clearly in colloids in which it has been concentrated by centrifugation. Figure 5A shows such a spectrum, and its resolution (17)[7] into Pd-Sn alloy and the stabilizing Sn^{2+} layer. Instead of washing the centrifuged material to remove traces of electrolyte containing dissolved Sn^{2+} and Sn^{4+} ions, we have taken spectra of the supernatant and subtracted a small fraction of the supernatant spectrum from the spectrum of the sedimented material. In this way, we could eliminate the lines due to dissolved tin ions without coagulating or otherwise changing the colloid in the process of making the absorber. Centrifugation did not coagulate the colloidal particles; they would redisperse spontaneously after standing for a few days. All of the measurements on the commercial sensitizers were done using the undiluted "stock solution" concentration, as supplied by the manufacturers.

Spectra such as those in Fig. 5A allow accurate determinations of line positions of the various components, and least squares fitting has shown small variations in isomer shift and line width for both the core and stabilizing layer components. Isomer shift values for the "Sn-Pd alloy" cores have been found to be up to 0.15 mm/sec less than values for the metallurgically prepared alloys shown at the top of Table I. This is very likely due to the lattice contraction occurring in very small particles.

[7] We have previously written a brief report (17) of the analysis of the particulate phase of these sols.

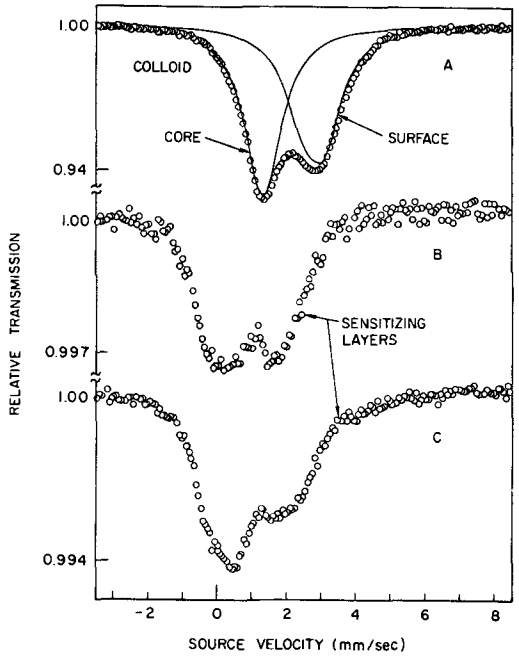

Fig. 5. Spectrum of sol particles (A), concentrated by centrifuging. This shows clearly the two lines which we attribute to the Pd-Sn alloy cores of the sol particles, and the broader line we ascribe to the stabilizing layer. This sample, made with a Sn/Pd ratio of 3, had finer particle size than the solutions shown in Fig. 6, and would be expected to have a relatively large amount of tin in the stabilizing layer, (*i.e.*, the smaller sol particles should have a large surface to volume ratio). Spectra of sensitizing layers (B and C) deposited on Kapton foil using MacDermid Metex PTH 9070 in accordance with the standard MacDermid dilution instructions. The (B) sample (688 layers) was rinsed with 0.5M HBF_4 as an "accelerator" (5) and then with water after sensitization; (C) (456 layers) was rinsed in water. The additional spectral intensity in (C) just to the right of the Pd-Sn alloy peak could very well arise from the mixed-valence (Sn^{2+} and Sn^{4+}) colloid shown in Fig. 6A of Ref. (3) (that material was produced by increasing the pH of a solution of Sn^{2+} and Sn^{4+} in HCl), or could be (3) $SnO \cdot 2H_2O$. Thus, the role of the accelerator is to remove the divalent tin so that it is not precipitated when the pH is raised during the wash step (see footnote 4). We were able to verify that the fluoborate ion is a complex former with Sn^{2+} in the concentrations used here.

Mössbauer measurements in very fine supported gold sols have already demonstrated the existence of this effect (18) and have shown that the observed isomer shift is the same as would be expected if the decrease of the lattice constant were produced by hydrostatic pressure (19). In the case of the Sn-Pd alloys, experiments on the variation of the isomer shift with (pressure-induced) lattice contraction have already been performed (20). The decrease in the lattice constant in Pd-Sn alloy under pressure decreases (20) the electronic density at the tin nucleus; this would produce a smaller isomer shift under lattice contraction, which is what we observe. Using the results of Ref. (20), we can estimate that the change in isomer shift we observe in the smallest sol particles corresponds to a contraction that would be produced by pressures of 100-200 kbar. Such high pressures are in line with previous observations on gold sol particles of comparable size (21).

X-ray measurements were made to determine the lattice constant and structure of the coagulated sol particles. These showed a pattern with only very broad lines, due to compositional inhomogeneities, small particle size, or strain. The lattice constant was appropriate for an alloy containing about 16% Sn in Pd, near the solid solubility limit.

Small variations in the isomer shift and line width of the Sn^{2+} stabilizing layer would be expected to arise from changes in the site (on the Pd-Sn core) to which the stabilizing tin was bound.

We also observed a small increase in isomer shift of the sol particle phase upon coagulation, and some precipitates actually had slightly larger isomer shifts than the Sn-Pd alloy. This probably arose from the incorporation of some of the Sn^{2+} stabilizing ions into the outer layers of the sol particle; as can be seen from Table I, all of the intermetallics containing more than 15 atomic per cent tin had larger isomer shifts than the Sn-Pd alloy.

Extension of Results to Commercial Sensitizer Systems

The results reported above are based on studies of solutions which differ in various ways from those sold commercially, and we have attempted to verify that the mechanisms that we describe are valid for those solutions. We have done this both by ultracentrifuging (which concentrates the particulate phase without coagulation) and by coagulating samples of the proprietary baths to concentrate the solid phase, and taking spectra of the precipitates. For the 6F and 9070 sensitizers, the colloid spectra were very similar to those of Fig. 5A, with minor differences attributable to different proportions between the Pd-Sn alloy and stabilizing Sn^{2+} components, and some uncertainty arising from the background subtractions as described above. The supernatant after centrifuging always appeared to be a simple mixture of dissolved Sn^{2+} and Sn^{4+} ions, as in Fig. 1A and 1B. This confirms the generalization of our results to the commercial systems described in Ref. (4) and (5).

We have also studied the reactions occurring in Sn-Pd solutions in concentrated (*i.e.*, 37%) HCl, and have found that the Mössbauer spectrum of the Sn-Pd complex produced is identical to that shown in Fig. 2A; this is good evidence that the complexes are identical. Although complex formation in the concentrated HCl is essentially instantaneous, the autoreduction reaction [1] is slower, and is still further slowed if a large excess of Sn^{2+} is present. Judging from the color of the solution, however, most of the complex has decomposed within 24 hr at room temperature. The sol produced from a tin-rich solution also contains a higher concentration of tin in the alloy, with the isomer shift of the coagulated particles approximately that of Pd_3Sn. No other attempt was made to stabilize the complex.

Sensitization Mechanism

The information above is consistent with the over-all picture [discussed, *e.g.*, in Ref. (4) and (5)] that sensitization occurs via the adsorption of Pd particles on the surface, and that the Pd alloy is the active agent in catalyzing deposition from the electroless solution. The detailed information above on the colloid composition and stabilization may lead to some additional understanding of the adhesion process, and we have supplemented studies of the baths with measurements of the sensitizing layer on a plastic surface.

Figure 5 shows Mössbauer spectra of many layers of Kapton[R] plastic film, sensitized with a commercial bath, given various rinse treatments, and dried in nitrogen. The surfaces were checked with a standard copper electroless solution to verify that sensitization had indeed occurred. The use of the "accelerator" wash dramatically increased the catalytic activity of the surface. The spectra are somewhat different from those of the sol particles; a strong line characteristic of stannic hydroxide appears, and the line (attributed in Fig. 5A to the stabilizing Sn^{2+}) is no longer present. Lines due to dissolved Sn ions are, of course, absent.

The differences can be readily explained on the basis of what is known about the chemistry of these colloids. When the substrate is immersed in the sensitizing bath, in addition to the adsorption of the sol particles, there will be some oxidation of the Sn^{2+} by oxygen adsorbed on the substrate and by dissolved oxygen in the solution used for surface pretreatment. (Note that the amount of Sn^{2+} deposited corresponds to only $\approx$ 1 monolayer, assuming uniform coverage, so that only very small amounts of dissolved oxygen suffice to produce this oxidation.) The chemical reaction at the interface could possibly promote stronger adhesion of the colloid particles since ionic, rather than van der Waals bonding, would then be operative.

Centrifugation Experiments

As a corollary to the Mössbauer experiments, samples of the concentrated commercial sensitizer formulations were centrifuged to determine qualitatively their particle size and size distributions. The results of those experiments are shown in Fig. 6, as photographs of the vials after centrifugation. The variation of optical density of the samples gives some indication of the particle size distribution. Note that for all the commercial formulations shown, the top layer of the vial is essentially colorless, indicating that the smallest particle size with substantial population is $\sim$ >10Å diameter.[8] However, the well-known Stokes-law breakdown is significant in this size range, and, more important, there is probably a large shell of Cl^- ions complexing the tin protective layer, and this would greatly decrease the effective density of the particle. Thus, the lower end of the colloidal particle size distribution is probably about 20Å in diameter.

Earlier in the paper we discussed the limitation of particle growth by the stabilizing layer of Sn^{2+}, and control of particle size by this mechanism. In the model presented, particles would grow and agglomerate until they were covered by a layer of Sn^{2+} ions [probably as $(SnCl_3)^-$ complexes], after which growth would stop. We have performed a critical test of this model, as follows: tin-palladium sols were made (starting with 100 mg $PdCl_2$ in 10 ml + 20 ml H_2O) using Sn/Pd ratios of 1.2, 1.5, 2 and 2.5 and 3. The complex was allowed to decompose at room temperature under nitrogen gas, to avoid oxidation. After the decomposition was complete (12 hr), some additional Sn^{2+} (Sn/Pd = 1) was added to decrease the sensitivity of the solutions to oxidation, and the mixtures were centrifuged. The results, in Fig. 7, show graphically that the smaller the amount of excess Sn^{2+} present when the sol was forming, the larger the particles grew before they were stabilized. This is exactly what the model would have predicted.

This approach can also be used to understand the differences in particle size distribution between the Shipley 6F and MacDermid 9070 sensitizer solutions. The Shipley process (4) generates the sol by mixing the Pd solution into a solution containing a large excess of Sn^{2+}. This should provide the finest possible

[8] We assume that Sn-Pd alloy has a density of 10 g/cc and that the viscosity of the electrolyte (at ~15°C) is the same as that of water at 20°C. Uncertainties arising from the presence of the shell of solvating ions are far larger than these approximations. Electron micrographs of the sol particles in the commercial systems show spherical particles, typically ~100Å in diameter (22).

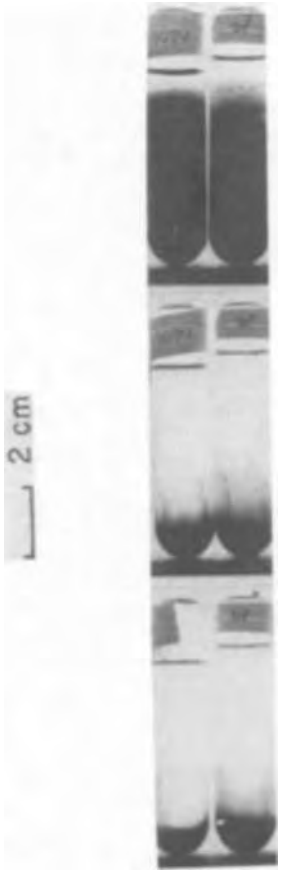

Fig. 6. Photographs of vials containing commercial sensitizers after centrifugation at 110,000G at 15°C. Centrifuging times are (from top) 4, 21, and 29 hr; samples are (from left) MacDermid 9070 and Shipley 6F.

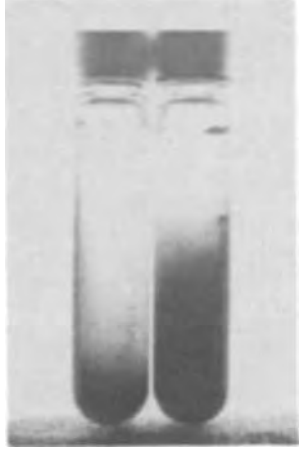

Fig. 7. Photographs of centrifuged Sn-Pd sols, made as described in text. With Sn/Pd = 1.5 and 1.8, coagulation occurred spontaneously within a few hours. The photograph shows sols with Sn/Pd = 2, left, and Sn/Pd = 2.5, right. An additional experiment with Sn/Pd = 3 (not shown) produced still finer particles. The decrease in particle size with increasing Sn/Pd ratio supports the picture of sol formation and particle stabilization given in the text. Centrifugation conditions were 15 hr at 110,000G. Note that the sedimentation rate for the left vial is essentially the same as that of the MacDermid colloid (Fig. 6), which is also generated with Sn/Pd = 2.

particle size, as the sol particles are quickly covered by Sn^{2+} from the solution, but should not provide especially uniform particle size. In Fig. 6, the 6F material is seen to have both the finest particle size and a relatively gradual tailing off of the top of the sedimented column, symptomatic of a range of small particle sizes. The MacDermid process (5), on the other hand generates the sol with a Sn/Pd ratio of 2, and then adds stabilizing tin after the sol has formed. The result should be somewhat larger sol particles than those made by the Shipley process, but particles of a more uniform size limit. The centrifuging results in Fig. 6 confirm this; the upper level of the sedimenting column is relatively sharp for the 9070 bath.

Thus, particle size analysis of the commercial sensitizers, and our own experiments with particle size control, provide strong confirmation of our mechanism of particle size control in these colloid systems.

Summary and Conclusions

We have defined a number of processes in the Pd-Sn sol system:

1. The sol-generating reaction is initiated by the formation of a Pd-Sn complex.
2. The stoichiometry of the complex has been determined to be Pd(II) · 3Sn(II).
3. The complex is unstable and autoreductive, yielding a Sn-Pd alloy.
4. The sol particle size is determined by a layer of Sn^{2+}, which limits further growth.
5. The model developed here correctly predicts relative colloid particle size, both in our test solutions and in the commercial sensitizing baths.
6. The chemical processes occurring in the adhesion of the colloid to the sensitized surface have been described.
7. Chemical changes due to air oxidation of the bath have been described.
8. The colloid sedimentation rate has been determined.

Acknowledgments

We are greatly indebted to the personnel of the Shipley, MacDermid, and Photocircuits companies for supplying samples of their sensitizers and their willingness to furnish technical information. Samples of the Kapton^{R} film used for sensitization were supplied to us by the du Pont Company. We would like to acknowledge discussions with D. Dinella and his staff, and with H. Cole, who first brought the existence of these sensitizer systems to our attention. The centrifuging experiments were performed using the ultracentrifuge of the Biophysics Research Department. The x-ray lattice constant measurements were performed by A. R. Storm.

Manuscript submitted June 15, 1972; revised manuscript received Nov. 20, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

An Improved Model for Capillary Diffusion with No External Stirring

Leonard Nanis,* Mitchell Litt, and Joseph Chen[1]

Department of Chemical Engineering, School of Engineering and Applied Science, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

Average capillary concentration as a function of time has been determined by computer simulation of the diffusion process from a capillary into an infinite stationary medium. These results may be used as the basis for experimental determination of diffusivity to eliminate the usual errors associated with stirring, and to correct results obtained without stirring but using the zero concentration boundary condition solution.

In engineering practice, the diffusion coefficient enters into important parameters for mass transport correlations such as the Schmidt and Sherwood numbers. The importance of diffusion coefficient to electrochemical engineering is associated directly with the limiting current density of all electrode reactions. The several methods available for the calculation and measurement of diffusivity have been amply reviewed (1-4). Of all the methods for diffusivity measurement, the capillary technique is the most universally adaptable, provided some analytic method exists for the determination of the chemical concentration in the capillary after a given time has elapsed. For this method, the problem of obtaining accurate diffusivity data is associated with the hydrodynamic conditions which prevail at the capillary mouth. Anderson and Saddington (5) are generally credited with introducing (1949) the capillary method. They performed studies of diffusion without stirring, but analyzed results according to a treatment which implies a stirred fluid at the capillary mouth. This procedure will lead to calculated diffusivities which are less than the true value. Where attempts have been made to utilize stirring to insure the proper concentration boundary condition at the mouth of the capillary, further difficulties have arisen because of hydrodynamic effects. When real liquids stream along an interface which suddenly gives way to a change in cross section such as at the lip of the capillary, a substantial pressure gradient occurs, forcing liquid into the capillary and removing a small amount of more concentrated solution from the mouth. The apparent diffusion coefficient thus measured is invariably too great. This phenomenon is generally known as the Δl effect and has been empirically studied by Borucka (6), Berne and Berggren (7), and Nanis, Richards, and Bockris (8). For very long diffusion times, it would be expected that these two cases would converge. Such a recourse, however, would be experimentally most inconvenient.

An apparent solution to this dilemma would be to use an experimental technique with no stirring, to eliminate the Δl effect, together with a model of the diffusion process which takes into account the true boundary conditions at the mouth of the capillary. This paper presents a method for precise prediction of the diffusion coefficients by using a capillary without stirring. A computer simulation of the diffusion process without stirring provides a procedure for the estimation of diffusion coefficients from the residual amount in the capillary at any time. The results may also be used to correct literature values of diffusivity where no stirring has been used experimentally but results fitted to the "stirred" equation.

Key words: diffusion, capillary method, diffusivity, Δl effect.

Mathematical Formulation

The diffusion of electrolyte from a capillary to an external bulk solution as shown in Fig. 1 is governed by Eq. [1], in which diffusivity is assumed to be constant and the following dimensionless parameters are introduced

$$\phi = \frac{c}{c_o},\ \eta = \frac{x}{L},\ \xi = \frac{y}{L},\ \beta = \frac{z}{L},\ \tau = \frac{Dt}{L^2}$$

where c = concentration of diffusant, c_o = initial concentration of diffusant inside the capillary, L = length of the capillary, D = diffusivity, and t = time.

In the region $0 \leq \eta < 1$, the diffusion is assumed to be one-dimensional, governed by

$$\left(\frac{\partial \phi}{\partial \tau}\right)_1 = \left(\frac{\partial^2 \phi}{\partial \eta^2}\right)_1 \qquad [1]$$

The subscript 1 indicates the region where one-dimensional diffusion prevails. The zero flux boundary condition at the closed end ($\eta = 0$) of the capillary is

$$\left(\frac{\partial \phi}{\partial \eta}\right)_1 = 0;\ \eta = 0,\ \tau \geq 0 \qquad [2]$$

The initial condition is

$$\phi_1 = 1;\ 0 \leq \eta \leq 1,\ \tau = 0 \qquad [3]$$

In the region $\eta > 1$, for the absence of convection, the diffusion is three dimensional. The three-dimensional version of the diffusion equation is

$$\left(\frac{\partial \phi}{\partial \tau}\right)_3 = \left(\frac{\partial^2 \phi}{\partial \eta^2}\right)_3 + \left(\frac{\partial^2 \phi}{\partial \xi^2}\right)_3 + \left(\frac{\partial^2 \phi}{\partial \beta^2}\right)_3 \qquad [4]$$

The subscript 3 refers to the three-dimensional region. The boundary condition is

$$\phi_3 = 0;\ \eta \to \infty,\ \xi \to \infty,\ \beta \to \infty,\ \tau \geq 0 \qquad [5]$$

The symmetry of diffusion perpendicular to the axis of the capillary gives

$$\left(\frac{\partial \phi}{\partial \xi}\right)_3 = 0, \left(\frac{\partial \phi}{\partial \beta}\right)_3 = 0;\ \xi = 0,\ \beta = 0,\ \eta > 1,\ \tau \geq 0 \qquad [6]$$

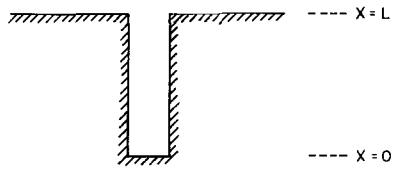

Fig. 1. Diffusion of electrolyte from a capillary to an external bulk solution.

The initial condition is

$$\phi_3 = 0;\ \eta > 1,\ 0 \leq \xi \leq \infty,\ 0 \leq \beta \leq \infty,\ \tau = 0 \quad [7]$$

At the mouth of the capillary ($\eta = 1$), where one- and three-dimensional regions join, equality of fluxes gives

$$\left(\frac{\partial \phi}{\partial \eta}\right)_1 = \left(\frac{\partial \phi}{\partial \eta}\right)_3 + \left(\frac{\partial \phi}{\partial \xi}\right)_3 + \left(\frac{\partial \phi}{\partial \beta}\right)_3 \quad [8]$$

at $\eta = 1$, $\xi = 0$, $\beta = 0$, and $\tau \geq 0$

The boundary conditions given here implicitly contain the assumption that the capillary mouth is a point source for the three-dimensional region, rather than an actual disk. The error arising from this assumption will be minimal unless the capillary diameter is a significant fraction (several per cent) of the length.

Finite Difference Formulation

An explicit form of the finite difference Eq. [9] was used to represent Eq. [1]-[8] for both one-dimensional and three-dimensional regions.

Let i = index for the step movement in x direction ($i = 1,2,3,...$), j = index for the step movement in y direction, k = index for the step movement in z direction, n = time, $\Delta\tau$ = step increment in dimensionless time, $\Delta\eta$ = step increment in η direction, $\Delta\beta$ = step increment in β direction, $\Delta\xi$ = step increment in ξ direction, $M = 1/\Delta\eta$: number of grid points in the capillary, $\lambda_1 = \Delta\tau/(\Delta\eta)^2$, $\lambda_2 = \Delta\tau/(\Delta\beta)^2$, and $\lambda_3 = \Delta\tau/(\Delta\xi)^2$.

For the one-dimensional diffusion region, $0 \leq \eta < 1$, Eq. [1] becomes

$$\phi_{i,1,1,n+1} = [1 - 2\lambda_1]\,\phi_{i,1,1,n} + \lambda_1\,[\phi_{i-1,1,1,n} + \phi_{i+1,1,1,n}] \quad [9]$$

where $1/\Delta\eta > i$

At the closed end of the capillary ($i = 1$), the zero flux boundary condition (Eq. [2]) leads to

$$\phi_{0,1,1,n} = \phi_{2,1,1,n} \quad [10]$$

The initial condition (Eq. [3]) becomes

$$\phi_{i,1,1,0} = 1 \quad [11]$$

For the three-dimensional diffusion region, $\eta > 1$, $0 \leq \xi \leq \infty$, $0 \leq \beta \leq \infty$, Eq. [4] becomes

$$\phi_{i,j,k,n+1} = (1 - 2\lambda_1 - 2\lambda_2 - 2\lambda_3)\,\phi_{i,j,k,n} + \lambda_1(\phi_{i-1,j,k,n} + \phi_{i+1,j,k,n}) + \lambda_2(\phi_{i,j-1,k,n} + \phi_{i,j+1,k,n}) + \lambda_3(\phi_{i,j,k-1,n} + \phi_{i,j,k+1,n}) \quad [12]$$

for $i > 1/\Delta\eta$.

Boundary conditions (Eq. [5], [6]) are

$$\phi_{i,j,k,n} = 0 \quad \text{as } i \to \infty,\ j \to \infty,\ k \to \infty \quad [13]$$

$$\phi_{i,0,k,n} = \phi_{i,2,k,n} \quad [14]$$

$$\phi_{i,j,0,n} = \phi_{i,j,2,n} \quad [15]$$

For simplicity, the capillary is considered as a drilled hole in a block. In order to account for the impermeable plane at the mouth level, $\eta = 1$, $\xi > 0$, $\beta > 0$, the following statement allows for zero flux perpendicular to the plane by the use of imaginary points below the plane, *e.g.*

$$\phi_{M+1,j,k,n} = \phi_{M-1,j,k,n} \quad [16]$$

The initial condition given by Eq. [7] becomes

$$\phi_{i,j,k,n} = 0 \quad \text{as } \tau = 0,\ i > \frac{1}{\Delta\eta},\ 0 \leq j \leq \infty,\ 0 \leq k \leq \infty \quad [17]$$

At the junction of the one- and three-dimensional regions just at the capillary mouth ($i = M$, $j = 1$, $k = 1$), Eq. [8] becomes

$$\phi_{M,1,1,n+1} = \frac{\phi_{M-1,1,1,n} + \phi_{M+1,1,1,n} + \phi_{M,2,1,n} + \phi_{M,1,2,n}}{4} \quad [18]$$

Equation [18] is based on implicit finite difference approximation, together with the assumption of equal spacing in the three-dimensional region ($\Delta\eta = \Delta\xi = \Delta\beta$).

Computation

Stability of the finite difference calculations required (9) that λ_1, λ_2, and λ_3 be smaller than 0.5. Ten grid points in the capillary ($\Delta\eta = 0.1$) and a dimensionless time increment of $\Delta\tau = 2 \times 10^{-4}$ were first used for the calculation except at early time ($\tau \leq 0.001$) where twenty grid points in the capillary were used to improve the computation of the average concentration by smoothing the concentration in the region $0 \leq \eta \leq 1$. The same step size ($\Delta\eta = \Delta\beta = \Delta\xi = 0.1$) was used in the three-dimensional diffusion region (Eq. [12]-[17]). Computation of the dimensionless concentration at all grid points was carried out as the dimensionless time, τ, increased to 1.5. The dimensionless concentrations in the three-dimensional diffusion region were calculated step by step from the mounth of the capillary to the infinite medium. However, computation was cut off and moved to the next time step when the dimensionless concentration, ϕ, at grid points became less than a preset value which, in this calculation, was chosen as 1.0×10^{-4}. Trial and error procedure showed that this value is the largest which can be neglected without affecting the final result for ϕ_{avg}. In this way, the actual computing time was reduced to about a quarter of that required to compute the concentration at every grid point out to $\eta = 2.5$. A computer time of about 10 min was required to carry out the calculation to $\tau = 1.5$ on the IBM 360/75.

Convergence was tested by reducing the time increment, λ, checking for changes in concentration profile and by checking the computed average concentration in the capillary as a function of dimensionless time with the analytical solution (Eq. [19]) for the case of diffusion with stirring and also one-dimensional diffusion along the axis of the capillary without stirring (Eq. [22]), the two limiting cases discussed below. The smallest time increment used ($\Delta\tau = 1.5 \times 10^{-4}$) provided for convergence of numerical results and also gave excellent agreement with analytic solutions for the fast and slow limiting cases. In Fig. 2, computer results are shown as points for comparison with the analytic limits given by Eq. [22] for the slowest possible bound and Eq. [19] for the fastest limit.

Analytic Solutions for Fast Limit

Anderson and Saddington (5) gave a solution to Eq. [1] with Eq [2] and [3] as boundary conditions which describes the average concentration remaining in the entire capillary at time t with the concentration at the mouth of the capillary maintained at zero. The solution, Eq. [19], permits the evaluation of a diffusion coefficient, D, for the limiting case of fastest extraction from the capillary.

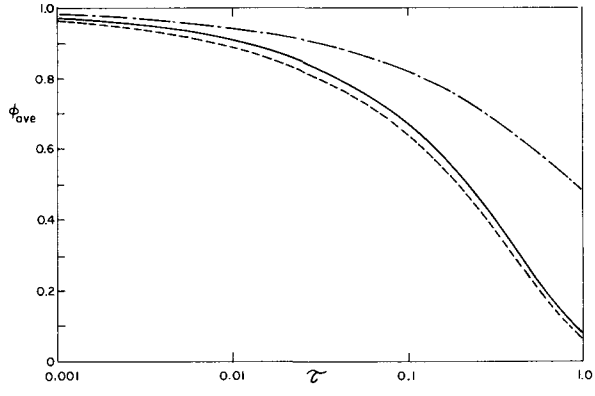

Fig. 2. Average capillary concentration vs. time (ϕ_{avg} vs τ). ——— No-stir, three dimensional, computed; —·—·—·— no-stir, one dimensional, analytic; - - - - - - stir, one dimensional, analytic.

$$\phi_{avg} = \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} e^{\frac{-(2n+1)^2 \pi^2 \tau}{4}} \quad [19]$$

A result entirely equivalent to Eq. [19] may be obtained by the use of Laplace transform methods (9) and is much more useful for small time, although different in form.

$$\phi_{avg} = 1 - 2\tau^{1/2} \left\{ \frac{1}{\pi^{1/2}} + 2 \sum_{n=1} (-1)^n \left[\frac{e^{\frac{-n^2}{\tau}}}{\pi^{1/2}} - \frac{n}{\tau^{1/2}} \operatorname{erfc} \frac{n}{\tau^{1/2}} \right] \right\} \quad [20]$$

It may be readily determined that the entire summation in Eq. [20] may be ignored for times which are small, *i.e.*, where the criterion $\tau < 0.06$ is valid. The first term within the large brackets in Eq. [20] represents the limiting case equivalent to diffusion out of a semi-infinite region. Thus, for small time, Eq. [20] simplifies to

$$\phi_{avg} = 1 - \frac{2}{\pi^{1/2}} \tau^{1/2} \quad [21]$$

Analytic Solution for Slow Limit

By making no provision for sideways (radial) spreading of diffusant in the no-stirring case, an estimate is possible for a hypothetical slowest extraction of diffusant as though it moved outside the capillary in a virtual constrained tube within the exterior liquid. By the use of Laplace transform methods with the diffusion equation (Eq. [1]) together with only one boundary condition, given by Eq. [2] (no restriction on the capillary mouth concentration), the concentration as a function of distance and time may be readily obtained. The solution is

$$\phi_{avg} = 1 - \frac{\tau^{1/2}}{\pi^{1/2}} \left[1 - e^{-\frac{1}{\tau}} \right] - \operatorname{erfc} \frac{1}{\tau^{1/2}} \quad [22]$$

For small times, the decreasing exponential and complementary error function terms in Eq. [22] are very small and may be ignored in favor of the approximation

$$\phi_{avg} = 1 - \frac{\tau^{1/2}}{\pi^{1/2}} \quad [23]$$

If it were possible to arrange the bounded one-dimensional diffusion into the external liquid, Eq. [23] would describe the actual amount remaining in the capillary for small time. The diffusant actually spreads beyond the constraining envelope for the case of three-dimensional diffusion with no stirring, thus providing for a more rapid removal of material than the one-dimensional bound given in Eq. [22]. Thus, the "actual" amount remaining given by Eq. [23] appears to be associated with a smaller apparent diffusivity for the same ϕ_{avg} substituted in Eq. [21], valid for stirring.

Using the "actual" diffusivity for the no-stir, one-dimensional treatment as D_{act} in Eq. [23] and calling the apparent diffusivity computed from Eq. [21] D_{appt}, equating amounts in the capillary gives as a limit at short time

$$\frac{D_{appt}}{D_{act}} = 0.25$$

This bounding lowest possible value is indicated in Fig. 4 and provides a limit for the negative error in D measurement introduced by using Eq. [21] (incorrectly) without the necessary stirring conditions.

* D_{appt}/D_{act} obtained by substituting computed ϕ_{avg} in Eq. [20] or Eq. [21] to determine D_{appt}.

Results and Discussion

Table I gives the values from the numerical computation for three-dimensional diffusion from a capillary into a stationary bulk solution. The results of the slowest possible bound, Eq. [22], and the fast-stirred bound, Eq. [20], are shown together in Fig. 2. There is a surprisingly similar behavior of ϕ_{avg} *vs.* τ for the true extremes of stirring (Eq. [20]) and the nonstirred three-dimensional computed result. As shown in Fig. 3, curves of concentration *vs.* distance at selected values of τ bear a close resemblance to the shape expected for stirring conditions at the mouth. Even without stirring, the concentration gradients just at the mouth show a nearly similar flux behavior.

If stirring is not provided in an actual experiment, the apparent value of D computed using Eq. [20] (zero boundary condition) will clearly be less than the true value of the diffusion coefficient. These negative errors arising from misuse of Eq. [20] with ϕ_{avg} for no stirring are listed in Table I as D_{appt}/D_{act}. A plot of D_{appt}/D_{act} *vs.* ϕ_{avg} is given in Fig. 4. The lower limit (for $\phi_{avg} > 0.95$) of the ratio was not determined because of program time interval limitations. D_{appt}/D_{act} increases from 0.6 to 0.93 as the concentration of material remaining in the capillary decreases toward zero. Thus, if sufficient time elapses, diffusivity measurements may be made to within a close approximation of the correct value even if an incorrect equation for ϕ_{avg} *vs.* τ is used with no stirring, as expected. For a 3-cm long capillary and diffusion coefficient on the order of 5×10^{-6} cm²/sec, a misapplication of Eq. [20] for the

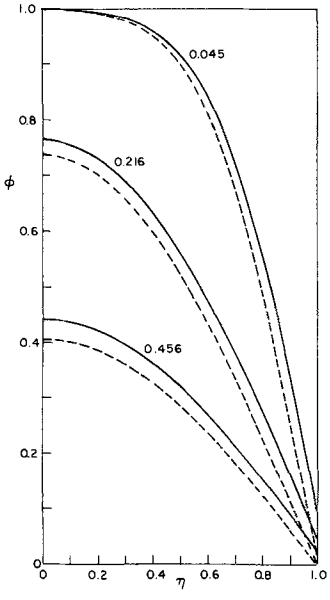

Fig. 3. Capillary concentration profiles for selected τ. ——— No-stir, $\phi \neq 0$, $\eta = 1$; - - - - - - - stir. $\phi = 0$, $\eta = 1$.

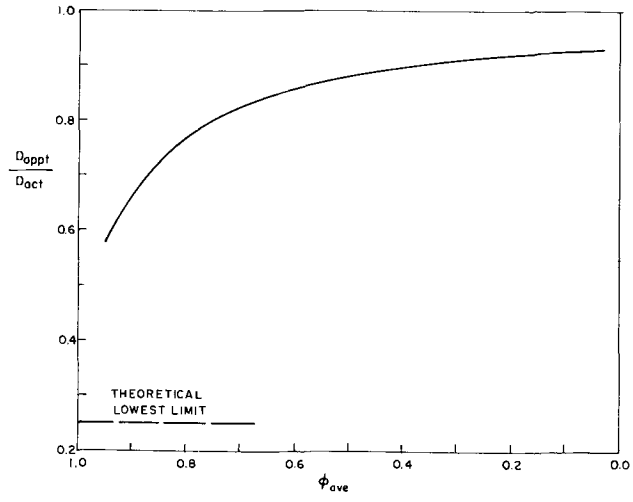

Fig. 4. Ratio of apparent to actual diffusivity obtained by using no-stir ϕ_{avg} in Eq. [20].

nonstirring case will result in less than 10% error only if the diffusion proceeds for longer than 375 hr. For a diffusion time of 32 hr, a 20% error will result from misapplication of Eq. [20]. Using the results shown in Fig. 2 and 4, however, it is possible to back-correct data in the literature where Eq. [20] has been used incorrectly with no stirring conditions. Furthermore, availability of these corrections implies that experimental use of the capillary technique with no stirring can be made to obtain accurate values of diffusivity and totally eliminate the ambiguity associated with stirring and the Δl effect. Errors may still arise from natural convection effects due to density differences between the diffusing and bulk solutions. For very dense solutions, such effects may be considerable and make stirring a preferable recourse. Preliminary results from an experimental test of the method indicate, however, that this problem can be overcome. Final results from that study will be the subject of a later communication.

Technical Notes

Grain Boundary Attack of 316L SS in Ammonia-Rich Environments

J. M. A. Van der Horst*

Surface Research, Incorporated, Olean, New York 14760

Urea synthesis plants are often subject to very severe corrosion. The materials used most often are austenitic stainless steels of the types 316 and 317 (1). Titanium has been used but it is also subject to corrosion (2). Zirconium has found limited application and appears to be completely inert.

Two forms of corrosion should be distinguished in urea synthesis. First, corrosion in the reactor proper, which is mostly confined to the welds (3). This type of corrosion seems to be connected with the high level of carbamate in the reactor, or, as others claim, the presence of ammonium cyanate (4). At any rate, sigma phase in the weld metal is primarily attacked and it can be reduced to relatively low levels by employing a filler material which does not form sigma phase as rapidly as 316 or 317 (5).

The second form of corrosion is found in areas exposed to the gas phase in urea synthesis. It is characterized by general attack of austenitic stainless steels, sometimes by preferential leaching of some of the constituent elements of the alloy or by intergranular attack. This is the type of corrosion which will be discussed hereunder.

The Huey test (ASTM A262C) has been specified for stainless steels used in urea synthesis plants. This test is conducted at a high redox potential and a low pH, whereas urea synthesis takes place at a low redox

* Electrochemical Society Active Member.
Key words: intergranular corrosion, austenitic stainless steel, ammonia, ASTM tests, complexing.

potential and a high pH. It would therefore appear inappropriate to use the test for this purpose.

Some limited cases can be made for the Huey test in the case of the reactor, because this test also attacks sigma phase. For corrosion in areas exposed to the gas phase it is completely out of place (6), as will be demonstrated presently.

Case Histories and Experimental

Among internals from the high pressure section of a urea synthesis plant were present a series of collars consisting of two parts of 316L stainless steel welded together. A number of these assemblies were found to have one of the two parts severely corroded, the other not (Fig. 1). This indicated the presence of some condition in the particular part of 316L making it more subject to urea corrosion than the other part. The chemical analysis however did not show any significant differences:

	Ni	Cr	Mo
Corroded portion (steel A)	13.92	17.05	2.36
Noncorroded portion (steel B)	14.50	16.96	2.42

The assembly was therefore sliced into segments and the individual segments subjected to the oxalic acid test (ASTM A262A) (Fig. 2), the Streicher test (ASTM A262B) (Fig. 3), the Huey test (ASTM A272C) (Fig. 4), and the Strauss test (ASTM A262E) (Fig. 5). Fresh metal surfaces were exposed for the test. The grain-boundary etching visible in the cross section is due to metallographic preparation.

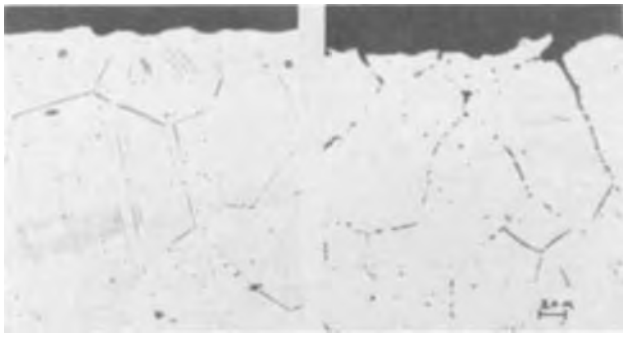

Fig. 3. 316L SS A (left) and B (right) after Streicher test (ASTM A262B).

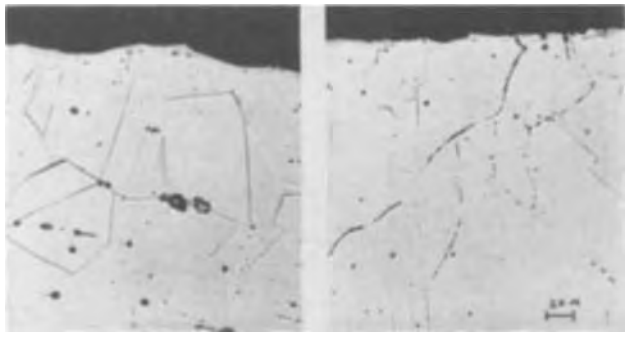

Fig. 4. 316L SS A (left) and B (right) after Huey test (ASTM A262C).

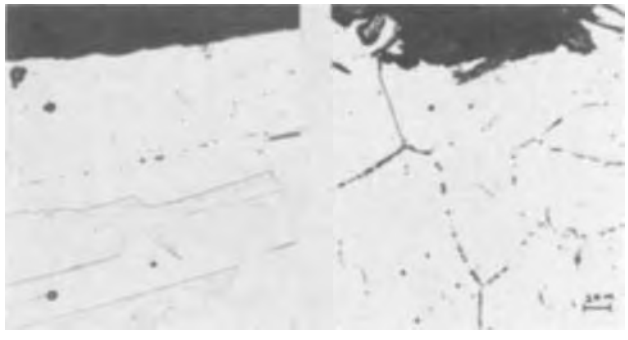

Fig. 5. 316L SS A (left) and B (right) after Strauss test (ASTM A262E).

Discussion

It is quite evident that while the urea synthesis environment can cause very severe intergranular corrosion in steel B, none of the ASTM intergranular corrosion tests does anything like it.

The photomicrographs (Fig. 1-5) clearly show a structural difference between steels A and B. They react quite differently to the metallographic etch, no

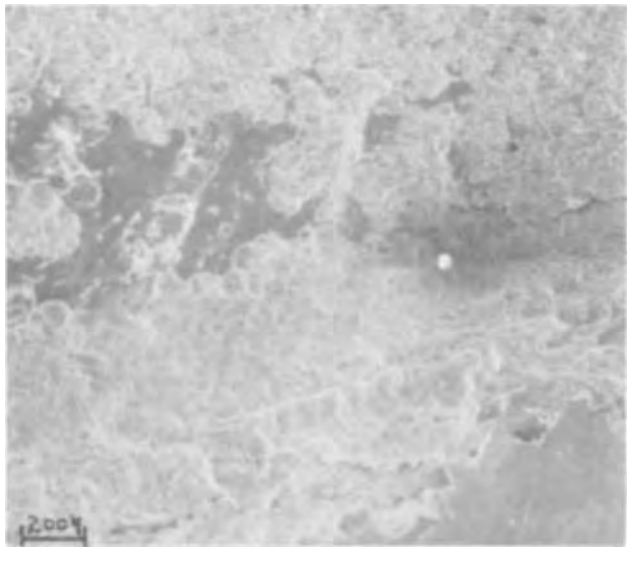

Fig. 6. SEM of partially leached out 316L SS; remaining metal lower left corner.

doubt due to a difference in heat-treatment. This difference however does not seem to have anything to do with Cr depletion at the grain boundaries, at which the tests of ASTM A262 are more or less aimed. Only the Strauss test (Fig. 5) caused considerable attack of steel B, but this attack appears to follow the internal grain structure rather than the grain boundaries.

The structure in Fig. 6-8 may clarify the matter somewhat. Apparently the corrosive environment we are dealing with in this case is an excellent solvent for Ni, a somewhat lesser solvent for Cr, and a poor solvent for Mo and Fe. This is also confirmed by the intergranular attack shown in Fig. 9-10, where the grain boundaries are Ni enriched. One might wish to make a case for corrosion caused by low C, but this would seem difficult.

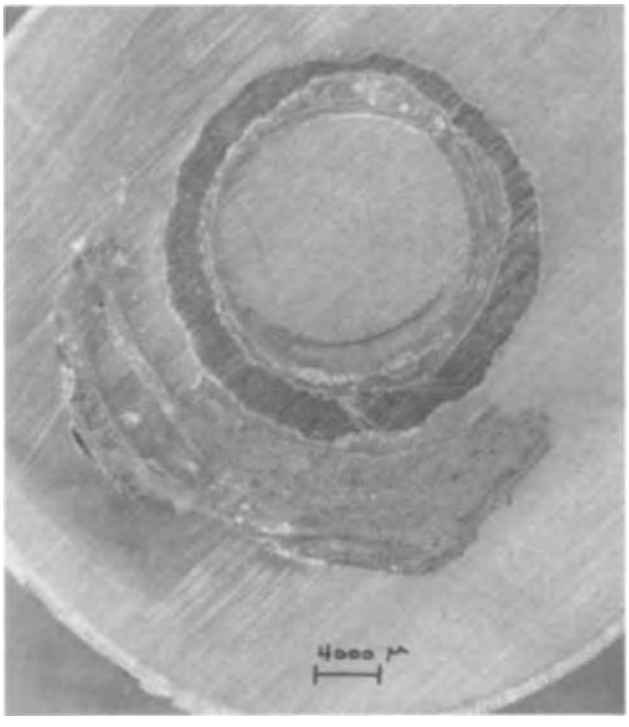

Fig. 7. Corroded assembly of 316L SS: inner circle rest of corroded tube, surrounded by partially corroded ring, and lower outside part of corroded plate.

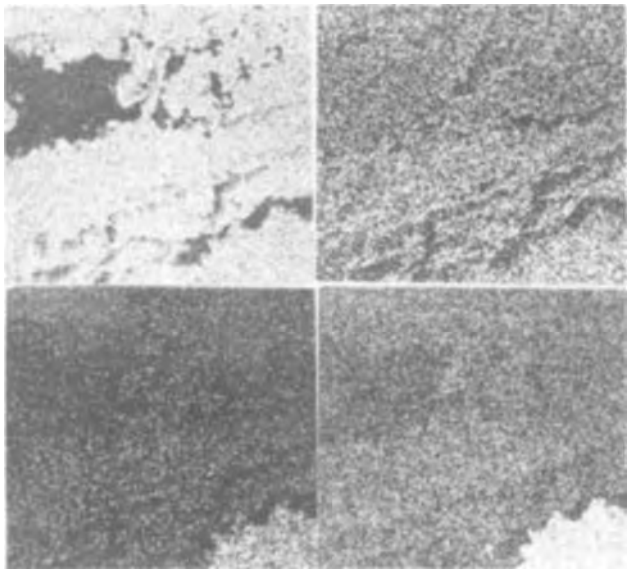

Fig. 8. Backscatter of Fig. 6 for Fe (upper left), Mo (upper right), Ni (lower left), and Cr (lower right).

The sequence of dissolution corresponds to the order of affinity for the formation of ammonia complexes, which has been widely investigated by Professor Janik Bjerrum (7), who confirmed to the author that increasing concentrations of ammonia are required to complex Ni, Cr, and Fe, in this order, while Mo is not complexed at all in this environment (8). These complexes are highly soluble in ammonia, and as a result the protective oxide layers of austenitic stainless steels become completely soluble.

Since all the metals concerned dissociate water when unprotected, and some water is always present in urea synthesis, the cycle, complexing, dissolution, dissociation, is continuous. At lower NH_3 concentrations it is capable only of complexing Ni, the result being preferential dissolution of areas with a high Ni concentration. At somewhat higher NH_3 concentrations both Ni and Cr are complexed and leached out of the matrix. At still higher NH_3 concentrations, Fe is also complexed and the stainless steel dissolves completely and cleanly.

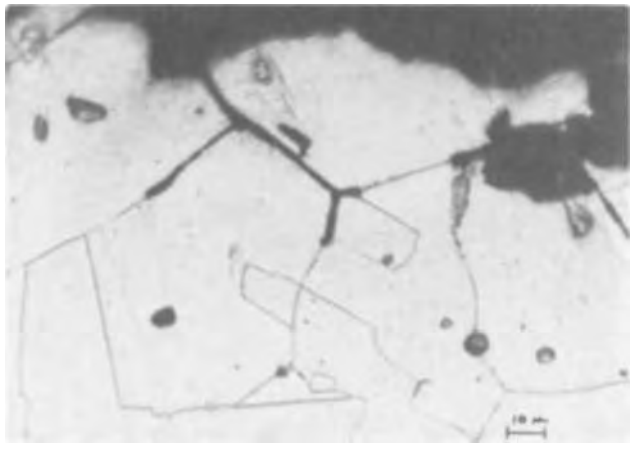

Fig. 9. 330 stainless corroded in a urea process stream

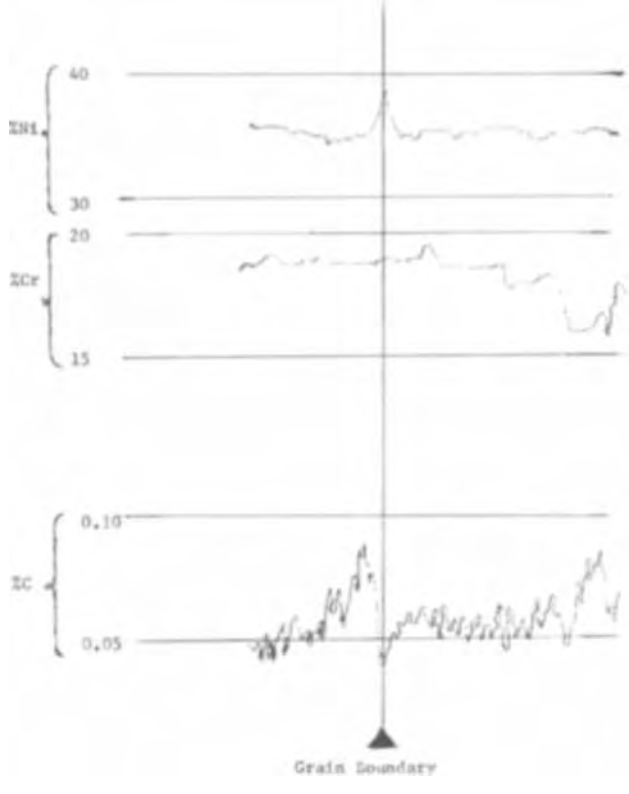

Fig. 10. Grain and grain-boundary composition of 330 SS for Ni, Cr, and C (electron microprobe).

Figure 6 shows a scanning electron micrograph of a piece of 316L SS (from the gas phase in urea synthesis) most of which is completely transformed into corrosion product. Only the lower left-hand corner is still metal. The corroded assembly is shown in Fig. 7. It was removed from a location close to that of the material shown in Fig. 1-5 and consists essentially of a tube, a ring, and a plate, only some of the ring still being in the form of metal.

In Fig. 8 one sees backscatter shots for the principal elements involved of the same area as Fig. 6. Quite obviously Fe and Mo have hardly been moved by the corrosion process, Cr has been considerably reduced, and Ni has virtually disappeared.

In another case, during testing in the gas phase of urea synthesis, a specimen of 330 SS showed severe intergranular attack (Fig. 9). Electron-microprobe traces (Fig. 10) for Ni, Cr, and C show no variation in Cr content, high Ni, and low C. Cr depletion, although obviously a cause, is apparently not the only cause for grain-boundary attack in austenitic SS. Ni enrichment, in the appropriate environment, can do the same thing.

Conclusions

The tests for intergranular corrosion in austenitic stainless steels specified in ASTM A262 are not applicable for this type of corrosion in highly ammoniacal environments.[1]

Intergranular corrosion of austenitic stainless steels in highly ammoniacal environments appear to be connected with increased Ni concentrations at the grain boundary.

The apparent corrosive mechanism is complexing of protective oxides by NH_3, dissolution of these oxides into ammonia, and dissociation of water by the unprotected metal.

Simultaneous Determination of Instantaneous Corrosion Rates and Tafel Slopes from Polarization Resistance Measurements

Florian Mansfeld*

North American Rockwell Science Center, Thousand Oaks, California 91360

Instantaneous corrosion rates are most commonly determined by the use of an electrochemical technique first described by Wagner and Traud (1) and Stern and co-workers (2, 3). This technique is now known as Stern-Geary technique, polarization resistance technique, or incorrectly (4) as linear polarization method.

It was shown by Wagner and Traud (1) and by Oldham and Mansfeld (4, 5) that for a polarization curve of the form

$$I = I_{corr}\left(e^{\frac{2.3(\phi-\phi_{corr})}{b_a}} - e^{-\frac{2.3(\phi-\phi_{corr})}{b_c}}\right) \quad [1]$$

the corrosion current I_{corr} is proportional to the slope of the polarization curve at the corrosion potential ϕ_{corr}

$$I_{corr} = \frac{1}{2.3}\frac{b_a b_c}{b_a + b_c}\left(\frac{dI}{d\phi}\right)_{\phi_{corr}} = \frac{1}{2.3}\frac{b_a b_c}{b_a + b_c}\frac{1}{R_p} = \frac{B}{R_p} \quad [2]$$

where R_p is the polarization resistance.

It is commonly believed that a serious limitation of the method discussed here is the fact that the actual current-potential measurement only leads to the value of R_p, while the values of the Tafel slopes b_a and b_c have to be guessed, taken from literature, or be determined in independent experiments. For this reason Hoar (6) expressed the opinion that the measurement of polarization resistance is superfluous in the electrical determination of corrosion rates. He overlooks, however, the important advantage of the polarization resistance method, namely that the system is disturbed only very little by the measurement which is especially important when the time behavior of corrosion rates is studied.

In the following it will be shown that the polarization resistance R_p and the Tafel slopes b_a and b_c can be determined simultaneously from the measured current-potential curve, thereby allowing calculation of instantaneous corrosion currents.

Combination of Eq. [1] and Eq. [2] leads to

$$I = \frac{1}{2.3}\frac{b_a b_c}{b_a + b_c}\frac{1}{R_p}\left(e^{\frac{2.3(\phi-\phi_{corr})}{b_a}} - e^{-\frac{2.3(\phi-\phi_{corr})}{b_c}}\right) \quad [3]$$

which can be written after rearrangement as

$$2.3\,R_p I = \frac{b_a b_c}{b_a + b_c}\left(e^{\frac{2.3\Delta\phi}{b_a}} - e^{-\frac{2.3\Delta\phi}{b_c}}\right) \quad [4]$$

where $\Delta\phi = \phi - \phi_{corr}$.

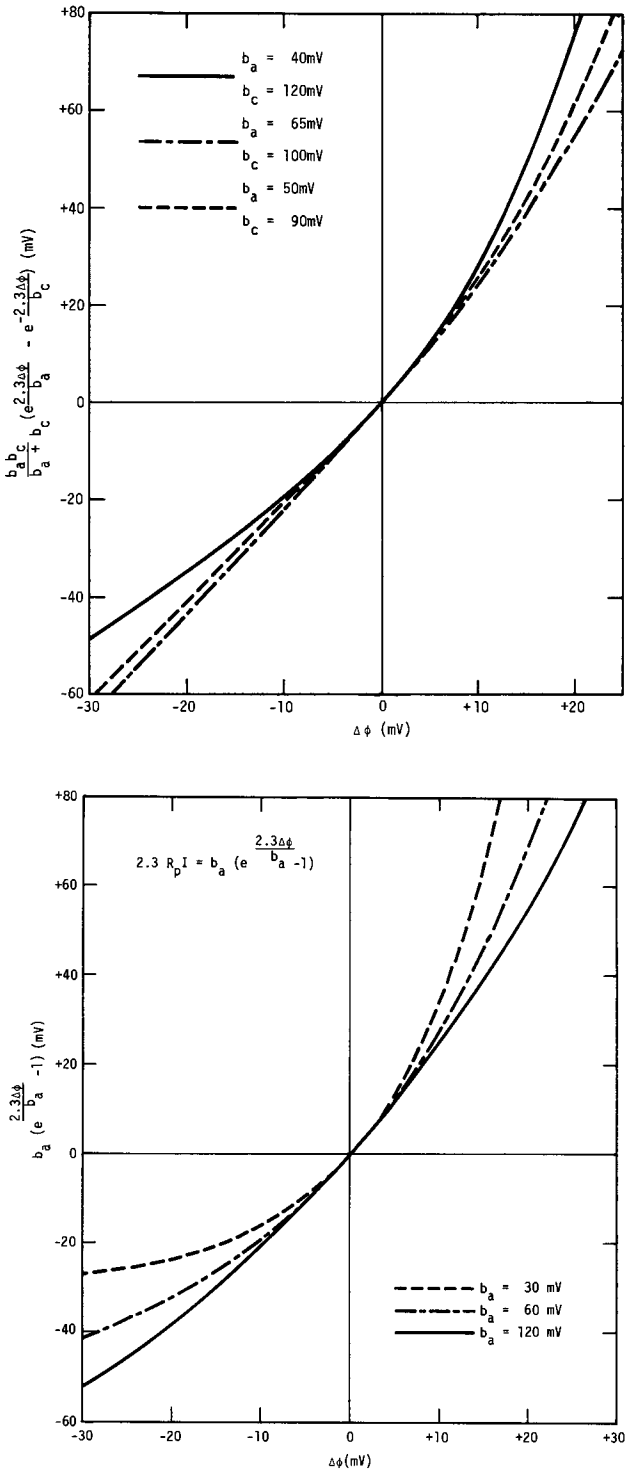

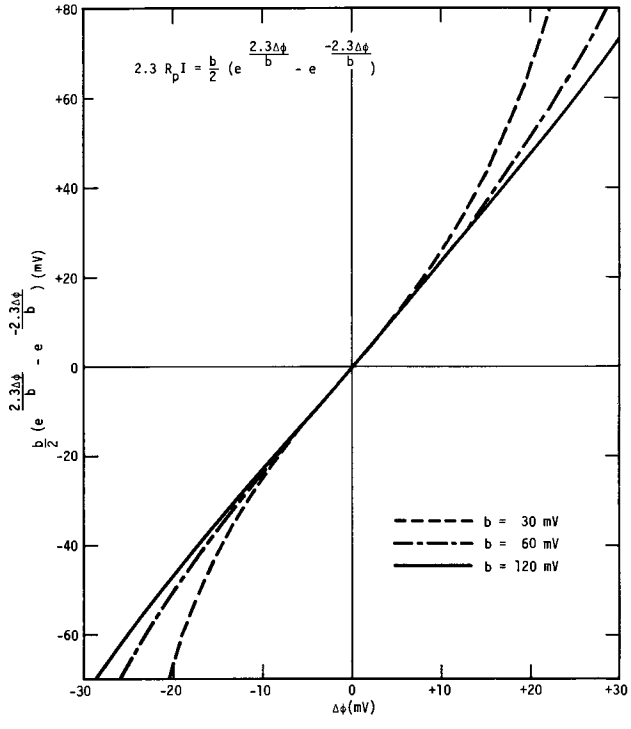

Fig. 1. Plots of right-hand side of Eq. [4] *vs.* $\Delta\phi = \phi$-ϕ_{corr}. (a, above left) Various combinations of Tafel slopes b_a and b_c, (b, left) $b_c = \infty$ (diffusion control), (c, above right) $b_a = b_c = b$.

It will be noted that the right hand side of Eq. [4] depends only on the Tafel slopes b_a and b_c. Figure 1 shows a plot of the right-hand side of Eq. [4] *vs.* $\Delta\phi$ for various combinations of Tafel slopes. It can be seen that the curvature of the plot depends on difference of the Tafel slopes b_a and b_c. Figure 1b shows a similar plot for the case where the cathodic reaction is under diffusion control ($b_c = \infty$), while in Fig. 1c it has been assumed that anodic and cathodic Tafel slopes are equal ($b_a = b_c = b$). Note the different curvature at cathodic potentials ($\Delta\phi < 0$) in Fig. 1b and Fig. 1c. These examples show that different kinetic behavior of a corroding metal, as expressed by different combinations of Tafel slopes, can be recognized based on plots according to Eq. [4].

The corrosion current I_{corr} can be calculated from the measured polarization curve in the following four steps which are based on Eq. [4] and Eq. [2]:

1. Determine the polarization resistance R_p from

$$\left(\frac{dI}{d\phi}\right)_{\phi_{corr}} = R_p^{-1}$$

by drawing a tangent at ϕ_{corr}.

2. Multiply the current I measured at a certain value $\Delta\phi$ by 2.3 R_p and plot

$$2.3\ R_p I \textit{ vs. } \Delta\phi$$

3. Determine from this plot the Tafel slopes b_a and b_c by curve fitting using theoretical curves calculated for various values of b_a and b_c.

4. Calculate I_{corr} from Eq. [2] using the R_p value determined in Step 1 and the Tafel slopes determined in Step 3.

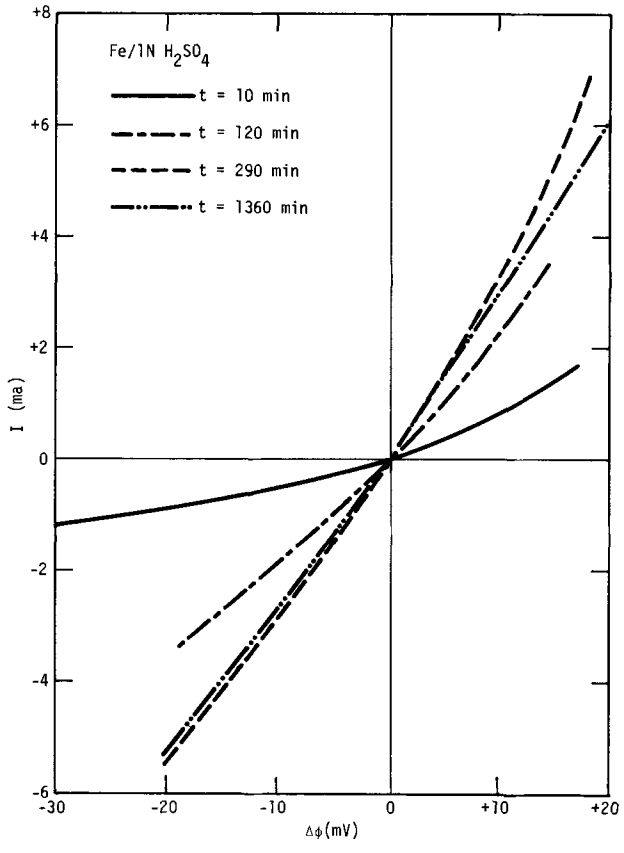

Fig. 2. Experimental polarization curves for iron in 1*N* H_2SO_4 as a function of time.

Experimental

This new type of analysis of polarization curves of corroding metals, described above, has been used for iron (99.9%, Johnson, Matthey & Company) corroding in 1*N* H_2SO_4. The polarization curves have been measured in the potentiodynamic mode using a sweep rate of 30 mV/min and $\Delta\phi = \pm 25$ mV. Duration of the experiment was 24 hr. Figure 2 shows some of the polarization curves obtained at various times of the experiment. From these curves the polarization resistance R_p has been determined graphically by drawing a tangent at $\Delta\phi = 0$. A plot of 2.3 R_pI *vs.* $\Delta\phi$ was then constructed according to Step 2. It was found using theoretical curves that the value of R_p could be determined within ±3%. An accurate determination of R_p is important for the success of the proposed method. If the graphically determined value of R_p is, for example, too high, then both b_a and b_c found by curve fitting will be somewhat too low. Experimental results are shown in Fig. 3a for the run recorded after 10 min and in Fig. 3b for the run recorded after 290 min. From Fig. 3a the values of b_a and b_c which fit the measured curve best are found to be $b_a = 30$ mV and $b_c = 95$ mV, while from Fig. 3b one finds $b_a = 55$ mV and $b_c = 105$ mV. The values of either the anodic or cathodic Tafel slope used to calculate the theoretical curves are varied in steps of 5 mV, since the procedure described here is not proposed for a quantitative determination of Tafel slopes but rather for a qualitative determination for situations where Tafel slopes are not known or where changes in Tafel slopes and corrosion rates are to be followed as a function of time, solution parameters, etc. While the calculations necessary for Steps 1-4 could be carried out best using a computer, the theoretical curves can be computed rather fast using desk top calculators. Once a set of theoretical curves corresponding to the right-hand side of Eq. [4] has been calculated, they can be used for analysis of any recorded polarization curve.

Results of the analysis of polarization curves for the system Fe/1*N* H_2SO_4 are summarized in Fig. 4. While there are some fluctuations of the cathodic Tafel slope b_c, there is a definite increase of the anodic Tafel

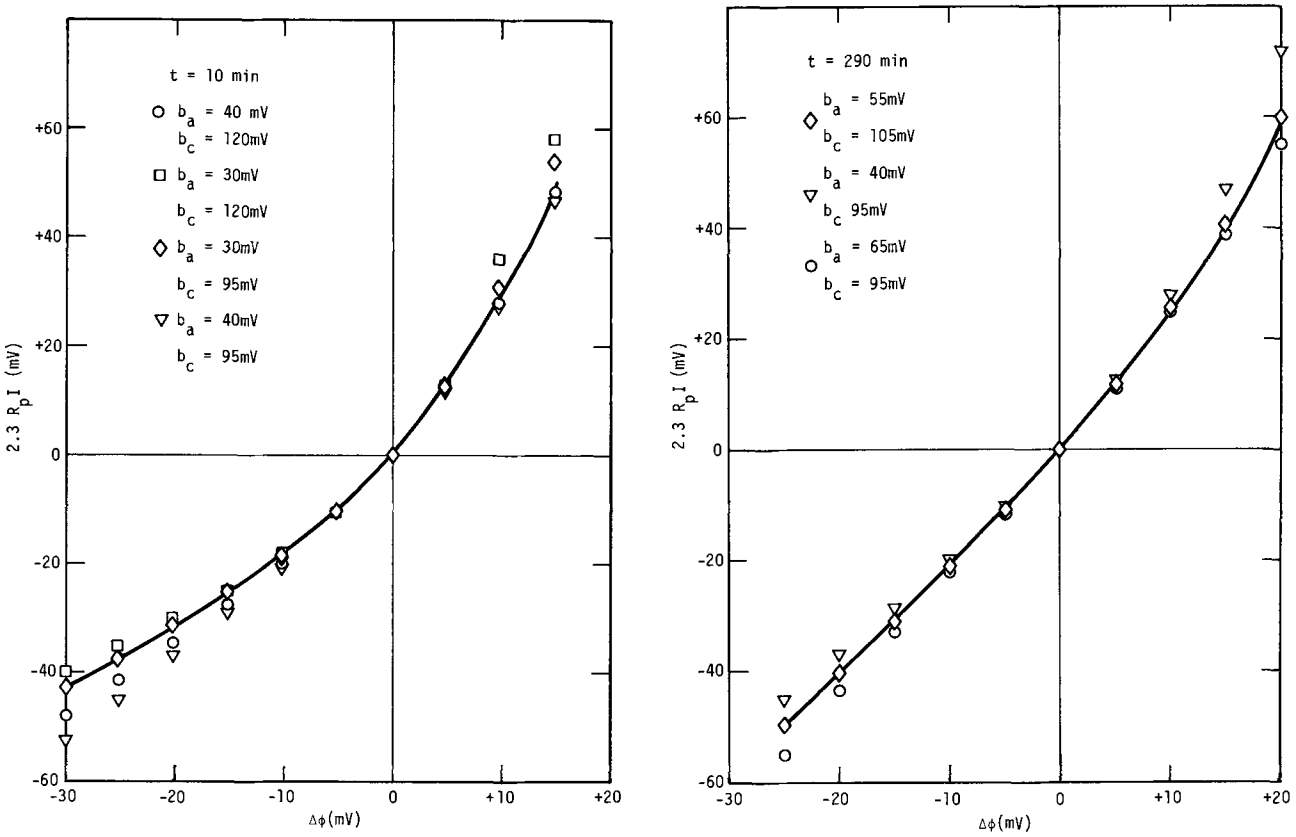

Fig. 3. Experimental curves (solid line) and theoretical curves, superimposed in order to obtain best values of b_a and b_c. (a, left) 10 min, (b, right) 290 min.

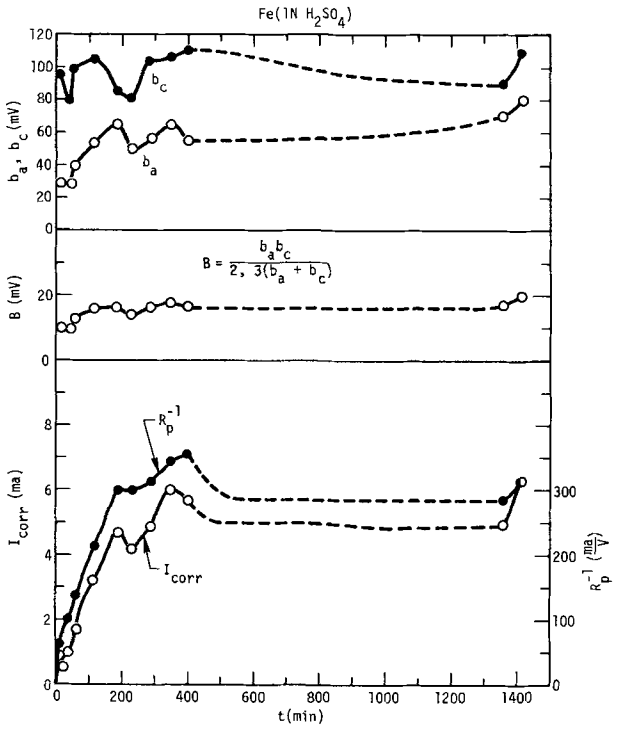

Fig. 4. Time behavior of corrosion parameters of iron in 1N H_2SO_4.

slope b_a with time. The factor $B = b_a b_c/2.3(b_a + b_c)$, which correlates polarization resistance R_p and corrosion current I_{corr} increases by about a factor of 2 from 9.9 to 20.2 mV during the 24 hr test.

Finally, the values of the inverse polarization resistance R_p^{-1} and the corrosion current $I_{corr} = BR_p^{-1}$ are shown in Fig. 4 for the 24 hr test. The corrosion current increases by about a factor of 10 in the first 6 hr of the experiment and then levels off. Similar results have been reported by Chin and Nobe (7) and Barnartt (8, 9). Since the factor B only increases slowly with time, the values of I_{corr} and R_p^{-1} show essentially similar behavior.

The experimental polarization curves, examples of which are shown in Fig. 2, have also been analyzed by a graphical method described recently by Oldham and Mansfeld (10). In this method the curvature of the polarization curve in the vicinity of ϕ_{corr} is used to obtain the corrosion current. A knowledge of the Tafel slopes b_a and b_c is not required for the determination of I_{corr}. In Fig. 5 corrosion current densities (C.D.) obtained with the two methods of analysis are plotted as a function of time. While there are some differences in the absolute values of i_{corr}, identical trends are observed. The fluctuations of i_{corr} between 200 and 400 min must be real because they appear in both analyses. It cannot be argued that they result from inaccurate determinations of the Tafel slopes b_a and b_c, because corrosion currents are determined directly from the measured polarization curve in the graphical method rather than being calculated from Tafel slopes and the polarization resistance.

After completion of the 24 hr test, the solution was analyzed for iron by atomic absorption spectroscopy. The amount of iron determined corresponds to a corrosion rate of 5700 mdd or a corrosion C.D. of 2.28

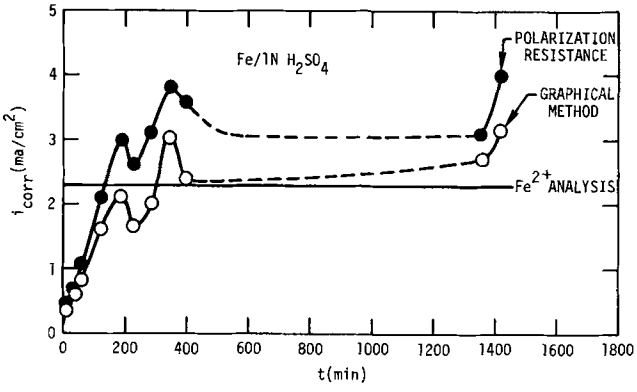

Fig. 5. Corrosion C.D. as a function of time obtained from two different analyses of experimental polarization curves and from chemical analysis of test solution.

mA/cm². This is in good agreement with the average corrosion C.D. from the electrochemical measurements especially when these are analyzed by the graphical method.

Barnartt using a galvanostatic procedure to obtain polarization curves which are then analyzed by a three-point method (11) has reported a similar time behavior of the corrosion parameters of iron in 1M $NaHSO_4$ (pH = 0.48) (8, 9).

Since the main purpose of this paper is to illustrate the new type of analysis of polarization curves of corroding metals, no attempts are being made to explain the observed variations of the Tafel slopes and corrosion rates with time. A complete analysis of the time behavior of all parameters of a corroding metal, would, however, certainly lead to a better understanding of mechanisms of corrosion.

Summary

It has been shown that polarization resistance values as well as Tafel slopes can be determined simultaneously from polarization curves in a potential region close to the corrosion potential so that instantaneous corrosion currents can be calculated. This new analysis of polarization curves is demonstrated in a study of the time dependence of the corrosion parameters of the system Fe/1N H_2SO_4.

Brief Communication

A Copper Ion Conducting Solid Electrolyte by Substitution of Silver in $RbAg_4I_5$

Bruno Scrosati*

Laboratorio di Chimica Fisica ed Elettrochimica, Università di Roma, Rome, Italy

The advantages of $RbAg_4I_5$ as a solid electrolyte are well known. The practical use of this electrolyte, however, has been limited, mainly because of the cost of the anodic material. This in fact has to be silver since the conduction through the electrolyte is due to silver ion movements. It is therefore obvious that an electrolyte with comparable properties but conducting via copper ions would be of great interest because of the low cost and large availability of copper. I will report here very preliminary results obtained in our laboratory in a program for the development of a copper solid electrolyte.

One possible candidate is cuprous iodide. It is known in fact that CuI possesses predominant ionic conductivity at low temperature, provided that there is not excess of halogen (1, 2). This conductivity is very low and assumes high values only above 300°C (1). Therefore cuprous iodide cannot be used as such since the main requisite for a useful solid electrolyte is a reasonably good ionic conductivity at room temperature. To approach this condition, we have tried to substitute to a certain extent the silver ions with copper ions in $RbAg_4I_5$. To realize this we have assembled the cell

$$Ag/RbAg_5I_4/Cu \qquad [1]$$

by pressing into pellets a mixture of powdered copper and electrolyte, the electrolyte, and a mixture of powdered silver and electrolyte. The electrolyte was added to the electrode materials to reduce interfacial polarization effects (3). The surface of each pellet was 1.25 cm^2, and the thickness was about 0.15 cm.

Cell [1] was polarized with the copper electrode as positive and maintaining the voltage below the decomposition potential of $RbAg_4I_5$ [0.67V at 25°C (4)]. Under these conditions, since the electronic conductivity of $RbAg_4I_5$ is very low [about 10^{-11} ohm^{-1}-cm^{-1} at 25°C (3, 4)], if copper did not dissolve in the electrolyte in the form of ions, the resulting current, under steady-state conditions, would be almost negligible. This is not the case, as shown by the current-voltage curve of cell [1], which applies to the initial behavior of the cell, reported in Fig. 1. Therefore a cell similar to [1] was submitted to constant-current electrolysis and a typical result, at I = 0.05 mA, is shown in Fig. 2. The rise in voltage is probably due to increase in cell resistance because of dendritic deposition at the negative with consequent loss of electrode/electrolyte contact (5, 6). Generally after a few coulombs were passed through the cell (four in the case shown in Fig. 2), the electrolysis was interrupted and the silver electrode was replaced by an iodine-benzidine (I_2-B) charge-transfer complex pellet. The iodine charge-transfer complexes act as iodine electrodes with reduced iodine vapor pressure (6). The resulting cell

$$Cu/Cu_x\text{-}RbAg_{4-x}I_5/I_2\text{-}B \qquad [2]$$

had at room temperature an open-circuit voltage of about 0.6V. Cell [2] was then discharged at constant currents and showed good discharge capabilities, as indicated by the discharge curves reported in Fig. 3. These are further indications that Cu^+ ions are present and mobile in the "substituted" $RbAg_4I_5$. Therefore it is reasonable to admit that silver can be, at least partially, substituted with copper in $RbAg_4I_5$.

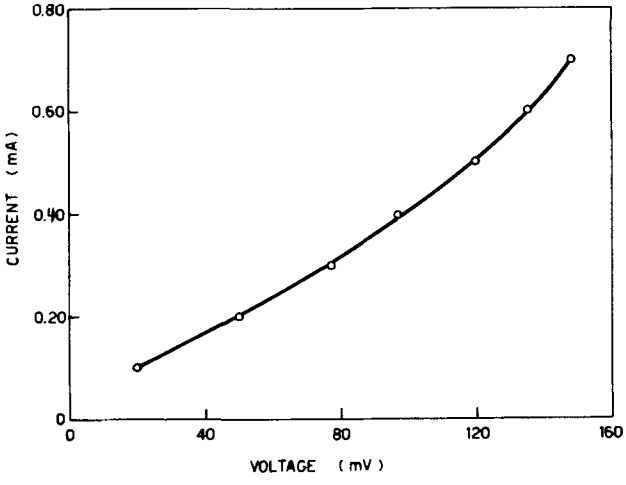

Fig. 1. Typical current-voltage curve of cell [1] at 25°C

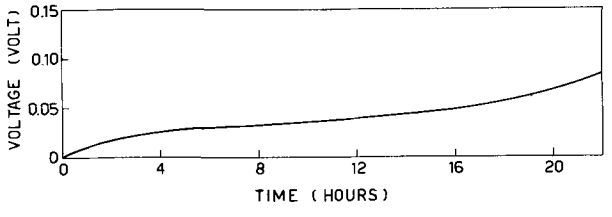

Fig. 2. Typical constant-current electrolysis (I = 0.05 mA) of cell [1] at 25°C.

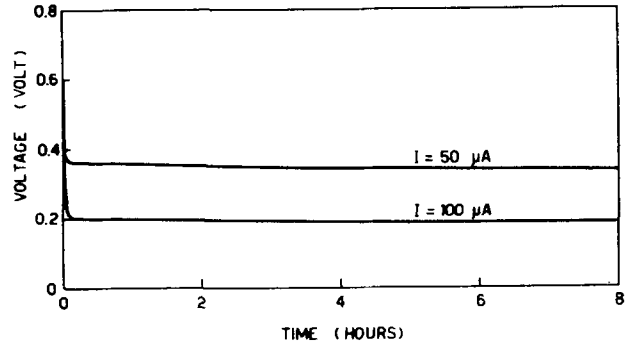

Fig. 3. Discharge curves of cell [2] at 25°C

* Electrochemical Society Active Member.
Key words: solid electrolyte, copper ions conductivity.

The study reported here is still in the very preliminary stage and further work is certainly needed to definitely characterize this electrolyte and determine the amount of silver which may be substituted with copper. Nevertheless, it seemed to be worthwhile to report these results since they tend to indicate that it could be possible to enhance the ionic conductivity of CuI by the formation of a double salt, as has been the case of AgI. Work in this direction is in progress in our laboratory and will be reported in a subsequent paper.

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

This paper describes a novel double-level metalization technique to fabricate charge-coupled devices (CCD's) where both metal levels are aluminum and the insulation between the two metalization levels is aluminum oxide formed by anodization. Anodization provides a simple, quick, method for forming the double-level system insulation. This technique relaxes the 3 μm (0.12 mil) electrode separation tolerance required for single-level metalization, since the thickness of the Al_2O_3 forms the interelectrode gap. The charge-transfer efficiency and stability of devices fabricated using this technique compare favorably with results obtained on devices fabricated using single-level metalization. A comparison of the Al-Al_2O_3-Al system with other double-level metalization systems indicates advantages in ease of fabrication and reliability, along with the capability of high speed operation of large arrays.

Charge-coupled devices (1-3), (CCD's) are semiconductor analog shift registers fabricated on a uniformly doped semiconductor substrate. The basic charge-coupling principle consists of storing minority carriers in potential wells at the semiconductor surface and transporting these carriers along the surface by translating the potential wells. The basic device structure is very simple and consists of a thermally oxidized semiconductor substrate with single-level metal electrodes on the oxidized surface. A cross section of the basic CCD structure is shown in Fig. 1 where silicon is the substrate material. The potential wells are produced by applying a voltage to the metal electrodes. The original, and the simplest, method of translating the potential wells along the silicon surface is to connect every third electrode to a separate clock line. Three electrodes then comprise an element: one electrode to hold and transmit the charge, the second electrode to receive the charge, and the third electrode to provide directionality to the charge flow. A three-phase pulse sequence may then be applied to the clock lines to transport a whole train of charge packets along the device surface. Diodes are generally used to inject charge into the potential wells at the input and to detect the presence of minority carriers at the output. The basis of the charge transport is the coupling of potential wells under adjoining electrodes so that the minority carriers may be transferred from under one electrode to the next. For reasonable substrate dopings and oxide thicknesses, this coupling requires electrode separations of approximately 3 μm or less. This metal separation is approximately four times narrower than present MOS production standards and presents one of the major problems in fabricating CCD's.

In addition to the tight metalization tolerances required, the single-level metal, three-phase system has two other drawbacks. The interconnection of three phases requires the use of a diffused tunnel to connect one of the sets of electrodes to the clock lines. Furthermore, the exposed oxide between the electrodes causes device operation to be sensitive to ambient effects. On a SiO_2 surface exposed to the ambient, ionic charges tend to accumulate and migrate under the influence of the electric fields. These migrating ions cause mirror charges in the silicon substrate which modify the potential barrier at the Si-SiO_2 interface, causing changes in the operating characteristics of the device. The problem of the close separation between metal electrodes can be alleviated by going to a double-level

Key words: high frequency operation, charge-transfer efficiency.

metal system (4, 5). In addition, a two-level system effectively seals the oxide surface from ambient effects. A double-level metal system has natural two- or four-phase symmetry. The two-phase system may be either a true two-phase, which uses a spatial asymmetry, or a pseudo two-phase system in which four electrodes actually are used for each element. True two-phase operation may be obtained by introducing an asymmetry in the fabrication process such as nonuniform oxide thickness (4-6) or an ion-implanted barrier (7). All of these two- or four-phase schemes have their own drawbacks, including additional processing steps. An excellent review article by Tompsett (8) provides a current evaluation of CCD development over the past two years.

This paper describes a novel double-level metalization technique in which both metal levels are aluminum and the insulation between the two metalization levels is aluminum oxide produced by anodization. The anodizing technique provides a simple, quick, method for forming the double-level system insulation. The insulation thickness of the Al_2O_3 forms the interelectrode gap, which allows normal metalization definition tolerances to be used. The double-level structure also seals the interelectrode gap from ambient effects and provides a coplanar, but overlapping, high conductivity metalization system.

Processing Concepts

The conversion of the surface of metallic interconnects to an insulating oxide by the process of anodization is used to form the interlevel insulator in this work. Aluminum has been chosen as the interconnect metal not only because of its capability of being anodized, but also because of its high conductivity. Any anodizable metal could, however, be used in the specific structure described above.

Aqueous and nonaqueous solutions of dibasic acids with finite solubility for the anodic oxide of aluminum have been used in this work. The resultant structures are assumed to be those modeled by Keller, Hunter, and Robinson (9). In this work, oxide thicknesses were determined by the product of current density and time, and the control parameter was that of time. Care must be exercised to eliminate extraneous current paths during the anodic process if adequate and simple controls are to be implemented. Specific details of the use of various electrolytes and the electrical characteristics of the anodization process are described by Young (10) and McMahon (11). Electrolytes which do not exhibit solubility for the anodic oxide may also be used to an advantage in that oxide thickness is then determined solely by the applied voltage and is found to be approximately 13.8 Å/V (12).

To ensure uniform rates of anodic conversion and uniform thickness of oxide coating, all surfaces subjected to the anodic processing must be at an equipotential during the anodization. In semiconductor processing this can be accomplished by connecting all clock electrodes to be anodized to a common potential and current-distribution bus during anodization. The distribution bus may be protected from the oxidation process by a photoresist coating during the anodic conversion. The lack of a protective oxide on the surfaces of such buses allows for their selective removal by etching during subsequent processing steps without additional masking operations.

Since the anodic oxide is grown atomistically from the metal itself, the adhesion between the metal and its oxide is excellent. It is also noteworthy that all surfaces exposed to the anodization condition, regardless of their topology or geometric orientation, are coated uniformly, since the propagation of the oxide-metal interface is perpendicular to the applied electric field. In addition, anodic processes are inherently self-healing, inasmuch as the maximum rate of conversion is found at the points of maximum field across the oxide film, *i.e.*, the thinnest oxide areas and pinholes in the oxide film are self-eliminating. The thin gate oxides exposed to the electrolyte and the applied field encountered in the anodic portion of the fabrication process are not affected if care is exercised in the selection of electrolyte and externally applied potentials.

Aluminum oxide is a recognized dielectric, and the electrical properties of the anodic form are well referenced in Young (10). Results of this work indicate that the anodic oxide of aluminum has a resistivity in excess of 10^{16} ohm-cm and a dielectric constant of approximately 8.6, with very little frequency dependence. Anodized films ranging from 700 to 6000Å are routinely grown in the fabrication of CCD's, and the breakdown strength of the films exceeds 6×10^6 V/cm (42V across 700Å). The pinhole density is less than 3/cm^2 with 5000Å of Al_2O_3.

Device Fabrication

The process steps used to fabricate a CCD using the aluminum-aluminum oxide-aluminum double-level metalization system are illustrated in Fig. 2; after the thick oxide is formed, the source-drain diffusion is made and the thin gate oxide is grown, (a), a layer of aluminum is evaporated over the entire wafer; (b), the aluminum is then patterned to form the first-level electrodes; (c), Patterning may be performed using standard photolithography techniques so that the minimum length of the electrodes and the separation between electrodes may be 10 μm (0.4 mil), as presently used in volume MOS production processes. Next, selected portions of the aluminum are covered with photoresist; these portions include, via holes from the first to second level, metal for bond pads and the anodizing connections. In a double-level metalization system there is no need for the clock electrodes to contact the semiconductor substrate; however, the electrochemical anodization process requires electrical contact to the CCD electrodes during anodization. The electrically isolated nature of the CCD electrodes in the finished device thus requires a temporary electrical connection to the anodizing contact. Typically, this anodizing contact (bus) is an extension of the first-level metal which is run to the scribe line. The first-level metal is then anodized; the portions covered with photoresist remain unanodized. In Fig. 2 (d), the anodizing converts an outer layer of the aluminum electrodes to Al_2O_3. The protecting photoresist is then stripped, and the second layer of aluminum is evaporated over the entire wafer. In Fig. 2 (e), this second level of aluminum is then patterned using standard photolithographic methods and acidic subtractive etching. In Fig. 2 (f), the patterning is performed so as to interleave the second-level CCD electrodes between the first-level CCD electrodes. The resulting structure consists of a set of coplanar, but overlapping, electrodes separated by a layer of anodized aluminum. During the patterning of the second-level electrodes, the anodizing contact (bus) to the first-level metal is also removed. The entire fabrication process can be accomplished with only one more additional photomask, the second-level metal photomask, than used to fabricate a single-level metal CCD. A reversal of the photomask normally used to open the protective oxide overcoat in the bond pad areas may be used to protect portions of the first-level metal from anodizing. The process of protecting the bond pads during anodization and of removing the bus bar along with second-level metal is illustrated in Fig. 3.

A photomicrograph of a finished device is shown in Fig. 4. The device was fabricated on 20 ohm-cm <111> n-type silicon using standard MOS techniques through the thin oxide growth step. The device shown is an eight-bit, four-phase, CCD shift register. The upper level metal (white in appearance) forms an interdigitated pattern consisting of the phase-one (ϕ_1) and phase-three (ϕ_3) electrodes. The lower level metal forms an interdigitated pattern consisting of phase-two (ϕ_2) and phase-four (ϕ_4) electrodes. Input and output

diode connections, along with transfer electrodes, complete the structure. The electrode length (measured in the direction of current flow) is 25 μm (1.0 mil) and the width is 250 μm (10.0 mils). The device was designed to test-fabrication concepts and for comparison with existing single-level metalization devices; no attempt was made to minimize bit size.

Electrical Evaluation

The drive circuitry shown in Fig. 5 was used to operate the eight-bit CCD shift register at data rates

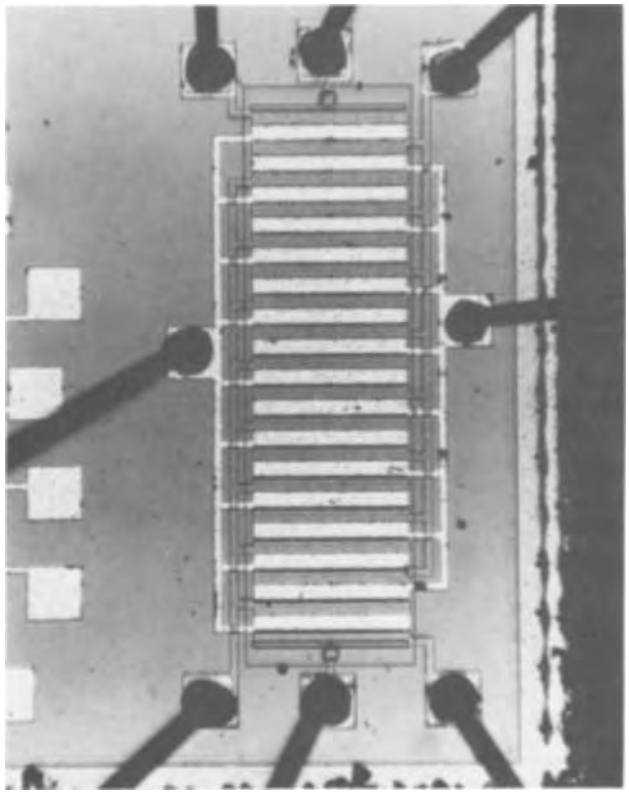

Fig. 4. Photomicrograph of eight-bit, four-phase Al-Al_2O_3-Al double-level metalization CCD shift register.

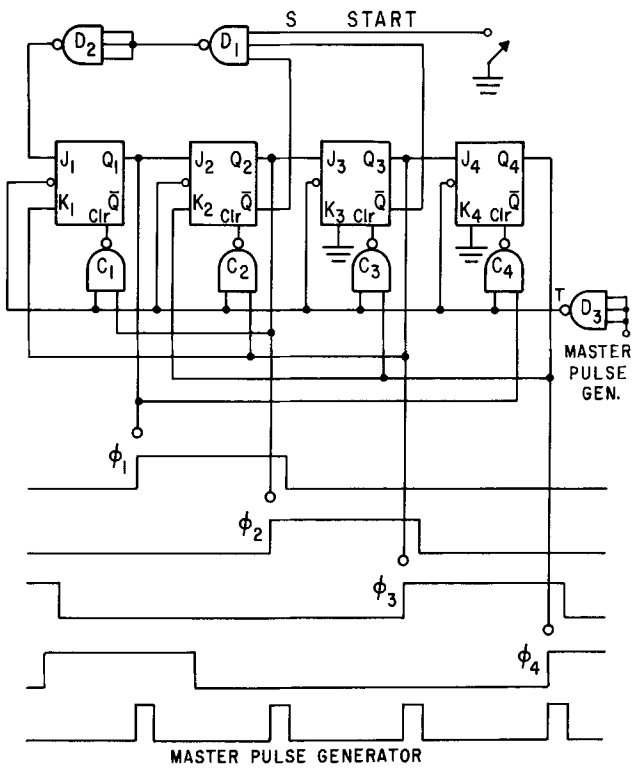

Fig. 5. Four-phase clock generator.

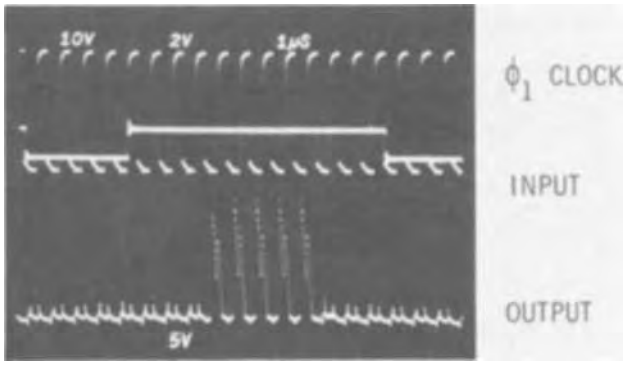

Fig. 6. Performance of anodized aluminum, double-level metalization, four-phase, eight-bit CCD shift register at 2 MHz, 25 μm (1.0 mil) electrode length, 15V clocks.

ranging from 100 kHz to 6 MHz.[1] Figure 6 shows the output of the shift-register, eight-clock periods after five "ones" are read into the register. The upper trace is the phase-one clock, the middle trace is the envelope of the input data, and the lower trace is the output. The output of five major pulses is followed by a small trailing pulse, illustrating the charge-transfer inefficiency associated with CCD (3). The charge-transfer inefficiency (percentage of charge not transferred from one electrode to the next) of this device is approximately 1.0×10^{-3} at 2 MHz. At 6 MHz the charge-transfer inefficiency increased to 7.0×10^{-3}. The departure from the ideal case of zero charge-transfer inefficiency is predicted by the time required for the thermal diffusion of minority carriers across an electrode of 25.4 μm (1.0 mil) length (13). The clock voltage used ranged from 9 to 15V, with the 15V necessary to obtain good charge-transfer efficiency at frequencies greater than 1 MHz. The stability of this device in an uncanned state was excellent. No change in operating parameters was observed over a testing period which extended over 1 month. The performance of a similar three-phase, single-level, metal shift register exhibited significantly poorer charge-transfer efficiency and stability. The three-phase device was fabricated in an identical manner to the double-level anodized device, except for the metalization, and had identical electrode geometry with 2.5 μm (0.1 mil) electrode separation.

Discussion

The primary advantage in using a double-level metalization system for the fabrication of CCD's is the elimination of the photolithographic requirement for close spacing between metal electrodes (<3 μm). However, if a significantly greater number of fabrication steps is required, or the technical problems involved in fabricating the double-level metalization system greatly exceed those encountered with single-level metalization, then little is gained by using a double-level system. The Al-Al_2O_3-Al system provides a simple fabrication method in which the separation between electrodes is determined by the Al_2O_3 thickness, not by photolithography, giving 3000Å rather than 3 μm electrode separation. Only one photomask, two photoresist definitions, one metal-etching step, and the anodizing are required in addition to the processing normally used for single-level metal devices. The anodization itself is quick, inexpensive, and simple. No high-temperature processing (>500°C) is necessary after the thin oxide growth. Both metalization levels are high-conductivity aluminum, and both levels have the same gate-insulator thickness, resulting in symmetric clock voltages. The insulation is quite reliable since the voltage used to form the Al_2O_3 is normally far higher than any voltages used in device operation.

The improved operating characteristics of the double-level metal anodized device shown in Fig. 6

[1] In the circuit shown in Fig. 5, each clock phase is overlapped by the preceding and following clock pulse in a controlled manner. At "start," a phase-one pulse appears first and at "stop," a phase-four pulse appears last. The circuit is self-correcting from any of the eight different error states which might occur due to noise transients or when power is first applied. Repetition rate and overlap are independently adjustable. Only four common TTL integrated circuits (two SN7473, one SN7410, and one SN7400) are used for input pulse rates ranging from 0.1 Hz to 24 MHz. The output phases are thus available up to 6 MHz with overlap equal to the width of the input pulse from the master pulse generator.

may be attributed to the close electrode separation on the n-type substrate. The narrow gap produced in the Al-Al_2O_3-Al system allows the fringing fields from the electrodes to suppress the potential barrier at the semiconductor surface. The removal of the barrier, in turn, allows a more complete transfer of charge to take place from one electrode to the next. The improved stability of the Al-Al_2O_3-Al system over the single-level Al system is explained by the sealed condition of the SiO_2 surface between electrodes. The SiO_2 surface between the electrodes in the Al-Al_2O_3-Al system is covered with a layer of Al_2O_3 which is covered with an equipotential layer of Al. Thus, surface migration of charged ions on the SiO_2 surface is prevented.

In addition to the Al-Al_2O_3-Al system, two other methods of fabricating CCD using double-level metalization have commonly been used. The first is the moly-SiO_2-aluminum (or the moly-SiO_2-moly) system (4). In this technology, one first deposits moly on the surface, patterns the moly, then insulates the first-level moly with a deposited oxide of some type. Finally, a second-level metal, either moly or aluminum, is deposited and patterned. In general, deposited oxides are less reliable than grown oxides and are subject to pinholes. Furthermore, the amount of insulation between two metal levels is critical, especially at the edges of the first-level moly, where the sharp corners, combined with high electric fields at these edges, have a tendency to cause breakdown in the weak deposited oxides. For reasonable fabrication yields, the deposited oxide must be at least as thick as the metal which it is covering. This would require approximately 2000Å of deposited oxide over the first-level metal and in the gap separating the first-level metal electrodes. This additional gate-oxide thickness under the second-level electrodes would necessitate asymmetric clock drives. Furthermore, since the higher oxides of moly are water soluble, any pinholes in the deposited oxide could cause reliability problems in a nonhermetic package. This system does have fairly high conductivity metal on both levels; and, as discussed below, with this system at reasonable frequencies we do not encounter the problem of two clock pulses getting out of phase as they travel down long electrodes. Because of the fabrication problems associated with this system, no large-scale MOS manufacturer is considering using it.

The second type of double-level system is the doped polysilicon-SiO_2-Al system (5) which is used extensively in MOS device manufacture. The attractive feature of this technology is that the insulator between the polysilicon and the aluminum is a uniformly grown insulator rather than a deposited insulator. This growth of the insulator makes it possible to have a reasonably thin insulating layer of SiO_2 of high integrity, as opposed to the deposited oxides, which never approach the integrity of a grown oxide. The problems with polysilicon revolve essentially around two aspects. First, due to the two oxide thicknesses, there is an asymmetry in the clock voltages necessary to run the device in a four-phase system. However, this system can be used very conveniently in a pseudo two-phase system where the polysilicon-work function difference, combined with the slight difference in oxide thickness under the two metalization layers, gives directionality.

The second problem with this system really lies in the difficulty of doping polysilicon to values near that of the conductivity of metal. The normal doping range of the polysilicon in MOS structures is in the 15-30 ohms per square range, which is approximately three orders of magnitude more resistive than aluminum. This high resistivity, along with an increased capacitance, causes clock pulses on different metalization levels to get out of phase. The propagation delay of a clock pulse in the distributed RC transmission line represented by the clock electrodes is approximately RC, where R and C are the lumped values of the line resistance and capacitance, respectively. Then

$$RC = \left(\frac{R_{\square} l}{w} \right) \left(\frac{\epsilon w l}{d} \right) = \frac{\epsilon R_{\square} l^2}{d} = \frac{8.8 \times 10^{-6}}{d(\text{Å})} R_{\square}$$

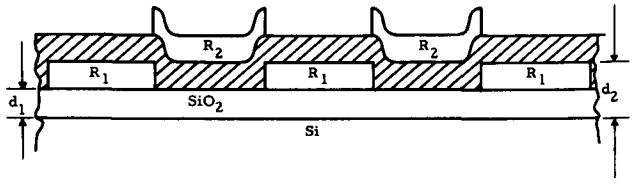
for $l = 200$ mils ($= 5080$ μm)

$$= \frac{5.5 \times 10^{-5}}{d(\text{Å})} R_{\square}$$

for $l = 500$ mils ($= 12{,}700$ μm)

where l is the length of the clock line, w is the width of the clock line, ϵ is the dielectric constant, and d is the thickness of the oxide under the clock line. In order to maintain proper phase relation between first- and second-level clock lines, the RC time constants for the two levels must differ by no more than a small fraction of the clock period. Assume a sheet resistance of 30 ohms/sq for for polysilicon, 3×10^{-2} ohms/sq for Al, and 5.7×10^{-2} ohms/sq for Mo. As shown in Table I, this requirement is best satisfied by the anodized aluminum electrode structure. The time constants associated with the polysilicon system will restrict operation to approximately 2 MHz for 200 mil long electrodes, and 300 kHz for 500 mil long electrodes. Since ultimate clock speeds of CCD's might exceed 5 MHz, this propagation delay is an important consideration in device layout. One could, of course,

Table I. Propagation delay along transfer electrodes, calculated as a distributed transmission line



System	Time constant of first-level R_1C_1 (sec) $l = 200$ mils (5080 μm)	$l = 500$ mils (12,700 μm)	Time constant of second-level R_2C_2 (sec) $l = 200$ mils (5080 μm)	$l = 500$ mils (12,700 μm)
Al-Al_2O_3-Al	8.8×10^{-11}	5.5×10^{-10}	8.8×10^{-11}	5.5×10^{-10}
Poly-Si-SiO_2-Al	8.8×10^{-8}	5.5×10^{-7}	7.5×10^{-11}	4.7×10^{-10}
Moly-SiO_2-Al	1.6×10^{-10}	1.1×10^{-9}	5.3×10^{-11}	3.3×10^{-10}

Calculated assuming
Al = 3×10^{-2} ohm/sq, Mo = 5.7×10^{-2} ohm/sq, poly-Si = 30 ohm/sq
and
$d_{1_{\text{Al-Al}}} = d_{1_{\text{Mo-Al}}} = d_{1_{\text{Poly-Si-Al}}} = 3000$Å $\quad d_{2_{\text{Al-Al}}} = 3000$Å, $d_{2_{\text{Mo-Al}}} = 5000$Å, $d_{2_{\text{Poly-SiO-Al}}} = 3500$Å

contact the polysilicon system with periodic ohmic contacts to a parallel metal electrode running alongside the polysilicon, thereby decreasing the resistivity. However, the use of ohmic contacts is a very inefficient use of area, and a polysilicon system that relied on a metal electrode running parallel with it to provide high conductivity would have such a large bit size as to preclude use of this system in the fabrication of large arrays.

Anodic Oxidation of Silicon in Organic Baths Containing Fluorine

M. Croset* and D. Dieumegard

Laboratoire Central de Recherches, THOMSON-CSF/Corbeville, Orsay (91), France

ABSTRACT

The anodic oxidation of silicon in organic solvents containing fluorine traces has been investigated by using nuclear microanalysis and electrical measurements. The results obtained show that the fluorine incorporation into the oxide N_F increases with the oxide thickness N_o and with the fluorine content of the bath $|F|$ following the experimental law $N_F = k\sqrt{N_O \cdot |F|}$. Most of the fluorine incorporated is located in a region close to the Si-SiO_2 interface; its surface distribution, studied by ion microprobe mass spectrometry analysis, appears to be uniform. The fluorine incorporation probably obeys a two-step mechanism. The breakdown field of the anodic layer decreases as a function inversely proportional to the fluorine contamination of the layer. The C-V measurements of the contaminated layers after annealing in H_2 show that the density of charges at the Si-SiO_2 interface is about $10^{11}/cm^2$. By comparing composition and electrical measurements, one may predict that fluorine is linked to silicon atoms as is oxygen in silicon oxide.

Anodic oxidation of single crystalline silicon samples in an organic electrolyte was proposed for the first time in 1957 by Schmidt (1). Since then the influence of the nature of the oxidation bath on the mechanism and kinetics of oxidation has been the subject of a number of studies (2-6). These studies have revealed the fundamental part played by traces of water present in the organic electrolyte and have shown the possibility of incorporating in the oxide impurities such as phosphorus, by contaminating the oxidation bath with phosphate ions. No systematic study has been undertaken concerning the presence of fluorine compounds in the electrolyte. Schmidt (1) pointed out that oxidation in an organic bath containing fluorine ions increases the current yield of the oxidation. The considerable chemical affinity of the F^- ion for silicon oxide justified a detailed study of the effect of fluorine on the kinetics and mechanism of the anodic oxidation of silicon. In the work described in this paper, two aspects of contamination were envisaged depending on whether the oxidation was conducted in an organic bath intentionally or not contaminated with fluorine. The addition of salts which could limit the effect of this contamination was envisaged and will be described in detail in a forthcoming article. The localization of the fluorine incorporated in the oxide was also studied.

We shall briefly describe the experimental techniques of cleaning, oxidation, and characterization used. The results which will be presented relative to the quantitative determination of traces of fluorine incorporated in the oxide by the use of the technique of microanalysis by direct observation of nuclear reactions (7-9). This technique, developed by Amsel and co-workers permits quantitative determination of the oxygen and the fluorine contained in the silicon oxide. All the nuclear measurements were carried out on the Van de Graaf accelerator of the Groupe de Physique des Solides of the Ecole Normale Supérieure de Paris.

Experimental

Oxidation technique.—The electrolytes were prepared from the same organic solvent: diethylene glycol containing potassium nitrite or aluminum nitrate. The choice of potassium nitrite was justified by past studies;

Key words: silicon dioxide, anodic oxidation, fluorine, oxygen, contamination, breakdown voltage, C-V measurements.

its concentration (4.7×10^{-2} mole/liter) assured a sufficient electrical conductivity. The aluminum nitrate had been selected for its possible effect on the fluorine ions contained in the bath, in view of the great affinity of aluminum and fluorine. The water content of the bath was adjusted to its optimum value (0.4% by weight) and verified by Karl Fischer determination. The fluorine-rich solutions were prepared by an addition of potassium fluoride. In order to eliminate the error due to a chance fluorine contamination of the starting glycol, the oxidation baths were prepared from the same batch solution of diethylene glycol and potassium nitrite.

Samples of N-type silicon supplied by Hoboken were used, with a resistivity close to 5 ohm · cm and orientation (1.0.0.), their surface being polished by a mechano-chemical process (11). Before oxidation, they were subjected to a cleaning cycle, the efficiency of which is discussed further on. The oxidation technique used was described in detail in Ref. (6). The Pyrex oxidation cell enables the sample to be placed as the anode opposite to a platinum cathode. The bath is homogenized throughout the oxidation by magnetic stirring. The electrical contact with the samples is effected by means of tantalum clamps previously oxidized at a voltage higher than that selected for the oxidation of the silicon. The contact surfaces of the clamps cleaned up with a file enable a satisfactory electrical contact to be obtained. The oxidation was performed at a constant current (most frequently 1 mA/cm^2) up to a predetermined voltage and was then followed by a stage at constant voltage. The final current was allowed to decrease to about 40 μA/cm^2 for all samples. After oxidation, the samples were rinsed in hot water and then in hot acetone.

Characterization of the layers obtained.—The composition of anodic SiO_2 films was characterized by nuclear measurement methods, their electrical properties were studied by C-V measurements and breakdown voltage determinations.

The growth law of the anodic film was studied by quantitative determination of the oxygen contained in the film as a function of the oxidation voltage; determination of the fluorine enabled the contamination of the silicon oxide in relation to a certain number of parameters (bath composition, oxidation voltage, etc.) to be followed. The O^{16} was determined by using the reaction O^{16} (d,p) O^{17*} initiated by a deuterons beam of 830 keV, the protons emitted being analyzed at a detection angle of 150°. The F^{19} was determined by using the reaction F^{19} (p,α) O^{16} initiated by a proton beam of 1270 keV, the α particles emitted being analyzed at a detection angle of 150°. The sensitivity calculated is 11×10^{14} atoms of F^{19}/cm^2 for a layer giving 100 counts for an irradiation of 200μ Cb and a solid detection angle of 0.12 steradians. The absolute oxygen standard was provided by a film of tantalum anodic oxide, the number of O^{16} atoms/cm^2 was known with an accuracy of about 3% (10). The absolute fluorine standard was a vacuum-deposited film of CaF_2 on a silicon substrate, known with an accuracy of about 7% (9).

C-V measurements were achieved on Si-SiO_2-Hg structures obtained by pressing an Hg drop at the oxide surface. This Hg probe technique permitted avoiding any change in the Si-SiO_2 interface state density and charge due to accidental thermal treatment during electrode deposition. Breakdown field determinations needed the use of well-defined capacitance geometry; Si-SiO_2-Al structures were obtained for the purpose by Al evaporation (1 μm thick, under a 10^{-6} Torr vacuum) and photolithographic localization of 650 μm diameter Al dots.

Results

Contamination of the surface of the silicon before oxidation treatment.—Influence of different cleanings.—The fluorine contamination of valve metal surfaces has already been studied by several authors (12-14). In the case of silicon, Kern (12) using F^{18} as a tracer showed that the surface immersed in HF solution adsorbs 10^{16}-10^{17} F atoms/cm^2; nevertheless, the major part of this contamination disappears by rinsing in cold water. Larrabee *et al.* (13) found contaminations of the order of 2×10^{14} atoms/cm^2 on silicon samples steeped in a buffer solution of fluorine (NH_4HF_2 + HF + H_2O) and rinsed in water. We have tried to reduce this contamination and to localize it. The results obtained after various types of cleaning are shown in Table I. It appears that the natural fluorine content on the surface of the silicon as delivered by the supplier is actually of the order of 10^{14} atoms/cm^2, whatever the origin of the silicon and the type of surface polishing used. This value thus seems typical of chemical post treatments of the surface rather than of its crystallographic state. The contamination does not disappear by simple dipping in solvents such as acetone and trichlorethylene. It increases after treatment in nitric acid but may drop below 10^{13} atoms/cm^2 after treatment in HF followed by rinsing in hot deionized water and acetone (duration of treatment in water was extended from 3 to 15 min without the fluorine content rising again above 10^{13} atoms/cm^2). Owing to these results, one may suppose that the fluorine is more probably incorporated in the layer of natural oxide at the surface of the silicon than located at the Si-SiO_2 interface or adsorbed on the natural oxide surface.

Fluorine contamination of the anodic oxide prepared in nonintentionally contaminated electrolytes.—The organic baths used for the oxidation were of the following composition: bath 1, diethylene glycol + ($4.7 \cdot 10^{-2}$ mole/liter) of KNO_2 and bath 2, diethylene glycol + ($6.7 \cdot 10^{-3}$ mole/liter) of $Al(NO_3)_3 \cdot 9H_2O$.

Bath 1 enables a formation voltage of 250-300V to be obtained without microbreakdown. At higher voltages, the oxide deteriorates, most frequently by the formation of pitting and local attack. Actually, the limit formation voltage V_{flim} is not absolute; it depends in particular on the silicon used (source, polishing, etc.). Thus certain samples of silicon free of dislocations enabled formation voltages of 350-400V to be reached in bath 1 without microbreakdown. In order to avoid these sources of irreproducibility, the measurements made were carried out on the same batch of silicon. Bath 2 enables distinctly higher voltages to be obtained which may exceed 600V without microbreakdown.

The fluorine content of the oxide layers, shown in Fig. 1, indicates that the incorporation increases with the formation voltage. The representative points of the linear part of the curves correspond to oxide layers which have no defects detectable by examination by optical dark field microscope. In that area, the amount of fluorine incorporated is proportional to the layer thickness, the F/O ratio being $2 \cdot 10^{-4}$. With high values of oxidation voltage ($V_f \geq 250$V), an excessive fluorine incorporation is found as compared with the linear law found previously. This excessive incorporation is associated with the occurrence of microbreakdowns which locally destroy the oxide layer.

The important effect of the aluminum ion on the limitation of contamination of the layers can be seen clearly in Fig. 1. It permits assuming that a stable aluminum-fluorine complex is formed in the oxidation bath. This effect, which occurs here in only slightly fluorine contaminated baths (natural contamination), shall be studied in detail for highly contaminated baths in a forthcoming publication.

Anodic oxidation of silicon in organic baths contaminated with fluorine.—The effect of electrolyte composition on the oxidation process and oxide composition has been studied in a more quantitative way by varying the fluorine ion concentration in the oxidation bath. Potassium fluoride has been selected to contaminate the bath, essentially because it yields a salt having the same cation as potassium nitrite and because its solubility limit in diethylene glycol permits high contamination levels.

The variation in fluorine content of layers prepared in baths with different KF concentrations is shown in Fig. 2 as a function of the oxygen content of the layers and their formation voltage, V_f. The same monotone variation of incorporation with oxide thickness as that in Fig. 1 is found qualitatively. Excessive incorporation at high thicknesses is associated in all cases with the occurrence of microbreakdowns during oxide growth. It appears that microbreakdowns occur for oxide thicknesses decreasing when bath contamination increases; however the highest quantity of fluorine which may be incorporated in the oxide without occurrence of microbreakdown is an increasing function of bath contamination. Thus, quantities up to 10^{15} atoms of fluorine per square centimeter can be incorporated in undisturbed oxide layers 100Å thick. In such layers, the average fluorine content defined by the ratio F/O reaches $F/O \simeq 2 \cdot 10^{-2}$. It should be pointed out that the proportionality between fluorine incorporation and oxide thickness for oxidation in a nonintentionally contaminated bath (Fig. 1) no longer applies to oxidation in contaminated baths. Here it seems (Fig. 2) that incorporation is proportional to the square root of oxide thickness, whatever the fluorine content of the electrolyte. Assuming that oxide thickness and bath contamination are independent variables, such incorporation may then be expressed by a law of the type

$$N_F = k \cdot \sqrt{N_O} \cdot g\,(|F|) \qquad [1]$$

where N_F and N_O are the quantities of fluorine and oxygen, respectively, contained in the oxide layer; $g\,(|F|)$ being a function of the independent parameter $|F|$ expressing the fluorine concentration in the bath.

The effect of the value of $|F|$ has been studied over a wide range of concentrations from $2 \cdot 10^{-3}$ to $2 \cdot 10^{-8}$ mole/liter of KF. The results obtained are shown in Fig. 3 which gives the variation in the ratio $N_F/\sqrt{N_O}$ for increasing formation voltages V_f *vs.* the bath composition. For potassium fluoride concentrations of the order of 10^{-5} mole/liter and over, the ratio $N_F/\sqrt{N_O}$ becomes saturated: the oxide layer formed is then fully disturbed. A typical aspect of a surface oxidized under these conditions is shown in Fig. 4; detachments of the oxide layer are noticeable and may result in corrosion of the silicon. In this region, the value of the ratio $N_F/\sqrt{N_O}$ is approximately 3% and can therefore correspond to the average limit composition of the nonadhering contaminated oxide layer. At KF concentrations in the bath below 10^{-5} mole/liter, the fluorine incorporation law is

$$\frac{N_F}{\sqrt{N_O}} = k\sqrt{|F|} \qquad [2]$$

This law is ascertained for various values of the oxidation voltage from 20 to 150V (Fig. 3). It confirms and defines Eq. [1] more accurately. The validity of the formula [2] for various oxide thicknesses permits assuming that the mechanism of fluorine incorporation in the oxide may be studied as a function of two parameters: the composition of electrolyte and the transport of the fluorine in the layer. These two parameters seem to be independent of each other. However, it should be noted that they seem to have

a different action on the maximum fluorine incorporation into the oxide. This fact will be discussed further on.

The mean value of the oxidation yield has been obtained by comparing the electrical charge used throughout the phases at constant current and voltage, and the quantity of oxygen fixed. Results are shown in Fig. 5 *vs.* the fluorine content of the oxidation bath. For KF values below 10^{-5} mole/liter, oxidation yield increases slightly. For KF values above 10^{-5} mole/liter, efficiency increases rapidly but such increase is associated with disturbances in the oxide layer and an excessive incorporation of fluorine.

Locating the fluorine in the oxide layer.—Location of fluorine atoms in the layer has been obtained by determination of the total quantity of fluorine remaining in the contaminated layer during chemical dissolution steps. In such experiments, the layer of silicon oxide had to be sufficiently contaminated to permit determining the fluorine content with sufficient accuracy; it had to be sufficiently thick to permit dissolving by steps.

Several experiments using silicon of different origin, have enabled fairly thick layers to be obtained (V_f = 170V) with a sufficient contamination level (bath of 2×10^{-6} mole/liter of KF) and an adequate surface condition after oxidation. Oxidations were carried out on large silicon samples which were then cut out in several pieces, each of which was dipped for increasing dissolving times in a 1% HF solution. The fluorine contamination of the oxide surface by this dissolution bath has been estimated by partial chemical dissolution of thermal and anodic silicon oxide layers. No contamination could be evidenced on anodic films containing about 10^{13} F atoms/cm^2; with thermal layers containing less than 10^{13} F atoms/cm^2, one could detect a possible level of contamination in the 10^{13} F atoms/cm^2 range. The curve drawn on Fig. 6 shows the variation in the fluorine quantity remaining in the layer *vs.* the remaining oxide thickness. The figure also shows the total quantity of fluorine incorporated in oxides during their growth in the same contaminated bath *vs.* their thickness. Results given by these two types of experiments are very similar. They are on good accordance for films thicker than 200Å; for thin layers a slight deviation may exist which may be due to various experimental irreproducibilities, such as nonhomogeneous dissolution, cumulative contamination, or irreproducibility of bath composition. The analysis of the shape of the curve shows that the greatest part of the fluorine is located in a region close to the silicon-silicon oxide interface, with a thickness not exceeding 100Å (expressed in stoichiometric silicon oxide). Assuming that contamination of this layer is homogeneous, its fluorine content is of the order of F/O $\simeq$ 4%. This result is comparable with that found as a limit contamination of the disturbed layers (see above). Since the layers analyzed in Fig. 6 correspond to a maximum contamination prior to the occurrence of microbreakdowns, it can be assumed that microbreakdowns occur when fluorine contamination of the interface region reaches this limit value of F/O $\simeq$ 4%. It appears that except for interface region, the fluorine content of the oxide layer is low and seems homogeneously distributed in the layer. From the slope of the curve, one can evaluate this content to about F/O = 0.25%.

Owing to the similarity of the results obtained by partial dissolution and direct growth, it may be supposed that fluorine incorporated in the oxide layer moves in a similar manner to oxygen, either during the oxide growth phase or during the current decay phase. Then, the inhomogeneous distribution of fluorine in the layer would imply two successive incorporation mechanisms. These assumptions will be discussed further on.

Electrical characterization of the layers.—Determination of the breakdown field.—Circular aluminum dots, 650 μm in diameter, separated by 1 mm were distributed over the whole surface of the SiO_2 layer to be tested. A voltage ramp (duration 0.5 msec) was applied across the MOS capacitance in a direction

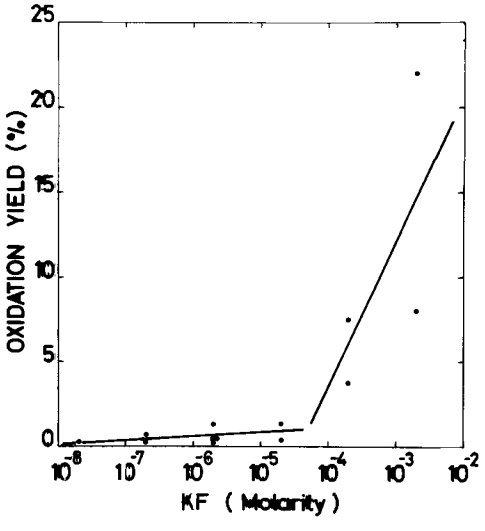

Fig. 5. Variation of the oxidation yield as a function of the KF concentration in the bath for SiO_2 films formed at V_f = 50V.

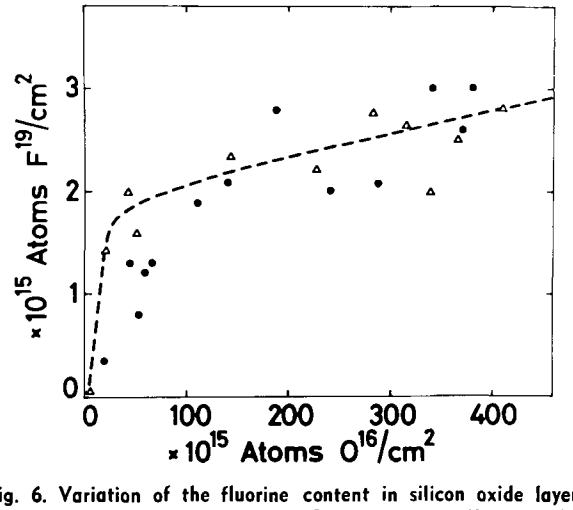

Fig. 6. Variation of the fluorine content in silicon oxide layers formed in glycol containing $2 \cdot 10^{-6}$ mole/liter of KF. The (Δ) distribution is obtained by determination of the fluorine quantity remaining in an oxide layer formed at V_F = 170V during its chemical dissolution by steps. The (●) distribution is obtained by counting the total quantity of fluorine incorporated as a function of oxide thickness.

such (positive bias on metal grid) that it created electron enrichment of the Si surface. The capacitance charging current $i(t)$ was stored and recorded immediately afterward on an XY recorder. The duration of this transcription (about 10 sec) enabled about a hundred MOS structures to be tested fairly quickly on each sample. Depending on the layers studied, various types of current *vs.* prebreakdown voltage curves are obtained, as shown in Fig. 7. For a given value of the breakdown voltage V_A of the oxide, the curve may exhibit (curve a) a first current peak corresponding to the first nondestructive microbreakdown. The increase of the electric field in the layer then causes breakdown V_D to occur. Note that the saturated value of the current is then defined by the electronic memory amplifier and has no experimental significance. Curve b corresponds to an exponential current increase up to breakdown V_D, with no appearance of pre-microbreakdown. Purposely contaminated layers (KF bath) lead to type a curves in all cases; layers prepared in nonintentionally KF-contaminated baths yield type a or type b curves.

Figure 8 is a breakdown field histogram taking electric field intervals of $1 \cdot 10^6$ V · cm^{-1} for layers slightly contaminated with fluorine and intervals of $0.1 \cdot 10^6$ V · cm^{-1} for contaminated layers. The thickness of the layers approximated 1000Å. The layers with a low level of contamination (about 1.4×10^{14} atoms/cm^2) has a maximum number of capacitors with a breakdown field within 6 and 7×10^6 V · cm^{-1}, this result is in agreement with those found by other

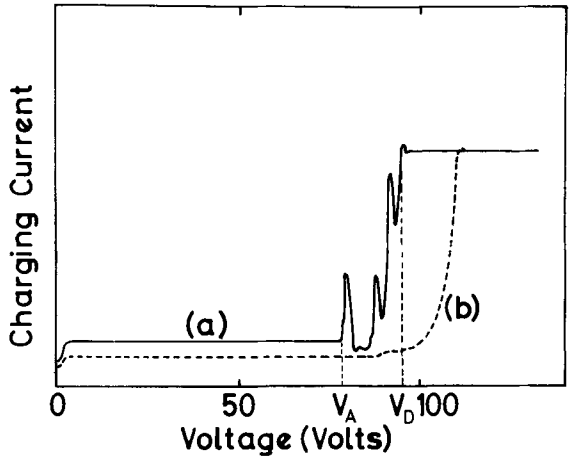

Fig. 7. Typical voltage current characteristics of Al-SiO_2-Si capacitance structures.

SiO_2 layer 1000Å thick containing $14 \cdot 10^{13}$ atoms F^{19}/cm^2. b. SiO_2 layer 1000Å thick containing $66 \cdot 10^{13}$ atoms F^{19}/cm^2.

authors (15-17). The results achieved on highly contaminated layers show that the breakdown field decreases as a function inversely proportional to the fluorine content of the layer. This is illustrated in Fig. 9 giving the variation of E_a and E_d (at $\Delta N/N = 30\%$) with the fluorine content of the layer. The small scattering of the values of E_a and E_d for the contaminated layers implies that the fluorine distribution at the Si-SiO_2 interface is homogeneous, at least at the scale of a circular surface 650 μm in diameter.

C-V *measurements.*—As is known, plotting of the curve $C = f(V)$ of a MOS capacitance is an easy way of analyzing the properties of silicon oxide and of the Si-SiO_2 interface (18). This method has been widely described and used by many authors, and a few essential results will be recalled here. The translation ΔV between the theoretical and experimental capacitance *vs.* voltage curves is characteristic of the presence of electric charges Q moving within the dielectric and of the presence of a surface state Q_{ss} located at the interface. A distortion of the experimental curve implies the presence of acceptor or donor traps N_{ss} located in or near the interface.

Measurements were made at a frequency of 50 kHz. Contact with silicon was achieved through a silver lac, the metal grid on the silicon was most of the time produced by compression of a mercury drop. Just after oxidation, the capacitance-voltage curves obtained on contaminated layers are translated and distorted with respect to the theoretical curve; a hysteresis effect is sometimes observed. The relative position of the curves obtained is at random with the fluorine content of the layers.

The effect of annealing treatments between 400° and 500°C in hydrogen has been studied using SiO_2 films 900Å thick containing about 10^{15} fluorine atoms/cm^2. Nuclear measurements of layers before and after thermal treatment at 500°C did not evidence any fluorine content variation; no redistribution could be evidenced by using a CAMECA ion microprobe mass spectrometer which gave similar fluorine profiles in SiO_2 before and after annealing. The *C-V* curves obtained after different types of treatment (duration and temperature) are shown on Fig. 10; the experimental and theoretical curves appear to be parallel and translated by a low amount ($\Delta V \simeq 1$V for the lowest saturation value) which corresponds to a density of charges at the Si-SiO_2 interface of about 10^{11}/cm^2.

Discussion

The essential subject of this work was to study the effect on anodic silicon oxidation of the presence of fluorine traces in the oxidation bath. The results obtained relate to layers obtained by oxidation at con-

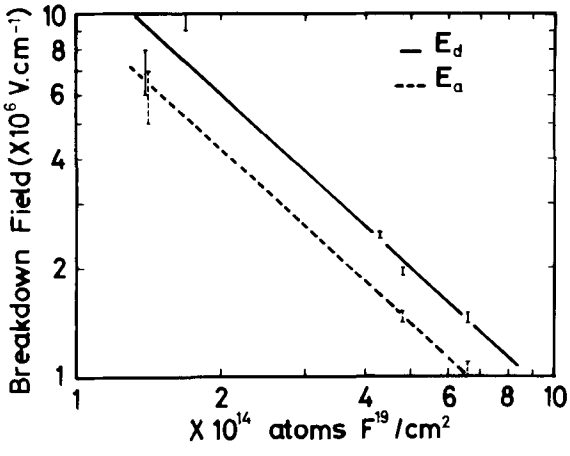

Fig. 9. Variation of breakdown field as a function of fluorine in SiO_2 film. The values E_d and E_a correspond, respectively, to V_D and V_A defined on Fig. 7.

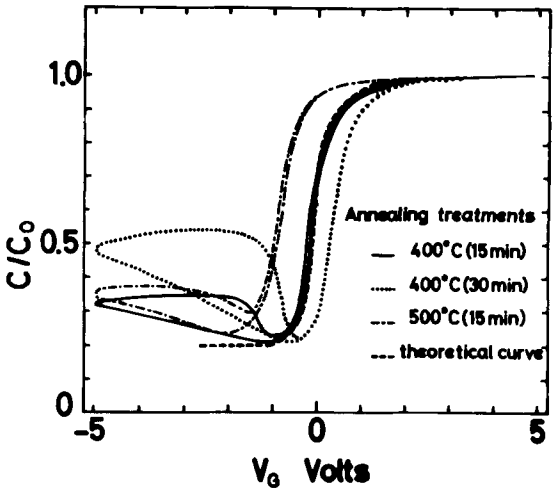

Fig. 10. Capacitance-voltage characteristic curves of MOS structures contaminated with fluorine. Influence of temperature and duration of annealing treatments in hydrogen ambient.

stant current followed by a phase at a voltage kept constant up to achievement of oxidation currents as low as 40 μA/cm^2. The influence of the value of the final oxidation current on the fluorine incorporation has not been studied in this work. A few preliminary oxidation experiments seem to show that incorporation is only slightly dependent on the value of the final current. Note that excessively long periods at constant voltage, seem to be associated with extra fluorine incorporation which might correspond to a recrystallization step of the oxide layer. More precise studies are being carried out on this subject.

In general, it was found that contamination of the electrolyte with fluorine results in a fluorine contamination of the silicon oxide obtained. This incorporation may be affected by the initial surface condition of the silicon sample, the oxidation parameters, and the electrolyte composition. Most of the oxidations have been carried out at a current density of 1 mA/cm^2; experiments at oxidation current densities varying between 0.5 and 10 mA/cm^2 have not evinced a significant variation in fluorine incorporation; it should be noted that in these cases the current decay phase may have masked possible differences associated with the initial value of the oxidation current.

The results obtained in the section on Contamination of the surface of the silicon show that natural contamination of the silicon surface of the order of 10^{14} atoms/cm^2 may be reduced to less than 10^{13} atoms/cm^2 by cleaning. It should be noted that exposure of such surface to the air results in the slow reconstitution of an oxide layer and in the restoration of the contamination level which depends on the environmental conditions. It seems that fluorine is incorporated in this natural oxide layer. Silicon surfaces, thus covered with their natural oxide, containing about 10^{14} fluorine atoms/cm^2, retain their contamination ratio, even after high-temperature heat-treatment in an oxidizing atmosphere. Thus, about 10^{14} atoms/cm^2 of fluorine are found again in a 1400Å oxide layer generated either at 1000°C in water vapor, or at 1100°C in dry oxygen. Oxidation under the same conditions of noncontaminated surface (less than 10^{13} atoms/cm^2) yields no noticeable incorporation of fluorine. Consequently, natural contamination of the silicon surface may be considered as stable and associated with the presence of a natural oxide layer. Anodic oxidations have all been carried out on surfaces free from such contamination.

The results obtained in the sections on Fluorine contamination and on Anodic oxidation of silicon show that the maximum oxidation voltage $V_{f\text{lim}}$ seems to depend on the origin and purity of the electrolyte. In particular, the addition of a fluorine salt involves a reduction of $V_{f\text{lim}}$ due to the early occurrence of microbreakdowns. The variation of $V_{f\text{lim}}$ *vs.* the level of contamination of the electrolyte (through addition of KF) permitted us to evaluate the order of magnitude of random contamination in the bath 1. The value found, about 10^{-9} equivalent mole/liter of KF, shows the predominant role of the handling of said baths on the oxidation results. In particular, their exposure to air in the laboratory, without precaution, may be the source of multiple irreproducibilities. In this work, all the oxidations were carried out in a sealed enclosure protected from the air; likewise, each series of experiments for the study of a given parameter has been carried out from the same batch solution of electrolyte.

Fluorine incorporation into the oxide increases with the oxide thickness and the fluorine content of the bath. Microbreakdowns of the oxide layer occur when the fluorine content of said layer reaches a limit value related to the bath contamination. Oxidation is then replaced by a corrosion of silicon due to successive periods of oxide formation and stripping of said oxide exposing local silicon areas which become oxidized in turn. The fluorine content of the disturbed oxide layer thus created (F/O = 3%), is unaffected by the fluorine content of the bath over the range studied. This limit content seems to be associated with the oxide stripping effect. It should be noted that there is a difference between contamination level of the oxide associated with the occurrence of microbreakdowns, which depends on the bath composition, and that associated with silicon corrosion, which does not seem to be related thereto over the concentration range considered. Fluorine incorporation into the oxide increases as the square root of the fluorine content in the electrolyte. This result may be due to a dissociation balance of the fluorine salt according to the law of mass action

$$KF \rightleftarrows F^- + K^+$$

where

$$|F^-| = K_C \frac{|KF|}{|K^+|}$$

and

$$|F^-| = |K^+|$$

Hence

$$|F^-| = \sqrt{K_C \cdot |KF|}$$

where only ionized fluorine fraction $|F^-|$ participates in the incorporation effect. The part played by the aluminum salt, limiting fluorine incorporation, may be attributed to the creation of an aluminum-fluorine complex which no longer participates either in full or part, in the incorporation. It should be noted that the variation of fluorine incorporation in the layers *vs.* intentional contamination of bath 1 with KF (Fig. 3) permitted the definition of the contamination level of bath 1; the result obtained (about 10^{-9} atom-gram/liter) is in agreement with the value estimated by analysis of the variation of $V_{f\text{lim}}$.

The results of the section on Locating the fluorine show that the fluorine distribution in the layer obtained by direct oxidation is very similar to that obtained by step dissolution. However, it should be emphasized that the oxide layers of the same thickness thus compared (by direct oxidation or after dissolution) have not been subjected to the same current decay phase at constant voltage. The model proposed below therefore presupposes that this final oxidation phase has a negligible effect on fluorine distribution. This point has to be verified. The result found means that the quantity of fluorine contained in a well-defined fraction of the oxide thickness (*e.g.*, within the first 100Å from the Si-SiO$_2$ interface) do not depend on the thickness of silicon oxide which covers this fraction; in other words, the quantity of fluorine in a silicon layer, x_0 thick, remains unchanged whether this layer is obtained by direct oxidation to x_0 or by oxidation to $x_0 + \Delta x$ and thinned by Δx, whatever the value

of Δx. Note that this interpretation is a schematic of the results which neglects the scattering of measurements clearly evinced in Fig. 6. It implies that at least the essential part of the fluorine incorporated during the growth is fixed at the very surface of the oxide in contact with the electrolyte and consequently that the fluorine does not migrate through the oxide layer by a long range migration mechanism.

Fluorine in the oxide exhibits a highly inhomogeneous distribution; the important part of the fluorine located at the $Si-SiO_2$ interface is fixed during the initial phase of the oxidation (corresponding to SiO_2 layer 100-150Å thick) and is not the result of an accumulation mechanism at the Si/SiO_2 interface during growth of thicker oxide film. It may be assumed that this high fluorine concentration in a region close to the $Si-SiO_2$ interface is associated with the existence in said region of silicon oxide layers more or less crystallized, such as that found for steam-grown oxide (19). This result seems to indicate the existence of two separate incorporation mechanisms, one affecting only an initial layer with a thickness approximating 100Å, the other affecting the remainder of the layer. In such a hypothesis, the square root dependence of fluorine incorporation on oxide thickness derived from Fig. 2 and 6 might only be the over-all result of these two successive steps. Then, both steps might independently obey a $\sqrt{|F|}$ law imposed by the electrolyte.

A separate study of the interface layer and of the bulk of the oxide would be required to define the fluorine incorporation mechanism more precisely.

The results obtained in the section on Electrical characterization show that after annealing of the MOS structures, the C-V curves have never exhibited an interface charge density higher than 10^{11} cm^{-2}. By comparing this value to the high concentration of fluorine atoms in this interface region (about 10^{15}/cm^2) and since annealing is associated with no detectable fluorine movement, one may suppose that fluorine is linked to silicon atoms, as is oxygen in silicon oxide.

It should be emphasized that the hysteresis of the C-V curves, from the viewpoint of an exchange of electrical charges between silicon and silicon oxide, confirms the existence of a disturbed interface whose composition and, probably, structure are different from those of the bulk silicon oxide.

The decrease in the dry breakdown field associated with fluorine incorporation into the layer was found to be very important. The uniform distribution of the breakdown field at the surface of the contaminated silicon oxide has shown, at least at the 650 μm scale, that surface fluorine distribution was homogeneous. Such a result has been complemented by ion microprobe mass spectrometry analysis of a thin silicon oxide layer highly contaminated with fluorine ($3 \cdot 10^{15}$ atoms/cm^2). The layer thickness, about 140Å, corresponded approximately to the thickness of the highly contaminated interface region. The image of the fluorine distribution was obtained with a CAMECA ion microprobe mass spectrometry apparatus which has a surface resolution of 1 μm; this image evidenced a uniform fluorine distribution on such a surface.

As a conclusion, this study has demonstrated that fluorine incorporation into silicon anodic oxide increases with the oxide thickness and with the fluorine content of the electrolyte. The essential fraction of fluorine incorporated is located at the Si/SiO_2 interface and has a uniform surface distribution. The fluorine incorporation obeys probably a two-step mechanism which is still under study. The fluorine contamination disturbs the growth kinetics of the oxide and its electrical properties.

Electrically Active Stacking Faults in Silicon

Central Research Laboratories, Motorola Incorporated, Phoenix, Arizona 85008

ABSTRACT

The influence of oxidation induced stacking faults on the electrical characteristics of p-n junctions in silicon has been studied by employing scanning and transmission electron microscopy in conjunction with electrical measurements. Diodes were fabricated with a junction depth $X_j = 4$ μm and an integrated boron concentration of $\sim 3 \times 10^{16}$ cm^{-2} in 1-3 ohm-cm n-type epitaxial silicon.

The presence of decorated stacking faults in the field region of the diodes examined is found to introduce excess reverse leakage currents in the junction. However not all faults introduce the same degree of leakage and the electrical activity of the faults is found to vary. The concept of the "threshold voltage" of a stacking fault is introduced which is a measure of the specific electrical activity of the fault. Electrically active faults introduce excess reverse currents in the diodes which are characterized by a relationship between the reverse log I/V ratio measured at low voltages and the characteristic "threshold voltage" of the faults. The electrical activity is related to both the size and the structure of the faults. The smaller faults which are also more prone to impurity decoration are electrically more active than larger faults which are decorated to a lesser degree. Models are presented to account for the electrical activity of the faults. These models are based on the strain effects of the decorated faults and on the distortions produced in the p-n junctions by the presence of faults.

In the manufacture of semiconductor devices crystallographic defects such as dislocations, stacking faults, etc. are often introduced into the single crystal material as a result of the various thermal-diffusional steps associated with the processing sequence. The types of defects introduced at various stages in the process have been well characterized (1-5). The electrical effects associated with these defects however have not been unambiguously demonstrated. Apart from statistical correlation between the presence of certain defects and the attendant electrical aberrations (6-8) most of the discussion in the literature is speculative and ambiguous. The difficulty is usually of an experimental nature in that the interaction between a particular defect in the semiconductor and the depletion field of the p-n junction cannot be observed directly by any of the conventional techniques. Furthermore there has been a tendency to rely on low resolution techniques such as x-ray topography (6, 7) and surface decoration methods (8) to detect the presence of defects that might be influencing the junction characteristics. These techniques can at best provide a rough correlation between the presence or absence of a defect and the electrical characteristics of the p-n junction. More recently, the application of the scanning electron microscope has permitted the direct observation of electrical effects such as charge carrier generation and recombination in semiconductor devices containing a p-n junction. However, the detailed structure of the defects and the nature of the interaction with the depletion field of the p-n junction are not understood or correlated.

In attempting to better understand defect interactions with p-n junctions a number of questions need to be answered. A first requirement is to determine the structure of a particular defect on an atomic scale. For instance, if a dislocation is suspected of influencing the junction properties, it is necessary to know if the dislocation is "clean" or decorated by a second phase. It has been suggested that dislocations decorated by metallic precipitates, which cut across p-n junctions, are responsible for factors such as excessive reverse currents below the normal avalanche breakdown voltages of the junctions, emitter-collector pipes in bipolar transistors, etc.

Dislocations have also been suggested as providing paths for locally enhanced diffusion and hence cause leakage between the emitter and collector of shallow diffused transistors (8, 9). A contrary viewpoint (10) indicates that grown-in, or the so-called primary dislocations, are generally decorated with other impurities and are hence incapable of functioning as diffusion pipes during subsequent operations.

The problem becomes more complex if details of the decoration process around the dislocations are important in the electrical ramifications of this particular type of defect. If decoration is necessary then the question arises whether the decoration is due to metallic impurities or nonmetallic insulating precipitates such as the oxides of silicon. Dislocations can function as heterogeneous nucleating sites for both metals dissolved in the silicon as well as for silicon oxides (11).

In the present work we have attempted to determine the electrical activity associated with oxidation induced stacking faults. It has been demonstrated that elevated temperature oxidation of silicon in both dry and wet environments can generate stacking faults in the surface (4, 12). The nucleation and growth of these faults have been linked to the formation of second-phase particles in the bulk silicon, the second phase being an oxide of silicon (13). By employing a combination of scanning and transmission electron-microscopy in conjunction with measuring the I-V characteristics of diffused p-n junctions in the presence of stacking faults, the nature of the electrical activity of stacking faults has been investigated. Models are proposed to account for the experimental observations.

Experimental Procedure

The wafers used for diode fabrication consisted of 2 ohm-cm n-type epitaxial films (thickness ~ 20 μm) deposited on <111> oriented chemical-slurry polished silicon substrates of 0.005 ohm-cm resistivity. The wafers were oxidized in a steam ambient at 1100°C to obtain an SiO_2 film thickness of 0.5 μm. The boron diffused diodes ($\sim 0.1 \times 0.1$ cm) were fabricated with a junction depth $X_j \approx 4$ μm at a diffusion temperature of ~1250°C with an integrated boron concentration

Key words: oxidation, diffusion, boron, diodes, precipitation.

$Q \approx 3 \times 10^{16}$ cm^{-2}. The dislocation density of the substrate and epitaxial layer was $<2 \times 10^3$ cm^{-2}.

Fully processed wafers containing diode arrays were electrically characterized by unit probe testing. Single data point measurements of individual diodes were obtained to determine the distribution and number of diodes exhibiting excess reverse leakage currents below the avalanche voltage. Typical diodes were selected for more complete electrical measurements and for subsequent structural analysis. The units were selected to cover the total range of *I-V* characteristics representing a given wafer. All diodes having anomalous reverse leakage currents due to process mask defects and surface damage were eliminated. Structural mapping and analysis was done nondestructively with the scanning electron microscope (SEM) utilizing the electron beam induced current mode (EBIC) (See Appendix I for a discussion of the EBIC technique).

The experimental procedure consists of mapping all selected devices at 0 bias to determine the total number of stacking faults. At relatively low magnifications, the complete diode structure is examined at 40 kV with a beam current of typically 5 nA. Under these conditions, the local recombination of beam generated electron-hole pairs produces sufficient contrast at 0V bias to reveal clearly the individual stacking faults. The total number of faults within the perimeter of each diode was recorded. Voltage-dependent current multiplication sites were observed at specific stacking faults in all diodes having a reverse leakage current above the nominal level for diodes selected at random. The current multiplication effects were observed to occur only at certain faults and these faults are termed "electrically active" faults. Electrically active faults were identified by applying a reverse bias less than or equal to the avalanche voltage.

Structural mapping of the electrically active faults at low magnifications was followed by a more detailed analysis of individual faults at higher magnifications. Instrument parameters for the SEM (*i.e.*, electron beam energy, probe current and magnification) were determined initially by optimizing display conditions and subsequently held constant throughout the investigation. This permitted a relative comparison of the current multiplication effects in terms of the "threshold voltage" of individual stacking faults. This "threshold voltage" is defined as the diode reverse voltage required to obtain local current enhancement at an active fault which corresponds to a video signal ~10% above the average background EBIC display level. This does not necessarily imply that a fault is inactive below the "threshold voltage" but that the current multiplication effects due to the fault are sufficiently small that the relative signal level is reduced by the noise generated in the device when biased. Further analysis with the SEM established the linear dimensions of individual faults and helped to detect the second phase particles associated with these defects.

The final detailed structural analysis at sub-micron resolution with the transmission electron microscope (TEM) required the preparation of thin silicon samples. The experimental technique consisted of chemical thinning selected regions of the diode with a jet polish assembly. Thin electron transparent regions permitted an extensive investigation of the defect structure and the second phase precipitates.

Experimental Results

Oxidation-induced stacking faults.—Transmission electron micrographs of a typical oxidation induced stacking fault are shown in Fig. 1. Figure 1(a) shows the fault fringes and the bounding partial dislocations in contrast while (b) shows the fringes out of contrast. Impurity precipitation is evident around the partials. These precipitates are very likely to be oxides of silicon which initiate and propagate the stacking faults (13). It is also observed that the precipitation around

the partial dislocation has resulted in the generation of other dislocations. It has been demonstrated elsewhere that oxidation-induced stacking faults can function as dislocation generating sources in silicon (22).

The stacking faults were typically ~1 μm in length and ~0.5 μm in depth following the oxidation process. However, the faults have been observed to grow during the subsequent diffusion operation, with the eventual size of the fault being related to the time and temperature of diffusion, *i.e.*, to the depth of the p-n junction. The following experimental results are obtained on boron diffused p-n diodes having a junction depth $X_j \approx 4$ μm.

Figure 2(a) is a typical fault as observed in the SEM operated in the EBIC mode. In the micrograph shown the scan direction is from left to right. As the beam encounters the fault, localized carrier recombination effects result in a decrease in signal and hence the fault has a dark leading edge. Since the d-c signal obtained has been capacitance blocked a bright trailing edge results as the beam moves away from the fault. Consequently recombination effects due to the presence of crystallographic defects result in the type of contrast shown in Fig. 2(a). A further point to be noted here is the presence of the two dark regions at the terminations of the stacking fault. This dark contrast results from the presence of second phase particles decorating the partial dislocation bounding the fault. This is more clearly evident in the transmission electron micrographs of a portion of the fault shown in Fig. 2(b) and (c). The micrographs show two beam images of the fault and the precipitate at the termination. In Fig. 2(a) both the fault and the precipitate are in contrast whereas Fig. 2(c) shows the fault out of contrast while the precipitate contrast remains.

Electrical activity of stacking faults.—Figure 3 illustrates EBIC displays of a diode having excess reverse leakage currents below the avalanche voltage. The individual stacking faults are evident in the 0V bias display as elliptically shaped recombination centers oriented along <110> directions. The reverse biased displays reveal the electrically active faults as local current enhancement sites while the inactive faults remain in a quiescent state with the bias applied. These displays show that the number of active faults in a given diode can be considerably less than the total number of stacking faults. Sirtl etch studies on sim-

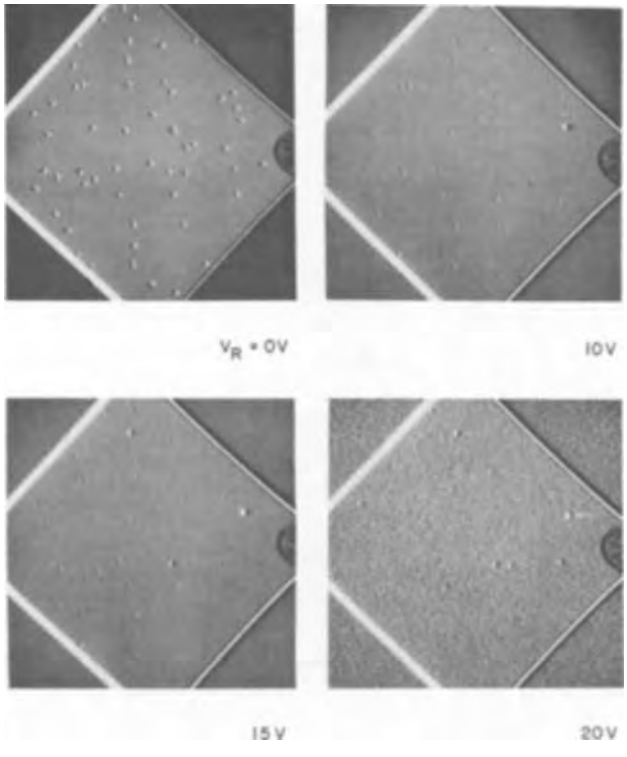

Fig. 3. EBIC displays of a diode with 0V bias and increasing reverse voltages to 20V illustrating the concepts of electrically active faults and the "threshold voltage" of a fault. The *I-V* plot corresponding to this diode is shown at the top of Fig. 4.

ilar structures indicate that a rather poor correlation exists between the total number of stacking faults in a given diode and the magnitude of the reverse leakage current at a given test voltage. Furthermore, it has been observed that a diode containing fewer stacking faults will often exhibit the greater leakage currents at a given voltage. These observations are more easily understood in view of the present results which suggest that the important parameter is more likely to be the number of electrically active faults. However, the "threshold voltage" for each fault within a given diode varies considerably. The diode shown in Fig. 3 contains ~55 faults of which eight are electrically active with "threshold voltage" levels distributed from ~4 to 20V. This series of micrographs suggests that in addition to the number of active faults, the "threshold voltage" for current multiplication effects also represents a significant parameter regarding excess leakage currents.

Test results are illustrated graphically in Fig. 4 which shows the reverse *I-V* characteristics of five diodes. The units were selected to sample the total range of *I-V* characteristics for a single wafer. The dark current limit represents the nominal characteristics of a diode containing no stacking faults, selected at random and represents the lower limit of leakage current for the ambient conditions existing during the measurements. The graph indicates the experimentally determined numerical values corresponding to the "threshold voltage," the number of active faults and the total number of stacking faults for each respective diode.

Note the poor correlation between the total number of stacking faults per diode, indicated at the end of each curve, and the current at a given voltage. For example the diode containing five faults has a reverse current of ≈50 μA at 60V, whereas, the diode containing three faults has a current of ≈200 μA at the same voltage. An even greater discrepancy exists between the two upper curves which are separated by less than an order of magnitude in current but differ by a factor of 18 in the number of faults.

A more convincing trend exists between the number of electrically active faults indicated at the center of

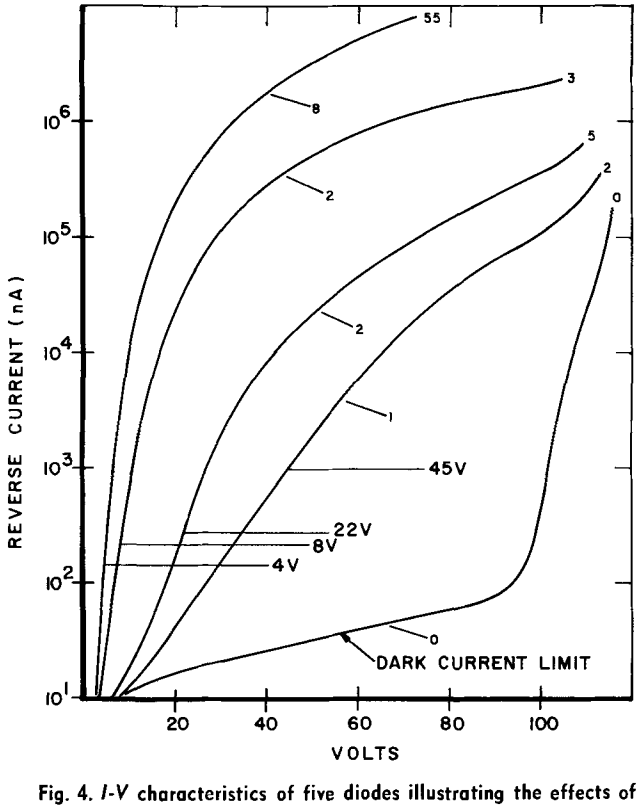

Fig. 4. *I-V* characteristics of five diodes illustrating the effects of electrically active stacking faults on excess reverse bias current. The total number of faults is shown at the ends of the curves and the total number of electrically active faults is indicated at the center. Arrows indicate the minumum threshold voltage for the group of active faults in a given diode.

each curve, but data obtained on a large number of diodes do not support a strong correlation. The values of "threshold voltage" indicated on this graph correspond to the stacking fault having the lowest "threshold voltage" for current multiplication in the electrically active group of each diode. A strong correlation between the "threshold voltage" and the reverse leakage current is indicated. The diodes containing faults of lowest "threshold voltage" display the greatest reverse leakage currents.

In Fig. 5 the reverse biased diode characteristics in decades of current per volt are plotted against the minimum "threshold voltage" V_{th} for a variety of diodes. A linear relationship is obtained with a negative slope which suggests a direct correlation between the "threshold voltage" of individual stacking faults and the excess leakage currents expressed in terms of reverse diode conductance. Moreover, the relationship indicates a current hogging effect which is dominated by the stacking fault having the lowest "threshold voltage," since many individual diodes contain more than one active fault.

Figure 6 shows a sequence of EBIC displays illustrating an electrically active fault as monitored under test conditions in the SEM. At 0V bias the fault exhibits primarily recombination contrast evident by the dark leading edge normal to the beam direction. At 15V a contrast reversal has occurred in a circular zone surrounding the fault which is characteristic of the current enhancement effect. With increased bias, annular contrast zones appear which are not presently understood in detail. A conservative calculation based on the geometry of the enhancement zone and on the current voltage characteristics of a low voltage fault indicates that a power density in excess of $\sim 10^4$ W/cm^2 can be realized locally. This high-power density may account for the particular type of contrast effects observed around the faults when biased.

Stacking fault structure and electrical activity.—In order to further understand the details of the electrical activity of stacking faults the detailed structure of the fault and the nature of the defect-depletion field interaction have to be examined. To illustrate this point, observe the fault displays in Fig. 7. Five distinct faults are shown with 0V bias on their respective diodes. The contrast observed in the EBIC display at 0V bias results from the recombination field of the stacking fault and the surface morphology of the fault particularly when second phase particles are present near the silicon surface. In Fig. 7 well-defined

second-phase particles are evident at the ends of the stacking fault where the bounding partial dislocation intersects the silicon surface. The curved contrast ridge between the decorated ends of the partial dis-

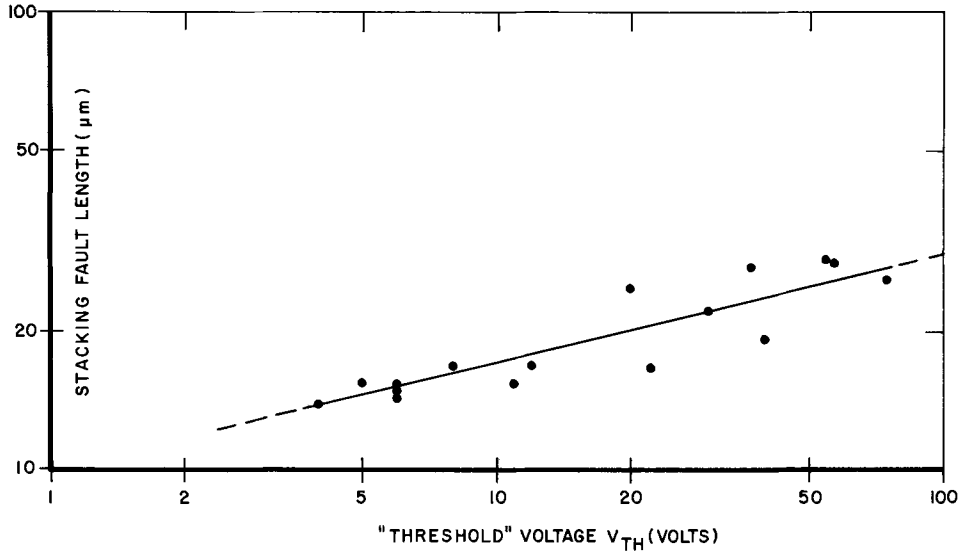

Fig. 8. Plot of threshold voltage as a function of fault length.

location results from the orientation of the stacking fault on a specific (111) type plane. The angle between the fault plane and the surface normal with respect to the beam direction will determine the geometry of the contrast ridge separating the leading and the trailing edge. Note the relationship between the measured value of "threshold voltage" which is indicated adjacent to each display and the linear dimensions of the faults. This observational trend which indicates that a correlation exists between fault length and "threshold voltage," is verified experimentally by the measurements plotted in Fig. 8.

The data cover the range of fault lengths (14 to 28 μm) for electrically active stacking faults in these structures. The "threshold voltage" measurements which correspond to these values range from 4 to 70V respectively. The upper limit of "threshold voltage" ($\sim$70V) represents $\sim$70% of the nominal avalanche voltage for these diodes (see Fig. 4). The extrapolated portion of the graph indicates that electrically inactive faults are represented by stacking faults having a length >30 μm (a "threshold voltage" approaching the avalanche limit of the diode). The lower value of "threshold voltage" ($\sim$4V) is apparently established by the detectability limit of the SEM utilizing the EBIC technique, particularly the signal to noise ratio inherent in the display. The greater data point scatter observed at the higher "threshold voltage" levels results from reduced sensitivity due to the increased noise level of the diode at voltages approaching the avalanche voltages.

Figures 5 and 8 reflect the strong correlation between the stacking fault length and the reverse diode conductance (decade of current per volt ratio). For example a factor of 2 decrease in the stacking fault length will increase the reverse diode conductance by one order of magnitude neglecting the current limiting effects which occur at higher current levels.

The significance of the defect structure on the degree of "electrical activity" for stacking faults in silicon requires a more detailed analysis of stacking fault structure. Figure 9 shows a series of TEM displays of four stacking faults with lengths ranging from $\sim$0.7 to 3.4 μm. The smallest faults (0.7 μm) consist of a partial dislocation loop bounding a faulted zone, both of which are heavily decorated with fine precipitates. The precipitates decorating the faults are thought to be predominantly silicon oxides and boron. Carbon can be eliminated as a likely candidate in view of the slower diffusion rates as compared to oxygen. Metallic impurities were ruled out by bulk phosphorus gettering (14) the diodes containing stacking faults and detecting no change in the excess reverse conductance before and after gettering. These micrographs were obtained following the diffusion of boron to establish the p-n junction. The decoration at the faults increases after the diffusion process. This is most obvious when the small fault in Fig. 9 is compared with the fault in Fig. 1. The fault shown in Fig. 1 shows the structure after oxidation and prior to boron diffusion. This effect of the diffusion on the fault and the resultant effect of the fault on the diffusion front is an important factor in determining the electrical activity of the faults as discussed subsequently. Note also the displacement-fringe contrast surrounding the fault which indicates the presence of local precipitate strain fields. The longer stacking faults are similarly decorated with precipitates; however, the decoration is in the form of well developed second-phase particles at the partial dislocation while the faulted region is generally free of precipitates. The bounding partial dislocation encloses a fault on an inclined (111) plane. The two

Fig. 9. Transmission electron micrographs of stacking faults of different lengths showing the effect of fault length on the degree of decoration of the fault.

longer faults are only partially visible because of the limited film thickness which is less than the fault depth after sample preparation, and consequently only the upper 0.4 μm of the fault is visible. Nevertheless, the common structural characteristic of these faults is the heavy precipitation, particularly at the partial dislocation and the attendant strain field. If one considers the fault structure in relationship to the metallurgical p-n junction of the diode we have the following observations; the upper limit for electrically active stacking faults in these diodes was 28 μm in length. Stacking faults greater than 28 μm in length were electrically inactive below the avalanche voltage. Because the junction depth $X_j \approx 4$ μm, the faults lie well within the depletion field of the p-n junction. Furthermore, the larger faults extend to a depth below the depletion edge at the avalanche voltage, the lower edge of the smaller faults will terminate within the depletion field. Since considerable experimental evidence has shown that the partial dislocation is decorated along its entire length, it seems highly probable that the second phase precipitates and their associated strain fields are interacting directly with the depletion field. However, since the growth and development of the fault is interrelated with the diffusion process itself, the complete physical model must include the mutual effects of both. Consequently hypothetical models are presented which attempt to visualize the mutual interaction which must include diffusion and precipitation processes occurring concurrent with the growth and development of these faults.

Discussion

The presence of decorated stacking faults in silicon has been shown to directly influence the reverse leakage characteristics of p-n junctions. The influence of the faults, however, is not straightforward in that not all faults in the active area of a diode interact with the depletion field of the junction and the degree of electrical activity is dependent on fault length. The concept of the "threshold voltage" of a stacking fault enables the specific electrical activity of a fault to be discussed in quantitative terms.

In order to develop a physical model for electrically active stacking faults it is necessary to consider the specific "threshold voltage" associated with individual faults. Furthermore the variation of "threshold voltage" with fault length also indicates that electrical activity is a function of the detailed structure of the fault. It was shown that the electrical activity of a fault varies with fault length, the smaller faults being more active than the larger faults.

The electrical effects associated with dislocations in the diamond cubic lattice have been dealt with theoretically (15) and experimentally (16) by the measurement of Hall mobilities in deformed crystals. The direct interaction between dislocations and charge carriers introduced in silicon by an electron beam has been reported previously (17). The existence of a one-dimensional energy band along edge and screw dislocations has been postulated to account for the electrical activity of dislocations (15). These models, however have been applied to fresh, undecorated dislocations. An oxidation-induced stacking fault is invariably formed in conjunction with a second phase. It has been observed that diffusion of boron into a surface decorated by these faults results in a further increase in the degree of decoration of the fault. Consequently the currently available theoretical treatments of dislocation-charge carrier interaction cannot be applied to the case of decorated stacking faults since the faulted region, the partial dislocation enclosing it, and the impurity decoration at the fault and at the dislocation introduce their own perturbations in the electronic structure of the otherwise perfect lattice.

The threshold voltage represents the onset of current multiplication at the stacking fault. Calculations on depletion layer width for 4 μm junctions suggest that the base of an active fault lies within ~1 μm of the upper edge of the depletion field at the threshold voltage of the fault (18). The base of the active fault is represented by the region where the Burger's vector of the bounding partial dislocation is approximately parallel to the electric field of the depletion region. This analysis assumes a planar diffusion front whose geometry is independent of the presence of stacking faults. However, since the growth of stacking fault is dependent on the diffusion process, the boron concentration profile in the vicinity of the fault is perhaps modified by the stacking fault structure and impurity decoration. Consequently, a simple analysis which assumes a planar diffusion front with a gaussian or erf distribution cannot be rigorously applied to determine the depletion-field width in the vicinity of the fault. Furthermore, severe contouring of the transition region may result from concentration profile anomalies which introduces geometry correction factors for the electric field in the depletion region. An added consideration is the degree of precipitation associated with stacking faults of different size, and the magnitude of the strain fields surrounding the partial dislocations. Based upon these hypotheses different models are discussed in an attempt to explain the experimental observations.

The schematic sketches in Fig. 10 show the two possible direct interactions of a stacking fault with the p-n junction. Since the junction is formed by the diffusion of boron into a surface covered with decorated stacking faults local contouring of the junction beneath the stacking fault can occur as shown in Fig. 10-1. The presence of precipitation at the fault (possibly SiO_2 precipitates) can retard the diffusion front by directly blocking the boron atoms, perhaps enhanced by the greater solubility of boron in the oxide precipitates. The accumulation of boron at the fault is also possible as a result of the differences in solubility of boron in the faulted and unfaulted regions of the crystal, *i.e.*, the Suzuki effect (19), although this is probably a secondary effect. The curvature introduced in the junctions can result in excessive reverse leakage currents (20).

In the event that the fault does not function as a block to the diffusion front, leakage can also be introduced in the junction due to the strain fields associated with faults as shown in Fig. 10-2. Elastic strains have

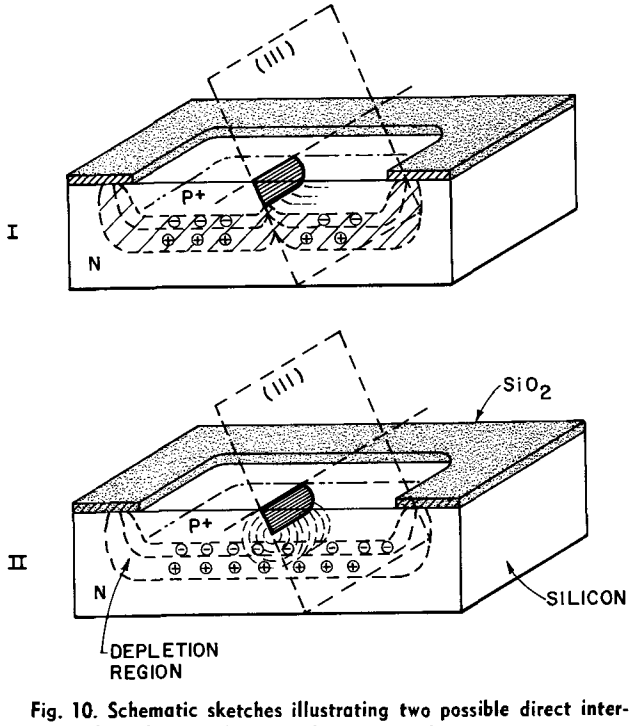

Fig. 10. Schematic sketches illustrating two possible direct interactions of stacking faults with the p-n junction.

been demonstrated to generate leakage currents in p-n junctions (21). The precipitation at the fault results in strong elastic strain fields in the lattice owing to the different specific volume of the precipitating phase (SiO_2) as compared to that of silicon. These strains can extend to considerable depths into the bulk of the material and interact with the depletion field of the junction.

A striking result of this study was the observation that the electrical activity of a fault was related to the fault length in an unexpected manner in that the smaller faults introduced greater leakage currents than the larger faults. The two models discussed above can be shown to account for this fact.

Figure 11 shows schematically the geometry of a diffused p-n junction beneath a stacking fault which is decorated both at the partial dislocation and within the fault. The physical p-n junction is curved all the way along the fault owing to the diffusion retarding effect of the decorated fault. The resulting structure of the fault is shown in the transmission electron micrograph in Fig. 11. The partial dislocation and the fault are observed to be decorated by a second phase. Such faults are typically small and extend to depths no greater than ~1 μm into the bulk. As discussed before they have also been observed to exhibit low "threshold voltages." Figure 12 shows schematically

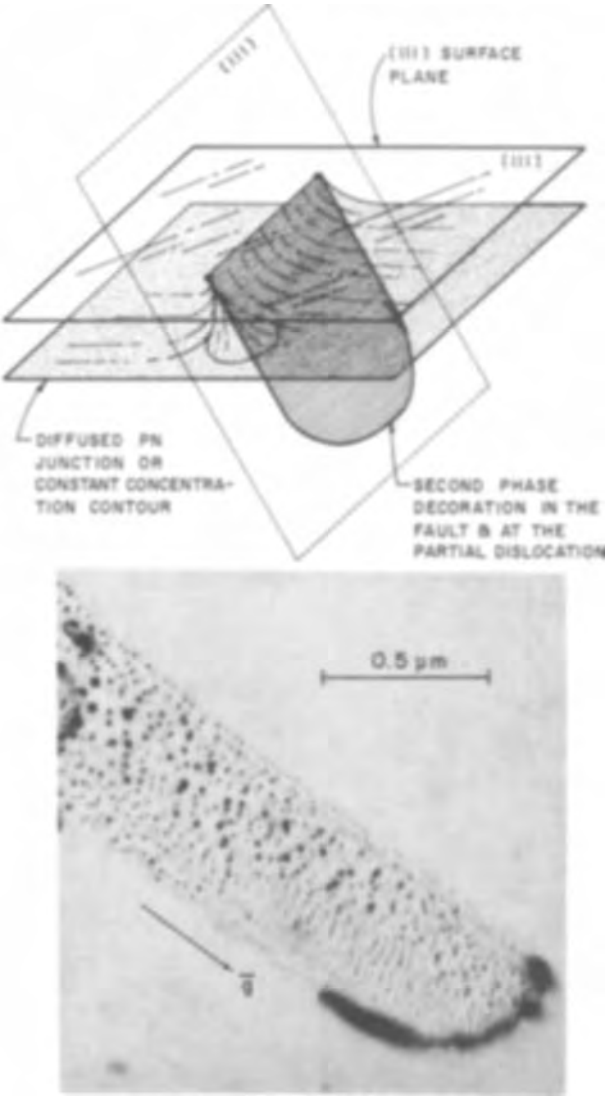

Fig. 11. Schematic of the contouring effect a decorated stacking fault has upon a p-n junction diffused into the faulted region. The TEM display shows a typical fault which is characterized by impurity decoration both at the bounding partial and within the fault.

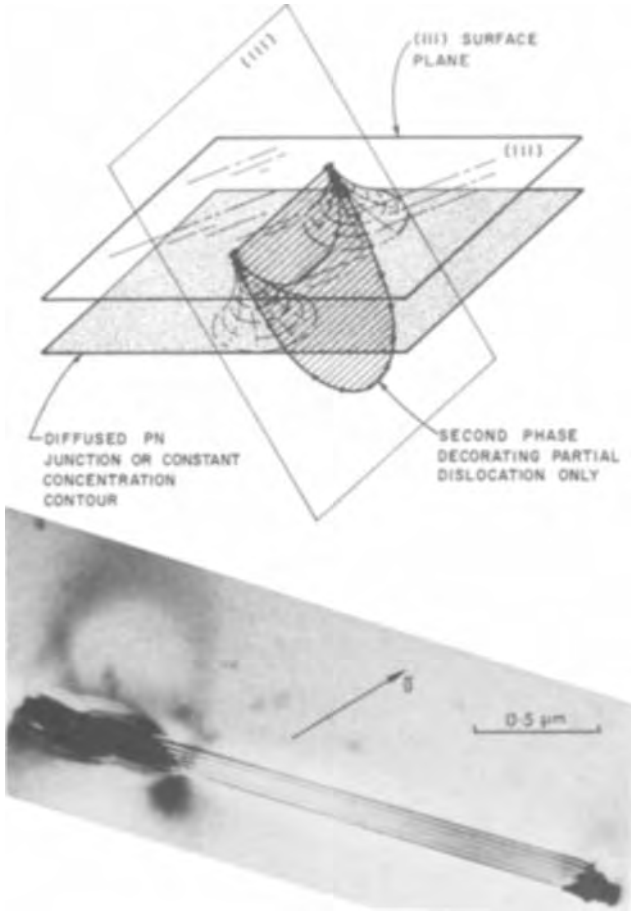

Fig. 12. Schematic of the contouring effect due to a fault which is decorated only at the bounding partial. The TEM display shows a typical fault of this kind.

the contouring effects of large faults where the second-phase decoration is primarily at the partial dislocations and not within the fault. The diffusion front is retarded only along the terminations of the fault and not within the faulted region. The transmission micrograph shows a large fault as observed after boron diffusion. The micrograph only shows a portion of the fault which can extend to considerable depths into the bulk. The terminations of the partial dislocation at the surface are profusely decorated whereas the fault is clean. The contouring introduced in the junction by such a fault is less severe than that due to small faults and hence the degree of leakage as a result of such faults is also less.

It must be emphasized that the process of diffusing impurities past a faulted region into the bulk results both in the modification of the diffused junction by the fault and a modification of the fault by the diffusing atoms. It has been shown elsewhere (22) that the diffusion process forces fault growth. Therefore the smaller stacking faults are more frequently found in diodes with shallow p-n junctions whereas deep junctions with their attendant long diffusion cycles force fault growth. Since the fault size and the distribution of segregated impurity in the fault are interrelated, the electrical activity is obviously related to both these factors. Furthermore, the position of the decorated fault in the depletion region of the p-n junction will also be related to the size and degree of decoration of the fault since the physical distortion introduced in the junctions will be a function of the fault size and associated impurity precipitation.

Fault growth can proceed by a combination of impurity precipitation and the diffusion of substitutionally diffusing atoms (boron) from within the fault into the surrounding silicon. Consequently large stack-

ing faults which have attained their final size as a result of the boron diffusing out of the faulted region are also prone to be less subject to decoration than the smaller faults which still have a large part of the accumulated boron decorating them. Consequently the electrical activity of smaller faults would be greater than large faults. The present study has been confined to the examination of the electrical activity of stacking faults on relatively deep p-n junctions (~4 μm). The effects of faults on shallow junctions (<1 μm) will be discussed in a subsequent publication.

APPENDIX

The electron beam induced current (EBIC) mode (23-25) is illustrated schematically in Fig. A-1. A focused electron beam is scanned in a square raster pattern on the surface of diffused p-n diode. Directly under the focused electron spot (typically 0.01-0.10 μm in diameter) electron-hole pairs are generated within a volume defined by the practical range of the electrons in silicon at the particular beam energy. In the range of 5-50 keV which is typical for an SEM, the penetration range for electrons in silicon is approximately 0.4-17 μm. The number of charge carriers generated within this volume is proportional to the number of penetrating electrons and their energy dissipation. When the diffusion length of the induced carriers is greater than the distance from the point of generation to the underlying p-n junction a fraction of the total number of charge carriers will be swept across the space charge region of the p-n junction. The sampling resistor and voltage source shown in Fig. A-1 are connected in series with the p-n diode. The operational amplifier which is connected across the sampling resistor in a d-c mode provides the necessary gain to modulate the brightness of a display CRT scanned in synchronism with the electron beam. When the diode structure contains relatively perfect crystalline material the beam-generated charge carriers produce a steady-state d-c current which results in a scan raster of uniform intensity.

However, when the semiconductor crystal contains localized surface and bulk imperfections such as dislocations, precipitates, or stacking faults within or near the diffused p-n junction, localized charge-carrier

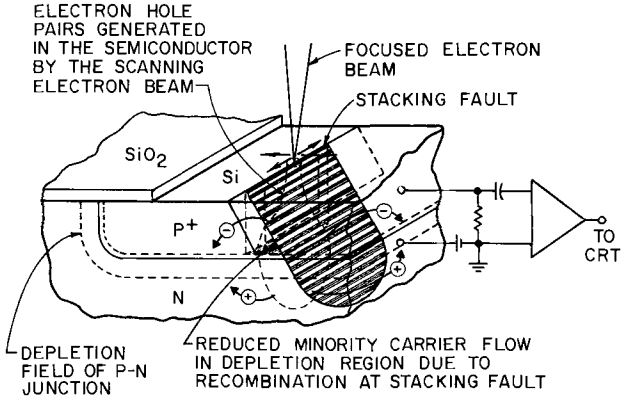

Fig. A-1. Schematic of the electron beam induced (EBIC) mode of operation.

recombination occurs. This reduces the number of charge carriers in the vicinity of the defect thereby reducing the net flow of charge carriers at the space-charge region. In this manner, the recombination processes associated with the defects modulate the charge-carrier flow, at the space-charge region revealing the structural imperfections of the diode in the video display.

With a reverse bias applied to the diode the electrical interaction between the defect and the depletion field can be investigated. The mechanism is attributed to charge carrier multiplication which increases the net flow of charge carriers in the depletion region. This effect produces a local current enhancement signal at the defect site which is dependent on the magnitude of the depletion field voltage and the degree of electrical activity of the particular defect. As a result of this interaction, electrically active defects are easily distinguished from electrically inactive sites, enabling a direct correlation between specific *I-V* characteristics and the associated defect centers.

The optimum electron beam energy depends on several considerations which involve the practical range of the electrons in the sample and the zone of maximum energy dissipation. These factors depend primarily on the density and thickness of the composite structure (*i.e.*, oxide layer and silicon). Additional considerations are the depth and distribution of the crystal defects with respect to the space charge region of the p-n junction and the minority carrier diffusion length near the point of generation of the beam-induced carriers.

When the depth of the defect is small compared to the metallurgical junction depth, low beam voltages are desirable for optimum resolution of the defects providing sufficient beam current is available to overcome the signal to noise limitations of the video amplifier including the sample. High-contrast displays often require a compromise of spacial resolution when increased beam current or voltage is required to improve the signal to noise ratio of the display. Practical considerations often involve the magnitude of leakage currents in diode structures containing defects. The leakage currents associated with the defects introduce current-voltage instabilities in a biased p-n diode resulting in scan rate dependent video noise. This requires a reduction of the video bandwidth by capacitive coupling or other means necessitating larger beam currents and voltages to increase the signal level at the sample.

In a typical EBIC display the reference voltage or ground for the video circuit is selected to obtain the desired signal polarity on the CRT when the beam crosses the vertical edge of the p-n junction. To avoid ambiguity in the interpretation of contrast the diode terminals are selected to provide an increased screen brightness when the p-n junction currents increase during the scan. Consequently, in the d-c coupled mode, the brighter areas of the display correspond to larger beam-induced currents at the p-n junction. In the capacitor-coupled EBIC display the bright and dark contrast levels correspond to the transient currents generated at regions where the junction currents change abruptly. The video circuit time constant is chosen to provide a display which approximates a time derivative of the d-c coupled display as illustrated in Fig. A-2.

The diodes used in this investigation have a p-n junction depth $X_j \approx 4.0$ μm. The stacking faults were typically 14-28 μm in length at the surface with a hemispherical boundary consisting of a partial dislocation enclosing the fault on the {111} planes. The depth of the fault measured normal to the surface is ~12 μm. For optimum interaction between the partial dislocation at the base of the faulted zone a beam energy of 40 keV was utilized. The electron penetration at this energy is ~12 μm. This energy was selected to insure that electron-hole pairs are generated near the base of the stacking fault. Since the depth of the stacking fault is greater than the metallurgical junction depth $X_j \simeq 4$ μm, a back diffusion of charge carriers is required to display the electrical interaction between the stacking fault and mobile charge carriers prior to their collection at the space charge region.

The capacitance coupled display was used exclusively to eliminate the d-c current instabilities of the reverse biased diode. A sampling resistor of 10^3 ohm

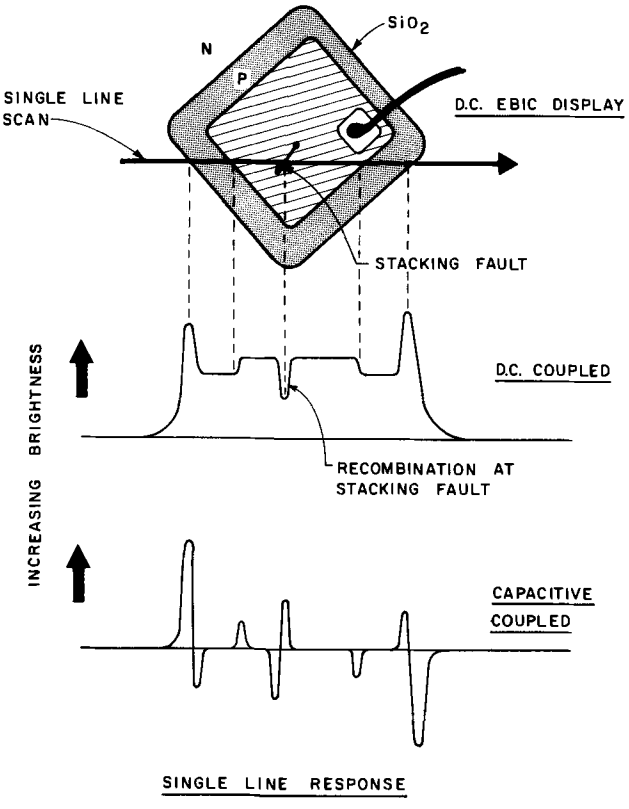

Fig. A-2. Schematic showing single line response of the EBIC display when used in the d-c and the capacitive coupled modes.

with a coupling capacitor of 0.02-0.05 μf provided adequate contrast at a nominal scan rate of 10 msec/line, with a beam current of $\simeq$ 1 nA at 40 keV.

Submicron Epitaxial Films for GaAs Field Effect Transistors

R. D. Fairman*,[1] and R. Solomon*

Fairchild Research and Development Laboratory, Palo Alto, California 94306

ABSTRACT

Uniform submicron epitaxial films have been prepared by an optimized version of the $AsCl_3$, Ga, H_2 process. Film requirements and properties of films necessary for high performance GaAs FET's are discussed. Growth rate dependences of the Ga source and substrate temperature are shown. Growth rate dependence upon the $AsCl_3$ mole fraction and mass transport effects are shown in the range of interest. Effects of the thermal gradient imposed during deposition are related to the film thickness and doping uniformity obtained with a 5°C/cm and 0.5°/cm process. Vapor doping from H_2S and Sn-doped Ga sources is discussed and related to the character of the epitaxial doping profile. Epitaxial films grown by this technique have been produced in the range of 0.2-0.4μ with variations in film thickness and doping of $< \pm 10\%$.

In recent years, GaAs Schottky-barrier field-effect transistors have attracted much interest as an active device with usable gain at microwave frequencies.

Recently, our device research group has developed a device with a cutoff frequency >30 GHz and a unilateral gain of 10 dB at 10 GHz (1). These devices have a theoretical frequency-gain slope of 6 dB/octave and a very low noise figure.

The GaAs Schottky-barrier FET is a transit-time-limited device which operates in the depletion mode. The voltage required to pinch off conductance in the channel is given by the following expression

$$V_p = V_o + \frac{q}{2\epsilon}(N_D t^2) \qquad [1]$$

where V_o is the built-in voltage, N_D the donor concentration, and t the film thickness. Figure 1 shows the relationship between donor concentration and film

Key words: gallium arsenide epitaxy, thin-film growth.

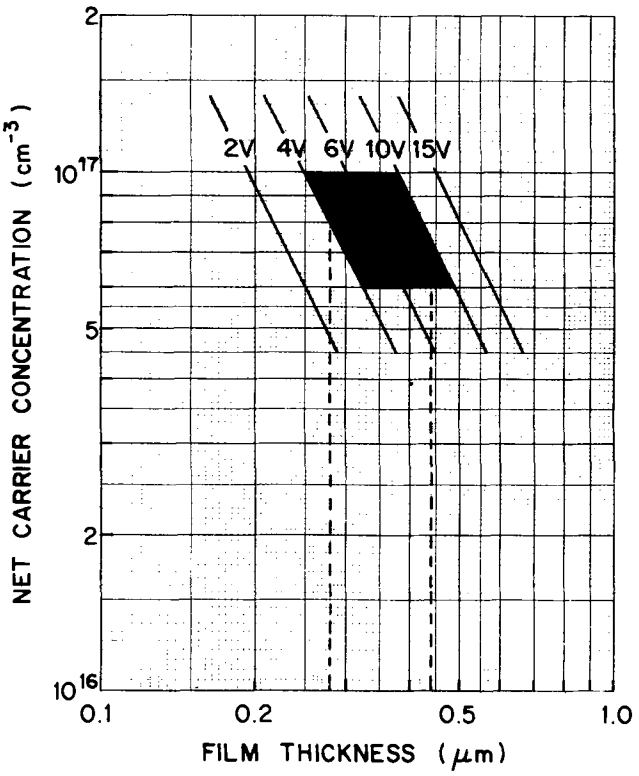

Fig. 1. Epitaxial film doping, film thickness relationship with pinch-off voltage, V_p, as a parameter.

thickness with the pinch-off voltage as a parameter. A desirable range of pinch-off voltages for an amplifier operating at 10 GHz lies between 4 and 10V. The useful range of donor concentrations in 6-10 $\times$ 10^{16} cm^{-3}. The upper end of this range is delimited by the gate breakdown voltage, whereas the lower end is constrained by backside gating from the semi-insulating substrate. Useful donor concentration and thickness combinations are shown in the cross-hatched trapezoidal region in Fig. 1. Film thicknesses lying between the dotted lines, *i.e.*, in the range from 0.28 to 0.44μ, have approximately an 85% probability of meeting the pinch-off voltage specification. In practice, we can extend the upper limit somewhat since thicker films can be etched into the useful range.

Experimental

The basic epitaxial process used to grow films for the GaAs FET is the $AsCl_3$, Ga, H_2 system (2). The $AsCl_3$ process has produced the highest purity vapor epitaxial GaAs to date (3). The principal reactions in the process are as follows

1. $4AsCl_3 + 6H_2 \rightarrow As_4 + 12HCl$ (400°-500°C)
2. $12HCl + 12GaAs \rightleftarrows 12GaCl + 3As_4 + 6H_2$ (800°C)
3. $6GaCl + As_4 \rightleftarrows 4GaAs + 2GaCl_3$

$AsCl_3$ is reduced to $As_{4(g)}$ and $HCl_{(g)}$ in the presence of H_2 at 400°-500°C. Both $As_{4(g)}$ and $HCl_{(g)}$ are transported over a Ga source held at 800°C until the source is saturated with As; following saturation a GaAs skin grows covering the As-saturated Ga source (4). Subsequent HCl passed over the saturated Ga source reacts with the GaAs skin as shown in Reaction 2 above. Thermodynamic calculations of the $AsCl_3$, Ga, H_2 system indicate that for source temperatures of 800°C and deposition temperatures of 750°C the deposition reaction is simply the reverse of Reaction 2. The contribution to deposition from the disproportionation Reaction 3 is negligible for the HCl concentrations involved in the present $AsCl_3$ process (5).

The experimental process parameters are as follows: gallium source temperature, 800°C; GaAs substrate temperature, 760°C; hydrogen flow rate, 200 cc/min; reactor tube diameter, 40 mm; $AsCl_3$ mole fraction, 1.0 $\times$ 10^{-2}.

The background doping of the process is controlled by the $AsCl_3$ mole fraction used (6). The residual background impurity is Si arising from a series of reactions between HCl, H_2, and Ga with the quartz reactor equipment (7). With an $AsCl_3$ mole fraction of 1 $\times$ 10^{-2} a net background doping of $\sim$1 $\times$ 10^{14} carriers cm^{-3} is experienced. The present work will deal with the optimization of the growth variables which affect growth rate and epitaxial film uniformity for films grown on (100) Cr-doped GaAs.

In order to achieve thickness control in the range from 0.25 to 0.5μ, it is desirable to operate at low growth rates so that reasonable deposition times can be used. The growth rate dependence on the Ga source temperature is shown in Fig. 2 for Ga source temperatures in the range from 770° to 810°C. The substrate temperature for these experiments was held constant at 760°C and the wafer was positioned in a thermal gradient of 5°C/cm. The $AsCl_3$ mole fraction was maintained at 10^{-2}. At this value the background donor concentration is several orders of magnitude lower than the final donor concentration. The growth rate is a rather steep exponential function of source temperature in the range measured. The dependence is similar to that obtained by Araki *et al.* (8) in the same range.

The growth rate dependence on the substrate deposition temperature is shown in Fig. 3 for substrate temperatures over the range of 760°-790°C. The Ga source temperature was held constant at 800°C, and the wafer was positioned in a thermal gradient of 5°C/cm.

The initial indication was that a substantial growth rate reduction could be made by a reduction of the Ga source temperature and by use of higher substrate temperatures. However, a vapor etch rate reduction occurs for substrate temperatures <800°C. Therefore a minimum source temperature of 800°C is maintained. Vapor etching of the substrate prior to thin film growth is required to eliminate interface states, traps, residual surface impurities, and to remove a thin surface film of

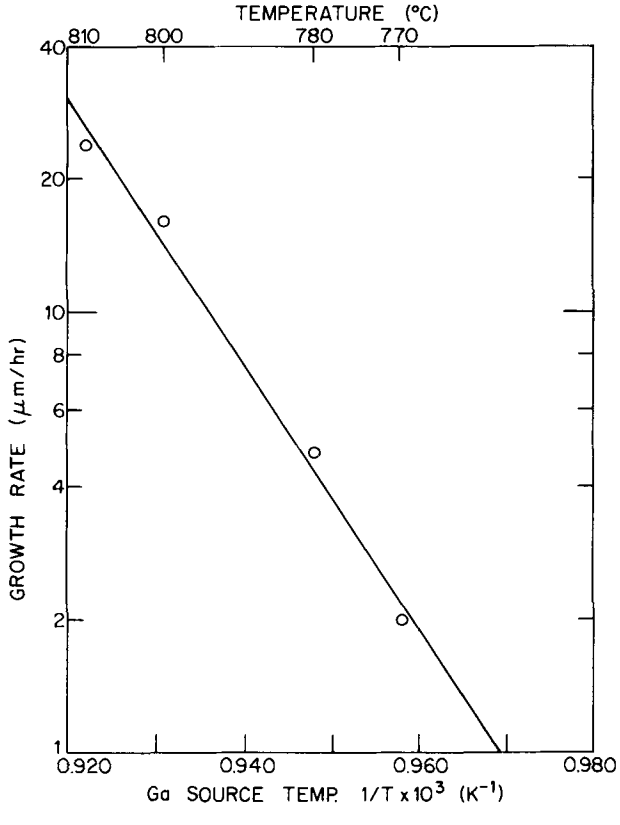

Fig. 2. Growth rate dependence of the Ga source temperature

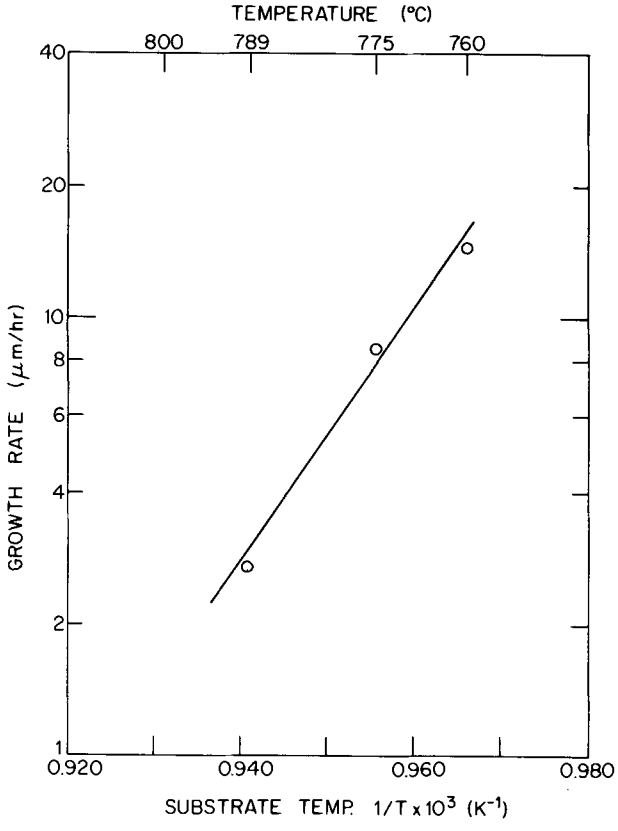

Fig. 3. Growth rate dependence of the GaAs substrate temperature

partially decomposed GaAs generated by As loss at 800°C. Thus, low growth rates are most easily achieved by increasing the substrate temperature. In the present work, a substrate temperature of 760°C was used, yielding an average growth rate of 0.1 μ/min.

For substrates held parallel to the gas flow direction an epitaxial film thickness gradient is observed in the direction of gas flow. This gradient is related to the ΔT imposed along the length of the substrate. Figure 4 shows the epitaxial film thickness gradient evaluated by Schottky-barrier profiling along the length of a wafer for a 5°C/cm and a 0.5°C/cm thermal gradient. The epitaxial thickness gradient produced by the 5°C/cm thermal gradient would reduce an FET device yield to ~15%, whereas the 0.5°C/cm gradient would allow a yield closer to 90%. The shallow thermal gradient also reduces the growth rate by a factor of 3 which greatly improves the growth rate reproducibility. The growth rate dependence on the $AsCl_3$ mole fraction is shown in Fig. 5. Changes made in the $AsCl_3$ mole fraction over the range of 6-9 $\times$ 10^{-3} mf makes a change in the growth rate of <10%. The growth rate dependence on the flow rate, with fixed $AsCl_3$ mf, is shown in Fig. 6. The independence of the growth rate on the

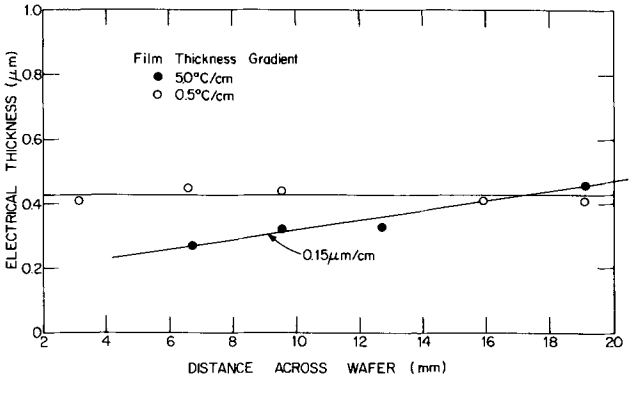

Fig. 4. Epitaxial film thickness gradient across the wafer as produced by two different deposition temperature gradients.

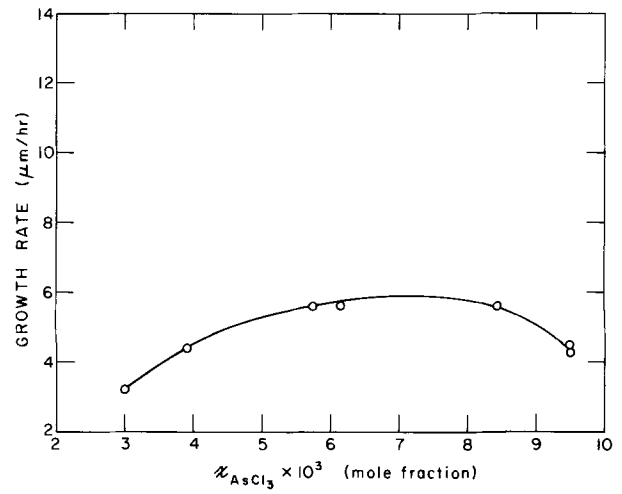

Fig. 5. Growth rate dependence upon the $AsCl_3$ mole fraction

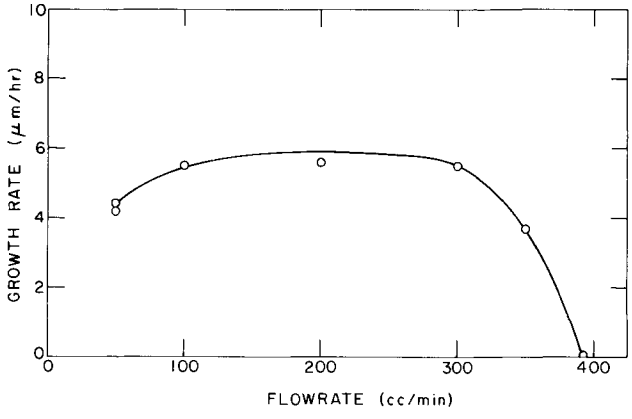

Fig. 6. Growth rate dependence upon mass transport with constant $AsCl_3$ mole fraction.

flow rate in the region of operation suggests that the process is not mass transport limited in this region. The decrease in growth rate with flow rates greater than 300 cc/min is related to the completion of the Ga source reaction.

Table I summarizes the results of a series of depositions performed with a 0.5°C/cm gradient, indicating the epitaxial film uniformity of both doping and thickness for two different dopants. The film thickness uniformity across a wafer and the corresponding pinch-off voltage uniformity are summarized in columns 3 and 4. The average doping variations are less than ±10% and the reproducibility is excellent. The yield on these films shows a combined 70% yield on both film doping and thickness.

The Sn vapor doping was accomplished by the use of a Sn-doped Ga source (9) and the S doping was achieved by metering H_2S into the reactor between the Ga source and the deposition region (7).

The epitaxial doping profile is another important factor in successful device processing. The film doping at the interface should drop an order of magnitude in approximately 0.1μ from the plateau of uniform doping as shown in Fig. 7. The doping profile for the Sn-doped case shows an extremely abrupt change in doping at the interface and a very uniform layer doping. In general, S-doped layers show a more graded profile as compared to the Sn-doped films. Both Czochralski-

31-4 thru 12 (8)	$8.2 \times 10^{16} \pm 7.3\%$	$0.36 \pm 8.7\%$	6.5 ± 0.8	Sn

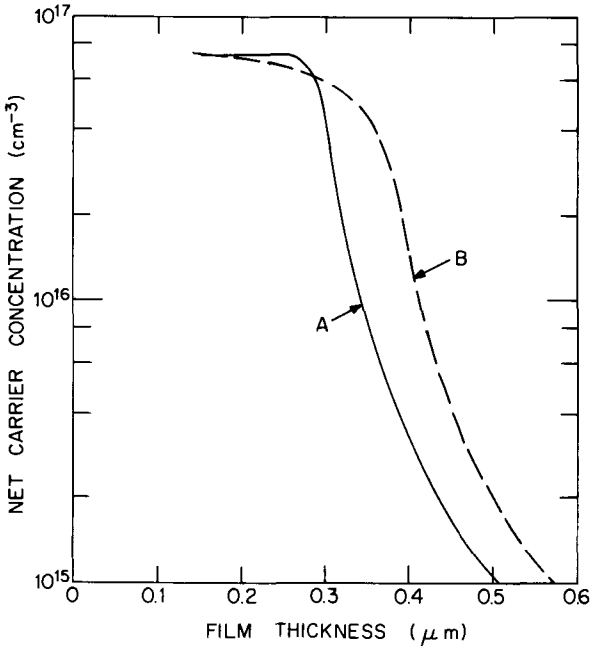

Fig. 7. Epitaxial doping profile for Sn-doped (A) and S-doped (B) (100) GaAs as deposited on Cr-doped semi-insulating substrates.

and boat-grown crystals have been used successfully. Figure 8 shows how the character of the substrate influences the shape of the doping profile. The sharp peaked profile (B) has been observed in selected lots of both Czochralski- and boat-grown substrates. Anomalous tails (A) are only observed for certain lots of Czochralski substrates. The epitaxial process variables have been monitored by alternating substrates from different lots and the doping profile anomalies have borne a 100% correlation with specific crystal lots rather than an uncontrolled process variable. We have not been able to determine which substrate defects are responsible for the graded profiles.

Figure 9 shows an example of the extremely thin film growth that is possible with this process, showing an electrical thickness of less than 0.1μ. The built-in surface barrier prevents us from profiling the flat portion of the profile. However, the mobility of this film is only about 10% lower than the average mobility

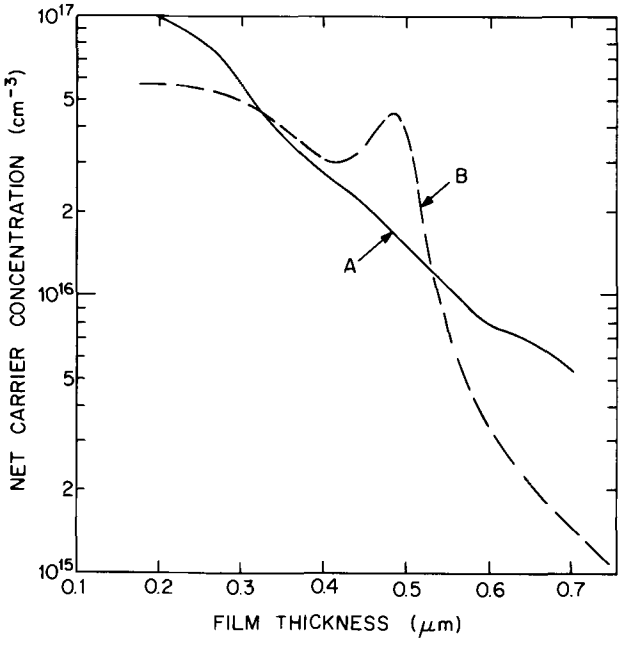

Fig. 8. Epitaxial doping profile characteristics of films grown on inferior substrates.

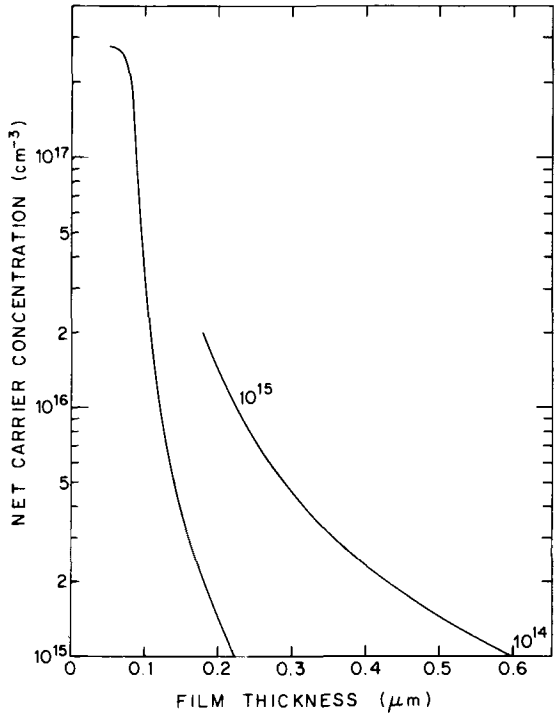

Fig. 9. Epitaxial doping profile of extremely thin film growth showing the capability of the vapor phase process.

for thick films which suggests that doping uniformity is still fairly good.

Hall mobilities of 4500 cm^2/V-sec have been measured on thin films at room temperature, and doping with either Sn or S to 1×10^{17} cm^{-3}. Thus reasonably high mobilities suitable for FET fabrication with high cut-off frequencies can be obtained with carrier densities as great as 10^{17} cm^{-3}.

In summary, it has been shown that careful control over substrate and source temperatures, temperature gradient, flow rate, and $AsCl_3$ mole fraction, can yield uniform films down to 1000Å. Devices fabricated from these films have exhibited cutoff frequencies of around 40 GHz with a noise figure of 2 dB at 3 GHz.

Iron Oxide See-Through Photomasks

Miles V. Sullivan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The decomposition of $Fe(CO)_5$ in an oxidizing atmosphere was employed to obtain a film of Fe_2O_3 2600Å thick on a glass substrate. Using standard photoresist technology with dilute HCl as the etchant, see-through photomasks with 1 μm patterned elements were obtained.

Photoresist processing often involves the positioning of a photomask over a partially completed device in such a manner that the mask is aligned with certain features of the device. This alignment is greatly facilitated by a see-through mask: that is, a mask which is capable of transmitting visible light to aid in the alignment process and also of blocking the actinic radiation (predominantly uv) necessary for photoresist work.

The semiconductor industry is becoming more interested in a good see-through mask because:

1. The trend toward smaller geometries has made alignment more critical, and the see-through characteristic allows direct observation of the most critical elements of a device pattern rather than depending on remote registration marks.
2. The trend toward the use of positive resists has resulted in an increased number of masks which are mostly opaque and, therefore, more difficult to align with standard techniques. Recent developments in projection photolithography have accelerated this trend.
3. The masking is due to absorption of the unwanted light rather than reflection (as in Cr masks) of the unwanted light and consequently minimizes halation effects and enhances contrast to reflecting substrates.
4. The trend toward larger scale integration and smaller features puts a high premium on low defect density, and defects such as pinholes are reduced considerably by the use of the new see-through materials.

Early attempts to design such a mask made use of sputtering to form a thin inorganic oxide film on a glass substrate (1). In this phase of the work it was determined that a desirable combination of optical, mechanical, and chemical properties could be obtained from iron or vanadium oxides or mixtures of the two.

The next phase was concerned with finding the most practical fabrication techniques. Several existing techniques were evaluated and none appeared attractive. Therefore, a new chemical vapor deposition (CVD) technique based on $Fe(CO)_5$ was developed and proved to be very effective (2).

Continuing work on the sputtering technique brought to light some modifications which have made that method much more attractive than it originally was (3). Speed of sputtering has been increased by almost an order of magnitude, sputter cleaning of the substrates before deposition has reduced film defects, and control of the chemical and physical composition of the film has resulted in control of etchability (related to resolution).

There are other competitive techniques for making thin films of iron oxide for masks, *e.g.*, a spin-on process described by Reid and Cukor (4). However, these films do not seem to have as desirable a combination of durability, etchability, and freedom from pinholes as have CVD films.

The purpose of the present article is to describe the CVD method of making a see-through photomask. A thin uniform semitransparent film of Fe_2O_3 on a glass plate was obtained by reacting $Fe(CO)_5$ vapor with O_2 on or near the surface of the glass which was maintained at 100°C. This film was then etched with dilute HCl using photoresist techniques to obtain a useful photomask.

Key words: photoresist, transparent photomask, lithography, photolithography.

Deposition chamber.—In the original development of the CVD process (2), the deposition chamber consisted of a bell jar on a hot plate as shown in Fig. 1a. In an effort to minimize defects caused by particles, this system has been inverted as shown in Fig. 1b. Figure 2 is a densitometer trace across a 2-in. plate with Fe_2O_3 deposited in a chamber such as shown in Fig. 1b. Since the plate is supported by the edges, very little deposit forms there and the transmission at the edges is quite high.

For applications where it was desirable to have deposition all the way to the edges, the plate was supported as shown in Fig. 1c or 1d. Both of these systems gave uniform deposition. Figure 3 is a densitometer trace of a plate with iron oxide deposited in a chamber such as Fig. 1c.

In order to reduce the time required to obtain gaseous steady state, the chamber size has been succes-

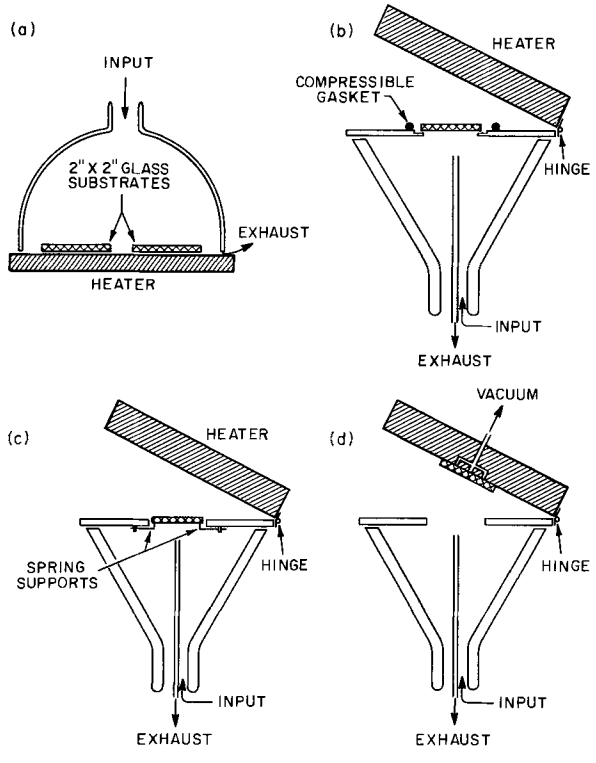

Fig. 1. (a) Bell jar on hot plate, 4 plates deposited simultaneously. (b) Inversion of system shown in Fig. 1 to minimize dust fall-out and reduction to one plate at a time. (c) Similar to Fig. 1b but plate supported by pins at the corners. This gives edge-to-edge coverage. (d) Similar to Fig. 1b but plate supported by a vacuum chuck in the heater block.

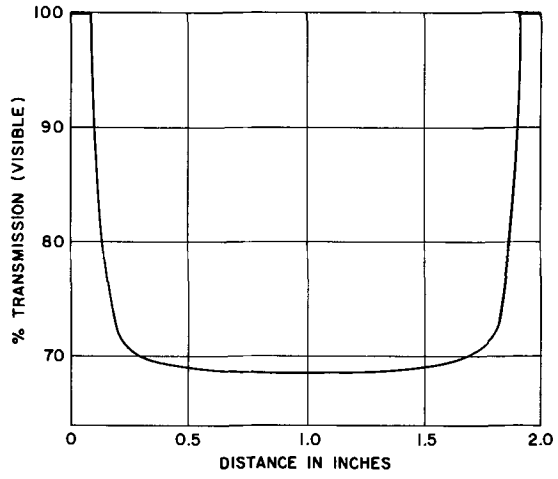

Fig. 2. Densitometer trace across a 2-in. plate deposited in a system such as in Fig. 1b. Note that transmission is high at the edges because of the method of plate support.

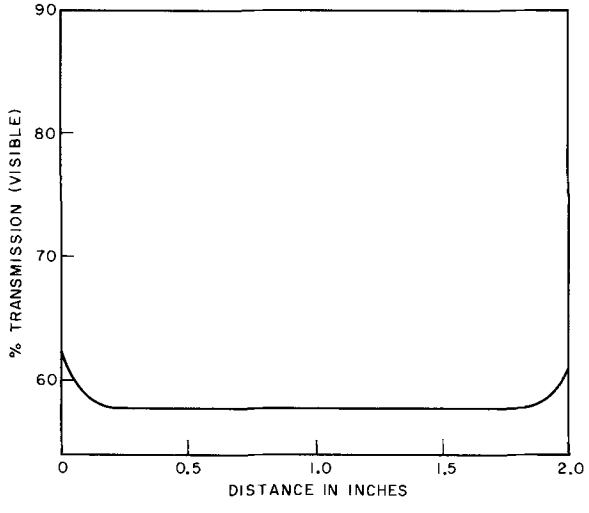

Fig. 3. Densitometer trace across a 2-in. plate deposited in a system such as in Fig. 1c.

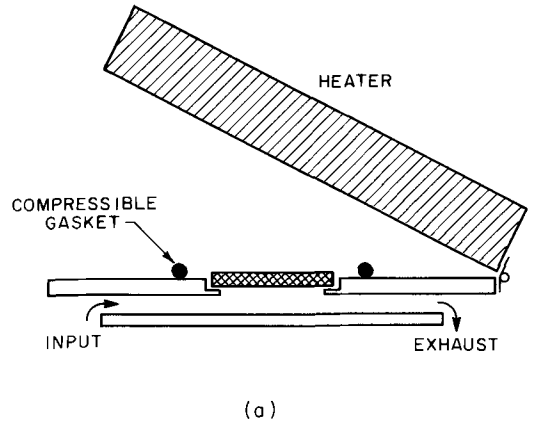

Fig. 4a. "Laminar" flow chamber with small volume (about 10 cc)

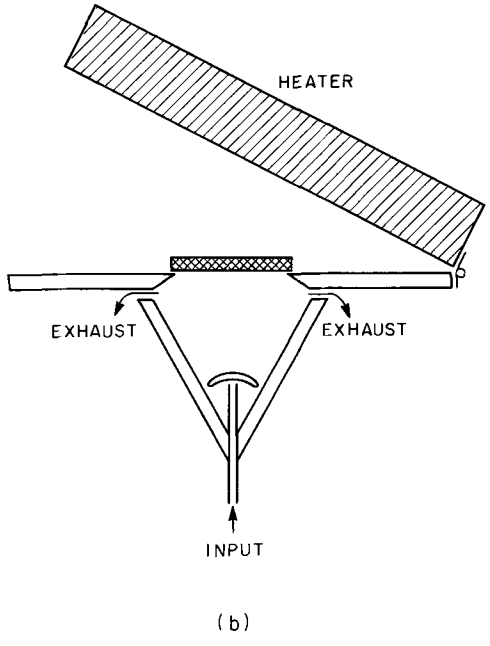

Fig. 4b. Most "successful" chamber design

sively reduced from over 1000 cc down to 10 cc. In this smallest chamber the gas was introduced along one edge and removed along the opposite edge as shown in Fig. 4a. With a high velocity of gas across the face of the plate, it was difficult to maintain uniform deposition. (The gas is not preheated but must be brought up to temperature by the glass plate on which deposition is taking place.)

The chamber that gave most consistently good results was funnel-shaped with the gas entering at the stem of the funnel and passing through a baffle as shown in Fig. 4b. The gas exited at the top edge in a symmetrical fashion. The chamber had a volume of 25 cc, and was made out of Plexiglas so that the deposition process could be monitored visually. To minimize deposition on the chamber walls they were water cooled or coated with a simple mineral oil. This not only makes visual observation easier but also increases the deposition rate on the desired area by maintaining a higher reactant concentration in the gas stream.

Heater.—The heater was a block of aluminum 1 × 6 × 6 in. in which was embedded a heating element, a controlling thermistor, and a thermometer. Since operating temperatures were within the range 80°-160°C, very little thermal insulation was necessary. A thin (0.03-0.07 cm) Teflon sheet placed between the aluminum block and the glass plate served two purposes: (*i*) it could be readily removed for cleaning, and (*ii*) it was a more uniform heat-transfer medium than the variable air gap that occurred between the imperfect glass plate and the polished metal surface of the heating block.

A proportional controller maintained the aluminum heating block within one degree of the desired temperature, and in a typical run the side of the glass on which deposition took place arrived within five degrees of this temperature in 27 sec (see Fig. 5).

Gas composition.—The two most essential gaseous ingredients for reasonable deposition rates are $Fe(CO)_5$ and O_2. The use of an inert gas carrier adds convenience, control, and increased safety. In the work reported earlier (2), Ar was always used as the inert carrier gas. It was suggested, however, that CO_2 be considered as a substitute for Ar on the basis of reducing the explosive range of CO-O_2 mixtures (CO is a product of the reaction). It was gratifying to discover that upon substituting CO_2 for the Ar, the deposition rate increased significantly. The deposition rate was so high that it was often desirable to have a diluent gas in the system to limit the deposition rate. Typical sets of operating conditions are shown in Table I. Under these conditions and with the glass plate held at 100°C, the deposition time is 2½ min for a film 2600Å thick.

The deposition rate can be increased or decreased by varying the O_2 flow rate as shown in Fig. 6. Optical transmission of these films are the same for equal film thickness. It is assumed, therefore, that they are similar chemically. Very low deposition rates (below 700

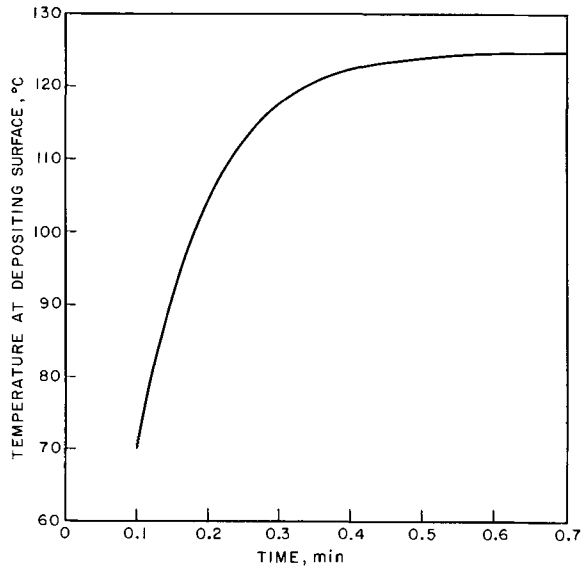

Fig. 5. Temperature of the outside surface (surface being coated) of 0.060-in. thick soda-lime glass plate in contact with a 125°C heating plate as measured with a 0.003-in. diameter thermocouple wire.

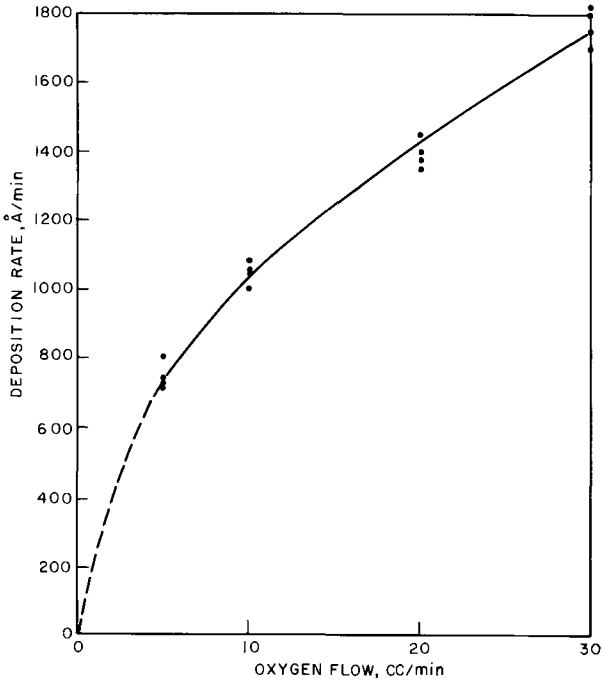

Fig. 6. Deposition rate as a function of oxygen flow at a constant CO_2 carrier gas flow rate of 200 cc/min.

Å/min) were of no particular interest and therefore, not investigated. At very high rates (over 1800 Å/min) it became increasingly difficult to maintain uniformity and reproducibility of the film. However, at higher deposition temperatures (140°-160°C) good films were obtained at rates as high as 9000 Å/min. This rate

* Bubbled through liquid $Fe(CO)_5$ at room temperature.

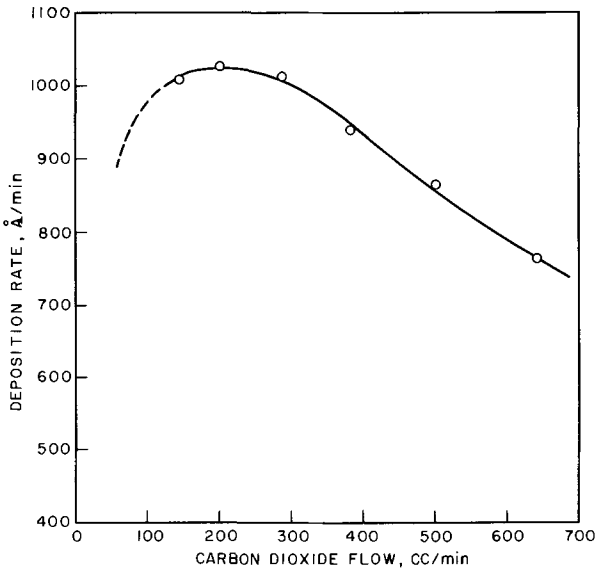

Fig. 7. Deposition rate as a function of CO_2 carrier gas flow at a constant oxygen flow rate of 10 cc/min.

means that a completed film can be deposited in about 20 sec.

The flow rate of the carrier gas also affects the deposition rate as shown in Fig. 7. The maximum in the curve seems to be real and may result from the cooling of the glass plate at high flow rates. It may also result from the decrease in $Fe(CO)_5$ concentration at high flow rates because of the evaporative cooling of the liquid in the bubbler and the resulting decrease in vapor pressure of the $Fe(CO)_5$. For higher deposition rates, the temperature of the bubbler and chamber may be raised. Only a modest increase can be tolerated because of the low temperature at which the desired reaction takes place (80°C).

Nitrogen is also an effective carrier gas for the carbonyl, and its substitution in place of the Ar used earlier increased the deposition rate still further. Indeed, when N_2 at 20 cc/min was bubbled through $Fe(CO)_5$ and mixed with oxygen at 5 cc/min the deposition rate was too fast to control easily. Therefore, such compositions are not recommended unless one is considering a continuous system for production.

The reason for the increased deposition rates with CO_2 or N_2 as compared with Ar is not clear. They both have higher thermal conductivity and higher specific heat than Ar, but to what degree this is responsible is not known.

Deposition temperature and etching.—Fe_2O_3 is not generally soluble in the dilute mineral acids that are most compatible with the photoresist processing. The oxide that is deposited from the CVD process is very difficult to dissolve in any concentration of HCl if the deposition temperature is over 180°C or if the film is given a postdeposition heat-treatment of over 400°C. Therefore, for ease of etching (and, thus, better pattern resolution) the temperature of deposition is kept below 160°C and all subsequent baking (before pattern delineation) below 200°C. Figure 8 is a graph showing the dependence of etching time (for a film 1700Å thick) on the deposition temperature. (See the section on Chemical analysis for a possible explanation of this relationship.) Resolution improves as the etch time becomes shorter, and the best resolution has been obtained at the lowest deposition temperature that has been used (80°C). The deposition rate, however, is relatively low at this temperature and also the absorption cutoff shifts too far toward the uv. Table II and Fig. 9 illustrate this shift in absorption cutoff. Optical transmission at 4000Å is plotted as a function of film thickness for films deposited at 100°, 120°, and 140°C. If transmission of 1% or less is desired in the spectral

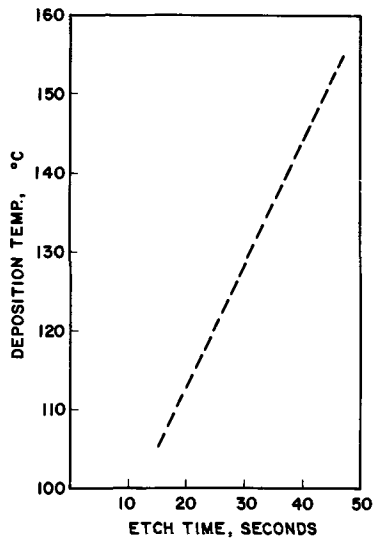

Fig. 8. Etch time as a function of the deposition temperature for films approximately 1700Å thick.

region below 4000Å, a film 1600Å thick will do if deposited at 140°C, but 2600Å will be required if deposited at 100°C. This shift in spectral transmission may be associated with the observed increase in what is assumed to be a carbonate content in the film (see section on Chemical analysis). Although some 4000Å light leaks through Fe_2O_3 films, absorption at 3600Å is very strong as indicated in Table II. Therefore, high contrast photomasking can be obtained with Fe_2O_3 by using visible cutoff filters (*e.g.*, Corning 5840) in the exposing source.

The transmission in the region 5500-7000Å is noticeably affected by interference and accounts for the occasional increase in transmission as the film gets thicker. This effect can be seen in Table II and also in Fig. 10.

Figure 10 is a graph of the transmission of a film about 2750Å thick which was deposited at 100°C. After photoresisting, a mask pattern was etched in this film in 1½ min using 6*N* HCl (1:1, concentrated HCl:water) at room temperature. A typical test pattern obtained under these conditions is shown by optical microscopy in Fig. 11 and by scanning electron microscopy in Fig. 12.

Because of the high vapor pressure of HCl it was also possible to use a vapor-etching process. It was satisfactory but did not seem to offer any real advantage over the simpler aqueous system. On the other hand, there are times when vapor etching can be very bothersome. For example, when experimenting with deposition chambers in which the glass plate would get a deposit on both sides, it was necessary to remove

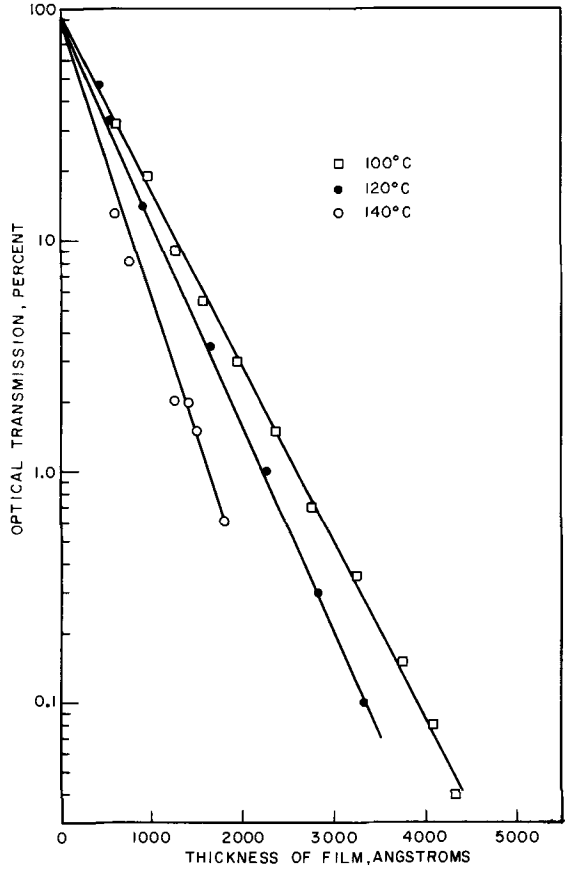

Fig. 9. Optical transmission at 4000Å as a function of film thickness for films depositel at 100°, 120°, and 140°C.

the deposit from one face with an etchant. If aqueous HCl was used as the etchant it was necessary to seal off the good Fe_2O_3 face to prevent its removal by HCl vapor along with the unwanted deposits. This was accomplished with an air curtain but a much more satisfactory solution to the problem is to use orthophosphoric acid which has a very low vapor pressure. The glass plate can readily be treated on one face only by saturating a filter paper with the acid and placing the plate on the filter paper. The etching rate is a little slower than for HCl.

Chemical analyses of Fe_2O_3 films.—In earlier work (2) it was indicated that the compositions of the CVD films "approximate that of Fe_2O_3 with possible minor concentrations of carbon and silicon." Specifically, it was noted that a film which was deposited at 155°C had 0.89% carbon, whereas a 200°C film had none.

However, the great solubility difference between those two films was not attributed to this difference in carbon content but was attributed to the more crystalline character of the higher temperature film.

More recently, Sinclair (5) has made some additional analyses that suggest a mechanism involving the carbon which may also account in part for this solubility difference. Infrared spectra were measured in the range 1-15μ. In the case of the CVD films this was done on very thick films which had spalled off of the glass substrate. With sputtered films (75% CO-25% CO_2 ambient), a calcium fluoride optical flat was used as the substrate. In both cases absorption was noted at about 6.7 and 7.4 μm which is consistent with the presence of carbonate or oxalate. Spot tests for oxalate were negative and chemical analyses for carbonate have been made by dissolving iron oxide films in 6M HCl

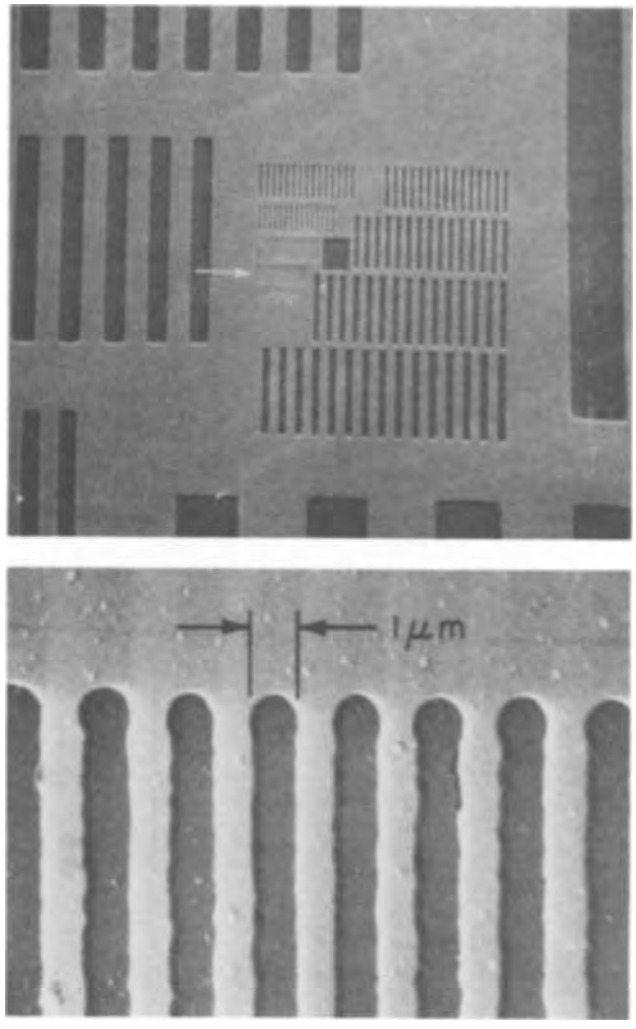

Fig. 12. Scanning electron microscope pattern of Ealing test pattern contact printed in Fe_2O_3 using AZ 1350 photoresist.

followed by gas chromatographic analysis of the liberated CO_2. The results are collected in Table III. These were unexpectedly large amounts of CO_2.

On the basis of these data it is suggested that the greater solubility of the CVD films and of the films sputtered in CO_2 as compared with films sputtered in Ar-O_2, may be due in part to the presence of a "carbonate" in the film. (The exact form of the compound from which the CO_2 was generated is not known. $Fe_2(CO_3)_3$ is not a recognized compound.) This mechanism would also account for the rapid conversion from the soluble to insoluble form by subsequent heat-treatment since the "carbonate" would decompose on heating. Such a treatment may be useful to decrease the solubility or increase the durability of the finished mask. It must be noted that the "carbonate" content is proposed as a possible influence on etching in addition to the crystal size influence described earlier (2). It is not obvious at this time which is the more important.

Defects.—Early in the development of the CVD process it was anticipated that the Fe_2O_3 film would have less tendency to form pinholes than the currently

Table III. Analyses for CO_2 evolved from Fe_2O_3 films

popular Cr films. This view was based in part on the higher degree of similarity between the Fe_2O_3 and the glass substrate and in part on the belief that the fluid precursor of the Fe_2O_3 may spread on the glass before the final reaction. Simple optical inspection as well as photoresist etching experiments designed to amplify pinholes indicate that the Fe_2O_3 films have fewer than 0.5 pinholes/cm^2. A more serious problem at present seems to be "antipinholes," that is, areas that etch with more difficulty than the majority of the film and thus tend to leave islands of unetched material behind. Elo (6) has compared Fe_2O_3 films with currently available Cr films and has suggested that "partial antipinholes" are due to residual photoresist arising from several sources. This is consistent with the observation that freshly deposited films dissolve uniformly in acids whereas after days of storage, antipinholes are noted. In other words, clean fresh films are reasonably free of defects, while films which have been exposed to possible contaminants (grease from airborne particles or bits of photoresist from poor processing) tend to show antipinholes. All Fe_2O_3 masks (~250) made over a three-month period were examined by a technique capable of detecting 2 μm defects. It was reported in that study that: "The R.M.S. concentration of defects 2 μm or larger in size is 0.5 defect/cm^2 in Fe_2O_3 films." Elo concluded that: "A significant reduction in the defect level (vis-a-vis evaporated Cr) appears possible with Fe_2O_3 semitransparent masks."

Summary and Conclusions

The decomposition of $Fe(CO)_5$ and oxidation of the decomposition product at 100°C in an O_2 or air ambient produces a films of Fe_2O_3 about 2600Å thick in 1-3 min. This film will block most of the actinic light employed with commercial photoresists. Using standard photoresist techniques and HCl as the etchant, photomasks have been made with 1 μm features.

The main advantage of such a photomask is the see-through characteristic which greatly simplifies alignment procedures in semiconductor processing. In addition, these masks have an impressive combination of other desirable qualities. For example, they are comparable to chromium masks in resistance to scratching, they have less halation effect than chromium, they are easier on the operator's eyes than chromium because of lower reflectivity, and finally the defect density is low.

The Epitaxial Growth and Properties of Silicon on Stoichiometric Spinel and Sapphire Substrates Using Silane-Helium Mixtures *vs.* Silane-Hydrogen Mixtures

Y. S. Chiang* and G. W. Looney

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Epitaxial growth of silicon on (111) and (100) stoichiometric spinel, $(1\bar{1}02)$, (0001), and $(11\bar{2}3)$ sapphire using silane in helium has been studied. (100) Si seems to be more compatible with sapphire than (111) Si, and exactly the opposite is true with stoichiometric spinel. Higher growth rate is preferred for epitaxial growth on sapphire and lower growth rate is favored for growth on stoichiometric spinel. Silicon films grown in hydrogen tend to have a smoother surface than that grown in helium, but larger contamination and interdiffusion effects. Lower optimum growth temperatures have also been observed for the silicon growth in helium than in hydrogen.

Effects of various growth parameters on the properties of the silicon layer using silane in helium were investigated. Hall mobilities comparable to bulk Si were realized in p-type films on (111) spinel. Hall mobility dependence, for both holes and electrons, on film thickness was found to be nearly constant for Si layers on spinel beyond 1 μm. The effect of stress on the mobility of (111) and (100) Si has been discussed.

The usual method of single crystalline Si deposition involves the silane-hydrogen system, where the deposition rate decreases to very low values below 1000°C. Silane-helium system, on the other hand, has been shown to give quite a high deposition rate (0.1 μm/min or higher) at 900°C both on Si (1) and on sapphire (2, 3). Furthermore, as discussed later, certain surface problems are always encountered in growth of Si on (111) stoichiometric spinel using hydrogen as the carrier gas which are not found with helium. Thus, the use of helium as a carrier gas instead of hydrogen

* Electrochemical Society Active Member.

Key words: silicon epitaxy, insulating substrate heteroepitaxy, spinel, sapphire, epitaxy by SiH_4-He system.

might be advantageous. However, the growth parameters and properties of the silicon change markedly when helium is substituted for hydrogen.

In this study, a variety of growth parameters such as surface treatment of substrate, growth temperature, and growth rate have been investigated using helium as the carrier gas. Comparison of the experimental results for silicon epitaxial growth on sapphire and stoichiometric spinel, as well as in hydrogen *vs.* helium, is made and discussed.

Experimental

The growth system used in this study has already been described in an earlier report (4). The silane source was 5% in He unless otherwise specified. The carrier gas was ultrahigh purity helium, passed through two molecular sieves at 77°K, and then filtered through a 0.8 μm filter. The dopant gases used were diborane and arsine of a concentration of 100 ppm in helium. Dilution of either of the dopants was effected by mixing the 100 ppm source gas with more ultrahigh purity helium in a glass mixing bulb. Fractions of the diluted mixtures were then bled into the reactant gas stream, while the rest was vented through an exhaust. In this manner, a few orders of magnitude of dilution of the dopant gas could be readily and reproducibly achieved in the resulting carrier gas stream.

The Czochralski stoichiometric spinel and sapphire were obtained from Linde Division of Union Carbide. All the sapphire wafers were cut and polished by Insaco (Quakertown, Pennsylvania), whereas the spinel wafers were polished either by our own in-house facilities or by Linde or Insaco. The finished wafers have been examined by electron diffraction for crystallinity and constitution. A cleaning procedure composed of trichloroethylene degreasing, alcohol rinsing, Caro's acid (5 parts H_2SO_4, 1 part 30% H_2O_2, and 1 part H_2O) cleaning, distilled water rinsing, and spin drying is used with all the substrates just prior to insertion into the growth chamber.

Layer thicknesses were determined exclusively by *IR* interference (transmission mode) technique (5) using a Cary 14 spectrophotometer. We have employed the Hall mobility of the majority carrier as the quality indicator of the electrical properties of the epitaxial Si films similar to many other investigators.

Results

Silicon on Czochralski Stoichiometric Spinel

Effect of substrate treatments prior to growth.—For both (111) and (100) oriented wafers, no apparent differences in Hall mobility can be distinguished from Si films grown on substrates mechanically polished by different sources. In addition, further chemical polishing of the substrates by phosphoric acid or borax fails to improve the Si films deposited on them.

Few *in situ* annealing schemes at elevated temperatures either in hydrogen or helium have been experimented. The effect of these treatments on Si films subsequently grown on (111) and (100) spinel is given in Tables I and II, respectively. For (111) Si on (111) spinel, the results indicate clearly that no predeposition annealing is necessary. Hydrogen annealing at 1000°C, however, has no adverse effect on Hall mobility for p-type films but slightly increases the acceptor concentration. More important, the hydrogen treatment produces a smoother surface of the Si deposit. Higher temperature hydrogen annealing is very undesirable even for p-type films. A 1040°C annealing would cause the Hall mobility to decrease by 50%, and from 1100°C upwards microcracking of the (111) spinel substrate would be observed.

In contrast with the (111) spinel, the (100) oriented substrate needs hydrogen or helium annealing for a smoother surface of the Si deposit, as well as higher Hall mobility. Hydrogen annealing is slightly more favorable than helium annealing for obtaining a smooth surface of the silicon layer.

Table I. Effect of surface treatment of melt-grown (111) stoichiometric spinel on epitaxial silicon films grown from silane-helium mixtures

A. P-type films

Surface treatment	Deposition temperature (°C)	Thickness of Si layer (μm)	Acceptor concentration (cm^{-3})	Hall mobility (cm^2/V-sec)
H_2, 1 hr at 1000°C	1040	1.8	3×10^{16}	310
H_2, 1 hr at 1040°C	1040	0.8	2×10^{15}	160
No annealing	1040	0.8	3×10^{15}	350
		1.0	1×10^{16}	370
He, 20 min at 1040°C	1040	0.8	3×10^{15}	320

B. N-type films

Surface treatment	Thickness of Si layer (μm)	Donor concentration (cm^{-3})	Hall mobility (cm^2/V-sec)
No annealing	1.0	3×10^{16}	535
H_2 annealing (1 hr at 1020°C)	1.0	2×10^{16}	400

Table II. Effect of surface treatment of melt-grown (100) stoichiometric spinel on epitaxial silicon films grown from silane-helium mixtures

A. P-type films

Surface treatment	Thickness of Si layer (μm)	Acceptor concentration (cm^{-3})	Hall mobility (cm^2/V-sec)
H_2 annealing (1 hr at 1000°C)	1.0	9×10^{16}	135
No annealing	1.0	4×10^{16}	120

B. N-type films

Surface treatment	Thickness of Si layer (μm)	Donor concentration (cm^{-3})	Hall mobility (cm^2/V-sec)
No annealing	1.3	2×10^{16}	70
Hydrogen annealing (1 hr at 1000°C)	1.4	5×10^{16}	320
Helium annealing (1 hr at 1000°C)	1.3	3×10^{16}	355

Influence of growth conditions.—The optimum epitaxial growth temperature on (111) spinel is found to lie around 1020°-1060°C. For p-type films, the Hall mobility at a growth temperature of 960°C is only one-half of that obtained in the optimum range, while at 1070°C three-quarters of the optimum value is obtained. In general, growth made at the higher end of the optimum temperature range tends to yield more uniform and smoother Si deposits.

The optimum growth temperature on (100) spinel is located similarly at 1020°-1050°C. But the surface smoothness of the Si deposit is much inferior to that obtained on (111) spinel; and at temperatures outside the optimum range, the appearance of the Si film is significantly degraded.

The Hall mobility of p-type Si films on (111) spinel grown at high silane concentration and helium flow rate is invariably much lower than that grown at low silane concentration and helium flow rate. The same is true for n-type Si films on (111) spinel as well as both n- and p-type Si films on (100) spinel except that inhomogeneity is also being introduced.

Resulting electrical properties of the Si films.—The Hall mobility of holes and electrons is measured and found to be essentially independent of carrier concentration in the range of 10^{15}-10^{17} cm^{-3} for Si films on both (111) and (100) spinel.

P-type Si layers on (111) spinel yield an almost linear dependence of Hall mobility on thicknesses from 0.2 to 0.8 μm (see Fig. 1). For 0.8 μm and thicker films, the Hall mobility of holes is approximately the value for bulk silicon (high 10^{15} to low 10^{17} acceptors/cm^3). Oxidation of the Si films at 1100°C for 1 hr

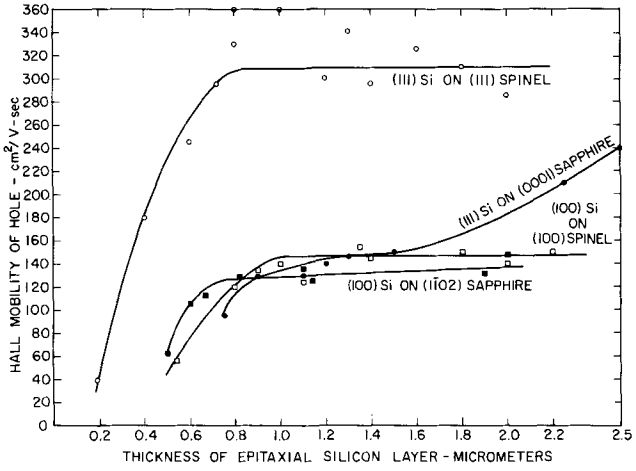

Fig. 1. Dependence of Hall mobility of holes in as-deposited (100) and (111) silicon on stoichiometric spinel and sapphire as a function of film thickness (carrier concentration: 3 to 8 × 10^{16} cm^{-3}) using silane-helium mixtures.

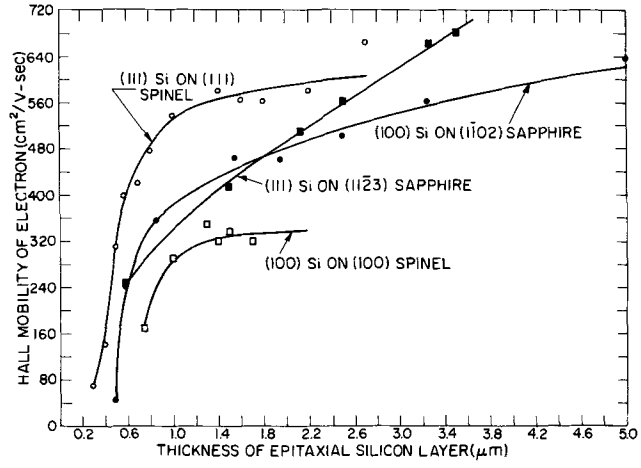

Fig. 2. Dependence of Hall mobility of electrons in as-deposited (100) and (111) silicon on stoichiometric spinel and sapphire as a function of film thickness (carrier concentration: 3 to 8 × 10^{16} cm^{-3}) using silane-helium mixtures.

usually would not degrade the Hall mobility value as exemplified by the few samples listed in Table III. On the other hand, a silicon layer grown in the same apparatus, but using hydrogen as the carrier gas, gives a Hall mobility of 60 at a 1 μm thickness (2 × 10^{17} acceptors/cm^3), about one-fifth of that obtained from films grown in helium.

The dependence of Hall mobility on film thickness of n-type films on (111) spinel is depicted in Fig. 2. At a thickness of 1 μm and more, the Hall mobility of electrons becomes independent of film thickness with a value of about 600 cm^2/V-sec.

The dependence of Hall mobility on film thickness of p- and n-type Si films on (100) spinel is very similar to that of Si on (111) spinel described above. Details of them are shown in Fig. 1 and 2, respectively. In contrast with the case of (111) spinel, excellent

Table III. The effect of thermal oxidation of p-type silicon epitaxial films on (111) melt-grown stoichiometric spinel

Thickness of Si layer (μm)	Acceptor concentration, N_A, cm^{-3}	Hall mobility, μ_p, cm^2/V-sec	After oxidation at 1100°C for 1 hr: Acceptor conc., N_A, cm^{-3}	After oxidation at 1100°C for 1 hr: Hall mobility, μ_p, cm^2/V-sec
0.6	4 × 10^{16}	245	2 × 10^{16}	195
1.3	5 × 10^{15}	330	2 × 10^{15}	345
1.4	1 × 10^{16}	295	6 × 10^{15}	275

epitaxial silicon films on (100) spinel can be grown in hydrogen at 1085°-1090°C (as compared with 1020°-1050°C in helium). The Hall mobilities of the films grown in hydrogen and helium are the same. For example, a 1.8 μm thick p-type film grown in hydrogen gives a Hall mobility of 140 cm^2/V-sec at an acceptor concentration of 3 × 10^{16} cm^{-3}. A n-type film grown in hydrogen has a Hall mobility of 300 cm^2/V-sec at a film thickness of 1 μm and a donor concentration of 1 × 10^{17} cm^{-3}.

Silicon on Sapphire

Effect of substrate treatments prior to growth.—The phosphoric acid chemically polished substrates were observed to offer no advantage over the normal mechanically polished wafers for growth of silicon films on sapphire. Among the various predeposition *in situ* treatments evaluated, hydrogen annealing at elevated temperatures (above 1200°C) is the most desirable process for both (1$\bar{1}$02) and (11$\bar{2}$3) oriented sapphire. And sulfur hexafluoride etching of the substrate in helium was found to be not as desirable as the hydrogen annealing.

Influence of growth conditions.—For (1$\bar{1}$02) and (11$\bar{2}$3) oriented sapphire, the optimum growth temperature was found to be 950°-1000°C; and for (0001) sapphire, 1030°-1050°C. As growth temperature departs more from the optimum range, the surface smoothness suffers.

Higher silane concentrations and higher flow rates of helium (higher deposition rate) are observed to be more favorable growth conditions in distinct contrast to the case of growth on spinel.

Resulting electrical properties of the Si films.—The dependence of Hall mobility on film thickness for p- and n-type (100) Si layers on (1$\bar{1}$02) sapphire is shown in Fig. 1 and 2, respectively. For p-type films, no appreciable increase in Hall mobility with film thickness can be seen for film thicknesses exceeding 1 μm. Also, the value of the measured Hall mobility of holes for helium-deposited films approximates closely the value of the Si film grown in hydrogen in the same epitaxial system with the same film thickness. In turn, the Hall mobilities measured on films grown in hydrogen agree well with the values reported (6). If the Si film grown in helium is oxidized at 1100°C for 1 hr, hardly any change in the value of the Hall mobility occurs. For example, a Hall mobility of 130 is measured from a 1.1 μm thick film at an acceptor concentration of 5 × 10^{16}; a Hall mobility of 120 is measured after the oxidation. The n-type (100) Si films on (1$\bar{1}$02), on the other hand, yield Hall mobilities ever increasing with film thickness up to 5 μm, the thickest film we have grown.

The dependence of Hall mobility on film thickness for p-type (111) Si on (0001) sapphire is also shown in Fig. 1. The Hall mobility continually increases with increasing thickness of the silicon layer. Epitaxial silicon films grown in the same system, but using hydrogen as the carrier gas, usually yield a comparable but slightly higher Hall mobility value than those grown in helium. For example, a 1.2 μm thick Si film grown in hydrogen at 1030°C gives a Hall mobility of 170 cm^2/V-sec (at an acceptor concentration of 9 × 10^{16} cm^{-3}) *vs.* 140 cm^2/V-sec for a helium grown film.

Similar to the case of (100) Si on (1$\bar{1}$02) sapphire, the Hall mobility of n-type (111) Si on (11$\bar{2}$3) sapphire rises with thickness of the layer as depicted in Fig. 2. The dependence of Hall mobility on thickness is almost linear throughout the range of practical interest, *i.e.*, 0.5-3.5 μm.

Discussion

The Hall mobility of holes for (111) Si on spinel is invariably greater than that of (100) Si on spinel. And at a film thickness exceeding 0.9 μm, the hole mobility

of (111) Si on sapphire is always larger than (100) Si on sapphire (see Fig. 1). These observations can be accounted for by a model of the effect of stress on the film properties (7, 8). Schlotterer (7) and Heywang (8) have postulated from theoretical considerations that stress enhances the hole mobility in (111) silicon but degrades the electron mobility in (100) silicon. The stress in the Si film is generated through the different thermal-expansion coefficient of silicon and the substrate. As the lattice mismatch between silicon and stoichiometric spinel is very small, *i.e.*, 0.3-0.9% (9), the stress effect is observed in the case of spinel from the very beginning. On the other hand, the larger lattice mismatch between silicon and sapphire, 4-12% (9), dominates at small thicknesses, and only at thicknesses greater than 0.9 μm does the stress effect become apparent in silicon on sapphire films.

Just as in the situation for p-type films, the n-type (111) Si on spinel invariably has a greater Hall mobility than that of (100) Si, and the n-type (111) Si on sapphire at first shows a lower mobility value than that of (100) Si, and subsequently surpasses the value of the latter at thickness greater than 2 μm (see Fig. 2). The effect of stress on the film properties as postulated by Schlotterer (7) and Heywang (8) is once again being observed.

Silicon films grown on the two sapphire orientations in either hydrogen or helium give very comparable if not identical results. But for Si on (111) spinel, the hole mobility for films grown in hydrogen is only about one-fifth of that grown in helium, suggesting a probable surface reaction of hydrogen with the substrate. Furthermore, comparable hole mobility is measured from the Si films on (100) spinel grown either in hydrogen or in helium. It seems that the (111) oriented spinel possesses a much higher surface reactivity with hydrogen than the (100) oriented material.

Surface treatments of the substrate, both sapphire and stoichiometric spinel, are of crucial importance in obtaining good quality silicon films. For sapphire, a prior *in situ* high-temperature annealing in hydrogen is necessary for growing a smooth silicon layer with acceptable Hall mobility. For (100) spinel, again an *in situ* high-temperature annealing in hydrogen or in helium is necessary to subsequently obtain a silicon film with reasonable appearance. As for (111) spinel, no *in situ* predeposition high-temperature annealing is necessary, and hydrogen annealing invariably degrades the electron Hall mobility.

In most aspects, epitaxial growth of Si on stoichiometric spinel and sapphire are very similar. For instance, the optimum growth temperatures (in helium) lie in the range of 950°-1050°C for both kinds of substrates. But the optimum silane concentration and helium flow rate for the two kinds of substrates are drastically different. Higher growth rate (higher silane concentration and helium flow rate) is more desirable for growth of Si on sapphire. And lower growth rate (lower silane concentration and helium flow rate) is more favorable for growth of Si on stoichiometric spinel. This is most likely related to the much reduced crystallographic mismatch of silicon to stoichiometric spinel than silicon to sapphire (9). Contamination by the constituents of the substrate is consistently less for stoichiometric spinel than for sapphire, as has been observed for alumina-rich spinel and sapphire (10).

The silicon films grown in helium, with the exception of Si on (111) stoichiometric spinel, are often not as smooth as that grown in hydrogen. On the other hand, the Si films grown in helium resist the degradation of Hall mobility by oxidation much better than those grown in hydrogen. The former is possibly caused by the larger amount of homogeneous nucleation in the gas phase of silicon in helium than in hydrogen, and the latter may be related to the inclusion of a reactive gas (hydrogen) in the Si film. The optimum growth temperature on sapphire as well as on stoichiometric spinel is usually 50°-100°C lower when helium is used instead of hydrogen as the carrier gas. In general the Si films grown in helium also have less contamination from constituents of the substrate. But they are much more sensitive to oxygen leaks in the epitaxial growth systems than their hydrogen counterparts.

Heteroepitaxial Growth of Si_xGe_{1-x} Alloys by Thermal Decomposition of SiH_4 and GeH_4

G. M. Oleszek*,[1] and R. L. Anderson*

Microelectronics Laboratory, Department of Electrical and Computer Engineering, Syracuse University, Syracuse, New York 13210

ABSTRACT

Epitaxial layers of Si_xGe_{1-x} alloys have been grown on germanium substrates by the simultaneous thermal decomposition of SiH_4 and GeH_4 in hydrogen. Growth was in the 800°-850°C temperature range at growth rates on the order of 0.1 μm/min for alloy epitaxy. Using the back-reflection Laue method, the alloys were determined to be single crystal with the substrate orientation, while x-ray diffractometer measurements indicated alloy compositions with x in the range $0 < x \leq 0.25$. The defect density of lower Si concentration alloys ranged from 10^4 to 10^7 cm^{-2}. Hall measurements of alloy layers without intentional doping indicated p-type alloy material with Hall (hole) mobility in the 250-400 cm^2/V-sec range at carrier concentrations of 2-5 $\times$ 10^{17} cm^{-3} for 4-5 atomic per cent Si in the alloy. Current-voltage characteristics of p-n heterojunctions formed between alloy and substrate were found to be rectifying while p-p heterojunctions were weakly rectifying. A frequency dependence of the junction capacitance was observed which presumably is a result of defect states at the interface between the substrate and alloy.

Germanium and silicon have the same crystal structure (diamond-cubic) and their lattice constants differ by 4% at room temperature. It is well known that Si and Ge form solid solutions over the entire range of composition where, presumably, the atomic positions are random (1). In the late 1950's and early 1960's Si_xGe_{1-x} alloys were made covering the full range of composition (2-6). However, these crsytals were grown from the melt and single-crystal material was obtained only for the alloy represented by the extreme Si and Ge ends of the phase diagram. Sandulova *et al.* (7) in 1962 reported growth over the entire alloy range from the vapor phase using Se as a carrier in a closed tube system. The method proved impractical because of growth times requiring 2-5 days and the poor control associated with the closed tube process.

Also in 1962, Miller and Grieco (8) reported epitaxial growth of Si-rich alloys containing up to 30 a/o (atomic per cent) Ge by the simultaneous vapor-phase reduction of $SiCl_4$ and $GeCl_4$. Si wafers were used as substrates and hydrogen carrier gas was bubbled through a solution of $SiCl_4$-$GeCl_4$ which then carried the halides to the reaction chamber. Different compositions were obtained by varying the proportions of the halides. X-ray diffraction and electron diffraction measurements indicated that the films were epitaxial. The dislocation count was on the order of 10^7 cm^{-3} although the films were not extensively characterized. Results complementary to those of Miller and Grieco were obtained in 1963 by Newman and Wakefield (9). Attempting to deposit Si onto Ge substrates by the disproportionation of SiI_2, they actually produced Si_xGe_{1-x} alloys in which x varied appreciably. They reported appreciable cavity formation in the resultant material.

Recent work in the U.S.S.R. (10, 11) has reported growth of silicon-rich Si_xGe_{1-x} alloys over an appreciable composition range by hydrogen reduction of $GeCl_4$ and $SiCl_4$. Separate evaporators were used for the two chlorides which were then mixed before entering the reaction chamber. Little has been reported on the vapor-phase growth of Ge-rich alloys, however Feucht (12) recently reported growth of Ge-rich alloys with $x = 0.1$ by the simultaneous pyrolytic decomposition of GeH_4 and SiH_4.

The purpose of this paper is to define growth conditions for achieving germanium-rich Si_xGe_{1-x} epitaxial alloys in the range $0 < x \leq 0.25$ by thermal decomposition of SiH_4 and GeH_4 in H_2 and to discuss the growth and material characteristics of the alloy material. This particular method is potentially advantageous for alloy growth since (*i*) undesirable impurity transport does not occur because the thermal decomposition of silane and germane is not a reversible process, (*ii*) epitaxial growth processes using both silane and germane occur at relatively low temperatures which minimize substrate and impurity out-diffusion, and (*iii*) the alloy composition may be easily changed by varying the gas stream concentrations of the hydrides.

Experimental

Epitaxial reactor system.—The epitaxial growth system used was a vertical reactor unit[2] in which the process gases pass downward, perpendicular to the substrates. All gas lines in the reactor are of 316 stainless steel and valves and regulators are stainless steel with Teflon packing. The reaction dome is constructed of quartz and is air cooled. The essential features of the epitaxial reactor are shown schematically in Fig. 1. Purification of the hydrogen is accomplished by passing it through a palladium purifier. Specified concentration of GeH_4 in H_2, SiH_4 in H_2, and HCl were obtained commercially in cylinders. The graphite susceptor, 5 in. in diameter, is heated by a pancake coil located directly below the susceptor and energized by a 10 kHz, 15 kW motor-generator set.

Growth procedure.—The Si_xGe_{1-x} alloys were grown epitaxially by the simultaneous thermal decomposition of SiH_4 and GeH_4 in H_2. The substrates were chemically-mechanically polished single-crystal germanium wafers. Prior to epitaxy the substrates were boiled in a 50:50 mixture of ethyl alcohol and trichloroethylene, boiled in a saturated potassium hydroxide-deionized water solution, consecutively immersed in hydrofluoric acid, deionized water, and ethyl alcohol, and then blown dry with nitrogen. The growth process consisted of the following procedures: with the substrates in place, the reaction chamber was initially purged with nitrogen. Hydrogen was then introduced

into the chamber and the germanium substrates heated to 850°C for 15 min. HCl was then admitted for 10 min to etch the substrates. The reaction chamber was then purged with H_2; the temperature adjusted to the growth temperature; and SiH_4, GeH_4, and H_2 introduced into the reaction chamber for the Si_xGe_{1-x} alloy growth. After completion of the growth, the chamber was purged with H_2 until the substrates cooled to room temperature. The reaction chamber was then purged with N_2 and the substrates removed.

Measurement techniques.—The temperature was measured using an infrared optical pyrometer. The instrument was initially calibrated by heating a polished Ge wafer to its melting point in the reactor chamber with an emissivity setting corresponding to Allen's (13) emissivity data for Ge. In this work all temperatures correspond to the germanium substrate temperature prior to the alloy growth since some clouding of the dome prevented accurate monitoring of the temperature during growth.

The percentages of GeH_4 and of SiH_4 in the gas stream were computed using the specified concentrations of GeH_4 and SiH_4 in H_2, and the flow rates of the hydrides and main-stream hydrogen which were measured using calibrated glass tube-ball flowmeters.

Measurement of the alloy thickness was determined by the cylindrical grooving method (14). In most cases, the alloy sample did not have to be chemically stained to see the boundary line between the alloy and substrate.

The crystallinity of the epitaxial layer was established by back-reflection Laue and x-ray diffraction techniques. The back-reflection Laue method was primarily used to establish the single-crystal nature of the alloys; however, information concerning crystal distortion was obtained as well. A copper x-ray tube, operated at 30 kV and 22 mA, was used as the x-ray source which results in a depth of penetration of the x-ray beam of about 25 μm in pure germanium.

The alloy composition was determined using a General Electric XRD-6 x-ray diffractometer. A cobalt tube was used as the x-ray source and operated at 24 kV and 10 mA. The diffraction peaks of both the alloy and the Ge substrate were observed for the $K\alpha_1$, $K\alpha_2$, and $K\beta$ radiation. The $K\beta$ peaks were used to determine the lattice constant of the alloy. Because the lattice constant varies slowly with Si concentration (15), accurate alignment of the sample is normally required to determine the concentration. However, since the epitaxial growths were thin (2-7 μm), the responses from both the alloy and the substrate were observed. The difference in the 2θ angle between response peaks and the known 2θ angle of the Ge substrate was used to determine the interplanar spacing (16) of the alloy and thus its composition. Following Cullity (17) we calculate that for Ge using Co $K\beta$ radiation, 30% of the total diffracted intensity originates in the first 2.4 μm of material, 67% in the first 7.7 μm, and 99% in the first 20.6 μm. The diffracted intensity for the alloy would not be expected to differ markedly from these values and thus diffraction from the substrate would be expected to be observed.

Room temperature resistivity, conductivity type, concentration and mobility were determined from Hall effect measurements on alloys which were electrically isolated from the substrates (those grown on n-type substrates since all deposits were p-type). Both Standard and Van der Pauw d-c methods (18, 19) were used for Hall measurements with a magnetic field of 2.5 kgauss and a current of 1 mA. Current and voltage leads were attached using silver contact paint[3] and cured at 60°C for 15 min in air. Resistivity was also measured by the standard four-point probe method.

Dislocations were delineated by etching the samples in 30% H_2O_2 at room temperature for periods on the order of 1 hr.

Si_xGe_{1-x}/Ge heterojunctions were fabricated from epitaxial alloys grown on polished Ge wafers. Small pieces of the wafer, usually about 2.5 mm square, were obtained by scribing and breaking. The small pieces were then dip etched, cleaned, and the Ge side bonded to a transistor header. Contact to the alloy was made using a silver contact paint. The silver contact area, lead wires, and header leads were then waxed, etched, and rinsed in deionized water. The etching was allowed to proceed until all unmasked areas of the alloy were etched away.

A transistor curve tracer was used for qualitative observations of the *I-V* characteristics at room temperature with and without incandescent (microscope light) illumination. *C-V* measurements were made using a Boonton Model 71A capacitance/inductance meter, at 1 MHz, and a signal level of 15 mV peak to peak. Measurements at 500 and 100 kHz were obtained using a Boonton Model 75C capacitance bridge.

Results and Discussion

Si_xGe_{1-x} epitaxial growth characteristics.—Both n and p conductivity type Ge substrates of (100) and (110) orientations respectively were etched *in situ* at 850°C in mixtures of up to 7% HCl in H_2. The resultant surfaces were mirror-smooth and structureless. The etch rate was linearly proportional to both HCl concentration and time at a hydrogen flowrate of 10 liters/min.

The past history of the reaction chamber was found to be important to the appearance of the wafer after etching. When the reaction chamber had been thoroughly cleaned after a prior Si_xGe_{1-x} growth or had been used exclusively for Ge growth, the Ge substrate remained highly polished and structureless during etching. However, if the reaction chamber was not cleaned after an alloy run, a deposit was seen to form on the Ge substrate during the etching cycle. It was found that by allowing the etching to continue until the susceptor was etched clean of the previous Si_xGe_{1-x} growth, the deposit could then be completely etched off the substrate surface. It is thought that the deposit which grows on the Ge substrate during the HCl etch step is a Si_xGe_{1-x} alloy which occurs through the use of HCl as a transport agent.

It was found that single-crystal epitaxial layers could be grown without HCl etching prior to epitaxy provided that care was taken during substrate cleaning and subsequent handling. However, without the HCl etching step the alloy layer usually was not electrically isolated from the substrate, since four-point probe and Hall measurements were characteristic of the substrate layer while the heterojunction devices did not rectify.

Si_xGe_{1-x} alloys were epitaxially grown onto n-type and onto p-type Ge substrates with (100) and (110) crystallographic orientations, respectively. Experi-

ments were conducted to determine the effects of process variables on the growth and material characteristics of the alloy layers. Table I lists the results of process runs for which analysis of the Si_xGe_{1-x} layers were made. The data shown in this table will be referred to in the following paragraphs.

An examination of Table I indicates that at constant flow rates and constituent concentration, the growth rate is reasonably independent of temperature (compare runs 3,7; 9,11; and 10,12), and that the growth rate is the same for (100) and (110) surfaces under similar conditions. In Fig. 2, it is seen that at fixed composition in the gas stream, the growth rate is linearly dependent on the total flow rate at constant temperature (runs 1-4). These data would indicate that the growth process of the Ge (since it is the major component of the alloy) is mass transfer controlled. Joyce and Bradley reported (20) that below 1100°C (to 950°C) the growth rate of Si by the pyrolytic decomposition of SiH_4 onto Si substrates is surface-reaction controlled. They suggest that surface reaction is limited by the rate of removal of hydrogen from the growth surface.

If the growth rate were limited by the rate of removal of hydrogen from the surface, it would be expected that for our case it would inhibit the growth of Ge and of Si. If, however, the Ge growth rate were mass-transfer controlled while the growth of Si were surface-reaction controlled, it would be expected that for an increase in flow rate at constant gas composition and temperature the alloy growth would become more Ge-rich, while for an increase in temperature with gas composition and flow rate fixed the Si content would increase. An examination of Table I shows that these do not happen, indicating that the growth rate of both Si and Ge are mass-transfer controlled. It must be emphasized, however, that this is merely a tentative conclusion since the range of temperature and flow rate used is small.

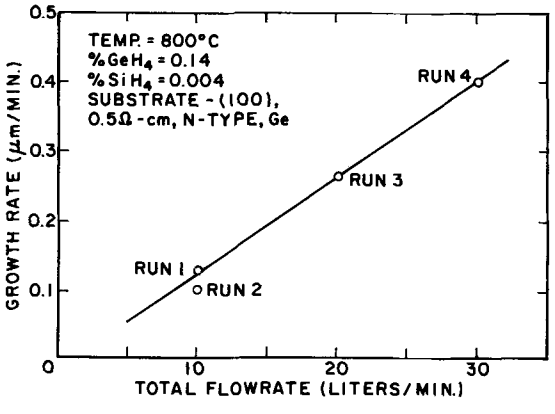

Fig. 2. Growth rate as a function of total flow rate at fixed composition and temperature.

Material characterization.—The surface characteristics of the Si_xGe_{1-x} alloy layers were observed by optical microscopy. The surfaces, in general, have a sandy appearance as shown in Fig. 3a. Surfaces of alloys grown on p-type (110) wafers appear to have a somewhat smoother and less textured surface than those grown on n-type (100) wafers. In general, as the growth rate was increased, the surfaces of low silicon concentration alloys ($x \simeq 0.05$) became more textured. As the alloy concentration or growth rate was increased the temperature of the growth process became the most important parameter with respect to surface appearance. For example, clusters or protrusions of the type shown in Fig. 3b were obtained for a 22 a/o Si alloy growth process at 800°C (run 9). Keeping all other process parameters constant but raising the temperature to 830°C (run 11) eliminated all the cluster defects and resulted in a surface comparable to that shown in Fig. 3a. Surface protrusions were also observed for runs 3 and 4 which were grown at 800°C at growth rates of 0.26 and 0.40 μm/min, respectively. However, run 7 which was grown under similar conditions to run 3, except that the temperature was raised 20°C (to 820°C), did not have surface protrusions. The elimination of these surface protrusions for higher growth temperatures is thought to be due to the fact that at the higher temperature the surface mobility of the silicon is larger. Thus the silicon atoms are able to diffuse more readily to the "growth steps" and complete growth planes rather than result in growth from localized nucleation sites associated with low surface mobility.

Etch-pit counts revealed dislocation densities from 10^4 to 10^7 cm^{-3} for alloys of low Si concentration. For higher Si content, the defect density was much higher than this; however the concentration could not be determined because of the tendency for the defects to be clustered.

From Laue back-reflection analysis it was determined that the Si_xGe_{1-x} growth was crystalline with the same crystal orientation as the substrate. In general, the spots were sharp. However, for those crystals which had surface protrusions as shown in Fig. 3b, partial Debye rings were observed indicating some lattice distortion.

Lattice parameters were determined from diffractometer measurements. All the alloys were found to be highly oriented with two distinct diffraction peaks corresponding to the alloy layer and the germanium substrate. Figure 4 shows a diffractogram, for cobalt radiation, of an alloy layer with $x = 0.25$ grown on (100) Ge substrate. The peak at $2\theta \simeq 71°$ results from diffraction in the alloy while that near 70° results from the Ge substrate.

Also in Fig. 4, it can be seen that the alloy diffraction peak is somewhat asymmetric. It was determined that the asymmetry was not due to misalignment of the diffractometer. It may be that the asymmetry is due to a transient variation in the SiH_4 and GeH_4 flow rates at the start of the epitaxy process. The hydrides

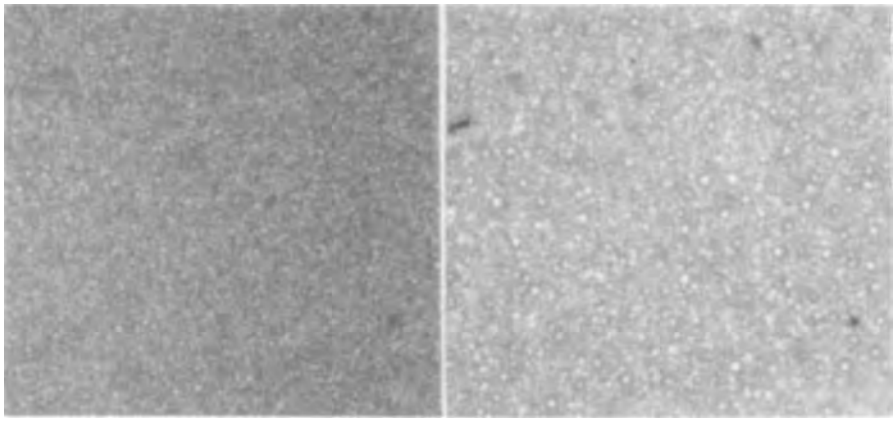

Fig. 3. Surface of Si_xGe_{1-x} epitaxial alloy layer with (a, left) orientation (110), $x = 0.25$ and (b, right) orientation (100), $x = 0.22$. (Magnification ×155.)

were not continually purged prior to their introduction into the reaction chamber and it is expected that a transient period is required before the flow rates attain their steady-state values. Thus, during the transient period the alloy growth layer would differ in composition from the remaining part with a resultant asymmetry in the alloy diffraction peak.

It is also seen in Fig. 4 that there is some broadening of the diffraction peak of the Si_xGe_{1-x} alloy in comparison to the Ge substrate peak. This type of broadening was observed for all of the alloy peaks and is thought to be due to the presence of some nonuniform strain in the alloy layer (17). We believe that this results from two effects: the mismatch in the lattice constant of the two materials and the different coefficients of thermal expansion. The latter would create a strain as the sample is cooled from the growth temperature even if crystal defects are introduced during growth to reduce the strain resulting from lattice mismatch.

For samples grown at growth rates 0.08-0.13 μm/min with low Si concentration (less than 5 a/o) the two peaks could be resolved using an input slit angle (1°), exit slit (0.05°), and high resolution Soller slits. However, for samples grown more rapidly than this, the alloy peak was broadened and the exit slit had to be reduced to resolve these peaks. An exit slit of 0.02° coupled with an entrance slit of 2° was adequate. We

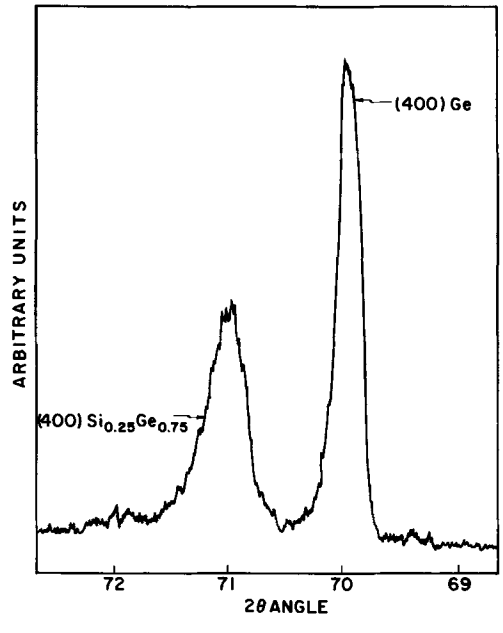

Fig. 4. X-ray diffractogram showing Kβ(400) $Si_{0.25}Ge_{0.75}$ and (400) Ge diffraction peak for cobalt radiation.

tentatively attribute this broadening to strain due to defects introduced during growth at these higher growth rates.

Although no impurity was intentionally introduced into the reaction chamber, Hall effect and thermal probing measurements indicated that the alloy was p-type. The alloy resistivity could be measured only for growths on n-type substrates since these cases provided the necessary junction isolation between the epitaxial growth and the substrate. The resistivity as measured with a four-point probe was generally on the order of 0.10 ohm-cm and reasonably independent of process parameters. The uniformity across a wafer surface was better than 10%. Some of the runs in which the HCl etch was not used gave considerable variation of resistivity with position. It is thought that this results from poor isolation at the interface and an influence of the substrate on the measurements.

From standard Hall measurements, the alloy resistivity was found to be comparable to that obtained from four-point probe measurements. The carrier concentration, obtained from the Hall data under the assumption that the ratio of drift to Hall mobility was unity, was determined to be $2\text{-}5 \times 10^{17}$ cm^{-3} with a Hall (hole) mobility in the 250-400 cm^2/V-sec range for 4-5 a/o Si in the alloy. In general, the resistivity and Hall mobility were somewhat larger as determined by the Van der Pauw method. This is thought to be a consequence of the fact that the contacts were not points nor were they located exactly on the boundary of the sample. This results in an additive error as shown by Van der Pauw (18, 19).

At a carrier concentration of 3×10^{17} cm^{-3}, the Hall mobilities of p-type Ge and Si are approximately 800 cm^2/V-sec and 200 cm^2/V-sec (21, 22), respectively. Since our measurements were made on alloys of 4-5 a/o Si we would expect the mobilities to be approximately equal to those of Ge instead of the measured values of 250 to 400 cm^2/V-sec. This reduced hole mobility could result from the increased carrier scattering expected from random positions of the Si atoms. However, it may be that the increased scattering is associated with the large defect concentration.

The origin of the p-type conductivity is not known. Acceptors may be introduced during growth from the reaction chamber (although depositions using $GeCl_4$ and $SiCl_4$ at higher temperatures result in high resistivity layers). Alternately they may be introduced from the gas streams or may result from the defects which occur in the growth, or from the strain introduced upon cooling. It is reported that regions of high deformation in germanium tend to be p-type (23).

Device characteristics.—Although without HCl etching just prior to growth, there appeared to be many regions of electrical shorting between the alloy and substrate, devices made from those runs in which the

HCl etch step was included yielded heterojunctions with electrical characteristics which seem to be qualitatively consistent with predictions based on heterojunction theory (24). Si_xGe_{1-x}/Ge p-n heterojunctions were found to be rectifying while p-p heterojunctions were found to be weakly rectifying and in some cases their *I-V* characteristics were not reproducible from unit to unit. The weakly rectifying characteristic observed for the p-p heterojunctions is expected because of the small discontinuity in the valence band edge and defect states at this interface (25). Some of the nonlinearity of the *I-V* characteristics can be attributed to the silver contacts used.

It should be pointed out, however, that if the acceptor is a typical shallow acceptor atom, considering the temperatures and times associated with the growth, it would be expected that the acceptor would diffuse into the Ge, creating a p-n junction in n-type substrates within the Ge and merely a p-p junction at the interface. If the p-type conductivity results from defects, on the other hand, negligible diffusion would be expected and the junction would be expected to be at the interface.

In Fig. 5 $1/C^2$ *vs.* voltage is plotted for a p-n Si_xGe_{1-x}/Ge heterojunction ($x = 0.22$) at three frequencies. The effective carrier concentration was calculated from the slope of the 1 MHz data and found to be 3×10^{15} cm^{-3}. This corresponds to the substrate doping level. This is as expected since the epitaxial layer is much more heavily doped than the substrate and so the depletion region would be expected to extend predominately into the lower doped substrate. The reverse breakdown (avalanche) voltage was also characteristic of the substrate doping level as expected.

A decrease in $1/C^2$ or an increase in capacitance under illumination with a microscope light was also observed at 1 MHz as shown. The carrier density as calculated from the slope, however, remained unchanged. Similar increases in capacitance with illumination were observed at the other frequencies. The frequency dependence of the capacitance is not expected from simple junction theory. However, Van Opdorp and Kanerva (26) have shown that interface states in heterojunctions can lead to such a dependence of capacitance on frequency. The influence of illumination on capacitance has been reported by Yawata and Anderson (27) and Oldham and Milnes (25) who attribute this effect to interface states. From this we conclude that enough interface states exist in our junction to affect the electrical properties. The origin of these states is not clear however. They may result from the lattice mismatch between alloy and germanium substrate, the strain introduced during cooling due to the different thermal coefficients of expansion or perhaps by defects present on the germanium substrate surface as growth started. These all have been reported to result in interface states.

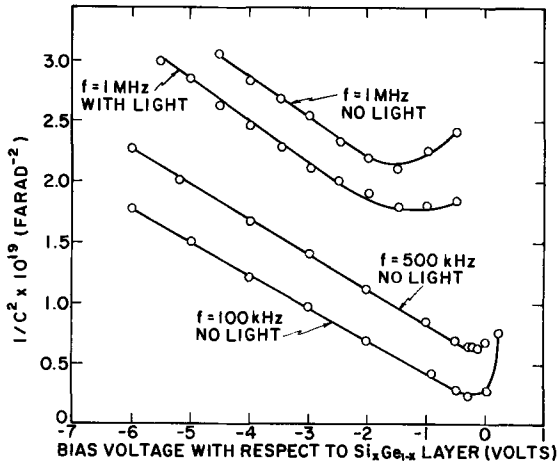

Fig. 5. $1/C^2$ *vs.* voltage for p-n Si_xGe_{1-x}/Ge heterojunction device with $x = 0.22$.

Summary

Si_x-Ge_{1-x} alloys with $0 < x \leq 0.25$ were grown epitaxially on Ge substrates by simultaneous thermal decomposition of SiH_4 and GeH_4 in hydrogen in the 800°-850°C temperature range. A vertical reactor was used in which the process gas passes downward and perpendicular to the substrate. The epitaxial growth process of both Si and Ge is thought to be mass-transfer controlled although the data is insufficient to conclude this. The surface morphology of low Si concentration ($x < 0.05$) layers was found to be dependent upon the growth rate at 800°C. For Si_xGe_{1-x} alloys with $0.22 \leq x \leq 0.25$, growth at 800°C resulted in the formation of defect clusters on the surface; increasing the temperature to 830°C yielded surfaces comparable to those of low Si concentration. Using the Laue back-reflection technique the alloys were found to be single crystal with the substrate orientation. Alloy compositions were determined using the x-ray diffractometer technique. Sharp spots in the Laue back-reflection patterns indicate that the strain in those films grown at less than 0.13 μm/min is not severe. However, partial Debye rings in the Laue patterns and broadening of diffractometer peaks indicate that strain is present in films with surface protrusions, *e.g.*, those grown at increased rates.

Although epitaxial growth occurs with or without *in situ* HCl etching, only those runs in which this etching step was included resulted in electrical isolation between substrate and growth. All deposits were p-type although no intentional doping was introduced. The origin of the p-type impurity is not known although it may be the high defect concentration as revealed by etch-pit counts (10^4-10^7 cm^{-2} on alloys of low Si content).

Si_xGe_{1-x}/Ge p-n heterojunctions were found to be rectifying and the general shape of the current-voltage characteristics are in qualitative agreement with heterojunction theory. The p-p heterojunctions were found to be weakly rectifying which was presumably due to the small potential barrier and defect states at the interface. The reverse breakdown voltage of the p-n structure and the slope of the $1/C^2$-*V* characteristics are characteristic of the substrate region as expected since the deposits were of higher net doping concentration.

The junction capacitance was found to be frequency and light dependent and presumably this effect is a result of lattice defect states at the interface.

Acknowledgments

The authors wish to acknowledge the assistance of Dr. Robert Thomas, RADC, in the design of the epitaxial reactor, Mr. Richard Gardner for the etch-pit studies, and Miss Martha Schwartzmann for many helpful suggestions and discussions during the course of this work. We are also indebted to Mr. Erwin Selleck for help with the diffractometer measurements and Drs. Bernard Waldman and John Schenck for critically reviewing the results. We also wish to thank the manuscript reviewers of this Journal for many helpful suggestions.

Manuscript submitted Feb. 15, 1972; revised manuscript received Nov. 27, 1972. This was Paper 272 presented at the Miami Beach Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Department of Metallurgical and Materials Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania 15213

ABSTRACT

The kinetics of the chemical vapor deposition of tungsten by the hydrogen reduction of WF_6 were studied over the system pressure range from 6 to 60 Torr and over the temperature range from 500° to 870°C to determine the operative rate controlling mechanisms. Within the pressure and temperature ranges studied HF desorption from the substrate was determined to be rate limiting for lower pressure-temperature combinations. An activation energy of 7300 cal/mole was associated with this mechanism. At higher pressure-temperature combinations WF_6 diffusion to the substrate was rate controlling. The activation energy for this process was found to be 1650 cal/mole.

The production of tungsten either in the form of coatings or free-standing shapes by chemical vapor deposition (CVD) has, in the last ten years, become an important manufacturing process. The over-all chemical reaction most usually associated with tungsten deposition and the one considered throughout this paper is given by

$$WF_{6(g)} + 3H_{2(g)} = W_{(s)} + 6HF_{(g)} \qquad [1]$$

A pertinent problem associated with this reaction is the nonuniformity of deposit thickness that is obtained when a substrate of considerable surface area (such as a removable mandrel or an item to be coated) is utilized. Deposit nonuniformity is the result of variations in reaction rate throughout the system. These variations are related to differences in temperature, pressure, and gas composition. To achieve deposit uniformity it is thus essential that the kinetics of the process be understood.

Holman and Huegel (1) have measured tungsten deposition rates under conditions of presumed negligible HF concentration and concluded that an unspecified surface process was rate controlling over a wide range of temperature and pressure. Data from the highest pressure-temperature combinations could not be explained by this analysis and were thought to represent the effect of inadequate supply of reactants. Haskell (2) developed a model in which the rate controlling mechanism for tungsten deposition was assumed to be HF desorption from the substrate. The model was checked by comparing its pressure dependence to that of a portion of Holman and Huegel's data for which the gas composition was considered to consist of essentially all hydrogen. Brecher (3), using the rate data of Berkeley *et al.* (4) obtained in a relatively high-pressure static system, has attempted to formulate a sorption-surface reaction model of the tungsten deposition process.

The work presented here is an investigation of the total range of pressure (6-60 Torr) and temperature (500°-870°C) normally associated with this CVD process. Rate-controlling mechanisms and involved species were tentatively identified by an analysis based on active-site theory. These findings were verified and a model was found to explain the experimentally determined behavior noted in both the high and low pressure-temperature subregions.

Experimental Procedure

The equipment used in this study is shown schematically in Fig. 1. An Inconel 718 deposition chamber

* Electrochemical Society Active Member.
Key words: tungsten fluoride (WF_6), tungsten preparation, desorption, diffusion, coating materials.

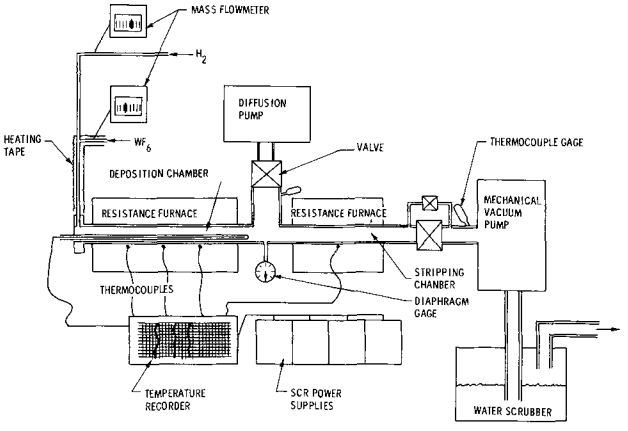

Fig. 1. Schematic drawing of CVD equipment

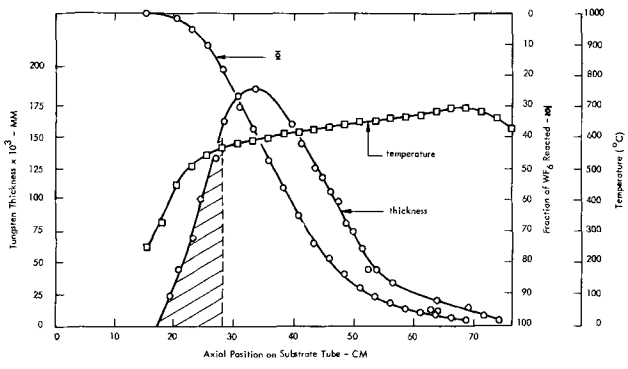

Fig. 2. Typical data used in calculation of gas composition

was heated by a surrounding clamshell resistance furnace whose three heating zones were each powered by a saturable core reactor and whose temperature was monitored with a Chromel-Alumel thermocouple. The downstream portion of the Inconel chamber was filled with stainless steel tubing and heated to approximately 700°C with a second clamshell furnace. This arrangement allowed this portion of the unit to serve as a stripping chamber wherein WF_6 not reacted in the deposition chamber could be spent to prevent its condensation further downstream in the system. Deposition pressure was controlled by the valves located forward of the mechanical vacuum pump and was measured with a diaphragm gauge. HF product gas was trapped in the water scrubber to prevent its discharge to the atmosphere. The unit was equipped with an integral high vacuum system to permit it being helium mass spectrometer leak checked prior to the start of a deposition trial.

Controlled flows of reactant gases entered the deposition chamber through an "O"-ring sealed, water cooled flange. Other features of the chamber included a removable, stainless steel liner tube and a thermocouple well equal in length to that of the tube.

The 4.88 cm ID liner tube, which served as the deposition substrate, was degreased and weighed prior to being inserted into the chamber. Further cleaning was provided during heat-up in flowing hydrogen to the deposition temperature. Hydrogen and WF_6 were admitted to the chamber at the respective rates of 2000 cc/min and 300 cc/min (STP). Temperatures between 500° and 870°C and pressures between 6 and 60 Torr were investigated. During deposition, temperature was measured as a function of axial position within the tube. A temperature profile was prepared from these data. Following deposition, the coated tube was removed from the chamber and its weight gain measured and compared with that calculated from the WF_6 flow rate and time of deposition. Tungsten was then removed from the tube along a line running 90° from vertical either by cutting a section from the coated tube and selectively dissolving the stainless steel or by repeated chipping of the nonadherent tungsten following cracking by application of a radial compressive force. Tungsten thickness was determined as a function of tube length to provide deposit thickness profiles as typified by the plot of Fig. 2.

The further use of a plot of this type to obtain the data necessary for kinetics analysis is best shown by the following sample calculation involving a tungsten thickness measurement at the position 28 cm from the inlet of the substrate indicated by the vertical dashed line in Fig. 2. Since the total amount of WF_6 injected during the 53-min run period was accounted for by the weight gain of the substrate tube, the fraction of WF_6 reacted at the 28-cm position was given by the area beneath the tungsten thickness profile from the point of its origin up to the 28-cm point (27.5 arbitrary area units) divided by the total area beneath the curve (152.5 arbitrary units). This calculation gave a value of 0.18 for Φ, the fraction of WF_6 reacted. (A plot of this parameter is included in Fig. 2)

Since the inlet gas flows (2000 cc/min hydrogen and 300 cc/min WF_6) are in the ratio 6.7 to 1, the over-all equation describing the deposition process can be written as follows

$$(6.7 - 3\Phi)H_{2(g)} + (1 - \Phi)WF_{6(g)} = (\Phi)W_{(s)} + (6\Phi)HF_{(g)} \quad [2]$$

The system pressure of 11 Torr was thus proportional to the sum of the coefficients for the terms involving gases $(7.7 + 2\Phi)$. Thus the partial pressure of hydrogen, for example, was given by

$$p_{H_2} = \left(\frac{6.7 - 3\Phi}{7.7 + 2\Phi}\right) 11 \text{ Torr} \quad [3]$$

which for the appropriate value for Φ of 0.18 gave 8.41 Torr. In a similar manner the partial pressures for WF_6 and HF were found to be 1.12 and 1.47 Torr, respectively.

The deposition rate, R, in cc/min $\times 10^3$ was found by division of the appropriate value for the tungsten thickness (150 mm $\times 10^3$) by the run time of 53 min to yield $R \times 10^3$ of 2.83.

The corresponding temperature was read from the measured temperature profile (superimposed on tungsten thickness profile in Fig. 2) and found to be 575°C.

Results

Numerous temperature, gas composition, and deposition rate combinations were found within a single deposition trial. This large amount of data made it possible to critically analyze the kinetics of tungsten deposition.

The deposition process was considered to consist of five steps as follows: (*i*) gas phase diffusion of reactants to the substrate, (*ii*) adsorption of reactants at the substrate, (*iii*) chemical reaction of reactants on the substrate, (*iv*) desorption of gaseous product at the substrate, and (*v*) gas phase diffusion of gaseous product from the substrate.

Steps (*ii*), (*iii*), and (*iv*) were examined with the aid of active site theory (5). With adsorption being the rate-controlling mechanism, an increased concentration of reactants due to a pressure increase would increase the deposition rate. Adsorption control is normally associated with low system pressure. At higher pressure the substrate surface would tend toward saturation with reactants. If the adsorbed molecules react faster than the product gas can be desorbed, desorption would become rate controlling. Desorption rate is dependent only on the fractional surface coverage of gaseous product and is independent of reactant concentrations. Thus, the deposition rate, if controlled by desorption, should be essentially independent of changes in system pressure (6). If chemical reaction of neighboring adsorbed species is the controlling mechanism at this same higher pressure, the deposition rate at a fixed ratio of reactant concentrations would

be pressure dependent while for a fixed value of pressure the deposition rate as a function of reactant concentrations should pass through a maximum.

To apply this means of analysis to the vapor deposition of tungsten by the hydrogen reduction of WF_6, experimentally determined deposition rates were plotted as a function of pressure for two combinations of reactant concentration ratios and temperature (Fig. 3). The observed strong dependence of reaction rate on pressure at very low pressures (less than 6 Torr) suggests adsorption control in this region. In the pressure range of interest in this work (6-60 Torr) reaction rate is essentially independent of pressure in the lower portion of the range. This suggests that desorption is the rate-controlling mechanism there. The low activation energy for HF desorption in comparison to that for F_2 desorption (2) suggests the former molecule to be important for this mechanism of rate control. The critical tests for chemical reaction control suggested above failed to identify this mechanism as rate controlling in this pressure-temperature region. It is reasonable to assume that for the higher pressures gas phase diffusion is the rate-limiting process (7, 8) and, since it is the least mobile molecule, WF_6 is the species of interest.

The validity of the two rate-controlling mechanisms (WF_6 diffusion and HF desorption) and their respective pressure-temperature region of dominance were ascertained by comparing experimentally determined deposition rates with rates predicted from models of each mechanism.

Following the analysis of Haskell (2), a model for HF desorption was formulated based on the equation

$$H_{(x)} + F_{(x)} = HF_{(g)} \qquad [4]$$

where the subscript x denotes atoms attached to sites on the substrate. Use was made of the postulate of absolute reaction rate theory that the reactants are in equilibrium with the activated complex $HF_{(x)}$ which decomposes to the product $HF_{(g)}$. The flux of HF from the substrate (which is proportional to the tungsten deposition rate) is the product of the concentration of surface sites occupied by the activated species and their frequency of vibration in a direction normal to the substrate surface. By combining all the constants and temperature-dependent terms into a single term, C_{des}, it was possible to express the deposition rate, R, in terms of the partial pressures of the reactants as follows

$$R_w = C_{des}\, p_{H_2}{}^{1/2}\, p_{WF_6}{}^{1/6} \qquad [5]$$

Partial pressure data from three temperatures (510°, 625°, and 705°C) were reduced to the appropriate values dictated by their fractional powers in Eq. [5]. Plots of actual deposition rates *vs.* $p_{H_2}{}^{1/2}\, p_{WF_6}{}^{1/6}$ are shown for each of the three temperatures in Fig. 4 through 6. Each data point, before being plotted, was

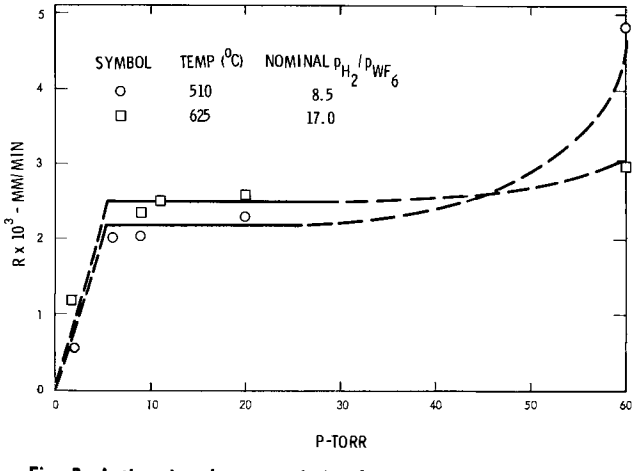

Fig. 3. Active-site theory analysis of tungsten deposition process

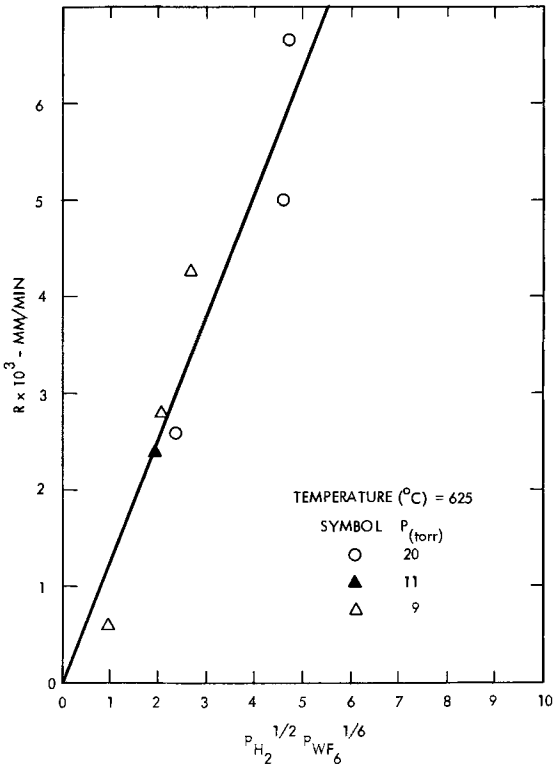

Fig. 5. Comparison at 625°C of experimentally observed deposition rates with rates predicted from the model for HF desorption.

first checked for agreement with the WF_6 transport model to be discussed subsequently. Only those points not fitting the latter model were used in this analysis. Good agreement between experimentally observed deposition behavior and that described by the model is indicated by each figure. To obtain a meaningful value for the activation energy of the HF desorption Arrhenius plots were made at constant values of concentration (constant $p_{H_2}{}^{1/2}\, p_{WF_6}{}^{1/6}$). From these plots (Fig. 7) an activation energy of 7300 cal/mole was obtained.

The data which did not fit the desorption model were generally from the higher pressure trials. It was reasonable to assume, therefore, that gas-phase diffusion was the rate-limiting step in the process for the

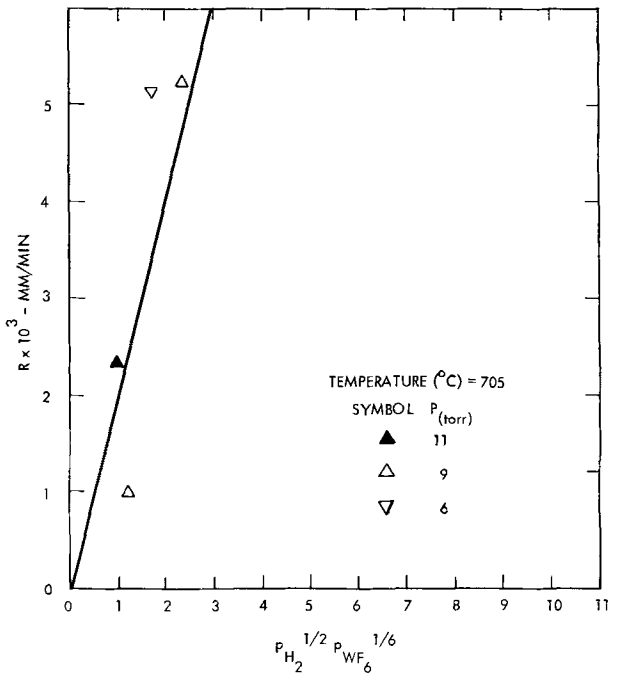

Fig. 6. Comparison at 705°C of experimentally observed deposition rates with rates predicted from the model for HF desorption.

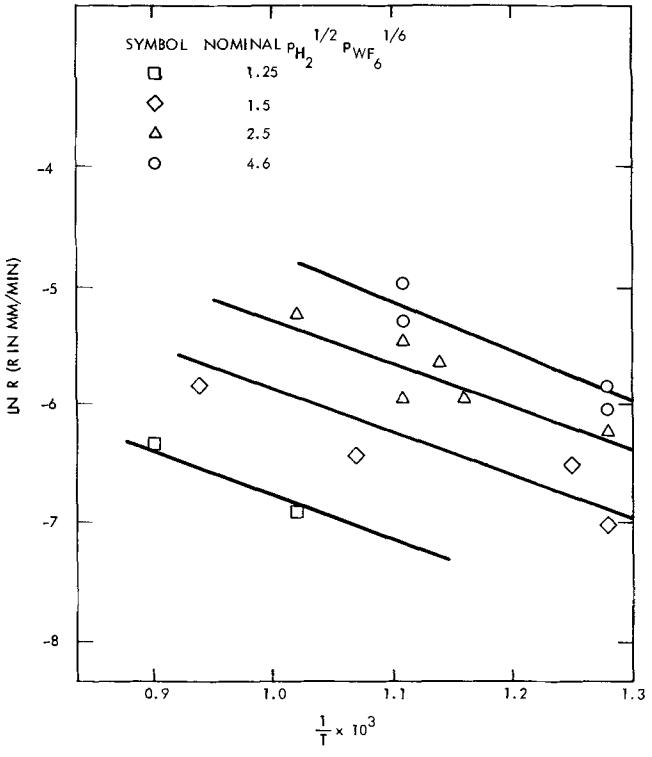

Fig. 7. Arrhenius plots for determination of activation energy for HF desorption.

experimental conditions associated with these data. WF_6 was assumed to be the diffusing species of interest because it is the heaviest and largest molecule in the system.

A model which considered nonequimolar counter-diffusion (8) was used. Thus, the diffusion-controlled deposition rate is given by the relation

$$R_w = k_1 k_g \Delta y \quad [6]$$

Here k_1 is a proportionality constant, k_g is a mass transfer coefficient, and Δy is the diffusion potential. Evaluation of these terms (described in the Appendix) led to the final relation

$$R = C_{diff}\, p_{WF_6}\, T^{1/2}/P \quad [7]$$

in which P is the total pressure and C_{diff} is the combined proportionality constant.

The experimentally determined deposition rates which were not described by the desorption model were plotted against corresponding values of $p_{WF_6} T^{1/2}/P$ (Fig. 8). The WF_6 diffusion model is seen to describe the rate data fairly well. Two minor deviations from model-predicted behavior are noted: the very low deposition rate data are not represented by the line of best fit nor does this line pass through the origin as it should.

Arrhenius plots at constant gas composition (represented by constant values of p_{WF_6}/P) yielded an activation energy of 1650 cal/mole for diffusion of WF_6 to the substrate surface (Fig. 9).

Discussion

The experimental results show that the kinetics of tungsten deposition by the reaction of WF_6 and hydrogen in the pressure and temperature ranges of 6-60 Torr and 500°-870°C, respectively, are well described by a model based on WF_6 transport to the substrate for high temperature-pressure combinations and by a model of HF desorption from the substrate at lower temperature-pressure combinations.

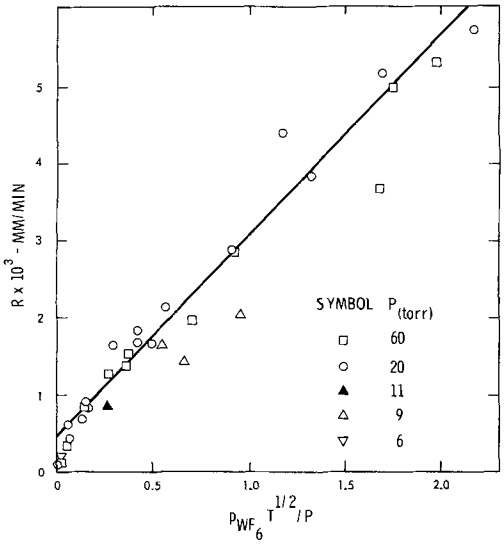

Fig. 8. Comparison of experimentally observed deposition rates with rates predicted from the model for WF_6 gas phase diffusion.

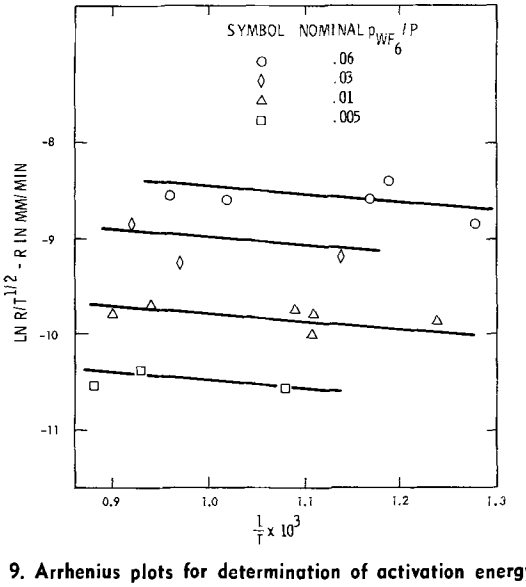

Fig. 9. Arrhenius plots for determination of activation energy for WF_6 gas phase diffusion.

The two regions of deposition control are separated by a boundary occurring at a pressure of approximately 20 Torr at 500°C and decreasing to approximately 6 Torr at 870°C.

HF desorption.—Tungsten deposition at the lower pressure-temperature combinations within the ranges studied is controlled by the rate of HF desorption from the substrate. This finding is in agreement with Haskell's analysis of the lower pressure-temperature data of Holman and Huegel for the same reaction. However, the latter investigators have calculated an activation energy of 16,000 cal/mole for the process as compared to the 7300 cal/mole found in the present study. At least part of this discrepancy is due to the manner in which Holman and Huegel plotted their rate data. They chose to plot the logarithm of the deposition rate as a function of the reciprocal of the absolute temperature in order to obtain the activation energy. This procedure is strictly correct only where the reactant concentration terms in the rate equation are constant. That this condition was obtained in their work is very doubtful. Their rate equation

$$R_m = C \exp(-16{,}000/RT) P^{1/2} \quad [8]$$

contains only one concentration related term, $P^{1/2}$. (The concentration of a single gas in a mixture of gases is given by the ideal gas law as $N/V = p/kT$ where N is the number of molecules and V is the volume.) Such an expression would be expected to be a reasonable approximation only where the gas phase is predominantly comprised of a single species. Thus, only for the conditions of high initial H_2/WF_6 ratio and low reaction temperature would this expression be reasonable and the activation energy value obtained therefrom be meaningful.

Several calculations were made to determine the magnitude of the adjustment to Holman and Huegel's gas compositions necessary to bring their value for activation energy in line with that found in the present work. The required fractional depletions of WF_6 necessary to effect this adjustment are greatly in excess of any value which would be considered reasonable in view of Holman and Huegel's experimental setup. Therefore, the difference in values for activation energy can only be partially explained by Holman and Huegel's not correcting their gas composition by allowing for WF_6 depletion.

Consideration was given to the possibility that the difference in activation energy was attributable to differences in experimental conditions, namely, deposition efficiency and temperature of the deposition gases. In the present work, the efficiency was very high, and the gas temperature was likely high owing to a relatively long period of contact with the hot substrate. In Holman and Huegel's setup both efficiency and gas temperature would necessarily be low.

To examine this effect further the deposition data of Shroff (10) were evaluated and compared (Fig. 10) to that of the investigations already discussed. Since Shroff employed a WF_6 flow of only 50 cc/min, the efficiency of his system would be expected to be high. However, judging from a description of his experimental setup (11), it would also be expected that the gases would be only moderately heated by the substrate. Thus, it could be considered that Shroff's experimental conditions were approximately intermediate to those of the other two investigations. Since the Shroff deposition rates were generally of intermediate value for fixed deposition parameters of temperature and $p_{H_2}^{1/2} p_{WF_6}^{1/6}$ product (Fig. 10) it would appear that experimental conditions do influence the rate of the deposition process. The activation energy of 10,000 cal/mole determined for the Shroff work further establishes this influence.

Based on the comparisons made here it seems reasonable to presume that the activation energy for the desorption-controlled deposition process is inversely related to the temperature of the deposition gas.

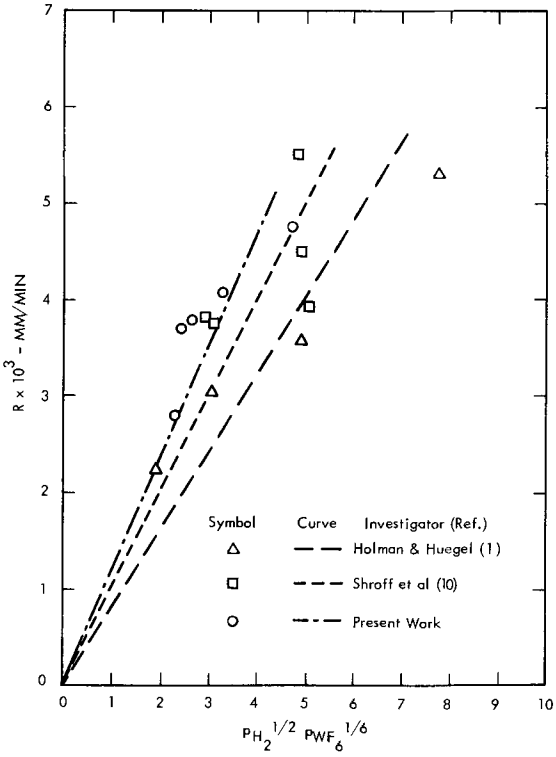

Fig. 10. Comparison of rate data at 600°C

Brecher's formulation of a model of sorption-surface reaction rate control produced the rate expression for tungsten deposition

$$R_w = k_r X_{WF_6} X_{H_2}^3 \quad [9]$$

where X is the mole fraction of the reactant at the substrate and k_r is the reaction rate constant given by

$$k_r = AP^2 \exp(-B/T) \quad [10]$$

The dependence of k_r on P^2 is not well established. This relation was obtained from rate data taken at 100-760 Torr and at temperatures between approximately 480° and 820°C. It was shown in the present work, however, that in this pressure-temperature regime sorption-surface reactions are not rate controlling. Instead, for these conditions, deposition is likely controlled (at low mole fractions of WF_6 at least) by WF_6 diffusion to the substrate or near the upper limit of pressure, even possibly by convection transport. The activation energy for Brecher's unspecified sorption-surface reaction (27,000 cal/mole) is therefore not easily interpreted.

WF_6 transport model.—From Fig. 8 it is noted that the data are not all represented by a straight line passing through the origin as required by the expression for deposition controlled by WF_6 transport (Eq. [7]). Two minor deviations from the behavior predicted by the model are responsible. In the formation of the model it was assumed that the diffusion coefficient was proportional to $T^{3/2}$ in agreement with kinetic theory for gases. It has been shown in actuality, however, that a $T^{7/4}$ dependence is more realistic (12). Use of this latter value yields a corrected rate equation given by

$$R_w = C_{diff} p_{WF_6} T^{0.55}/P \quad [11]$$

This correction offsets the data plot of Fig. 8 sufficiently to permit its passage through the origin.

The second deviation from predicted behavior is constituted by the failure of the measured rates corresponding to very low $p_{WF_6}T^{1/2}/P$ values to equal those predicted by the model. The one feature common to each of these deviant data points is the very low associated values of p_{WF_6} and p_{HF}. Thus at low R_W values the presence of hydrogen cannot be ignored as it was

in the formulation of the WF_6 transport model since in this region the rate of WF_6 diffusion through hydrogen rather than through HF is controlling.

The activation energy for WF_6 transport in this system has not been previously determined. The value of 1650 cal/mole obtained in the present work is reasonable since gas-phase diffusion is generally associated with very low activation energies.

It is interesting to note that WF_6 diffusion controlled the deposition kinetics for the higher pressure-temperature combinations. This result is in disagreement with that of Holman and Huegel (1) who, for the same pressure-temperature regime, attributed control of the deposition rate to the same surface reaction that they found controlling at lower pressure-temperature combinations. In their work an inadequate supply of reactants was offered as the cause of the difference in deposition rate dependence on temperature on going from the lower pressure-temperature regime to the higher.

Conclusions

It is concluded from the results of this work that two tungsten deposition rate-controlling mechanisms are operative in the pressure and temperature ranges usually associated with hydrogen reduction of WF_6. At the lower pressure-temperature conditions HF desorption is the controlling step in the process, while for higher pressure and temperature, WF_6 gas-phase diffusion is the rate-limiting mechanism.

APPENDIX

Formulation of Model for WF_6 Transport

If it is assumed in the system of gases WF_6-HF-H_2 that the hydrogen can be ignored (and such is the case as is shown subsequently in this development) the rate of tungsten deposition as a function of the nonequimolar counterdiffusion of WF_6 and HF to and from the substrate is given by the relation

$$R_w = k_1 k_g \Delta y \qquad [A\text{-}1]$$

where k_1 is a proportionality constant, k_g is a mass transfer coefficient, and Δy is the diffusion potential.

The diffusion potential (determined from the Stefan-Maxwell equations) for WF_6 transport in this system is given by (9)

$$\Delta y = \frac{1}{1-x} \ln \frac{1-(1-x)X_{s1}}{1-(1-x)X_{g1}} \qquad [A\text{-}2]$$

where x is the ratio of molar flow to the substrate to the molar flow away from the substrate (taken to equal 1/6 from the stoichiometry of the deposition reaction) and X_{g1} and X_{s1} are, respectively, the mole fractions of WF_6 in the gas stream and at the substrate surface. With the assumption of negligible WF_6 at the substrate (owing to the greater rate of the surface reaction as compared to the rate of WF_6 transport) and substitution of the value 1/6 for X, Δy can be expressed as

$$\Delta y = \frac{6}{5} \ln \frac{1}{1-5/6X_{g1}} \qquad [A\text{-}3]$$

For the small X_{g1} values investigated ($X_{g1} \leq 0.13$), Eq. [A-3] can be rewritten within an error of 1% as

$$\Delta y \approx -\frac{6}{5} \ln (1-5/6X_{g1}) \qquad [A\text{-}4]$$

Substitution of p_{WF_6}/P for X_{g1} and again utilizing the fact that only small molar fractions of WF_6 are being considered permits the diffusion potential to be written as

$$\Delta y = X_{g1} = p_{WF_6}/P \qquad [A\text{-}5]$$

The mass transport coefficient is given by

$$k_g = D_{12}P/ZRT \qquad [A\text{-}6]$$

where Z is a geometric constant and D_{12} is taken to be the concentration dependent diffusivity of the pair WF_6-HF in the WF_6-HF-H_2 mixture. Recalling the assumption that the hydrogen can be ignored in this particular case and assigning the subscript 3 to this gas permits D_{12} to be expressed as follows (13)

$$D_{12} = \mathcal{D}_{12}\left\{1 + \frac{X_3\left[\frac{M_3}{M_2}\mathcal{D}_{13} - \mathcal{D}_{12}\right]}{X_1\mathcal{D}_{23} + X_2\mathcal{D}_{13} + X_3\mathcal{D}_{12}}\right\} \qquad [A\text{-}7]$$

Here X_i and M_i are the mole fraction and molecular weight of species i, respectively, and $\mathcal{D}_{ij}$ is the binary diffusivity in the system i-j and is virtually independent of composition.

$\mathcal{D}_{ij}$ values were calculated from Bird's expression

$$\mathcal{D}_{ij} = 0.0018583 \frac{\sqrt{T_3\left(\frac{1}{M_i} + \frac{1}{M_j}\right)}}{P\sigma_{ij}^2 \Omega_{\mathcal{D}_{ij}}} \qquad [A\text{-}8]$$

Maximum and minimum values for the dimensionless parameter $\Omega_{\mathcal{D}_{ij}}$ were calculated for the range of temperatures covered in this investigation and found to be 1.01 and 0.92, respectively. Thus in the calculation of $\mathcal{D}_{ij}$ values it was reasonable to take $\Omega_{\mathcal{D}_{ij}}$ equal to unity. The other Lennard-Jones parameter appearing in Eq. [A-8], σ_{ij}, can be considered to be a collision diameter equal to $\frac{1}{2}(\sigma_i + \sigma_j)$. Calculations of these collision diameters and the subsequent evaluation of each $\mathcal{D}_{ij}$ value permitted the reduction of Eq. [A-7] to the form

$$D_{12} = \mathcal{D}_{12}\left\{1 - \frac{1.11X_3}{8.51X_1 + 7.28X_2 + 1.84X_3}\right\} \qquad [A\text{-}9]$$

Since the composition of the gas mixture is given by the chemical reaction (where Φ is the fractional amount of WF_6 reacted) as

$$(1-\Phi)p_{WF_6} + (6.7 - 3\Phi)p_{H_2} + (6\Phi)p_{HF} = (7.7 + 2\Phi)P \qquad [A\text{-}10]$$

and the condition

$$X_1 + X_2 + X_3 = 1 \qquad [A\text{-}11]$$

must be satisfied, D_{12} can be written solely as a function of $\mathcal{D}_{12}$ and Φ.

In the current study the value of Φ ranged from 0.42 to essentially 1.0 to give a corresponding range of D_{12} values of $0.818\mathcal{D}_{12}$ to $0.918\mathcal{D}_{12}$. Thus over the range of gas compositions studied D_{12} is essentially a fixed fraction of $\mathcal{D}_{12}$ (taken to be $0.868\mathcal{D}_{12}$) and thus the earlier assumption that the hydrogen can be ignored is supported. That such an assumption would be invalid over all possible gas compositions (represented by Φ varying in value from zero to 1.0) is shown by the corresponding calculated values of D_{12} of $0.643\mathcal{D}_{12}$ to $0.918\mathcal{D}_{12}$.

Using the relation

$$D_{12} = 0.868\mathcal{D}_{12} \qquad [A\text{-}12]$$

the diffusivity of WF_6 in the system (D_{WF_6}) can be written as

$$D_{WF_6} = D_{12} = 0.868(1.84 \times 10^{-5})T^{3/2}/P \qquad [A\text{-}13]$$

Further substitution into [A-6] yields for the mass transport coefficient

$$k_g = \frac{0.868(1.84 \times 10^{-5})T^{1/2}}{ZR} \qquad [A\text{-}14]$$

Substitution of [A-14] and [A-5] into [A-1] combined with a consolidation of constants into C_{diff} yields the final relation for the WF_6 diffusion limited deposition rate

$$R_w = C_{diff} p_{WF_6} T^{1/2}/P \qquad [A\text{-}15]$$

SYMBOLS

R_m	tungsten deposition rate (maximum), mm/min
R_w	tungsten deposition rate, mm/min
p	partial pressure, Torr
D	concentration dependent diffusion coefficient for gaseous pair, cm^2/sec
T	absolute temperature, °K

P	total pressure of system, Torr
N	number of molecules
V	volume, cc
k	Boltzmann's constant
k_r	reaction rate constant
X	mole fraction
n	number of particles per unit volume, liter^{-1}
S_d	average particle cross section, mm^2
M	molecular weight, g/mole
N_o	Avogadro's number
R	gas constant, cal/mole °K
k_g	mass transfer coefficient, g/sec cm^2
Δy	diffusion potential, (dimensionless)
Z	characteristic dimension of system, cm
Φ	fractional amount of WF_6 reacted, (dimensionless)
$\mathcal{D}$	binary diffusivity (concentration independent), cm^2/sec
σ	Lennard-Jones parameter (collision diameter), cm
$\Omega_{\mathcal{D}}$	Lennard-Jones parameter, (dimensionless)
x	ratio of molar flow to substrate to molar flow from substrate
X_{g1}	mole fraction of WF_6 in the gas stream
X_{s1}	mole fraction of WF_6 at substrate surface
A, B, C	constants
k_1, k_2, k_3	constants

Subscripts

g	gas phase
s	solid phase
x	substrate site attached species
des	desorption
diff	diffusion

ABSTRACT

In OH^- "free" NaCl:Cd system the isothermal time evolution of the solution process of I.V. (impurity-vacancy) dipoles to achieve the thermodynamical equilibrium was studied by means of the I.T.C. (ionic thermoconductivity) method in the annealing temperature range from 323° to 423°K. Two stages were found, both described by a monomolecular first order kinetics. The early fast stage and the subsequent slow one are characterized by activation energies of $\epsilon_1 \sim 1$ eV and $\epsilon_2 \sim 0.8$ eV, comparable with the activation energy for impurity diffusion, and pre-exponential frequency factors $\nu_{01} \sim 6 \times 10^{11}$ and $\nu_{02} \sim 3 \times 10^6$ sec^{-1}. The sources of I.V. dipoles in the two stages were tentatively identified with dipolar precipitates responsible for the additional peaks in I.T.C. spectrum. The energy required to decompose one kind of the above microprecipitates $\epsilon_B^S \sim 0.24$ eV is close to the solution energy of I.V. dipoles. The role of preannealing on thermodynamical equilibrium value n_s and on the solution kinetics was also analyzed.

Recent precipitation and solubility measurements (1-8) show that the knowledge of the aggregation state of divalent cation impurities in alkali halides is preliminary to both optical and electrical studies. Information about precipitation phenomena is still restricted and sometimes contradictory (1-6), chiefly with regard to the nature of the first precipitation products. The occurrence of an initial stage of dimerization (4) of I.V. (impurity-cation vacancy) dipoles

[1] On leave from Instituto de Fisica da Universidade de S.Paulo and Instituto de Energia Atômica, S.Paulo, Brazil.

Key words: alkali halides, solution of impurities, dielectric properties, dissolution kinetics.

was recently discussed by Crawford (9, 10) and Wintle (11): the latter has shown that a diffusion-controlled dimerization reaction can simulate the third order kinetics, experimentally detected by many authors by means of various techniques in different alkali halide systems (1-6, 10). Precipitation of divalent impurities out of the solid solution is accompanied by the growth, in addition to microprecipitates, of larger aggregates of metastable phases and stable segregated ones, which were detected by means of x-ray diffraction (12), electron microscopy (13), and Mössbauer spectroscopy (14).

On the other hand the solution of the impurities can supply a complementary view on the nature of the precipitates. The study of the thermodynamical equilibrium (8, 15) concentration of I.V. dipoles *vs.* temperature gave considerably lower solution activation energies for I.V. dipoles of the order of 0.1-0.2 eV in various systems. Moreover it was shown that the thermodynamical equilibrium value is reached quite slowly even at rather high annealing temperatures.

In our opinion a detailed analysis of the isothermal time evolution of I.V. dipole concentration in the solution process can throw light both on the dynamics of the solution reaction and on the nature of I.V. dipole sources. Moreover additional information can be gathered from the solution kinetics by affecting the nature and distribution of the early precipitates by submitting the sample to suitable preannealing.

To monitor the I.V. dipole concentration we employed the ionic thermoconductivity method (16) which, due to its high sensitivity, allows the detection of relaxation peaks associated with even low concentration of dipolar microprecipitates. Moreover I.T.C. runs are performed at temperatures below 273°K so that the point defects situation determined by annealing at higher temperatures can be frozen in. We chose NaCl:Cd system because precipitation measurements (4) suggested that defect mobility is high, so the thermodynamical equilibrium concentration can be achieved in a reasonably short time.

Experimental Procedures

The samples were grown in our laboratory by means of the Kyropoulos method in controlled atmosphere (dry nitrogen) in order to minimize contamination by OH^-, H_2O, and oxygen (17), which are present in air and affect solubility and precipitation phenomena (18). Cadmium dichloride salt was added to the molten NaCl in percentages ranging from 10^{-4} to 10^{-2} by weight.

In order to get samples with very low OH^- concentration ($<10^{14}/cm^3$), the starting powders were submitted to a suitable procedure. An alternative treatment with Cl_2 followed by HCl (at the pressure of ~250 mm Hg) is very efficient in eliminating OH^-, O^{--}, Br^-, and I^- if the gases react in the powdered salt at about 700°C, *i.e.*, about 100°C below the melting point of NaCl (19, 20).

The I.T.C. measurements were performed by the usual technique (16). The crystal slab (area: 2-3 cm^2, thickness: 0.5-1 mm) was polarized in a static electric field (ranging from 10^4 to 3×10^4 V/cm) for 3 min at the temperature T_p and then cooled down to the temperature T_f, generally 120°K; after which the field was switched off. During these steps the dipoles become polarized at saturation and remain orientated in the same configuration obtained at the polarization temperature, because at low temperature the relaxation time is practically infinite. The crystal was then warmed up at the nearly constant rate of 0.1°K/sec: the dipole relaxation time for orientation gets shorter and the dipoles lose their preferred orientation giving rise to a depolarization current. This was detected at linearly increasing temperature by a vibrating reed electrometer (Cary 31V) and recorded by Speedomax. The apparatus can measure currents as low as 10^{-16}A.

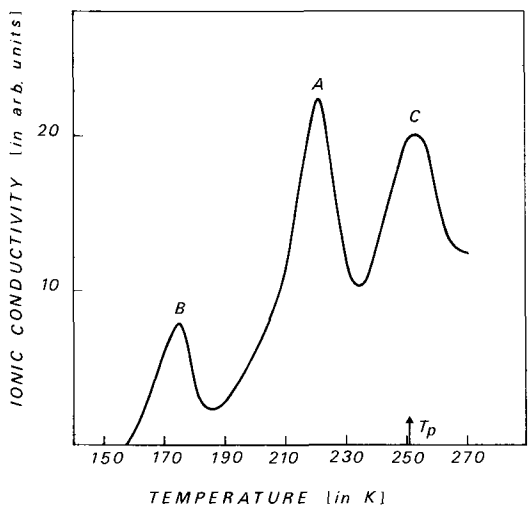

Fig. 1. Ionic thermocurrent of NaCl:Cd (OH^- free): the polarization temperature is indicated by an arrow.

The procedure followed in order to obtain solubility and precipitation curves is described in detail in a previous paper (8).

The aging of samples at temperatures below 530°K was performed directly in the measuring cryostat; in order to "quench" the sample the cryostat was filled with dry N_2 and cooled down to 273°K in a time shorter than 4 min.

Two cryostats with different performances were employed: the former, with vertical identical shaped aluminum electrodes assured the minimum temperature gradient through the sample; in the latter, with horizontal gold electrodes, the top one can be put in contact with liquid nitrogen in order to get a very fast quenching of the sample. The electrical contact between sample and electrodes was improved with colloidal graphite. The reproducibility of measurements was within 2%.

Results

The ionic thermoconductivity curve for a sample of NaCl:Cd "chlorinated" as described above, and polarized at $T_p = 252$°K shows three principal peaks at 174°, 220°, and 250°K. The activation energies for orientation of the dipole responsible for the three peaks are 0.4, 0.67 (16), and 0.62 eV. The peak at 220°K (peak A) is due to I.V. dipole relaxation, the peak at 174° (peak B) is related to microprecipitates, and that at 250°K (peak C) was usually detected in samples with very high Cd concentration (8). The curve in Fig. 1 corresponds to the I.T.C. of a sample "as received," *i.e.*, after aging for a long time at room temperature. The isothermal time evolution of I.V. dipole concentration to achieve the thermodynamical equilibrium value was studied by measuring the I.V. dipole concentration[2] as a function of the aging time at a given temperature, until a saturation is reached.

The isothermal time evolutions of I.V. dipoles were studied for annealing temperatures T_a: 323°, 331°, 340°, 346°, 353°, 364°, 374°, 390°, 405°, and 423°K. In Fig. 2 are shown the solubility curves at $T_a = 353$°K for peak A (curve 1) and for peak B (curve 2) in a sample aged only at temperatures lower than 346°K. Solubility curves always at $T_a = 353$°K for peak A (curve 3) and peak B (curve 4) are related to the same sample but annealed at room temperature after obtaining curves 1 and 2. Figure 2 exemplifies the behavior of solubility curves in the annealing temperature range between 323° and 374°K both for first and second run. It must be pointed out that the higher the annealing temperature T_a, the faster the saturation value was achieved. A change in the solubility curve behavior

[2] The concentration can be evaluated from the area under dipole peak or from the height if the warming rate during I.T.C. measurements is held constant (8).

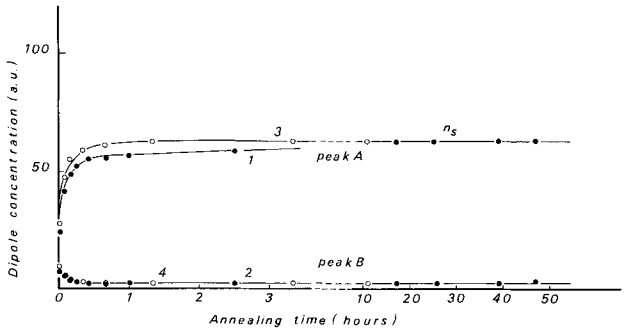

Fig. 2. Solubility curves at T_a = 353°K. Intensity of peak A (curve 1) and peak B (curve 2) vs. annealing time in a sample aged only at temperatures lower than 346°K (first run). Curve 3 and 4, the same as above, but related to same sample annealed at R.T. after getting curves 1 and 2 (second run).

occurred between 374° and 390°K, as can be observed in Fig. 3, where the I.V. dipole concentration normalized to the saturation value at each T_a *vs.* annealing time are compared for T_a = 364°, 374°, and 390°K, respectively curves a, b, and c. On going from 374° to 390°K the solubility process was slowed down and the saturation value was attained in a longer time. Starting from T_a = 390°K the rate of solution became again faster by increasing the annealing temperature.

The isothermal time evolution of the solution process was strongly affected by the "thermal history" of the sample. In Fig. 4 are shown the precipitation and solubility curves at T_a = 331°K. Curve a shows the precipitation of I.V. dipoles after quenching from T_q = 470°K; curve b, the solubility after quenching from T_q = 470°K followed by a precipitation at room temperature; curve c (open circles), the solubility of a sample annealed at room temperature after obtaining curve a; curve c (full circles), the solubility of a sample annealed previously at the same T_a and left at room temperature. Both curves a and c show a monotonic decrease and increase, respectively, to the saturation value n_s, while curve b shows an initial overshoot followed by a smooth decrease to n_s.

From Fig. 2 and 4 it turns out that the same saturation value n_s at a given T_a is obtained independently of the previous "thermal history" of the sample.

The results reported above were checked on different samples.

Discussion

Influence of preannealing on the solution reaction.— The experimental results show that the solution process at a given T_a is a complex one depending on the

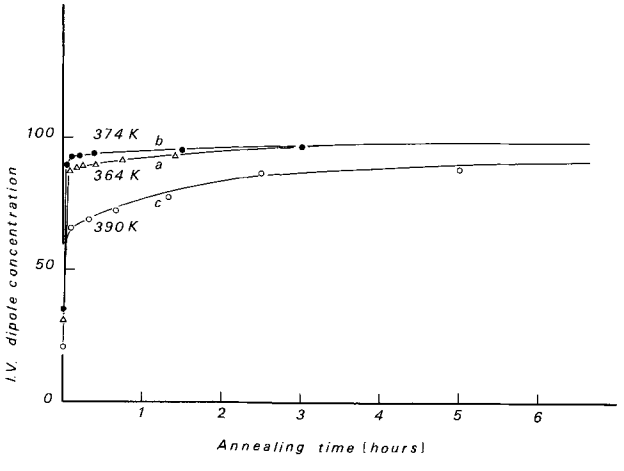

Fig. 3. Solubility curves (first run) at different annealing temperatures T_a for I.V. dipoles (peak A). The dipole concentration was normalized to the saturation value at each annealing temperature. Curve a: T_a = 364°K, curve b: T_a = 374°K, and curve c: T_a = 390°K.

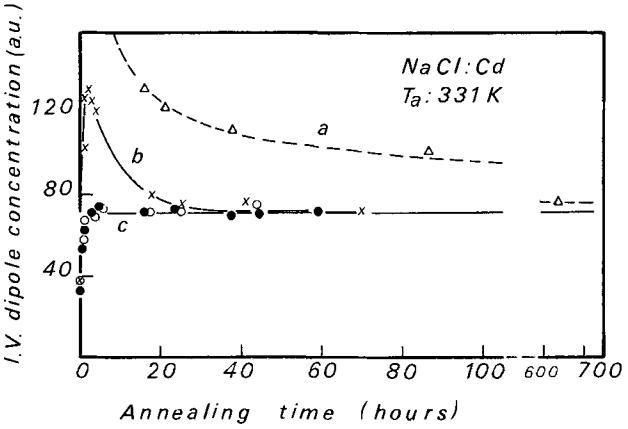

Fig. 4. Precipitation and solubility curves for I.V. dipoles at T_p = 331°K. Curve a: precipitation, after quenching from T_q = 470°K (only a part of curve is drawn for the sake of convenience; the ordinate at t = 0 is ~1200; curve b: solubility after quenching from T_q = 470°K followed by precipitation at R.T.; and curve c: (open circles) solubility of the sample annealed at R.T. after getting curve a; (full circles) solubility of the sample annealed at R.T. after getting curve c (open circles).

thermal history of the sample, even if the saturation value n_s is the same, as one would expect for thermodynamical equilibrium situation. As shown in Fig. 2 the I.V. dipole concentration grows monotonically with the annealing time while dipoles responsible for the small peak B decrease to a saturation value in both runs. This behavior supports that peak B must be related to precipitates, whose dissolution contributes to the I.V. dipole growth. The saturation value of I.V. dipole concentration is reached more quickly in the second annealing, for instance, at T_a = 353°K the saturation is obtained after ~15 hr and after 1½ hr in the first and second runs, respectively, further runs show practically the same features as the second one. The disparity between the first and second run in the early stage of the solution reaction can be explained by different kinds and distribution of the precipitates in the sample, due to different preannealing. In fact at the beginning of the second run (also at higher T_a) the concentration of B dipoles is always higher than that at the beginning of the first run.

The role of preannealing is still more evident in Fig. 4, where the overshoot which appears in curve b can be interpreted as follows: during the annealing at room temperature after quenching from T_q, the thermodynamical equilibrium among I.V. dipoles and microprecipitates is not yet achieved, due to the low mobility of defects. The latter ones are in excess with respect to the thermodynamical equilibrium, so the subsequent annealing at T_a > room temperature breaks readily the microprecipitates to give I.V. dipoles in concentration higher than n_s at T_a; n_s is then reached by precipitation of I.V. dipole excess. Moreover it is noteworthy that n_s is reached more quickly by solution process than by precipitation from supersaturated solution (curves a and c) even if the early stage of precipitation is extremely fast.

Analysis of solubility curves.—As reported in a previous work (18) dissolution of I.V. dipoles to reach thermodynamical equilibrium value n_s in KBr:Sr at relatively high temperature (334°K) takes long annealing times (~100 hr) and can be described by the simple law

$$n = n_o + (n_s - n_o)\,[1 - \exp(-t/\tau)] \qquad [1]$$

where n, n_o are the actual and initial I.V. dipole concentration, t is the time, and τ the time constant. A logarithmic plot *vs.* annealing time t of $n_s - n$ obtained from our solubility data at T_a ranging from 346° to 423°K does not show a behavior as simple as that predicted by [1]. Curve a of Fig. 5 exemplifies the

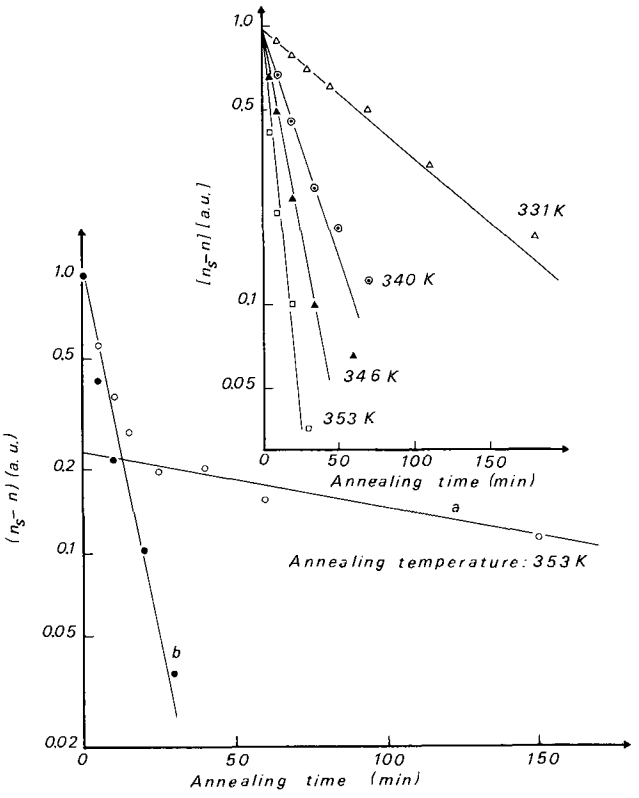

Fig. 5. Logarithmic plot vs. annealing time of $n_s - n$ at T_a = 353°K: open circles, first run; full circles, second run. The inset gives the logarithmic plot vs. annealing time at various T_a (second run).

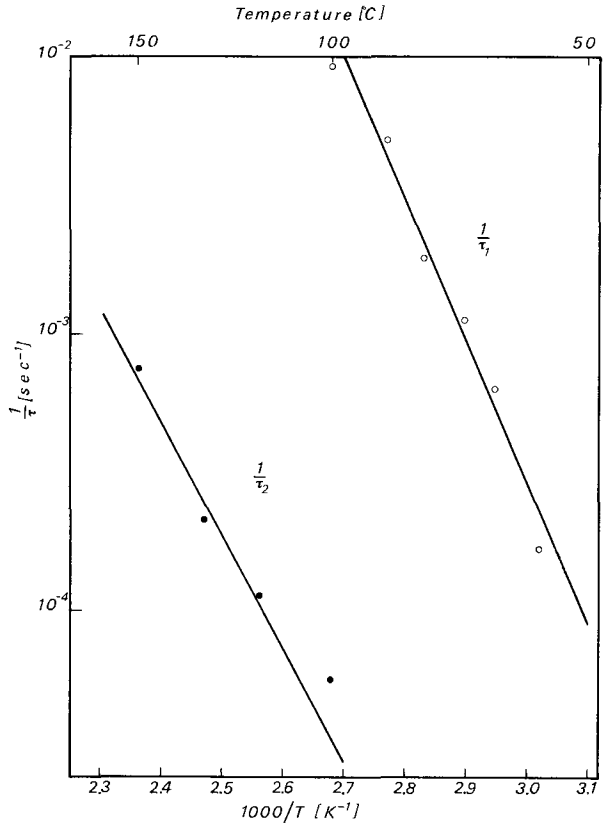

Fig. 6. Arrhenius plot of the reciprocal of time constants τ_1 and τ_2 vs. 1000/T.

solution reaction (first run) in our NaCl:Cd at T_a = 353°K. Two straight lines instead of one alone fit the experimental data well enough. The solution reaction appears more complex, with a "fast" early stage followed by a slower one. Hence the experimental results suggest that solubility reaction is better described by introducing two time constants τ_1 and τ_2 for the "fast" and "slow" stages, respectively. The second run data always at 353°K, reported for comparison in Fig. 5 (curve b) show surprisingly that the early "fast" stage predominates and now the reaction appears to follow closely the simple equation [1]. The inset in Fig. 5 shows the logarithmic plot at various T_a, for second run solubility data. The occurrence mainly of a "fast" stage in the second run can be explained by the presence of small microprecipitates. These, grown during the former annealing at T_a and subsequent precipitation at room temperature, are easily and rapidly broken during the latter annealing at T_a. The "slow" stage can be attributed to the slow dissolution of "hard" and larger microprecipitates. Hence the whole isothermal time evolution of I.V. dipoles is assumed to be governed by the following monomolecular kinetics combination

$$n_s - n = A_1(n_s - n_0)\exp(-t/\tau_1) + A_2(n_s - n_0)\exp(-t/\tau_2) \quad [2]$$

where $A_1 + A_2 = 1$, A_1 and A_2 are the statistical weights of the "fast" and "slow" stages, respectively. Moreover A_1 and A_2 can be related to the concentration of different kinds of microprecipitates: the easily and the hardly soluble ones. It is worthwhile noticing that the drastic change in the solubility curves between 374° and 390°K in Fig. 3, can be interpreted as follows: at 390°K the fast stage contributes at comparatively lower extent to the solution reaction, while the slow stage fractional contribution increases. This effect will be better understood in the light of different kinds of precipitates, discussed in the section on Microprecipitates and thermodynamical equilibrium.

τ_1 and τ_2 characteristics.—From Fig. 5 it turns out that the information about τ_1 and τ_2 can be more conveniently obtained utilizing data from second and first runs, respectively. The values of $1/\tau_1$ and $1/\tau_2$ are then reported in the Arrhenius plot shown in Fig. 6: activation energy $\epsilon_1 \sim 1$ eV and $\epsilon_2 \sim 0.8$ eV and pre-exponential factor $\nu_{01} \equiv (\tau_{01})^{-1} \sim 6 \times 10^{11}$ sec^{-1} and $\nu_{02} \equiv (\tau_{01})^{-1} \sim 3 \times 10^6$ sec^{-1} are evaluated for the first and second stage, respectively. The activation energy values are comparable with $\epsilon_d = 0.92$ eV, the activation energy for diffusion, *i.e.*, the exchange energy (21), chiefly if one takes into account that the data for the ϵ_2 calculation are not precise enough.[3] Therefore one can assume that the solution process is ruled by diffusion of impurity-vacancy dipole far from the precipitates in a similar way as that proposed by Wintle (11) for the precipitation reaction in a supersaturated solid solution. An appreciable insight on the nature of precipitates is pursued by comparing ν_{01} and ν_{02}. The rather high value of ν_{01} permits the assumption that only a few atomic jumps are required to release the I.V. dipole from the parent microprecipitate, and to give it the reorientability necessary to be monitored by I.T.C. technique. On the other hand ν_{02} is at least five orders of magnitude lower than ν_{01}, indicating that a convenient sequence of events able to liberate the I.V. dipole occurs with a very low probability and requires a very large number of atomic jumps. These results are consistent with the assumption that the solution stage characterized by τ_1 involves the break-up of simple I.V. clusters, so the free dipoles can escape easily enough. The extremely long sequence of atomic jumps which precedes the solution of a I.V. dipole in the stage described by τ_2 can be accounted for if large and "hard" precipitates are the only I.V. dipole sources still present. Geometrical and correlation factors can play a very important role in determining the most favorable jump sequence.

[3] It must be outlined that in the temperature range 346°-364°K the values obtained for τ_2 do not show a definite temperature dependence, possibly due to a mixing of different processes.

Microprecipitates and thermodynamical equilibrium. —The study of thermodynamical equilibrium concentration of dipoles responsible for peak A, B, and C *vs.* annealing temperature can throw light on the nature of microprecipitates involved in the solution process. In Fig. 7 the logarithmic plot of the saturation value of peak B is reported *vs.* $1000/T_a$ as obtained from the present work; for comparison the similar plot for peak A (I.V. dipoles) and peak C are drawn from Ref. (8). The behavior of peak A was also checked by using the present data. Moreover the temperature ranges where τ_1 and τ_2 were more conveniently measured, are indicated. In thermodynamical equilibrium, the dipoles responsible for peak B decrease with increasing temperature, further supporting the assumption that they are microprecipitates and I.V. dipole contributors. At annealing temperatures higher than 375°K the B dipole contribution becomes negligible. Peak C after a moderate growth till 365°K shows a sharp decrease in temperature range between 365° and 415°K. It is worthwhile noticing that in the temperature ranges where τ_1 and τ_2 were more conveniently studied, there occurs the decrease of peak B and C, respectively. This coincidence strongly supports that B and C dipoles are the principal sources of I.V. dipoles during the fast and slow stages, respectively. In the section on Results it was pointed out that on raising the annealing temperature from 374° to 390°K the solution process is slowed down: this can be understood by considering that decomposition of B dipoles contributes to I.V. dipole solution for a smaller fraction, and the thermodynamical equilibrium concentration n_s can be achieved only by the slow dissolution of the hard microprecipitates. From the straight line of Fig. 7 an activation energy of 0.24 eV is obtained for the B dipoles dissolution, which is quite close to the I.V. dipole solution energy $\epsilon_s^{I.V.} = 0.235$ eV (8).

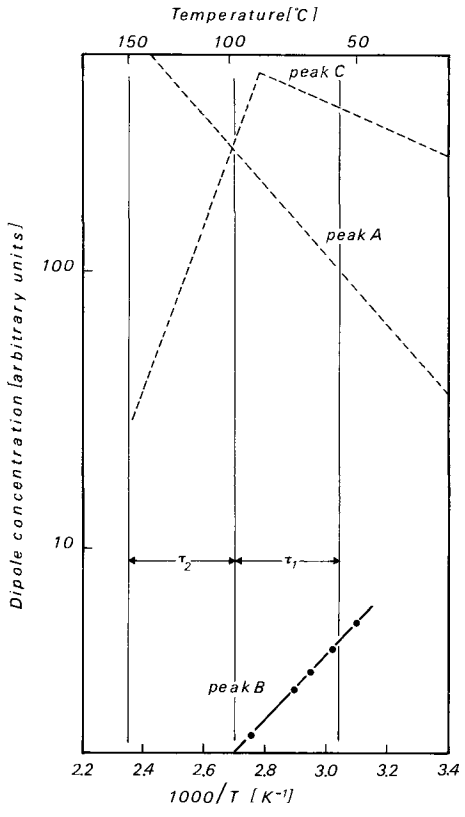

Fig. 7. Arrhenius plot of the thermodynamical equilibrium concentration of A(I.V.), B, and C dipoles *vs.* 1000/T. The dotted lines are taken from Ref. (8). The temperature ranges, where the time constants τ_1 and τ_2 were measured more conveniently, are indicated.

Conclusions

The accurate analysis of the time evolution of I.V. dipole concentration to achieve the thermodynamical equilibrium value has shown that:

1. The saturation value does not depend on the previous thermal history of the sample, as thermodynamical equilibrium requires.
2. The saturation value is reached more readily if the solution process is preceded by a proper preannealing which breaks the hard precipitates and allows the growth of the simpler ones.
3. At least two stages can be distinguished in the solution process: the early one is much faster than the subsequent one. Both can be separately described by a first order monomolecular kinetics, in which the time constants τ_1 and τ_2 are temperature dependent. The difference in activation energy for diffusion (21) is within 8 and 13% of the activation energies of our fast and slow stages, so the time evolution of the solution process is assumed to occur through a diffusion of I.V. dipoles from precipitates, in fact the energy to release an I.V. dipole from precipitates, *i.e.*, $\epsilon_s^{I.V.}$ turns out to be considerably less (0.235 eV) (8). Both the relatively high diffusion energy and the pre-exponential factors of τ_1 and chiefly of τ_2 explain why the solution reaction is so slow even at moderately high temperatures.

Moreover the study of thermodynamical equilibrium values *vs.* annealing temperature of dipoles responsible for peak B and C suggests that:

1. The growth of I.V. dipoles in the fast and in the slow stage can be related mainly to the decay of B and C dipolar precipitates.
2. The activation energy for the thermal decomposition of B dipoles is the same as the solution energy of I.V. dipoles (8) as expected if a single I.V. dipole is released from the dipolar microprecipitate B.

From the above results one has the general impression that the precipitation and dissolution of impurities in solids is a rather intricate phenomenon. In order to understand it, a careful and detailed study of its behavior is necessary avoiding schematic and oversimplified descriptions.

Galvanic Cell Studies Involving Calcium Carbide Solutions

D. R. Morris,*[1] C. Aksaranan,*[2] B. S. Waldron, and S. H. White[3]

Department of Chemical Engineering, University of New Brunswick, Fredericton, New Brunswick, Canada

ABSTRACT

The galvanic cell

$$Fe[C]_{(s)} \mid CaC_2,\ CaCl_{2(l)} \mid C_{(s)}$$

has been studied in detail in the temperature range 800°-1000°C using electrodes containing carbon at different activity levels. Calcium metal, the electroactive species, is present in the electrolyte by virtue of the heterogeneous equilibrium

$$CaC_{2(soln)} \rightleftharpoons Ca_{(soln)} + 2C_{(electrode\ or\ crucible)}$$

The electromotive force of an electrode couple is given to a precision of about 1% by the Nernst equation for the theoretical emf in terms of the ratio of calcium activities, and hence indirectly of the ratio of carbon activities, at the electrodes.

An electronic conduction model has been developed to describe the observed irreversible behavior. A time-independent electromotive force is achieved when an external current, equal to that predicted by the model, is imposed upon the cell.

In earlier work with the cell (1)

$$Fe[C]_{(s)} \mid CaC_2,\ CaCl_{2(l)} \mid C_{(s)} \qquad [I]$$

where [C] represents carbon in solid solution, the cell reaction was postulated to be

$$C_{(s)} \rightarrow [C] \qquad [1]$$

and the cell electromotive force to be given by

$$E_I = -\frac{RT}{F} \ln a_C \qquad [2]$$

However, possible problems with the cell were indicated by (*i*) cell voltages corresponding to carbon activities lower by 0-10% than those from gas equilibration studies using CO/CO_2 and CH_4/H_2 gas mixtures (2), (*ii*) a need to introduce a nickel gauze partition between the electrodes to prevent carburization, and (*iii*) the possibility of less than equilibrium voltages because of electronic conduction in the melt as has been discussed for similar cells (3-5).

In this paper we present evidence that the galvanic cell is more complex than is implied by [I]; that it is more accurately represented by

$$\begin{array}{lll} \text{anode} & Fe[C]_{(s)} & Ca,\ CaC_2,\ CaCl_{2(l)}, \\ & a'_C & a'_{Ca} \end{array}$$

$$\begin{array}{lll} Ca & C_{(s)} & \text{cathode} \\ a''_{Ca} & a''_C & \end{array} \qquad [II]$$

This evidence is founded upon a thermodynamic argument (6), and is supported by unpublished chronopotentiometric and voltammetric studies of the electrolyte used in the galvanic cell, and by experiments upon the multiple cell

$$\begin{array}{l} \longleftarrow\!\!\!

to the furnace windings, coupled to a Eurotherm controller. Because oxide and boron nitride crucibles react with CaC_2, steel, nickel, and graphite crucibles were used. The design of the steel crucible used in the "cold wall" furnace is shown in Fig. 1; this crucible permitted the simultaneous measurement of the emf of 7 anode/cathode couples including the steel crucible/cathode couple. Simple cylindrical crucibles of steel, nickel, or graphite were also used. Experiments were conducted with and without the partition described by Hawkes and Morris. When a graphite crucible was used, it also served as the cathode of the galvanic cell.

The cell emf was measured by the use of a potentiometer (Leeds and Northrup 8691), a digital voltmeter (Solartron LM 1420.2), or by a Keithley Electrometer Model 601 used in conjunction with a two-channel "YEW" (Yokogawa Company) recorder. The input impedance of the electrometer was of the order 10^{14} ohms. The cell temperature was measured by Pt/Pt 13% Rh thermocouples positioned in the wall of the crucible or placed inside a nickel thimble immersed in the electrolyte. The cell temperature fluctuation was ±2°C.

Electrodes

The carbon cathodes (3.2 mm diameter) were machined from a high-purity graphite (Grade AUC) supplied by Union Carbide or from spectra pure graphite supplied by Johnson Matthey and Company Incorporated. The austenite electrodes of known composition were supplied by the British Iron and Steel Research Association and by the Guest, Keen and Nettlefold Company, Limited, England. These were machined to a diameter of 3.2 mm, approximately 8 cm long.

The design of the calcium electrode for cell [III] was similar to that used by Bronstein (7) for various metal/metal halide electrodes. It was fabricated from a steel thimble 6.4 mm ID, 9.5 mm OD, by 7 cm long, in the side of which were incorporated two layers of steel felt (Feltmetal Grade FM 1501 rolled to about 65% density *ex* Huyck Metals Company). A steel cover plate with a 0.25 mm diameter hole was welded to the steel thimble over the steel felt. Steel was used for the construction of this electrode as calcium does not alloy with iron (8). Prior to use, the thimble was purified by placing it in a closed steel crucible containing a quantity of calcium metal. The crucible and contents were maintained at a temperature of 900°C for 75 hr under an argon atmosphere. The thimble was then washed with boiling distilled water and diluted hydrochloric acid, and the purification process repeated. Calculation indicated that this would be sufficient time to remove more than 90% of the carbon contained in the steel thimble. This procedure also removed many other impurity elements from the steel (*e.g.*, S, O, N). Finally, the thimble was again washed in boiling dilute hydrochloric acid, boiling water, then dried, and heated to 950°C under vacuum. The thimble was closed by a threaded plug, incorporating a bleed hole to ensure pressure equality. A steel rod was attached to the plug to serve as the electrode lead. The thimble was charged with 2.5g dried calcium chloride, 0.5g of calcium, and 0.5g calcium carbide. These quantities were sufficient to saturate the calcium chloride with calcium (9) and with calcium carbide (10).

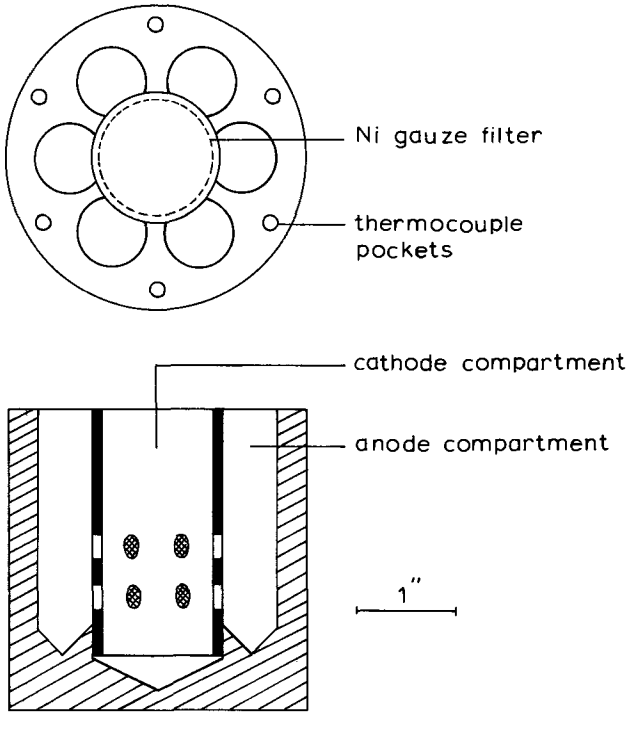

Fig. 1. Design of multicompartment steel crucible

Two types of electrode suspension have been used: (*i*) an assembly in which the electrodes were supported by "fired" pyrophyllite legs suspended from a water-cooled metal tube arrangement passing through a vacuum seal installed in the furnace closure flange (1). The electrical resistance between the electrodes, and between an electrode and ground, with the electrodes in the raised position at the cell operating temperature was of the order 10^7 ohms, and the leads to the electrodes were of platinum wire; and (*ii*) an assembly consisting of precision glass tubular sliding joints (Jencons Limited, England) situated on a water-cooled brass head (11), the electrodes being supported by steel rods which were also used as the electrode leads and where the order of magnitude of the electrical resistance between the electrodes in the raised position at the operating temperature was 4×10^8 ohms By the use of either assembly, the electrodes were immersed into the molten electrolyte approximately 2.5 cm, and raised at the completion of the experiment.

Electrolyte

Calcium chloride (reagent grade, J. T. Baker Chemical Company) was dried by heating stepwise in an oven to 200°C for approximately 6 days, after which it was transferred to a vacuum furnace in which the temperature was raised stepwise to the melting point.

Two modes of preparation of the electrolyte solution have been used, (*i*) by the addition, to the prefused $CaCl_2$, of CaC_2 synthesized from the elements, according to the procedure described by Aksaranan (12), and (*ii*) by the addition, to the prefused $CaCl_2$, of Ca metal and carbon in the stoichiometric proportions. Further Ca metal was added to the electrolyte in some experiments. In those crucibles in which a partition had been fitted, the CaC_2 or the Ca and C mixture was added to the carbon electrode compartment. A time period of the order of hours was allowed for reaction and, or solution prior to immersion of the electrodes.

Samples of the electrolyte were analyzed for calcium carbide, oxide, chloride, calcium metal, and carbon according to the procedure of Aksaranan *et al.* (6). The samples were taken either by drilling the solidified electrolyte as quickly as possible to minimize contact with air, or by use of a graphite sampling crucible which could be dipped into the melt and withdrawn.

Results

Galvanic Cell [II]

Experiments conducted in steel crucibles.—Experiments conducted in the "cold wall" furnace using multicompartment steel crucibles (Fig. 1) were characterized by a fairly rapid (of the order of 2-4 hr) attainment of approximately the same emf by all the Fe[C]-C couples, irrespective of the initial anode composition. Further, it was observed that this emf was some 10-20 mV above the emf of the steel crucible-C couple. This observation suggested that all the austenite electrodes had attained the same composition.

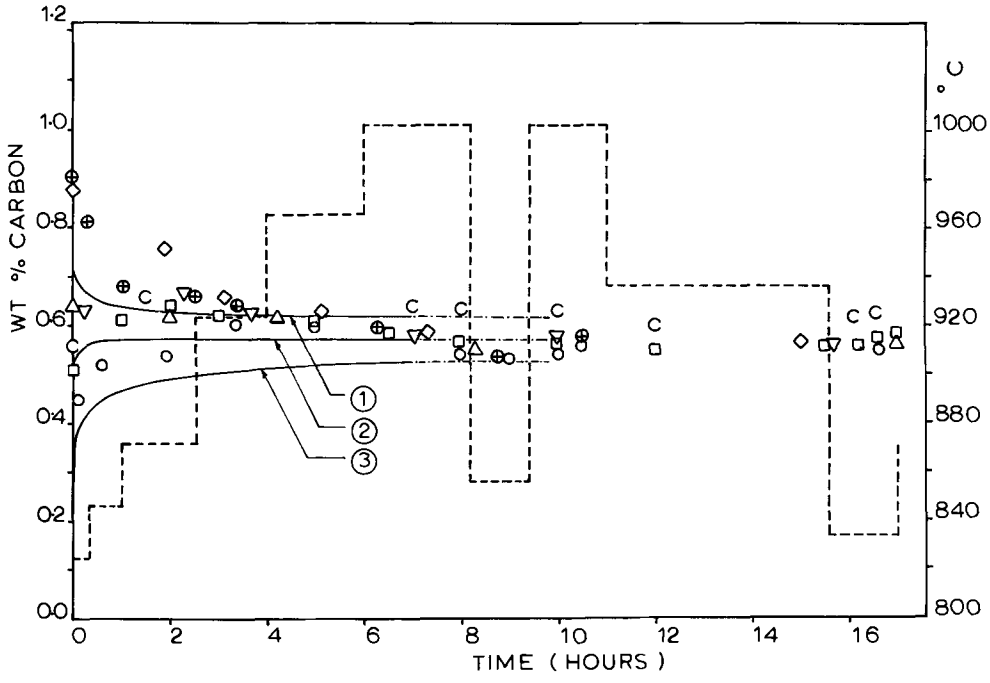

Fig. 2. Results of typical experiment (BSW 11) using multicompartment steel crucible. (For austenite electrode ref. No. see Table I.) □, BISRA V1827; ▽, BISRA S345; ⊕, BISRA V1664; ○, GKN66; △, GKN2; ◇, GKN37; C, crucible; - - - - - -, temperature history of experiment; ——·—·—·—, electronic conduction model: calculations based upon temperature of 860°C; mean value $\overline{\Delta G^\circ}$. line 1, initial C conc 0.72 weight per cent (w/o) C; line 2, initial C conc 0.51 w/o C; line 3, initial C conc 0.20 w/o C.

This was verified by chemical analysis. The results of a typical experiment are summarized in Table I. It is noteworthy that electrodes of relatively high carbon concentration had partially decarburized. This behavior was observed irrespective of the detail of the cell assembly or ancillary equipment. The results of the typical experiment are presented in more detail in Fig. 2 as a plot of the surface carbon concentration of the austenite electrodes as a function of time. The carbon concentration was calculated from the measured emf and temperature using Eq. [2] in conjunction with the correlation given by Ban-ya, Elliott, and Chipman (13) for a_C based upon gas equilibrium studies

$$\log a_C = \frac{3770}{T} + 2.72 \log T - 10.525 + \frac{3860}{T} y_C + \log Z_C \qquad [3]$$

This procedure has been adopted to demonstrate the response of the cell emf to the concentration (activity) of the carbon in the austenite electrode. It is seen that the surface carbon concentration is essentially independent of time and temperature, some 2-4 hr after insertion of the electrodes into the electrolyte. This calculated carbon concentration is in reasonable agreement with the results of chemical analysis of "bulk" samples of the electrodes taken from that part of the electrodes which had been immersed in the electrolyte (see Table I).

Experiments conducted in nickel or graphite crucibles.—The results of experiments conducted in nickel or graphite crucibles were qualitatively the same; characterized by the attainment of an emf of the Fe[C]-C couple near zero corresponding to essentially complete carburization of the austenite electrode as confirmed by chemical analysis. The results of typical experiments conducted in a graphite crucible are presented in Fig. 3 and in a nickel crucible in Fig. 4, again as a plot of the calculated surface carbon concentration of the austenite electrodes as a function of time. The asymptotic approach of the carbon concentration in the electrode to the saturation concentration at the operating temperature is seen. The final calculated carbon concentration agrees closely to that determined by chemical analysis.

During the course of the experimental work, considerable effort was directed toward the elimination of electrical interference upon the galvanic cell from

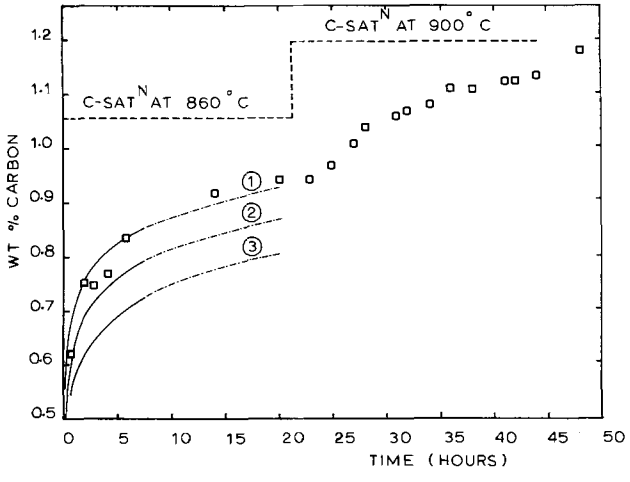

Fig. 3. Results of typical experiment (CCA 14) using graphite crucible. □, Experimental points. external sources, *e.g.*, the furnace heating circuits. Thus some experiments were conducted using a d-c power supply to the furnace and the whole assembly was independently earthed. The adoption of such procedures made no substantial difference to the behavior of the galvanic cell. The fitting of a gauze partition between the electrodes had little influence.

Multiple Galvanic Cell [III] and [IV]

The multiple cell experiment was conducted using a nickel crucible to contain the electrolyte which consisted of fused calcium chloride containing an excess of calcium carbide. The experimental procedure was to immerse the carbon and austenite electrodes in the electrolyte at time zero and record $E_{[IV]}$ as a function of time. After approximately 5 hr, the carbon electrode was raised clear of the electrolyte and the calcium electrode immersed. $E_{[III]}$ was recorded continuously as a function of time and $E_{[IV]}$ measured upon momentary immersion of the carbon electrode. The results are presented in Fig. 5. It is seen that in the first period $E_{[IV]}$ declined with time; in the second period $E_{[III]}$ declined with time, but $E_{[IV]}$, measured intermittently, increased. This cycle was reproducible.

Theoretical Analysis

It is well known that calcium metal is soluble in its halides, possibly in the form of a molecule-ion Ca_2^{2+} (14). The results of chemical analysis of calcium carbide-chloride solutions equilibrated in graphite crucibles have been interpreted using a thermodynamic argument based upon equilibrium [4] (6). Chronopotentiometric studies by White (11) and voltammetric studies by Dosaj (15) have been interpreted in terms of a dissociative equilibrium preceding the electrochemical step at low current densities.

A model is postulated for the galvanic cell in which calcium metal in solution is viewed as the electroactive species, and at the electrode-electrolyte phase boundary there exists the chemical equilibrium

$$CaC_{2(soln)} \rightleftharpoons Ca_{(soln)} + 2C_{(electrode)} \qquad [4]$$

and the electrochemical equilibrium

$$Ca_{(soln)} \rightleftharpoons Ca^{2+}{}_{(soln)} + 2e \qquad [5]$$

Cell [I] is therefore more accurately represented by cell [II] in which the calcium metal activities at the two electrodes are determined by equilibrium [4]. It is thus similar to the bimetallic cells with alkali metal anodes in which Hesson *et al.* (5) have found an irreversible (non-Faradaic) transfer of alkali metal from the anode to the bimetallic cathode to take place. They termed this transfer the self-discharge of the cell and presented a theoretical analysis of the cell based upon the equations of irreversible thermodynamics. They concluded that the self-discharge was largely due to the presence of dissolved alkali metal in equilibrium with alkali metal ions and electrons in the electrolyte resulting in partial electronic conduction in the electrolyte. They further stated that the predictions of the theory were in qualitative agreement with their experimental results. It is of interest to apply this theory to cell [II].

Carbon concentration at the electrode surface.—Following Hesson *et al.* (5) and Heyne (16) an equation may be derived assuming the electrolyte is of uniform composition in CaC_2, for the carbon flux, j_C at the austenite electrode surface, by noting the equivalence of the carbon flux to the electron current density. The equation is

$$j_C = \frac{RT\sigma_i}{F^2BA} \ln \left[\frac{K_e K^{1/2} a^{1/2}_{CaC_2} (a''_C)^{-1} + \sigma_i}{K_e K^{1/2} a^{1/2}_{CaC_2} (a'_C)^{-1} + \sigma_i} \right] \qquad [6]$$

The concentration of carbon at the electrode surface as a function of time is given by an appropriate solution to Fick's second law. Neglecting the change in the diffusion coefficient of carbon in iron with changing composition, the solution is (17)

$$\frac{4}{3} D_C t = \int_{c_i}^{c_s} \frac{2(c_s - c_i) f(c_s) - (c_s - c_i)^2 f'(c_s)}{f^3(c_s)} d(c_s) \qquad [7]$$

Equation [7] may be shown to be valid for $t \not> 15$, 4.5, and 1.0 hr at 800°, 900°, and 1000°C, respectively (18).

Emf of the galvanic cell.—The cell emf may be shown to be

$$E_{[II]} = -\frac{RT}{\mathbf{F}} \ln\left(\frac{a'_C}{a''_C}\right) - \frac{AB}{\sigma_i}(i_t - i_e) \quad [8]$$

For $i_t = 0$ (open-circuit condition) the second term in Eq. [8] is small (approximately 10^{-2} times) relative to the first term; it is zero when $i_t = i_e$. The current in the external circuit is then given by

$$I = i_t A = \frac{K_e}{B}\frac{RT}{\mathbf{F}} K^{1/2} a^{1/2}_{CaC2}\left(\frac{1}{a''_C} - \frac{1}{a'_C}\right) \quad [9]$$

Interpretation of Results

Galvanic Cell [II]

It is apparent from Eq. [6] that the magnitude and sign of the carbon flux is determined by the relative magnitudes of a'_C and a''_C. In the simplest case with $a''_C = 1$ (graphite crucible-cathode) the carbon flux is to the austenite anode. The results of a typical computation are shown in Fig. 3 including the uncertainty limits due to the uncertainty in K. It is seen that the surface composition calculated from the measured cell potential is within these limits.

The use of steel or nickel crucibles will lead to fluxes between the various cell components. The additional assumption was made that the dominant flux was that between the electrodes and the crucible. This is justified in view of the large mass (10^2-10^3 times) and large surface area (10^1-10^2 times) of the crucible relative to the electrodes, then $a''_C = \exp(-\mathbf{F}E_{cr}/RT)$. For nickel crucibles, E_{cr} was zero ± 20 mV. This is a consequence of the relatively high solubility of calcium in nickel (19) whence it may be shown that the nickel crucible is identical to a graphite crucible in the sense that $a''_C = 1$. The results of typical computations for an experiment using two austenite electrodes and a graphite cathode are shown in Fig. 4. The effects of the eccentricity of the geometrical arrangement were not taken into account. It is seen that the surface compositions of the austenite electrodes calculated from the measured cell potentials are in good agreement with those calculated by the above procedures. In the case of steel crucibles, E_{cr} was typically in the range 50-100 mV. The observed rate of change of this emf was small relative to the rate of change of the emf of the austenite test electrode. The results of a typical computation for an experiment using the multicompartment steel crucible (Fig. 1) are shown in Fig. 2. The model predicts carburization ($a'_C < a''_C$) or decarburization ($a'_C > a''_C$) of the austenite electrodes in accord with experimental observation. The computed steady-state compositions attained by the electrodes agree closely with the results of chemical analysis (see Table I).

Multiple Galvanic Cell [III] and [IV]

The multiple cell experiment represents an excellent qualitative demonstration of the influence of the calcium activities at the reference electrode (graphite or calcium) relative to the calcium activity at the austenite electrode, upon the cell emf (see Fig. 5). Thus in the first period of the experiment in which the austenite and carbon electrodes were immersed in the electrolyte, $a'_C < a''_C$ (and hence $a'_{Ca} > a''_{Ca}$) and carburization of the austenite electrode will ensue. In the second period in which the calcium and austenite electrodes were immersed, $a^o_{Ca} > a'_{Ca}$ leading to decarburization of the austenite electrode. These deductions from the model are in accord with experiment.

Further it should be noted that the emf of the calcium-carbon couple should correspond to $E^\circ_{CaC_2} = \Delta G^\circ/2\mathbf{F}$ and is given by

$$E^\circ_{CaC_2} = E_{[III]} + E_{[IV]} \quad [10]$$

neglecting terms accounting for the finite electronic conductivity of the electrolyte (cf. Eq. [8]). From Fig. 5, $E^\circ_{CaC_2}$ is found to be 350 ± 40 mV; from ΔG°, $E^\circ_{CaC_2}$ is calculated to be 360 ± 40 mV. The large standard deviation on the experimental value is a consequence of the short periodic time of immersion (approximately 30 sec) of the carbon electrode in the second period.

Influence of External Current

According to Eq. [8], $E_{[II]}$ equals the theoretical emf when $i_t = i_e$; Eq. [9] gives I, the current in the external circuit, in terms of the carbon activities of the electrodes and other relevant quantities.

In order to test these predictions, an experiment was performed using a graphite crucible-cathode and a single, centrally located, austenite electrode of known composition. External circuitry was assembled consisting of a Hewlett Packard Model 6206 B d-c power supply operating in the constant current mode, and a standard 10 ohm resistor connected in series with the electrode terminals. Upon immersion of the electrode, the current in the external circuit was adjusted such that the theoretical emf calculated according to Eq. [2] and [3] was attained. The cell emf was observed to remain constant. The current in the external circuit was calculated from the measured potential drop across the standard resistor. This procedure was repeated at several temperatures. The results of this experiment are summarized in Table II, in the fourth column of which are also shown the values of I calculated from Eq. [9]. The agreement between the measured and calculated values of I is seen to be excellent.

Conclusions

1. The electromotive force of a Fe[C]-C couple immersed in an electrolyte of calcium carbide dissolved in molten calcium chloride is a function of the temperature and the carbon activity in the alloy electrode, and the electronic conductivity of the electrolyte.
2. The particular form of the irreversible process in this galvanic cell is associated with the partial electronic conductivity of the electrolyte due to the finite concentration of calcium in the electrolyte.
3. A mechanism of the galvanic cell has been proposed based upon the chemical equilibrium $CaC_2 \rightleftharpoons Ca + 2C$ and the electrochemical equilibrium $Ca \rightleftharpoons Ca^{2+} + 2e$ in solution.
4. A mathematical model to calculate the carbon concentration at the surface of the austenite electrode as a function of time has been constructed. Results show a close agreement to those obtained from the measured emf of the galvanic cell.
5. The model predicts that by supplying current from an external source, a time independent emf can be achieved. This has been demonstrated. Further the magnitude of the current agrees closely with that calculated from the model.
6. The experimental results of Hawkes and Morris who used this cell to measure the carbon activity in Fe[C] alloy, have not been confirmed. The reasons for this are not known.

APPENDIX

Estimation of Constant K_e

In order to calculate K_e it is assumed that conduction electrons are formed in the electrolyte by equilibrium [5] and hence

$$n_e = K' a_{Ca}{}^{1/2} \qquad [A\text{-}1]$$

According to Rice (20) electron movement in metal/metal salt solutions proceeds by a hopping mechanism akin to diffusion with activation energy of $4kT_b$. Hence the electron diffusion coefficient D_e may be written

$$D_e = D^o_e \exp(-4T_b/T) \qquad [A\text{-}2]$$

Use of this relation with the Einstein relation $u_e = q\,D_e/kT$, and the defining relation $\sigma_e = n_e\,q\,u_e$, gives

$$\sigma_e = \frac{K'\,q^2\,D^o_e \exp(-4T_b/T)}{kT}\,a^{1/2}_{Ca} \qquad [A\text{-}3]$$

Dworkin *et al.* (14) have measured the electrical conductivity of solutions of calcium in calcium chloride at 1128°K. The conductivity was found to increase with increasing concentration of metal. Assuming the excess conductivity is due to electrons, a relation of the form of Eq. [A-3] is readily verified. For $a_{Ca} = 1$ (saturated solution), $T = 1128$°K, $T_b = 1756$°K, $\sigma_e = 40$ ohm^{-1}-m^{-1}, Eq. [A-3] becomes $\sigma_e = K_e\,a^{1/2}_{Ca}$ with

$$K_e = \frac{2.28 \times 10^7}{T} \exp(-4T_b/T)\ ohm^{-1}\text{-}m^{-1} \qquad [A\text{-}4]$$

Oxidation of GaP in an Aqueous H_2O_2 Solution

B. Schwartz* and W. J. Sundburg

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The oxidation of GaP in aqueous H_2O_2 has been accomplished by both galvanic action at ~100°C and by externally applied anodic reaction at room temperature. Films as thick as 1400 and 3500Å, respectively, have been prepared using these two approaches. A detailed examination of the kinetics of galvanic oxide growth indicates that: (*i*) the oxidation mechanism involves predominantly the transfer of holes, (*ii*) the rate-controlling step in the growth mechanism involves the diffusion of the oxidant, through the grown oxide, (*iii*) the index of refraction of the grown oxide is 1.58 ± 0.01, and (*iv*) a drying procedure to remove the water of hydration is necessary in order that the passivating amorphous oxide required for device use may be obtained. The growth of an oxide by externally applied anodic bias has resulted in the facts that: (*i*) the oxide thickness is linearly dependent on the applied bias up to about 100V, with the constant of proportionality being 12 Å/V, (*ii*) an upper forming voltage of about 200V has been found for obtaining uniformly colored (*i.e.*, thickness) films, and (*iii*) the index of refraction of the grown films depends on the forming voltage used, and (*iv*) a drying procedure to remove the water of hydration is necessary in order to obtain a stable amorphous oxide.

The achievement of controlled oxidation of silicon surfaces has been a major factor in the attainment of the very complex integrated circuits available today on the open market. With the advent of compound semiconductor devices as a commercial reality, it was obvious that the question of the availability of equivalent native surface oxides would be asked. It has not been obvious, however, that totally equivalent native oxides do exist (1, 2).

In a recent paper, Schwartz (3) described the results of a preliminary study on the oxidation of gallium arsenide and gallium phosphide. When GaP was placed in room-temperature water for seven days, approximately 60Å of amorphous oxide was grown on the surface; this is to be compared with a native oxide of only ~25Å on a freshly polished surface. When GaP was exposed to a concentrated[1] solution of H_2O_2 for seven days at room temperature, approximately 250Å of an amorphous oxide was grown.

In this paper some additional studies on the oxidation of GaP will be described.[2] Two techniques have been pursued: (*i*) boiling the GaP in concentrated H_2O_2 and (*ii*) anodic oxidation of GaP in concentrated H_2O_2 at room temperature. Thick oxides (>1000Å) have been obtained by the two techniques. The influence of conductivity type and the effect of a nonreactive ohmic contact will be shown. A linear dependence of the oxide thickness on forming voltage with a slope of about 12 Å/V, as well as an apparent upper forming voltage limit of about 200V, has been found in the anodic approach.

To be able to measure the oxide thickness it has been necessary to develop the reference curves for the ellipsometer, and reference will be made to these data.

Experimental Procedure

Oxidation in boiling hydrogen peroxide.—A 30% aqueous solution of H_2O_2 boils at about 106°C. Since the explosion hazard with this material is minimal [see Ref. (4)] it was decided to go directly to this temperature for the first phase of this study.

A simple all-quartz system was used, consisting of a 1000 ml tall-form beaker, a watch glass, a sample holder[3] (see Fig. 1B) and a commercial heating mantle. Because the beaker always extended well beyond the hot zone of the heating mantle, a simple reflux system was operative and the open pour spout acted as the pressure release. In this configuration, when the beaker was filled to the top of the heating mantle (approximately 500-600 ml) with concentrated H_2O_2 and boiling commenced, it took about 2 hr for the surface of the solution to fall about ¼-½ in. (about 50-100 ml of loss); at this point, fresh H_2O_2 solution was added to the beaker. A check of the temperature of the system during a continuous 6-hr boiling-and-refill operation showed that the temperature of the solution always

[3] A number of kinds of sample holders were constructed, but only holder B in Fig. 1 was used for the oxidation of GaP slices; the other two holders were constructed for use on packaged devices.

* Electrochemical Society Active Member.

Key words: compound semiconductor surfaces, native oxides, anodization.

[1] The concentrated H_2O_2 solution referred to in this paper was sold under the trade name Superoxol (CP) by Merck & Company, Rahway, New Jersey, and is nominally a stabilized 30% aqueous solution.

[2] All the oxidation data in this paper were obtained on Br_2-CH_3OH polished, P-faces of (111)-oriented GaP slices cut from liquid encapsulated Czochralski-grown ingots.

ranged between 105° and 106°C. This very narrow boiling range was taken to indicate that there was relatively little composition change of the H_2O_2 solution and that prolonged boiling of this kind was feasible.[4]

In order that oxidation-rate data might be obtained, samples were prepared from a slice of n-type, sulfur-doped GaP ($N_D \cong 10^{18}/cm^3$) which was polished and then broken into nine pieces. One piece was put aside as the reference and the other eight were placed in holder B, Fig. 1, and immersed in boiling H_2O_2. One piece was then removed every hour,[5] rinsed in 15 megohm deionized water, and blot dried. All of the samples, including the reference piece, were then put through the standard bake-drying procedure (see section on Sample drying procedure) and subsequently measured with an ellipsometer to determine the thickness of the grown film.

Thickness measurement.—The method of determining film properties by ellipsometry is to characterize a beam of monochromatic polarized light before and after the beam has been reflected from a test surface at some angle of incidence. The parameters that characterize the reflected light are ψ, the arctan of the ratio of the electric vectors of the beam in the perpendicular to the plane of incidence, and Δ, the phase difference between them. From the values of these two angles the thickness and index of refraction of the film can be determined.

Before one can do much in ellipsometry it is necessary to generate a series of reference curves for any new material which plots ψ and Δ as a function of film index of refraction. This was done for GaP using a computer program developed by Cox (5), the fundamentals of which will be found in the Appendix. Once these curves have been developed, the experimentally determined ψ and Δ for each sample is plotted on these reference curves. The particular curve on which the point falls corresponds to the index of refraction of the film, and the position along that curve, or the value of δ, indicates the thickness of the film.

Figures 2 and 3 are computer-generated curves for $\lambda = 5461$ and 6328Å, respectively, and for fixed thin film refractive index $n_1 = 1.58$.[6] The two curves are not identical because the index of refraction of the substrate changes with the wavelength of the impinging radiation; the values for n and k of the substrate were obtained from the literature (6, 7) and are indicated on each figure. Segments of curves for $n_1 = 1.57$ and 1.59 are also presented to indicate the sensitivity of the function to the input information. Total curves were not drawn because they converge for all values of n_1 as δ gets small and would only confuse the diagram.

The thickness and index of refraction of the films under study were measured with an L119 Gaertner (5461Å) and a 200E Rudolph (6328Å) ellipsometer. Both instruments were arranged in the manner described by Archer (8) with a constant angle of incidence of 70°. More than one wavelength was used because proximity of the bandgap of GaP to that of the available light sources (*i.e.*, 2.26 eV for GaP at room temperature, as compared with 2.28 eV for the 5461Å source and 1.97 eV for the 6328Å source) offered the possibility of errors associated with rapidly changing substrate optical properties near the band edge. We shall see that there is very good agreement between the two sets of measurements, and that this potential source of error is unimportant.

Sample drying procedure.—Because the oxidizing solution under study is an aqueous solution of hydrogen peroxide, it was thought very probable that the formed oxide would contain an appreciable quantity of water in the as-grown condition. An examination of the effect of baking freshly prepared oxidized samples at 200°-400°C for a short time (a few hours) always indicated that the films became about 20-25% thinner. In order that the baking process might be examined, a slice of n-type, Te-doped GaP with $N_D \cong 10^{18}/cm^3$ was pulverized in an agate mortar and pestle. The GaP powder was then divided into two equal parts. One part was not treated further, but the second portion was oxidized in boiling H_2O_2 for about 6½ hr, then filtered and air dried at room temperature on the filter paper. Samples of oxidized powder and unoxidized powder were then sent for both thermogravimetric and thermomass spectrographic analyses. Another set of equivalent powder samples was sent for infrared absorption analysis. The latter measurement was inconclusive because of (*i*) the lack of attenuation due to the limited mass of oxidized material on the surface of the powder and (*ii*) the hindrance by the obviously incorporated H_2O in the wavelength region of interest. However, thermogravimetric analysis showed (see Fig. 4A) that for the H_2O_2-oxidized powder there was a small weight loss up to about 250°C,[7] after which the weight of the sample stabilized and remained constant. Meanwhile, the unoxidized powder neither lost nor gained weight when exposed to the same temperature excursion (see Fig. 4B). During the time the oxidized sample was being heated so that the weight-change data could be obtained, the output gas was collected and passed into a mass spectrometer. The major component measured was water, indicating

[4] M. L. McNamara of Bell Laboratories, Reading, Pennsylvania, informs us that if a small quantity (about 25-50 ml) of concentrated H_2O_2 is boiled for about 1 to 2 hr, enough water is boiled off to cause an increase of the H_2O_2 concentration well into the explosive range; a simple reflux condenser system eliminates this hazard and is now the standard reactor for all high temperature oxidations.

[5] The last three samples were removed at 2-hr intervals.

[6] A complete set of curves has been calculated for each wavelength and for n_1 varying from 1.2 to 2.4, but the curves are not included because of their bulky nature. The curves can be generated from the information in the Appendix and in Ref. (5-8).

[7] The technique used is to raise the temperature 10°C/min while monitoring the mass of the sample; see Ref. (9) for details.

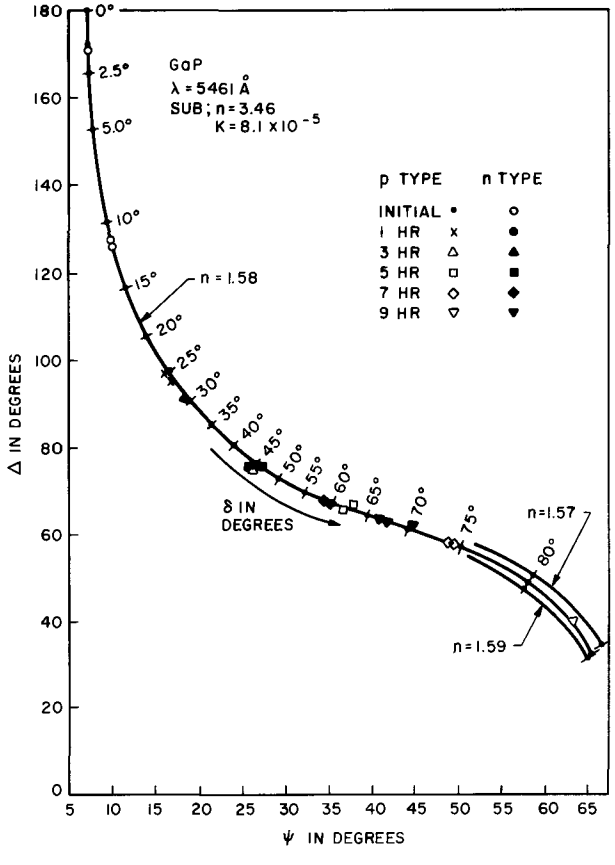

Fig. 2. Computer-generated curve of Δ *vs.* ψ for the wavelength 5461Å and a film refractive index of 1.58. Partial curves for index of refractions 1.57 and 1.59 are also included. In addition, the experimentally determined values of Δ and ψ are indicated to show the precision of the measurement.

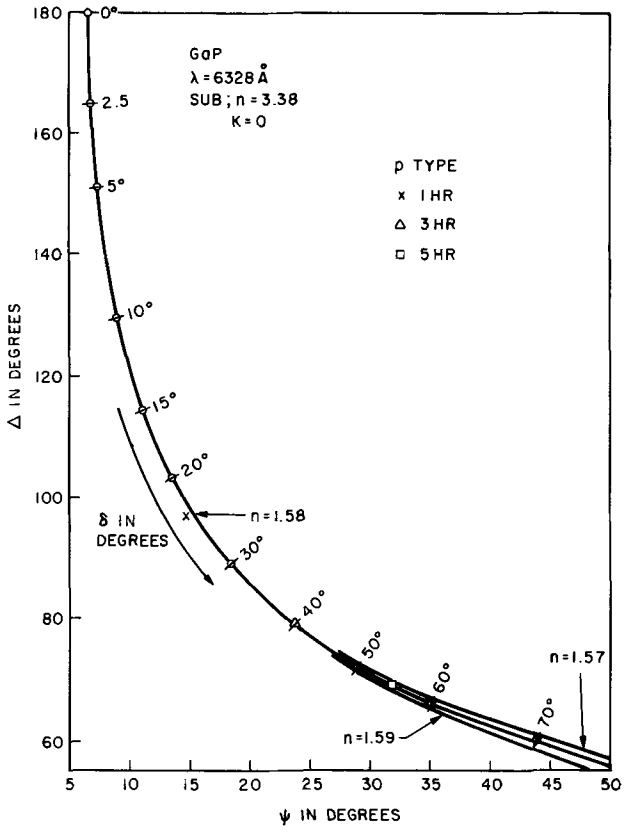

Fig. 3. Computer-generated curve of Δ vs. ψ for the wavelength 6328Å and a film refractive index of 1.58. Partial curves for index of refractions 1.57 and 1.59 are also included. In addition, the experimentally determined values of Δ and ψ are indicated to show the precision of the measurement.

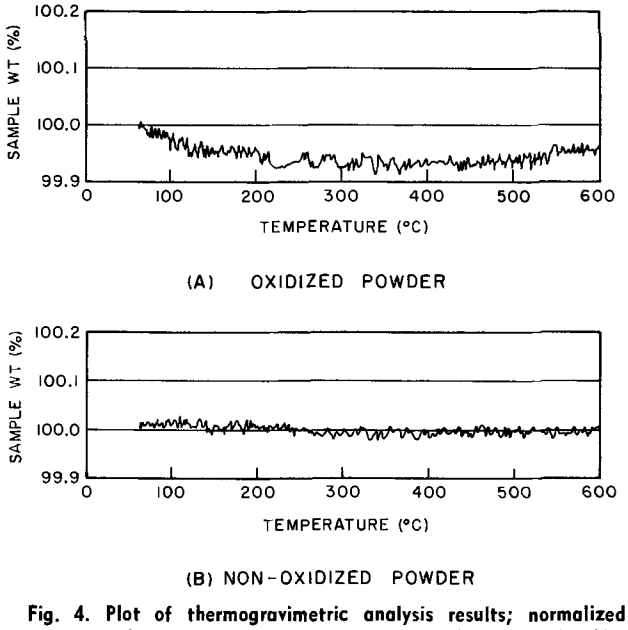

Fig. 4. Plot of thermogravimetric analysis results; normalized weight as a function of temperature for oxidized GaP powder (A), and for nonoxidized GaP powder (B).

that a drying of the oxide film was indeed taking place. As a consequence of all these findings, an arbitrary drying procedure was instituted, except where otherwise noted, for all subsequent oxidations which consisted of drying the samples in a nitrogen-purged oven at 95°C for 1 hr, at 150°C for 2 hr, and then at 250°C for 2 hr.

Anodic oxidation.—Since all oxidation-reduction reactions involve electron transport, one can also envision the reaction as an electrochemical cell, and it is a natural extrapolation to attempt to substitute external electrical driving forces for the thermal conditions described in the preceding section. A study of the anodic oxidation of GaP at room temperature was undertaken with concentrated H_2O_2 as the electrolyte. The choice was made to investigate a constant voltage system with a platinum cathode (see Fig. 5) and to monitor the current with time. The decay of current with time in Fig. 6 is a clear indication of the growth of a resistive oxide on the surface of the GaP anode. An examination of the anodized samples showed that very uniform oxides were grown over the entire exposed surface area.

Results and Discussion

Boiling H_2O_2.—The results of the experiment to determine the oxidation rate of GaP in boiling H_2O_2 are shown as curve A in Fig. 7. Merely raising the temperature of the oxidizing system from 25° to 106°C did not produce an increased oxide film thickness. However, when another (111)-oriented, n-type slice (*i.e.*, Se-doped to an $N_D \cong 5 \times 10^{17}/cm^3$) containing a large area Au-Si ohmic contact on the Ga face was exposed to boiling H_2O_2 for periods up to 9 hr, the data shown as curve B of Fig. 7, 0-9 hr,[8] were obtained; the difference between the contacted and noncontacted situation is striking. Repeating this procedure on a p-type $3 \times 10^{17}/cm^3$, Zn-doped slice containing a large area Au-Be ohmic contact on the Ga face resulted in the data shown as curve C, Fig. 7, time 0-9 hr. As a verification that the data of curves B and C were meaningful, two other slices, one from each of the same ingots used to obtain curves B and C, were equivalently contacted and boiled in H_2O_2 for 8 hr, then removed, rinsed in D.I. water, blot dried, stored overnight at room temperature in a laminar flow hood before being boiled in fresh H_2O_2 for 6½ hr the next day, and then baked. These two data points are included in curves B and C of Fig. 7 as the 14½ hr values. Since the latter two points fall on the curves projected from the initial data points, the oxidation times appear to be additive.[9]

The explanation of the effect of the ohmic contact is very straightforward. Without the ohmic contact the entire surface is oxidized, and because the oxide is a "dielectric," the cathodic component of the oxidation-reduction reaction is quenched and oxidation ceases. With the nonreactive ohmic contact in place, the cathodic reaction proceeds on the noble metal surface and thus acts to drive the oxidation of the GaP forward. This is, in effect, a galvanic action, and we will therefore refer to the oxide grown in boiling H_2O_2 with the contact present as the galvanic oxide.

It should be noted here that the measurements of ψ and Δ used for obtaining curves B and C of Fig. 7 are shown in Fig. 2 and 3. The data indicate that the index of refraction of the galvanic oxide is 1.58 ± 0.01 independent of conductivity type of the GaP.

We can now look at curves B and C of Fig. 7 and obtain two more points of understanding. The first is that the p-type specimen clearly oxidizes faster than the n-type specimen. An oxidation reaction can be written as an electron loss, or a hole addition, or a combination of both. Therefore, it would not be surprising to see conductivity type and/or charge concentration effects in the oxidation of GaP. Since we have evaluated only one carrier concentration in this study, we cannot comment further on the effects of doping level except to note that such an effect has been reported for the oxidation of GaAs in H_2O (10). However, the primary influence of hole concentration previously reported in the anodization of germanium (11) is clearly evident in the data of Fig. 7. The second point concerns the fact that curves B and C look very much like a square root of time relationship which is normally found in diffusion-controlled reactions; from the p- and n-type data of Fig. 7, the exponents have been found to be 0.6 and 0.4, respectively. Combining this information with the fact that the GaP ratio is constant in depth into the oxide film, as determined from a Rutherford scattering analysis of thick galvanic films (12), we can conclude that diffusion of the ionic oxidant through the oxide is the rate-controlling step in this process.

Anodic oxidation.—Let us consider the data obtained on the anodically grown oxides. Table I presents the results of a study of the effect of voltage on oxide thickness. On examination of these data, three factors become obvious: (*i*) the oxide thickness is linearly dependent on voltage with a slope of about 12 Å/V up to about 100V, (*ii*) the index of refraction appears to decrease as the films get thicker, and (*iii*) there seems to be an upper anodization voltage above which uniformly colored films cannot be grown.

The linear dependence of the oxide thickness on voltage is a standard phenomenon well known for silicon and germanium anodization (13). The observation that the index of refraction changes with thickness (*i.e.*, forming voltage) is consistent with the observation from Rutherford scattering analysis (12) that the composition of the film is not uniform in depth. Whereas the galvanic oxide was uniform with a stoichiometric analysis of approximately $Ga_2O_3 \cdot P_2O_5$, the anodic oxide appears to be depleted of the Ga_2O_3 component at the oxide semiconductor interface and this region is believed to be almost exclusively vitreous P_2O_5. Studies are under way that should produce a better understanding of this phenomenon. It is believed that a study of the influence of field on the composition of the oxide grown anodically should explain the upper voltage limit on uniform oxide growth.

General results.—With reference to the composition of the oxides, it is worth noting that all attempts, [*i.e.*, x-ray diffraction, reflection electron diffraction, transmission electron diffraction (14), etc.] to determine

Table I. Effect of voltage on oxide thickness

Anodic bias* (volts)	Thickness** (Å)	Apparent refractive index	Interference color
10	125	1.70-1.75	None
25	300	1.70-1.75	None
50	525	1.68	Brownish
100	1125	1.61	Blue
100	1230	1.63	Blue
160	3500†	~1.2	Gold
≥225	—	—	Mottled surface over purplish range

* Constant oxidation time of 2000 sec at constant specified bias.
** Samples not bake-dried.
† Because of the large change in the refractive index, this value is to be used only as an approximation.

[8] Multiple data points for a given growth time indicate that the sample was measured at different positions on the surface or at different wavelengths. The very close agreement in the values implies the good uniformity achieved in oxide thickness over the surface as well as the high degree of precision measuring the thickness at both 5461 and 6328Å. It has been estimated that there is an error of only about 2% caused by errors in reading the ellipsometer or the computer-generated curves.

[9] Additional experiments indicate that the oxidation time is additive only if the drying bake is performed at the conclusion of the series of oxidations and is not interposed between two successive oxidations.

if there was any crystal structure to the galvanic or anodic oxides once they had been properly baked have shown that the film was amorphous (*i.e.*, of ordered dimension less than 20Å). It was found that baking caused the films to get thinner and water to be lost; in addition, the dielectric properties of the oxide were found to improve greatly (15). It has been determined that heating either of these films, galvanic (12) or anodic (16), to temperatures of 650°C and above for short times in nitrogen results in the appearance of polycrystalline $GaPO_4$ in the x-ray diffraction pattern. It is interesting to speculate that in the as-grown condition the oxide is a hydrated "gel" and that baking at 250°C results in the formation of a metastable "vitreous" composite; subsequent heating at the higher temperature (>650°C) merely causes a transformation to the crystalline modification.

It should also be noted that the native oxide, once grown, either by the galvanic or the anodic technique, and subsequently baked, appears to be attacked by many mineral acids and inorganic bases, but is insoluble in most organic solvents.

Conclusions

The results of this study may be summarized as follows:

1. Native oxide films of the order of 1000Å or more can be grown on GaP in aqueous H_2O_2.
2. Both a galvanic system, operating at ~106°C, and an anodic system, operating at 25°C, can be used to grow thick oxides on GaP.
3. The rate-limiting step in the growth of the galvanic oxide is the diffusion of the oxidant ion to the oxide-semiconductor interface.
4. The oxide as initially grown, by either the galvanic or the anodic technique, is rich in water, and adequate drying is required before a useful oxide is achieved.
5. The predominance of the hole transfer mechanism in the oxidation of GaP is shown by the higher oxidation rate of p-type GaP over n-type GaP.
6. There is a linear dependence of the anodic oxide thickness on forming voltage (*i.e.*, 12 Å/V) up to a limiting voltage of about 200V.
7. The index of refraction of the galvanic oxide is 1.58 ± 0.01.
8. The index of refraction of the anodically grown oxide varies from over 1.7 to about 1.2, depending on the forming voltage.
9. When these films are heated to 650°C and above for short periods of time, crystalline $GaPO_4$ appears.
10. These oxides are soluble in many mineral acids and common bases, but is not attacked by the standard Br_2-CH_3OH etchant.

It is obvious that much more work is required before the system reported on here can be fully understood.

Acknowledgment

The authors would like to thank numerous people for assistance and encouragement during the course of this work: J. P. Luongo for his infrared absorption measurements, P. K. Gallagher for the thermogravimetric analyses, Mrs. M. Read for the x-ray analyses, G. Kamlott for the reflection electron diffraction analyses, T. T. Sheng and R. C. Manz for the transmission electron diffraction analysis, S. M. Spitzer for the analysis of dielectric properties, R. L. Fields, Jr. for the information on heat-treatment effects, and R. A. Furnanage for applying the ohmic contacts. In addition, discussions with the following people have been both enlightening and stimulating: P. J. Boddy, J. M. Poate, J. Yahalom, T. M. Buck, R. L. Hartman, M. Kuhn, and F. A. Trumbore. The extremely able assistance of R. C. Manz and A. J. Sayko deserves a special note of thanks.

Manuscript submitted July 14, 1972; revised manuscript received Nov. 23, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

APPENDIX

The following equations, taken from Archer (8), may prove useful in constructing a computer program to generate curves such as those shown in Fig. 2 and 3 for other values of n_1.

The fundamental equation of ellipsometry in terms of the Fresnel reflection coefficients is

$$\tan \psi e^{i\Delta} = \frac{r_{1p} + r_{2p}e^{-2i\delta}}{1 + r_{1p}r_{2p}e^{-2i\delta}} \cdot \frac{1 + r_{1s}r_{2s}e^{-2i\delta}}{r_{1s} + r_{2s}e^{-2i\delta}} \quad [A\text{-}1]$$

when

$$\delta = \left(\frac{360}{\lambda}\right) X_o \, (n_1^2 - \sin^2\phi)^{1/2} \quad [A\text{-}2]$$

In Eq. [A-2], λ = the wavelength of measuring light, X_o = the oxide thickness, ϕ = the angle of incidence, and n_1 = the index of refraction of the film.

In the equations above, the subscript numbers 1 and 2 refer to the film and substrate, respectively, and the subscript letters p and s refer to the electric vector of the light in and perpendicular to the plane of incidence.

The general Fresnel equation for reflection of light from a surface "b" into a medium "a" can be written as

$$r_p = \frac{n_a \cos \phi_b - n_b \cos \phi_a}{n_a \cos \phi_b + n_b \cos \phi_a} \quad [A\text{-}3]$$

$$r_s = \frac{n_a \cos \phi_a - n_b \cos \phi_b}{n_a \cos \phi_a + n_b \cos \phi_b} \quad [A\text{-}4]$$

where n_a and n_b are indices of refraction of the two media and in general are complex. ϕ_a and ϕ_b are the angles of incidence and reflection, respectively. Since these angles can be related by Snell's law, the Fresnel coefficients of Eq. [A-1] can be written in terms of the optical constants of the film and substrate. Equations for ψ and Δ may be obtained by substituting Eq. [A-2], [A-3], and [A-4] in Eq. [A-1] and separating the resulting expression into real and imaginary parts.

Technical Notes

Auger Spectra of HCl Vapor-Etched n^+ GaAs {100} Substrates

R. L. Moon* and L. W. James

Central Research Laboratories, Varian Associates, Palo Alto, California 94303

Often incorporated into the procedures used for vapor-phase epitaxy (VPE) of III-V materials is an etching phase to ensure a clean substrate prior to growth. The effect of this etching is usually judged by the final device characteristics or by carrier-concentration profiles. During the course of our investigations of possible contaminants present on the surface of vapor-grown GaAs, we examined the effects of HCl etching on the Auger spectra of n^+ GaAs {100} substrates.

Our procedure consisted of preparing the GaAs substrate for VPE, taking an Auger spectrum, etching with HCl and H_2 in the vapor reactor, and finally taking a second Auger spectrum. Auger analysis was performed with a Varian Cylindrical Mirror Analyzer system at a vacuum of 1×10^{-10} Torr. Substrates were Czochralski grown {100} GaAs doped to about 1×10^{18} cm^{-3} with Si, Sn, or Te. Final substrate preparation before beginning the test included, besides the appropriate intermediate rinses, a hot trichlorethylene and acetone degrease, a $5H_2SO_4:H_2O_2:H_2O$ etch, and a Br_2–methanol etch. The wafer was placed in methanol for transfer between the various stages.

At least for short periods, immersion of GaAs wafers in electronic-grade methanol does not appear to affect the surface-impurity distribution within the sensitivity of the Auger analysis. Besides Ga and As, only C and O peaks are seen; oxygen will always disappear with heating. Sulfur is the next most common contaminant seen, but only when the wafer is stored in methanol for several hours. Putting the methanol in a dry nitrogen atmosphere did not eliminate the sulfur contamination. The source of the sulfur is unknown.

Vapor etching was carried out in a vapor reactor designed for the $Ga|AsH_3|HCl$ process (1). The wafer was inserted through an H_2-purged antechamber into the hot zone of a reactor held at temperature. Approximately 3-5 min were required for the wafer to reach the steady-state temperature of 780°C. Then the wafer was etched for 10 min, followed by a 3 min wait before removing the sample. An etch rate of 0.3 μm/min was obtained with flow rates of 4 cm^3/min of a 10% HCl/H_2 mixture plus 1000 cm^3/min of H_2.

A typical Auger spectrum for GaAs {100} substrates just before etching is seen in Fig. 1. (This particular spectrum is from a Sn-doped wafer.) Substrates placed into the hot reactor with only H_2 flowing produce the same spectrum.

Some samples, after receiving the HCl etch, produce a different type of Auger spectrum. Figure 2, taken from a Te-doped sample after etching, shows an essentially unchanged spectrum. The same results are obtained from Si-doped substrates. Only C, O, N, Ga, and As peaks are seen. For Si-doped wafers, at energies above the final As peak, the spectrum is again featureless even when the sensitivity and sweep time are increased by a factor of 5; in particular, at secondary energies between 1500 and 1650 eV, where Si peaks are expected, nothing is seen. Tin-doped samples after etching produced the Auger spectrum seen in Fig. 3. In this case, an accumulation of Sn on the surface is noted.

Although this behavior may seem anomalous at first glance, it is understandable upon examination of the thermodynamic data of the dopants. Looking first at the vapor pressure of the dopants (Table I) at 800°C (2) it is apparent that Te would not be expected to accumulate on the surface because of its high vapor pressure. However, from vapor pressure considerations

alone, Si, not Sn, would be expected to segregate on the surface.

The behavior of Si and Sn becomes clear when the stabilities of their chlorides are taken into consideration. Standard free energies at 800°C for the production of 1 mole of metal chloride were obtained by calculating the standard enthalpy and entropy (3), $\Delta H°_{298}$ and $\Delta S°_{298}$, respectively, for the reaction and then computing the free energy, $\Delta G°_T$, from $\Delta H°_{298} - T\Delta S°_{298}$. Since both $\Delta H°$ and $\Delta S°$ are functions only of the change in heat capacity and of the temperature, a change in one tends to cancel the change in the other, thus not greatly affecting $\Delta G°_T$ (4). Data for the thermochemical computations are from JANAF (5) and NBS (6) tables. From the equilibrium constants for the formation of the divalent and tetravalent chlorides, it is apparent that the equilibrium pressures are always greater for the Si chlorides than for the Sn chlorides (Table II). In the case of tetravalent chlorides for example, P_{SiCl_4}/P_{SnCl_4} is 10^7, assuming the Henry's Law constants for Sn and Si in the solid are the same. If HCl is considered to react with the metal oxides rather than the elemental metal, a stabilization against metal-chloride formation is seen. Since all standard energies of formation are positive, while the entropies of formation of MCl_4 and MCl_2 are negative and positive, respectively.

These observations should help in clarifying the relationship between substrate dopant and I-layer formation when undoped GaAs is grown by vapor epitaxial methods. Wolfe *et al.* (7) have shown that a high-resistance region appears at the undoped GaAs layer/Si-doped GaAs substrate interface when growth takes place in a low As_4-pressure atmosphere. At low arsenic pressures silicon outdiffusing from the substrate will be preferentially incorporated into arsenic sites, hence acting as an acceptor. Since the Ga in any $Ga/AsCl_3/H_2$ reactor requires a short period to resaturate as a result of dissolution and exposure of fresh Ga to the decomposed $AsCl_3$ vapor (8), the initial growth of high purity GaAs is always at low As_4 pressures unless special precautions are taken. These results have been substantiated by the work of Hirao and Nakashima (9) and also Saito and Hasegawa (10) who have shown that a critical pressure of arsenic vapor of about 3 Torr is necessary before I-layer formation is prevented. Of particular relevance are etching experiments (9) performed on Si, Sn, and Te-doped GaAs substrates with an impurity concentration of $\sim 1 \times 10^{18}$ cm^{-3} where high resistance regions were formed in all cases if growth commenced before arsenic saturation was complete. If the Ga was saturated and the substrates vapor etched, high resistance regions were not observed for layers grown on substrates doped with Sn or Te, but a slight dip in carrier concentration was seen for those doped with Si.

During growth, some HCl is always present as a result of incomplete reaction with the GaAs crust. Silicon chlorides can then form at the surface, thereby reducing the number of Si atoms available for the preferred Ga site when the As_4 pressure is high. A region having a lower donor concentration results. Further evidence supporting the idea of silicon chlorides being very stable in a GaAs VPE reactor is shown in another study by Hasegawa and Saito (11) where the final carrier concentrations of films grown from a Si-doped GaAs source or a Si-Ga mixture were always lower than those of the source; values of $N_d + N_A$ for films grown with a Ga-Si or just a Ga source were almost the same.

In the same work (11), Sn-doped layers with a 4-6 $\times 10^{16}$ cm^{-3} carrier concentration deposited on a 2×10^{16} cm^{-3} Sn-doped substrate showed a peak rather than a dip in carrier concentration near the interface. This is consistent with our observation of Sn accumulation on the surface after etching. The reason for the beneficial behavior of Te-doped substrates is not as clear, but is probably related to its totally donor nature and the stability of both GaTe and As_2Te_3.

Complete clarification of the relationship between I-layer formation, HCl etching, As_4 pressure, and substrate doping will require more detailed experiments. From our evidence here, coupled with carrier-concentration profiles (7, 9, 11), substrates doped with Sn appear to be superior to those doped with Si and possibly even to those doped with Te because of Sn accumulation at the surface during etching.

Table I. Vapor pressure of Te, Si, and Sn at 800°C

Current-Controlled Growth and Dopant Modulation in Liquid Phase Epitaxy

M. Kumagawa,[1] A. F. Witt,* M. Lichtensteiger, and H. C. Gatos*

Department of Metallurgy and Materials Science and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A crystal growth method is reported which uses Peltier cooling at the crystal-melt interface (associated with the flow of electric current from seed to solution) to initiate and sustain liquid phase epitaxial growth while the temperature of the over-all growth system is maintained constant.

"Rate striations" (1), which permit the determination of microscopic growth rates and the interface morphology during the growth process, were introduced (through current pulses of short duration) both in regular epitaxial growth obtained by decreasing the temperature of the system and in epitaxial growth induced by Peltier cooling. The width and intensity of these striations can be controlled by the amplitude and duration of the current pulses. Thus current pulses were also used to modulate the growth rate and consequently the dopant concentration.

The method was applied to the growth of InSb layers (doped with tellurium) on InSb substrates from indium and antimony solutions. The apparatus used is shown in Fig. 1. The growth cell is similar in design to those commonly employed (2), however, it permits controlled flow of electric current through the growth interface.

In a growth experiment, seed-solution contact is established after thermal equilibration by appropriately positioning the boron-nitride slide between the seed and the solution.

Representative results with rate striations introduced in epitaxial layers obtained with controlled furnace cooling at a rate of approximately 0.1°C/min and 0.04°C/min respectively, are shown in Fig. 2 and 3. The "rate striations" (revealed by etching) (3) were introduced by current pulses (56 A/cm^2) of 1 sec duration applied at intervals of 17.5 (Fig. 2) and 20 min (Fig. 3) with the first pulse transmitted 11 and 32 min after starting the respective cool-down cycles. These striations delineate unambiguously the morphology of the interface during the growth process and permit the determination of the microscopic growth rate from the known repetition rate of the current pulses and the spacing of the striations.

In the case of Fig. 2, it can be seen that at constant cooling rate, the microscopic growth rate changed

from 1.5 μm/min at the beginning to 0.45 μm/min toward the end of the growth. In the case of Fig. 3, seed-solution contact was established while the temperature of the system was slightly higher than its equilibrium value. Consequently a small fraction of the seed was dissolved and a flat seed solution interface was formed. Upon lowering the temperature (by about 1.2°C) to its equilibrium value (457.0°C), a new irregular interface was formed. It is seen from the morphology of the rate striations that this irregular interface becomes smooth upon initiation of growth and remains smooth throughout the growth process. The rate striations in Fig. 2 and 3 indicate clearly pronounced differences in the microscopic growth behavior with the growth rate going through a minimum in Fig. 2 and decreasing steadily in Fig. 3.

Epitaxial growth achieved by passing electric current across the seed-solution interface at constant furnace temperature is shown in Fig. 4. The unidentified precipitates at the original growth interface, which as can be seen do not interfere with epitaxial growth, are presumed to be the result of inadvertent oxidation during equilibration. The three growth regions B_1, B_2, and B_3 seen in the figure were obtained by passing continuous electric current of 0, 5.5, and 1 A/cm^2, respectively, through the growth interface. In all three regions rate striations were introduced by superimposing current pulses of 0.1 sec duration (100 A/cm^2) at a repetition rate of 0.01, 0.02, and 0.01 sec, respectively. The growth irregularities upon transition from regions B_2 to B_3 (changing interface morphology) are as yet unexplained and are subject to further investigations. It is seen that in the first growth region (B_1) where only intermittent pulses were applied but no "base current" was passed, the growth was very limited. Over a period of 5000 sec, an epitaxial layer of a total thickness of 25 μm was intermittently formed (due to cooling brought about by the pulses) at a net growth rate of 3×10^{-1} μm/min. A base current of 5.5 A/cm^2 for a period of 1200 sec (middle region) led to a layer (B_2) of a total thickness of 1.25 μm at an average growth rate of about 6 μm/min. It should be noted that in this region the growth rate during the superposition of each pulse was about 4000 μm/min (as determined from the width of the rate striations associated with the 0.1 sec pulse duration), *i.e.*, about 670 times greater than the average growth rate. The epitaxial region obtained at a base current density of 1 A/cm^2 (B_3 in Fig. 4) grew at an average rate of 3 μm/min; during the superposition of the pulses the rate was approximately 1500 μm/min.

In the region grown at a base current of 5.5 A/cm^2 the rate striations resulting from the pulses appear as bands rather than lines. This result reflects a high growth rate induced by the base current which is further increased by a factor of close to 700 for the duration of each high current density pulse. This sudden increase in growth rate should lead to a substantial increase in dopant concentration, which in turn is expected to be attenuated within the duration of the pulse, because of boundary layer depletion. Such a segregation behavior is indeed observed through the etching characteristics of the bands (4) which reveal pronounced concentration increases at their lower edge (beginning of pulse) and gradual transitions on their upper edge (termination of pulse). Thus, controlled modulation of chemical composition may be achieved by the appropriate choice of pulse shape and duration.

It is shown that Peltier cooling associated with current flow across the growth interface can be successfully used to achieve controlled crystal growth. Superimposed current pulses can serve for the introduction of rate striations as well as for localized modulation of dopant segregation.

Resistivity Characterization of Semiconductor Crystal Ingots

F. Padovani* and G. Valant

Texas Instruments Incorporated, Dallas, Texas 75222

The resistivity characterization of semiconductor crystal ingots is an important step in the manufacture of slabs or slices suitable for device manufacture. Such characterization is usually performed by a two-point probe or four-point probe measurement on the ingot surface. Such resistivity measurements are usually found not to be in agreement with each other and with subsequent measurements performed on slices obtained from the ingot. It is the purpose of the present work to demonstrate that four-point probe and two-point probe measurements performed at the same location on an ingot surface, can be used to estimate more accurately the resistivity profile of the ingot than either of the measurements independently. The presence of a radial resistivity gradient is first shown to affect the resistivity derived from a two-point probe resistivity measurement and hence to be a reason for discrepancy between two-point probe and four-point probe resistivity measurements. Correction factors to the two-point probe resistivity measurement are then calculated for two different radial resistivity profiles. Finally, it is shown that, assuming a given radial resistivity profile, combined two-point probe and four-point probe resistivity measurements can be used to evaluate the axial resistivity of the semiconductor ingot but cannot be used to deduce the local radial resistivity gradient.

Influence of a Radial Resistivity Gradient on Two-Point Probe Resistivity Measurement

Let us consider a two-point probe resistivity measurement arrangement as shown in Fig. 1. The crystal ingot will be assumed to have a uniform diameter $2R$, a uniform resistivity along the crystal axis, and a radial gradient with cylindrical symmetry. It will be further assumed that current is supplied to the crystal at two equipotential planes normal to the cylinder axis and located at distance from the probes much larger than the crystal diameter. Under these assumptions the equipotential surfaces in the crystal will be planes normal to the crystal axis and the crystal electrical properties can be described by an infinite number of concentric cylinders of resistivity, $\rho(r)$, thickness, dr, and cross-sectional area, $2\pi rdr$. If V is the potential existing between two probes separated by a distance, l, the current density, i, flowing in a cylinder of radius, r, will be

$$i = v/\rho(r)l \qquad [1]$$

where $\rho(r)$ is the resistivity of the cylinder considered. The total current, I, flowing in the crystal is

$$I = \int_0^R 2\pi irdr \qquad [2]$$

Hence, by combining Eq. [1] and [2] it is clear that

$$v/I = l/2\pi \left[\int_0^R \frac{rdr}{\rho(r)} \right]^{-1} \qquad [3]$$

Since the resistivity ρ_2 derived from a two-point probe measurement is equal to

$$\rho_2 = \pi R^2 v/Il \qquad [4]$$

we conclude that ρ_2 is equal to

$$\rho_2 = R^2 \left[2 \int_0^R \frac{rdr}{\rho(r)} \right]^{-1} \qquad [5]$$

It thus appears that the resistivity of an ingot as deduced from two-point probe resistivity measurements can be significantly affected by the radial resistivity profile of the ingot. This might explain the often encountered discrepancies occurring between resistivity measurements performed at the same location of an ingot surface by the four-point probe and the two-point probe techniques. Most four-point probe systems use a probe spacing of 40 mils and therefore the resistivity deduced from such a technique will reflect the ingot surface resistivity provided that the crystal diameter is very large compared to 40 mils. If one denotes by ρ_4 the resistivity deduced from such a four-point probe resistivity measurement, one can write that

$$\rho_4 = \rho(R) \qquad [6]$$

and thus in general

$$\rho_4 \neq \rho_2 \qquad [7]$$

We will now show that Eq. [6] and [5] can be used to estimate both the resistivity of an ingot along its axis and the radial resistivity gradient.

A Technique for Estimating Ingot Axial Resistivity and Radial Resistivity Gradient

As noted in the preceding section, four-point probe measurements and two-point probe measurements performed at the same location on an ingot surface will generally disagree as a result of the radial, nonuniformity of the ingot resistivity. The purpose of this section is to demonstrate that this difference in deduced resistivity can be used to more accurately characterize the ingot provided one has a knowledge of the functional dependence of the radial resistivity profile. This knowledge is required, as demonstrated by Eq. [5], if one desires to relate the resistivity deduced from a two-point probe resistivity measurement to the resistivity at a given point of the crystal radius.

Most semiconductor crystals produced today exhibit small (0-30%), uniform radial resistivity profiles. As a result, a semiconductor slice resistivity is usually characterized by the resistivity at the center of the slice and an average radial resistivity gradient (1). Let us assume thus that through experience one has gathered information on the functional dependence of the radial resistivity gradient and that although the magnitude of this gradient may vary from crystal to crystal its functional dependence is fairly constant. This is a good assumption since the radial resistivity gradient is a representation of the growth conditions which should be fairly reproducible for a given crystal growth apparatus.

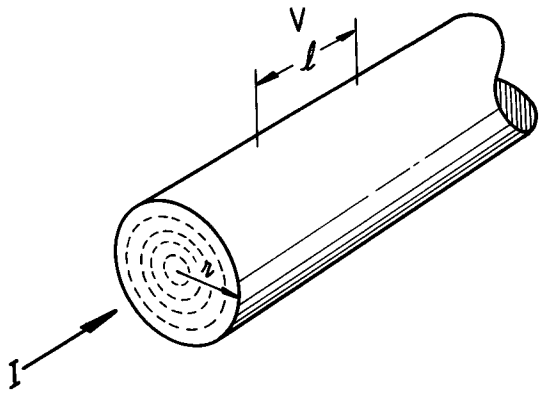

Fig. 1. Two-point probe resistivity measurement

* Electrochemical Society Active Member.

Key words: ingot radial resistivity gradient.

Through experience it has been found in our laboratory that two types of functional dependence of the radial resistivity profiles are usually encountered: the linear and the quadratic profiles. These two simple radial resistivity distributions will be used to illustrate the proposed technique.

Linear profile.—In this case, it is assumed that, if ρ_o is the axial resistivity, the resistivity of the ingot at a distance, r, from its axis is given by

$$\rho(r) = \rho_o + ar \qquad [8]$$

combining Eq. [8] and [5] yields

$$\rho_2 = \frac{a^2R^2}{2}\left[aR - \rho_o \ln\left(1 + \frac{aR}{\rho_o}\right)\right]^{-1} \qquad [9]$$

and, since $\rho_4 = \rho_o + aR$, we have

$$\frac{\rho_4}{\rho_2} = 2(1 + x)[x - \ln(1 + x)]/x^2 \qquad [10]$$

and

$$\rho_o = \rho_4/(1 + x) \qquad [11]$$

where $x = aR/\rho_o$ is the radial resistivity gradient. Equations [10] and [11] demonstrate that four-point probe and two-point probe resistivity measurements performed at the same location on a crystal ingot surface can be used to estimate the resistivity of the ingot axis as well as the radial resistivity gradient. Figure 2 shows a plot of the resistivity gradient x *vs.* the ratio ρ_4/ρ_2 as given by Eq. [10].

Quadratic profile.—In this case it is assumed that, if ρ_o is the axial resistivity, the ingot resistivity at a distance, r, from its axis is given by

$$\rho(r) = \rho_o + ar^2 \qquad [12]$$

Following the above treatment one deduces that

$$\rho_4/\rho_2 = \frac{(1 + x)}{x}\ln(1 + x) \qquad [13]$$

and that ρ_o is given again by Eq. [11]. Figure 2 also shows a plot of the resistivity gradient x *vs.* the ratio ρ_4/ρ_2 as given by Eq. [13]. Note that in this particular case the gradient n is equal to a R^2/ρ_o.

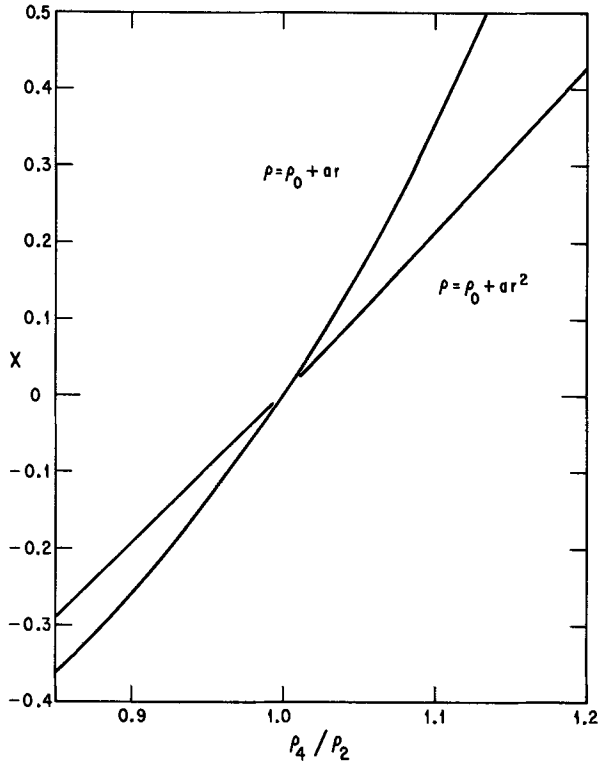

Fig. 2. Variation of the ratio ρ_4/ρ_2 *vs.* radial resistivity gradient x

Examination of Eq. [10], [11], and [13] reveals that, provided a radial resistivity profile is assumed, the radial resistivity gradient, x, and the axial resistivity profile, ρ_o, can be determined from simultaneous two-point probe and four-point probe resistivity measurements performed on the ingot surface. In practice, provided a set of measurements ρ_4 and ρ_2 one would first evaluate the radial gradient x by use of appropriate curve shown on Fig. 2. Having done so, one would subsequently use Eq. [11] to determine the axial resistivity.

An estimate of the errors encountered in the determination of the axial resistivity and of the radial resistivity profile can be obtained through an error calculation performed on Eq. [10], [11], and [13]. It can readily be shown that the relative error existing on the value of the axial resistivity is equal to the relative error existing on either the four-point probe or two-point probe resistivity measurements provided that these two relative errors are equal. As evidenced by Ref. (1) this is a good approximation.

Similar error calculations can be performed to obtain the relative error on the deduced radial resistivity gradient. Figure 3 shows the results of such calculations for both types of radial resistivity profiles previously considered, when the total relative error resulting from the two-point probe and four-point probe resistivity measurements is taken to be equal to 10% (1). Note that the proposed technique does not offer a great deal of accuracy toward the determination of the ingot radial resistivity gradient. Typical silicon crystals for example may exhibit a radial resistivity gradient of up to 30%. The proposed technique will only enable a one to 200% accuracy in the determination of the radial resistivity gradient of such crystals.

Experimental Verification of the Technique

In order to verify the applicability of this technique, silicon crystals were grown in the laboratory. These

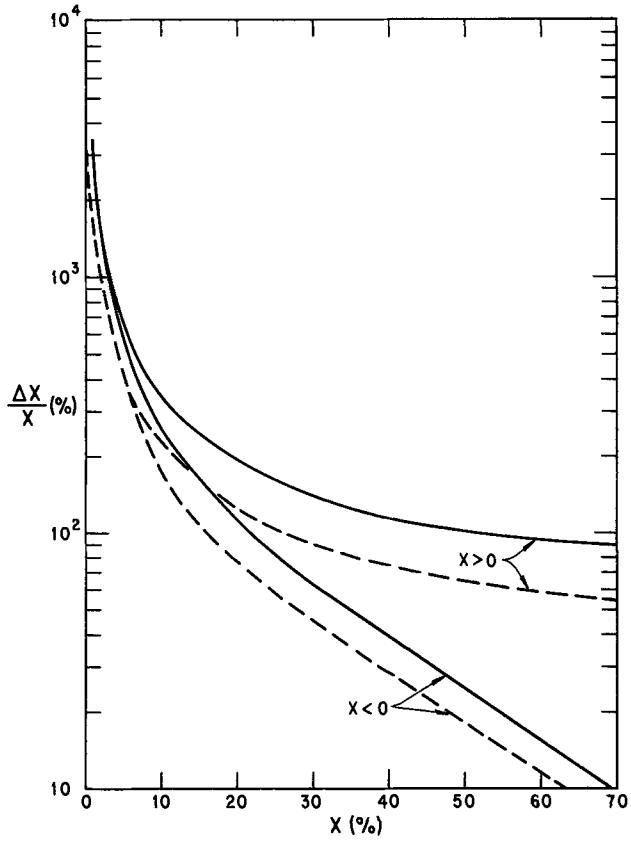

Fig. 3. Relative error on the deduced resistivity gradient *vs.* deduced resistivity gradient. Solid line is for a linear profile and dashed line for a quadratic profile.

crystals were grown using the Czochralski method from a 4 kg charge and had a nominal diameter of 2.25 in. Pull rate was maintained at one thousand of an inch per second during the whole growth. These crystals prior to resistivity characterization were centerless ground to 2 in. diameter to insure that diameter fluctuations would not give rise to erroneous readings. The crystals were subsequently heat-treated to dissolve oxygen donors and stabilize the resistivity. Two-point probe and four-point probe resistivity measurements were subsequently performed along the ingot axis at well-defined locations. Slices 20 mils in thickness were subsequently obtained at these locations and their resistivities characterized using a four-point probe technique. The various resistivities obtained from these measurements are shown on Fig. 4 for a typical crystal together with the values deduced from the four-point and two-point probe resistivity measurements by assuming a linear or quadratic functional dependence of the radial resistivity profile. Note that, assuming a linear resistivity profile, the resistivity along the crystal axis can be found to corrolate reasonably well with the resistivity subsequently measured at the center of the slices: namely both set of data points are within ±5% of each other.

The radial resistivity gradient deduced from these measurements is compared on Fig. 5 with the resistivity gradient subsequently measured on slices. Note there, as predicted, the agreement between any two sets of data points is poor. This technique should certainly not be used to estimate the magnitude of the radial resistivity gradient.

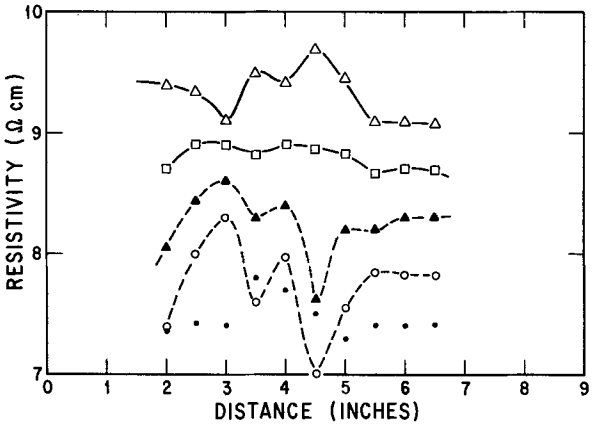

Fig. 4. Comparison of resistivity data obtained on an experimental crystal. Data designated by △ represent measurements performed along the ingot surface using a colinear four-point probe. Data designated by □ represent measurements performed along the ingot surface using a two-point probe. Axial resistivities deduced from the two above measurements by assuming a linear radial resistivity profile are represented by ○ while resistivity deduced under the assumption of a quadratic radial resistivity profile are denoted by ▲. Resistivities measured at the center of slices cut from the ingot are denoted by ●.

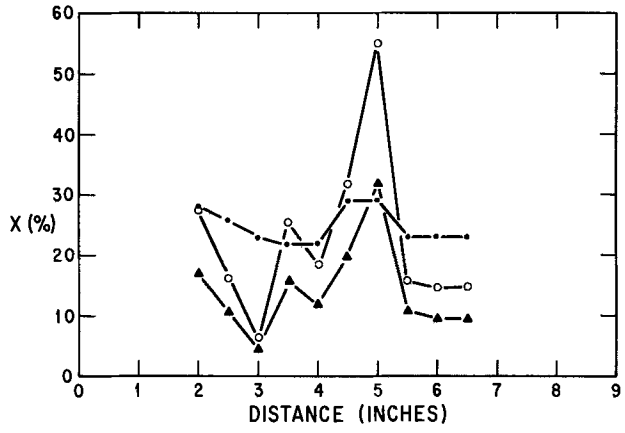

Fig. 5. Radial resistivity gradient vs. distance. The ● indicate values measured on slices; the ○ indicate values deduced assuming a linear profile, the ▲ indicate values deduced assuming a quadratic profile.

Conclusion

The influence of a radial resistivity gradient on two-point probe resistivity measurements along a semiconductor crystal ingot has been considered. The relationship existing between two-point probe resistivity measurements, four-point probe resistivity measurements, and radial resistivity variation was derived in the case of two typical resistivity profiles. Finally, an empirical technique was proposed to evaluate the resistivity gradient as well as the axial resistivity of an ingot. This technique was finally used to characterize an experimental crystal. It was found that for the particular crystal considered use of a linear resistivity profile gave results for the crystal axis resistivity within at most 8.5% of the value measured on subsequently cut slices. This type of agreement can be considered as quite acceptable in view of the fact that four-point probe and two-point probe resistivity measurement techniques have a basic accuracy of ±5% (1). Finally, it was shown that, although the proposed technique results in a good determination of the ingot axial resistivity, this technique should not be used to evaluate the radial resistivity gradient of an ingot because of its inherent inaccuracy.

Brief Communications

Growth of Low Strain GaP by Liquid-Encapsulation, Vertical-Gradient Freeze Technique

S. E. Blum* and R. J. Chicotka

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Liquid-encapsulated Czochralski crystal pulling (LEC) was first described by Metz *et al.* (1) in 1962. In 1967 Bass *et al.* (2) showed how this technique can be used for the growth of single crystal gallium phosphide. Since then several manufacturers have been marketing high pressure Czochralski pullers able to withstand the pressures (>35 atmospheres) and temperatures (~1500°C) required for the single crystal growth of this compound, and growth in these pullers has become the "standard" means for preparing single crystal GaP. The experimental procedures of LEC growth have been described adequately by Bass and Oliver (2) and Nygren *et al.* (3).

With the increasing interest in devices made from GaP, most especially light-emitting diodes, there is a trend to produce larger diameter crystals for the obvious advantage these could offer the manufacturing process. However, the LEC growth of GaP invariably produces crystals that: (*i*) are highly strained, (*ii*) have high dislocation densities (10^4-10^6/cm^2), (*iii*) are somewhat difficult to grow with a uniform diameter, (*iv*) exhibit growth striae, and (*v*) require relatively close attention during the growth cycle. When large diameter (~35 mm) crystals are grown most of the above problems are even more severe. These difficulties were described recently by Nygren (4) who showed that a knowledge of the complex thermal properties of the high pressure ambient-GaP melt-B_2O_3 encapsulant system must be combined with a knowledge of the cooling processes that are normally found in the Czochralski growth system in order to successfully design a system for the growth of large crystals of controlled diameter. Crystals so grown will still exhibit strain and will have dislocation densities in the interior of the ingot of 10^4-10^5/cm^2.

We have developed and tested a technique that has produced GaP single crystals that: (*i*) can be grown with virtually no attention during the growth period, (*ii*) are uniform in diameter, (*iii*) are significantly less strained than the conventional LEC grown GaP, (*iv*) have dislocation densities that are ~10^3/cm^2, *i.e.*, one to three orders of magnitude less than LEC grown GaP, and (*v*) exhibit no growth striae. The technique we have used is a combination of the principles of liquid-encapsulation and vertical-gradient freezing. The entire apparatus can be enclosed in a relatively simple pressure vessel. The vessel should be sufficiently sturdy to contain an operating pressure of about 1000 psi of neutral gas and be fitted with the appropriate rf and thermocouple feedthroughs. A schematic representation of the apparatus we used is shown in Fig. 1. The gallium phosphide polycrystalline ingot we used was obtained by a synthesis method previously described by us (5). The ingot along with the boric oxide encapsulant and a single crystal GaP seed is placed within a boralloy (pyrolytic boron nitride) crucible as shown in Fig. 1. The crucible is positioned within the susceptor and the system is closed, evacuated to remove the air, and backfilled to 900 psi of nitrogen. The susceptor is heated by 500 kHz rf and the temperature within the susceptor is monitored by thermocouple (TC1) and controlled by a conventional L&N-CAT control system. The temperature at the ingot-seed interface is brought to a few degrees above the GaP melting point in order to effect wetting of the seed crystal. The temperature at the top of the melt, at the B_2O_3-melt interface (TC2), is approximately 50°-100°C above the melting temperature. Freezing of the melt is obtained by slowly lowering the control temperature (TC1) until the top of the melt (TC2) is below the GaP melting point. The system is then cooled slowly to room temperature. Typically the crystal is grown at about 1 in./hr and the solidified ingot cooled to room temperature in about 1 hr. This method has produced a crystal that is virtually strain free. A transmission micrograph of a polished-liquid encapsulation, vertical-gradient freeze (LE-VGF) wafer taken between crossed Nicol prisms is shown in Fig. 2 with two conventionally grown LEC wafers for comparison. In addition, a transmission micrograph of a wafer cut parallel to the growth direction shows the crystal to be striae free. LEC crystals always exhibit striae whose spacings obey the f/ω relationship.

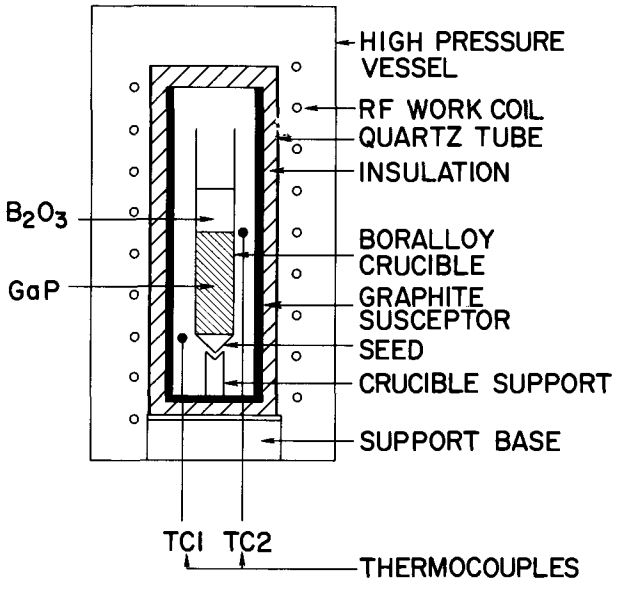

Fig. 1. A schematic representation of the apparatus used to grow single crystal gallium phosphide by the liquid-encapsulation, vertical gradient, freeze technique (LE-VGF).

* Electrochemical Society Active Member.

Key words: gallium phosphide, crystal growth, low strain crystals, light-emitting diodes, liquid encapsulation.

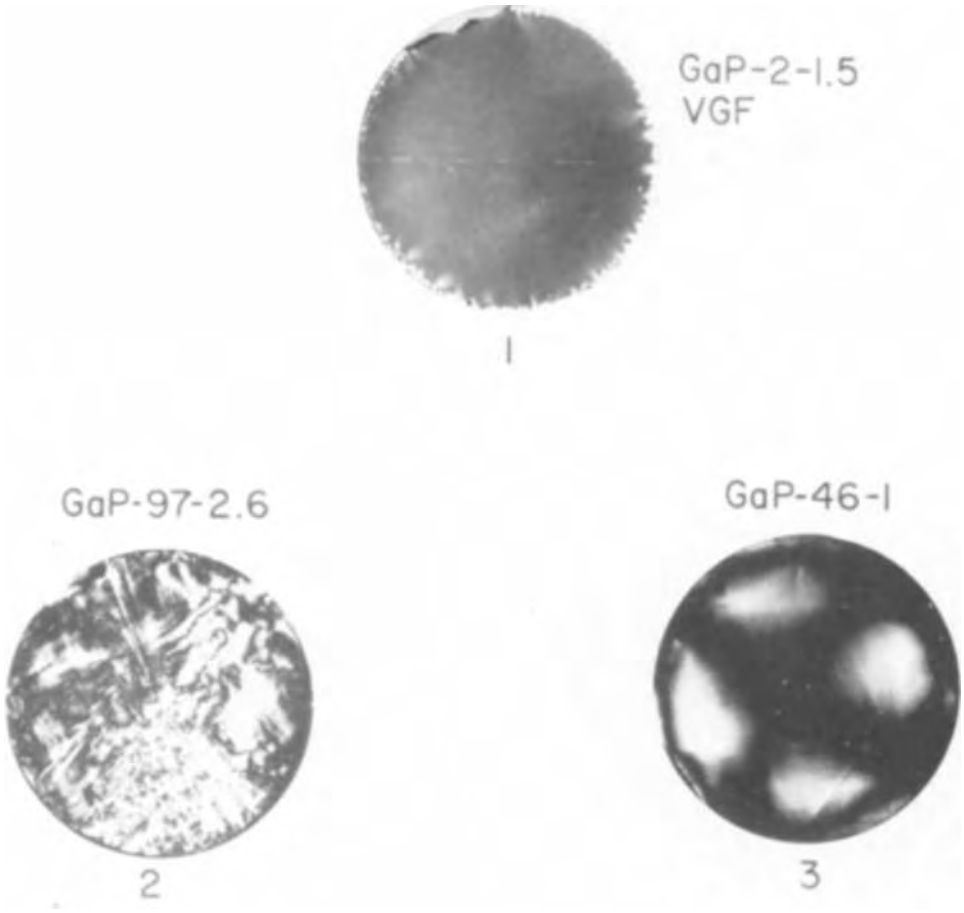

Fig. 2. Transmission micrographs taken between crossed Nicol prisms. The samples are transverse cuts of 1, 1.5 cm diameter crystal grown by LE-VGF, 2, and 3, 1.1 cm and 1.5 cm in diameter crystals, respectively, grown by conventional LEC.

The dislocation density of crystals grown by the LE-FGF technique and by conventional LEC were obtained by etching polished <111> wafers with the ferricyanide-KOH-H_2O etch (3). Dislocation densities of about $10^3/cm^2$ were obtained in the LE-VGF crystal and $>10^4/cm^2$ in LEC crystals.

Crystals grown by the LE-VGF technique are appreciably less strained, lower in dislocation density, excellent in diameter control, and easier to grow than the conventional LEC GaP.

Manuscript received Nov. 2, 1972.

Use of Sirtl Etch for Silicon-Slice Evaluation

W. A. Porter, A. Gupta, and D. L. Swindle

Electrical Engineering Department and Activation Analysis Research Laboratory, Texas A & M University, College Station, Texas 77843

In recent years research on the influence of crystallographic defects on devices has been done to establish that yield problems are definitely related to material defects, and the importance of having defect-free starting material has been recognized by many researchers (1-3). The advent of LSI has given added importance to obtaining high quality starting material because of the inherent larger chip sizes and shallower base widths associated with LSI arrays. Gupta and Lathrop (4) have recently discussed this problem. As devices and their geometries become more complicated, the importance of having a nondestructive technique for evaluating silicon starting material, before device processing is begun, cannot be overemphasized. Some of the more common nondestructive techniques for evaluating silicon are x-ray diffraction, infrared spectrometry, and electron microscopy. In general, these techniques are unsuitable during mass production because of the time and expense associated with their use. This note describes the results of an investigation into the possibility of using Sirtl etch as a "nondestructive" evaluation step for categorizing silicon wafers before device fabrication is begun. It is known that chromium is deposited as a residue during the chemical reaction associated with etching silicon in Sirtl etch (5, 6). The detection of chromium as a cation contamination has been explained as due to either an irreversible electro-

Key words: crystal defects, surface damage, defect measurement.

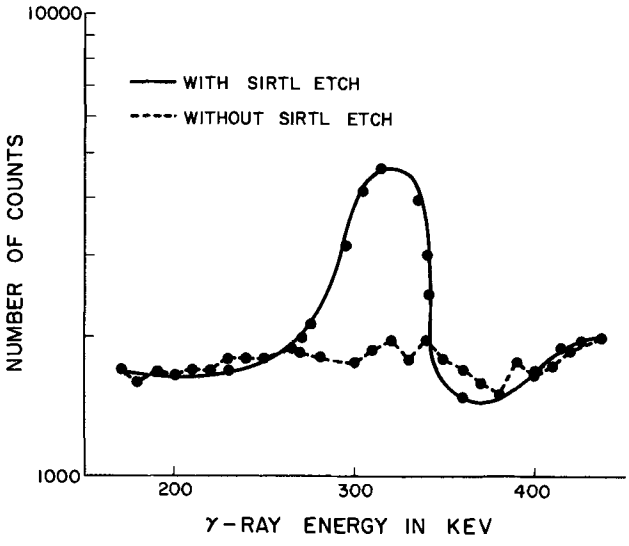

Fig. 1. Chromium content on silicon slice

chemical reaction at the silicon-liquid interface, or by reversible physical absorption (6). Contrary to the usual concern about the use of Sirtl etch resulting in chromium diffusing into the silicon slice during subsequent high-temperature processing steps, this note reveals that the residual chromium resides only on the surface of the slice and can easily be removed.

Experimental

Chemically polished silicon slices grown in the [111] direction were Sirtl etched for varying time periods. The amount of residual chromium on the slice after etching was determined by using neutron activation analysis. Gamma-ray spectrometry was used to detect the 320 keV γ-rays emitted by radioactive Cr^{51} produced by neutron bombardment.

Results

The 1 in. diameter silicon slices initially had less than 10^{12} atoms of chromium. After Sirtl etching, the total number of chromium atoms on the slice was 4×10^{16}. This indicated that chromium is deposited on the slice surface during Sirtl etching. Figure 1 shows a comparison γ-ray spectrum of two irradiated silicon slices; only one slice was Sirtl etched while the other was also subjected to irradiation and counting to establish any chromium background.

The slices were subsequently given various treatments to remove the chromium. Both the standard slice-cleaning procedure of hot (water-nitric-water cycle) and an aqueous solution of saturated KOH and 30% H_2O_2 in equal volumes, were sufficient to remove all the chromium deposited during Sirtl etching. Hence, the residual chromium is easily removed from the silicon surface. It was also found that it is sufficient to Sirtl etch for only 2 min to reveal all the defects on the slice. Surface defects are revealed with a much shorter etch time. In order to record the presence of both surface and bulk defects the wafer should be etched in 15 sec intervals and inspected at each interval (7).

It has been found during this investigation that wafers that are Sirtl etched from both sides result in low yields when MOS devices are subsequently fabricated. On the other hand, wafers that are Sirtl etched from the backside only have been successfully used to repeatably build standard yield MOS devices. Apparently, when the silicon wafer is etched from the front side the general flatness of the material is not maintained and the resulting fabrication problems associated with bowed wafers reduce the yields (8).

The use of Sirtl etch from the backside only has not yet been proven to be a definitive technique of identifying the starting quality of the wafer. However, the ability to fabricate devices with good yields on silicon material that has been Sirtl etched renders the possibility of using Sirtl etch as a "nondestructive" evaluation technique more feasible than it is generally accepted to be. Nondestructive here is used in the sense that operational semiconductor devices can still be fabricated on the material after etching. Thus, it has been shown that chromium impurities can be successfully removed, and operational MOS devices with standard yields fabricated, after the silicon material is exposed to the chromium atoms during a chemical-etch evaluation.

Chlorine—Caustic Soda

I. Production.—U.S. chlorine output declined in 1971 for the first time in 10 years. 1971 production was 9,308,500 tons, down 4.2% from 1970, the highest year on record. This total does not include production from a major new plant that went into production in Puerto Rico during 1971. Canadian production was 860,900 tons, up about 1% from 1970 (1).

At the year's end, production rates were increasing. U.S. operations dipped to 84.9% of capacity in May and increased over 92.2% in November and December. The average operating rate was about 87.9%. In Canada, operations rose from a low of 82.8% in May to a high of 91.4% in September. In the United States, new capacity offset shutdowns during the year and as of December 1, 1971, capacity was 29,005 tons/day, essentially unchanged from 1970. Canadian capacity increased 5% to 2,769 tons (1).

The high demand for caustic continued for the second year. As a result, caustic prices, which were being discounted in 1970 from $66/ton for 50% caustic, were firm at $71-$76/ton ($81/ton west of the Rockies). Chlorine which is "loose" is continuing at $75/ton with probable discounting (6, 9, 10, 11, 14).

PPG Industries provides the following breakdown of recent caustic sales, which is close to the industry total: chemical process industries, 45%; aluminum and petroleum, 19%; pulp and paper, 15%; soaps and detergents, 5%; textiles, 1%; and miscellaneous and export, 14% (5).

The drop in chlorine demand is due to the slump in its major market areas; chlorinated hydrocarbons such as vinyl chlorides, PVC and chlorinated solvents, chlorinated pesticides, and paper (5-7).

The drop in chlorine demand, together with plant shutdowns and a lagging economy were held responsible for the caustic shortage, rather than any radical growth in demand for any of caustics applications. Some producers disagree and feel users who switched from other sources of alkalinity will not switch back (18). The use of caustic soda to replace soda ash is occurring in the glass and alumina processing industries (19).

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.
The material presented herein has been gathered from many sources, as noted in the references, and does not necessarily represent the opinions of the authors.

II. Shutdowns and Expansions (2-5, 8, 12, 20)

Company and Location	Type of Cell	Capacity tons/day	Completion date
A. Shutdown			
BASF Wyandotte Wyandotte, Mich.	Mercury	150	March 1971
American Magnesium Corp. Snyder, Texas	Magnesium	175	July 1971 (temporary for alterations)
Sobin Chemicals, Inc. Niagara Falls, N. Y.	All Cl_2 production	40	February 1972
Olin Corp. Saltville, Va.	All Cl_2 production	300	March 1972
Dow Chemical of Canada Sarnia, Ontario	All Hg cell Cl_2 production	700	Early 1973
GAF Corp. Linden, N. J.	Mercury	235	October 1971
BASF Wyandotte Geismar, La.	Mercury	150	1973
B. Production Started			
Hooker Chemical Corp. Taft, La.	Hooker S4 Diaphragm	120	Partial 2nd Quarter 1971, Balance 2nd half 1971 conversion to DSA
Dow Chemical Co. Freeport, Texas	Dow Diaphragm	—	1971 Expansion
PPG Industries Guayaville, Puerto Rico	DeNora Mercury	500	2nd Quarter 1971
Dow Chemical Co. Midland, Mich.	Dow Diaphragm	—	1971-1972 Modernization
Standard Chemical Ltd. Beauharnois, Quebec	Uhde Mercury	220	February 1971
Hooker Chemical Co. Montague, Mich.	Hooker S3B Diaphragm	220	1971-1972 Conversion to DSA plus expansion
Hooker Chemical Co. Nanimo, B.C.	Hooker Diaphragm	100	1971-1972 Conversion S4 to H2 at higher load
Hooker Chemical Co. North Vancouver, B.C.	Hooker Diaphragm	500	1971-1972 Conversion to DSA plus expansion
C. Building or Planned			
NL Industries, Inc. Grantsville, Utah	BASF Magnesium	45,000 T/yr Magnesium 80,000 T/yr Cl_2	Early 1972
PPG Industries Lake Charles, La.	PPG-DeNora Bipolar	1,500	Not Announced
Hooker Chemical Corp. Niagara Falls, N. Y.	Hooker Diaphragm	1,000	1973-1976 Modernization

BASF Wyandotte Corp. Geismar, La.	Diamond Diaphragm	Two plants 350 each	Modernization
Dow Chemical of Canada. Ltd. Sarnia, Ontario	Convert Mercury to Diaphragm	700	Early 1973
Vulcan Materials Co. Wichita, Kan.	Hooker Diaphragm	275	Convert to DSA May 1972
Diamond-Shamrock Deer Park, Texas	Diaphragm	—	Convert to DSA
Dow Chemical Co. Dallesport, Wash.	Dow Magnesium	24,000 T/yr Magnesium 50,000 T/yr Cl_2	1st Quarter 1975

III. Developments.—A. Metals anodes.—Metal Anode Associates, a joint venture of Union Carbide Corporation and Engelhard Minerals and Chemical Corporation announced withdrawal from metal anode field in December 1971 (17).

A new titanium anode for chlorine cells has been jointly developed by Olin and ICI's Imperial Metal Industries, Limited (Birmingham, England). Olin will install the first commercial system at Augusta, Georgia. The anodes are made from titanium, utilizing advanced technology in titanium fabrication and surface-coating techniques, and will be used with the new Olin anode adjuster (18).

Electrode Corporation reports that 50% of the North American mercury-cell capacity has expanded capacity using the higher current densities available with Dimensionally Stable Anodes with (DSA^r). DeNora, Uhde, Solovay, and Olin mercury cells of various sizes are satisfactorily operating with DSA in 18 mercury cellrooms using sodium and potassium salts. Electrode Corporation's new DSA's account for 3 million tons chlorine capacity/yr, or 30% of U.S. chlorine capacity (13).

DSA installations in diaphragm cells are expanding rapidly through the association between Electrode Corporation and Hooker Chemical Corporation. Hooker has North American rights for conversion of Hooker Diaphragm cells. Using DSA's in diaphragm cells results in savings in power and labor because of less frequent maintenance, longer diaphragm life, and better cell efficiency.

Modern mercury cells generally operate at currents from 100,000-300,000A. Diaphragm cells with graphite anodes operate to 60,000A. The first diaphragm cells using DSA's operated at 70,000-80,000A (20).

DSA's are being supplied to a number of companies developing new design of chlorine cells. Commercial tests are being evaluated to use DSA's for chlorate, hypochlorite, copper, and nickel production (13).

B. New cell designs.—The environmental problem with mercury has resulted in the development and perfection of new types of diaphragm cells. Hooker Chemical Corporation has developed a new H-2 diaphragm cell using DSA's. The new cell operates at 90,000A and test cells have been operated at 150,000A (20).

The new bipolar cell announced in 1970 and developed jointly between PPG Industries and DeNora has been named the Glanor V cell. After successful testing, it is available in two sizes; 11/22 rated at 36 kA and 11/44 rated at 72 kA (15).

Other cells offered with metal anodes include the Diamond-Shamrock, Elcinore Cell and two from Japan manufactured by Showa Denko and Nippon Soda (21).

C. New hypochlorite cell.—Four companies have developed cells to produce sodium hypochlorite using sea water as cell feed instead of brine. New York City is planning to test 3 systems to disinfect effluents from the city's sewage treatment plants: (*i*) the Pepchlor unit made by Pacific Engineering and Production Company of Henderson, Nevada; (*ii*) the Sea-cell manufactured by A. Johnson and Co., Limited, of London, England, and marketed by Parkson Corporation, Fort Lauderdale, Florida; and (*iii*) the Sanilec cell made by Diamond-Shamrock Corporation, Cleveland, Ohio.

Estimates for production from the new units range from 3-5.5¢/lb for hypochlorite compared to 13¢/lb at present market price (16).

Sodium hypochlorite, generated on site, will be used as a bacterecide at the Department of the Interior's desalting plant at Wrightsville Beach, North Carolina. Engelhard Minerals and Chemicals will install one of is chloropoc plants at Wrightsville (22).

D. Mercury.—The widespread publicity given to mercury in the environment, and the health hazards of mercury in 1970 continued in 1971. Mercury cell chlor-alkali producers, in an incredibly short period of time, found ways and means to reduce the mercury content of plant wastes. These programs were continued and perfected in 1971. These programs cost money. The problem of removing past accumulation of mercury from the beds of downstream lakes and rivers of these plants is difficult, or in some cases impossible, to solve. The result is that many mercury cell plants have been, or are being, closed (21).

Proposed air-emission standards for mercury were published in the December 7, 1971 Federal Register by the Environmental Protection Agency. The standard requires mercury cell chlorine plants and primary mercury plants to limit emissions to a maximum of 5 lb of mercury over a 24 hr period (23).

The 1971 consumption of mercury was estimated at 54,000 flasks, a decline of 12% from 1970. The largest decreases from 1970 were in agriculture, catalysts, electrolytic chlorine production, and industrial instruments. The use of mercury for gold production ceased, and the use of mercurial slimicides in the pulp and paper industry was negligible. Gains were registered for paint and electrical apparatus.

U. S. production of mercury in 1971 was the lowest since 1964. Eighteen thousand flasks were produced from about 60 mines compared to 27,303 from 79 mines in 1970. By the end of the year only about 30 mines were active. About 16,000 flasks of mercury became available due to the closing of several mercury-cell chlorine plants and releases by the General Services Administration. California produced 73% of the mercury, Nevada 7%, with the remainder from Alaska, Arkansas, Idaho, Oregon, and Texas.

Imports were up to 27,000 flasks compared to 21,672 in 1970. Canada supplied 60%, Mexico 15%, Spain 13%, Turkey 5%, and Italy less than 1%.

The GSA exported 5,700 flasks of mercury to India under programs of the Agency for International Development.

The average New York price was estimated at $295/flask compared to $407.77 last year. Year end prices were in the $250-$260/flask range.

Other Alkalis and Electrolytic Processes

Caustic potash.—Caustic potash production in 1971 was 186,819 tons, up 7% over 1970 production (24).

PPG Industries, Incorporated announced in December that they had converted their 8,000 ton/yr liquid caustic-potash facilities at Natrium, West Virginia to produce liquid caustic soda. The company will continue to produce both liquid and flake caustic potash at Corpus Christi, Texas (25).

Under terms of a proposed agreement between Hooker Chemical Corporation and Sobin Chemical Company, the mercury-cell unit at Hooker's Niagara Falls plant will continue in operation producing chlorine and caustic potash (28). Sobin plans to shut down its Niagara Falls plant, with a caustic potash capacity of 23,000 tons/yr, in February 1972 (3). The Hooker facility has a 36,000 tons/yr capacity.

In May, Sobin Chemicals initiated a price increase for caustic potash from west coast terminals to $7/cwt. for 50% liquid, FOB terminal, while others posted $6.70 and $6.77 (26). On July 5, all producers were at $7.00 (27)

Soda ash.—Production of natural sodium carbonate in 1971 totaled 2.8 million short tons valued at $62.5

million, an increase of over 7% in quantity and nearly 11% in value over 1970, according to the Bureau of Mines. The trona mines of Wyoming supplied a major portion of the output, and the remainder came from dry lake beds in California (29). Synthetic soda ash production in 1971 was 4.3 million tons, down 3.2% from 1970. Production included 1,829,769 tons synthetic, light, and 2,337,037 tons, dense (30).

About half of the total sodium carbonate produced in the U. S. goes to the manufacture of glass, 40% to the manufacture of other chemicals, and 8% to the processing of wood pulp into paper. About 4-6% of production is exported (29). Some replacement of soda ash by caustic soda is occurring in the glass and alumina processing industries (31).

Year end soda ash prices were quoted at $2.35/100 lb for light, and $2.40-$2.45/100 lb for the dense. Bulk soda ash in carlots was quoted at $1.65/100 lb for light, and $1.65-$1.80/100 lb for dense (29). However, increases of $2.50/ton for light and dense soda ash have been proposed, but must be approved by federal officials under the terms of the price freeze ruling in the U. S. (32).

Hooker Chemical's $20 million plant at Searles Lake, California will use a new solar evaporation process to produce borax, soda ash, and potassium sulfate from mineral deposits in the area (33).

Allied's Green River, Wyoming soda ash plant is undergoing a 550,000 tons/yr expansion which will boost Green River's annual capacity to about 4.2 million tons by early 1973. This represents an increase of roughly 50% in total U. S. capacity for natural soda ash (34).

Olin Mathieson has closed down its Solvay process soda ash plant (300,000 tons/yr) at Saltville, Virginia as a result of state legislation reducing permissible effluent chloride levels The availability of cheap soda ash in the United States apparently made it uneconomical to modify the plant to reduce chloride levels (35). This was apparently the reason for PPG's decision to shut down its Barberton, Ohio, Solvay system soda ash facility (36).

Sodium chlorate.—U. S. production of sodium chlorate in 1971 was 196,469 tons, down 1% from 1970 production of 198,460 tons (30).

Production facilities in the U. S. are (37):

Company	Capacity (tons/yr)
Hooker Chemical Corp. Niagara Falls, N. Y. Columbus, Miss.	15,000 65,000
American Potash & Chemical Corp. Hamilton, Miss. Henderson, Nev.	60,500
Penn-Olin Corp. Calvert City, Ky.	31,000
Penwalt Corp. Portland, Ore.	15,000
PPG Industries, Inc. Lake Charles, La.	15,000
Huron Chemicals Co. Butler, Al. Riegelwood, N. C.	11,000
Georgia-Pacific Corp. Bellingham, Wash.	5,000
Brunswick Chemical Co. Brunswick, Ga.	7,000
Pacific Engineering & Production Co. Henderson, Nev.	6,000
	230,500

Hooker Chemical announced plans to build a new 45,000 tons/yr plant at Taft, Louisiana. The plant will use radically new cell design which was 4 yr in development. The site was chosen to be near the southern pulp and paper industry. This industry uses about 70% of the chlorate production to make chlorine dioxide bleach. Hooker anticipated increased demand as a result of the Hooker "SVP" (single vessel process) chlorine dioxide generating system which is said to produce lower cost product with no acid effluent (37).

Sodium chlorate prices for pulp and paper grade product was lowered from $140/ton to $134.50/ton which continued throughout the year (38).

Sodium.—Metallic sodium production in 1971 totaled 153,075 short tons, a decrease of about 10% from 171,190 tons in 1970 (39, 40).

The decrease is undoubtedly due to the decline of the manufacture of lead alkyls for gasoline additives in the U. S. Exportation of tetraethyl lead and tetramethyl lead have also declined as the European and Japanese manufacturing facilities have been expanded, thereby affecting the production rate of sodium in the U. S. (40, 41).

Prices for sodium were increased during the year and are quoted at $0.27½/lb for regular fused material in drums (Reactor grade $0.32). The 12 lb bricks are up $0.04-$0.30/lb. Smaller bricks are up $0.05-$0.35/lb for 5 lb bricks, $0.40/lb for 2.5 lb bricks, and $1.06/lb for 1 lb bricks (42, 43).

Fluorine.—Fluorine is derived from the mineral fluorite, commonly known as fluorspar. Three grades of fluorspar are generally recognized: Metallurgical—60, 70, and 72.5% effective calcium fluoride (CaF); Ceramic—85-96% CaF; and Acid—more than 97% CaF.

Cryolite (Na_3AlF_6) is a fluorine mineral required by the aluminum industry to dissolve alumina in the process of reducing alumina to aluminum by electrolysis. Greenland is the only known natural source of the natural mineral. However, large quantities are produced synthetically from caustic soda, alumina, and hydrofluoric acid.

In 1968, the U. S. produced 118,000 tons fluorine, or 18% of total U. S. demand. The remaining 82% is imported, chiefly from Mexico, or supplied from stockpiles. U. S. dependence on foreign supplies has existed since 1952 and is increasing (44).

Consumption patterns
(Based on 1968 figures)

A. Form used	Per cent
Fluorspar	44
Cryolite	18
Hydrofluoric acid	35
Fluosilicates	3
	100

B. Use	1,000 Tons fluorine	Per cent
Refrigerant, aerosols, solvents, and plastics	228	35.3
Steel fluxing	215	33.3
Auminum	114	17.6
Electrometallurgy flux	30	4.6
Gas opacifier and flux	16	2.5
Iron foundry flux	12	1.9
Ferroalloy and non-ferrous flux	11	1.7
Other*	20	3.1
	646	100

* Other uses include cement production, water fluorination, uranium isotope separation, catalyst for high octane gasoline production; polymerization, esterification, acidifying oil wells to increase oil production, extracting silica from carbon and graphite electrodes and many other processes.

The following data concerns fluorspar (45). In 1971, 14 companies shipped 269,000 tons of finished fluorspar from mines in 7 states. Two firms in Illinois provided over half the total shipments. Twelve other firms in Illinois, Colorado, Montana, Nevada, and Utah provided the rest.

Fluorspar statistics
(1,000 Tons)

		1968	1969	1970	1971*
Production		252	183	269	269
Imports:	Acid grade	638	695	676	697
	Metallurgical	412	455	416	341
Exports:	Ceramic and acid	13	4	15	15
Consumption:	Acid grade	678	736	767	650
	Metallurgical and ceramic	565	621	605	670
Price:	Average mine value per ton	$46.18	$46.07	$61.00	$62.00

* Estimated.

Imports were from Mexico, 76%, Spain 14%, Italy, 8%, other, 2%.

At 1971 production rates, the U. S. has a 25 yr supply before deposits are depleted.

Aluminum.—Output of primary aluminum metal was estimated at 3,935,000 tons, just slightly below the production level in 1970 of 3,976,148 tons. Domestic aluminum demand was slightly higher in 1970. Imports of aluminum in crude form increased 60% to a record 750,000 tons while exports dropped precipitously from 612,000 tons in 1970 to 300,000 tons in 1971, changing the balanced trade established in 1969 and 1970 (46).

Total inventories of aluminum metal in all forms increased to an estimated 2.5 million tons, up from 2.2 million at the end of 1970. The low demand level for primary metal resulted in the shutdown of reduction lines to reduce output. By year end, approximately 15% of available capacity was shut down (46).

Two new primary aluminum plants were started early in 1971. In February, Noranda Aluminum, Incorporated started production at New Madrid, Missouri, marking an entry of the tenth primary aluminum producer in the United States and the twenty-eighth plant. In March, Gulf Coast Aluminum Corporation, a subsidiary of Swiss Aluminum, Limited, started production at its new plant at Lake Charles, Lousiana (47, 48).

Aluminum Company of America is starting a new aluminum potline at its Warwick plant in Evansville, Indiana. The 50,000 tons/yr line, built earlier this year but so far unused, will raise the annual capacity of the facility to 190,000 tons/yr. Total capacity at Warwick is 275,000 tons/yr.

Two older potlines were closed because of a coal shortage. These two lines, with an annual capacity of 85,000 tons/yr, remain closed, but a third line with a capacity of 45,000 tons/yr reopened in late November (49).

Amax Pacific postponed the start-up of its proposed $120 million two-pot aluminum reduction plant at Warrenton, Oregon. Construction for this 150,000 tons/yr plant is scheduled to begin in the spring of 1972 with completion by the spring of 1974 (50).

The Battelle Development Corporation is touting aluminum alloy electroplating as an attractive alternative to cadmium plating in terms of corrosion resistance and the absence of pollution. Licensed from National Steel Corporation, Battelle further developed the process. Incorporating 10-18% manganese results in a smooth, dense, but dull coating. Increasing manganese to 20-30% results in a bright fine grain coating. Coating is done in a fused salt at 350°F. Compared with cadmium plating, the economies are a trade-off. Capital costs are higher for the alloy system, but raw materials are cheaper (51).

Magnesium.—The production of primary magnesium in 1971 is estimated at 115,000 short tons, up slightly from 1970. Shipments for the first three quarters were up 4% from 1970 and output was up 13% for the same period. Imports of magnesium from January through September were 2,362 tons and exports were 19,685 tons. Production of magnesium compounds decreased from 1970. Magnesite, brucite, and olivine production remained at about the 1970 level (52, 53).

Imports of caustic-calcined magnesia for January through October were 10,967 tons, while in the same period importation of dead-burned and grain magnesia, and periclase totaled 126,008 tons, up from 30,000 tons in 1970 (53).

The General Services Administration continued the disposal of magnesium metal in the national stockpile; at the end of the third quarter 99,790 tons remained in the stockpile.

New magnesium plants and expansions announced include Alcoa's proposal to build a plant in Addy, Washington and NL Industries 45,000 ton/yr plant in Utah. The magnesium will be cast into ingots following recovery from electrolytic cells (54). Norsk Hydro plans to invest $14 million in a 7,000 ton/yr plant at its magnesium operation at Heroya, Norway, bringing production up to 47,000 tons/yr. The expansion will incorporate a newly developed Norsk-Hydro process using magnesium chloride brine as the raw material and yields chlorine as a by-product (55).

Manganese.—There was no production of manganese ore concentrate, or nodules, containing 35% or more manganese in the U.S. in 1971. However, manganiferous ore continued to be produced in Minnesota and New Mexico. Domestic consumption of ore containing 35% or more manganese, expected to total 2 million short tons, was lower than in 1970. Consumption of ferromanganese and silicomanganese also dropped (56).

Major manganese ferroalloy producers reported progress in their installation of equipment to reduce air pollution. Foote Mineral Company announced that it was phasing out its Knoxville, Tennessee electrolytic manganese operations in favor of its newer New Johnsonville, Tennesee plant.

The GSA was authorized to dispose of 4,424,840 short tons of metallurgical grade manganese and 4,805 short tons of synthetic manganese dioxide from national stockpiles. GSA policy continued to limit deliveries of metallurgical manganese to 300,000 short tons per year, divided evenly between quarters (56).

The price of metallurgical ore containing 46-48% manganese was increased from 56-59¢/ton to 59-63¢/ton. Standard high carbon ferromanganese (74-76% manganese) continued to be priced at $184.50/long ton, FOB producer plant, and 78% minimum grade continued at $190. Imported standard ferromanganese was quoted by Metals Week at $180/long ton until March, then increased to $182-$184. Standard electrolytic manganese metal sold at 33.25¢/lb. FOB producer plant for shipment of 30,000 lb or more (56).

Imports of manganese ore (35%) from Brazil and Gabon were expected to approach 2 million short tons, over half of total U. S. imports. Ferromanganese imports were comparable to those of 1970 with the Republic of South Africa and France as principal suppliers, followed by India. Manganese metal imports were considerably increased from those of 1970, principally from the Republic of South Africa (56).

Two subsidiaries of Armcor, Metallorp, Limited and Ferrometals, Limited announced a $42 million expansion program in the Republic of South Africa which will make Amcor one of the world's largest ferroalloy producers (56).

Bureau of Mines RI 7473, "Processing Manganiferous Sea Nodules," reported Bureau research on manganese nodules from both the Atlantic and Pacific ocean floors. RI 7051, "Autoclave and Ambient Pressure Leaching of Lake Superior Manganiferous Ores," reported leaching studies on ores from three Cuyuna Range mines (56).

The commercial potential of ocean nodules has attracted some 18 commercial and governmental organizations in 5 countries. Deapsea Ventures, Incorporated appears to hold the lead, and has already spent $20 million on exploration and development, and anticipates an additional $200 million to achieve production. Plans call for progressive scale-up from present 1 ton/day pilot plant, to 75 and 750 ton pilot plants before building a full scale 3,000 ton/day plant. By processing 1,000,000 tons/yr of nodules they expect to produce 12,600 tons nickel, 10,000 tons copper, 2,400 tons cobalt, and 260,000 tons manganese.

The present process involves an HCl reaction, leaching, ion exchange, stripping, electrolysis, crystallization, and metal reduction (57, 58).

Beryllium.—The consumption of beryllium ores decreased slightly in 1971, from 6,000 tons in 1970. Of the total consumption, 53% is used in electrical equipment, 21% in electronic components, 18% in nuclear reactors, and 8% for miscellaneous uses (59). Domestic produc-

tion was from 3 states and consisted almost entirely of bertrandite.

Imports, largely from Brazil, declined in 1971 and are estimated at 4,200 tons and valued at $1.5 million. Midyear government stockpile inventories included 21,008 tons of beryl (11% BeO equivalent), 7,387 tons of beryllium-copper master alloy, or metal from 1970 inventories.

Kawecki Berylco Industries, Incorporated installed a 4 ft reversing mill producing the widest beryllium metal sheet available. Kawecki have also formed a joint venture with Trefimetaux GP to produce and market beryllium-copper products in Europe.

Brush Wellman, Incorporated planned to begin mining in new open pit reserves near their present pit in Utah (60).

The Environmental Protection Agency has proposed an emissions ceiling of 10g per day per plant to maintain an ambient ceiling of 0.01 $\mu g/m^3$ on a 30 day average. This will mainly affect facilities that extract beryllium from ore (61).

Chromium.—The U. S. continued to rely on imports and purchases from government stockpiles for its chromite requirements (62).

U.S. Salient Chromite Statistics (63)
(Short tons)

Year	Imports for consumption	Exports	Consumption
1970	1,405,527	40,877	1,400,538
1971	1,298,886	34,818	1,086,229
% Change	−7.6	−14.9	−22.6

U.S. Consumption and Stocks of Chromite by Industry (63)
(Short tons)

Consumption

Year	Metallurgical	Refractory	Chemical	Total
1970	911,697	277,646	213,195	1,402,538
1971	719,779	186,524	179,926	1,086,229

Stocks at end of year

Year	Metallurgical	Refractory	Chemical	Total
1970	387,572	309,616	110,792	807,980
1971	666,638	229,908	119,620	1,016,166
% Change	+72.0	−25.7	+8.0	+25.8

Various grades of chromite were offered for sale during the year by the General Services Administration. However, only refractory grade was sold, 21,048 tons for nonrefractory use and 8,300 tons for refractory use.

Union Carbide was authorized in October by the Department of the Treasury to import 150,000 tons of chromite from Southern Rhodesia which was paid for prior to United Nations economic sanctions. To date only 26,000 tons have been imported.

Published prices for chromite ore for 1971, per long ton delivered at Atlantic ports were as follows:

Country	% Cr_2O_3	Ratio	Price $/ton
Turkish	48	3-1	55-56
So. African Transvaal	44	no ratio	25-27
Russian Chromite (quoted per metric ton FOB loading point)			
	48	4-1	51.50-55.00
	55	—	59-63

Titanium.—Through October 1971, sponge-metal production had dropped 26% below the corresponding period for 1970, and 2 of the 3 domestic producers had closed down. Stocks of sponge and scrap increased 25 and 16%, respectively, during the ten month period as ingot production dropped 18% (64).

Type	Metal production (short tons) 1970	1971	% Change	Metal consumption (65) 1970	1971	% Change
Sponge			−34%	16,413	12,145	−26%
Ingot	24,331	18,450	−24%			
Scrap				7,242	6,149	−15%

There are 10 consumers of sponge, 15 of scrap, and 18 of ingot (64). Estimated industry capacities are 85 million lb/yr for ingot and 30 million lb/yr for sponge (66). Production of ilmenite was down 21%, while imports were down 32%, from 1970. No rutile was produced domestically and imports, mostly from Australia, declined by 24%. Importation of titanium sponge, mostly from Japan, totalled 3,905 short tons, a decrease of 40.5% from 1970 (65). Exports of sponge were expected to total about 1,500 tons for the year reflecting a decrease of about 48% from the 1970 level. Exports of wrought titanium and mill products were down 78% (64).

The General Services Administration stockpiles remained unchanged at 35,015 tons of sponge and 56,525 tons of rutile (64).

Domestic prices for titanium sponge (99.3% purity) remained unchanged from the previous year at $1.32/lb while the same grade Japanese and United Kingdom sponge was $1.20-$1.25. The price of rutile pigment at year end was 26-27¢/lb.

First quarter indications of an increased demand for titanium disappeared with the elimination of the Boeing SST and lower than anticipated production of both military and commercial aircraft.

Additionally, the titanium pigment industry capacity decreased by 36,000 tons with the closing of American Cyanamid's Piney River, Virginia plant and PPG's shutdown of its Natrium, West Virginia chloride process plant. NL announced abandonment of the chloride process of TiO_2 manufactured in the United States and Canada with closing of plants at Sayreville, New Jersey, St. Louis, Missouri, and Varennes, Quebec (64, 67).

At the same time, du Pont has announced development of a process to produce anatase TiO_2 pigments using the chloride route. The new development permits manufacture of both anatase and rutile crystal forms of TiO_2 pigment by one process (67).

Other interesting developments include the marketing of the Benilite Process by Cabot to reduce the manufacturing cost of upgraded titanium ores and expanded uses of diffusion bonding processes (68, 69).

The Soviet Union is building its largest sulfate process TiO_2 plant to date (about 20,000 tons/yr), which will double USSR sulfate process TiO_2 (65).

The American Smelting and Refining Company announced development of a new ilmenite mine in New Jersey expected to begin production in 1973 at a rate of 150,000 tons/yr of concentrate.

The Ceylon Mineral Sand Corporation is expanding the ilmenite extraction plant at Pulmoddai Beach and integrating it with a rutile and zircon recovery plant. The expansion will enable exports of 60,000 metric tons/yr of ilmenite and 11,000 metric tons of rutile by mid 1975 (70).

Lithium.—Domestic production of spodumene and lithium carbonate was the largest ever reported. Domestic and international consumption of lithium products was at an all time high.

Three domestic companies continued to process primary lithium products (production data not available): (*i*) Foote Mineral Company, Sunbright, Virginia, and Silver Peak, Nevada; (*ii*) American Potash and Chemical Corporation, Trona, California; and (*iii*) Lithium Corporation of American, Bessemer City, North California.

The Great Salt Lake Minerals and Chemical Corporation, formed by Lithium Corporation of America and Salzdetfurth, A.G., West Germany, harvested salts from the Great Salt Lake in Utah, but do not have facilities to recover lithium (71).

Honeywell, Incorporated announced the development of a small high-energy lithium battery for industrial applications requiring long term storage. Developing markets for lithium included large scale use of lithium carbonate by the aluminum industry and increased use of lithium hypochlorite for bleaches as a sanitizing agent for swimming pools. Other domestic industrial uses were in ceramics, glass, welding and brazing fluxes, air conditioning equipment, rubber, and pharmaceuticals.

United States Imports of Lithium, 1971 (72)

		Quantity	Value ($)
A.	Minerals: short tons		
	Brazil	5,292	225,899
	Republic of South Africa	1,115	82,613
		6,407	308,512
B.	Compounds: lb	18,200	51,257
C.	Lithium metal: lb	53	459
D.	Lithium salts: lb	33	1,166

Exports of lithium hydroxide (9 months) were 227 tons valued at $228,648. Figures for mineral and metal exports were not available. December 1971 prices for lithium products were (71):

Lithium metal, 1,000 lb lots	$8.18/lb
Lithium carbonate, carload lots	$0.50½/lb
Lithium chloride	$0.89/lb

Copper.—During 1971, the domestic copper industry experienced curtailed mine, smelter, and refinery outputs due to labor strikes at most plants during July, August, and September. In addition to production lost as a result of strikes, several mines curtailed operations during the latter part of the year due to utilization of smelter capacity for processing accumulated stocks of copper concentrates.

Mine production was 1.533 million tons, a decrease of 11% and the smallest output since 1968. Smelter output from domestic ores was 1.470 million tons, a decrease of 8.4% from the record high of 1970. Refinery production was 1.41 million tons from domestic ores and 0.181 million tons from foreign ores for a total of 1.591 million tons of primary metal, down 10% from 1970. Secondary metal production was 0.40 million tons (73).

Demand for refined copper was sluggish at the start of the year, increased to a relatively high level during the second quarter, and then slumped during the labor strikes in the third quarter. The total consumption of refined copper during 1971 was 2.00 million tons, down 1.5% from 1970 (73, 74).

U. S. imports of unmanufactured copper totaled 359,431 short tons for 1971, down 8% from 1970. U. S. exports of refined and scrap copper totaled 206,100 short tons, down 13% from 1970 (74).

Stocks of refined copper decreased from a level of 130,000 tons in January to 75,000 tons by the end of December. Fabricators' stocks of copper in all forms decreased from 515,000 tons at the start of 1971 to 487,000 tons by the end of October (73).

Price cutting by several copper companies in late November underscored the pessimism in the industry during the last quarter of 1971. Several of the larger producers indicated that they did not expect the problems of overcapacity and low prices to improve soon. Domestic producers changed prices three times during 1971 with a net decrease of 2.5¢ to a year end quote of 50.25-50.5¢/lb. Prices on the London Metal Exchange increased from an average of 45.2¢/lb equivalent for January to 56.3¢ for April, then declined erratically to 46.7¢ in December (73, 75). At one point the LME price was as low as 44.625¢/lb.

With copper demand off, prices down, new restrictions on air pollution, and previously announced facilities coming on stream, there was no significant expansion activity during 1971. Newmont Mining Corporation announced that their Magma Copper Company permanently closed its Superior, Arizona smelter in July. Magma will process all concentrates at their enlarged San Manuel, Arizona smelter (73, 76).

American Smelting and Refining announced a $300 million, 5 year program to boost production of copper, lead, zinc, and silver at its Mount Isa, Australia complex (76). Noranda announced a $19 million prototype continuous copper smelter as part of a $123 million expansion in Quebec. This unit will add 55,000 tons/yr smelting capacity for Noranda's Gaspe Copper Mines.

A continuous copper smelting process that is economical and does not pollute the air will be used in Japan's Onahama Smelting and Refining Company in a 1,500 metric ton/month plant. The process runs continuously using a converter which is higher than the furnace and slag flows downward while copper matte moves upward. SO_2 generated during smelting is completely recovered (83).

A new factor in copper production is ecology which has already deterred exploration operations in the western U.S. Stringent new regulations on sulfur emissions from copper smelters imposed by Arizona, Montana, and Nevada require that producers install equipment and have it operable by 1974. A number of processes have been proposed and are undergoing pilot-plant evaluation for removal of sulfur oxides from stack gases. Among the processes being considered are continuous resmelting, making it easier and more economical to couple to an acid plant requiring continuous gas feed, electrostatic precipitation, caustic or ammonia scrubbing, catalytic oxidation and reduction to elemental sulfur, chemical refining of ores, and absorption techniques for smoothing out of the flow and composition of the smelter off-gases (77-82).

Nickel.—Nickel consumption, excluding secondary nickel, was approximately 130,000 tons, down 18.7% from 1970. Nickel imports were about 145,000 tons, and domestic mines produced 17,000 tons of nickel laterite ore. The year was marked by a substantial excess of supply over demand and unusually high imports in the form of ferrous nickel (84).

On February 10, 1971, the Office of Emergency Preparedness announced that the nickel national stockpile objective was changed from 55,000 tons to 0. Thus, 40,096 tons became excess to stockpile needs. Congress did not enact the laws necessary to dispose of the excess nickel. Under the Strategic and Stockpiling Act, congressional approval of sales plans is necessary to protect producers, processors, and consumers against disruption of their usual markets. American Metal Climax, Incorporated (AMAX) purchased the Port Nickel Refinery at Braithwaite, Louisiana in February. Originally built in 1959 to process nickel concentrates from Cuba, the plant had been maintained in standby condition since 1960 due to the Cuban nationalization of U.S. owned mines (84).

International Nickel Company of Canada announced production cutbacks of 7% in August followed by another 15% in November, necessitated by the sharp decline in nickel sales in 1971 (85).

Zinc.—U.S. mine production of recoverable zinc declined 8% from 1970 to 491,419 tons, the lowest for any year since 1961. Only 19 states reported mine production of zinc in 1971; 4 states registered increases, 15 showed decreases, and no production was reported for Kansas or Oklahoma (86, 87).

Smelter production of zinc slab was 840,178 tons, down 12% from 1970. Imports of ores and concentrates dropped to 342,600 tons, down 35% from the previous year. However, imports for consumption jumped from a deficit of 22% for the year at the end of August to a

plus of 32% in September when 204,445 tons of zinc in concentrates was withdrawn from bonded warehouses pursuant to a notification by the Secretary of the Treasury exempting all warehouse entries prior to August 16, 1971, from the surtax if withdrawn from the warehouse before October 1, 1971 (86).

Imports of slab zinc increased to 319,072 tons in 1971, an increase of 18.5% over 1970. Exports of zinc slab increased from 289 tons in 1970 to 13,347 tons in 1971. Exports of scrap were projected to decrease to 2,000 tons for 1971, a decrease of 34% from 1970.

U. S. consumption of zinc in 1971 is indicated below:

Basis: recoverable zinc content	Tons 1970	Tons 1971	Per cent change
Zinc slab	1,186,591	1,259,043	+6.1
Ores	124,781	123,400	−1.0
Zinc-base scrap	93,451	87,600	−6.2
Copper-base scrap	160,027	135,200	−15.5
Al-Mg base scrap	6,386	6,000	−6.0
Total	1,571,596	1,611,243	+2.5

The mounting cost-price squeeze, prevalent throughout the zinc producing industry, was a major factor contributing to the loss of almost one-fourth of all U. S. slab-zinc smelter and refinery capacities in 1971, according to the Bureau of Mines, U. S. Department of the Interior. Five mines and 4 slab-zinc producing plants were shut down during 1971. However, what is reportedly the largest single zinc mining operation in the U. S. was opened in Balmat, New York by St. Joe Minerals Corporation. This should help ease an increasing dependency on the use of imported concentrates and metals (88). Strong demands for galvanized products in construction and die casting for the automobile and appliance markets were evident in the first half of the year.

Comparing the principal broad use categories for 1971 with 1970, galvanizing was up 8%, brass and bronze up 14%, and zinc base alloys up 7%. The minor uses declined, including rolled zinc by 22%, zinc oxide by 4%, and other uses by 8%.

General Services Administration (GSA) sales of zinc continued during the year amounting to 2,017 tons through December, leaving 20,580 tons in the existing disposal authorization. Sales to government agencies amounted to 90 tons; 22,097 tons remain of the original 50,000 tons authorized for government use in 1965.

The need for the zinc industry to reduce costs and control pollution has put more emphasis on electrolytic production of the metal. Electrolytic production now accounts for about 60% of the total. Significant improvements and modifications in electrolytic practices should further reduce costs and upgrade recoveries. Such modifications include fluid bed roasters, Jarosite leaching process for iron removal, automatic and continuous purification of leaching solution, and improved electrolysis and cathode stripping (89).

Prime western zinc was quoted at 17¢/lb at the end of 1971. During the year 2½¢ increases and a 1¢ increase were posted. The average monthly London Metal Exchange price varied between 12.33 and 13.05¢/lb (U. S. equivalent) January through June and between 14.05 and 14.62¢/lb July through December.

The foreign producers price increased from 13.93 to 16.46¢/lb in June which remained unchanged through the end of the year. Changes in the sterling exchange rate caused fractional changes in the average monthly U. S. equivalent price.

Electrical Energy

U. S. generation.—The following tables summarize the production and consumption of electrical energy for the 12 month period January through December 1971:

Production of electric energy (90, 91)
(Million-kWhr)

	1970	1971	% Change
Production by electric utilities			
Coal fired plants	706.1	714.8	+1.2
Gas fired plants	372.0	375.9	+1.0
Oil fired plants	182.5	218.2	+19.6
Nuclear plants	21.8	37.9	+73.9
Total fuel burning	1,282.3	1,347.6	+5.1
Hydroelectric	247.3	266.3	+7.7
Total	1,529.5	1,613.9	+5.5
Private industy, self-generated	108.4	103.5	−4.5
Total U. S. power consumption	1,638.0	1,717.5	+4.9

Installed generating capacity (90)
(Million-kW)

	1970	1971
Public owned capacity		
Steam	35.6	42.8
Hydro	36.3	36.8
Nuclear	6.5	0.9
Total	78.4	80.5
Investor owned capacity		
Steam	238.2	260.0
Hydro	18.8	19.1
Nuclear	5.7	7.8
Total	262.7	286.9
Total electrical utility industry capacity*	341.1	367.4

* Not including privately owned capacity.

Fuel consumption—electric utility (90)
(12 months ending Dec. 31, 1971)

	1970	1971	% Change
Coal—millions of tons	322.36	327.93	+1.73
Gas—billions of cu ft	3894.00	3992.98	+2.54
Oil—millions of barrels	332.10	396.24	+19.31
Coal and coal equivalent—millions of tons	583.14	618.16	+6.0

Sales to ultimate consumers (90, 91)
(12 months ending Dec. 31, 1971)
Total industry (million-kWhr)

	1970	1971	% Change
Residential	465.9	499.1	+7.1
Commercial	306.4	328.6	+7.2
Industrial	570.4	589.8	+3.4
Other	48.0	50.6	+5.4
Total	1,390.7	1,468.1	+5.6

On December 1, 1971, electric utility coal stocks on hand for production of electric energy totaled 76.1 million tons, or an 88 day supply, compared with 70.8 million tons, or an 80 day supply, as of December 1, 1970. Stocks of oil as of December 1, 1971 were 50 million barrels, or a 37 day supply, compared with 38 million, or a 40 day supply a year earlier (92).

Fuel problems resulting from the coal miners' strike affected a number of coal-burning power plants, and coal stocks at some locations are now low enough that serious shortages of electricity could occur in some areas if coal production and deliveries cannot be maintained at a sufficiently high rate to compensate for low stockpiles (93).

The Federal Power Commission's National Power Survey Task Force on Environment has urged the electric utility industry, as a whole, toward resolving environmental problems associated with energy supply. Environmental conflicts are only one source of major threats to the national power supply, according to the task force. Others include fossil fuel shortages, equipment failures, and underestimated forecasts of demand. The task force also pointed out the delays in

new power plants may result from changes in air and water quality standards.

While it might be assumed that the presently decreasing population growth would slow the rate at which demand for electric power is growing, this effect may be offset by increased family incomes and rising standards of living; reflected in increased per capita consumption of electric energy. Additionally, environmental requirements will place a heavy demand on available energy supplies (94).

Federal Power Commissioner, Pinkney Walker, has stated that a fundamental of the current energy problem is that it is becoming increasingly difficult and costly to obtain incremental increases in the domestic supply of primary fuels. This results from the basic economics of exploiting finite natural resources. The most accessible and promising fossil-fuel reserves were exploited first and now the industry faces developing those reserves which are not so accessible or promising (108).

Nuclear power.—Only 2.2% of our present electrical energy requirements are provided by nuclear power, up from 1.3% in 1970. This may increase to 15% or 300 Mwe. by 1985. This is equivalent to 8.5 million barrels/day of oil, or 55 billion cu ft/day of natural gas (95).

During 1971, 21 new nuclear units with a total design capacity of 20,810 Mw of electricity were ordered by U. S. utilities. The AEC licensed 2 nuclear power reactors for fuel-power operation and 4 units for fuel loading and/or low power testing and issued construction permits for 4 others (96).

At the end of 1971, the status of nuclear power plants in the U.S. was as follows (97, 98):

23 operable plants	10,040,800 Mwe.
54 being built	45,779,000 Mwe.
52 ordered	51,571,000 Mwe.
Total 129	107,390,800 Mwe.

Of the plants ordered, 39 have not yet received construction permits.

During 1971 the AEC undertook a major reshaping of its regulating process for nuclear facilities; the objectives being a proper regard for environmental quality, increased efficiency in licensing and regulation of nuclear power plants, and more effective participation of the public in the licensing process (99).

As a result of this new policy the licensing of plants from the AEC is becoming more and more difficult as the AEC switches from its "booster" to "neutral" role, deciding to abide rather than contest a circuit court's judgment in favor of environmentalists. Under this ruling, the AEC is required to conduct a thorough review of any such plants' environmental effects, including thermal effects, before granting a license for construction or operation (100). Environmentalists believe one result of this will be a requirement by the AEC that nuclear plant operators install cooling towers or cooling ponds (101).

Although 1971 will be the first year in which more than half of newly orderd electrical generating capacity will be based on nuclear energy, the near-term outlook is for a slowdown in the trend to nuclear power generation. What this slowdown means to the chemical process industries is: (i) a slowdown in demand for fuel, coolants, moderators, and other components of nuclear plants, (*ii*) higher costs of fossil fuels (coal, petroleum, and natural gas) and fossil fuel derivatives, and (iii) spot shortages of low cost interruptable power for aluminum smelters, chlor-alkali plants, and other large users of electrical energy (100).

The annual growth of nuclear power since 1957, when the first commercial plant (Shippingport, Pennsylvania) went into operation has been (102):

Year	Nuclear units ordered	Installed capacity (Mwe.)
1971	21	20,810
1970	14	14,252
1969	7	7,225
1968	15	13,955
1967	31	26,233
1966	20	16,384
Thru 1965	21*	8,532
Total	129	107,391

* Excludes 6 small prototype plants no longer in operation or which are now used only for experimental work.

Demand for nuclear fuel.—According to the AEC, the U. S. nuclear power capacity will rocket from 10,000 Mwe. now, to possibly 150,000 Mwe. by 1980, and demand for uranium will rise from 2,658 tons in 1968 to 63,400 tons in the year 2000, according to the U. S. Bureau of Mines (103). The demand for uranium will present additional demands on reprocessing plants. Assuming 1 ton/day fuel reprocessing capacity for every 10,000 Mw of generating capacity, this will create a demand for at least 15 tons/day of reprocessing capability. Two new reprocessing plants now under construction will more than double today's commercial capacity of about 5 tons/day. Without any recovery process, uranium stocks would dwindle rapidly, because fissionable U-235 makes up only 3-4% of nuclear fuel. The remainder is nonfissionable U-238 (104).

The AEC has ended its 1967 ban on private research on uranium enrichment; however, uranium enrichment technology will remain classified under terms of an AEC contract. No federal funds will be available to assist the private work (105).

New developments.—In the next decade, U. S. electric utilities will not only have to double their generating capacities, but also their existing transmission capacity. Consolidated Edison and Cleveland Electric Illuminating Company are installing short transmission lines of very high voltage that are insulated with sulfur hexafluoride (SF_6). Because of the gas insulation, these 345 kV lines can be placed so close together that they will occupy as little as 1/20 of the normal space.

The technology also applies to utility substations. Generally, an SF_6 station is expected to cost anywhere from 20-100% more than conventional ones, not counting savings on land costs, which are expected to be a significant factor in the years ahead (106).

Fuel cell systems have been developed to generate electricity from natural gas at the point of use. The unit feeds on natural gas and reforms it to produce hydrogen which goes to a hydrogen-air fuel cell. The d-c electricity output can be converted to a-c in an inverter (107).

Manuscript received October 16, 1972. This report was presented at the Industrial Electrolytic Division Luncheon at the Houston, Texas, Meeting of the Society, May 7-11, 1972.

Any discussion of this report will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Design and Materials of Construction for Electrolytic Cells

R. B. MacMullin*

R. B. MacMullin Associates, Niagara Falls, New York 14303

The scope of this paper is broader than it sounds. Clearly, it is the essence of electrochemical engineering. Like all engineering disciplines, it combines two ingredients, theory and practice, or, if you will, science and art. Historically, the art has preceded the science by decades. We have been making chlorine and caustic soda by electrolysis long before we understood electrode kinetics. We have been making aluminum long before we understood the chemistry of fused-salt baths. We have been electroplating gold and silver long before we had knowledge of complex ions and ligands.

Theory is at last catching up with practice and it is now possible to think in terms of applying theory to practical electrochemistry in ways previously ignored. So, it behooves the present generation of electrochemical engineers to have a working knowledge of theory. My remarks, however, will be focused on the application. I think it worthwhile to first consider the fundamental difference between a purely chemical reactor and an electrochemical reactor, that is, a cell.

In a chemical reactor (Fig. 1), the various reaction steps are limited to those which are thermodynamically possible. The selectivity and the space-time yield are foreordained by temperature, pressure, the composition of the reactants, and the catalysts that may be present.

In an electrochemical reactor (Fig. 2), reactions that are *a priori* thermodynamically impossible are forced by supplying the missing free energy at the electrodes. The reactions take place on a heterogenous surface which is capable of accepting or donating electrons to the reacting species in accordance with Faraday's law.

* Electrochemical Society Active Member.

	Δ H°	Δ G°
	k cal	k cal
$N_2 + 3\,H_2 \longrightarrow 2\,NH_3$	- 22.08	- 7.95

Fig. 1. Chemical reactor. To obtain products, the free energy change must be negative.

	ΔH°	ΔG°	E°
	k cal	k cal	volt
$2\,NaCl + 2\,H_2O \xrightarrow{2\,F} 2\,NaOH + Cl_2 + H_2$	+ 106.8	+ 100.9	- 2.18
2 FARADAYS x CELL VOLTAGE = ENERGY INPUT	- 166.0	- 166.0	+ 3.60
EXCESS ENERGY USED	- 59.2	- 55.1	+ 1.42

Fig. 2. Electrochemical reactor. To obtain products, the free energy change is made negative by applying energy at the electrodes.

The selectivity depends on the usual laws of mass transport, but the action takes place in the incredibly attenuated layer adjacent to the electrode. The electrical energy consumed is invariably greater than the Gibbsian free-energy requirement, the excess depending on the efficiency of the transport processes required to bring reacting species up to the electrode and to take away the reaction products.

To reduce this to a quickly grasped metaphor, chemical reaction, like politics, is the art of the possible; electrochemical reaction, like military tactics, is the art of overriding the impossible by applying electrical force.

The Scope of Industrial Electrolysis

Before we get too involved in our subject, I must caution you that it covers a very broad field, as shown in Table I. You can classify electrolytic systems in many arbitrary ways, as illustrated in Table II. Every practical industrial cell represents a particular combination of these eight categories. There are over 200,-

Table I. Some industrial applications of electrolysis

Category	Examples
1. Inorganic chemicals, preparative	Chlor-alkali; chlorate
2. Inorganic chemicals, purification	NaOH
3. Metals, electrowinning	Al, Mg, Na, Mn, Ni
4. Metals, electrorefining	Cu, Pb, Zn
5. Metals, electroplating	Ag, Cu, Ni, Cr
6. Metals, electroforming	Steel, alloys
7. Metals, electromachining	Steel, alloys
8. Metals, electropolishing	Steel, alloys
9. Metals, anodizing	Al, Ti
10. Organic chemicals, preparative	Adiponitrile; p-aminophenol; fluorocarbons, TEL
11. Electrodialysis	Desalting/conc'n. saline water
12. Batteries	Primary, secondary
13. Fuel cells	H_2/O_2, Na/S
14. Films, electrophoretic deposition	Rubber latex

Table II. Cells classified by various functions

By mode	Example
Charge	Electrowinning cells, power consumed
Discharge	Prim. batteries, fuel cells, power generated
Reversible	Sec. batteries, power stored

By polarity	Example
Monopolar assemblies	Hooker Cl cell
Bipolar assemblies	Erco chlorate cell
Combination assemblies	Dow Cl cell

By type of anode	Cell type	Anode
Consumable	Al pot	Carbon
Soluble, solid	Ni cell	Nickel matte
Soluble, liquid	Al ref.	Molten Al
Insoluble, solid	Cl/Alk. cells	Graphite, DSA
Insoluble, porous	Phillips ECF	Carbon
Insoluble, packed particles	Nalco TEL	Pb
Insoluble, fluidized particles	Newcastle, CN removal	Metal, graphite

By type of cathode	Cell type	Cathode
Rigid metal	Metal win., refin.	Start. metal/plated metal
Rigid metal	Cl/Alk. (dia.)	Steel mesh
Rigid porous solid	Fuel, H_2/O_2	C, graph., metal
Packed particles	Cl/Alk., Hg	Graphite in decomposer
Fluidized particles	Newcastle	Metal, graphite
Liquid metal	Cl/Alk. (Hg)	Amalgam
Liquid metal	Chlor metal (Na)	Molten Pb/Na
Liquid metal	Ford Na/S bat.	Liquid Na

By type of electrolyte	Example
Aqueous solutions	Brine
Nonaqueous organics	THF, DMSO, Et_2O plus support. electrolyte
Nonaqueous inorganic	KH_2F_3
Homogenous combinations	Monsanto EHD, H_2O, QAS, AN/ADN
Heterogenous emulsions	Phillips EHD, H_2O, buffer salt, DS, AN/ADN
Fused salts	NaCl, $CaCl_2$, $MgCl_2$, LiCl/KCl
Solid electrolytes, (liq./liq.)	Ford Na/S, beta Al_2O_3
Solid electrolytes, (gas/gas)	G.E. H_2/O_2, stab. ZrO_2

By type of divider	Type of cell	Divider
Undivided cells	Chlorate cells	None
Partly divided		
Curtain walls	MEL Mg	Ceramic
Baffles, screens	Downs Na	St. steel mesh
Isolated by fluid metal	Cl/Alk., Chlormetals Na	Mercury, Molten Pb
Permeable diaphragms		
Rigid, porous	Wet batteries, fuel cells	Ceramic, metal
Flexible, porous	Cl/Alk.; Mn	Asbestos; textiles
Ion selective membranes		
Organic	Electrodialysis, desalting	Anionic, cationic
	Electro hydrodimerization	Cationic
Solid electrolyte	Ford Na/S battery	Beta alumina, Na^+
Solid electrolyte	G.E. H_2 generator	Stabilized ZrO_2, $O^=$

By hierarchy	Cell type	Products
Cell products = electrode products	Chlor-alkali	Cl_2, NaOH, H_2
Cell products formed by secondary chem. react. away from electrodes	Hypo cells	Na OCl
	LeDuc	Ethylene oxide
Combinations of above	Erco, Krebs	$NaClO_3$

By change of state at electrode	Examples	
	At anode	At cathode
No change, prods. sol. in bath	Oxidation	Reduction
Gas is evolved	O_2, Cl_2	H_2
New liquid phase forms		
Heavier than bath		Al, Mg
Lighter than bath	S (Ford bat.)	Na, Mg
Solid phase forms		
Adherent deposit	PbO_2	Mn
Nonadherent deposit	MnO_2	$Mg(OH)_2$

000 combinations of these categories, but the industrially important types probably number less than 50. This suggests that there is plenty of room left for innovative designs, and alternate, but not necessarily economic, cell designs for making even the commonly produced electrolytic products.

It is certainly worthwhile to evaluate the advances made in one branch of electrochemistry in terms of application to another branch. For example:

(*i*) The polarograph is an analytical tool which makes separations on a scale measured in microamperes (Fig. 3). Some of these separations have been duplicated in commercial amalgam cells in the multikiloampere range (Fig. 4).

(*ii*) New close-coupled cell geometries, found useful in oxyhydrogen fuel cells (Fig. 5), are now being applied in reverse, to oxyhydrogen generators (1).

(*iii*) Porous, carbon anodes, long useful in the air-depolarized zinc batteries of commerce, find application in cells for Phillips Petroleum Company's new ECF process for the electrochemical fluorination of hydrocarbon vapors (2). We will take a closer look at these later.

(*iv*) The Ford sodium/sulfur rechargeable battery (Fig. 6), employing a β-alumina solid electrolyte, which is selective to sodium ions, is attracting attention as a possible new way of making metallic sodium (Fig. 7) (3).

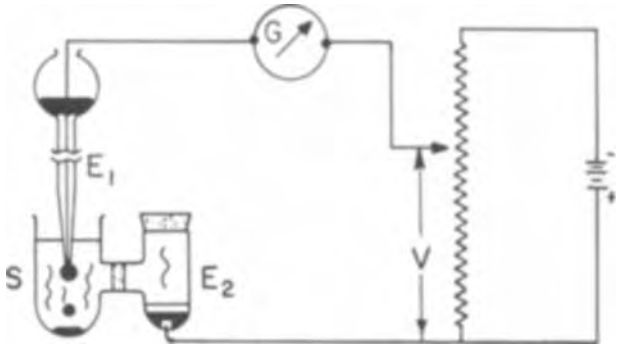

Fig. 3. Basic electrical circuit for polarography. This is a mercury cell in its simplest form. Current is usually in the microampere range.

Fig. 4. A mercury cathode chlor-alkali cell. This cell, of the DeNora type, can handle currents up to 450 kA.

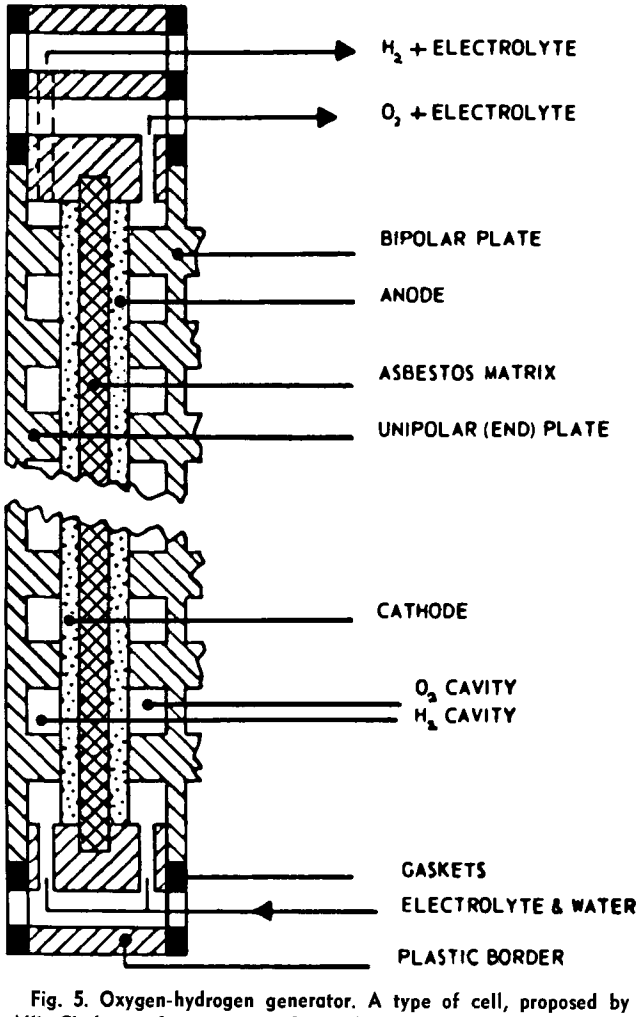

Fig. 5. Oxygen-hydrogen generator. A type of cell, proposed by Allis-Chalmers, for running a fuel cell in the charge mode.

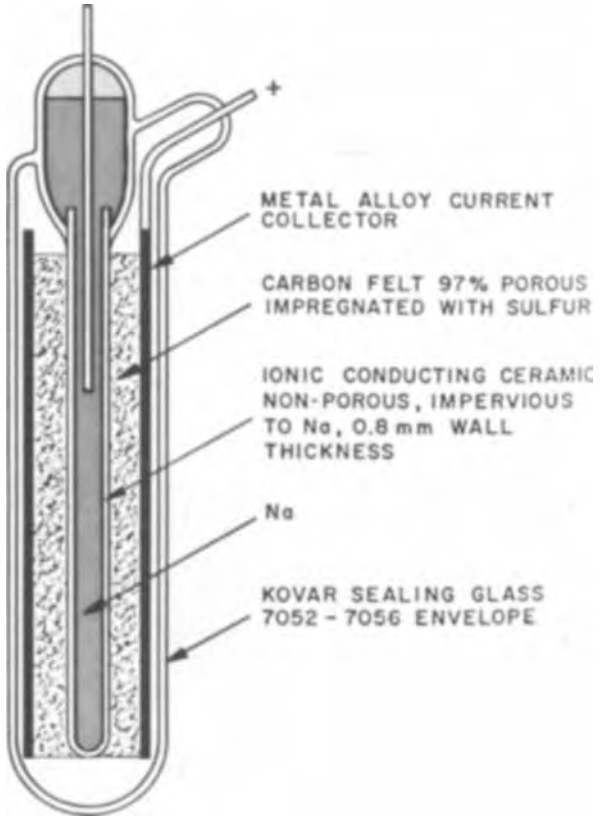

Fig. 6. A small Na-S secondary battery. The solid electrolyte is polycrystalline beta alumina. (Courtesy Ford Motor Company.)

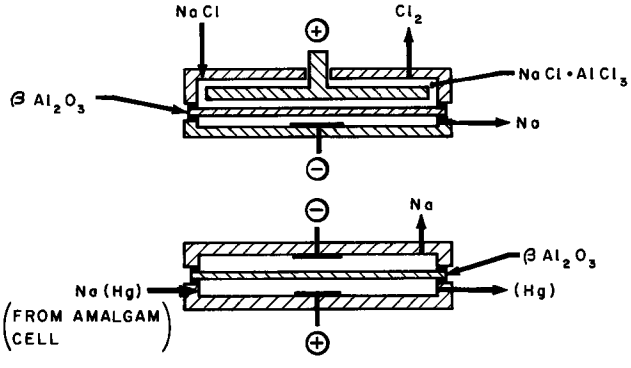

Fig. 7. Two schemes for recovering sodium from NaCl. Upper, from NaCl rich melt of NaCl · $AlCl_3$; lower, from Na(Hg) made in amalgam cell.

(*v*) The discovery that organic free radicals can be generated in certain kinds of nonaqueous electrolytes led to a new commercial process for making tetraalkyl lead (4).

(*vi*) The development of ion exchange membranes for the desalination of water is now being put to use to produce salt, and chlor-alkali from seawater (5) (Fig. 8), and also tonnage electro-organics, like adiponitrile (6).

Since it is obviously impractical to cover the whole field of applied electrochemistry, I will devote the rest of my paper to specific examples of (*i*) advances in design concepts, and (*ii*) advances in materials available to carry out those concepts.

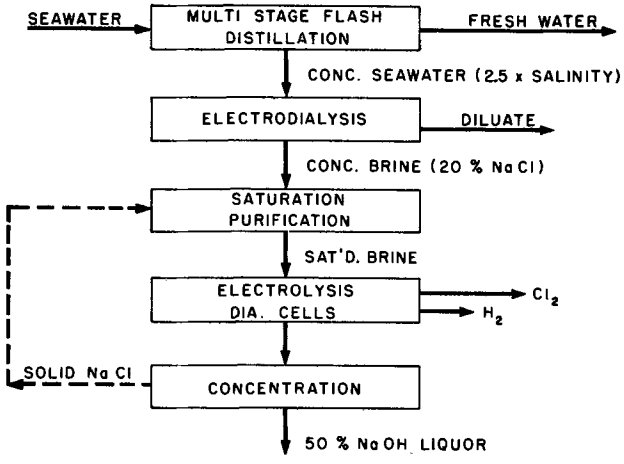

Fig. 8. A Japanese scheme for making chlor-alkali from seawater. This scheme combines seawater desalination with the diaphragm cell process for chlor-alkali.

Techniques of Design and Scale-Up

In 1962 I presented a pioneering paper in *Electro-Chemical Technology* on the problems of scale-up of electrolytic processes (7). The processes considered were the preparative ones, in which power is used to make chemicals or to win metals. Within this field, the recommended procedures were fairly comprehensive, and are just as applicable today as then. This primer was extended, in 1964, to include electro-organic processes (7).

In a magnificent paper Eisenberg covers the principles of design and scale-up of fuel cells (8). The techniques are equally applicable to running cells in the charge mode to make chemicals.

I will now mention a number of new techniques which have come to light since 1962. I will first deal with those only indirectly related to materials of construction.

Porous electrodes.—These have been with us for a long time, but modeling what takes place inside is extremely complex. Much work has been done, and some progress made, in developing models for mass transport, current distribution, and heat transport (9, 10). Flow regimes may be dead-ended, as in most fuel cells, or flow-through (the electrolysis zone), as in making chlorohydrin from ethylene, or flow-by, as in the cells for the Phillips ECF process already referred to.

The flow-by concept is new and seems to involve action at a distance like a gravitational field (Fig. 9). A specie of elemental fluorine, identified as a C...F complex, is generated at the surface of the anode, yet is quite effective in fluorinating hydrocarbon gas flowing by, even as far away as 1 or 2 cm. The electrolyte, KH_2F_3, is repelled by surface-tension effects and very little penetrates into the pores. The gas is free to rise through the porous anode like flue gas up a chimney. The system has been modeled and simulated on a computer. Naturally, experimentally determined design factors have to be fed into the program, in order to use the program for design purposes.

Extended surface electrodes.—The idea of carrying out electrolysis in fluidized beds of solid particles was conceived by our British friends at the University of Newcastle upon Tyne (11). They have come up with a number of interesting applications, and have also learned something about its limitations. Being good electrochemical engineers, they have modeled the technique and are presenting papers on this subject later in this symposium. One extraordinary result has been to increase the voltage gradient to the point where each (conducting) particle acts as a bipolar electrode.

Forced circulation of electrolyte.—There is really nothing conceptually new in boosting limiting current

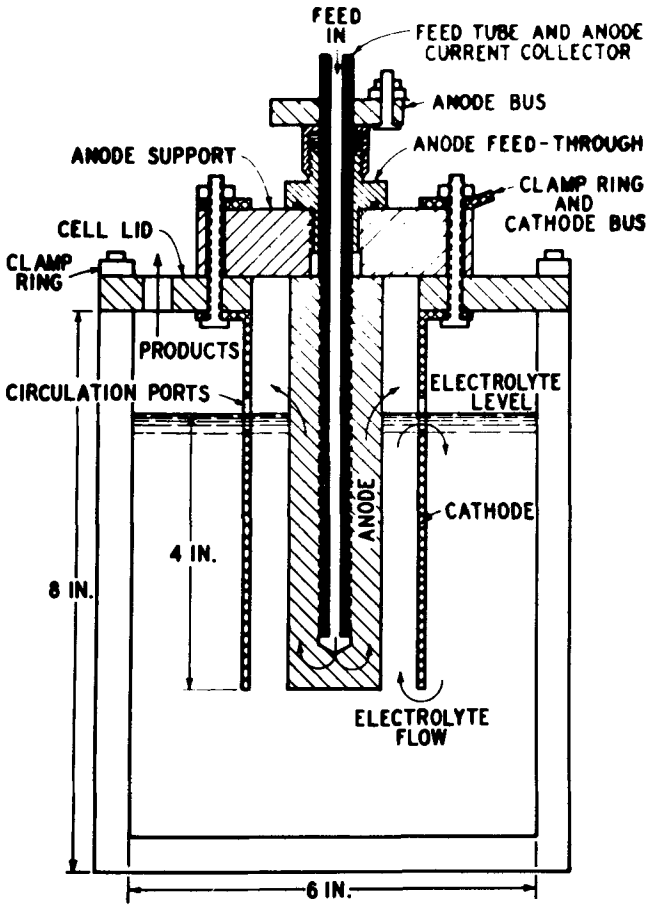

Fig. 9. Experimental fluorination cell. This illustrates the flow-by technique for electrochemical fluorination of hydrocarbon gases in a porous carbon anode. (Courtesy Phillips Petroleum Company.) See *This Journal*, 118, 1248 (1971).

density by increasing turbulence in the electrolyte flowing past an electrode. You can spin the electrode, or promote circulation by the gas-lift effect created by gas evolved on the electrode. Or you can force the electrolyte to flow by at high velocity. The diffusion film thickness depends on the velocity. The only remarkable thing is that cell designers have made so little use of forced circulation.

Certain electro-organic syntheses would have little commercial interest without forced circulation at velocities in the range 0.5-1.5 m/sec. This is particularly true in EHD cells for making adiponitrile. These cells are expensive, and since forced circulation permits higher current density, it also cuts capital cost. Lastly, a great light has dawned on electro-organikers: the selectivity of the electrode toward the desired product often depends on shear velocity. I speak from experience.

Anode effects.—These annoying interruptions in an otherwise smooth electrolysis are more frequently encountered at graphite or carbon anodes, in fused-salt baths, particularly in fluoride baths. The cause and cure of anode effects, when they occur, has been pretty well mastered in an aluminum-cell pot line. It is generally the signal to stir more alumina into the cryolyte bath.

In oxide-free systems, the anode effect is generally more serious. In an ECF cell, the voltage may suddenly rise from 7 to 70V, the porous anode may be "electro-machined" in places where free fluorine is generated, and the free fluorine, in contrast to the C...F complex, may cause the coking of the hydrocarbon gases being fluorinated. The cure is quite simple: when the anode effect occurs, force full current through the polarized electrode for about 1 min, then drop the current to

zero. Within seconds, normal electrolysis may be resumed. The technique has been extended to multiple anode cells and for series circuits of such cells, without unduly complicating the rectifier. Incipient anode effect can be detected and cured by inducing the anode effect by momentarily increasing the current supply to the sick anode (12, 13).

Current reversal and pulsing.—The effect of superimposing alternating current on direct current has been a favorite pastime for inquisitive electrochemists for years, usually with disappointing results. The a.c. contributes no Faradays, only I^2R heat. If you try to depassivate platinum-coated titanium anodes by this scheme, you quickly lose the platinum.

On the other hand, periodic reversal of the d.c. in bipolar cells is sometimes quite useful. If both electrodes are alike in size and materials, as in a bipolar chlorate cell with graphite electrodes, occasional periodic reversal evens wear and prolongs life. In bipolar cells with similar electrodes which corrode while anodic (*e.g.*, lead), frequent and automatic current reversal can be used to prevent the accumulation of adherent oxide films which lead to total polarization, or shorts, or blockage to flow of electrolyte (12).

Currently, there is great interest in the use of either d-c reversal or pulsed d.c. in the electroplating of metals (14). It has been demonstrated that the technique gives smooth, level deposits at high current density, and it relaxes the usual built-in stresses of electroplated metal. In fact, two papers on this technique are being presented at this symposium (15). For industrial application, the circuitry and power supply are not without their problems, but the answers do not seem unduly complicated.

Halide polyanions.—The equilibrium between free halogen and halogen ion to form polyanions is pretty well known. Among these, Br_3^- and I_3^- are quite stable. This property can be put to good use in new kinds of batteries, for example the H/Br cell. On charge, the liberated Br_2 is stored as $LiBr_3$.

On the other hand, if you set out to electrolyze NaBr in an ordinary diaphragm cell, most of the bromine stays in the brine as $NaBr_3$, and after passing through the diaphragm is reduced back to NaBr at the cathode. Result: impossibly low current efficiency. Additionally, graphite anodes are intercalated by bromine and fall apart. If you are still interested in making tonnage bromine in a diaphragm cell, do not give up. You only have to shift the polyanion equilibrium. If you run the cell at the boiling point, very high current efficiencies are obtained. If you substitute amorphous carbon for graphite, you achieve reasonable anode life (12).

Enhancement of heat transfer on gas-evolving electrodes.—The enhancement of mass transfer by gas evolution has been much studied. It seems natural to expect a similar enhancement of heat transfer. The degree of enhancement has now been measured, and it is of the order of threefold. Occasionally an electrochemical engineer has need of cell cooling for temperature control, particularly when chemical reactions, following electrode reactions, liberate excessive heat. Now cooling of electrodes is an old technique. Making use of the enhancement factor is new (Fig. 10) and has led to some innovative and economically optimum cell designs (16).

Conformal plotting as an aid in predicting current distribution.—Conformal plotting is an old technique, much used by civil engineers to predict distribution of fluid flow through porous soils, and by mechanical engineers for predicting distribution of heat flow. Electroplaters have tried to use it for predicting current distribution and deposit thickness. There are complications: when the overvoltages are an appreciable percentage of the over-all potential differences, you have to allow for the fact that overvoltage is usually not a

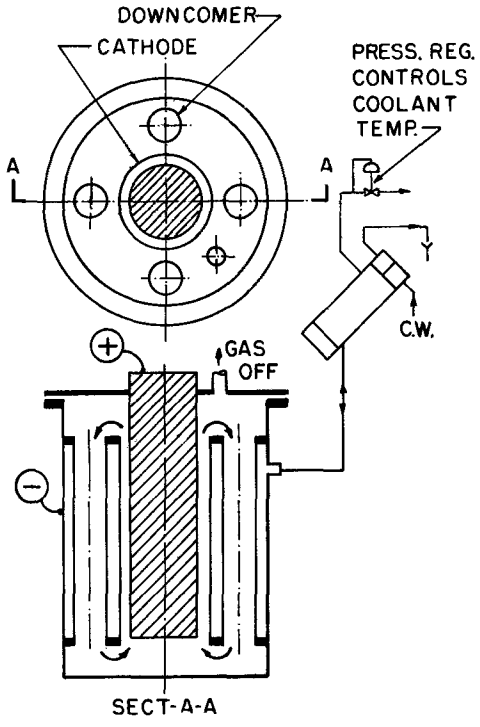

Fig. 10. Cell used to demonstrate enhancement of heat transfer on a gas evolving electrode. The evolution of H_2 gas on the heat transfer surface enhances the coefficient of heat transfer by a factor of about 3. See *This Journal*, 118, 1582 (1971).

linear function of current density (17). For some electrode configurations, a mathematical solution is beyond the ken of the average engineer. For the average person, conformal plotting is easy, and gives surprisingly realistic results. Figures 11-14 show how this was done in a Hall-type cell for producing molten uranium metal from uranium oxide. Where overvoltage is a complication, the trick is to change the shape of the areas between the intersecting flux and potential lines from squares to appropriately proportioned rectangles. Three-dimensional estimates are no problem (12).

Shock removal of metal from cathodes.—There are plenty of problems in the electrowinning of manganese metal, that is, putting a good deposit onto a starting cathode. Getting the deposit off, and reconditioning the starting sheet, is another. Foote Mineral has developed a neat way of doing this, by sonic shock in a water bath. The shock is produced by a sudden electrical arc discharge from an electrical condenser (18). This technique has greatly simplified cell house practice. The lesson is, not all electrochemical problems are confined to the cells proper.

Computer simulation in cell design.—Computer simulation of almost anything has become "old hat." The program shown in Fig. 15 was a pioneer effort in 1970, to do this for an old style Hooker diaphragm cell (19). The computer print out did not tell us much in the way of results that we did not know before. To set up the program, however, forced us to investigate in detail, and for the first time, the many separate relations between the variables. The computer merely solved the problem of how all these separate relations interacted.

I highly recommend the discipline of computer simulation, because it so often brings to the surface many embarrassing problems of which we have been blissfully ignorant. The solution of these problems always leads to improved design.

Directive salts.—In the electro-hydrodimerization of acrylonitrile to produce adiponitrile, various alkyl quaternary ammonium salts are added to the catholyte

to control selectivity (current yield) of the desired product. The nature of the cathode is also important. Neither factor taken separately is self-sufficient. A proper combination can lead to very high current yields indeed. Clearly, we are dealing with surface chemistry and catalysis. Some theories of reaction mechanisms have been advanced, but are not too helpful (20). The point is, here is a new tool for improving electro-organic reactions, that could spell the difference between success and failure for industrial exploitation.

Exotic fields for metal deposition.—We ordinarily think of metal as being plated out on a cathode in an electric field. That is, there is a voltage gradient between bulk solution and cathode, and with it, an associated concentration gradient. Until recently, little thought has been given to the possible effect of other kinds of energy fields. The following effects have now been studied, some of them with beneficial results in electroplating:

(*i*) Thermal field—Should the cathode be hotter or colder than the bulk solution (21)?

(*ii*) Magnetic field—Should this be parallel or perpendicular to the plane of deposition (22)?

(*iii*) Acoustic field—What wave length is most effective (23)?

Materials for Cell Construction

The engineer's term for this is "hardware." Traditionally, cells have been built of the best materials available at the time. You recall the couplet about the bridal gown, which consists of

"Something old, something new,
Something borrowed, and something blue."

Cells are like that. The something blue is often pure whimsy, like a blue garter.

The way a cell is fashioned invariably reflects the properties, and especially the limitations and cost of the available materials. The way a cell performs is thus a compromise, generally somewhere between a "solid gold Cadillac" and a "tin Lizzie."

A more sophisticated approach, if you have the time, is to first design an ideal cell, write the specifications, and then hunt for the materials. If you cannot buy them you invent them, which of course means research and development. Some of the recent spectacular advances in chlor-alkali cell design were made possible by the ultimate success of a deliberate ten year campaign to find another kind of anode, better than graphite.

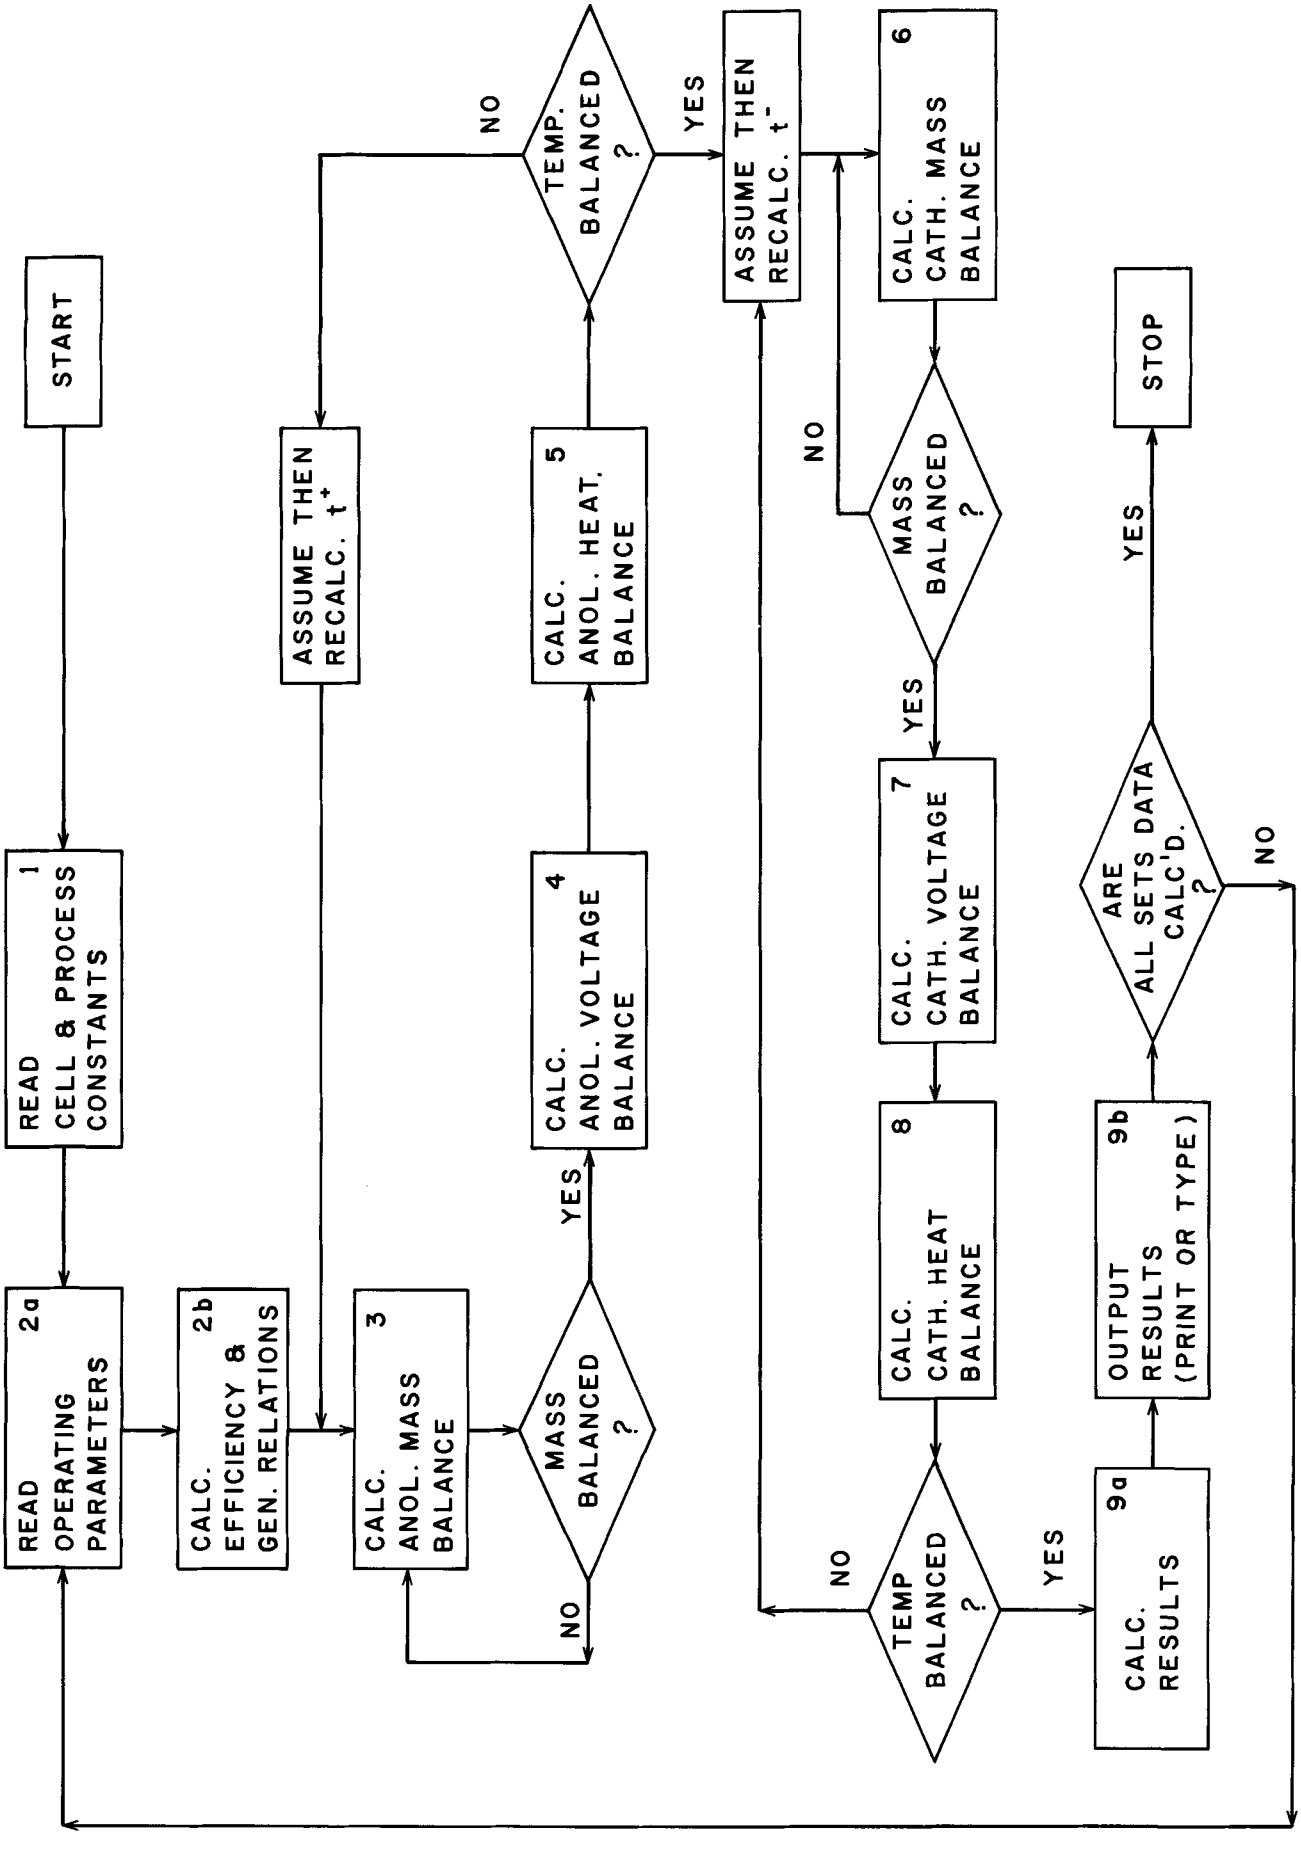

Fig. 15. Program for computer simulation of a diaphragm-type chlor-alkali cell, with graphite anodes. The computer predicts the day-to-day conditions in a single typical cell throughout its life cycle. The average results conform to performance of a cell line comprising a large number of such cells.

Some new, or at least different, materials for cell components are:

Anodes.—Graphite still plays an important role in industrial cells, particularly in fused salt systems. For aqueous systems, the quality of anode graphite is better than ever. The old stand-by, linseed oil impregnated graphite, was never good enough for mercury cells, but Nippon Carbon Company has come up with a vinyl polymer impregnant that gives about 70% longer life in actual cells running at 10 kA/m^2 (24).

Some other forms of carbon, quite expensive and not necessarily better for anodes, are: pyrolytic carbon, glassy carbon, and filaments, felt, and woven cloth of both carbon and graphite. You can get superdense graphite, and porous graphite composites which include built-in catalysts and surface-tension control agents. You can even "ruthenize" graphite and arrive at a compromise between ordinary graphite and DSA's in performance. And lead dioxide, electroplated onto a graphite or metal substrate, is used extensively in chlorate, perchlorate, and hypochlorite cells.

The most exciting new kind of anode is of course, the dimensionally stable anode, or DSA®, which consists of a metal substrate, usually titanium, on which an adherent catalytic coating is deposited (25). The titanium is quite stable in oxidizing aqueous solutions, but it is a valve metal, and of no use as an anode by itself. Platinum, and other metals of the same group will activate the titanium. However, these are not good enough, and the loss of the noble metal is prohibitive in most applications, like chlor-alkali. There are a number of metal oxides which are good electronic conductors, and some of these exhibit remarkable resistance to corrosion. Ruthenium dioxide is one of the best (26). Various other oxides are used in combination with RuO_2, to reduce cost. The patent and technical literature on metal anodes is by now extensive and known to most of you. DeNora will tell you, later on, about the new Glanor diaphragm cell, which employs DSA's (27). A few pertinent points to keep in mind are: (*i*) Completely new and more advantageous cell geometries are possible. (*ii*) Higher current densities, and/or lower cell voltages are possible. (*iii*) The field of application is much wider than chlor-alkali, but there are some limitations. (*iv*) Watch out for nitrogen compounds in the electrolyte—they could strip the coating. (*v*) DSA's cannot be used in anhydrous fused salt baths that contain halides. Under these conditions, the titanium anodically dissolves.

Cathodes.—In electro-organic synthesis, the choice of metal is important (28). Hydrogen overvoltage can be used as a rough guide in selecting the proper metal. Having made a choice, from tests *in vitro*, the cell designer must be careful to exclude other, less noble metals from the cell parts, feed materials, and the system in general, that might plate out on top of the selected cathode and reduce or destroy its selectivity.

In diaphragm type chlorine cells, the cathode is most commonly a woven steel wire screen. The hydrogen overvoltage on steel is an appreciable component of the total cell voltage. A number of other metals are available that exhibit lower H_2 overvoltage. When these are used as cathodes they do not remain active, because it is almost impossible to eliminate iron as a trace impurity in the system. One possible way of reducing the voltage is to depolarize the cathode with air. This is not new, of course, and lots of technology can be borrowed from the fuel cell experts.

Ion exchange membranes.—A great variety of these are now available, and much progress has been made along these lines: (*i*) Mechanical strength, built-in glass fiber reinforcement. (*ii*) Greater stability in aggressive environments, higher range of temperature. A recent example is duPont's new cation exchange membrane, a modified fluorocarbon polymer (29). (*iii*) Improved selectivity at higher electrolyte concentrations, where selectivity has heretofore been too low to be interesting. (*iv*) Specific selectivity to particular ions.

Past attempts to use cation exchange membranes in place of permeable diaphragms in chlorine cells have been frustrating, using the membranes then available. A recent news item, perhaps only a rumor, seems to indicate that Asahi Chemical Industry Company is more optimistic about such an application (30).

Permeable diaphragms.—I have little new to report here, except that it is a sadly neglected subject and worthy of attention (31). Asbestos diaphragms have wide usage, but nobody seems to know why they work as well as they do, or how to make them work better.

Synthetic fibers have largely replaced cotton duck for separators and anode bags in many metal winning and refining cells. Woven PVC cloth can be heat-shrunk to give the desired low permeability in commercial periodate cells.

Solid electrolytes.—This is an exciting new development in solid-state science, which opens up new vistas of application in electrochemical technology. Solid electrolytes are usually polycrystalline ceramic materials which, in certain ranges of temperature, are good conductors for certain ions, while being substantially nonconductive to electrons. They are also, ideally, impermeable to liquids and gases.

As a first example, there is β-alumina, essentially $Na_2O \cdot 11Al_2O_3$, and β''-alumina, $Na_2O \cdot 5Al_2O_3$, usually doped with minor amounts of MgO or other oxides. These are excellent conductors for sodium ions, at 300°C and over. In the Ford sodium/sulfur battery, the ceramic membrane separates liquid sodium on one side from liquid sodium polysulfide on the other. The open-circuit voltage is about 2V, and on discharge Na reacts with sulfur to form Na_2S_x. On charge, metallic sodium and S are regenerated, all at 100% current efficiency. The use of β-alumina for the electrowinning of sodium is a distinct possibility. The membrane can be modified to conduct other alkali metal ions (32).

As a second example there is zirconium oxide usually doped with yttria, which is an excellent conductor for oxygen ions $O^=$ at temperatures above 900°C (33). This material is used in a new type of fuel cell, and also in new types of instruments that measure the oxygen content of liquid metals (34). It has also been proposed as a way to make cheap hydrogen, by the electrolysis of superheated steam. The water vapor dissociates, the oxygen is ionized at a cathode and passes through the solid electrolyte, then gives up its electrons at an anode to form oxygen gas. The hydrogen is left behind, and is easily separated from the steam (35).

As a third example, there is the double salt $RbAg_4I_5$, which easily conducts silver ion even at room temperature. This forms the basis for a new type of battery (36, 37).

These are but the first indications of the possible development of a wide class of solid-state materials, engineered for use in industrially important electrolytic cells.

Baths.—Although not properly part of the hardware, the nature of the electrolyte used is a determining factor in cell design. The bath can be engineered as well as the hardware. Supporting electrolytes are added to increase conductivity; hydrotropes, to increase solubility of aromatic organics; directive salts to control selectivity; and buffers, inhibitors, levelers, and so on. Cations can be complexed into anions, and *vice versa.*

Tanks.—Concrete, a poor material at best, can be greatly improved in strength and corrosion resistance by including resins in the mix. Het-crete (38) is such a material, which contains a chlorinated polyester resin. Epoxy-sand mixtures, are useful. Solid PVC plastic tanks are in use in periodate cells. Glass fiber reinforced plastics can be used standing, or as liners

for steel tanks. Titanium or titanium-clad steel is sometimes used. Flexible plastic bag liners have also been used in concrete tanks, or even wood tanks, in place of lead.

For low temperature fused salt baths, cells of carbon steel or alloy steel are often quite satisfactory, if maintained cathodic in respect to the bath. For higher temperatures, brick, carbon or graphite linings are standard. There are cases where "skulls" of frozen bath have been used to protect exposed metal.

Cover and seals.—Tank covers need not be rigid. DeNora amalgam cells have two-ply flexible covers, the inner ply to resist chlorine, the outer to resist air oxidation. It is also commonplace to bring anode conductors right into the anode chamber. If these are of copper, they can be protected with sleeves of ceramic, vinyl polymers, or they may be titanium clad. Flexible seals can be made of neoprene, PVC, or poly vinylidene fluoride.

Insulators.—There are many new ceramic materials that have proved their worth in such difficult spots as thermocouple wells, reference cell probes, or simply as insulators in aggressive environments where glass, alumina, or plastics have proved unsuitable. Boron nitride is one such ceramic (39).

Bus and conductors.—Aluminum is now widely used in place of copper. Joints should be welded if possible, and good bolted joints must be carefully engineered. Sodium in a steel pipe makes an excellent bus. Sodium-filled polyethylene pipe is quite acceptable and inexpensive for underground cable.

Conclusion

Electrochemical engineering has indeed established a foothold as a scientific discipline. There seem to be endless opportunities for more advanced design of cells and materials of construction for producing chemicals from energy or energy from chemicals on the industrial scale, and in the service of mankind. This paper marks the end of my own lifetime effort in this field, and I hope that some of my own optimism about the future has rubbed off onto the competent people taking part in this wonderful symposium arranged by my good friend Dr. Wranglén.

Phase Diagram of the Pseudoternary System Li_2Se-Se-(LiBr-RbBr Eutectic)

P. T. Cunningham, E. J. Cairns,* E. J. Hathaway, S. A. Johnson, and V. A. Maroni

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The phase diagram of the Li_2Se-Se-(LiBr-RbBr eutectic) system at 360°C has been determined using data obtained from a variety of physicochemical measurements and emf studies. Of particular interest is a large region of three-liquid equilibrium.

Phase-equilibria studies on systems comprised of alkali metals, chalcogens, chalcogenides, and alkali halide salts have been investigated extensively in this laboratory (1-5). Interest in these systems stems primarily from their application in the development of high-specific-energy, high-specific-power secondary cells based on alkali metal-chalcogen couples utilizing molten alkali halide electrolytes (6-10). In this paper we describe results of physicochemical studies on the pseudoternary system Li_2Se-Se-(LiBr-RbBr eutectic) and related systems using solubility, thermal analysis, centrifugation, and quenching techniques. The following article (11) in This Journal presents results of electromotive force (emf) measurements for the Li_2Se-Se-(LiBr-RbBr eutectic) pseudoternary system and related systems. The physicochemical and emf data are herein interpreted in terms of a ternary phase diagram in which the eutectic salt mixture is considered as a single component.

Experimental

Materials.—The selenium (99.999+ % purity, obtained from American Smelting and Refining Company, South Plainfield, New Jersey) and lithium (99.98+ % purity, obtained from Foote Mineral Company, Philadelphia) were used as received. The Li_2Se was prepared from the elements by a method that has been described elsewhere (1). The compositions of the alkali metal halide eutectic mixtures used in these studies are listed in Table I together with their melting points. They were prepared from the anhydrous salts in a purified-helium-atmosphere glove box (13) in which the maximum concentrations of H_2O, O_2, and N_2 are less than 1, 5, and 10 ppm, respectively. The preparative procedure consisted of contacting molten mixtures of the eutectic compositions with lithium for several hours to remove any water and to reduce heavy metal ions, followed by filtration of the eutectic through a double quartz frit filter. The LiCl, LiI, LiBr, and RbBr were obtained from Anderson Physics Laboratories, Champaign, Illinois, and were reportedly 99.99% pure. The LiF was single-crystal optical grade obtained from Harshaw Chemical Company, Cleveland.

Solubility studies.—The solubility studies were carried out in a furnace well attached to the floor of a helium-atmosphere glove box (13). Samples were equilibrated in quartz tubes 460 mm long and 13 mm in diameter. These tubes were inserted into a 16-mm-diameter hole drilled to a depth of 150 mm in a copper block which was positioned in the hot zone of the furnace well. In all cases an excess of the solute material was provided so that the solvent phase would be saturated. Enough solute plus solvent mixture was added to fill the sample tube to a depth of about 100 mm. After equilibration for 4-6 hr with periodic stirring, a 3-mm-diameter quartz extraction tube with a fine quartz frit fused in the lower end was immersed into the phase to be sampled using a vernier depth gauge. The entire assembly was then allowed to come to thermal equilibrium and a sample was drawn into the extraction tube. The extraction tube was then withdrawn from the hot zone and the sample above the frit was submitted for chemical analysis.

Centrifugation studies.—A high-temperature centrifuge similar in design to one described by Friedman (14), was constructed for the centrifugation studies. A drawing of the centrifuge has appeared elsewhere (15). Samples of the desired composition were loaded into quartz tubes, sealed under vacuum, and equilibrated at temperatures of about 400°C in a rocker furnace for times in excess of 24 hr. The equilibrated samples were then removed from the quartz tubes, ground to fine powder, and loaded into special quartz ampules, which were placed in the metal holding

Table I. Compositions and melting points for LiF-LiCl-LiI and LiBr-RbBr eutectics

Eutectic composition, m/o	Melting point, °C
LiF — 11.7 LiCl — 29.1 LiI — 59.2	340.9
LiBr — 59 RbBr — 41	277[a]

[a] This value is 18° higher than the value reported by Gromakov and Gromakova (12).

* Electrochemical Society Active Member.

Key words: selenium, lithium selenide, alkali halide, phase diagram, cathode.

buckets of the centrifuge. The samples were heated to 360°C and centrifuged for periods of 8-10 hr at speeds in excess of 1200 rpm and with a minimum centrifugal force on the sample of 100*g*. The temperature in the sample compartment of the centrifuge was found to vary by less than 2°C during operation. After centrifugation, the holding buckets (containing the ampules) were removed from the centrifuge and immersed in liquid nitrogen. In most cases all of the samples could be removed from the centrifuge and quenched in less than 2 min from the time at which the furnace was opened. The ampules were then transferred to the helium-atmosphere glove box for examination prior to analysis.

Analytical procedures.—Solid samples obtained in solubility, centrifugation, and quenching experiments were subjected to chemical analyses using the following general procedure. The samples were first digested in glacial acetic acid for several hours. Selenium present in the elemental form appeared as a precipitate whereas selenium present as selenide evolved as gaseous hydrogen selenide, which was recovered in a nitric acid trap. The precipitated selenium was recovered from the acetic acid solution and combined with the selenide in the HNO_3 trap by dissolution. The resulting solution (now containing all of the selenium) was spot-checked for halogen (none was ever found) and analyzed for selenium using the standard potassium iodide method (16). The acetic acid solution from the digestion step (now free of selenium) was analyzed for bromide amperometrically using a silver electrode and for lithium and rubidium using flame photometry. For samples containing the LiF-LiCl-LiI eutectic, no attempt was made to analyze for the halogens.

Other procedures.—The methods used in mounting and polishing the samples for microscopic examination as well as procedures used for differential thermal analysis (DTA) have been described elsewhere (1). The experimental procedures used in the emf studies are described in detail in the following paper (11).

Results

Solubility studies.—Prior to examination of ternary samples containing lithium selenide (Li_2Se), selenium (Se), and salt eutectic (LiX), a series of solubility studies was conducted to determine important phase relationships for the Li_2Se-LiX and Se-LiX binary systems. The phase boundaries for the Li_2Se-Se system were known from the work of Cunningham *et al.* (1).

A study of the solubility of Li_2Se in three lithium halide-containing eutectics indicated that the amount of Li_2Se dissolved in these molten salts does not exceed 1 m/o (mol per cent) for temperatures below 450°C. These data are given in Fig. 1. The points for the all-lithium halide eutectics appear to lie on a straight line with a slope corresponding to a heat of solution of 13.3 kcal/mol. Data for the LiBr-RbBr eutectic lie on a line of nearly the same slope but displaced to significantly lower solubility values.

Results of a series of measurements of the solubility of selenium in two lithium halide-containing eutectics are given in Table II. Although there is considerable scatter in the data for the LiF-LiCl-LiI eutectic, it is clear that the solubility of elemental selenium in these eutectics is less than 0.1 m/o at temperatures below 500°C. A linear least squares analysis of the data for the LiF-LiCl-LiI eutectic yielded the equation

$$\log_{10} n_{Se} = 2.628 - 2776/T$$

where n_{Se} is the mole fraction of selenium and T is temperature in degrees Kelvin. The single determination for the LiBr-RbBr eutectic indicates that the selenium solubility is not appreciably affected by changing the constituents of the eutectic.

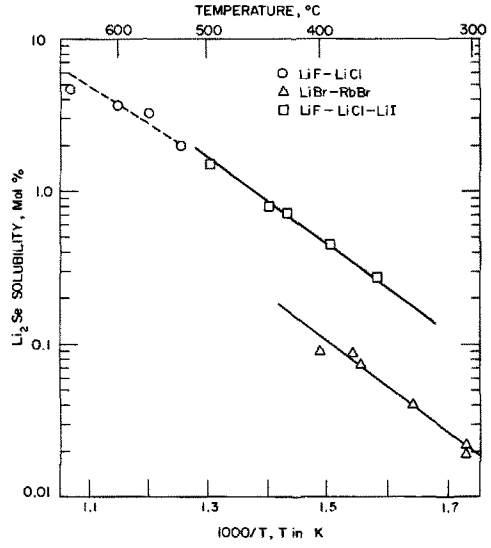

Fig. 1. Solubility of Li_2Se in eutectics containing lithium halides

A single measurement was made of the solubility of a molten salt eutectic in selenium. In this experiment the quantity of LiBr-RbBr eutectic dissolved in selenium at 394° ± 10°C was found to be less than 0.01 m/o. From this result and the data given in Table II for selenium solubilities in lithium halide-containing eutectics, it appears that at 360°C an extensive miscibility gap exists in the pseudobinary systems Se-(LiBr-RbBr eutectic) and Se-(LiF-LiCl-LiI eutectic) extending from <0.1 m/o selenium to >99.9 m/o selenium.

Preliminary studies of the solubility of Li_2Se-Se mixtures in LiX indicated that the quantities of selenium dissolved in the salt were enhanced considerably by the presence of Li_2Se. For example, the respective solubilities of Li_2Se and Se separately in LiBr-RbBr eutectic are only 0.030 and 0.026 m/o at 363°C, but a LiBr-RbBr sample equilibrated at 364°C with a Li_2Se-Se mixture (moles Se/mole Li_2Se = 4.0) was found to contain 1.45 m/o selenium. This observation of increased selenium solubility in the salt-rich phase for samples containing both Li_2Se and Se provided the basis for a clearer understanding of the emf and phase-equilibrium results which follow.

Emf studies.—Typical emf results, such as those presented in Fig. 3 through 7 of the following paper (11), were in qualitative agreement with results expected from the phase equilibria for the Li_2Se-Se binary system (1) in that composition ranges for which emf was decreasing or constant at a given temperature had a one-to-one correspondence with those regions of the phase diagram where such variation was expected on the basis of the phase rule. However, the compositions at boundary crossings where the slope of emf-*vs.*-composition plots changes abruptly did not agree with the compositions of corresponding boundaries as determined by other methods.

Table II. Solubility of selenium in LiBr-RbBr and LiF-LiCl-LiI eutectics

In view of the solubility-study results and of the discrepancy noted above between the early emf data and the phase equilibria found for the Li_2Se-Se binary system, it was concluded that the behavior of Li/LiBr-RbBr (eutectic)/Li in Se emf cells should be interpreted in terms of a pseudoternary system. A summary of the data on the locations of phase boundaries based on emf measurements for Li/LiBr-RbBr (eutectic)/Li in Se cells at 360°C is given in Table III and the locations are shown in Fig. 2.

The emf cells were operated so that the atom fraction of lithium with respect to selenium in the cathode was varied while the atom fraction of selenium with respect to the electrolyte was constant. The values for these atom fractions are listed in columns 2 and 3 of Table III. The atom fractions of lithium at the break points, which are listed in column 4, were converted to mole per cent Li_2Se for plotting on Fig. 2. The constant selenium to eutectic ratio in the emf cell means that the data from any one cell lie on a line parallel to the Se-Li_2Se boundary of the phase diagram.

DTA, quenching, and centrifugation studies.—To further characterize the pseudoternary systems, a series of DTA curves were obtained for samples of various compositions containing the LiBr-RbBr eutectic. The results are presented in Table IV. These data show three thermal effects at about 280°, 249°, and 220°C which are apparently associated with the disappearance of L_3, L_2, and L_1, respectively. The thermal data provide qualitative limits to the range of compositions covered by L_2 and L_3. For example, for compositions lying near the lithium selenide-selenium binary, the thermal effect associated with the disappearance of L_3 is not observed. This would indicate that L_2 extends far enough into the phase diagram to prevent formation of L_3 from these compositions.

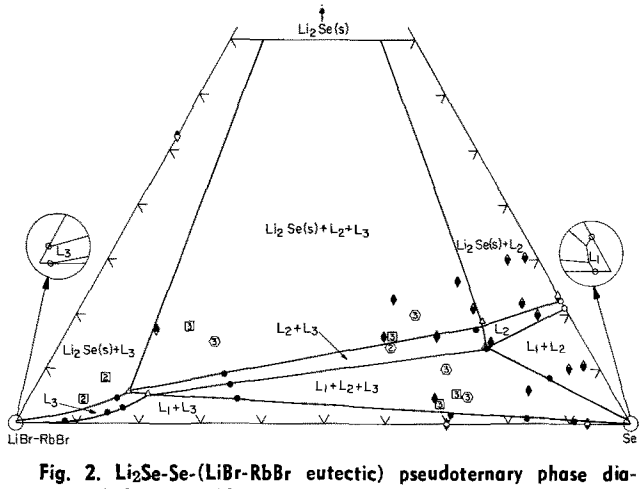

Fig. 2. Li_2Se-Se-(LiBr-RbBr eutectic) pseudoternary phase diagram at 360°C. ●, Phase boundary locations determined by emf measurements. ○, Phase boundary locations for the binary systems determined by solubility studies and from Ref. (1). △, Phase boundary locations determined by chemical analysis. ⬡ and □, regions found to contain the number of phases indicated by quenching and emf methods, respectively. ◇, Compositions examined by DTA. See text for explanation of shading.

These data are also plotted on Fig. 2 using diamond-shaped symbols which are shaded at the bottom, middle, or top indicating thermal effects at 220°, 249°, and 280°C, respectively. A fully shaded diamond would indicate that all three effects were observed.

An effort was made to determine the degree to which L_2 and L_3 extend into the phase diagram by equilibration and quenching of samples having compositions lying within the three-liquid region. Microscopic examination of the quenched samples showed that, in addition to L_1, there were indeed two other liquid phases present, but their densities were apparently quite similar and separation was not adequate to permit chemical analysis. Other quenched samples having compositions in the two-liquid region between L_2 and L_3 were examined and were found to contain two liquid phases, as expected.

In view of the difficulties encountered in separating the three liquid phases, L_1, L_2, and L_3 during quenching studies, an attempt was made to accomplish this separation using a high-temperature centrifugation technique. Centrifuged samples consistently showed nearly quantitative separation of all of the constituent phases. The selenium-rich liquid, L_1, was always found to be the most dense phase with the selenide phase, L_2, intermediate, and the salt-rich phase, L_3, the lowest-density phase. In cases where solid Li_2Se was present, it appeared in the upper portion of the salt-rich liquid phase. Normally, four samples were centrifuged simultaneously for each composition. The phases of two of these samples were separated at the interfaces between the phases and were submitted for chemical analysis. The other two samples were mounted, polished, and examined microscopically. By examining compositions near the upper boundary of the $L_1 + L_2$

[a] The exact temperature of a reaction is difficult to determine using DTA. Here we consistently report peak temperature. Uncertainties of ±2°C due to changing peak size might be expected. Values in ( ) are shoulders (not peaks) and may be associated with a liquidus crossing.

[b] The only effect seen is the mp of Li_2Se at 1302°C. This value is confirmed by other methods (1).

[c] The Li-Se binary has a monotectic reaction at 350°C (1).

+ L_3 field and near the lower boundary of the $Li_2Se(s)$ + L_2 + L_3 field (see Fig. 2) we were able to determine the boundaries of the L_2 + L_3 field from chemical analyses.

Discussion

The experimental data in Fig. 1 and Tables I through IV, as well as results of other solubility studies discussed above, are consistent with the pseudoternary phase diagram for the Li_2Se-Se-(LiBr-RbBr eutectic) shown in Fig. 2. The determination of this diagram started with a consideration of the binary systems from which it is constituted. The Li_2Se-Se system has been well-studied by Cunningham *et al.* (1). The terminal phases melt at 1302°C (Li_2Se) and 220°C (Se). There are no intermediate phases and the system has a simple monotectic structure. Starting from the Li_2Se phase, the upper liquidus drops sharply with the liquid which becomes L_2 in the pseudoternary system undergoing monotectic reaction at 350°C to form the selenium-rich liquid, L_1, and $Li_2Se(s)$. The monotectic composition is about 22 m/o Li_2Se. The L_1 phase freezes at 220°C with considerable tendency to undercool. Both the tendency to under-cool and the freezing point (indistinguishable from that of pure Se) confirm the very slight solubility of Li_2Se in Se. The miscibility gap between L_1 and L_2 extends from about 22 m/o Li_2Se to less than 0.5 m/o Li_2Se and has very steep boundaries. The phase boundaries in the Li_2Se-Se system at 360°C obtained from the work of Cunningham *et al.* (1) are indicated in Fig. 2. Phase relationships in the LiX-Se and Li_2Se-LiX binary systems as determined from the solubility studies[1] are also indicated in Fig. 2.

Results of the solubility studies, the centrifugation experiments, and the Li_2Se-Se phase-diagram work locate the corners of the L_1 + L_2 + L_3, L_2 + L_3, L_2, and L_3 regions as shown in Fig. 2. The emf data in Table III establish the boundaries of L_3 and locate the boundaries between two- and three-phase regions implied by the other studies. The compositions corresponding to boundary crossings as given in Table III are shown in Fig. 2. When microscopic or chemical analyses were performed, the nature of the phases present was always consistent with Fig. 2. In particular, both microscopic and chemical analyses of equilibrium samples from the L_1 + L_2 + L_3 field obtained in centrifugation experiments clearly showed the presence of all three liquid phases.

The phase diagram of this pseudoternary system is particularly interesting because of the region of three-liquid equilibrium and the presence of a salt phase, L_3, which can contain appreciable quantities of dissolved selenium-bearing species. The single-phase regions, L_1, L_2, and L_3, probably expand monotonically across the diagram with increasing temperature. Coincidentally, the L_2 + L_3 region would be expected to expand steadily in the direction of the three-phase fields, L_1 + L_2 + L_3 and L_2 + L_3 + $Li_2Se_{(s)}$, while giving way laterally to L_2 and L_3 and eventually disappearing. With decreasing temperature (from 360°C), the salt-rich phase, L_3, must retreat rapidly since that phase was shown (by DTA) to freeze within a few degrees of the freezing point of pure LiBr-RbBr eutectic (277°C).

[1] The existence of Rb_xSe_y compounds may not show up in the solubility studies. Emf studies (11) show effects possibly attributable to these compounds but their limited presence does not seem to invalidate the assumption of pseudoternary behavior.

The pseudoternary phase diagram of the Li_2Se-Se-(LiBr-RbBr eutectic) system is important to the understanding of the operation of the Li/LiBr-RbBr(eutectic)/Se cell (6-9), which has been investigated as a rechargeable electrochemical power source. The extent of the L_3 phase is related to the degree of (undesirable) transfer of selenium to the lithium electrode (9). Steps have been taken to reduce the extent of L_3 by decreasing the activity of selenium through the use of thallium (17).

Thermodynamic Studies of the Lithium-Selenium System by an EMF Method

E. J. Cairns,* G. H. Kucera, and P. T. Cunningham

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Emf measurements on cells of the type Li/lithium halide eutectic mixture/Li in Se have been used to determine thermodynamic quantities for the Li-Se system. For low lithium concentrations in the cathode, the over-all cell reaction can be written as $2Li + xSe \rightarrow Li_2Se_x$. From the cell data, the activity coefficient of lithium was calculated to be 6×10^{-32} in the dilute Li region; the standard free energy of formation of Li_2Se at 360°C was calculated to be −94.0 kcal/mol.

The thermodynamics of lithium-selenium mixtures are of interest in connection with the chemistry of alkali metal-containing binary systems having components of widely differing electronegativities because of the applicability of these systems to electrochemical energy conversion (1, 2). A study of secondary cells involving lithium-chalcogen couples has been underway at this laboratory for several years. The potential of these cells in various applications requiring high-specific-energy, high-specific-power batteries has been discussed (1-5). The phase diagram of the lithium-selenium system has been previously reported (6) and phase equilibria in pseudoternary systems of selenium, lithium selenide, and alkali metal-halide mixtures are presented in the preceding paper (7). In this paper we report the results of a series of emf measurements on cells of the type Li/LiF-LiCl-LiI (eutectic)/Li in Se, and Li/LiBr-RbBr (eutectic)/Li in Se, and the thermodynamic quantities calculated therefrom.

Experimental

The sources and purities of lithium, selenium, and the electrolyte salts have been described in the preceding paper (7). The emf data were obtained from cells of two different designs.

The type I cell, shown in Fig. 1, consisted of a lithium reference electrode and a lithium-selenium-alloy electrode, which were positioned in separate compartments and immersed in the molten-salt electrolyte. The lithium electrode was a porous stainless steel cylinder (~10 mm in diameter and 10 mm high) saturated with lithium, which was retained within the voids of the porous metal structure by surface-tension forces. The lithium-selenium-alloy electrode was prepared by mixing selenium pellets with the desired amount of powdered Li_2Se. The Li_2Se was prepared by the reaction of selenium vapor with lithium metal (6). The selenium-Li_2Se mixture was placed in a niobium cup (700 mm^3) which had a tight-fitting niobium lid containing a porous Al_2O_3 wick to insure contact between the mixture and the electrolyte. Two different eutectic salt mixtures were used as electrolytes: 59 m/o (mole per cent) LiBr-41 m/o RbBr (mp 277°C) and 11.7 m/o LiF-29.1 m/o LiCl-59.2 m/o LiI (mp 340.9°C). The type I cell was operated in a furnace well attached to the floor of a high-purity-helium-atmosphere glove box (<2 ppm O_2 and N_2, <1 ppm H_2O) (8) in which the cell was assembled. This type of cell has been used primarily to study the effect of temperature variation on cell emf for various fixed-cathode-alloy compositions.

The type II cell, which is shown in Fig. 2, utilized a three-compartment quartz housing. The lithium electrode was again a porous stainless steel cylinder impregnated with lithium. The selenium alloy electrode was contained in the lower end of one leg of the housing and was contacted with a niobium wire coil which served as a current collector. The compartments were loaded with weighed amounts of lithium, selenium, and electrolyte in the helium-atmosphere glove box and sealed. The cell was operated outside the glove box in a molten $NaNO_3$-KNO_3 bath to insure temperature uniformity. The helium atmosphere inside the cell was maintained at a slight positive pressure to limit dif-

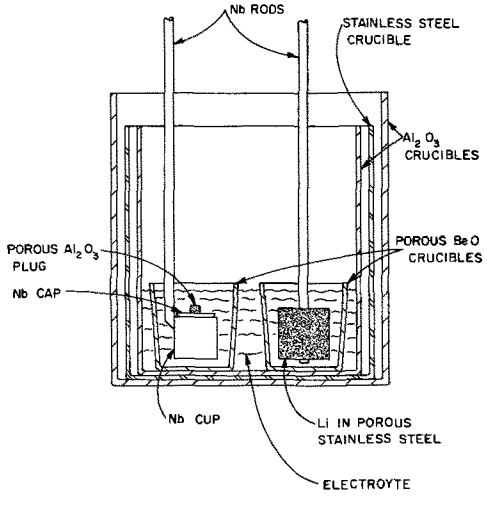

Fig. 1. EMF cell of type I

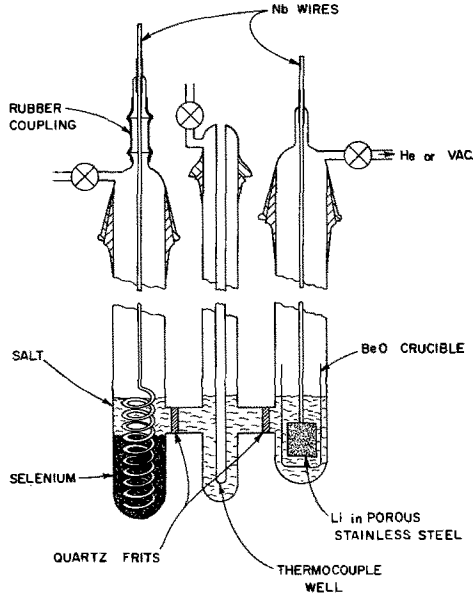

Fig. 2. EMF cell of type II

fusion of impurities into the cell. The type II cell was used primarily to study the effect of changing composition on cell emf at constant temperature, although some temperature-variation studies were performed with this type of cell. The cell was usually started with pure selenium, and the composition of the alloy electrode was changed by electrochemical transfer of lithium into the alloy, keeping count of the number of coulombs involved. The ratio of selenium to electrolyte was also varied over a wide range from one cell to another so that the effects of the solubility of selenium-bearing species in the electrolyte (7) could be evaluated. For cells with a large selenium-to-electrolyte ratio, the details of the H-cell construction were modified slightly from those shown in Fig. 2 so that the volume of the selenium compartment could also be varied. Thus the increased volume of the lithium-selenium alloy with increasing lithium content could be accommodated without altering the electrolyte level within the selenium electrode compartment. Corrosion of cell parts by reactants, products, or electrolyte was not detected.

The emf measurements were made with a Hewlett-Packard Model 3420B differential d-c voltmeter having an input impedance of 10^{10} ohms (some early measurements were made with a Keithley Model 630 having 10^{13} ohms input impedance). Individual measurements had a precision of 1.0 mV or better and the accuracy of the measurements is estimated to be ±10 mV or better. The current for changing the composition of the lithium-selenium alloy was supplied by a Wenking Model 61RS potentiostat connected as a galvanostat and was measured with a standard resistor and a L&N Type K-3 potentiometer. Cell temperature was measured using Chromel-Alumel thermocouples and the K-3 potentiometer. All data were monitored on strip-chart recorders as appropriate.

Results and Discussion

Typical results for emf as a function of temperature for various mole ratios of lithium to lithium plus selenium $[n_{Li}/(n_{Li} + n_{Se})]$ for the selenium alloy electrode are shown in Fig. 3. The data points for the composition $n_{Li}/(n_{Li} + n_{Se}) = 0.10$ through 0.276 have been eliminated for clarity because they are too numerous and closely spaced to be shown. The data used in this figure were taken from a cell using the LiBr-RbBr eutectic as electrolyte and having a mole ratio of selenium to selenium plus electrolyte in the alloy compartment $[n_{Se}/(n_{Se} + n_E)]$ equal to 0.384. In Fig. 4 results are shown for emf as a function of lithium content of the alloy electrode at 360°C and for $n_{Se}/(n_{Se} + n_E)$ again equal to 0.384.

Four general types of behavior can be noted based on the data shown in Fig. 3 and 4: (*i*) for lithium mole ratios less than about 0.19 [*i.e.*, $n_{Li}/(n_{Li} + n_{Se}) < 0.19$], $(\partial E/\partial T)$ is positive and $(\partial E/\partial \ln x_{Li})$ is equal to $RT/2F$; (*ii*) in the range of lithium mole ratio from about 0.19 to about 0.28, $(\partial E/\partial T)$ and $(\partial E/\partial \ln x_{Li})$ are both zero; (*iii*) in the range of lithium mole ratio from about 0.28 to about 0.32, $(\partial E/\partial T)$ is probably negative and $(\partial E/\partial \ln x_{Li})$ certainly negative; and (*iv*) for lithium mole ratios greater than 0.32 and up to at least 0.46, $(\partial E/\partial T)$ is negative and $(\partial E/\partial \ln x_{Li})$ is zero.

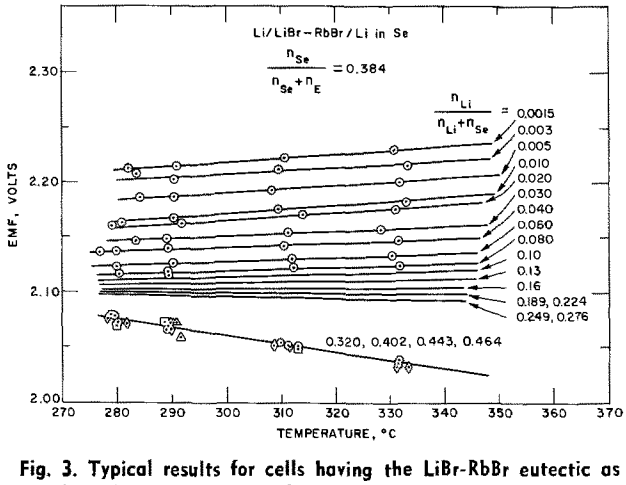

Fig. 3. Typical results for cells having the LiBr-RbBr eutectic as electrolyte showing emf as a function of temperature for various lithium contents of the alloy electrode.

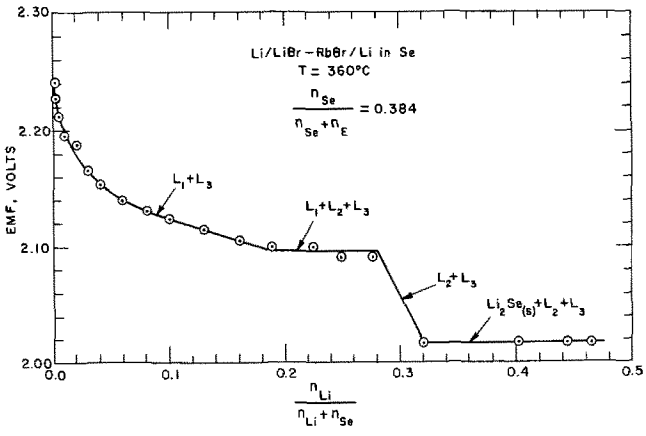

Fig. 4. Typical results for cells having the LiBr-RbBr eutectic electrolyte showing emf as a function of the lithium content of the alloy electrode at 360°C.

The significance of these four regions is clear when considered in connection with the pseudoternary phase diagram presented in the preceding paper (7). The results shown in Fig. 4 represent the emf of the cell as the composition progressed across the phase diagram along a line parallel to the Li_2Se-Se side and intersected the (LiBr-RbBr)-Se side of the diagram at a point corresponding to 0.384 mole fraction selenium. The discontinuous change of slope at 0.188 mole fraction lithium in Fig. 4 corresponds to the point in the pseudoternary phase diagram located at 4.4 m/o Li_2Se, 33.9 m/o Se, and 61.7 m/o LiBr-RbBr which lies on the boundary between the $L_1 + L_3$ and $L_1 + L_2 + L_3$ regions (see Fig. 2 of the preceding paper). The additional slope discontinuities correspond to the crossing of other phase boundaries.

As the extent of the solubility of the lithium-selenium alloy electrode in the lithium halide-containing electrolyte became clear (7), the modified H-cells described above were used to obtain data where the mole fraction of selenium with respect to electrolyte $[n_{Se}/(n_{Se} + n_E)]$ was made as large as the cell design would permit. Results from three such cells are shown in Fig. 5 and are quite similar to those shown in Fig. 4. In Fig. 5 the composition is plotted on a log scale in the low lithium range to emphasize the observed relation $\partial E/\partial \ln x_{Li} = RT/2F$ and on a linear scale in the high lithium range to prevent crowding so that the four distinct regions are apparent. In the two regions corresponding to three-phase equilibrium, however, there is a definite negative slope to the emf-*vs.*-com-

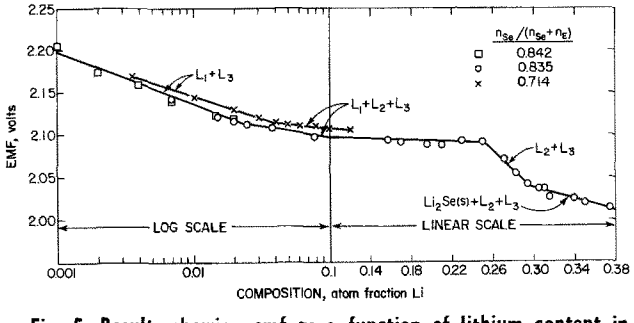

Fig. 5. Results showing emf as a function of lithium content in the alloy electrode for cells using LiBr-RbBr eutectic as electrolyte and for which $n_{Se}/(n_{Se} + n_E)$ has been maximized.

position plot instead of a zero slope line as expected for a three-phase region in a three-component system. This variation is attributed to exchange of rubidium and lithium at the electrolyte-cathode interface in the cathode chamber. The formation of some Rb_2Se_x would be expected to lower the cell potential slightly as the lithium concentration increases in the cathode alloy. This interpretation is also supported by the observation that, for cells using only lithium cations in the electrolyte, negative slopes were not obtained in the three-phase regions for $n_{Se}/(n_{Se} + n_E)$ up to 0.53.

Typical emf-*vs.*-temperature and emf-*vs.*-composition curves for cells in which the LiF-LiCl-LiI eutectic was used as electrolyte are shown in Fig. 6 and 7. The resemblances to the corresponding figures for the LiBr-RbBr eutectic are clear. Data were obtained using this eutectic in a number of cells having different selenium to selenium plus eutectic mole ratios. The information obtained relating to phase equilibria and the location of phase boundaries at 390°C is presented in Fig. 8. In this figure the data have been tentatively interpreted in terms of a pseudoternary system similar to that presented in the preceding paper (7) for the LiBr-RbBr eutectic containing system.

As stated above, the data for low-lithium regions (such as the data presented in Fig. 4, 5, and 7) correspond to $\partial E/\partial \ln x_{Li} = RT/2\mathbf{F}$, indicating that two electrons and two lithium atoms are involved in the over-all cell reaction, which may be written

$$2Li + xSe \rightarrow Li_2Se_x$$

The corresponding Nernst equation (with pure lithium as the reference electrode) is then

$$E = -\frac{RT}{2\mathbf{F}} \ln \gamma_{Li_2} x_{Li_2}$$

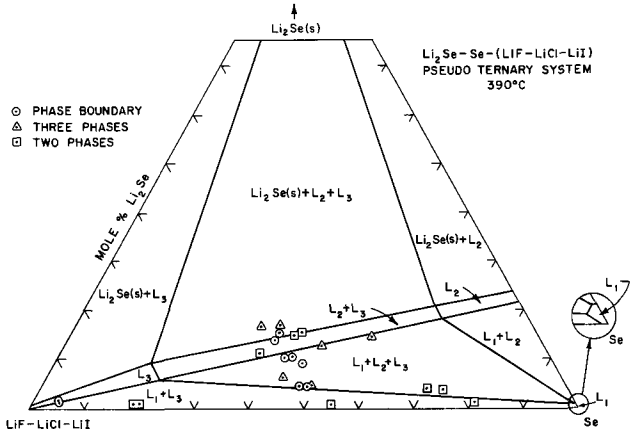

Fig. 8. Phase equilibrium data and phase boundary locations determined by emf measurements on cells using the LiF-LiCl-LiI eutectic electrolyte. Data are tentatively interpreted in terms of a pseudoternary system.

The activity coefficient (γ_{Li_2}) of lithium in liquid L_1 at 360°C has been calculated using data from Li/LiBr-RbBr(eutectic)/Li in Se cells. The activity coefficient was found to be 6×10^{-32} and is quite insensitive to variation in composition in the region where L_1 and L_2 are in equilibrium.

From the emf in the $Li_2Se(s) + L_2 + L_3$ region, and the knowledge that the lithium activity in L_1 saturated with L_2 (and L_3) is equal to the lithium activity in L_2 saturated with L_1 (and L_3), it was possible to apply the Gibbs-Duhem equation (assuming that the activity coefficient of the salt in L_2 and L_3 was constant) in correcting the free energy of formation of Li_2Se to unit activities of lithium and selenium. At 360°C, $\Delta G°_f$ (Li_2Se) = −94.0 kcal/mol.

Acknowledgment

The authors wish to thank Dr. R. C. Vogel and Dr. A. D. Tevebaugh for their encouragement and support, and Mr. P. D. Hunt for help with some of the experiments. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript submitted Oct. 4, 1972, revised manuscript received Dec. 28, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Mathematical Characterization of Corrosion Currents in Local Electrolytic Cells

L. Gal-Or, Y. Raz,[1] and J. Yahalom

Israel Institute of Metals and the Department of Materials Engineering, Technion-Israel Institute of Technology, Haifa, Israel

ABSTRACT

A previous mathematical analysis of Simmons *et al.* related to the corrosion currents in local rectangular electrolytic cells is extended here to the more realistic case of circular cells which develop in pitting processes. The present work is based on a typical local electrolytic cell, in which the anode and cathode are represented by coplanar concentric circles. The cell current is calculated as a function of the anode and cathode radius, thickness, and conductivity of electrolyte, potential difference between anode and cathode at zero current flow, and a linear polarization parameter. The present results are then compared with the theoretical results of Simmons *et al.* and with experimental data obtained in this study for a system of two coplanar circular electrodes made of Fe and Ni in an 0.01*N* NaBr aqueous solution.

Many corrosion reactions proceed through an electrochemical mechanism based on the action of local electrolytic cells (1, 2). The local cells are developed due to the electrochemical heterogeneity of the metal surface or of the electrolyte. The causes of electrochemical heterogeneity of the metal include: heterogeneous metal structure, grain boundaries, pores in protective films, nonuniform deformations, etc.

The mechanism of such corrosion processes, mainly the pitting reaction, has been extensively studied (3-5). Nevertheless, so far, only two theoretical attempts have been made to characterize quantitatively the corrosion current of local electrolytic cells (6, 7).

Waber *et al.* (6, 8) used a one-dimensional model, in which the anodes and cathodes of the local cells were described as an array of alternately infinitely long electrodes. They calculated the current of the cell as a function of the width of the electrodes, thickness of the electrolyte layer, the conductivity of the electrolyte, and the polarization parameters.

In 1967 Simmons *et al.* (7) generalized the one-dimensional geometry employed by Waber *et al.*, and calculated the current for a cell in which the cathode and anode are described as coplanar concentric rectangulars.

However, in many actual cases of local corrosion the geometry of the anode is much closer to a circular cross section than to a rectangular one. Therefore, the aim of the present analysis is to quantitatively characterize the corrosion current of a local cell with a circular geometry.

Cell Geometry

The geometry of the local electrolytic cell used in this analysis is illustrated in Fig. 1. The anode and cathode are coplanar, and are represented by two concentric circles, with radii a and b, respectively. The electrolyte thickness is designated by c, and it represents the height of the cylinder formed. Therefore, the mathematical treatment is done with cylindrical coordinates, whose origin is located at the center of the upper plane, where $Z = 0$, so that the anode and cathode lie in the plane $Z = -c$. This model represents a typical (statistically averaged) circular electrolytic cell analogous to cell models employed in, for instance, statistical thermodynamics (9), or hydrodynamics (10).

The expected corrosion current of the cell, I_{total}, is to be derived as a function of the following parameters

$$I_{total} = f(a, b, c, E, \sigma, k)$$

where: a = radius of anode; b = radius of cathode; c = electrolyte thickness; E = potential difference between anode and cathode at zero current flow; σ = conductivity of electrolyte; and k = linear polarization parameter, $k = \sigma(dV/di)$, where dV/di represents the slope of the polarization curve at the operating current densities (for further elucidation of k see the following assumptions).

The following simplifying assumptions employed in this work are similar to those employed by Waber *et al.* (6) and Simmons (7).

1. Variations in the composition of the electrolyte, of cell geometry, and of surface conditions of the electrodes, during the corrosion process, are neglected.

2. The polarization parameter k is the same for both electrodes, and is independent of the current density. This independence is a result of the assumption of a linear relation between potential and current density, so that dV/di = const. For many practical cases these assumptions may be considered as reasonable approximations.

3. The envelope $r = b$, as well as the upper plane of the cylinder $Z = 0$, are perfect insulators (*i.e.*, no current flows between the numerous electrolytic cells on the metal surface).

Governing Equations and Boundary Conditions

1. The total cell current can now be derived by integration of the equation describing the local current distribution, over the area of the anode or cathode. This integration is based on the aforementioned assumptions.

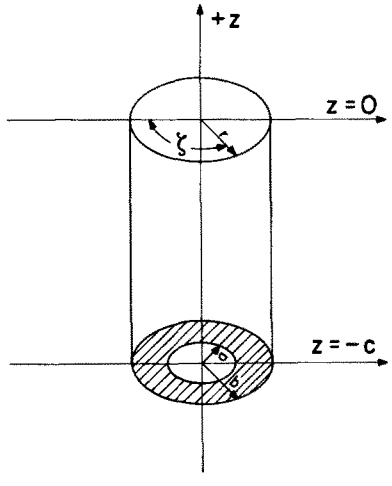

Fig. 1. Geometry of the mathematical model for an electrolytic cell.

[1] Department of Computer Science.

Key words: pitting, mathematical model, localized corrosion.

2. The local current flow to or from the electrodes, is characterized by the potential distribution through Ohm's law, *i.e.*

$$I_{(r,\zeta,-c)} = -\delta \frac{\partial \phi}{\partial z} \Bigg|_{(r,\zeta,-c)} \quad [1]$$

where r,ζ,z are the cylindrical coordinates and $\partial\phi/\partial z$ the local gradient of the potential normal to the metal surface.

3. The potential distribution in the cell is governed by the Laplace equation

$$\nabla^2\phi = 0 \quad [2]$$

The solution of this equation with suitable boundary conditions, should give the distribution of the potential in the cell.

Equation [1] stems from the Poisson law, which states that the relation between potential and charge density is given by

$$\text{divgrad}\,\phi = \nabla^2\phi = -\frac{4\pi\rho'}{\epsilon} \quad [3]$$

where ρ' is the charge density and ϵ the dielectric constant.

Since the net charge in an electrolytic cell is zero, $\rho' = 0$ and $\nabla^2\phi = 0$.

In cylindrical coordinates the Laplace equation becomes

$$\nabla^2\phi = \frac{\partial^2\phi}{\partial r^2} \perp \frac{1}{r}\frac{\partial\phi}{\partial r} \perp \frac{1}{r^2}\frac{\partial^2\phi}{\partial\zeta^2} \perp \frac{\partial^2\phi}{\partial z^2} = 0 \quad [4]$$

The total expected cell current will be derived by solution of Eq. [4], differentiation of the solution with respect to z to obtain $\partial\phi/\partial z$, substitution of $\partial\phi/\partial z$ in Eq. [1] to obtain $I_{(r,\zeta,-c)}$, and integration of the resulting equation of $I_{(r,\zeta,-c)}$ over the anode surface area as follows

$$I_{\text{total}} = \int\int_{s(\text{anode})} I_{(r,\zeta,-c)}\, ds = \int_0^a I(r,-c)\, 2\pi r dr$$

4. The boundary conditions used for the solution of Eq. [1] are

$$\frac{\partial\phi}{\partial r/r = b} = 0 \quad [5]$$

and

$$\frac{\partial\phi}{\partial z/z = 0} = 0 \quad [6]$$

Equations [5] and [6] stem from the assumption that the envelope of the cylinder describing the typical cell (except the metal planes of the electrodes) are insulators.

The third boundary condition is derived as follows:

On the cathode area (*i.e.*, $a < r < b$)

$$\phi_{(r,\zeta,-c)} = E_c \perp k\frac{\partial\phi}{\partial z/z = -c} \quad [7]$$

where E_c is the open-circuit single potential of the cathode.

5. Choosing the potential scale so that $E_c = 0$ we obtain

$$\phi_{(r,\zeta,-c)} = k\frac{\partial\phi}{\partial z/z = -c} \quad [8]$$

for $a < r < b$.

On the anode (*i.e.* at $r < a$)

$$\phi_{(r,\zeta,-c)} = E \perp k\frac{\partial\phi}{\partial z/z = -c} \quad [9]$$

where E is the difference between E_a (open-circuit single potential of the anode) and E_c.

Equations [8] and [9] can thus be combined to give

$$\phi_{(r,\zeta,-c)} = ES(r) \perp k\frac{\partial\phi}{\partial z/z = -c} \quad [10]$$

where $S(r)$ is a step function with the properties

$$S(r) = 0 \quad a < r < b$$

$$S(r) = 1 \quad r < a$$

Mathematical Solution

Equation [4] is solved by the separation of variables technique, *i.e.*, by assuming that the solution is given as a product of three separate functions, each being dependent on a single variable

$$\phi_{(r,\zeta,z)} = R(r)\theta(\zeta)Z(z) \quad [11]$$

Introducing now the dimensionless parameters

$$a^* = \frac{a}{b},\quad c^* = \frac{c}{b},\quad r^* = \frac{r}{b},\quad z^* = \frac{z}{b},\quad k^* = \frac{k}{b}$$

the Laplace equation and its boundary conditions take the form

$$\frac{\partial^2\phi}{\partial r^{*2}} \perp \frac{1}{r^*}\frac{\partial\phi}{\partial r^*} \perp \frac{1}{r^{*2}}\frac{\partial^2\phi}{\partial\zeta^2} \perp \frac{\partial^2\phi}{\partial z^{*2}} = 0 \quad [12]$$

and

$$\frac{\partial\phi}{\partial r^*/r^* = 1} = 0 \quad [13]$$

$$\frac{\partial\phi}{\partial z^*/z^* = 0} = 0 \quad [14]$$

$$\phi_{(r,\zeta,-c^*)} = ES(r^*) \perp k^*\frac{\partial\phi}{\partial z^*/z^* = -c^*} \quad [15]$$

where

$$S(r^*) = \begin{cases} 1 & r^* < \dfrac{a}{b} \\ 0 & \dfrac{a}{b} < r^* < 1 \end{cases} \quad [16]$$

Equation [11] is thus represented as

$$\phi_{(r^*,\zeta,z^*)} = R(r^*) \times \theta(\zeta) \times Z(z^*) \quad [17]$$

By substituting Eq. [17], and its derivatives, in Eq. [12], and dividing by $R\theta Z$, we obtain

$$\frac{1}{R}\left[\frac{d^2R}{dr^{*2}} \perp \frac{1}{r^*}\frac{dR}{dr^*}\right] \perp \frac{1}{r^{*2}\theta}\frac{d^2\theta}{d\zeta^2} \perp \frac{d^2Z}{Zdz^{*2}} = 0 \quad [18]$$

which can be rewritten as

$$\frac{R''}{R} \perp \frac{1}{r^*}\frac{R'}{R} \perp \frac{\theta''}{\theta} \times \frac{1}{r^{*2}} \perp \frac{Z''}{Z} = 0 \quad [19]$$

Since

$$\frac{Z''}{Z} = k^2\,\text{const} \quad [20]$$

$$Z = c_1e^{-kz^*} \perp c_2e^{-kz^*} \quad [21]$$

where c_1 and c_2 are constants.

Now

$$\frac{\theta''}{\theta} = -\nu^2 \quad [22]$$

and

$$\theta = c_3e^{i\nu\zeta} \perp c_4e^{-i\nu\zeta} \quad [23]$$

where c_3 and c_4 are constants.

Equation [19] can be written now (after multiplying by r^{*2}/R) as

$$r^{*2}R'' \perp r^*R' \perp (k^2r^{*2} - \nu^2)R = 0 \quad [24]$$

substituting $x = kr^*$ in Eq. [24] we obtain

$$x^2\frac{d^2R}{dx^2} \perp x\frac{dR}{dx} \perp (x^2 - \nu^2)R = 0 \quad [25]$$

Equation [25] is a Bessel equation whose regular solu-

tions at $x = 0$ are $J_\nu(x)$, the Bessel functions. Therefore $R(r^*) \sim J_\nu(kr^*)$.

Since the problem is axi-symmetric (no dependence on ξ), $\nu = 0$ and, therefore

$$\theta(\xi) = 1 \quad [26]$$

$$R(r^*) \sim J_0(kr^*) \quad [27]$$

and

$$\phi_{(r^*,z^*)} = R(r^*)Z(z^*) = J_0(kr^*)[c_1e^{kz^*} \perp c_2e^{-kz^*}] \quad [28]$$

Boundary condition [13] gives

$$\left.\frac{dR(r^*)}{dr^*}\right|_{r^*=1} = \frac{d}{dr^*}[J_0(kr^*)]_{r^*=1} = 0 \quad [29]$$

using the identity

$$J'_0(x) = -J_1(x) \quad [30]$$

Eq. [30] becomes

$$\left.\frac{d}{dr^*}J_0(kr^*)\right|_{r^*=1} = -kJ_1(k) = 0 \quad [31]$$

The solutions k_n of [31] are the zeroes of $J_1(x)$.

Boundary condition [14] demands that for any n

$$\left.\frac{d\phi}{dz^*}\right|_{z^*=0} = \frac{dZ(z^*)}{dz^*} = c_1k_n - c_2k_n = 0 \quad [32]$$

so that $c_1 = c_2$.

The potential field (Eq. [28]) will be given by

$$\phi(r^*,z^*) = \sum_{n=1}^{\infty} C_nJ_0(k_nr^*)\cosh(k_nz^*) \perp C_0 \quad [33]$$

The above series are the Dini series and by differentiation of Eq. [33] with respect to z^*, at $-c^*$, and by substituting in boundary condition [15], we obtain

$$ES(r^*) = \sum_{n=1}^{\infty} C_nJ_0(k_nr^*)\cosh(k_nc^*) \perp k^*k_n\sinh(k_nc^*) \perp C_0 \quad [34]$$

C_n will be calculated by differentiation of Eq. [34] with respect to r^* with the use of identity [31], and the relation

$$2\int_0^1 J_1(k_nr^*)J_1(k_mr^*)r^*dr^* = \delta_{mn}[J'_1(k_m)]^2 \quad [35]$$

where

$J'_1(k_n) = J_0(k_m)$ and δ_{mn} is the Kronecker delta

$$\delta_{mn} = \begin{cases} 1 & m = n \\ 0 & m \neq n \end{cases}$$

This gives

$$C_n = \frac{2a^*EJ_1(k_na^*)}{[J_0(k_n)]^2k_n[\cosh(k_nc^*) \perp k^*k_n\sinh(k_nc^*)]} \quad [36]$$

Since the expansion [34] is a Dini series, $C_0 = Ea^{*2}$.

Substituting C_n and C_0 into Eq. [33] we obtain

$$\phi(r^*,z^*) = 2a^*E \times \sum_{n=1}^{\infty} \frac{J_0(k_nr^*)\cosh[k_nz^*]J_1(k_na^*)}{[J_0(k_n)]^2k_n[\cosh(k_nc^*) \perp k^*k_n\sinh(k_nc^*)]} \perp Ea^{*2} \quad [37]$$

The current density on the electrode surface is thus given by

$$I_{(r^*,-c^*)} = \frac{-\sigma}{b}\left.\frac{\partial\phi}{\partial z^*}\right|_{z^*=-c^*} = \frac{2}{b}a^*E\sigma \times \sum_{n=1}^{\infty} \frac{J_0(k_nr^*)J_1(k_na^*)\sinh(k_nc^*)}{[J_0(k_n)]^2[\cosh(k_nc^*) \perp k^*k_n\sinh(k_nc^*)]} \times \frac{1}{[\coth(k_nc^*) \perp (k^*k_n)]} \quad [38]$$

and the total corrosion current by

$$I_{\text{total}} = 2\pi\int_0^{a^*b} I(r^*,-c^*)r^*dr^* = 4\pi a^{*2}bE\sigma\sum_{n=1}^{\infty}\frac{[J_1(k_na^*)]^2}{[J_0(k_n)]^2} \times \frac{1}{[\coth(k_nc^*) + k^*k_n]k_n} \quad [39]$$

For the integration step we used

$$\int x^nJ_{n-1}(x)dx = x^nJ_n(x)$$

I_{total} had been computed from Eq. [39] by employing a digital computer, as described in Appendix A. The analysis of the error involved in computing I_{total} is also given in Appendix B.

To express I_{total} for a wide spectrum of systems, independently of specific values of E, a, and σ, one can transform I_{total} to the dimensionless expression

$$I^*_{\text{total}} = \frac{k\,I_{\text{total}}}{4Ea^2\sigma} = \frac{k\,I_{\text{total}}}{4\pi E\sigma(\text{anode area})} \quad [40]$$

Results and Discussion

The dependence of I^*_{total} on a^*, c^*, and k^*, is given in Fig. 2. This figure shows that I^*_{total} increases with c^* for various values of k^* and a^* up to a saturation level.

Figure 3 shows the dependence of the cell current, I_{total}, on the anode radius, a, the polarization parameter, k, and the electrolyte thickness, c. I_{total} increases with c up to a saturation level.

Comparison of the results of the present model with the results of Simmons et al. (7).—To compare the results obtained by the present model with the results of Simmons *et al.* (7), I^*_{total} was computed from Eq. [40], for different values of a^*, k^*, and c^* (see Table I). The error, R, involved in the above computations of I^*_{total} is related to N, the number of terms employed in the calculation of the series which appears in Eq. [39]. In the present study N was taken as 1000. The error involved can be calculated as follows:

According to Eq. [A-B-9] of Appendix B one obtains that for $a^* >> 10^{-3}$, $R \leq 1/a^* \times 10^{-4}$.

Therefore, for $a^* = 0.5$, $R \leq 0.0002$; and for $a^* = 0.1$, $R \leq 0.001$.

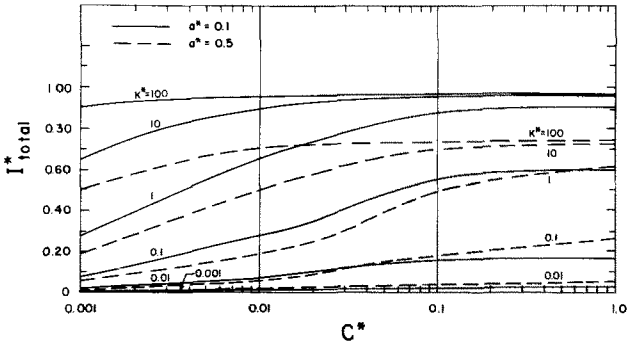

Fig. 2. Dependence of dimensionless cell current I^*_{total} on k^*, a^*, and c^*.

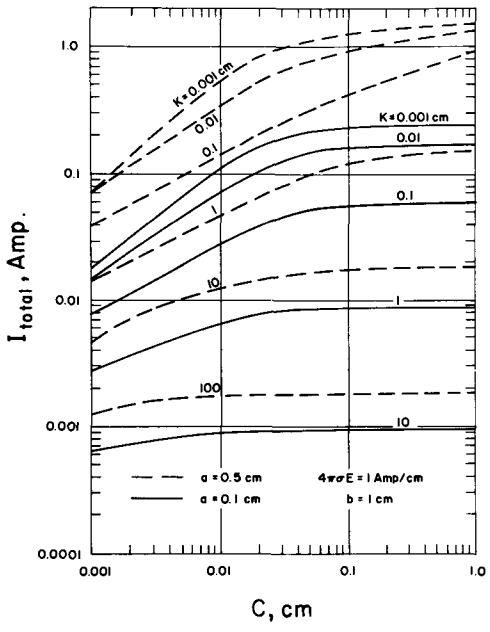

Fig. 3. Dependence of cell current I_{total} on polarization parameter k, anode radius a, and electrolyte thickness c.

The terms in the series were computed with an accuracy of 10^{-7}, therefore, the accumulative truncation error, which can have a positive or negative value, would not exceed a value of 10^{-4}. Therefore, the total error $\overline{R}$ must be for $a^* = 0.5$, $0 < \overline{R} < 0.0003$; and for $a^* = 0.1$, $0 < \overline{R} < 0.0011$.

Since $\overline{R} > 0$ the exact value of I^*_{total} is to be within the interval $[I^*_{total}, I^*_{total} + \overline{R}]$.

In general, as the value of a^* decreases, the number of terms employed in the calculation of the series in Eq. [39] should increase, in order to obtain a given accuracy (*q.v.* Eq. [A-B-9]-[A-B-11] in Appendix B).

Table I gives the values thus computed, compared to the values of I^*_{total} computed by Simmons *et al.* The comparison shows that there is a good agreement between the predicted results of the two analyses at relatively high values of a^*, k^*, and c^*. The discrepancy between the two models grows with a decrease of c^* and k^*. This implies that there is a greater effect of the cell geometry on the computed cell current for low polarization and thin electrolytes, than for high polarization and thick electrolytes.

Table I. Values for I^*_{total} based on the present model and as obtained by Simmons *et al.* (7)

	$a^* = 0.5$		$a^* = 0.1$

Experimental Comparison

An experimental system was built for the purpose of comparing the theoretical predictions with an actual system. The system was designed to enable measurement of the current of an electrochemical cell with a defined geometry as a function of the parameters employed in the theoretical analysis. The experimental results are then compared with the predicted values of the analytical model at the same operating conditions.

The experimental set up is described in Fig. 4. It includes a galvanic cell made of two circular coplanar concentric electrodes. The anode is made of Swedish Pure Steel 0.4 cm in diameter and the cathode is made of 99.85% nickel 0.8 cm in diameter. The two electrodes are isolated by a thin Teflon tape of 0.01 cm thickness. The plane of the electrode surfaces is maintained above and parallel to the bottom of the solution container. A micrometric screw enables varying the distance between the electrode plane and the plane of the glass vessel bottom. In this way the electrolyte thickness c can be varied.

I_{total}, the cell current, is measured as the potential drop on a known resistance using a Hewlett Packard V.T.V.M. Model 412A and an amplifier with a 10^{12} ohm impedance, Knick Model 72Z. I_{total} was measured as a function of c.

The following parameters of the cell needed for the computation of I_{total} were measured:

E the open-circuit potential was measured using the Hewlett Packard V.T.V.M. and the Knick amplifier.

σ the conductivity of the solution was measured by using a standard conductivity measuring system previously calibrated with a KCl solution of similar conductivity.

k the polarization parameter has been deduced from the anodic polarization curve of the Swedish Pure Steel. The polarization measurements were carried out in a standard polarization cell. The approximated slope, M, of the V *vs.* i curve was used in the estimation of k ($k = \sigma M$). It is assumed that because of the smaller anodic area the reaction is anodically controlled (also concentration polarization effects in the cathodic reaction are not expected since I_{total} was recorded shortly after the circuit was closed).

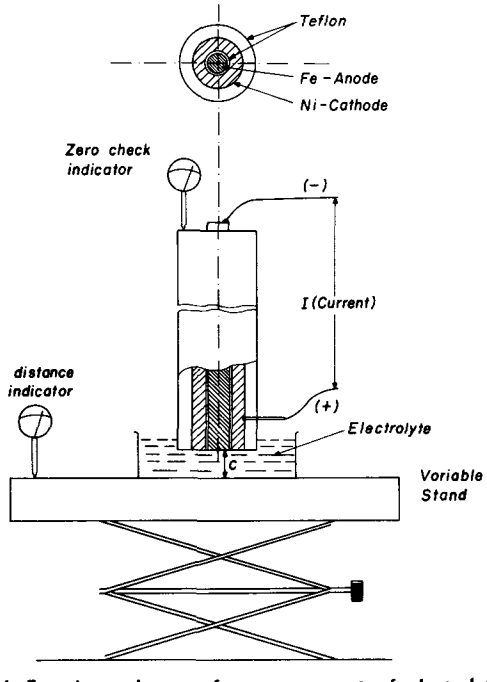

Fig. 4. Experimental setup for measurement of electrolytic current as function of electrolyte thickness.

Table II. Experimental data for calculation of I_{total}

k, cm	M, ohm-cm²	σ, ohm⁻¹-cm⁻¹	E, V	b, cm	a, cm
0.80	55.5	0.0145	0.175	0.4	0.2

The measurements were carried out in an aqueous solution of 0.01N NaBr buffered to pH = 2.2 with a 0.05M sulfate buffer. (The bromide solution was chosen because of its relevance to a study on the mechanism of corrosion by bromine which was studied at the same time.) Table II summarizes the measured parameters.

I_{total} was computed by Eq. [39] using an Elliott 503 computer. In each computation 1000 terms of the series in Eq. [39] were summarized. The comparison of experimental and theoretical results of I_{total} as a function of c is given in Fig. 5.

Figure 5 shows that the theoretical and experimental curves are qualitatively similar. Quantitatively the theoretical and experimental results differ by a factor up to 2. This discrepancy probably stems partly from the simplifying assumptions employed in the deduction of the analytical model, as well as from the experimental errors involved in the measurements of the parameters. As to the simplifying assumptions, the one involving a linear relation between the potential and the current density is probably the weakest one, since it is theoretically justified only for small values of current density. In our experiments, the current densities were of the order of 1 mA/cm² and were still in the approximate linear region. Variations of k due to nonlinearity of the extension of the curve are of the order of ±30%. The reproducibility of k, for the same current density and different polarization curves, was in the range of ±20%. (A typical polarization curve for the system studied is given in Fig. 6.) While the aforementioned variations of k introduce inaccuracies in the computed cell currents, they do not account for the entire discrepancy between the essentially exact theoretical results and the experimental ones, as can be judged from Fig. 3. Other factors, such as the assumption that the whole electrode area acts as an anode, or cathode, contribute to the discrepancy. A large number of experimental data, under various operating conditions, is required in order to distinguish between the influence of the various individual factors.

APPENDIX A

Computation of total cell current I_{total}

I_{total} is computed from Eq. [39]. The number of terms in the series is dictated by the chosen degree of accuracy (see Appendix B).

k_n which are the zeroes of J_1 have been computed by a combination of the regula falsi and bisection methods using the asymptotic expression

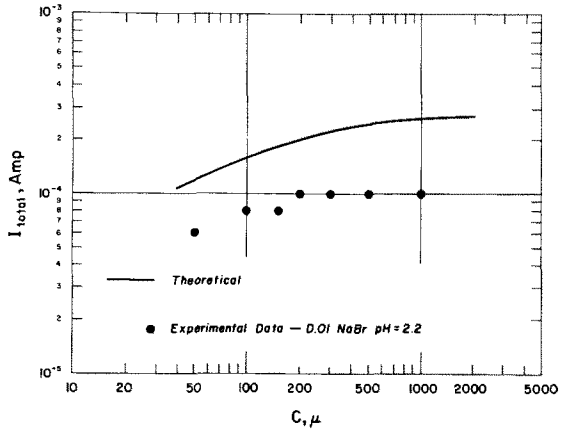

Fig. 5. Comparison of experimental and theoretical results for effect of electrolyte thickness on cell current.

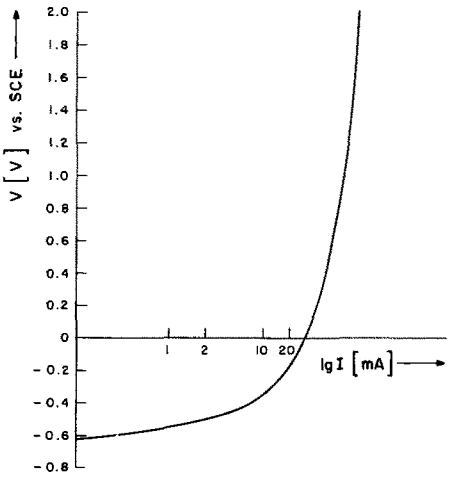

Fig. 6. Anodic polarization curve for Swedish Pure Steel in 0.01N NaBr, pH 2.2

$$k_n = \left(n \perp \frac{1}{4}\right)\pi \perp O\left(\frac{1}{n}\right) \text{ and the inequality}$$

$$n\pi < k_n < \left(n \perp \frac{1}{2}\right)\pi \text{ for } n = 1, 2, \ldots$$

An appropriate number of k_n were computed with an accuracy of 7 decimals and stored on the computer tape. The stored values were used for any computation of I_{total}.

$J_0(x)$ and $J_1(x)$ were computed up to 8 decimals.

The computation was carried out by an Elliott 503 computer.

APPENDIX B

Evaluation of the error in computing I_{total}

I_{total} is computed from Eq. [39] which contains a series that can be expressed as

$$A = \sum_{n=1}^{\infty} a_n \qquad \text{[A-B-1]}$$

where

$$a_n = 4\bar{k}\left[\frac{J_1(k_n a^*)}{J_0(k_n)}\right]^2 \cdot \frac{1}{[\coth(k_n c^*) \perp k^* \cdot k_n]k_n} \qquad \text{[A-B-2]}$$

The truncation error in the computation of a_n is of the order of 10^{-7}, while the round off error is much smaller. Therefore in order to achieve a chosen accuracy the necessary number of terms in the series A has to be determined.

In the following the "tail" of the series

$$R_n = \sum_{n=N\perp 1}^{\infty} a_n \qquad \text{[A-B-3]}$$

is estimated.

The following asymptotic expression is valid for the Bessel function

$$J_\nu Z = \sqrt{\frac{2}{\pi Z}}\cos\left[Z - \left(\nu \perp \frac{1}{2}\right)\frac{\pi}{2}\right] \perp O\left(\frac{1}{Z^{3/2}}\right) \qquad \text{[A-B-4]}$$

therefore

$$\frac{J_1(a^*k_n)}{J_0(k_n)} = \frac{1}{\sqrt{a^*}} \frac{\cos\left[a^*k_n - \frac{3}{4}\pi\right] \perp O\left[\frac{1}{(na^*)}\right]^{3/2}}{\cos\left[k_n - \frac{\pi}{4}\right] \perp O\left[\frac{1}{n}\right]^{3/2}} \qquad \text{[A-B-5]}$$

Using

$$k_n = \left(n \perp \frac{1}{4}\right)\pi \perp O\left(\frac{1}{n}\right) \qquad \text{[A-B-6]}$$

We obtain

$$\frac{J_1(a^*k_n)}{J_0(k_n)} = \frac{1}{\sqrt{a^*}} \frac{\cos\left[a^*k_n - \frac{3}{4}\pi\right] \perp O(na^*)^{-3/2}}{\cos\left[\left(n \perp \frac{1}{4}\right)\pi - \frac{1}{4}\pi\right] \perp O\left(\frac{1}{n}\right)}$$

$$= \frac{1}{\sqrt{a^*}} \frac{\cos\left[a^*k_n - \frac{3}{4}\pi\right] \perp O[(na^*)^{-3/2}]}{(-1)^n \perp O\left(\frac{1}{n}\right)}$$

or

$$\left[\frac{J_1(a^*k_n)}{J_0(k_n)}\right]^2 \leq \frac{1}{a^*} \frac{1 \perp O[(na^*)^{-3/2}]}{1 \perp O\left(\frac{1}{n}\right)} \quad \text{[A-B-7]}$$

Therefore

$$|a_n| = a_n \leq \frac{4k^*}{a^*} \frac{1 \perp O(na^*)^{-3/2}}{1 \perp O\left(\frac{1}{n}\right)} \cdot \frac{1}{\left\{\coth(k_n\pi c^*) \perp k^*\left[\left(n \perp \frac{1}{4}\right)\pi \perp O\left(\frac{1}{n}\right)\right]\right\}\left[\left(n \perp \frac{1}{4}\right)\pi \perp O\left(\frac{1}{n}\right)\right]}$$

$$\leq \frac{4k^*}{a^*} \frac{1 \perp O[(na^*)^{-3/2}]}{k^*\pi^2\left(n \perp \frac{1}{4}\right)^2} = \frac{4(1 \perp O[(na^*)^{-3/2}]}{a^*\pi^2\left(n \perp \frac{1}{4}\right)^2} \quad \text{[A-B-8]}$$

Therefore

$$|R_N| = R_N \leq \frac{4(1 \perp O[(Na^*)^{-3/2}])}{a^*\pi^2} \int_N^\infty \frac{dx}{x^2} = \frac{4(1 \perp O[(Na^*)^{-3/2}])}{Na^*\pi^2} \quad \text{[A-B-9]}$$

To obtain a chosen accuracy of R the number of terms N has to fulfill

$$N >> \frac{1}{a^*} \quad \text{[A-B-10]}$$

$$N \geq \frac{4}{\pi^2 R a^*} \quad \text{[A-B-11]}$$

Since $I^*_{\text{total}} < 1$, R will always be $R < 0.1$ and therefore condition [A-B-11] is sufficient.

Effects of Molybdenum on the Pitting Potentials of Ferritic Stainless Steels at Various Temperatures

A. P. Bond*

Research Laboratory, Climax Molybdenum Company of Michigan, Ann Arbor, Michigan 48106

ABSTRACT

Pitting potential measurements were performed by potentiodynamic scanning at 200 mV/hr in 1M NaCl and in 1M NaBr, each saturated with nitrogen. Over the entire temperature range studied, 1°-70°C, molybdenum additions up to the limit of solid solubility caused a continuous increase in the pitting potentials of 18% Cr ferritic stainless steels. Exposure tests were also performed in various chloride-containing environments, and it was found that pitting rate decreased as the molybdenum content increased.

It has been suggested that at low temperatures molybdenum additions may not be beneficial to the pitting resistance of austenitic stainless steels exposed to chloride solutions (1). Data have also been presented indicating that above room temperature, the beneficial effects of molybdenum on resistance to pitting may decrease (2). Furthermore, it has been reported that molybdenum additions are ineffective in sodium bromide solutions (2, 3).

In view of the present interest in molybdenum-containing ferritic stainless steels, it was thought important to investigate these questions and establish more clearly the range of conditions under which molybdenum content has a favorable effect on pitting resistance of ferritic stainless steels. To do this, pitting potential measurements were undertaken on a series of

* Electrochemical Society Active Member.
Key words: corrosion, polarization.

18% chromium steels containing 0-5% Mo. These measurements were made in 1M NaCl and 1M NaBr over a temperature range from 1° to 70°C. Concurrently, some exposure tests were performed in various media containing chlorides or bromides.

Experimental

The experimental alloys were produced by induction-melting in an argon atmosphere using the split-heat technique. By this technique, the base composition was melted and part of the melt was poured off to produce an ingot. To the balance of the melt, the required molybdenum addition was made and the next ingot was cast. This process was repeated until the desired compositions were cast. By this procedure, the impurity levels were held nearly constant within each series. The compositions of the steels produced are given in Table I.

The resulting ingots were hot-forged and hot-rolled to 0.76 cm thick strips and then cold-rolled to 0.38 cm thickness. All strips were given a 1-hr anneal at 815°C and water-quenched before the test specimens were prepared.

The electrodes for the potentiodynamic studies were mounted in epoxy plastic with a single exposed surface parallel to the rolling plane. Electrical contact was made by soft-soldering a nickel wire to the back of the electrode. Contact between the solder or lead wire and the electrolyte was excluded by the plastic and glass tube. The 0.5 by 0.6 cm exposed surface was polished by using standard metallographic techniques, finishing with a distilled water slurry of 0.3μ alumina. The edges of the electrode were masked with clear Glyptal varnish to prevent crevice corrosion.

The coupons for the exposure tests, 2.5 by 2.5 by 0.3 cm, were surface ground and then polished through No. 600 wet silicon carbide paper. They were solvent degreased and rinsed in methanol before exposure.

The potentiodynamic scanning experiments were performed using standard equipment and techniques. The platinum auxiliary electrode was isolated from the test solution by means of a glass frit. The solution used was nitrogen-saturated 1.0M NaCl or 1.0M NaBr. All potential measurements were made using a saturated calomel reference electrode. The scans were started at −0.7V and continued in the noble direction at 200 mV/hr. The temperature was controlled within ±0.5°C of the reported temperature. Below room temperature an ice bath was used, while the elevated temperatures were maintained by a heating mantle and temperature controller.

Results and Discussion

A typical pitting potential determination is shown in Fig. 1. It can be seen that the current rise corresponding to pitting is extremely sharp. This was true at all temperatures investigated. It can also be seen that very short pulses of current were sometimes observed as the pitting potential was approached. As discussed previously (4), these pulses correspond to formation of very tiny pits that do not propagate if the potential scan is stopped below the pitting potential for time periods up to 24 hr.

The effect of variation in the rate of potential scan was checked for the 18% Cr-2% Mo alloy (Table II).

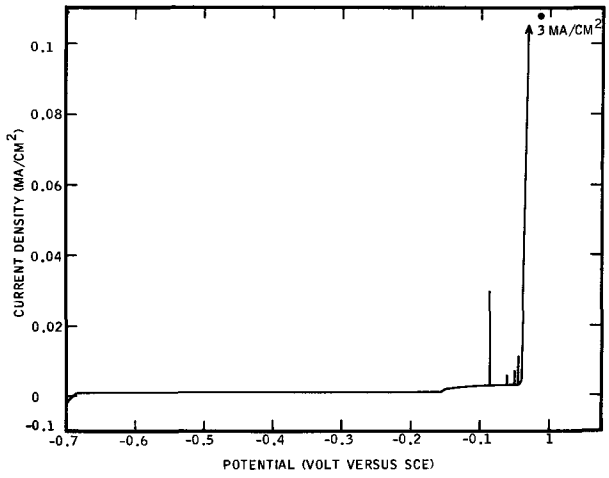

Fig. 1. Polarization curve obtained on scanning a masked electrode of alloy 4354D (3.5% Mo at 200 mV/hr in nitrogen-saturated 1.0M NaCl at 70°C).

No significant difference in pitting potential was obtained when the scan rate was increased from 200 to 2000 mV/hr. This is in contrast to results obtained in a previous study of an 18% Cr-14% Ni-3% Mo austenitic steel (4). This austenitic steel showed a significant decrease in pitting potential as scan rate increased. In general, it has been observed that pitting potentials of ferritic steels are less affected by variations in experimental conditions than are pitting potentials of austenitic steels of similar chromium and molybdenum content.

After each run, the electrode was examined under the microscope. Only if well-developed pits, away from the masked edges, were present was a run accepted as valid. In many cases, there was simultaneous attack at the edges where crevices may have existed, but this was disregarded if distinct pits were visible. The crevice attack was more likely to occur as the test temperature decreased. At 70°C, most electrodes were free of any crevice attack, while at 1°C, most electrodes suffered crevice attack as well as pitting. This effect may be partially a result of the physical properties of the Glyptal mask, which tended to be brittle at low temperatures.

When pitting occurred, a large number of pits were usually found. If the scan was stopped at this point, but without the potentiostat switched off, the pits would continue to grow until the electrode was destroyed.

Results of the tests in 1M NaCl are shown in Fig. 2. While temperature had a very large effect on pitting potentials of these alloys, it is striking that the effect of molybdenum was nearly the same at each of the test temperatures. Thus, over the temperature range studied, molybdenum exerts a definite beneficial effect on pitting potentials. Note that an increase in the pitting potential in the noble direction corresponds to an increase in resistance to pitting corrosion. However, the pitting potentials of the 4.7% Mo alloy did tend to be lower than those observed for the 3.5% Mo steel. Since this difference was observed at each temperature, it appears to be a true effect and not the result of experimental variation.

A similar tendency for a maximum in pitting potential to occur at intermediate molybdenum content was also observed for an austenitic stainless steel series (4). This behavior in the austenitic series was attri-

buted to the occurrence of a second phase at high molybdenum contents. In the present series of ferritic steels, a second phase also occurs in the high molybdenum steels. According to the work of McMullin *et al.* (5), at 815°C, this phase is chi, a compound containing about 25% Mo, 18% Cr, and the balance iron. According to the phase diagram, at 815°C the maximum solubility of molybdenum is about 3.5% in 18% Cr-Fe (5). Thus, the 4.7% Mo alloy does not have any more molybdenum dissolved in the matrix than does the 3.5% Mo alloy. Examination of the microstructures of the steels annealed at 815°C indicated that a very small amount of chi was present in the 3.5% Mo steel and a large amount in the 4.7% Mo steel (Fig. 3). Therefore, it is concluded that the failure of the 4.7% Mo alloy to exhibit a higher pitting potential than the 3.5% Mo steel is a consequence of the phase constitution of the alloys. The slight decrease in pitting potential that was apparently observed could either indicate that chi itself is not as resistant as the matrix to pitting or that the chi-ferrite interface forms preferential pitting sites. In any event, the decrease in pitting potential of the 4.7% Mo steel as compared to the 3.5% Mo steel was too small to be of practical significance.

In an effort to avoid the chi phase, the three alloys with the highest molybdenum content were annealed at 980°C and water-quenched. Microscopic examination confirmed that all of these steels did not contain appreciable chi after treatment. However, the pitting potentials found in 1.0M NaCl at 25°C were considerably reduced by the 980°C treatment (Table III).

It is known that this heat-treatment also sensitizes these steels to intergranular corrosion (6). It is thought that the intergranular corrosion is the result of precipitation of carbides and nitrides rich in chromium and molybdenum, causing depletion of the adjacent matrix (7). Thus, it is to be expected that steels heat-treated so as to be sensitive to intergranular corrosion would

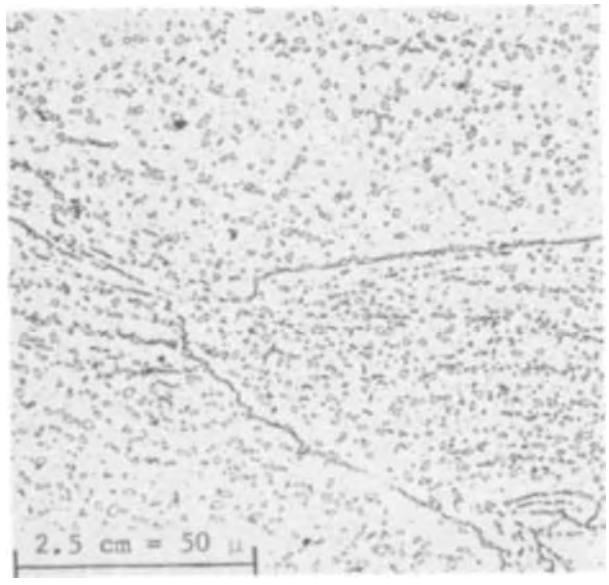

Fig. 3. Structure (islands of chi in a ferrite matrix) of the 18% Cr-5% Mo alloy (4354E) annealed 1 hr at 815°C and water-quenched; 500×.

be more susceptible to pitting corrosion than would properly annealed steels, as was recently reported for 26% Cr ferritic alloys (8). A similar effect has been observed for austenitic stainless steels exposed in ferric chloride (9).

The foregoing results lead to the conclusion that the maximum useful molybdenum content of 18% Cr steels containing the usual amounts of interstitial elements and not fully stabilized is about 3.5%. Steels fully stabilized by titanium or columbium additions that tie up all carbon and nitrogen, or steels of such low interstitial content that carbides or nitrides do not precipitate, could be annealed at high enough temperatures to dissolve chi without suffering chromium depletion because of carbide or nitride precipitation. In this case, larger molybdenum additions can contribute to corrosion resistance, as was demonstrated in work on high-purity 25% Cr steels containing up to 5% Mo (10).

In order to demonstrate that titanium stabilization can prevent loss of pitting resistance as well as sensitization to intergranular corrosion as a result of exposure to high temperatures, the pitting potential of an 18% Cr–2% Mo–0.5% Ti alloy was determined as a function of heat-treatment. It was found (Table IV)

Table III. Effect of heat-treatment on pitting potentials in N_2-saturated 1M NaCl at 25°C

Heat	% Mo	Pitting potential, V (SCE) 815°C, WQ	980°C, WQ
4354C	2	0.25 0.26	−0.01

Table IV. Effect of heat-treatment on the pitting potential of Ti-stabilized 18% Cr-2% Mo ferritic stainless steels in nitrogen-saturated 1M NaCl at a scanning rate of 2000 mV/hr at 45°C

Heat	Ti content (weight) per cent)	Pitting potential, V (SCE), after water quenching from the indicated temperatures 815°C	925°C	1035°C
4073A	0.47	0.27 0.35 0.29	0.30	0.53 0.59 0.50

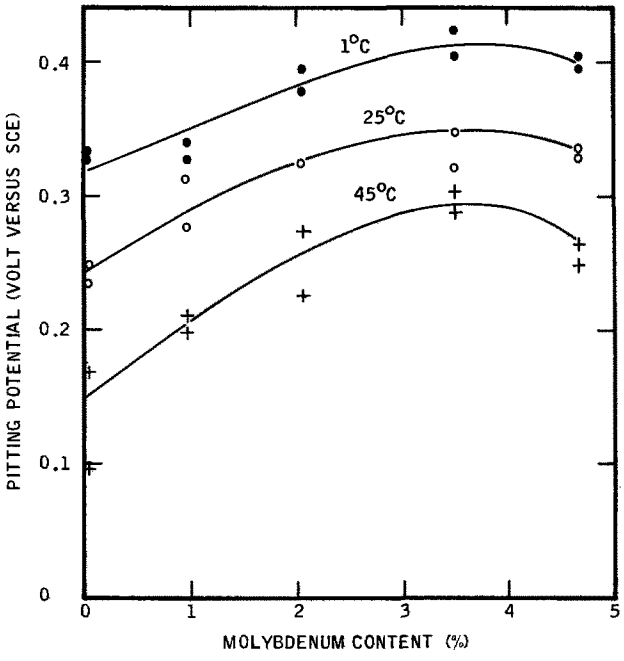

Fig. 4. Pitting potentials obtained from potentiodynamic polarization scans at 200 mV/hr in nitrogen-saturated 1.0M NaBr.

that, as expected, heat-treatment at temperatures up to 1035°C had no deleterious effect on pitting potential. In fact, after treatment at 1035°C, the pitting potential was more noble than it was after the normal anneal at 815°C. It was also noted that the titanium-containing alloy had a more noble pitting potential than the titanium-free alloy under the same conditions. Earlier work with this alloy at 25°C also indicated that titanium was beneficial to pitting resistance (11).

Pitting potentials measured in 1M NaBr varied with composition in the same way as in 1M NaCl (Fig. 4). Pitting potentials were more noble in NaBr, especially at higher temperatures. The beneficial effect of molybdenum additions on pitting potentials of this series of steels in NaBr is just as clearly defined as it is in NaCl. The pitting potentials measured in 1M NaCl and in 1M NaBr at 25°C indicate that all the steels studied should be subject to pitting in 0.33M $FeCl_3$, 0.5M $CuCl_2$, and 0.33M $FeBr_3$ solutions. Exposure tests did indeed show pitting of all the test steels in these solutions at 25°C (Table V). In all cases, the rate of attack decreased with increasing molybdenum content up to 3.5%. The behavior of the 4.7% Mo steel was erratic in these solutions.

Exposure tests were also performed in less aggressive media at 90°C (Table VI). In both solutions, the molybdenum-free steel was severely pitted, while the steels containing molybdenum were attacked only very slightly or not at all. These exposure test results were in good qualitative agreement with the pitting potential results.

Table V. Results of exposure tests in acidified halide salts at 25°C

Medium	Corrosion rate (mdd) of indicated alloys				
	4354A 0% Mo	4354B 1% Mo	4354C 2% Mo	4354D 3.5% Mo	4354E 5% Mo

0.33M $FeBr_3$ + 0.1*N* HBr	920	230	120	75	140
0.5M $CuCl_2$ + 0.1*N* HCl	740	610	650	330	560

Table VI. Results of 30 day complete immersion tests in oxygen-saturated aqueous solutions at 90°C

Solution	Corrosion rate (mdd) of the indicated alloys				
	4354A 0% Mo	4354B 1% Mo	4354C 2% Mo	4354D 3.5% Mo	4354E 5% Mo
3% NaCl	63	nil	0.4	nil	0.3
125 ppm Cl^-, 60 ppm Cu^{++}	95	0.4	0.4	nil	0.3

As a result of the polarization measurements, it is clear that molybdenum has a beneficial effect on pitting potentials in 1M NaCl over a range at least from 1° to 70°C. This result is in partial conflict with the results of others on some austenitic steels. The conflict is more definite at 1°C, since Horvath and Uhlig (1) found that molybdenum had a detrimental effect on pitting potentials of an austenitic stainless steel series in 0.1M NaCl at 0°C. The small differences in experimental conditions and technique do not appear sufficient to explain a reversal in direction of pitting potential change with molybdenum content. Thus, the effect of molybdenum may be different in austenite than it is in ferrite even though there is no obvious rationalization for the difference. These same considerations also apply to the difference in molybdenum effect on austenite and ferrite tested in NaBr.

There is less obvious conflict in the behavior of molybdenum-containing steels at higher temperatures in NaCl. The previously reported results (2) were obtained by counting pits formed at constant current density. This involved driving the potential beyond that required to produce pitting without determining any pitting or breakthrough potential. It is quite possible that the number of pits found in this manner does not correlate at all with pitting potentials as measured in the present work.

Conclusions

In fully annealed (815°C) 18% Cr ferritic stainless steels, molybdenum additions up to the limit of solid solubility increase pitting potentials. This is true over the entire temperature range studied *i.e.*, 1°-70°C in 1M NaCl and 1°-45°C in 1M NaBr. Heat-treatments that sensitize the steels to intergranular corrosion also drastically lower the pitting potential.

On the Role of Iron Dissolution in Crack Propagation During Hydrogen Charging of an Fe-Pt Alloy

H. W. Pickering*,[1] and P. J. Byrne[2]

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

Iron dissolution during cathodic charging of iron and its alloys is generally negligible, in agreement with thermodynamic conditions at the surface. This is not true, however, of iron alloys for which hydrogen discharge is easy, and also may not in general be true within cracks or cavities. For Fe-10 atom per cent (a/o) Pt in 1*N* H_2SO_4 at 293°K appreciable iron dissolution (~0.05 A/cm^{-2}) occurs for hydrogen-charging currents as high as 1.6 A/cm^{-2}. Crack propagation occurs for specimens loaded in tension which (*i*) is independent of the level of hydrogen charging and (*ii*) has anodic dissolution of iron associated with it. Internal (hydrogen-produced) cracking does not occur. The role of ohmic drops in promoting anodic dissolution at the base of the cracks during hydrogen charging is discussed.

A possible role of hydrogen in crack propagation of anodically polarized specimens has generally been recognized in recent years (1-4). The occurrence of hydrogen discharge within a cavity or crack when the outer surface of the specimen is held at potentials positive or noble of the standard hydrogen electrode (SHE) is understandable in terms of the ohmic drop through the electrolyte within the cavity. The sign of the ohmic drop for anodic polarization is such that the electrode potential becomes less noble or less positive with increasing distance into the cavity or with increasing anodic current density in the cavity (4). The occurrence of hydrogen discharge requires that the electrode potential be in the vicinity of, or less noble than (depending on the *p*H), 0.0V (SHE). Potentials in this region have been directly measured within cavities in Fe while the outer surface was held at potentials as positive as 1.4V (SHE) (4, 5). Potential variations within crevices in stainless steels and Ti alloys have also been measured (6-8).

The purpose of the present paper is to consider the analogous situation which exists for cathodic polarization. This is of interest since the occurrence of an anodic process within cracks and cavities during cathodic polarization is generally disregarded, and in view of the practical consequences of anodic dissolution in cavities in connection with hydrogen cracking of metals.

Theoretical

When a net cathodic current flows in a cavity, it can readily be shown that the electrode potential at the bottom of the cavity increases in the positive (noble) direction with increasing depth of the cavity, *i.e.*, for all other conditions the same, the oxidizing power of the system is greatest at the base of the cavity. Thus, during hydrogen charging of a metal, anodic reactions may in principle occur at the base of cavities, even though they may not be thermodynamically possible at the outer surface of the metal.

The magnitude of the potential drop in the electrolyte within the cavity as a function of depth may be calculated for certain simple situations. Such calculations, however, give only the smallest potential changes, whereas under actual conditions much larger (>0.5V) ohmic drops may occur within the cavity as a result of the presence of gas (4). If the latter occurs, the measured potential at the outer surface is of little value for the determination of the electrode potential or, hence, of the possibility of anodic reactions, at the base of the cavity. For example, at high hydrogen discharge rates on iron in 1*N* H_2SO_4 the potential at the outer surface may be several tenths of a volt negative of the standard potential for the formation of ferrous ion, in which case no iron is dissolved. If, however, the surface contains a cavity or crack which in turn contains a hydrogen bubble, the electrode potential within the cavity may be in the region of iron dissolution.

This situation is analogous to that found for conditions of anodic polarization within a pit, as mentioned above, but differs in the sign of the ohmic drop. In the absence of constrictions (gas bubbles), on the other hand, the shifts in potential are relatively small; calculations for anodic polarizations (4, 9, 10) show that the ohmic drop per unit depth into a cavity is on the order of 0.1 V/mm^{-1} in the less noble direction, at a current density of 0.1 A/cm^{-2}.

Experimental

A study of the amount of iron dissolution and of its role, if any, on crack propagation during hydrogen charging of Fe-10 atomic per cent (a/o) Pt (Fe10Pt) alloy follows. The use of Fe-Pt alloy specimens provides the special features: (*i*) the occurrence of iron dissolution is easily recognized by the formation of a porous reaction layer; (*ii*) hydrogen discharge occurs at low overpotentials and, consequently, at high rates in the potential region of iron dissolution; and (*iii*) platinum does not dissolve at the potentials of interest.

Materials and procedure.—Results were obtained for a Fe-10 a/o Pt (Fe10Pt) alloy in 1*N* H_2SO_4. The Fe10Pt alloy was induction vacuum-melted from pure Fe (99.95) and Pt (99.95). The ingot was homogenized at 1373°K (2012°F) in the stable austenite (γ) region for 168 hr in an evacuated capsule. On cooling to room temperature a martensitic γ to α transformation is expected (11) and indicated in the etched microstructures (Fig. 1c and 4c). The absence of macrosegregation in the ingot was shown by chemical analysis. The ingot was then swaged and wire drawn with one intermittent anneal to 0.22 cm diameter. Specimens cut to 1.42 cm were held in evacuated capsules at 1373°K for 20 hr and water quenched. Some of the specimens were then annealed at 973°K (1292°F) for 12 hr in the stable, two-phase, austenite/ferrite region. After a light emery treatment (4/0 paper) and attachment to a Teflon-covered, stainless steel rod they were rinsed in

Key words: iron, hydrogen cracking, embrittlement, alloy corrosion, stress corrosion.

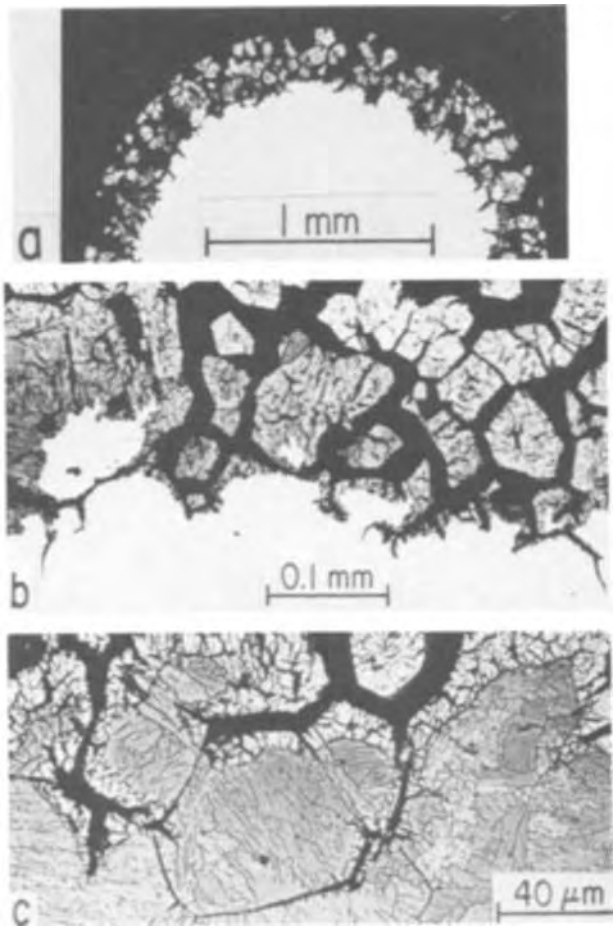

Fig. 1. Cross-section micrographs showing anodically produced reaction layer for austenized specimens. The reaction front has proceeded into the alloy from the top to about the midline of each micrograph. (a) $E_a = -1.00$V (SHE), 2 hr, $i_{Fe} = 60$ mA/cm^{-2}; (b) same as (a); (c) etched, $E_a = -0.40$V.

methanol and distilled water and placed in a cell of all Pyrex construction for the polarization runs.

The potential at the outer surface of the specimen was held constant throughout the test with a Wenking potentiostat. The 130 cm^3 cell also contained the Pt counterelectrode and Luggin capillary. Purified He was passed continuously through the cell to reduce oxygen and also to provide mixing of the electrolyte. Neither He nor mixing appeared, however, to influence the dissolution reaction. The (net) current in the external circuit was recorded and the partial current due to iron dissolution was determined by periodic chemical analysis of the electrolyte by the 1, 10 orthophenanthroline color procedure (12) using a Beckman DU spectrophotometer. The rate of hydrogen discharge is the difference in these currents

The procedure for determination of the amount of dissolved iron was as follows. Prior to draining the cell, any iron which may have deposited on the Pt counterelectrode during the (anodic) polarization runs was redissolved by an impressed current from an auxiliary circuit; the counterelectrode of this circuit was in an adjoining cell (1N H_2SO_4 bridge) connected through a closed stopcock. The electrolyte was then drained from the cell for chemical analysis, and fresh 1N H_2SO_4 was added. Further dissolution at the same potential occurred upon reinsertion of the specimen in the cell.

Tensile specimens, 1.5 cm in length and 0.10 × 0.32 cm reduced cross section, were prepared from the homogenized ingot, and subsequently annealed at 1373°K and quenched. For a run a specimen was connected to the potentiostat, placed in a cell similar to the above-described one but specially designed for the Instron Tensile Testing Machine, and strained a given amount at a constant rate of extension of 0.034 min^{-1}. The electrode potential was preset at a value in the same range as for the nonstressed cylindrical specimens, and the polarization treatment begun by filling the cell with the test electrolyte. The cell was continuously flushed with He. The load on the specimen at constant extension (crosshead stopped) and the current were monitored. Grips and other parts of the apparatus which were in contact with the electrolyte were made of titanium alloy and coated with Halocarbon wax.

All experiments were performed at room temperature, 293°K. Potentials are given in terms of the standard hydrogen electrode (SHE).

The scanning-electron micrographs were taken in stereo with a Cambridge Stereoscan microscope. Examination of the micrographs in stereo gives a much more complete and correct impression of the corrosion structure than does a monocular examination. The stereo figures in this paper may be seen in stereo with the aid of a stereo viewer.

Results for cylindrical (nonstressed) specimens.— The Fe10Pt cylindrical specimens were held at applied potentials, E_a, in the range, −1.00 to +0.15V (SHE) in 1N H_2SO_4. At each potential, the net current and the iron-partial current were obtained from the ammeter in the potentiostat circuit and from periodic chemical analysis of the electrolyte, respectively. The meter current is cathodic over most of this potential range ($E_a < 0$V) in accord with an expected and observed profuse hydrogen evolution, Table I. Since the net (meter) current at the more negative potentials is of the order of 1 A/cm^{-2} cathodic, the actual potential across the surface is considerably more noble than the applied value, E_a. Corrected potentials, E, are given in Table I; the correction equals the ohmic drop between the tip of the Luggin capillary and the specimen surface (2 mm); each E is an approximate calculated value using the conductivity of the bulk electrolyte. At $E > 0$V, for which only iron dissolution occurs, the meter current is anodic, *i.e.*, $i_{meter} = i_{Fe} \cong 0.065$ A/cm^{-2}. This is in excellent agreement with i_{Fe} determined by periodic chemical analysis of the electrolyte: $i_{Fe} = 0.066$ and 0.064 A/cm^{-2} at $E = 0.12$ and 0.02V, respectively. The precision of the chemical analysis method was determined to be ±3% in the amount of dissolved iron.

After an initial period of less than 1 hr the rate of iron dissolution at all potentials was found by chemical analysis to approach a quasi-stationary value in the range 0.040-0.065 A/cm^{-2}, Table I.[3] The occurrence of iron dissolution was confirmed at all potentials by the gradual development of a pale yellow-green color of the electrolyte and by the results (to be described) of electron-microprobe and x-ray diffraction analyses of these specimens. The occurrence of iron dissolution during cathodic charging follows most directly from a superposition of cathodic and anodic current-poten-

[3] The listed current densities are apparent values based on the original area. The true surface area increases with time. The electrochemically active surface area for iron dissolution, however, is expected essentially to level off, since iron dissolution will occur mainly at the advancing front of the developing surface perturbations.

tial curves as demonstrated by Wagner and others (13-15).

The hydrogen partial current is the algebraic difference between the meter current and the partial iron current. The hydrogen partial current predominates at the more negative potentials with values of $i_H \gtrsim 1$ A/cm^{-2}. When the specimens were removed from the test cell and rinsed, the evolution of a gas, presumably H_2, was observed within the adherent water film. A large amount of heat is also given off during the rinse (H_2O followed by methanol). The heat is so high that on occasion the paper towel used for drying the specimen was singed.

A porous metal layer forms on specimens polarized at all potentials. The morphology and general appearance of the reaction layer are the same over the entire potential range in Table I, *i.e.*, at the negative potentials of simultaneous hydrogen evolution and iron dissolution and at the positive potentials of sole-iron dissolution. Typical morphologies are shown in cross section in Fig. 1. The large amount of porosity appears in the form of a continuous network of crack-like cavities varying in size from 10 μm down to less than 0.1 μm. The cavities of all sizes have faceted surfaces, as shown by scanning-electron microscopy (SEM) in Fig. 2 and 3. These are typical structures of the reaction layer at all depths and at all potentials. Figures 2 and 3 are stereo pairs and provide a much easier to interpret view of the corrosion structure than does a monocular view. The alloy microstructure (1373°K, quenched) is shown in the bottom portion of Fig. 1C.

Examination of etched specimens reveals that the alloy microstructure influences the course of the corrosion process. The attack (cavities) penetrates faster along prior austenite-grain boundaries than elsewhere, and this often results in encirclement of original alloy, Fig. 1b. Much finer cavities than those that form along grain boundaries grow along the interfaces of the martensite plates, Fig. 1c. These are by far the most numerous cavities in accord with the high density of martensite plates.

This influence of the microstructure is illustrated further by comparison with specimens annealed in the ferrite/austenite region after quenching from the

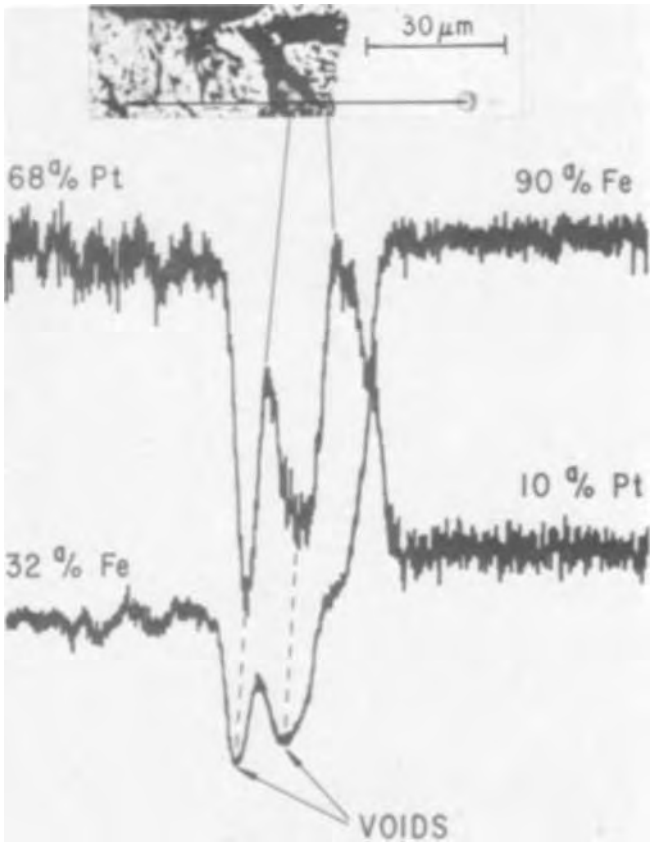

Fig. 5. Electron-microprobe traces of Fe and Pt. Arrow in micrograph shows path of electron beam starting in original alloy at right and proceeding into reaction layer. E_a = — 1.00V, 3 hr.

austenite region, Fig. 4. Much less grain-boundary attack occurs in the annealed specimens. The attack is localized, though, to the interface (presumably Fe-rich ferrite) regions of the plate-like structure, Fig. 4c. The alloy microstructure (1373°K, quenched, followed by 12 hr at 973°K) is shown in the bottom portion of Fig. 4c.

Results of the electron-microprobe and x-ray diffraction analysis of the porous layer were the same at all of the potentials. The microprobe results are shown in Fig. 5. A sharp change in the Fe and Pt contents occurs at the boundary between the porous metal and the unattacked portion of the alloy; the porous metal is rich in Pt. An x-ray diffraction analysis (Fig. 6) shows in addition that the porous metal at all potentials is a single-phase solid solution of Fe in Pt (~60-100% Pt) in agreement with diffraction analyses of other alloys undergoing preferential dissolution (16, 17).

Results for tensile specimens.—The Fe10Pt tensile specimens were held at applied potentials in the range —1.00 to + 0.50V in 1*N* H_2SO_4. At all potentials the load was observed to fall for the polarized tensile specimens at a rate faster than that for room-temperature creep of (nonpolarized) specimens in air; in a matter of minutes the rate of falloff began to increase with time for the polarized specimens, followed by fracture of the specimen within about 1 hr. A typical result is shown in Fig. 7 in which the load has been converted to stress. The cross-sectional area for the fracture (solid) curve at the start of load relaxation (time = 0) is assumed to be $A^o(l^o/l)$; A^o and l^o are the original cross-sectional area and length, respectively, and l is the length after elongation. This relation presupposes uniform elongation. The "creep-in-air" and "corrected" fracture curves for the specimen are also included; this correction takes into account a continuous reduction in cross section as a result of corrosion generally over the surface during the test.

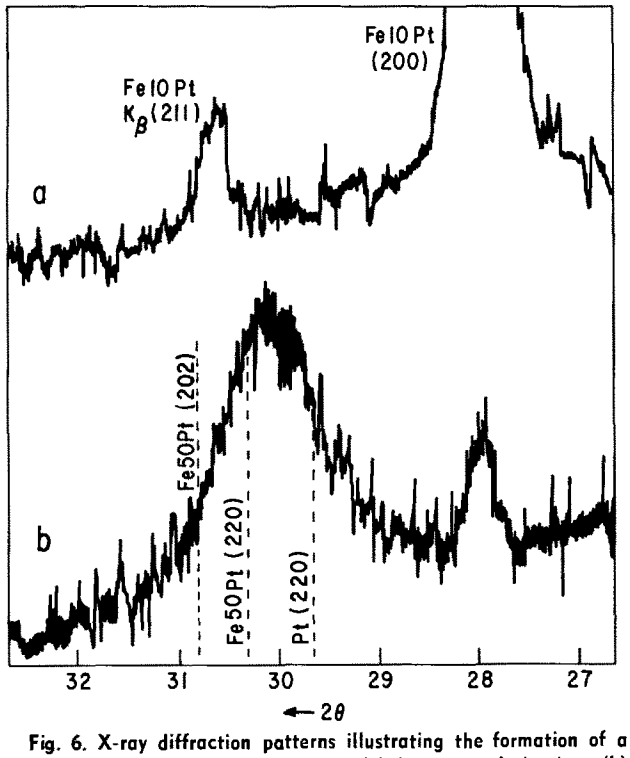

Fig. 6. X-ray diffraction patterns illustrating the formation of a Pt-rich alloy of variable composition. (a) Prior to polarization; (b) E_a = — 0.05V, 8 min.

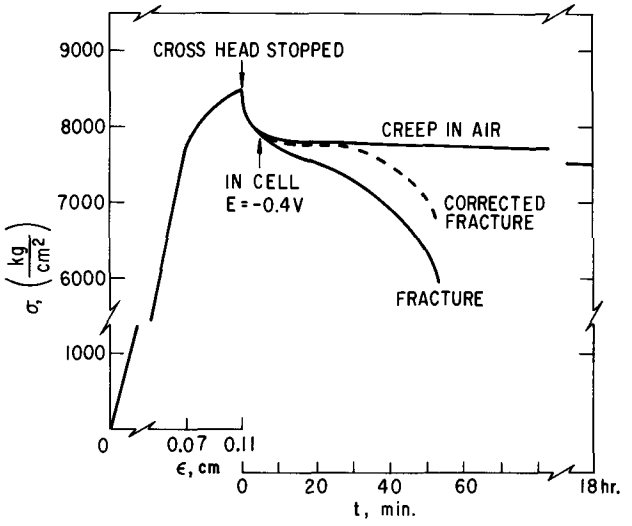

Fig. 7. Stress-relaxation curve showing accelerated falloff in stress to failure of a sample polarized at $E_a = -1.00$V.

Prior to the onset of cracking the "corrected fracture" and "creep-in-air" curves nearly superimpose.

Visual observation of the specimens during load relaxation revealed the evolution of large gas bubbles from several stationary sites which presumably were cavities or cracks. These bubbles were readily distinguished from the much smaller hydrogen bubbles which evolve generally over the surface at all negative potentials.

Cross-section examination of the failed specimens showed that there usually were a few cracks in addition to the main fracture crack, Fig. 8. The cracks propagate in a mixed mode, *i.e.*, along, as well as across, prior austenite-grain boundaries.

Anodically produced porous structure can be resolved along the fracture surface by scanning-electron microscopy. The amount of anodic dissolution associated with crack propagation varied. On the basis of only a few runs it appears to increase with decreasing propagation rate, the latter being at least in part a function of the elongation prior to load relaxation. Figure 9 shows the anodically produced porous structure at the very tip of a crack. In this case the electrolyte was removed after some crack propagation had occurred and the specimen immediately elongated to ultimate failure so that fracture of the remaining cross section was by the ductile mode. The porous structure extends to (into) the dimpled (ductile) structure (Fig. 9a) which shows that anodic dissolution was occurring right at the crack tip. This same result was obtained at different potentials, E_a ranging from -1.00 to $+0.50$V (SHE) and, hence, for widely different hydrogen-charging rates. Figure 9b is a stereo pair and shows the marked three-dimensional nature of the fracture surfaces. Anodically produced crack growth has also been observed for anodically polarized Cu-Au alloys in instances of slow crack growth. Anodic dissolution was found to occur at the crack tip; here again the anodic dissolution process was identified by the formation of a porous reaction layer along and ahead of the crack (18). The same result has been found for a Ni-Au alloy by Swann and Duff (19).

Discussion

It is shown by chemical analysis of the electrolyte and by electron-microprobe, x-ray diffraction, and cross-section metallographic analyses of the porous metal layer that iron dissolves rapidly from Fe10Pt alloy over a broad range of negative potentials including those for which the rate of hydrogen discharge is greater than 1 A/cm^{-2}. The thickness of the anodically produced porous metal layer may be calculated from the moles of dissolved iron. The number of moles of

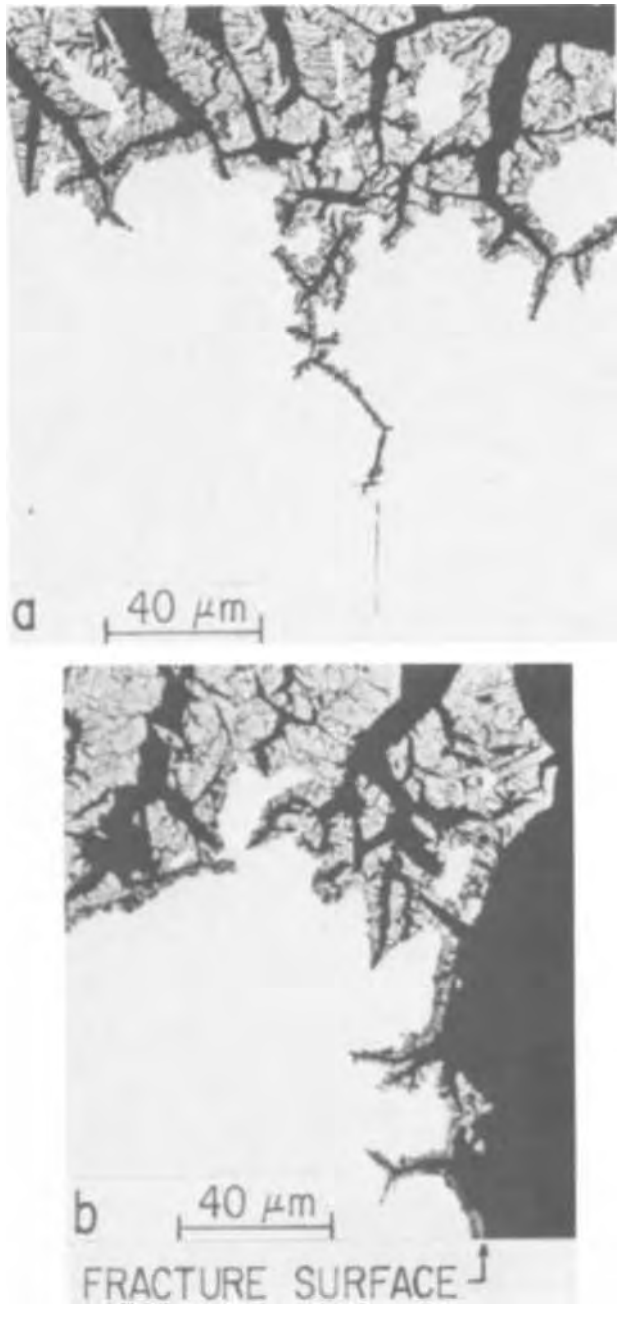

Fig. 8. Cross-section micrographs showing (a) secondary crack and (b) one half of main crack which propagated through a tensile specimen. $E_a = -1.00$V.

dissolved iron is $i_{Fe}t/n\mathbf{F}$, in which i_{Fe} is the partial iron current density, t is the time of iron dissolution, and n and $\mathbf{F}$ have their usual meaning. For $i_{Fe} \cong 0.06$ A/cm^{-2}, $t = 2$ hr, and $n = 2$ for the formation of ferrous ions, 0.0021 mole-cm^{-2} of iron dissolve. Multiplying by the molar volume of the alloy, $V_M \cong 8$ cm^3 mole^{-1} and dividing by 0.7, the fraction of iron removed according to the microprobe analyses, gives 0.026 cm for the depth of the reaction layer. This is in good agreement with the average measured values, *e.g.*, 0.025 cm in Fig. 1c, and 0.022 cm in Fig. 4c.

The identification of the reaction layer by x-ray diffraction as a Pt-rich solid solution of variable composition agrees with data found for other alloys, and indicates that interdiffusion of the components within a (shallow), vacancy supersaturated surface layer, rather than some other transport mechanism, is mainly responsible for the preferential dissolution of iron from Fe-Pt alloy (16, 17). Cuddy (20) has shown that there is a point defect in iron with an activation energy

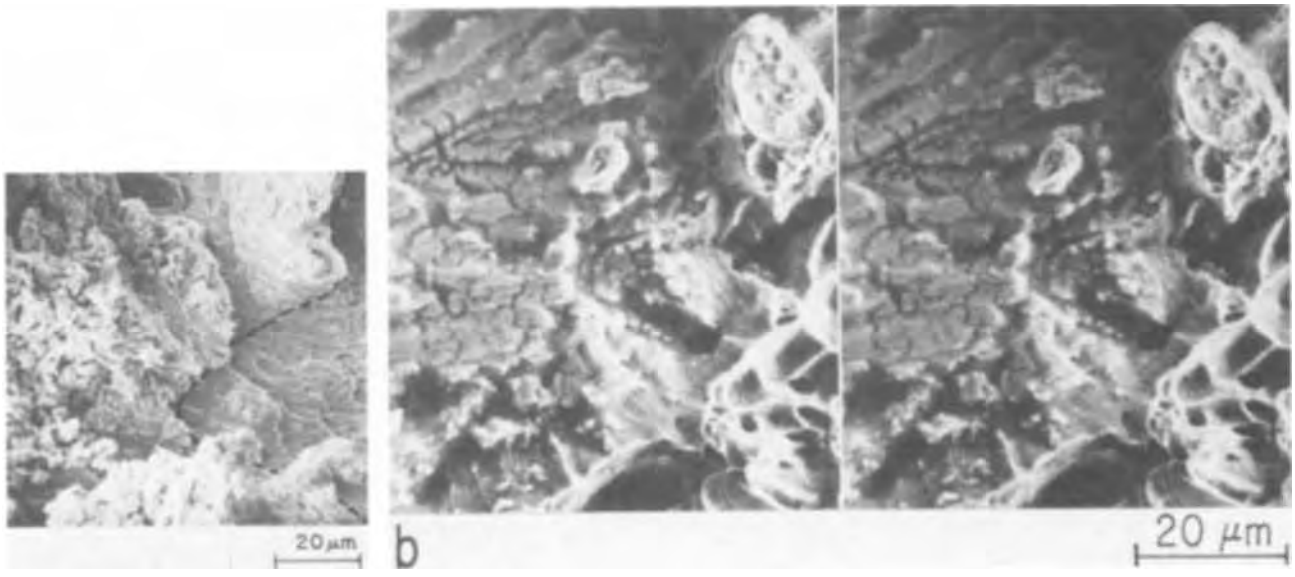

Fig. 9. SEM micrographs showing anodically produced porous material at the crack tip. (a) $E_a = -1.00V$. Anodically produced fracture has proceeded from left to dashed line; mechanically produced (ductile) fracture is to the right of the dashed line. (b) $E_a = -0.40V$. Stereo pair. Anodic fracture progressed from left to right of center.

of 0.55 eV. If, as Cuddy concludes, these are single vacancies, the mean-square displacement, $\overline{\Delta x^2}$, of a single vacancy in iron is $2D_{\square}t$ or $2t\nu a_o^2 \exp(-E_m/kT)$ in which ν is the jump frequency, a_o is the lattice parameter, E_m is the migration energy of a single vacancy, T is the temperature, t is the time, k is the Boltzmann constant, and $D_{\square}$ is the diffusivity of a single vacancy.

For $\nu = 5 \times 10^{13}$ sec^{-1} and $a_o = 2.86 \times 10^{-8}$ cm, one obtains at 25°C after 10^3 sec the rather large value of $\overline{\Delta x^2} = 4 \times 10^{-8}$ cm^2, or an average migration distance of 2 μm for a single vacancy. This value is larger than that for mono- or divacancies at 25°C in Cu (21, 22). Consequently, somewhat lower concentrations of excess vacancies, or conversely larger pore sizes, will yield dissolution rates which are comparable to those in the Cu-Au or Cu-Zn alloy systems discussed elsewhere (16, 17).

In view of the occurrence of hydrogen evolution, absorption of some hydrogen by the metal must occur. The heat evolved during rinsing of specimens polarized at the negative potentials could be the oxidation of hydrogen which had been absorbed in the metal or which had been present as bubbles trapped within the electrolyte of the porous structure. Certain usual features of hydrogen absorption however, were not present, *e.g.*, internal cracks were not observed in either the cylindrical or tensile specimens. Furthermore, the over-all rate of crack propagation observed in the tensile specimens is approximately the same at all the applied potentials, and, hence, the same for all rates of hydrogen discharge insofar as it occurs generally over the surface, *i.e.*, for zero as well as for 1 A/cm^{-2} hydrogen discharge; this observation, coupled with the observed high rates of iron dissolution, indicate that crack propagation is by anodic dissolution. The cracking observed in this system, thus, is similar to the anodically produced cracking which has been observed in anodically polarized Cu-Au alloys (18), an alloy system in which hydrogen discharge can be ruled out on thermodynamic grounds, both at the outer surface and within cavities, since the standard potentials of Cu and of Au are both noble to that of hydrogen by $>> RT/n\mathbf{F}$. The absence of a major role of hydrogen in the formation of the porous structure or in crack propagation does not mean, of course, that hydrogen-induced cracking may not occur in this alloy for other conditions of cathodic charging.

Formation of hydrogen gas within the cavity or crack may, in general, be important, as already discussed in the theoretical section of this paper for obtaining large ohmic drops within the cavity. Hence, hydrogen gas which forms a constriction at the crack tip may cause ohmic drops of whatever values are necessary to shift the electrode potential (in the positive sense) into a potential region of rapid iron dissolution.

In the present research a large shift in potential was not required for the occurrence of iron dissolution in the crack since the actual potentials, E, at the outer surface were in the region of iron dissolution. Therefore, gas bubbles, though probably present in the cavities, were not necessary for the occurrence of iron dissolution at the bottom of the cavities. A large shift in potential would be needed, however, at more negative applied potentials, and for most conditions of hydrogen charging of iron and steels of high, rather than low, hydrogen overvoltage.

Conclusions

The partial iron i_{Fe} and hydrogen i_H currents at several potentials E ranging from 0.12 to about −0.40V (SHE) are given for Fe10Pt in 1N H_2SO_4 at 293°K. The partial iron current varies little over this potential range, approaching a quasi-stationary value of between 0.040 and 0.065 A/cm^{-2} in less than 1 hr. The partial hydrogen current varies from zero at $E \cong 0$ to 1.6 A/cm^{-2} at $E = 0.40V$. Since platinum does not dissolve at these potentials the surface is enriched in Pt, and the surface area increases sharply. X-ray diffraction shows the resulting porous structure to be a solid solution of Fe in Pt, in agreement with results for other alloys undergoing preferential anodic dissolution of the less noble component, and indicative of the occurrence of volume diffusion during the dissolution process.

Crack propagation is observed for specimens loaded in tension which is independent of the level of hydrogen charging. These cracks are deduced to be anodically produced. The presence of porous (anodically produced) metal at the crack tip supports this conclusion. Internal (hydrogen produced) cracking is not observed.

The role of ohmic drops in promoting anodic dissolution at the base of cracks during hydrogen charging is discussed.

Electroless Deposition of Nickel-Boron Alloys

Mechanism of Process, Structure, and Some Properties of Deposits

K. M. Gorbunova, M. V. Ivanov, and V. P. Moiseev

Institute of Physical Chemistry, Academy of Sciences of USSR, Moscow, USSR

ABSTRACT

The conditions for electroless nickel-boron plating, the process mechanism, and the structure of the alloys as-plated and after annealing at 150°-700°C were investigated. A correlation of the mechanical and magnetic properties with the changes of phase structure was established.

Following the success of electroless plating of the transition metals by the use of the hypophosphite ion, investigations were begun to find other reducing agents to obtain coatings with new properties meeting the requirements of modern industry.

In this respect alkali metal borohydrides and alkyl amine boranes (borazanes) appeared to be of the greatest interest (1-4).

The present paper presents data on both the conditions of nickel reduction by borohydride and the mechanism of reactions involved, as well as data on the deposit structure which revealed the correlation of some of their properties, such as magnetic, hardness, wear resistance, etc., with phase transformations proceeding during annealing of nickel-boron plates.

Electroless Nickel Bath

The plating bath as described contains nickel salt, sodium borohydride as the reducing agent, sodium hydroxide, complexing agent (ligand), and stabilizer.

Ligands.—In order to find the most effective ligands the following substances were investigated: ethylenediamine, mono-, di-, tri-ethanolamine, iminodiacetic, nitrilotriacetic, ethylenediaminetetraacetic, 2-oxyethyliminodiacetic, oxyethylidendiphosphonic, and ethylenediaminebisisopropylphosphonic acids. These substances were selected on the basis of their ability to interact with nickel ions to form rather stable complexes.

Key words: electroless plating, nickel-boron alloys, borohydrides.

The results of the study of the behavior of these ligands indicated that ethylenediamine was the most appropriate one. The comparison of the characteristics of the ethylenediamine complex and other complexes allows one to state some considerations concerning the choice of ligands. It was revealed, in particular, that the data on the stability constants are not sufficient to evaluate the ligand efficiency in this process. The important part seems to be played by both the formed complex structure and its charge. On the basis of the plating rate and the solution stability one may conclude that conditions favorable for the process are those which lead to the formation of coordinationally saturated complexes with zero or positive charge. Under these conditions the probability of the destruction of complexes in the bulk of the solution appears to be the smallest owing to the hindrances to the penetration of both water molecules and borohydride ions to a nickel ion. Also, the absence of a charge or a positive charge favors the adsorption of a complex on the negatively charged surface of the metal catalyst.

Stabilizers.—It should be noted that in spite of the presence of the most effective ligands the solution shows insufficient stability as manifested by the formation of metal powder in the bulk of the solution. For preventing or lessening this undesirable phenomenon some substances, stabilizers, are introduced into solution. As a result of studying the stabilization effect of different sulfur-containing substances of organic nature, some inorganic salts and oxides (5),

Table I. Compositions of plating solutions and conditions of process

including substances proposed in the patent literature (6, 7), thallium nitrate and lead chloride together with 2-mercaptobenzothiazole were chosen for investigation, the results of which are given below. Table I represents the compositions of the plating solutions. The solution stability was estimated as the ratio of the weight of plate to the total weight of reduced alloy including the metal deposited as a powder in the bulk of solution. The boron content in the alloys was determined by a photocolorimetric method using acetylchinalizarin (8). Figures 1, 2, and 3 show the influence, respectively, of the concentration of the sodium borohydride, ethylenediamine, and temperature on the deposition rate of nickel-boron plates and the solution stability. The data of Fig. 1 draw attention to the important role of the nature of the stabilizing additives; Fig. 3 reveals the specific influence on the deposition rate of $TlNO_3$, which allows the process to be carried out at a relatively low temperature with a rather high rate.

Mechanism of Electroless Nickel-Boron Plating

The available literature concerning the mechanism of nickel-boron plating is rather limited and proposed ideas are not confirmed by experimental data. According to the notions of different authors (2, 9, 10)

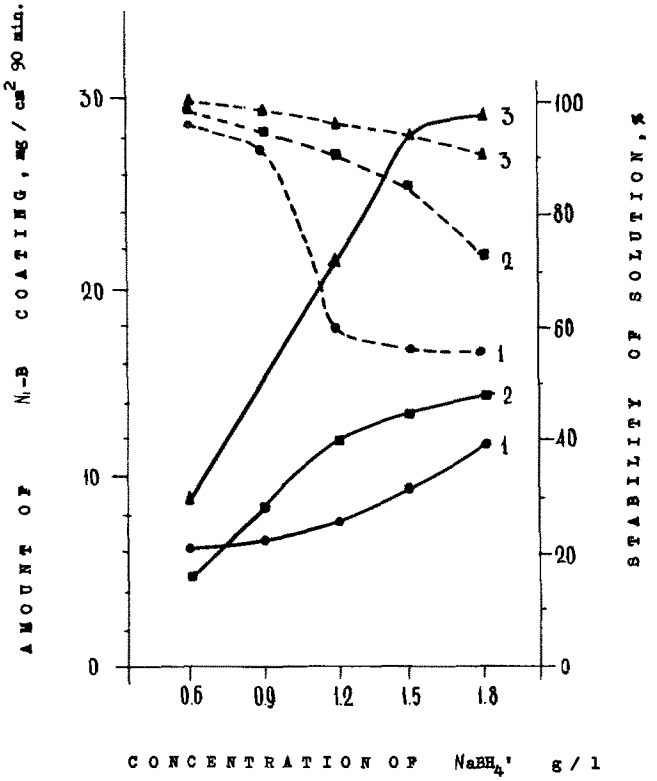

Fig. 1. Influence of the concentration of $NaBH_4$ on the plating rate (solid lines) and solution stability (dashed lines): 1, solution without a stabilizer; 2, solution with $PbCl_2$ and 2-mercaptobenzothiazole; 3, solution with $TlNO_3$.

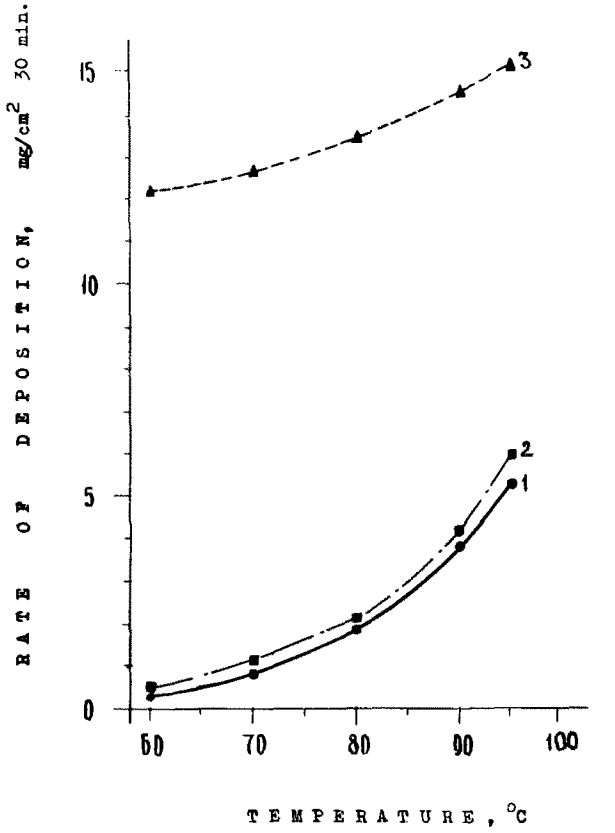

Fig. 3. Influence of the temperature on the plating rate. Numbers correspond to those in Fig. 1.

each borohydride ion reduces four nickel ions (Table II), *i.e.*, all four hydride ions of borohydride are oxidized to the proton state.

The reduction of boron is discussed by these authors from various points of view. Thus, in Ref. (2) it is

Table II. Reaction equations of the process of formation of Ni-B coating proposed in the literature

Reduction of nickel

$NaBH_4 + 4NiCl_2 + 8NaOH = 4Ni + NaBO_2 + 8NaCl + 6H_2O$ (2, 9, 10)

Reduction of boron

1. $2NaBH_4 + 4NiCl_2 + 6NaOH = 2Ni_2B + 8NaCl + 6H_2O + H_2$ (2)
2. $2NaBH_4 + 5NiCl_2 + 8NaOH = 2B + 5Ni + 10NaCl + 8H_2O$ (9)
3. $2NaBH_4 + 2H_2O = 2B + 5H_2 + 2NaOH$ (10)

assumed that only three hydride ions are oxidized to protons. The fourth hydride ion is oxidized to the atomic state, leading to the formation of a molecule which is evolved as a gas (Table II, Eq. [1]). However, in Ref. (9) it is supposed that all hydride ions are oxidized to protons (Table II, Eq. [2]). The reaction of boron reduction is considered by authors (10) as a catalytic process of decomposition of the borohydride ion, which takes place independently of the reduction of the metal (Table II, Eq. [3]).

However, the hypothesis that hydrogen atoms, formed during oxidation of hydride ions of borohydride, are an intermediate product which can take part in the reduction of nickel or boron is subject to serious objections based on earlier data relating to the reduction process by hypophosphite (11-13). Based on the results of these investigations and on the data about the stepwise hydrolysis of borohydride in alkali solution (14), the scheme of the reactions proceeding at the formation of Ni-B plates shown in Table III was proposed (5, 16). According to this scheme the hydrogen atoms arising from hydrolysis of borohydride combine to form hydrogen molecules and do not take part in nickel reduction. The increase of the acidity observed in this process is due to the proton from the water molecules only. The reduction of boron proceeds according to the idea proposed in Ref. (15) as a catalytic decomposition reaction of the reductant.

The proposed mechanism was confirmed by the results of mass-spectrometric measurements of the isotope composition of the gaseous hydrogen evolved in the process carried out using heavy water (16). The investigations were carried out by use of a solution prepared with D_2O (99.7%) containing (grams/liter): $NiCO_3$, 13; NaOD, 41; ethylenediamine (70%), 86 ml/liter; $NaBH_4$, 0.8 at 95°C, and pH 14. The hydrogen evolved during the reaction was passed through a liquid nitrogen trap and collected in evacuated ampoules. The isotopic composition of the hydrogen was established by using the mass spectrometer MI-1311; the absolute error in the measurements was below 1.5-2.0%. Results of these measurements are presented in Table IV. The data of the measurements are in accordance (within 6-8%) with those of the gas composition calculated following the reduction scheme given in Table III. The calculations made on the basis of the ideas of the feasibility of hydride ion oxidation to a proton results in a considerable (~200%) deviation from the experimental data.

Structure of Nickel-Boron Plates

hydrogen in face-centered cubic β-nickel and an amorphous phase. The samples with 5.7 and 6.4% B are single-phase alloys of amorphous structure. The cross section of Ni-B deposits shown in Fig. 4 revealed a column-lamellar structure which is similar to that of electroless Co-P alloys (17). This type of deposit seems to reflect the periodic change of the ratio of the reduction rates of nickel and boron; this change is due to pH alternations in the layer adjacent to the surface.

Peculiarities of the phase transformations proceeding during annealing of Ni-B alloys were revealed by using the combination of the thermographic, x-ray methods (18) and electronmicroscopic examinations. Figure 5 shows the thermograms of the alloys of different composition which were heated in a helium atmosphere at the rate of 10°/min. In the thermograms one can see the three exothermic effects at 305°, 405°, and 425°C.

The thermographic investigations of the alloys containing 6.4-6.9% boron allowed one to distinguish more clearly exothermic effects in the range 400°-430°C (Fig. 6).

The results of x-ray analysis have shown that the effect at 305°C relates to the formation of the Ni_3B phase, the effect at 425°C to the formation of the Ni_2B. According to the thermographic data of Fig. 5 the higher the boron content in the alloy, the higher is the relative quantity of the Ni_2B phase. It is of interest that in this case the absolute quantity of the Ni_3B phase decreases.

There is reason to suppose that the exothermic effect at 405°C is due to the appearance of the very unstable phase of the Ni_7B_3 compound, revealed first in Ref. (19).

In Table V are given the data on the phase compositions of the deposits isothermally annealed over the temperature range of 150°-700°C. The annealing was

carried out in vacuum ($5 \cdot 10^{-4}$ Torr) for 1 hr. After cooling and investigating the structure and properties at room temperature, the specimens were subjected to further annealing at a temperature 50° higher than the preceding one.

The data of this table show that the higher the content of the boron in the alloys the higher the temperature of the formation of Ni_3B. It is consistent with the results of thermographic analysis.

The estimation of the quantity of hydrogen which was included in the Ni-B plate and investigation of the process of its evaluation during heating these plates at the rate of 10°/min were carried out by use of the method of vacuum extraction. It should be noted that the hydrogen content in the alloys is almost independent of the boron content, and equal to about 200 cm^3/100g, but the intensity of its evolution reflects the phase transformation in the coatings proceeding during annealing. Figure 7 shows that the formation of the Ni_3B and Ni_2B (Ni_7B_3) is associated with the additional hydrogen evolution.

Some Properties of Nickel-Boron Plates

The observed dependence of the phase composition on the annealing temperature allows one to under-

stand the nature of the changes of the coating properties, observed after heat-treatment.

Hardness.—The hardness of Ni-B deposits plated on a copper substrate was examined on the hardness meter (by Vickers) with diamond pyramid and a load of 50g; the thickness of deposits was in the range of 35-45μ. The increase of plating hardness after isothermal annealing in the ranges 150°-300°C and 400°-550°C shown in Fig. 8 appears to be due to both the dispersion hardening as a result of the Ni_3B and Ni_2B phase formation and their high hardness; the decrease of plating hardness after reaching its maximum value can be considered to be a result of relaxation of the internal stresses and coagulation of boride particles. A very high hardness (~1500 kg/mm²) exceeding the hardness of chromium coatings can be reached if the annealing is carried out in nonisothermal conditions with a rate of heating of 400°/min.

Wear resistance.—The wear resistance of the Ni-B and Ni-P coatings deposited on the hardened steel CT-45 was studied by use of the butt-end friction apparatus; the friction was applied to the nickel-plated specimens by contact with the same steel. The tests were carried out at the specimen rotation rate of 300 rpm under a load of 5 kg/cm² with alcohol-glycerine lubrication. The temperature of the specimens during tests was measured by a thermocouple introduced into the hole of the immovable part of the friction pair.

Figure 9 shows comparative data on the wear resistance of annealed nickel-boron (6.4% B) and

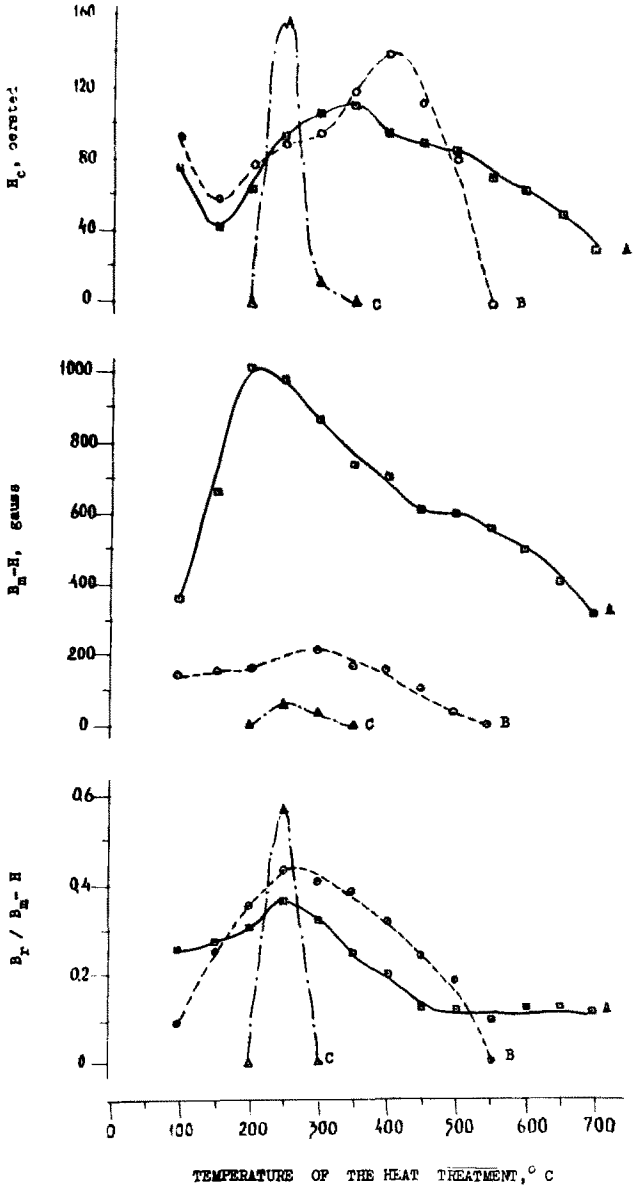

Fig 10. Dependence of the magnetic properties of the electroless nickel-boron plates on the annealing temperature. Letters correspond to those in Fig. 5.

nickel-phosphorus (9.7% P) plates. It is evident from this figure that the wear resistance of the nickel-boron deposits is much higher than that of the nickel-phosphorus alloys. The almost complete absence of the dependence of wear resistance on time is restricted to the nickel-boron deposits. The temperature measurements in the course of testing show the friction coefficient to be lower for the nickel-boron alloys than for the nickel-phosphorus alloys.

Magnetic properties.—It was of special interest to determine to what extent boron incorporation affects the magnetic characteristics of nickel. The measurments of magnetic properties of nickel-boron alloys 35μ thick were carried out by using a combination of ballistic and oscillographic methods in the magnetizing field of 1200 oersteds. The coatings were deposited on copper rods; the length of the specimen was 50 mm and their diameter was 3 mm.

Figure 10 gives the data on the effect of isothermal annealing temperature on the value of maximum induction, the loop rectangularity, and the coercive strength of nickel-boron alloys of different compositions. The effect of boron incorporation on the magnetic properties of nickel is not as strong as that of phosphorus, although in the as-plated state the ferromagnetic properties in nickel-boron alloys cannot be detected beginning with 6.4% B. However, the heating of these coatings to 250°C also resulted in a sharp rise of their magnetic characteristics. It is due to the appearance of the weakly ferromagnetic Ni_3B phase. The changes of magnetic characteristics with further increase of annealing temperature resulting in the formation of the Ni_2B phase, suggest the latter boride to be completely nonferromagnetic.

The Effect of Third Metal on the Magnetic and Storage Properties of Electrodeposited Permalloy Films

H. V. Venkatasetty*,[1]

Honeywell Corporate Research Center, Bloomington, Minnesota 55420

ABSTRACT

Controlled quantities of reducible metal ions like molybdenum and indium are introduced in the appropriate form into a nickel-iron bath and the magnetic properties of the ternary alloy films of Ni-Fe-Mo and Ni-Fe-In are measured over a wide range of concentration of molybdenum and indium in the bath. These films show much improved magnetic properties as well as some improvement in creep resistant characteristics when compared with permalloy films. The improved properties of these films are discussed in terms of the improved magnetic parameters and thickness.

In recent years electrodeposited ferromagnetic thin films of nickel-iron and nickel-iron containing small quantities of elements like cobalt, copper, molybdenum, arsenic, phosphorus, and sulfur have received considerable attention as possible memory elements in digital computers (1-8). These films have moderately low coercive force (H_c) and uniaxial anisotropy field (H_k), have rectangular hysteresis loops, and much faster switching mode for flux reversal compared to ferrite core material. The magnetic properties such as the wall motion coercive force (H_c), the anisotropy field (H_k), the dispersion of the easy axis (α_{90}), and creep threshold of thin films are important parameters for use as memory elements and these properties are influenced by the substrate characteristics, the composition, and thickness of the films. The most useful memory properties of nickel-iron films are obtained at zero magnetostrictive composition of 80% Ni and 20% Fe. The composition of the electrodeposited films is dependent on the composition of the bath and on the

plating parameters. In the case of the deposition of nickel-iron films from their simple salt solution (Watts type of bath) the rate of iron deposition is higher (>30%) in the initial stages (~500Å) of the deposit even though the nickel to iron ratio in the bath is about 50:1, and their standard electrode potentials indicate that nickel ($E°$, Ni = −0.25V) should plate out faster than ferrous iron ($E°$, Fe = −0.44) (9). This anomalous codeposition has been attributed to local hydrolysis of iron ions at the cathode and the adsorbed hydroxide causes preferential iron deposition (10). The nonzero magnetostrictive deposit not only results in increased dispersion of the easy axis (α_{90}) and the anisotropy field (H_k) but the memory properties of the film become very sensitive to strain (11). In thin films, a good control on gradients in composition during electrodeposition is necessary to improve the magnetic properties and the storage characteristics. This paper describes the results of experiments carried out in an effort to achieve this.

Experimental Procedure

A citrate complexed nickel-iron bath with nickel to iron ratio ~22:1 was prepared as described elsewhere (12). The Ni-Fe-Mo bath preparation was essentially similar to that described by Freitag and Mathias (3). It was made by dissolving reagent grade chemicals in distilled water, 100g $NiSO_4 \cdot 7H_2O$, 6.9g $FeSO_4 \cdot 7H_2O$, 0.37-1.88g $Na_2MoO_4 \cdot 2H_2O$, 32g citric acid, 15g sodium citrate, 2.5g K_2SO_4, ~0.2g sodium lauryl sulfate, and 1g saccharin, and diluting the solution to one liter. The pH was adjusted to 5.2 by NaOH and/or citric acid, the bath operated at temperatures from 26° to 40°C at a current density of 15.3 mA/cm² to get zero magnetostrictive films. The Ni-Fe-In system was also a citrate-complexed bath but to prepare zero magnetostrictive films, the bath had to contain more iron, 7.5 g/liter $FeSO_4 \cdot 7H_2O$ indium as indium sulfate varied from 0.25 to 2.5 g/liter, the bath *p*H was adjusted to 5.2 and the bath operated from 25° to 35°C at 15:3 mA/cm² current density. As substrates, 10 mil and 40 mil glass slides with chromium and gold evaporated on them were used. The procedure for preparing these films and making magnetic measurements has already been described (12). The reported magnetic parameters represent an average value of at least five samples and the difference between the samples was less than 5%.

The standard spectrophotometric method using a Cary 14 spectrophotometer was used to carry out quantitative estimation of various elements present in the electrodeposits. Iron was separated from the other metals and complexed with 2, 2′-dipyridyl and estimated at 522 mμ (13). Molybdenum was complexed with mercapto acetic acid and estimated at 365 mμ (14). Indium was determined by complexing with 5, 7-dibromo 8-quinolinol and extracting the complex with chloroform and measuring absorbance at 415 mμ (15). These determinations are accurate to ±2%.

In creep measurements large area films (24 × 15 mm), varying in thickness from about 1000 to 5000Å, that were deposited on 10 mil microsheet glass and made conducting with evaporated chromium (~300Å) and gold (~1000Å) were used to minimize demagnetizing field effects. Measurements were made by applying a combination of an a-c field in the hard direction and a d-c field in the easy direction. The observations of the extent of film switching were made by detecting the associated flux changes with a suitable pickup loop and observing the induced signal with the help of an oscilloscope. The various creep and switching curves refer to about 50% of film switching.

Background

In the case of codeposition of two or more metals from a bath prepared by complexing the metal ions with suitable ligands, the resultant deposition potentials of the metals, the relative rates of dissociation of metal complexes, and the diffusion of metal and complex ions control both the deposition process and the structure of the deposit. Although the theory of alloy formation by codeposition which has been treated elsewhere (16, 17) is not well understood (18), it is apparent that the bath composition, the substrate crystal structure, and surface topography (19) as well as the structure of the double layer at the electrode-solution interface influence the deposition process and the properties of the deposit.

It has been shown that in flat thin ferromagnetic films, when a d-c magnetic field is applied in both easy and hard direction, magnetization reversal takes place at a smaller critical field. A plot of this critical field as a function of hard direction d-c field is known as the critical curve for wall motion. However, when an a-c field whose amplitude is equal to the magnitude of the d-c field is substituted in the hard direction, magnetization will creep into a demagnetized state even though the applied field combination is below the uniaxial switching threshold curve (20). The creep threshold has been shown to be dependent on the type of domain walls existing in the film and the types of fields applied (21). It has been shown that the wall creeping is caused by Block-Néel-Bloch wall transitions in thick film (>850Å) and Block line motions in thin film (<850Å) which occur under the influence of the hard direction a-c field (21, 22). Attempts have been made to analyze the nature of domain wall creeping and several mechanisms and models proposed, but the creep mechanism is not well understood (21, 23).

Results and Discussion

When nickel and iron ions were complexed with organic ligands like citrate to control the concentration of free metal ions and to prevent hydrolysis of iron ions and nickel-iron deposited using pulsing current, the composition gradient was minimized, but not eliminated (12). Recently it has been shown that the composition gradient in the initial stages of the deposition process of nickel-iron films can be controlled by adding small quantities of cathodically easily reducible ions like antimony, selenium, or tellurium to the electrolyte so that these nonmagnetic elements are incorporated preferentially in the initially deposited film zones and thus produce more homogeneous films with good magnetic properties (24). It has been shown that zero magnetostrictive films of Ni-Fe-Cu with excellent control over alloy composition and magnetic properties from 400 to 2000Å can be prepared (4). It was thought desirable to investigate Ni-Fe-Mo and Ni-Fe-In systems over a wide range of molybdenum and indium concentration in an appropriate bath because these metals are not only nonmagnetic but may be more easily reduced electrochemically than iron. To prepare such films with zero magnetostriction, the deposition has to be done within a narrow concentration range. Zero magnetostrictive films of Ni-Fe-Mo and Ni-Fe-In covering the thickness range of ~1000-5000Å from a bath with wide range of molybdenum and indium concentrations at known concentration of nickel-iron were prepared and their magnetic properties like H_c, H_k, and α_{90} measured and their composition determined. It should be pointed out that Ni-Fe-Mo films prepared by Freitag and Mathias (3) were 600-800Å thick and were highly magnetostrictive and hence not suited for examining their storage characteristics.

The composition of the deposits as a function of molybdate and indium concentration of the baths are shown in Fig. 1 and 2. It is interesting to note that the iron content remains about 20% (weight) over the entire range of composition in both the systems. The magnetic properties of Ni-Fe-Mo films (~5000Å) as a function of molybdenum content are shown in Fig. 3, while those of Ni-Fe-In films (~5000Å) are shown in Fig. 4. Magnetic parameters and composition measured on zero magnetostrictive thin films (~1200Å) of Ni-Fe-Mo and Ni-Fe-In show similar behavior to those of

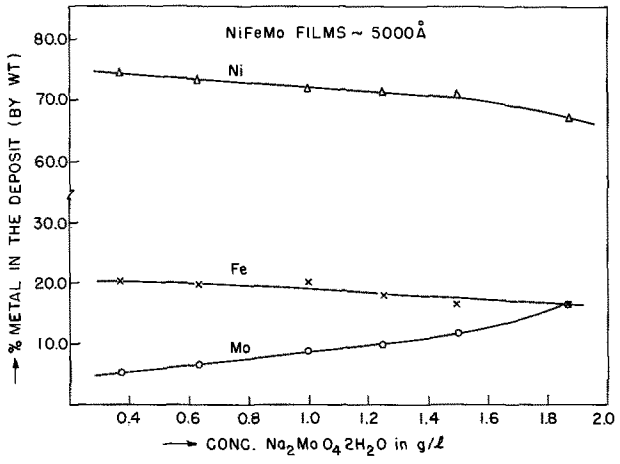

Fig. 1. Variation in the composition of Mo, Fe, and Ni with change in the concentration of molybdenum in the bath.

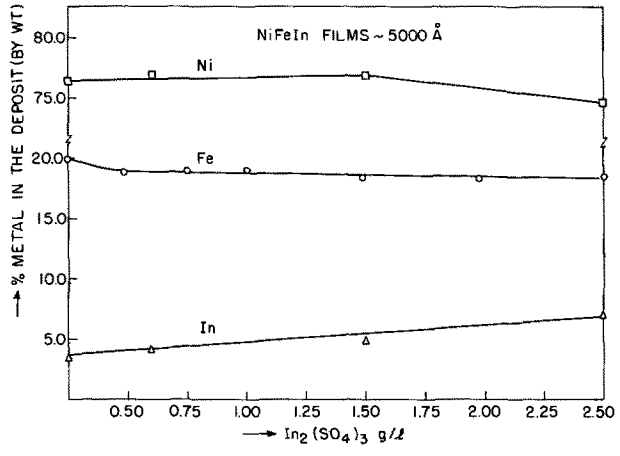

Fig. 2. Variation in the composition of In, Fe, and Ni with change in the concentration of indium in the bath.

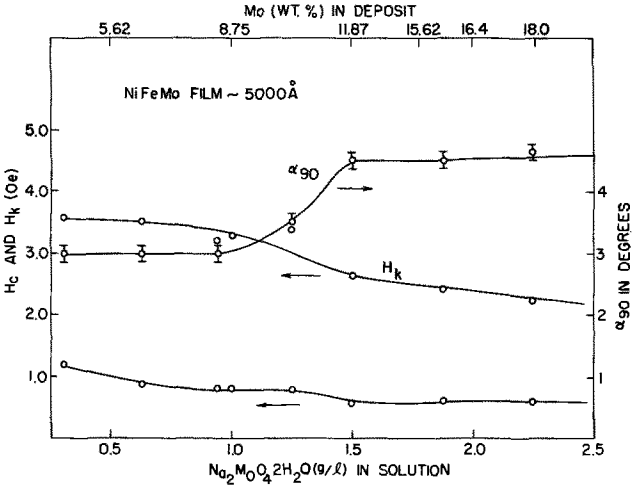

Fig. 3. Variation of H_c, H_k, and α_{90} of Ni-Fe-Mo films with amount of molybdenum in the bath and the amount of molybdenum in the deposit.

5000Å films. The magnetic parameters and iron content in zero magnetostrictive Ni-Fe-In films were determined as a function of thickness from 1000 to 5000Å and are shown in Fig. 5. The iron content of the film remains very close to 20% (weight) above 2000Å but appears to be slightly higher in the initial stages of the deposit. The decrease in H_k with thickness can be attributed to the reduced influence of the initial deposit in the thicker films.

Since very thin films (~1000Å) have low output signals and their magnetic properties are very sensi-

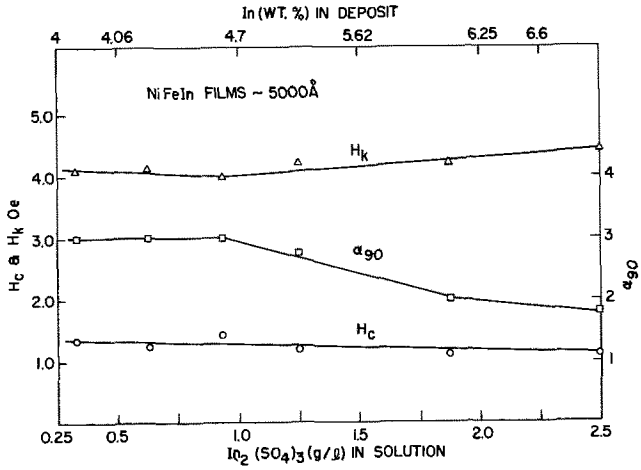

Fig. 4. Variation of H_c, H_k, and α_{90} of Ni-Fe-In films with amount of indium in the bath and the amount of indium in the deposit.

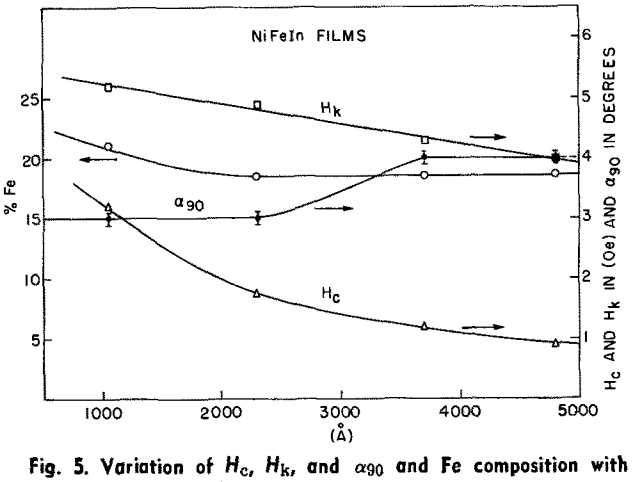

Fig. 5. Variation of H_c, H_k, and α_{90} and Fe composition with thickness of Ni-Fe-In films.

tive to substrate characteristics, it was decided to deposit films of about 5000Å with zero magnetostriction. The wall motion coercive force (H_c) for zero magnetostrictive permalloy films has a logarithmic relationship with thickness of the form $H_c = At^{-B}$ where t is thickness, the constant A relates to substrate roughness, and B to plating conditions (25, 26). In order to increase H_c of these films (~5000Å) with a view to increase their creep threshold, experiments were conducted to relate the magnetic properties of zero magnetostrictive films of Ni-Fe-Mo, Ni-Fe-In, and Ni-Fe with substrate surface roughness by preplating copper at varying current densities and measuring roughness by a radioactive tracer technique (19). As a result of such a study, optimum plating conditions were developed to obtain zero magnetostrictive films of Ni-Fe-Mo, Ni-Fe-In, and Ni-Fe with good magnetic properties.

Some of the parameters that influence the creep threshold in flat magnetic films are the film thickness, film composition, coercive force, anisotropy field, dispersion of the easy axis, and film geometry. The creep threshold measurements are important because the information stored in these memory elements can be destroyed by domain wall creeping under the influence of disturbances occurring in actual memory environment, thus limiting the bit density in memory design. It is therefore necessary to know the maximum field combination for which domain wall creeping still does not occur. Various attempts have been made to increase the disturb threshold for flat films. Although very thin films (~300Å) which have Néel walls have better disturb threshold, they have small signals and

are very sensitive to substrate characteristics. Another approach is to use multilayer films wherein the wall motion coercive force of the composite film is influenced through magnetostatic and exchange coupling effects (27). It has also been shown that the storage properties of Ni-Fe films can be improved either by directly diffusing (28) or electroplating nonmagnetic metal and diffusing (29) into permalloy.

Although a great deal of data on creep measurements is available on vacuum-deposited binary and ternary flat films, very little data are available on electrodeposited films (20, 23, 30, 31). Therefore, zero magnetostrictive films (~1000 and ~5000Å) of Ni-Fe-Mo, with the composition 72.4% Ni, 20% Fe, and 7.6% Mo, and Ni-Fe-In films (~1000 and ~5000Å), with the composition 74% Ni, 20% Fe, and 6% In, with suitable magnetic properties were selected and their creep threshold and switching properties measured and compared with those of 80:20 Ni-Fe films (~1200 and ~5000Å). By noting the separation between the switching and creep curves for each of the films, it is apparent from Fig. 6 that the curves for the Ni-Fe-Mo films (~1000Å) are closer and therefore they exhibit better creep threshold characteristics than those of Ni-Fe-In and Ni-Fe films. In the case of ~5000Å films (Fig. 7) the Ni-Fe-In films have slightly better creep threshold characteristics than Ni-Fe-Mo and Ni-Fe films although the differences are smaller than those in the 1000Å films.

The improved creep thresholds observed in the case of thinner films (~1000Å) compared to those of 5000Å films (Fig. 6 and 7) can be attributed partly to their increased coercive force and partly to reduced demagnetizing field effects. Since the domain wall structure changes with film thickness (12), the dependence of the creep process on film thickness is expected (32, 33). It has been observed recently that in addition to film thickness, film composition also influences creep threshold (34).

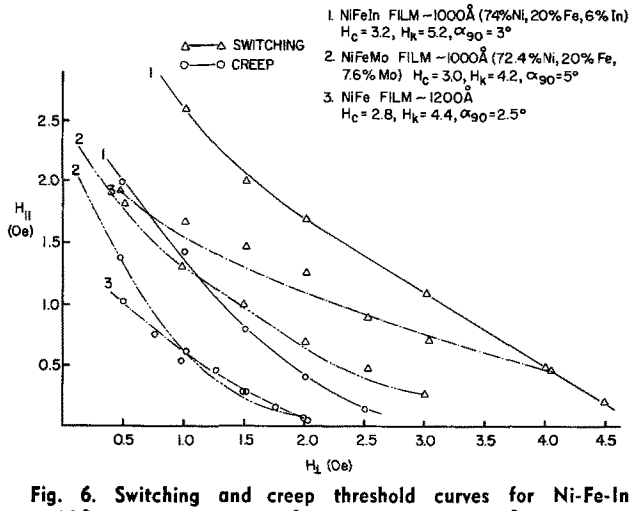

Fig. 6. Switching and creep threshold curves for Ni-Fe-In (~1000Å), Ni-Fe-Mo (~1000Å), and Ni-Fe (~1200Å) films.

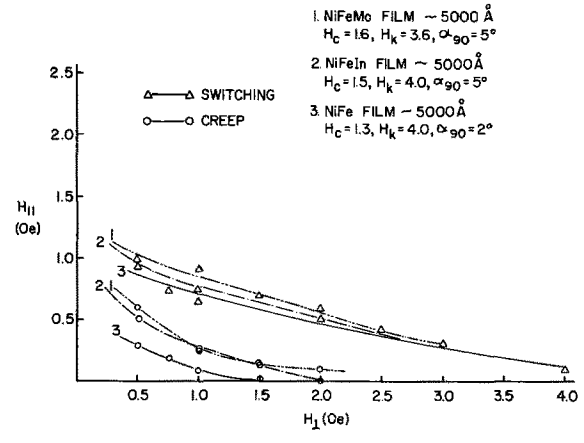

Fig. 7. Switching and creep threshold curves for ~5000Å Ni-Fe-In, Ni-Fe-Mo, and Ni-Fe films.

Conclusion

Zero magnetostrictive Ni-Fe-Mo and Ni-Fe-In films of varying thickness have been prepared. The magnetic properties such as H_c, H_k, and α_{90} of these films containing a wide range of molybdenum and indium have been measured and their composition determined. The films of different thickness with optimum composition were evaluated for their creep threshold and switching properties and compared to those of Ni-Fe films. The improved disturb thresholds of Ni-Fe-Mo and Ni-Fe-In films are attributed to improved magnetic properties and film thickness.

Molybdenum Carbide by Electrolysis of Sodium Molybdate

A. K. Suri, T. K. Mukherjee, and C. K. Gupta

Metallurgy Division, Bhabha Atomic Research Centre, Trombay, Bombay-85, India

ABSTRACT

Preparation of di-molybdenum carbide from sodium molybdate dissolved in fused bath of sodium carbonate, sodium tetraborate, sodium fluoride, and potassium fluoride was investigated. Under the optimum conditions established, a maximum electrodeposition rate corresponding to 0.5 g/A-hr of the carbide was obtained. In the follow-up investigation the carbide was admixed with monitored amounts of molybdenum dioxide for vacuum thermal sintering treatment to yield molybdenum metal of purity comparable to conventional molybdenum extraction process.

Production methods of molybdenum carbide have been extensively researched. A review on this subject has been forwarded by Schwarzkopf and Kieffer (1), and more recently by Kosolapova (2). Processes based on molybdenum or molybdic oxide carburized with graphite, carbon black, carbonaceous gases, or calcium carbide for the manufacture of di-molybdenum carbide have been patented. There has also been parallel interest in electrometallurgical routes in carbide production. Electrolyses of alkali fluoride-carbonate-borate-molybdic oxide baths have been conducted, and conditions of di- and mono-molybdenum carbide deposition have been established by Andrieux and Weiss (3). In a recent work Heinen *et al.* (4) from the U.S. Bureau of Mines have reported electrolysis of potassium fluoride-potassium chloride-sodium metasilicate and sodium fluoride-potassium fluoride-sodium carbonate-sodium tetraborate baths containing molybdenite for the production of di-molybdenum carbide, the maximum yield being 0.42 g/A-hr. No reference is found on any previous work producing molybdenum carbides from molybdates such as calcium and sodium molybdate. Molybdenum electrowinning processes on laboratory scale from calcium molybdate have been recently investigated (5). With sodium molybdate on the other hand Campbell (6) reported that not much success on metal deposition was achieved in aqueous or organic electrolytes. This alkali molybdate, because of its low fusion temperature (627°C) without any decomposition, has been considered as a preferred salt in molten electrolyte systems also. Senderoff and Brenner (7) examined the possibility of inert atmosphere fused salt electrolysis of molybdenum in various baths. In the instance of sodium molybdate dissolved in molten sodium chloride-potassium chloride the cathodic deposit consisted of molybdenum metal, di-molybdenum carbide, and lower oxides.

Studies incorporated in the present paper pertain to production of di-molybdenum carbide by molten salt electrolysis of sodium molybdate. A similar tungsten compound, sodium tungstate which has been successfully electrolyzed for tungsten carbide production may be pointed out here as a reference (8) of interest. The paper also embodies an extension of work involving metal preparation from the carbide electrowon from sodium molybdate.

Electrolysis

Chemicals used in the electrolytic investigation included sodium fluoride, potassium fluoride, sodium tetraborate, sodium carbonate, and sodium molybdate. With the exception of sodium molybdate these were commercial or technical grade available from the open market. Sodium molybdate was prepared in the laboratory through chemical dissolution of commercial molybdenum trioxide in soda-ash solution.

Key words: fused salt electrolysis, sodium molybdate, molybdenum carbide, molybdenum.

Electrolyses were conducted in 8 in. high by 2 in. ID open cells made of high density graphite serving as both anode and electrolyte container. A ½ in. diameter graphite rod suspended centrally into the molten bath functioned as the cathode. The cell was heated externally by a resistance furnace and the direct current for electrolysis was furnished by a 0-250A, 0-12V stepless selenium rectifier. In batch electrolysis, 350g of total salt mixture was formed according to the composition desired, charged into the graphite crucible, furnaced, and the temperature was raised gradually to the intended level. At any desired test temperature the graphite cathode rod was lowered and held above the molten bath for drying before immersion. Positioned at 1 in. from the crucible bottom (total bath depth 3.5 in.) the cathode rod was allowed to attain the electrolyte temperature before starting the electrolysis. Amperage appropriate to a desired initial cathode current density was regulated with voltage varying between 0.5 and 1V. At the end of 10 A-hr the cathode was lifted and the deposit immediately scraped, leached first in water and then in 10% HCl solution before final washing and drying. The effects of different experimental parameters, viz., the cathode current density, sodium molybdate, sodium carbonate concentrations, and temperature on the quality and yield of electrodeposits as shown in Table I were investigated. These are discussed below.

Cathode current density.—An electrolyte bath at 10 weight per cent (w/o) sodium molybdate composition, maintained at 1000°C, was tested at different cathode current densities varying from 300 to 1350 A/ft^2. In each case adherent shining silvery crystals, identified as Mo_2C by x-ray diffraction determination, were obtained. There was, however, no observable effect on the yield. In the cathode current density range investigated, the rate of di-molybdenum carbide deposition varied from 0.225 to 0.3 g/A-hr.

Sodium molybdate.—From electrolyses carried out at 1000°C and a cathode current density of 800 A/ft^2, the following corresponding values of sodium molybdate content (w/o) and di-molybdenum carbide deposition rate (g/A-hr) were obtained: 10, 0.3; 16, 0.42; 18, 0.315; 20, 0. It can be seen that at 16 w/o sodium molybdate concentration a maximum deposition rate of 0.42 g/A-hr occurred. Further addition of sodium molybdate in the bath resulted in a declining deposition rate. Almost no carbide deposition at 20 w/o composition suggested the bath to be in a condition where carbide redissolution appeared competitive to its cathodic deposition.

Sodium carbonate.—Holding the bath composition at 16 w/o sodium molybdate, with other operational parameters, cathode current density (800 A/ft^2) and temperature (1000°C) fixed, experiments were performed to examine the cathodic deposition with sodium carbonate additions varying from 0 to 30 w/o.

[a] Unidentified.

The electrolysis with no sodium carbonate produced lusterless electrodeposits at 0.365 g/A-hr. The material on x-ray examination was found to be a mixture of di-molybdenum carbide, molybdenum metal, and trace amount of unidentified phase. Di-molybdenum carbide free from other associations started appearing at and above 10 w/o sodium carbonate concentrations. A maximum rate of 0.42 g/A-hr was obtained at 14 w/o of sodium carbonate. Any further increase of concentration was ineffective in improving the carbide yield as shown in run No. 10 and 11 in Table I.

Temperature.—The electrolysis at a cathode current density of 800 A/ft², with a bath composition (in w/o) of: 16 Na_2MoO_4, 14 Na_2CO_3, 4 $Na_2B_4O_7$, 34 NaF, and 32 KF, produced a maximum rate of deposition of 0.5 g/A-hr at a test temperature of 960°C. Electrolyses carried out at lower (900°C) and higher (1000°C) temperatures yielded reduced deposition rates as shown in run No. 13 and 5, Table I.

Adopting the optimum operational parameters with which maximum yield (0.5 g/A-hr) was obtained, a larger scale electrolysis was conducted in a 4 in. ID by 8 in. high graphite cell. In a 200 A-hr electrolysis test about 100g of carbide was recovered. The electrodeposit after initial x-ray examination as di-molybdenum carbide was further evaluated. Combustion of the carbide in air gave a weight gain of 40.6% compared to the theoretical value of 41.2%. The carbon and oxygen content of the electrowon carbide were 6 (theoretical 5.9%) and 0.03%, respectively.

Metal Preparation

Utilization of di-molybdenum carbide electroextracted from sodium molybdate was studied in an additional area of interest. In a reference quoted earlier, preparation of di-molybdenum carbide by electrosynthesis of molybdenite was pointed out. In addition, the work also was concerned with metal preparation by inert atmosphere sintering of the electrosynthesized carbide and molybdenum trioxide mixture. Sintered product was finally arc-melted into buttons for which a lowest hardness value of 172 VPN was reported. Except for this single reference there seemed to have been no other work involving carbide conversion to metal. The present work dealt with the metal preparative route through vacuum thermal treatment of di-molybdenum carbide and molybdenum dioxide.

Molybdenum dioxide was prepared by hydrogen reduction of molybdenum trioxide at 450°C. The reduced product was then calcined under a flowing HCl gas stream at red heat to effect removal of residual MoO_3 as $MoO_3 \cdot 2HCl$. A series of charges composed of 5g of di-molybdenum carbide dry mixed intimately with variable amounts of molybdenum dioxide were prepared. These charges were pelletized at 25 tons/in.² and subsequently each was examined for its response to vacuum thermal treatment carried out in a 12 kW tantalum resistance furnace. The thermal treatment commenced at the vacuum level of 5×10^{-5} Torr. The first break in vacuum indicating the onset of carbide-oxide reaction, was observed around 600°C. Under controlled heating and vacuum conditions the temperature was gradually raised to 1400°C and soaked for 30 min. During the final stage the furnace vacuum levelled at better than 2×10^{-5} Torr. The sintered products were argon arc-melted and evaluated rapidly for the purity by hardness testing. The percentage of molybdenum dioxide in the carbide-oxide mixture was varied from 0 to 15% excess over stoichiometric. The product resulting from using 10% molybdenum dioxide in excess of stoichiometric on melting recorded the lowest hardness value of 170 VPN. This hardness value, it may be mentioned here, is close to the value reported for the arc-cast molybdenum produced by hydrogen reduction of molybdenum trioxide.

Conclusion

The preparation of Mo_2C type molybdenum carbide was demonstrated by molten salt electrolysis of sodium molybdate. Carbide yield corresponding to 0.5 g/A-hr was achieved under the following conditions: bath composition (w/o) 16 Na_2MoO_4, 14 Na_2CO_3, 4 $Na_2B_4O_7$, 34 NaF, 32 KF; bath temperature 960°C; and the cathode current density of 800 A/ft².

Electrowon Mo_2C in further work was thermally reacted under vacuum with monitored amounts of MoO_2 to yield a product whose melt hardness was 170 VPN, similar to arc-cast molybdenum values.

Acknowledgments

The authors gratefully acknowledge Shri C. V. Sundaram, Head, Extractive Metallurgy Section, for his interest in the present work and Dr. V. K. Moorthy, Head, Metallurgy Division, for his kind approval in the publication of this research report.

Manuscript received July 26, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Behavior of the Silver, Silver Chloride Electrode in Concentrated Aqueous Sodium Chloride

H. Frank Gibbard, Jr.

Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, Illinois 62901

ABSTRACT

The reported solute and solvent activities of concentrated aqueous sodium chloride are not thermodynamically consistent within the apparent experimental errors. This result is attributed to a deviation of the silver, silver chloride electrode owing to the formation of a solid solution of silver chloride and sodium chloride. Electrochemical cell measurements and x-ray diffraction results are reported in support of these conclusions. The mole fractions and activities of silver chloride in the solid solutions are calculated from solubility equilibria and are correlated with literature values of the activity coefficients of sodium chloride.

The thermodynamic properties of aqueous sodium chloride have been studied more extensively than those of any other electrolyte. The activity of the solvent has been measured in dilute solutions (1) and in concentrated solutions (2, 3) by freezing point measurements and in concentrated solutions near room temperature (4-6) by direct vapor pressure measurements. The solute activity has been determined from electrochemical cell measurements in both dilute (7) and concentrated (8-10) solutions.

The thermodynamic consistency of the solvent and solute activity data is quite important owing to the use of sodium chloride as the standard reference substance in most isopiestic vapor pressure studies. In dilute solution the osmotic coefficients calculated from solute activity data by integration of the Gibbs-Duhem equation are in satisfactory agreement with the values obtained directly from solvent activity data. At concentrations higher than 2*M* the osmotic coefficients calculated from solute and solvent activities differ, and this difference reaches nearly 2% for saturated sodium chloride at 25°C (6, 9). This discrepancy seems quite large in view of the apparent precision of 0.1-0.2% in the osmotic coefficients determined by vapor pressure measurements (4-6, 11).

The electrochemical cell measurements of Harned and Nims (8), Lanier (9), and Caramazza (10) all rely on the silver, silver chloride electrode, and they are in agreement within a few tenths of a millivolt from 0 to 4*M*. Because of the variety of ways in which reference electrodes may fail in concentrated electrolyte solutions, we suspected a failure of the silver, silver chloride electrode to be responsible for the inconsistency in the solvent and solute activities. In this paper electrochemical experiments which confirm the imperfection of the silver, silver chloride electrode in concentrated aqueous sodium chloride are reported. Further experiments and calculations are used to explain this behavior in terms of the formation of a solid solution of silver chloride and sodium chloride.

Key words: activity, electrolyte, solution, electrochemical.

Experimental

Electrochemical Measurements

An H-type cell with a stopcock in the horizontal arm was constructed to measure the emf of the cell

$$Ag(s) \mid AgCl(s) \mid NaCl(aq) \mid Hg_2Cl_2(s) \mid Hg(l) \quad [1]$$

as a function of sodium chloride concentration. Silver, silver chloride electrodes of the thermal-electrolytic type were made according to the method of Bates (12) and calomel electrodes by the method of Hills and Ives (13). The extensive precautions suggested by these authors regarding purification of materials and preparation of the electrodes were followed carefully. Precipitated rather than electrolytic calomel (13) was used in these studies. The outside of the cell was painted black to avoid possible deterioration of the light-sensitive halides.

Sodium chloride was purified by the following procedure: chlorine gas was bubbled through a nearly saturated salt solution to remove bromide; then hydrogen chloride gas was passed through the solution to precipitate sodium chloride. The precipitate was fused in platinum crucibles under dry nitrogen, cooled, and ground to a fine powder, and stored in a desiccator.

The H cell was placed in a water bath at 25.00 ± 0.01°C. EMF measurements were made with a calibrated Leeds and Northrup Type K-5 potentiometer. All recommendations of the manufacturer regarding grounding and shielding of the electrochemical cell, the potentiometer and its power supply, null detector, and standard cell were followed. Nitrogen passed first over red-hot copper turnings in a quartz tube and then through presaturators was bubbled through the cell compartments to exclude oxygen. The presaturators were immersed in the water bath and contained solution of the same concentration as that in the cell. Their use permitted operation of the cell for several days without appreciable changes in the concentration of the cell solution.

Six silver, silver chloride electrodes were prepared; the largest difference in potential between any two of these electrodes in 0.01*M* hydrochloric acid was 20 μV. After their preparation these electrodes were stored immersed in conductivity water in the dark.

Measurements were made at sodium chloride concentrations of 0.100, 3.658, and 4.597*M*. Separate portions of the two more concentrated solutions were shaken for 48 hr with amounts of silver chloride and calomel just sufficient to saturate the solutions at room temperature. These saturated or nearly saturated solutions were used in the cell compartments to prevent excessive dissolving of the electrode materials. At 0.100 and 3.658*M* the cell required 2 days to reach a stable equilibrium; the most concentrated solution required 3 days. The criterion of equilibrium was taken as stability of the cell potential within 10 μV for 2-3 hr. The extreme sluggishness of the cell was caused by the calomel electrode. A fresh silver, silver chloride electrode, rinsed several times with solution of the same concentration as the cell solution, would reach equilibrium within 4-5 hr after its insertion into the cell.

Two silver, silver chloride electrodes were used at each concentration, and the cell potential was taken as the average of the readings of these two *vs.* the calomel electrode. The largest deviation between a pair of silver, silver chloride electrodes at equilibrium was 19 μV.

X-Ray Powder Studies

Materials.—Matheson, Coleman and Bell analytical reagent grade sodium chloride and silver nitrate were dried overnight at 115°C and used without further purification. Silver chloride was prepared by dropwise addition of 0.1M silver nitrate to 0.1M sodium chloride. The precipitate was filtered and washed thoroughly with 0.01M nitric acid and dried overnight at 115°C.

Procedure.—A 5g sample of silver chloride was ground with a mortar and pestle to a fine powder. The powdered sample was placed in an Erlenmeyer flask, 250 ml of 4, 5, or 6*M* sodium chloride was added, and the flask was capped. The solution was stirred for 72 hr at 25° ± 1°C. The solid was recovered by filtration in a porcelain crucible, dried for 30 min by suction, and dried several hours at 115°C.

The suspected solid solutions and samples of pure sodium chloride and silver chloride were ground to fine powders and sieved. Initially powder x-ray diffraction patterns were recorded on the General Electric XRD-5 Diffractometer; more precise a_o values were obtained by the use of a precision back-reflection symmetrical focusing powder camera (14, 15). Positions of the Cu K_α lines were estimated to 0.01 mm by the use of a Nikon optical comparator. Best values for the a_o parameters were obtained by plotting apparent a_o values against $\cos^2\theta$ and extrapolating to $\cos^2\theta = 0$.

Results and Discussion

Because of the known tendency of silver chloride to form complex anions in concentrated chloride solutions (16), a junction potential in our cell due to the increased solubility of silver chloride might be suspected. However, Gerke (17) and Randall (18), in careful measurements on the cell

$$Ag(s) \mid AgCl(s) \mid HCl(aq) \mid Hg_2Cl_2(s) \mid Hg(l) \qquad [2]$$

found the potential to be independent of chloride concentration up to nearly 15*M*. This result suggests that the suspected anomalous potential of the silver, silver chloride electrode must be related to the presence of sodium ion, not chloride ion.

The present electrochemical cell measurements strongly support a change in the silver, silver chloride electrode induced by sodium ion at high concentrations. For the cells [1] and [2] the change in state for the passage of one Faraday of electricity is

$$Ag(s) + \tfrac{1}{2}\,Hg_2Cl_2(s) = AgCl(s) + Hg(l) \qquad [3]$$

The emf of this cell should be independent of electrolyte concentration unless the activity of one of the solids or of liquid mercury should vary from unity. The experimental potentials presented in Table I clearly show a variation with sodium ion concentration. The values at 0.100*M* may be compared with the values obtained from the standard reduction potentials at 25° of the calomel electrode on the first day after its preparation (19), 0.26797V; the calomel electrode at equilibrium (20) 0.26812V; and the silver, silver chloride electrode (21), 0.22234V. The corresponding values for the "first day" and stable calomel electrode for cell [1] are 0.04562 and 0.04578V, respectively. The agreement with the values of Table I shows the remarkable reproducibility of both electrodes in dilute solutions.

The deviations of the potential ξ of cell (1) from the standard potential ξ° are consistent with a silver chloride activity of less than unity. This follows if it is assumed that calomel, silver, and mercury are at unit activity, in which case for cell [1] at 25°

$$\xi - \xi^\circ = -0.05915 \log_{10} a_{AgCl} \qquad [4]$$

That the activity of silver chloride might be less than unity is suspected because of the known complete miscibility of silver chloride and sodium chloride in the solid phase at high temperatures (22-28). Below about 170°C a miscibility gap appears in the phase diagram for the solid solutions; at room temperature the gap extends from about 5 to 87 mole per cent (m/o) sodium chloride (28, 29). A reasonable assumption is that silver chloride in equilibrium with a concentrated sodium chloride solution forms a solid solution dilute in sodium chloride.

Formation of a solid solution should affect the mechanical, electrochemical, and other properties of solid silver chloride. However, the most direct evidence for solid solution formation comes from the x-ray diffraction results which are discussed below.

The extrapolations used to find the lattice parameters a_o for pure silver chloride and the solid solutions are shown in Fig. 1. Only the lines corresponding to diffraction angles greater than 65° were used in making the extrapolation. The variation of a_o with the concentration of sodium chloride in which the precipitates were immersed is reproducible and independent of sample equilibration time from 48 to 108 hr. We have found no suitable explanation for this variation except solid solution formation. No sodium chloride diffraction lines were present in the solid solution diffraction films. The lattice parameters determined from Fig. 1 and a similar extrapolation for sodium chloride are given in Table II. In the first column the solids are identified; the second column gives the a_o parameters determined from our measurements. The third column shows the mole percentage of sodium chloride in the

solids calculated by Vegard's law, which has been shown to be valid for NaCl-AgCl solid solutions (26).

An independent method of calculating the compositions of the solid solutions in equilibrium with aqueous sodium chloride of any concentration may be derived from the criterion for equilibrium in this heterogeneous system. At equilibrium at constant temperature and pressure the chemical potential of sodium chloride has the same value in the solid and aqueous phases; thus the activity of sodium chloride in the solid phase is proportional to its activity in the aqueous phase. This relation may be written

$$f_2 x_2 = m_{Na^+} m_{Cl^-} \gamma_\pm^2 / K \qquad [5]$$

where f_2 and x_2 are the activity coefficient and mole fraction of sodium chloride in the solid phase, m_i is the molality of ion species i, $\gamma_\pm$ is the mean molal ionic activity coefficient of sodium and chloride ions in the aqueous phase, and K is the solubility product constant of sodium chloride. The constant K is evaluated from the equilibrium solubility of sodium chloride at 25°C, 6.144M, and the activity coefficient, 1.0004 (6). Setting $x_2 = f_2 = 1$, we find $K = 37.78$.

In order for Eq. [5] to be used for an accurate calculation of x_2, the dependence of f_2 on x_2 must be known. This may be found from an expression for the Gibbs function of mixing and the limits of miscibility of the solid solution at 25°C. The Gibbs function of mixing the pure components to form the solid solution is defined by

$$G^M \equiv n_1(\mu_1 - \mu_1^\circ) + n_2(\mu_2 - \mu_2^\circ) \qquad [6]$$

where μ_i is the chemical potential of component i in the solution, and μ_i° is the molar Gibbs function of pure component i. We assume that the Gibbs function of mixing per mole of solid solution, $\bar{G}^M$, may be expressed by

$$\bar{G}^M/RT = x_1 \ln x_1 + x_2 \ln x_2 + Bx_1x_2 + Cx_1x_2(1 - x_2/2) \qquad [7]$$

where R is the gas constant, T is the absolute temperature, and B and C are functions of temperature and pressure but not of composition. Expressions for the logarithms of the activity coefficients of the components may be derived from Eq. [7]; these are given by

$$\ln f_1 = (B + 3C/2)x_2^2 - Cx_2^3 \qquad [8a]$$

$$\ln f_2 = Bx_1^2 + Cx_1^3 \qquad [8b]$$

The condition for a miscibility gap in the solid solution is that a single straight line be tangent at the two solubility limits to the curve of $\bar{G}^M/RT$ *vs.* x_2. After some algebra this condition with the solubility gap extending from $x_2 = 0.05$ to $x_2 = 0.87$ gives $B = 1.5445$; $C = 1.7408$. Insertion of these values into Eq. [5] and [8b] gives

$$x_2 = (m^2\gamma_\pm^2/37.78)\, e^{-(1.5445x_1^2 + 1.7408x_1^3)} \qquad [9]$$

where it is assumed that the effect on m_{Cl^-} and $\gamma_\pm$ of dissolved silver chloride is negligible, so that $m_{Cl^-} = m_{Na^+} = m$.

With the use of sodium chloride activity data (6) Eq. [9] may be solved iteratively for the mole fraction of sodium chloride in the solid solution at various sodium chloride concentrations. The results of these calculations are presented in the first three columns of Table III. Comparison of the values of x_2 at 4.0, 5.0, and 6.0M sodium chloride with the experimental values of Table II shows fairly good agreement.

The calculation of the effect of solid solution formation on electrochemical cell measurements is straightforward. Harned and Nims (8) and Caramazza (10) used sodium amalgam cells which may be written

$$\text{Ag(s)} \mid \text{AgCl(s)} \mid \text{NaCl(aq,m')} \mid \text{Na(in Na}_x\text{Hg)} \mid \text{NaCl(aq,m")} \mid \text{AgCl(s)} \mid \text{Ag(s)} \qquad [10]$$

The reference solution with molality m' is so dilute that solid solution formation is entirely negligible in the left side of the cell. For thermodynamic comparisons we are interested in the value of the logarithm of the apparent mean activity coefficient, $(\gamma_\pm")_{app}$, calculated with the neglect of solid solution formation, less the true value of the logarithm of the activity coefficient. This difference is given by

$$\log(\gamma_\pm")_{app} - \log\gamma_\pm" = -(\tfrac{1}{2})\log a"_{AgCl} \qquad [11]$$

Values of the right side of Eq. [11] calculated by Eq. [8a] and [9] are given in the fourth column of Table III.

For a comparison with experimental results we identify the "true" values of $\gamma_\pm"$ with those calculated from solvent activities (6, 11) and the "apparent" values with those determined by electrochemical cell measurements. Values of the left side of Eq. [11] are plotted in Fig. 2 for the measurements of Harned and Nims (8) and Caramazza (10), and for the results of Lanier (9), who used a sodium-sensitive glass electrode in combination with a silver, silver chloride electrode. The broken curve shows the prediction of Eq. [8a], [9], and [11]. The agreement of the calculated curve with Caramazza's values is good up to 4M. At higher concentrations his values of the activity coefficients give large positive deviations from our curve and from Lanier's results. The points labeled "this work" are calculated from Eq. [4] and [11] and the experimental results of Table I. The calculation from solubility considerations of both the compositions of the solid solutions and the deviations of the

emf results yields strong support to the present interpretation of those deviations.

Further evidence in support of solid solution formation comes from the mechanical properties of silver chloride immersed in concentrated aqueous sodium chloride. Levine *et al.* (30) and Westwood *et al.* (31) found that treatment of both polycrystalline and single-crystal forms of silver chloride with concentrated sodium chloride solution greatly embrittles the solid. The effect becomes evident at concentrations of 2-3*M* sodium chloride but is not found with potassium chloride or cesium chloride. These observations are consistent with solid solution formation at the surface of silver chloride crystals. It is just at concentrations of 2-3*M* that solid solution formation begins to cause significant deviations in the emf measurements. Neither potassium ion nor cesium ion is compatible with the silver chloride lattice, so no solid solution formation would be expected with these ions.

Concentration Recovery in the Downstream of a Rotating Disk Electrode

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A simple and systematic method based on the principle of maximal balance is used to discuss mass transfer mechanisms in various diffusion regions on a finite rotating disk electrode. A wake solution is presented to describe the concentration distribution in the far downstream of the electrode. It is shown that the wake length behind the disk electrode is ten times smaller than that behind a flat-plate electrode in plane flow.

The rotating disk electrode (RDE) is one of the most versatile tools used in the study of electrode kinetics. In theory (1), the electrode is assumed to be infinitely large, and the diffusion field to be one-dimensional, independent of the radius. This leads to a "uniformly accessible surface" for the electrode and has the advantage that the reaction rate at the electrode is everywhere the same. In practice, the electrode is finite and is usually made of a circular disk electrode mounted flush in the center of an electrically inert rotating disk. At the limiting current potentials, the concentration of the diffusing ion becomes zero at the electrode surface, whereas on the insulating surface there is no reaction taking place. This difference in the surface conditions in effect produces a radial diffusion flux near the edge of the disk electrode as well as on the insulating disk; consequently, the concept of the uniformly accessible surface fails to hold in these regions.

To attack the diffusion problem for such a finite rotating disk electrode, we divide the concentration boundary layer into three regions as shown in Fig. 1. The first region is the MAIN region over the disk electrode, where the diffusion field can be approximated as one-dimensional. The second region is the EDGE region, which is a narrow zone spanning a portion of the electrode surface near the edge of the disk electrode and a portion of the insulating plane in the immediate neighborhood of the disk electrode. The third region is the WAKE region in the far downsteam of the disk electrode. In the main region the Levich theory (1) gives a fair description of the rate of diffusion at high Schmidt numbers (Sc). The diffusion problem in the edge region has been discussed recently by Smyrl and Newman (2). Presently, we are interested in the concentration recovery of the diffusing ion in the wake region. Such information would not only serve as a complement to the transfer theory of the RDE, but would also be most useful in connection with the rotating ring-disk electrode.

Since different regions involve different transport mechanisms, the problem of deducing differential equations for each of the regions is a tricky one. In the classical procedure, the deduction is often made by setting forth a number of prior assumptions, such as $\partial C/\partial r = 0$, etc. The modern method of order-of-magnitude estimate based on a principle of "maximal balance" appears not to have been widely used in the electrochemical literature. According to this principle, the deduction should be performed in such a way that the maximum amount of physical knowledge can be retained in the resulting differential equation. Quite often there appears to be a number of ways to simplify the transfer equation for a given region. However, the most desirable way is the one achieved by use of a set of order-of-magnitude information which gives the least simplification, and which maintains the maximum number of comparable terms in the simplified equation. Thus, the principle of maximal balance is also called the principle of "maximal complication," or the principle of "least degeneracy." Good illustrations of this principle can be found in the works by Van Dyke (3), Kruskal (4), and Chin (5).

The purpose of this paper is: (*i*) to use the RDE as an example to demonstrate that the principle of maximal balance is a simple and systematic method for deduction of transport equations for various concentration regions, and (*ii*) to present a wake solution describing the concentration distribution in the far downstream of the disk electrode.

Key words: principle of maximal balance, mass transfer, concentration boundary layer, ring-disk electrode.

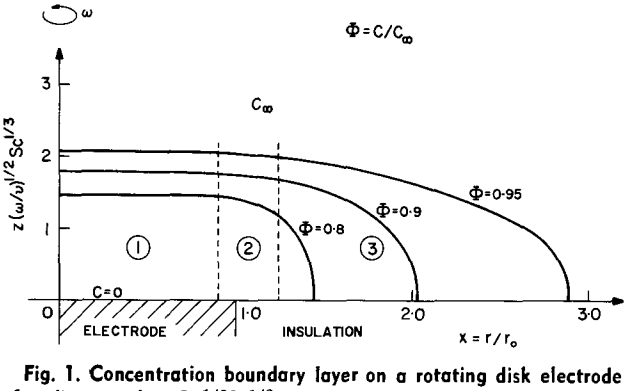

Fig. 1. Concentration boundary layer on a rotating disk electrode of radius r_0 when $Re^{1/2}Sc^{1/3} \to \infty$. (1) The MAIN region; (2) the EDGE region; (3) the WAKE region. The concentration profiles in the main region are calculated from the Levich equation, and those in the wake region are the results of the present analysis.

Theoretical

Maximal balance and diffusion layer equations.—In this analysis we assume that a disk electrode of radius, r_0, is embedded concentrically in an insulating rotating disk of infinite size as shown in Fig. 1. The disk is rotating with an angular velocity, ω, in a solution of constant properties. The solution contains an excess of supporting electrolyte, and the Schmidt number of the diffusing ion is assumed to have a large value. Under these conditions, the equation of convective diffusion in the neighborhood of the disk electrode may be given as

$$\left(a\eta - \frac{1}{2}\eta^2 + \ldots\right)x\frac{\partial\Phi}{\partial x} + \left(-a\eta^2 + \frac{1}{3}\eta^3 + \ldots\right)\frac{\partial\Phi}{\partial\eta} = \frac{1}{Sc}\frac{\partial^2\Phi}{\partial\eta^2} + \frac{1}{ReSc}\frac{\partial^2\Phi}{\partial x^2} + \frac{1}{ReSc\,x}\frac{\partial\Phi}{\partial x} \quad [1]$$

with the boundary conditions

$$\begin{aligned} &(i) && \Phi = 0 && \text{at } \eta = 0 \text{ for } x < 1 \\ &(ii) && \frac{\partial \Phi}{\partial \eta} = 0 && \text{at } \eta = 0 \text{ for } x > 1 \\ &(iii) && \Phi = 1 && \text{at } x \text{ and } \eta \to \infty \\ &(iv) && \frac{\partial \Phi}{\partial x} = 0 && \text{at } x = 0 \end{aligned} \qquad [2]$$

Our task here is to apply the principle of maximal balance to obtain a simplified equation for each of the concentration regions shown in Fig. 1. This requires an estimate of the order of magnitude of every single term in Eq. [1]; the terms with smaller orders will be dropped, retaining only those having the same order of magnitude. Since Sc is assumed to have a large value, we will make our order-of-magnitude estimation in terms of this parameter. To do this, we introduce a set of stretched coordinates defined as

$$\left.\begin{aligned} Z &= \mathrm{Sc}^{\alpha}\eta \\ X &= \mathrm{Sc}^{\beta}(x-1) \end{aligned}\right\} \alpha > 0,\ \beta \geqq 0 \qquad [3]$$

Substituting the new variables into Eq. [1], we have

$$\begin{aligned} &\left(a\mathrm{Sc}^{\beta-\alpha}Z - \frac{1}{2}\mathrm{Sc}^{\beta-2\alpha}Z^2 + \dots\right)\frac{\partial \Phi}{\partial X} \\ &\quad + \left(a\mathrm{Sc}^{-\alpha}Z - \frac{1}{2}\mathrm{Sc}^{-2\alpha}Z^2 + \dots\right)X\frac{\partial \Phi}{\partial X} \\ &\quad + \left(-a\mathrm{Sc}^{-\alpha}Z^2 + \frac{1}{3}\mathrm{Sc}^{-2\alpha}Z^3 + \dots\right)\frac{\partial \Phi}{\partial Z} \\ &\quad = \mathrm{Sc}^{2\alpha-1}\frac{\partial^2 \Phi}{\partial Z^2} + \mathrm{Sc}^{2\beta-1}\frac{1}{\mathrm{Re}}\frac{\partial^2 \Phi}{\partial X^2} \\ &\quad + (\mathrm{Sc}^{\beta-1} - \mathrm{Sc}^{-1}X + \dots)\frac{1}{\mathrm{Re}}\frac{\partial \Phi}{\partial X} \end{aligned} \qquad [4]$$

The exponents of Sc in the leading terms in Eq. [4] are

$$\beta - \alpha : -\alpha : -\alpha : 2\alpha - 1 : 2\beta - 1 : \beta - 1 \qquad [5]$$

The objective of the principle of maximal balance is to determine values of α and β for each of the concentration regions such that the maximum number of comparable terms can be preserved in the governing equation. To achieve this, a trial and error method is used. Numerical values are assigned to α and β, and a comparison is carried out among the terms in Eq. [5]. The terms with smaller order in Sc are dropped, retaining only the terms of the highest order in Sc. This procedure is repeated until one finds a set of values for α and β which keeps the maximum number of terms. It should be noted that the main region and the wake region do not include the point, $x = 1$. Thus, in these two regions, the stretch of the x-coordinate in the vicinity of $x = 1$ is not necessary, and β is zero. On the other hand, the edge region is located in the immediate neighborhood of $x = 1$, and β is nonzero.

Using the above procedures we find that in the main and the wake regions, $\alpha = 1/3$, and $\beta = 0$. Substituting these values into Eq. [4] and rearranging, we have

$$\begin{aligned} &aZx\frac{\partial \Phi}{\partial x} - aZ^2\frac{\partial \Phi}{\partial Z} - \frac{\partial^2 \Phi}{\partial Z^2} \\ &\quad = \mathrm{Sc}^{-1/3}\left(\frac{1}{2}Z^2x\frac{\partial \Phi}{\partial x} - \frac{1}{3}Z^3\frac{\partial \Phi}{\partial Z}\right) + 0\,(\mathrm{Sc}^{-2/3}) \end{aligned} \qquad [6]$$

where $Z = \mathrm{Sc}^{1/3}\eta$.

To the zeroth-order approximation of Sc, we may neglect the right-hand side of Eq. [6], and the equation is simplified to

$$aZx\frac{\partial \Phi}{\partial x} - aZ^2\frac{\partial \Phi}{\partial Z} - \frac{\partial^2 \Phi}{\partial Z^2} = 0$$

(for the main and the wake regions) [7]

Using the method of separation of variables and making use of the boundary conditions, (*i*) (*iii*), and (*iv*), it can be shown that the main-region solution takes the form of the Levich solution (1), being independent of the dimensionless radial coordinate, x

$$\Phi_M = 0.62\int_0^Z \exp\left(-\frac{a}{3}Z^3\right)dZ \qquad [8]$$

For the edge region, we find $\alpha = \beta = \frac{1}{2}$. Furthermore, by stretching the independent variables again with respect to large Re, Eq. [4] can be reduced to

$$\frac{\partial^2 \Phi}{\partial Z^{*2}} + \frac{\partial^2 \Phi}{\partial X^{*2}} - aZ^*\frac{\partial \Phi}{\partial X^*} = 0 \qquad [9]$$

with $X^* = \mathrm{Re}^{3/4}\mathrm{Sc}^{1/2}(x-1)$ and $Z^* = \mathrm{Re}^{1/4}\mathrm{Sc}^{1/2}\eta$.

This equation implies that (*i*) the radial diffusion and convection terms have the same order of magnitude as the axial diffusion term in the edge region; (*ii*) for $N = \mathrm{Re}^{1/2}\mathrm{Sc}^{1/3} \to \infty$, the size of the edge region diminishes to a single point at $x = 1$ and $\eta = 0$, and its existence can be ignored for practical calculations. The second point is especially important in electrochemical applications, for now the wake region equation can be solved by directly matching with the main region solution at $x = 1$. This has been the basic assumption in deriving the prevalent ring-disk theory (6, 7), although none of the previous investigators explicitly mentioned it.

Equation [9] has been solved numerically by Smyrl and Newman (2). Their results concerning the contribution of the edge region to the average mass flux on the surface of the disk electrode can be summarized as

$$J_E/J_M = 1.92/\mathrm{Re}^{3/4}\,\mathrm{Sc}^{1/2} \qquad [10]$$

Here J_E and J_M are the contributions to the mass flux from the edge- and the main-region solutions, respectively. The total average rate of transfer to the electrode surface is the sum of these two quantities.

Wake-region solution.—For $N = \infty$, Smyrl and Newman (7) have used a Stieltjes integral method to obtain a surface concentration distribution in the downstream of the disk electrode by matching the boundary conditions with Eq. [8]. For finite values of N, we have found the following equation

$$\Phi_W = 1 + \frac{A}{x^2}\exp\left(-\frac{a}{3}Z^3\right) \qquad [11]$$

satisfying both Eq. [7] and the boundary conditions (*ii*) and (*iii*) of Eq. [2]. To determine the constant, A, one needs to match Eq. [11] with the solution on the insulator side of the edge region. Since there is no general solution available for the edge region when N is finite, the matching operation is not possible. An alternative way is to apply the principle of mass balance. Accordingly, the flux of the diffusing ion carried by the electrolyte flow to the rotating disk should be equal to the sum of the flux consumed at the surface of the central disk electrode and the flux returning to the bulk of the electrolyte in the downstream of the disk electrode. Mathematically, this criterion may be obtained by integrating Eq. [1] over the concentration boundary layer

$$\int_0^{2\pi}\int_0^{\infty} \text{Eq. [1]} \cdot d\eta \cdot r_0 x d\theta$$

At high Schmidt numbers, this integration can be simplified to

$$\frac{d}{dx}\int_0^{\infty} ax^2Z\,(\Phi - 1)\,dZ = -x\left(\frac{\partial \Phi}{\partial Z}\right)_{Z=0}$$

In the wake region, we have $x > 1$, and the above equation can be integrated to give

$$\int_0^\infty ax^2Z\,(\Phi - 1)_{x>1}\,dZ = -\int_0^1 x\left(\frac{\partial\Phi}{\partial Z}\right)_{Z=0} dx \quad [12]$$

Substituting Eq. [8] and [10] in the right-hand side of Eq. [12], and Eq. [11] in the left-hand side of Eq. [12], we find

$$A = -0.413\left(1 + \frac{1.92}{Re^{3/4}Sc^{1/2}}\right)$$

Thus, the concentration distribution in the far downstream of a rotating disk electrode is described by

$$\Phi_W = 1 - \frac{0.413}{x^2}\left(1 + \frac{1.92}{Re^{3/4}Sc^{1/2}}\right)\exp\left(-\frac{a}{3}Z^3\right) \quad [13]$$

Discussion of Results

The concentration recovery of the diffusing ion on the insulating surface is shown in Fig. 2 for three different values of $Re^{1/2}Sc^{1/3}$. The thick solid curves are calculated from Eq. [13] by setting $Z = 0$. The thin solid curves are Smyrl and Newman's numerical solutions (2) for the edge region. It is seen that the present results correctly predict that the surface concentration would asymptotically approach $\Phi = 1$ at large radial distances in the downstream of the disk electrode; however, it fails to give a zero concentration at the edge of the electrode ($x = 1$). On the other hand, Smyrl and Newman's edge-region solution correctly predicts the concentration recovery in the immediate vicinity of $x = 1$; it gives a false value of Φ larger than the bulk concentration ($\Phi = 1$) at some distance from the disk electrode. In a later report, Smyrl and Newman published a more complete solution (7) for the surface concentration on the insulating surface when $N \to \infty$. This solution is plotted in Fig. 2 as the dashed curve, which appears to be a smooth connection between the edge-region and the wake solutions. It is seen that the edge-region solution is valid only for $x < 1.1$. On the other hand, the present wake solution represents only an asymptotic behavior of the diffusing ion at large x. It begins to be valid at $x \geq 1.5$; within this region the accuracy is expected to be better than 98%.

Equation [13] shows that the concentration deficiency, $1 - \Phi_W$, in the far downstream of the disk electrode is inversely proportional to the square of the radial distance. For large values of $Re^{1/2}Sc^{1/3}$, it takes a distance about twice the radius of the disk electrode to attain a 95% recovery (Fig. 1). This rate of recovery is faster than that found in the downstream of a flat-plate electrode in channel flow. For flows over a flat-plate electrode embedded in an insulating plane, the recovery of the surface concentration in the wake region is shown to be proportional to the 2/3 power of the distance from the leading edge of the electrode (8), and it would take twenty-four times the length of the electrode to reach a 95% recovery. Thus, the length of the wake region on the rotating disk is ten times smaller than that in plane flow. From the electroanalytical point of view, this leads to a disadvantage for the ring-disk electrode because the ring-disk distance is more critical than if one places the indicator electrode in the downstream of a flat-plate electrode in plane flow. The results of this analysis also indicate that the existing ring-disk theory is valid only for $N \to \infty$; correction to the theory for finite N requires further investigation.

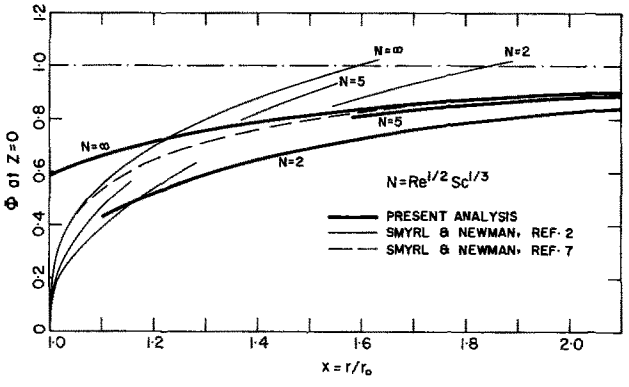

Fig. 2. Concentration recovery on the insulating surface in the downstream of the disk electrode. The present wake solutions are given as the thick solid curves. The thin solid curves are Smyrl and Newman's edge-region solutions. The dashed lines represent graphically interpolated values which would smoothly connect the two solutions.

Summary

In summary, we have used the principle of maximal balance to discuss transfer mechanisms in various diffusion regions on a finite rotating disk electrode. An analytical solution is presented to describe the concentration distribution in the wake region. It is shown that the wake length behind the disk electrode is ten times smaller than that in the downstream of a flat-plate electrode.

Greek Symbols

- α a nonzero positive number for the stretch of the axial distance, see Eq. [3]
- β a positive number for the stretch of the radial distance, see Eq. [3]
- η dimensionless axial distance defined as $(\omega/\nu)^{1/2}z$
- θ circumferential coordinate, rad
- ν kinematic viscosity of the electrolyte, cm²/sec
- Φ dimensionless concentration defined as C/C_∞
- Φ_M concentration profile in the main region, dimensionless
- Φ_W concentration profile in the wake region, dimensionless
- ω angular velocity of the rotating disk, rad/sec

A Rotating Ring-Hemispherical Electrode for Electroanalytical Applications

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A study has been made of the combination of a rotating hemispherical electrode with a ring electrode of a larger radius for use in investigations of reaction intermediates. Cyclic voltammetry in an acid copper solution was used to test the feasibility of the combination, and a ferricyanide/ferrocyanide redox reaction was used to measure the collection efficiency at the ring electrode. The collection efficiency was found to be independent of the rotational speed in laminar flow, and its value was comparable to that obtained from the rotating ring-disk electrode theory. The results indicate that the ring-disk theory can be used as a rough approximation for the ring-hemisphere electrode if the inner radius of the ring electrode is a minimum of 1.08 times the radius of the hemispherical electrode. Easy replacement of the central hemispherical electrode is a big advantage of this new geometry. This offers electrochemists an alternative choice where the use of a ring-disk electrode would fail to give a meaningful result and where frequent replacement of the disk electrode is needed.

In electrochemistry a powerful technique that permits the quantitative study of reaction intermediates is the rotating ring-disk electrode (RRDE) (1). The RRDE consists of a circular disk electrode and a ring electrode of a larger diameter mounted flush and concentrically in the surface of an insulated rotating disk. An intermediate that is produced by an electrochemical reaction occurring at the central disk electrode is transported by a radial flux to the ring, and the ring electrode then serves as an indicator to analyze the electrochemical properties of such an intermediate. From these properties, the nature of the intermediate and the kinetics of the intermediate reaction can be identified. Experimentally, the RRDE requires a perfectly flat surface. This requirement has impeded the application of the RRDE to high-rate dissolution reactions such as electrochemical machining, electrochemical polishing, high-rate corrosion, etc., because the disk electrode made of the metal being dissolved would recede into the support surface and upset the fluid flow characteristics. This would result in a greater loss of the intermediate being transferred to the ring electrode.

Recently, the electrochemical application of a rotating hemispherical electrode was discussed in a number of papers (2-5). A theory of convective diffusion was formulated for the rate of ionic transfer at the spherical surface, and an experimental setup for the use of such an electrode was described. There are several advantages in the use of this geometry:

1. The basic theory of the rotating sphere differs from that of the rotating disk by only a numerical factor in the proportional constant; thus, the method of application for electrochemical studies will be the same as that for the rotating disk electrode.

2. The hemispherical electrode protrudes from the surface of the inert support. The electrode can be replaced easily; only one support rod is needed. On the other hand, the fabrication of a replaceable rotating disk electrode is difficult because the disk electrode has to be flush with the support surface.

3. The hemispherical electrode merely reduces in size during the dissolution reaction. This change will not alter the fluid flow characteristics within a reasonable duration of experimental runs.[1]

4. The primary current distribution is uniform across the surface of the hemispherical electrode.

Considering these advantages, it was thought that by replacing the central disk electrode on the RRDE with a hemispherical electrode (HSE) as shown in Fig. 1, one might offer electrochemists an alternative method for the study of reaction intermediates, especially for dissolution reactions. We call the electrode combination of this kind the rotating ring-hemispherical electrode (RRHSE). The fluid flow around the HSE, observed in a previous study (4), involves an inflow of the electrolyte toward the spherical surface along the axis of rotation, and a swirling motion of the electrolyte along the electrode surface toward the equator. In the vicinity of the equator, the flow bends smoothly 90° toward the radial direction, and then moves along the support surface to the bulk of the electrolyte. No vortex was observed at the equator when the flow was laminar (for Reynolds number less than 10^4). Thus, any intermediate generated at the hemispherical electrode is carried by the electrolyte flow to the ring electrode, where the nature of the intermediate can be analyzed.

The purpose of this study was to investigate the feasibility of the RRHSE for electroanalytical applications. Cyclic voltammetry in acid copper solutions was used to demonstrate the ability of the RRHSE to detect the reaction intermediate, and a ferricyanide/ferrocyanide redox system was used to measure the collection efficiency at the ring electrode. This paper describes the results of these investigations.

* Electrochemical Society Active Member.
Key words: ring-disk electrode, cuprous/cupric reactions.

[1] It has been found that slight deviation from sphericity does not effect the flow pattern appreciably, however, a severely etched surface may produce localized disturbances and cause an early transition to turbulent flow. Prolonged experimental runs should be avoided for dissolution reactions.

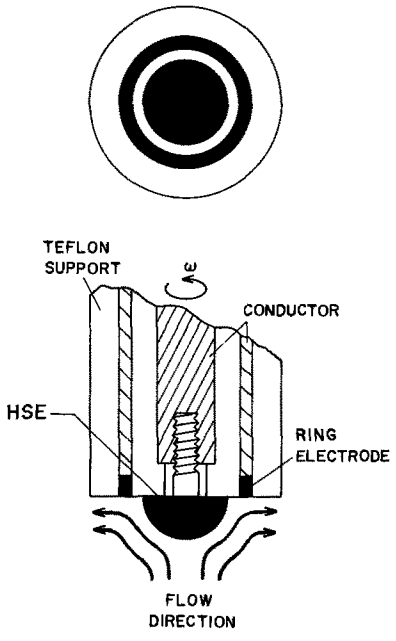

Fig. 1. Rotating ring-hemispherical electrode

Experimental

Rotating ring-hemispherical electrode.—The RRHSE used was modified from a Pine Instrument DT ring electrode. It consisted of a Teflon support rod, a platinum ring electrode, and a replaceable gold-plated hemispherical head electrode. Figure 1 illustrates the construction details.

The Teflon support was a 1.9 cm diameter rod. A platinum ring electrode, 0.798 cm ID × 1.003 cm OD, was embedded in the end of the support. At the center of this support end, there was a 0.396-cm hole which reached to a stainless steel shaft inside. The steel shaft had a 6-32 female thread to accommodate the hemispherical electrode. The other end of the Teflon support rod was attached to a stainless steel collet which was machined to fit into a high speed rotator.

A 6-32 brass screw having a hemispherically shaped head was used as the replaceable hemispherical electrode. The surface of the hemispherical head was electroplated with a smooth layer of gold. To assemble the RRHSE, a thin film of silicone grease was applied to the backside of the hemispherical head; the hemispherical electrode was then screwed into the steel shaft until the under surface of the screw head mated tightly with the Teflon support surface. Six such hemispherical electrodes were constructed, with the diameter of the hemispherical head varying from 0.634 to 0.788 cm.

Cell arrangement and electrical measurements.—An acrylic plastic vessel, 16.5 cm ID × 15 cm high, was used as the cell container. It was equipped with several baffles on the sidewall and two platinum counterelectrodes on the cell bottom. Each of the counterelectrodes had an approximate surface area of 2.5 cm^2 exposed to the electrolyte. The container also had two reference electrode compartments which had capillary tubes extending to the downstream side of the RRHSE. Two saturated calomel electrodes (SCE) placed in the compartments were used as the reference electrodes: one for the HSE, and the other for the ring electrode.

The potential of the hemispherical electrode was controlled by a Magna 4700M potentiostat. A Magna 4510 linear scan unit was used in conjunction with the potentiostat in order to sweep the HSE potentials. The ring potential was controlled by a battery-powered potentiostat designed and constructed at the General Motors Research Laboratories. This potentiostat was floating with respect to ground; thus together with the second reference and counterelectrodes, it offered an electric circuit independent of the HSE. The electric currents collected from the hemispherical and the ring electrodes were measured by passing the currents through two standard resistors; the voltage drops across the resistors were fed to the vertical channels of a Honeywell 540 XYY' recorder. The horizontal channel of the recorder was used to indicate the HSE potentials.

Rotation of the RRHSE was provided by a Pine Instrument PIR high-speed rotator, which had a speed range of 400 to 10,000 rpm. Electrical connections to the hemispherical and the ring electrodes were made by two silver/carbon slip-ring contacts mounted on the rotator. For each run, the surface of the ring electrode was lightly polished on a 600 grit Carbimet wet grinding paper; the hemispherical electrode was then fastened to the Teflon support. The assembled RRHSE was cleaned with ethanol and was cathodically treated at −2V in a 2M NaOH solution for 2 min followed by a rinse in running distilled water. The clean RRHSE was transferred immediately to the cell filled with the test electrolyte and was installed on the rotator. To provide approximately infinite surroundings for the RRHSE, the spacing between the RRHSE and the counterelectrodes was kept at 4 cm throughout the experiments. All the runs were performed at a temperature of 24°±1°C.

Feasibility test.—To test the ability of the RRHSE to detect reaction intermediates, a triangular voltammetric sweep was carried out for the Cu^{2+}/Cu^{0} reactions. The electrolytes used for the tests were: (*i*) 0.01M $CuCl_2$ plus 0.5M HCl; and (*ii*) 0.01M $CuSO_4$ plus 0.5M H_2SO_4. These solutions were saturated with nitrogen before and during the experimental runs. The potential of the Au-HSE was scanned between 0.4 to −0.4V *vs.* SCE in the chloride solution, and between 0.2 to −0.2V *vs.* SCE in the sulfate solution. To detect the formation of Cu^{+} ion during the scan, the potential of the Pt-ring electrode was maintained at 0.4V *vs.* SCE for the chloride system, and at 0.58V *vs.* SCE for the sulfate system. At these potentials cuprous ion is oxidized to cupric ion.

Measurement of collection efficiency.—Limiting current measurements for the reduction of $Fe(CN)_6^{3-}$ to $Fe(CN)_6^{4-}$ at the HSE and the oxidation of $Fe(CN)_6^{4-}$ to $Fe(CN)_6^{3-}$ at the ring electrode were used to determine the collection efficiency. A nitrogen-saturated solution containing 0.01-0.05M $K_3Fe(CN)_6$ and 0.5M NaOH was used for the measurements. The potentials of the HSE and the ring electrode were maintained at −0.1 and 0.4V *vs.* SCE, respectively, and the collection efficiency was calculated as the ratio of the ring current (minus any residual current when the HSE was at open circuit) to the HSE current.

Results and Discussion

Effect of the hemispherical head on the rate of mass transfer to the ring electrode.—Before the RRHSE experiments, a run was made to investigate the behavior of the ring electrode in the presence of an HSE on the upstream side of the electrolyte flow. The reduction of ferricyanide ion in a solution containing 0.01M $K_3Fe(CN)_6$, 0.01M $K_4Fe(CN)_6$, and 0.5M NaOH was used for the study. Limiting currents were measured on the ring while the HSE was at open circuit. The results are given in Fig. 2, where the ratio of the ring current in the presence of the HSE to the ring current in the absence of the HSE (same size ring electrode) is plotted against rotational speeds for various sizes of the hemispherical electrodes. The experimental data are represented by the symbols, ○, □, △, etc., and the average of these values is shown as the solid line. The dashed lines are the reproducibility of the measurements. It is seen that within the experimental error of ±5%, the limiting current on the ring electrode is not affected by the presence of the central hemispherical head; the average of the ratio data shown in the figure is 1.005. This is an interesting discovery, for despite a convex geometry presented by the HSE in the upstream, the ring behaves as though it were mounted on the surface of a flat rotating disk. The

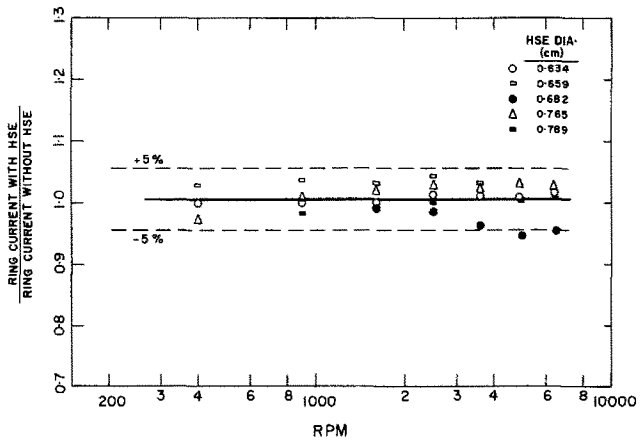

Fig. 2. Effect of HSE on the limiting current on the ring electrode. The ring electrode used was 0.798 cm ID x 1.003 cm OD in size, and the currents were measured while the central hemispherical electrodes were at open circuit.

significance of this point will be discussed in a later section.

Results of feasibility tests.—The ability of the RRHSE to detect reaction intermediates is shown in Fig. 3, where a series of cathodic sweep curves are given for a 0.765 cm diameter Au-HSE in acidic cupric chloride solution. Two waves are obtained for the HSE current during the scans (Fig. 3A). The first wave corresponds to the reduction of Cu^{2+} to Cu^{+}. The second wave, which begins at a potential of −0.2V *vs.* SCE, corresponds to the reduction of Cu^{2+} to metallic copper at the HSE. Figure 3b is a plot of ring current against the HSE potential; the ring potential was maintained at 0.4V *vs.* SCE to oxidize any Cu^{+} generated at the HSE and carried by the electrolyte flow to the ring surface. It is seen that the ring current increases with the HSE potential as the first wave reaction occurs and then levels off when the reaction reaches the limiting current potentials. The level of the ring current increases correspondingly with the level of the HSE current as the speed of rotation increases. When the HSE reaches the potential where the second wave reaction starts to occur, the ring current drops immediately, and becomes zero at a potential corresponding to the limiting current for the reduction of cupric ion to copper at the HSE. The collection efficiency of cuprous ion, calculated by dividing the magnitude of the ring current plateau by the magnitude of the first HSE current plateau, is found to be 33%, independent of the speed of rotation.

Figure 4 shows the results of a triangular sweep in the cupric chloride solution for the same RRHSE used above. The rate of scan was 0.8 V/min, and the rotational speed of the electrode was 1600 rpm. The result for the cathodic scan is seen to be the same as in Fig. 3 and will not be discussed further. For the anodic sweep, a current peak is obtained for both the ring and the hemispherical electrodes. These peaks are caused by the dissolution of deposited copper on the HSE and by the pickup of a dissolution product in the form of Cu^{+} at the ring electrode. The ratio of the height of the ring peak to that of the HSE peak is 32%, in close agreement with the result of the cathodic sweeps shown in Fig. 3. This indicates that within the potential range scanned, cuprous ion is the primary product formed during the dissolution of copper in HCl.

That the ring-hemispherical electrode is capable of differentiating the Cu^{2+}/Cu^{0} reaction in H_2SO_4 from that in HCl is shown in Fig. 5, where the triangular sweep curves from the same RRHSE are plotted for the acid cupric sulfate solution. Figure 5 shows that only one reaction wave occurs at the HSE during the cathodic scan and no detection of Cu^{+} is made at the ring electrode. For the anodic scan, a current peak is observed for the ring electrode as well as for the HSE. However, the ring current is very small compared to the HSE current (note the μA scale of the ring current in Fig. 5B). This implies that Cu^{+} ion is not the major dissolution product, but rather is a soluble species resulting from a secondary reaction at the HSE. By setting the ring electrode at −0.2V *vs.* SCE, the potential at which Cu^{2+} ion is reduced to Cu^{0}, it was found that the major product resulting from the dissolution of copper in H_2SO_4 is Cu^{2+}. Thus, the generation of Cu^{+} may be the result of a secondary chemical reaction between the copper deposit on the HSE and

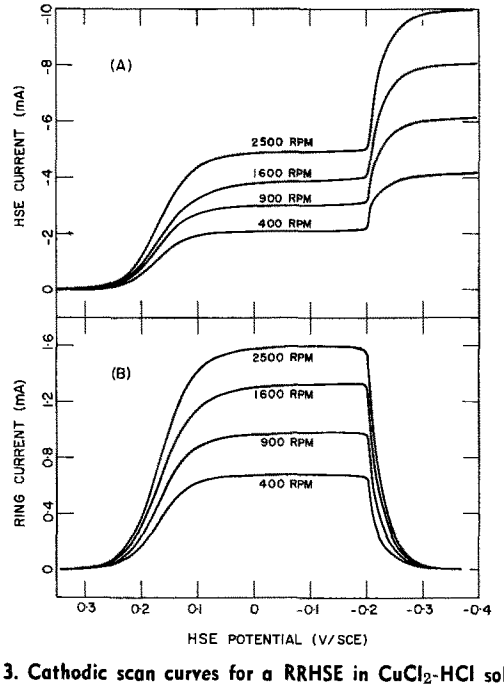

Fig. 3. Cathodic scan curves for a RRHSE in $CuCl_2$-HCl solution. The ring potential was maintained at 0.4V *vs.* SCE while the HSE potential was scanned at a rate of 0.27 V/min.

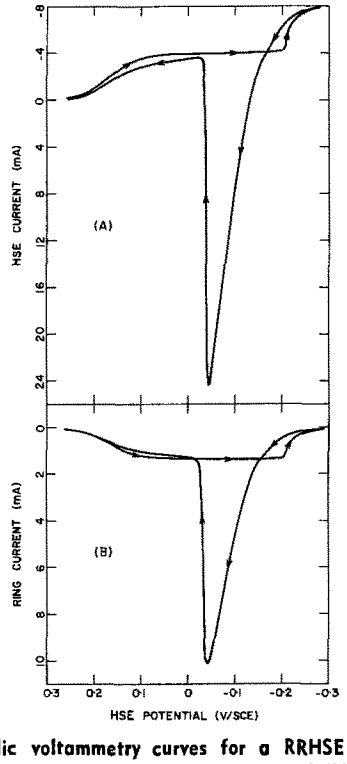

Fig. 4. Cyclic voltammetry curves for a RRHSE in $CuCl_2$-HCl solution. The ring potential was maintained at 0.4V *vs.* SCE, while the HSE potential was scanned between 0.4 and −0.4V *vs.* SCE at a scan rate of 0.8 V/min. Rotational speed was 1600 rpm.

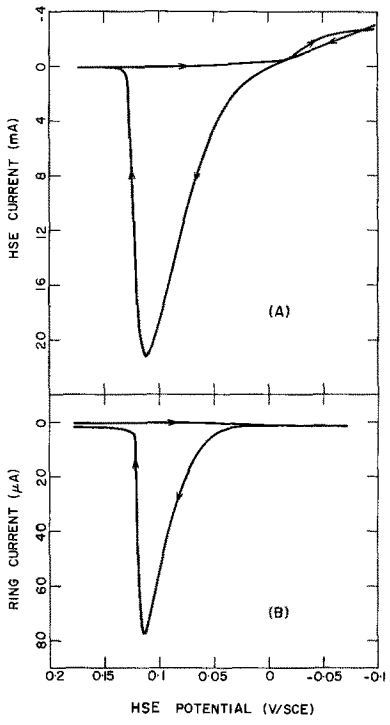

Fig. 5. Cyclic voltammetry curves of a RRHSE in $CuSO_4$-H_2SO_4 solution. The size of the RRHSE used was the same as that used for data in Fig. 3 and 4. The ring potential was maintained at 0.58V vs. SCE, while the HSE potential was scanned between 0.2 and —0.2V vs. SCE at a scan rate of 0.4 V/min. Rotational speed was 1600 rpm.

cupric ions in the electrolyte. These results agree with a ring-disk experiment reported earlier (6).

Collection efficiency.—The results of the collection efficiency measurements are presented in Fig. 6 as a function of the spacing between the equator of the HSE and the inner edge of the ring electrode. The spacing between electrodes was varied by using different sizes of hemispherical electrodes, and the measurements were made for two different ferricyanide concentrations. It was found that the collection efficiency was independent of the speed of rotation. Each data point represents an average of the measurements over a speed range of 400-4900 rpm, and the scattering of the data is given as the I-bars. This speed range covered a span of Reynolds numbers from 1000 to 13,000 for the ring electrode, and 400 to 8000 for the HSE, which was well within the laminar flow region. The thick line in the figure represents a smooth curve

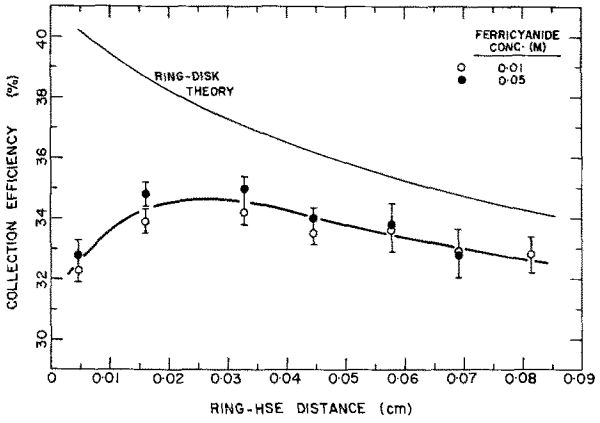

Fig. 6. Results of collection efficiency measurements. A ring electrode of 0.798 cm ID x 1.003 cm OD was used, and the ring-HSE spacing was varied by using different sizes of hemispherical electrodes. The measurements were made in a ferricyanide/ferrocyanide redox system over a speed range of 400-4900 rpm.

drawn between the data points. For comparison, the collection efficiency calculated from the ring-disk theory (7), using the projected area of the HSE, is plotted as the thin curve.

It is seen that the change in the ferricyanide concentration had no significant effect on the measurement. The measured collection efficiency increases slowly with decreasing spacing between the HSE and the ring electrode. After reaching a maximum, it then decreases with a further decrease in spacing. In the region to the right of the maximum, *i.e.*, at a ring-HSE spacing greater than 0.03 cm, the ring-disk theory gives a collection efficiency only 2-3% higher than that of the RRHSE. However, for ring-HSE spacings less than 0.03 cm, the theory predicts a continuous increase in the collection efficiency with decreasing electrode separation. This difference in behavior between the ring-disk electrode and the RRHSE can probably be attributed to an uneven distribution of the local reaction rate near the equator of the HSE rather than to the ring electrode, for the limiting current at the ring is not affected by the presence of an HSE at open circuit (Fig. 2).

According to the diffusion theory of the rotating sphere (5), the local limiting current density is highest at the pole and decreases meridionally toward the equator. Thus, the rate of the diffusion-controlled reaction would be expected to reach a minimum at the equator, where the least amount of the reaction intermediates (or products) would be generated. Since the steamlines of the electrolyte flow bend smoothly in the neighborhood of the equator toward the support surface (Fig. 1), there would be a "corner space," within a short distance from the equator, where the concentration of the reaction intermediate would be smaller than that in the main stream. If the ring electrode, or a portion of the ring electrode, is located within this corner space, it is expected that a lower collection efficiency would be obtained as is shown to the left side of the maximum point in Fig. 6. The transport details in this corner space are not clear because no mathematical theory pertaining to such hydrodynamic flow is available at the present time. However, if one regards the region to the left of the maximum in Fig. 6 as the corner space, it can be calculated that the corner space is located within 1.08 radii of the hemispherical electrode. Thus, to achieve the best electrode combination for the RRHSE, it is recommended that the inner radius of the ring electrode be at least 1.08 times greater than the radius of the HSE. Under these conditions, the ring-disk theory gives a good approximation of the collection efficiency at the RRHSE.

Conclusions

The results of the feasibility tests have clearly demonstrated that the rotating ring-hemispherical electrode can be used for electrochemical studies. Easy replacement of the central hemispherical electrode is a big advantage of the RRHSE. In laminar flow, the collection efficiency is found to be independent of the rotational speed, and its value is comparable to that obtained from the ring-disk electrode theory. The RRHSE offers an alternative choice where the use of the ring-disk electrode would fail to give a meaningful result and where frequent replacements of the disk electrode would be needed. However, in view of the lack of a mathematical theory, it is recommended that each RRHSE should be calibrated beforehand with a known electrochemical reaction. The ring-disk theory can be used as an approximation for the estimate of the collection efficiency if the inner radius of the ring electrode is at least 1.08 times greater than the radius of the hemispherical electrode.

Evaluation of Porous Electrodes Through Cell Power Maximum Measurements

S. Szpak[1] and G. E. McWilliams[1]

Chemistry Laboratory, Mare Island Naval Shipyard, Vallejo, California 94592

ABSTRACT

A method for the analysis of porous electrodes, based on cell power maximum *vs.* time measurements, has been developed. The electrode effectiveness factor was determined without resorting to tedious chemical procedures. Good agreement with published analyses was obtained for the HgO(C)/30% KOH system.

Discharge of a primary battery is an energy-producing process accompanied by structural changes of the electrodes. The fundamental difference in the analytical approach to primary batteries and to some other types of energy conversion devices, *e.g.*, fuel cells, is in the manner in which reactants are supplied. In the latter case, reactants are continuously admitted from an external source; in the former case, they are incorporated into the electrode structure, usually in the form of sparingly soluble substances. Because of this difference, a fuel cell can operate indefinitely and a true steady state can be achieved. In contrast to this, in the course of battery operation the supply of reactant diminishes and, when all active material is used up, the battery ceases to function. Thus, a true steady state cannot be realized.

In what follows, we are concerned with monitoring changes that occur on discharge via measurements of the power maximum. It will be shown that, in certain cases, measurements of the power maximum provide information on the electrode performance and, in those cases, they can be used to determine the rate of penetration of the reaction zone into the electrode structure.

Relevant Concepts and Equations

For convenience, we begin the analysis by considering an idealized system: a galvanic cell consisting of two smooth electrodes, spaced d cm apart. Electrode reactions are well defined but otherwise quite arbitrary. The open-circuit potential is assumed to be equivalent to the thermodynamic potential. The conductivity of the solution and the cell geometry remain invariant during cell operation. Furthermore, we adapt the following definitions and properties: (*i*) cathode is positive and anode is negative, (*ii*) reaction is spontaneous on discharge, (*iii*) potential drop at the electrode is modified by the passage of cell-generated current, and (*iv*) the sign of the cell-generated current is such that the quantity $i \cdot \eta$ is always positive. The thermodynamic potential, $V_r = V_{r,c} - V_{r,a}$, plays a dominant role. It determines the reaction's driving force, $V_r - V_i(i)$, which in turn, is modified by the flow of cell-generated current, i. For this reason, the electrochemical cell discussed here—a primary battery—cannot be regarded in terms of a single electrode concept, unless we clearly define properties of the other electrode.

When a variable external load, R_e, is engaged, current i begins to flow and a potential difference at the battery terminals, $V_e(i)$, is established. In particular

$$V_e(i) = V_r - V_i(i) - iR_i \qquad [1]$$

where $V_i(i) = \eta_c(i) + \eta_a(i)$ is the sum of overpotentials developed at the cathode and anode, respectively. R_i is the cell internal resistance, so that iR_i is the ohmic drop in the electrolyte. Subscripts i and e denote the internal and external part of the complete circuit.

One of the properties of a galvanic cell that we wish to examine is the cell power, P. Evidently, it is zero at $i = 0$, *i.e.*, at the open-circuit potential and when $V_e(i) = 0$. Since at $0 < i < i_{lim}$, alternatively at $V_r > V_i(i) > 0$, P is positive, it follows that there exists at least one value of current and/or potential where P is maximum.

Starting with Eq. [1], multiplying it by i differentiating it with respect to i, we obtain the following

$$P = i\,[V_r - V_i(i)] - i^2R_i \qquad [2]$$

and

$$\frac{dP}{di} = V_r - V_i(i) - i\frac{dV_i(i)}{di} - 2iR_i \qquad [3]$$

The quantity, $dV_i(i)/di$, appearing in Eq. [3], may be identified as the differential resistance of the electrochemical cell, being in many cases approximately constant over roughly 60% of the cell currents. The deviation from constancy is evident at the extreme ends of cell operation. At low currents it is due to activation control while at the other extreme it exhibits the effects of limiting current.

The condition of power maximum, P_m, together with the corresponding i_m, may be calculated by taking $dP/di = 0$. Thus

$$P_m = \frac{[V_r - V_i(i_m)]^2}{2R_i + \dfrac{dV_i(i_m)}{di}}\left[1 - \frac{R_i}{2R_i + \dfrac{dV_i(i_m)}{di}}\right] \qquad [4]$$

and

$$i_m = \frac{V_r - V_i(i_m)}{2R_i + \dfrac{dV_i(i_m)}{di}} \qquad [5]$$

For the operating region exhibiting constant differential resistance, $dV_i(i)/di = kR_i$ (with $k \geq 0$), Eq. [4] is somewhat simplified and takes the form

$$P_m = \frac{(k+1)\,[V_r - V_i(i_m)]^2}{(k+2)^2\,R_i} \qquad [6]$$

[1] Present address: Electronic Materials Sciences Division, Code 2600, Naval Electronics Laboratory Center, San Diego, California 92152.

Key words: primary battery, porous electrode, electrode effectiveness factor, mercuric oxide electrode, cell power maximum.

The shape of the P-i curves and thus, the position of P_m, depends on electrode kinetics and the cell geometry. The P-i curves for various kinetic and geometric parameters were examined by Bockris and Srinivasan (1). They found that the maximum power is close to the limiting current, except in cases where the internal resistance is high or the kinetics even for one electrode is slow. To illustrate this, computer generated $dV(i)/di$ *vs.* i and P *vs.* i curves for a selected set of parameters are shown in Fig. 1 and 2, respectively. Evidently, the $dV(i)/di$ *vs.* i curves are constant over the range of currents and/or potentials of interest, thus Eq. [6] implies parabolic representation in the vicinity of power maximum.

The displacement of power maximum as a function of internal cell resistance is clearly displayed in Fig. 2. Similarly, a shift is indicated in the potential or current at which P_m occurs. These two displacements are characteristic of battery performance and depend on internal cell resistance. If the battery construction involves smooth electrodes, then according to Eq. [6], the P_m^{-1} *vs.* R_i plot is a straight line with a slope $(k + 2)^2/(V_r - V_i)(i_m)^2(k + 1)$. In the case of a battery employing even one porous electrode, a more complex dependence is expected.

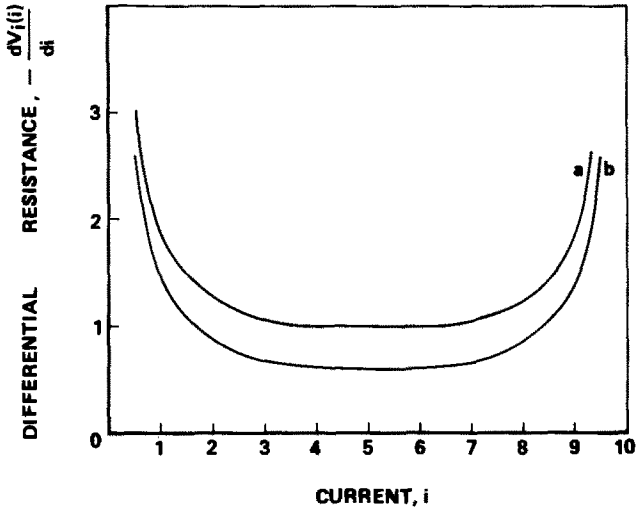

Fig. 1. Differential cell resistance as function of R_i. Data: $i_{o,c} = 10^{-3}$ Acm^{-2}; $\alpha_c = \frac{1}{2}$, $i_{o,a} \geq 1$ Acm^{-2}, $\alpha_a = \infty$. Curve a, $R_i = 0.5$ ohm and curve b, $R_i = 0.1$ ohm.

P-i Curves for Cell with Porous Electrode

Basic cell components of a battery with a porous electrode are shown in Fig. 3. Cathode (A) represents a porous electrode consisting of a conductive matrix with a uniformly distributed active material. For simplicity, anode (B) is assumed to be nonpolarizable.

It is known from the theory of porous electrodes that there exists a reaction zone, *i.e.*, the electrochemical process takes place within a relatively narrow part of the electrode volume. In the case of devices operating with a continuous supply of reactants, *e.g.*, fuel cells, this zone is immobilized. In the case of batteries, the reaction zone travels across the electrode volume. At the beginning of the discharge, it is usually localized at the electrode/solution interface. At the end of the discharge, it is in the vicinity of the "back-up" plate. Such behavior is expected in most batteries, with the exception of cases where the current density distribution is anomalous (2).

Upon initiation of battery discharge, *e.g.*, at constant current density, a reaction profile (current-density profile) is established throughout the electrode volume, having highest density at the electrode/solution interface, *i.e.*, at $x_o(t) = 0$. In the course of battery discharge, active material is used up, forcing the $x_o(t)$ plane to proceed inwards and, in effect, increasing the ohmic part of the cell internal resistance by a factor proportional to $x_o(t)$. Because of the porous structure, the increases may be substantial and therefore experimentally detectable.

In deriving the P-i curves for a cell employing porous electrodes and, for example, operating under galvanostatic conditions, it is necessary to compute the $V_i(i)$ measured with respect to the reference point located at the electrode/solution interface when the reaction zone has penetrated to a new position, $x_o(t)$. This reference point is convenient, since $V(i)$ can be decomposed into its ohmic part and a component due

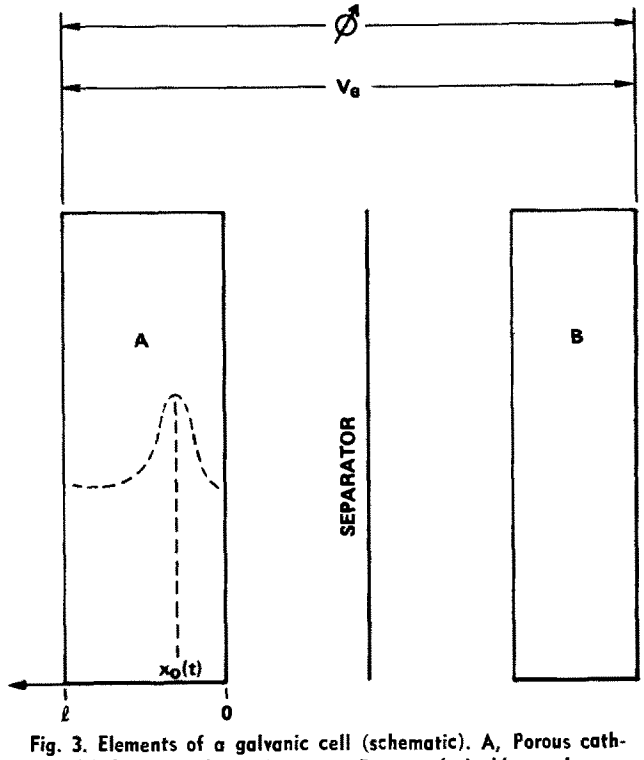

Fig. 3. Elements of a galvanic cell (schematic). A, Porous cathode; $x_o(t)$, location of reaction zone; B, nonpolarizable anode.

to the porous electrode behavior of a length $[l - x_o(t)]$ discharging under specified current.

Following Winsel (3), we write for the galvanostatic case

$$V_i(i) = \frac{\rho I}{a^2\pi} x_o(t) + \frac{\rho I\lambda}{a^2\pi} \coth [(l - x_o(t))/\lambda] \quad [7]$$

where ρ and a are solution resistivity and pore diameter, respectively. I is the discharge current (per pore), and λ is a constant depending upon the electrochemical system and electrode construction. Evidently, both the ohmic part, $[\rho I/a^2\pi]\ x_o(t)$, and the potential $[\rho I\lambda/a^2\pi]$ coth $[(l - x_o(t))/\lambda]$, which operates at the electrode/solution interface, when the latter has shifted to a new position, are time dependent. This clearly indicates and also defines the transient behavior of a battery when it operates under constant current output. Substitution of Eq. [7] into Eq. [2] yields

$$P = i\,[V_r - \rho i\lambda \coth\,(l - x_o(t))/\lambda] - i^2[R_i + \rho x_o(t)] \quad [8]$$

(The factor $a^2\pi$ has been removed, because the pore current I has been replaced by current density i).

Equation [8] is of little value in this form, since $x_o(t)$ is experimentally not accessible without destructive examination of the electrode. More effective use of Eq. [8] can be made, if the position of the reaction zone is related to the active material available, alternatively, to the time needed for complete cell discharge, $t_m = Q_o/i$ (Q_o is the total charge available). Again following Winsel (3), this relationship is

$$\frac{x_o(t)}{l} + \frac{\lambda}{l} \tan\left[\left(1 - \frac{x_o(t)}{l}\right)\frac{l}{\lambda}\right] = t/t_m \quad [9]$$

Equation [9] was derived subject to following restrictions: (*i*) linear potential/current dependence within the reaction zone, *i.e.*, for $x_o(t) \leq x \leq l$, and (*ii*) absence of faradaic current outside the reaction zone, *i.e.*, for $0 \leq x \leq x_o(t)$. The rate of penetration of the reaction zone was determined by differentiation of an expression formed by equating the time-integrated local faradaic current with the amount of active material stored on the pore wall. The position of the $x_o(t)$-plane was obtained upon integration of this expression and upon setting the integration constant equal to the time necessary for the complete discharge of the active material located at $x = 0$. Graphical solution of Eq. [9] in the form of a plot of $x_o(t)/l$ *vs.* t/t_m [cf. Ref. (3), Fig. 7], was used in subsequent analysis and computations.

Experimental

The experimental arrangement employed in this investigation is shown in the form of a block diagram in Fig. 4. The power *vs.* cell voltage was continuously plotted on the XY recorder (Hewlett-Packard, Model 7001 A) with the cell voltage connected to the X-axis input. The battery under test was driven by a linear current sweep (0.7 $Asec^{-1}$) supplied by a power source (Kepco, Model BOP-36-5M) controlled by a function generator (Exact, Model G1103 with A 1202 amplifier). Cell power was computed using Philbrick multiplier (Model 4430) with the output fed into the Y-axis input.

Examples of experimental *P-i* curves for the HgO(C)-Zn battery at various stages of discharge are shown in Fig. 5. Even a cursory examination reveals similarities to the calculated curves of Fig. 2, as evidenced by the decline in power maximum with time and a shift in potential in the direction predicted by the elementary treatment (cf., Eq. [4] and [5]). In particular, curve a represents initial behavior, curves b and c after 5 and 10 hr of discharge at 60 mA, respectively.

A plot of P_m^{-1} *vs.* t/t_m for a series of type BA-1516 U batteries is shown in Fig. 6. This plot consists of two regions. The first region, AB, terminated at $t/t_m = 0.3$,

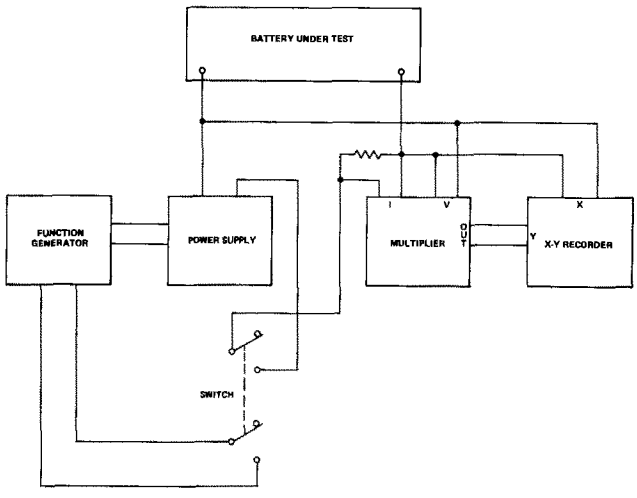

Fig. 4. Block diagram for measurements of battery power maximum.

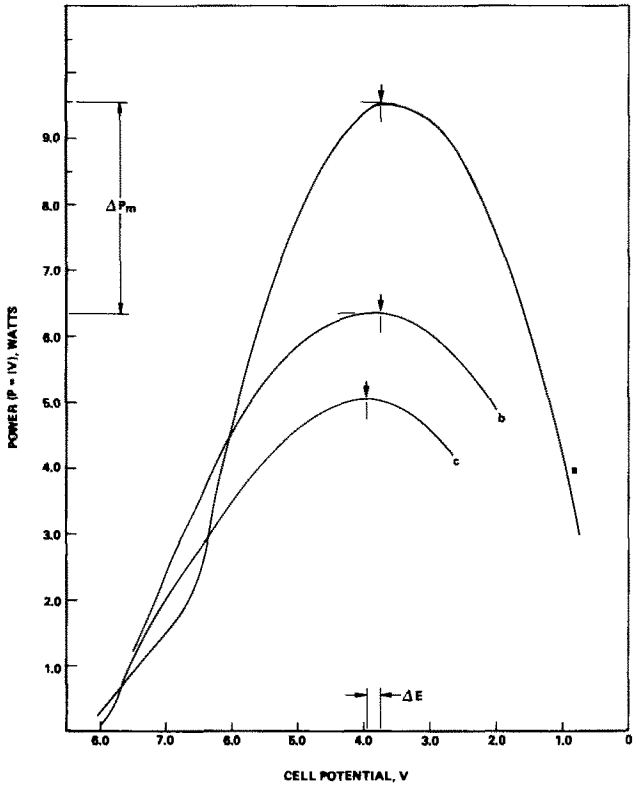

Fig. 5. Power maximum *vs.* cell potential curves. Data: HgO(C)-30% KOH-Zn, battery type AB 1516 U. Discharge current, — 60 mA. Curves: a, new battery; b, after 5 hr of discharge; c, after 10 hr of discharge.

roughly 10 hr after commencement of discharge at 60 mA. The second, less steep segment, BC, persisted until total discharge occurred. When the reciprocal of the power maximum was plotted against the discharge time, each time, 16 hr after interruption of battery discharge, the lower plot (curve b) was obtained. This new plot probably reflects the well-known fact of "recovery" characteristic of mercuric oxide batteries.

Before attempting any interpretation of presented results, we will consider the construction of the type BA-1516 U battery in some detail. This battery consists of 6 HgO(C)-30% KOH-Zn(Hg) cells. Electrodes are flat disks, 3.5 cm in diameter. The cathode is a mixture of HgO (14g) and graphite in the form of a pellet, 0.25 cm thick; the anode is constructed from amalgamated zinc ribbon, weighing 3.5g and wound to

form a 0.62 cm thick electrode. A separator, 0.04 cm thick, is used. All dimensions and weights are approximate.

Discussion

For comparison, calculated P_m^{-1} *vs.* t/t_m curves are shown also in Fig. 6. They were drawn for the effectiveness factor, $l/\lambda = 10$, 3 and 2; curves c, d, and e, respectively, employing Winsel's (3) model. Qualitatively good agreement between calculated and experimental curves is displayed for $t/t_m > 0.3$. A less satisfactory situation prevails for $t/t_m < 0.3$.

In order to resolve this difficulty, consider Eq. [8] which, as $x_o(t) \to 0$ and for $l/\lambda > 3$, yields

$$\lim_{x_o(t) \to 0} P_m = i_m [V_r - \rho i_m \lambda - i_m R_i] \qquad [10]$$

Equation [10] applies during the initial period of cell discharge, specifically before total depletion of reactant at $x_o(t) = 0$ has occurred. Because of the time required for a complete depletion of reactant at the electrode/solution interface, the initial slope of the P_m^{-1} *vs.* t/t_m curve should be zero (segment A'B', Fig. 6). This is just the opposite of what has been observed. Evidently, the initial behavior must be attributed to changes in λ.

Physical significance of λ.—The parameter λ arises in the solution of the second order differential equation with respect to potential, *e.g.*, Ref. (3). For a tubular geometry and negligible matrix resistance, $\lambda = \sqrt{ar/2\rho}$, where r specifies the local current/potential relationship, $i = r^{-1}V$. This quantity has the dimension of length, and it is usually referred to as the reduced pore length or depth of penetration. It is within this distance that most of the reaction occurs. By multiplying and dividing the terms under the square root by $a^2\pi$, we obtain after rearrangement

$$\lambda = \sqrt{\frac{r/\delta S}{\rho/\delta V}}$$

where δS is the surface element associated with the volume element δV, or simply $\lambda = \sqrt{R_{chem}/R_{ohmic}}$. Consequently, λ, may be viewed as a relative measure of the ratio of surface resistance to resistance in the electrolyte. Thus, in principle, it is applicable to any porous electrode provided certain dimensional criteria are met (4, 5). It is noteworthy that λ can be related to certain characteristic group of general interest to electrochemical engineering (5).

Time evolution of λ *for* $t/t_m < 0.3$.—The effect of parameter λ on the power maximum enters through the expression for potential. Thus, the time evolution of λ can be determined from experimentally obtained data points of P_m and $V_{e,m}$ as a function of t/t_m. Such data for the HgO(C) electrode are presented in Fig. 7. For convenience, i_m-data were used.

It is seen that $V_{e,m}$ remains constant up to $t/t_m = 0.18$, approximately. By Eq. [10], the constancy of $V_{e,m}$ requires that $\lambda = \frac{1}{\rho}\left[\frac{V_r - V_{l,m}}{i_m} + R_l\right]$, that is to say, λ must increase, since i_m decreases with time. Evidently, the characteristic number for the HgO(C) electrode increases with the depletion of HgO. At later times, when $t/t_m > 0.3$, it becomes stabilized and the electrode effectiveness, is $3 < l/\lambda < 5$, as inferred from Fig. 6.

Formation of reaction zone.—Upon initiation of electrode discharge and shortly thereafter, the highest local current density is at the electrode/solution interface, estimated to be not less than sixfold its average value (6). Qualitatively, as the active material is used up, the reaction rate (local current density) is less and the reaction zone extends somewhat into the electrode structure. When all active material is exhausted or is reduced to a level which only slowly varies with time, the reaction zone is said to be fully developed. Quantitatively, for λ = const, the reaction zone is fully developed when the time-integrated faradaic current exceeds certain known value, q_o Asec/cm^2. At this time, t_o, all the available active material at the electrode/solution interface is consumed. Other methods of calculations require the assumption of a reaction path (7).

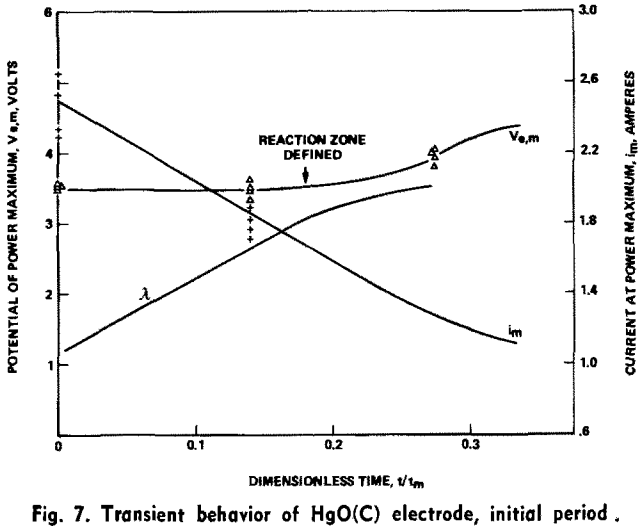

Fig. 7. Transient behavior of HgO(C) electrode, initial period.

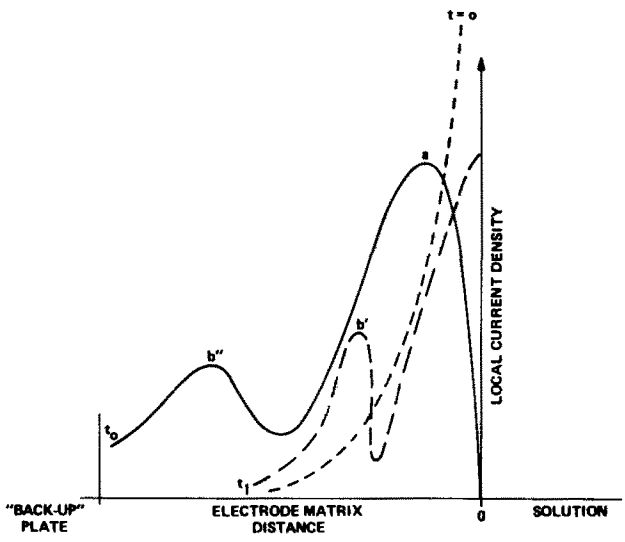

Fig. 8. Formation of reaction zone (schematic).

The evolution of the reaction zone in a practical electrode, such as HgO(C), is more complex. Discharging this kind of electrode at constant current, Euler (6) found a secondary peak in local current-density distribution. The existence of the secondary maximum is consistent with our observation concerning the time evolution of the parameter λ.

The formation of a secondary maximum is shown schematically in Fig. 8. Upon initiation of discharge (at $t = 0$), a reaction profile is established. At some later time, t_1, owing to the increase in relative measure of surface to ohmic resistance, the local current densities at corresponding locations are less than they were at $t = 0$. Condition of constant-charge current forces the reaction to occur in adjacent areas with lower λ. Consequently, secondary maximum is formed.

On the basis of the experimental data reported in Fig. 6 and 7, it can be concluded that the formation of the fully developed reaction zone took place when approximately 18% of the total active material was used up, *i.e.*, when there is a noticeable shift in $V_{e,m}$. More or less regular current density distribution occurred at $t/t_m > 0.3$. The regularity in current distribution, or the constancy of λ, may be attributed to the disappearance of the secondary current maximum. This interpretation is in good agreement with Euler's (6) findings.

Conclusions

Electrode behavior upon discharge can be examined by following the decline in cell power with time of discharge. In principle, any point of the cell power *vs.* voltage curve can be utilized; in practice, however, the position of the power maximum is sought and expressed in terms of the time needed to complete the electrode discharge.

The decline of the cell power is associated with the penetration of the reaction zone into the electrode structure. The rate of penetration depends on the mode of cell discharge. The presented analysis is based on galvanostatic discharge. Analytical expressions for the potentiostatic mode are also known (3).

The electrode effectiveness factor, l/λ, was determined for the HgO(C) electrode in the BA-1516 U battery. The decrease in the effectiveness factor is associated with the initial battery discharge, followed by its stabilization to a value $3 < l/\lambda < 5$ after 30% of all the active material has reacted. The formation of a fully developed reaction zone required approximately 18% of the total time needed for completion of cell discharge.

Technical Notes

Asymmetric Induction by Alkaloids in Electrolytic Reductions

E. Kariv, H. A. Terni, and E. Gileadi*

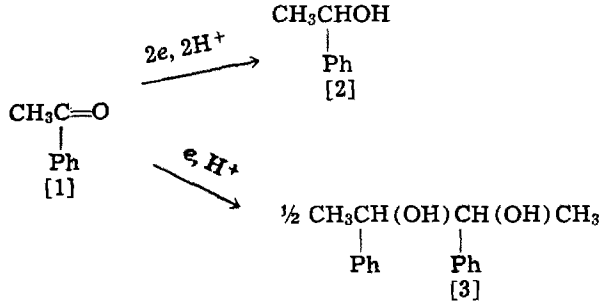
Institute of Chemistry, Tel-Aviv University, Ramat-Aviv, Israel

Chemical and electrochemical reactions, in which an asymmetric center is generated, normally lead to an optically inactive racemic mixture. It was shown recently that optical activity can be induced in the electrolytic reduction of certain compounds if a chiral electrolyte is present in the solution. Appreciable optical yields have been reported by Grimshaw *et al.* (1) in the reduction of coumarin derivatives in the presence of certain alkaloids. These authors related the activity of alkaloids in inducing asymmetry to their activity in catalytic hydrogen evolution, and postulated a similar mechanism. Horner *et al.* (2-5)

* Electrochemical Society Active Member.
Key words: asymmetric, electroreduction, acetophenone.

studied the reduction of various unsaturated functions in the presence of different alkaloids and asymmetric ammonium salts. These authors found no correlation between the ability of a compound to induce optical activity and its function as a catalyst for electrolytic hydrogen evolution. Their interpretation of this phenomenon was that the asymmetric electrolytes create an asymmetric environment in the near vicinity of the electrode, thus inducing optical activity of the product.

In the present note, the effect of several alkaloids on the electroreduction of acetophenone [1] on a mercury pool cathode is reported, with particular reference to the optical activity of 1-phenylethanol [2] formed and the ratio between the yields of the alcohol [2] and the pinacol [3] produced during electrolysis.



A mercury pool (25 cm^2) served as the cathode, with a platinum foil (4 cm^2) anode and a mercury-mercuric sulfate (MSE) reference electrode. The reference electrode compartment was separated from the bulk of the solution and electrolytic contact was made through a Luggin capillary which was brought to within 1 mm of the surface of the cathode. The cathode compartment contained alkaloid in 70 ml aqueous acetate buffer ($pH = 4.8$) and 15 ml methanol. The anode compartment contained 20 ml of the aqueous acetate buffer only. The two compartments were separated by "thirsty glass" (Corning Type 7930 glass). Nitrogen was bubbled through the catholyte during electrolysis. A solution of 2 ml of acetophenone [1] in 25 ml methanol was added to the cathode compartment drop by drop during electrolysis at a rate of *ca.* 4 drops per min. The concentration of the alkaloid in the catholyte at the beginning of electrolysis was $3.2 \times 10^{-2}M$ and reduced gradually with the addition of the acetophenone solution to a final value of $2.3 \times 10^{-2}M$. The amount of acetophenone [1] added corresponds to a final concentration of $0.15M$ if no reaction has taken place. The actual concentration of [1] in solution at any time during the electrolysis was lower than the above value.

Electrolysis was conducted at a potential of −1.90V (MSE). After all the acetophenone was added, electrolysis was continued until the current (which was initially *ca.* 250 mA) dropped to its background value (*ca.* 50 mA) measured in the absence of acetophenone [1]. The average duration of a run was 16 hr. Methanol was removed from the product under reduced pressure at room temperature. The organic fraction was extracted with ether and washed free of alkaloids with a 10% HCl solution. The mixture obtained after evaporation of the solvent was distilled at 52°-56°C (1 mm Hg). The pot residue, a white solid, was found (by comparison with an authentic sample) to be a mixture of the three isomers of pinacol [3]. It caused no optical rotation, indicating that the amounts of the (R),(R)- and (S),(S)-isomers in it were equal. The ratio between the meso-isomer and the racemic mixture of [3] was determined by analysis of the nmr spectrum. The ratio of the yields of the isomers of [3] formed during the reaction was not affected by addition of alkaloids to the catholyte. The distillate consisted of a mixture of (R)- and (S)-1-phenylethanol [2]. The $[\alpha]_D$ of this fraction was measured and the optical yield was calculated.[1] Results are shown in Table I.

Some of the alkaloids tested were electrochemically active and could be reduced at less negative potentials than those required to reduce acetophenone. When this was the case, the solution was pre-electrolyzed at −2.00V (MSE) before addition of acetophenone for about 5 hr, until the current dropped to the background value.

Detailed consideration of Table I reveals several phenomena. It may be seen that the addition of any of the alkaloids tested increased the relative amount of alcohol [2] produced during electrolysis. This is probably due to the fact that the alkaloid is adsorbed on the electrode (6) and in this way inhibits surface recombination of the intermediate radicals leading to pinacol [3], either by reducing the concentration of the radical intermediate or by hindering its lateral motion on the surface. All the alkaloids tested induced preferential formation of one of the enantiomers of the alcohol [2] but the absolute configuration and the yield of the one formed in excess seems to depend on the detailed structure of the alkaloid used. Thus, for example, the effect observed for cinchonine and cinchonidine is substantially smaller than for quinidine and quinine, although these compounds differ only by one methoxy group on the quinoline ring. This observation can also be best explained by the effect of the methoxy group on the adsorbability of the alkaloid. It is also noteworthy that quinidine and quinine (and likewise cinchonine and cinchonidine), which are diastereomers (opposite configurations at C-8 and C-9), induce symmetry in opposite directions. This finding, although not surprising, is reassuring and indicative of the specific interaction which must exist between the (adsorbed) alkaloid molecule and the reactant or

[1] The value of $[\alpha]_D$ for (S)-1-phenylethanol in methanol (4) is −45.5° and for the (R)-isomer its value is +45.5°. The optical yield is defined as

$$\frac{[\alpha]_D \text{ of product}}{[\alpha]_D \text{ of pure enantiomer}} \times 100$$

Table I. Product distribution and optical yield in the reduction of acetophenone[a]

Asymmetric electrolyte	Chemical yield of alcohol [2] (%)	Chemical yield of pinacol [3] (%)	Ratio of alcohol [2] fraction to pinacol [3] fraction	$[\alpha]_D$ of the alcohol [2] fraction	Optical yield (%)
—	14	73	0.19	0.0°	0.0
Quinidine[b]	22	63	0.35	−6.80°	14.9
Quinine[b]	34	39	0.88	+3.11°	6.9
Cinchonine[b]	20	77	0.26	−4.39°	9.7
Cinchonidine[b]	27	48	0.56	+0.97°	2.2
Yohimbine	17	55	0.31	+1.80°	4.0
Reserpine	20	74	0.27	+0.86°	1.9
Sparteine	26	52	0.50	−0.63°	1.4
Eserine[b]	16	76	0.21	−0.62°	1.4

[a] Each of the results in Table I represents the average of four experiments, at least. The spread of results was ±0.15° on $[\alpha]_D$, ±0.5% on optical yield, and ±0.1 on the ratio of yields of alcohol and pinacol.
[b] Pre-electrolysis required.

intermediate(s) formed in the electrochemical reaction sequence.

Reduction of acetophenone was conducted at a potential of −1.90V (MSE), less cathodic than the potential at which catalytic activity on hydrogen evolution of any of the alkaloids tested could be observed in the same solution. Thus, a mechanism in which the critical step is the homogeneous charge transfer, as proposed by Grimshaw *et al.* (1), cannot be operative in the systems studied here. A detailed study of the reduction of acetophenone in the presence of quinidine, which was found to be the most effective in inducing optical activity, under a wide range of experimental conditions, will be published elsewhere (7).

Calculation of Liquid Junction Potentials

E. C. Moreno and R. T. Zahradnik

Physical Chemistry Section, Forsyth Dental Center, Boston, Massachusetts 02115

In chemical and biological systems it is often desirable to assess the junction (or diffusion) potentials originating when two solutions of the same electrolyte are brought into contact. Thus, in studying the permselectivity of membranes, the liquid junction potential constitutes the minimum "membrane potential" when the system does not display any permselectivity. Solutions to the problem are available if ideal behavior is ascribed to the electrolyte (1-3) or if the ionic transference numbers are considered invariant with concentration (4). In most real systems, however, these assumptions are not warranted even if the solutions are in the dilute range; this is particularly true in the case of nonsymmetrical electrolytes. For uni-univalent electrolytes an expression was derived (5) on the assumption that the ion activities of the positive and negative ions are both equal to the mean ion activity. Recently, the calculation of liquid junction potentials has been reported using simulation techniques (6, 7). These techniques may become useful in ascertaining time rises and estimates of individual ionic activity coefficients; they, however, do not provide analytical solutions to the problem nor yield unique values for liquid junction potentials (7). In the present research, we were interested in establishing an analytical expression in closed form for the calculation of the LJP that takes into account the concentration dependence of both the ionic activity coefficient and the transport numbers.

In this communication we derive a generalized expression in closed form for the liquid junction potential ψ_j applicable to nonsymmetrical binary electrolytes. Ionic activity coefficients are defined by an extension of the Debye-Hückel limiting law and use is made of empirical functions of transference numbers on concentrations. It is shown that the calculated junction potentials for various electrolytes are consistent with the over-all emf values of concentration cells reported in the literature up to ionic strengths of about 0.3M.

The flux J_i of the ith ionic species at an absolute temperature T is defined by

$$J_i = -\frac{c_i|u_i|}{|z_i|e}\left(\frac{\partial\bar{\mu}_i}{\partial x}\right)_T \qquad [1]$$

in which c, u, z, and $\bar{\mu}$ are the concentration, the electrical mobility, the charge number, and the electrochemical potential of the subscripted ionic species i; the gradient is taken in the direction x.

Considering the components of $\bar{\mu}_i$, we can write

$$\frac{\partial\bar{\mu}_i}{\partial x} = \frac{\partial\mu_i}{\partial x} + z_i\mathbf{F}\frac{\partial\psi}{\partial x} \qquad [2]$$

in which μ, $\mathbf{F}$, and ψ are the chemical potential, the Faraday, and the electrical potential, respectively. In terms of the chemical activity a_i, μ_i can be defined as $\mu_i = \mu_i^\circ + RT \ln a_i$ (R being the gas constant). Introducing the ionic activity coefficient γ_i, $a_i = c_i\gamma_i$. Therefore, we may write

$$\frac{\partial\mu_i}{\partial x} = RT\left(\frac{1}{\gamma_i}\frac{\partial\gamma_i}{\partial x} + \frac{1}{c_i}\frac{\partial c_i}{\partial x}\right) \qquad [3]$$

The activity coefficient is defined here logarithmically as

$$\ln\gamma_i = -\frac{z_i^2A\sqrt{I}}{1 + B\,\alpha_i\sqrt{I}} \qquad [4]$$

in which I is the ionic strength ($I = (\frac{1}{2})\Sigma_j c_j z_j^2$), A and B are temperature and solvent dependent constants and α_i (often referred to as the distance of closest approach) is a length parameter the value of which depends on the ionic species considered. The coefficient $\partial\gamma_i/\partial x$ is given by

$$\frac{\partial\gamma_i}{\partial x} = \frac{d\gamma_i}{dI}\frac{\partial I}{\partial x} \qquad [5]$$

since γ_i is a function of I only. It is convenient to define a function $\Phi_i(I)$ by

$$\Phi_i(I) = -\frac{A\sqrt{I}}{1 + B\,\alpha_i\sqrt{I}}$$

therefore

$$\frac{d\gamma_i}{dI} = \frac{\gamma_i z_i^2\Phi_i(I)}{2I(1 + B\,\alpha_i\sqrt{I})} \qquad [6]$$

Also, from the definition of I, it follows that

$$\frac{\partial I}{\partial x} = \sum_j \frac{\partial I}{\partial c_j}\frac{\partial c_j}{\partial x}\ (j = 1,2,\ldots\ldots i) \qquad [7]$$

Substitution of Eq. [6], [7], and [5] into Eq. [3] yields

Key words: transference, activity, cell, mobility, electrolyte.

$$\frac{\partial \mu_i}{\partial x} = RT\left[\frac{z_i^2\Phi_i(I)}{2I(1+B\,a_i\sqrt{I})}\sum_j \frac{\partial I}{\partial c_j}\frac{\partial c_j}{\partial x} + \frac{1}{c_i}\frac{\partial c_i}{\partial x}\right] \quad [8]$$

and substitution of Eq. [8] into Eq. [2] followed by substitution of the resulting expression into [1] gives a generalized form for the flux equation

$$J_i = -\frac{c_i|u_i|}{|z_i|e}\left(RT\left[\frac{z_i^2\Phi_i(I)}{2I(1+B\,a_i\sqrt{I})}\sum_j \frac{\partial I}{\partial c_j}\frac{\partial c_j}{\partial x} + \frac{1}{c_i}\frac{\partial c_i}{\partial x}\right] + z_i F\frac{\partial \psi}{\partial x}\right) \quad [9]$$

In the subsequent equations the quantities related to the properties of the cation and the anion of the binary electrolyte will be subscripted with the numerals 1 and 2, respectively. The condition of zero current is

$$\sum_{i=1}^{2} z_i J_i = 0 \quad [10]$$

Substitution of Eq. [9] into [10] and subsequent use of the condition for electrical neutrality, $\Sigma_j z_j c_j = 0$, and the definition of the transport number, $t_i = c_i|u_i|/\Sigma_j c_j|u_j|$, yield the general differential equation

$$\frac{\partial \psi}{\partial x} = \frac{RT}{4F}\left[\frac{(z_1^2z_2 - z_1^3)t_1\Phi_1(I)}{I(1+B\,a_1\sqrt{I})} + \frac{(z_2^2z_1 - z_1^2z_2)t_2\Phi_2(I)}{I(1+B\,a_2\sqrt{I})}\right]\frac{\partial c_1}{\partial x} - RT\left(\frac{t_1}{z_1}+\frac{t_2}{z_2}\right)\frac{1}{c_1}\frac{\partial c_1}{\partial x} \quad [11]$$

The transport numbers t_i appearing in Eq. [11] are not independent of concentration. It has been found empirically (8-10) that for many binary electrolytes, the dependence of t_1 on concentration is described very adequately by

$$t_1 = \frac{K_1}{I + K_2\sqrt{c_1}} - 1 \quad [12]$$

in which the values of the constants K_1 and K_2 depend on the electrolyte considered. Equation [2] is now substituted into Eq. [11] recalling that $t_2 = 1 - t_1$ and that $I = [z_1^2 - z_1z_2]c_1/2$. The integration of the resulting differential equation is done across the boundary, from solution "to solution," considering that this region is made up of an indefinite number of layers with concentrations intermediate between the two solutions in question. Thus one obtains

$$\psi'' - \psi' = \psi_j = \left(1 + \frac{K_1B\alpha_1}{K_3 - B\alpha_1}\right)\Gamma_1(I) - \left(2 + \frac{K_1B\alpha_2}{K_3 - B\alpha_2}\right)\Gamma_2(I) + L_1(I) - L_2(I) + \frac{RTK_1}{F}\left[\left(\frac{1-K_1}{z_1K_1} - \frac{2-K_1}{z_2K_1}\right)\ln\frac{I''}{I'} - \left(\frac{2}{z_2} - \frac{2}{z_1}\right)\ln\frac{1+K_3\sqrt{I''}}{1+K_3\sqrt{I'}}\right] \quad [13]$$

The new terms in Eq. [13] are defined as

$$\Gamma_i(I) = \frac{RTAz_i(\sqrt{I'} - \sqrt{I''})}{F(1+B\alpha_i\sqrt{I'})(1+B\alpha_i\sqrt{I''})};$$

$$K_3 = \sqrt{2}\,K_2/(z_1^2 - z_1z_2)^{1/2}$$

$$L_i(I) = \frac{RTA}{F}\frac{K_1K_3z_i}{(K_3 - B\alpha_i)^2}\ln\frac{(1+K_3\sqrt{I''})(1+B\alpha_i\sqrt{I'})}{(1+K_3\sqrt{I'})(1+B\alpha_i\sqrt{I''})}$$

Equation [13] is rather cumbersome but it constitutes an analytical solution to the stated problem; its validity, of course, depends on the validity of the extra-thermodynamic functions used in its derivation, namely, the use of the Debye-Hückel theory to calculate ionic activity coefficients and the empirical dependence of transport numbers on concentrations. We have tested the adequacy of Eq. [13] using emf values reported in the literature for concentration cells with NaCl, LiCl, KCl, $BaCl_2$, $CaCl_2$, and $LaCl_3$ at 25°C. For this purpose we defined the calculated potentials, E_c, of these cells as

$$E_c = -\frac{RT}{F}\ln\frac{c_2''\gamma_2''}{c_2'\gamma_2'} + \psi_j \quad [14]$$

The activity coefficients γ_i and the junction potential ψ_j were calculated from Eq. [4] and [13], respectively. Thus, assessment of the adequacy of Eq. [13] can be obtained by comparison of the E_c with the observed emf values E_{ob} for the various electrolytes. Typical results for four of the electrolytes studied are given in Table I. For the case of $BaCl_2$ the values used for the constants K_1 and K_2 in Eq. [12] as well as the values for E_{ob}, were those reported by Jones and Dole (8). For $LaCl_3$, the values used for K_1 and K_2 were those reported by Jones and Prendergast (10) and the E_{ob} values were those reported by Shedlovsky and MacInnes (11). Values used for K_1 and K_2 for LiCl were those reported by Jones and Bradshaw (9) and the E_{ob} values were those reported by MacInnes and Beattie (12). For NaCl the best values for K_1 and K_2 were obtained by a least squares procedure (index of determination, 0.994) from the data on transference numbers reported by Longsworth (13). Values for E_{ob} for NaCl were those reported by MacInnes (14). The values used (15) for $a_i \times 10^8$ were: 4.5, for Na^+; 5 for Ba^{2+}; 9, for La^{3+}; and 3, for Cl^-. Values for the constants $A/2.303$ and B in Eq. [4] were 0.512 and 0.329×10^8, respectively (16), for water at 25°C.

The data in the last two columns of the table show good agreement (within 3%) between E_c and E_{ob} for systems with ionic strengths up to 0.3M. It is evident that a more satisfactory agreement was obtained for NaCl and $BaCl_2$ than for $LaCl_3$. This is not surprising since the use of the Debye-Hückel theory for single ionic activity coefficients is less satisfactory the higher the ionic charge number. Lack of agreement between the E_c values calculated by Eq. [4] and the E_{ob} values reported in the previously mentioned references became larger at higher ionic strengths; for systems (not included in the table) with ionic strengths from 0.5 to 3M the two values differed from about 5 to 10%. It is conceivable that the use of higher order terms in Eq. [4] might result in an expression that could give satisfactory results at higher concentrations; its concomitant increased complexity, however, would probably prevent its use in most practical situations.

Equation [14] is substantially simplified if t_i values, intermediate between the two electrolyte concentrations, are considered to be independent of concentration. However, calculations made on this basis for the examples listed in the table yielded disagreements between E_{ob} and E_c in the order of about 3-6% for the cases of NaCl and $BaCl_2$ and it amounted to 6-12% for the case of $LaCl_3$.

ECM of Nickel in $NaClO_3$ Solution

Mitchell A. LaBoda,* Armand J. Chartrand, James P. Hoare,* Charles R. Wiese, and Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

A certain amount of success has been achieved by correlating the electrochemical machining (ECM) behavior of steel in a given electrolyte with the passivation characteristics of steel in the electrolyte determined from polarization, film stripping, and mass balance studies (1-7). There is some evidence (8-10) that the results valid for iron and steel may not be valid for some other metals. Consequently, the machining of Ni by ECM may be an entirely different proposition.

Since the ECM behavior of a given metal in a given electrolyte has been shown to depend on the nature of the anodic film formed on the metal surface (1-6) and on the interaction of the anodic film with the anions present in the electrolyte (7), it would seem highly probable that the machining of iron or steel in $NaClO_3$ solutions would be much different from that of nickel in $NaClO_3$ solutions. It is the purpose of this note to present the results of an investigation showing that the polarization, film stripping, and mass balance data for steel and nickel anodes in 3M $NaClO_3$ solution are very different, and that the machining characteristics of steel and nickel samples in a laboratory ECM plunge-cut machine are equally so.

All experimental techniques have been described in earlier reports (6, 7). The samples were mild steel (Type 1020) and nickel (99.5% pure). The electrolyte studied was a solution of 350g of $NaClO_3$ per liter. The steel and nickel tubes machined in the ECM machine had the same geometric dimensions.

The steady-state polarization curves along with the film stripping data are plotted in Fig. 1. The difference between the two curves for steel and nickel is striking. At low potentials (below 0.5V), steel is active and surface films are undetectable; whereas nickel is passive in the same potential region and the surface is well covered with an anodic film. Instead of a negative resistance region (active-passive transition) exhibited by steel anodes, a limiting current region appears on the polarization curve obtained on Ni anodes. In the transpassive region, the anodic film on steel anodes becomes thinner with increasing potential, but that on nickel anodes not only becomes thicker but also a new phase appears (filled circles in Fig. 1b) at potentials where O_2 evolution begins (11).

Nearly all the current is consumed in O_2 evolution on Ni anodes at current densities below about 2 A/in.². After a polarization run, the Ni wires remained bright and the electrolyte was clear and colorless. Under similar experimental conditions, the diameter of a steel wire was greatly reduced and $Fe(OH)_3$ sludge collected in the electrolyte. Such behavior indicates that the anodic film on Ni anodes in $NaClO_3$ solution possesses a higher degree of electronic conductivity. Oxygen is evolved by the chemical decomposition of a higher oxide and current is consumed in the electrochemical formation of the higher oxide from the lower form (11).

Although the current efficiency for metal removal at Ni anodes in $NaClO_3$ solution increases with increasing current density as noted by Landolt (10), it does not increase as fast with current density as that at steel anodes in $NaClO_3$ solution, nor does it reach as high values at high current densities ($\sim$ 300 A/in.²). These facts are contained in the data of Table I. For this

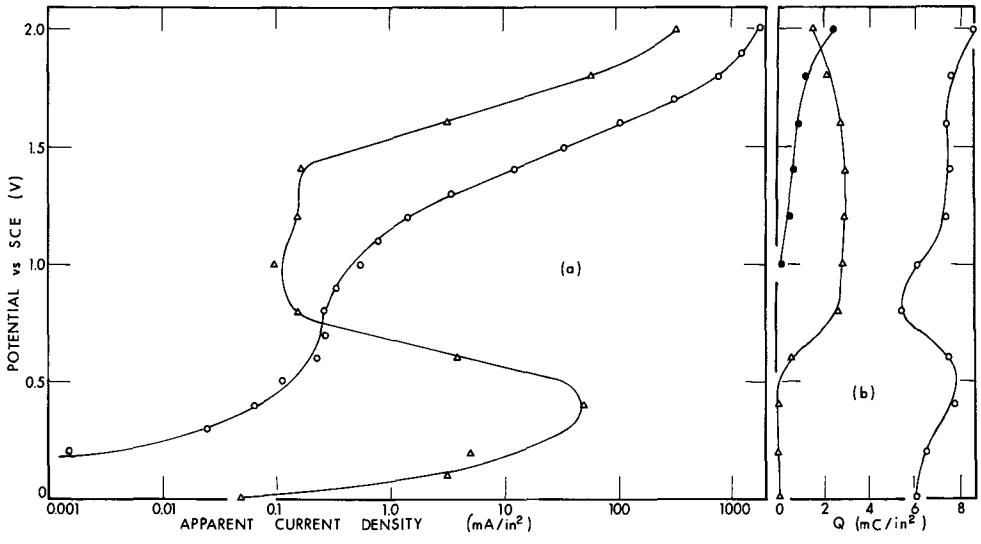

Fig. 1. (a) Steady-state polarization curves for nickel (open circles) and steel (open triangles) anodes in O_2-saturated $NaClO_3$ solution (350 g/liter). (b) A plot of the charge (Q) associated with anodic film formed on the surface of nickel (open circles) and steel (open triangles) anodes as a function of potential in $NaClO_3$ solution (350 g/liter); the filled circles represent the charge associated with a higher oxide formed on Ni anodes in the potential range where O_2 is evolved.

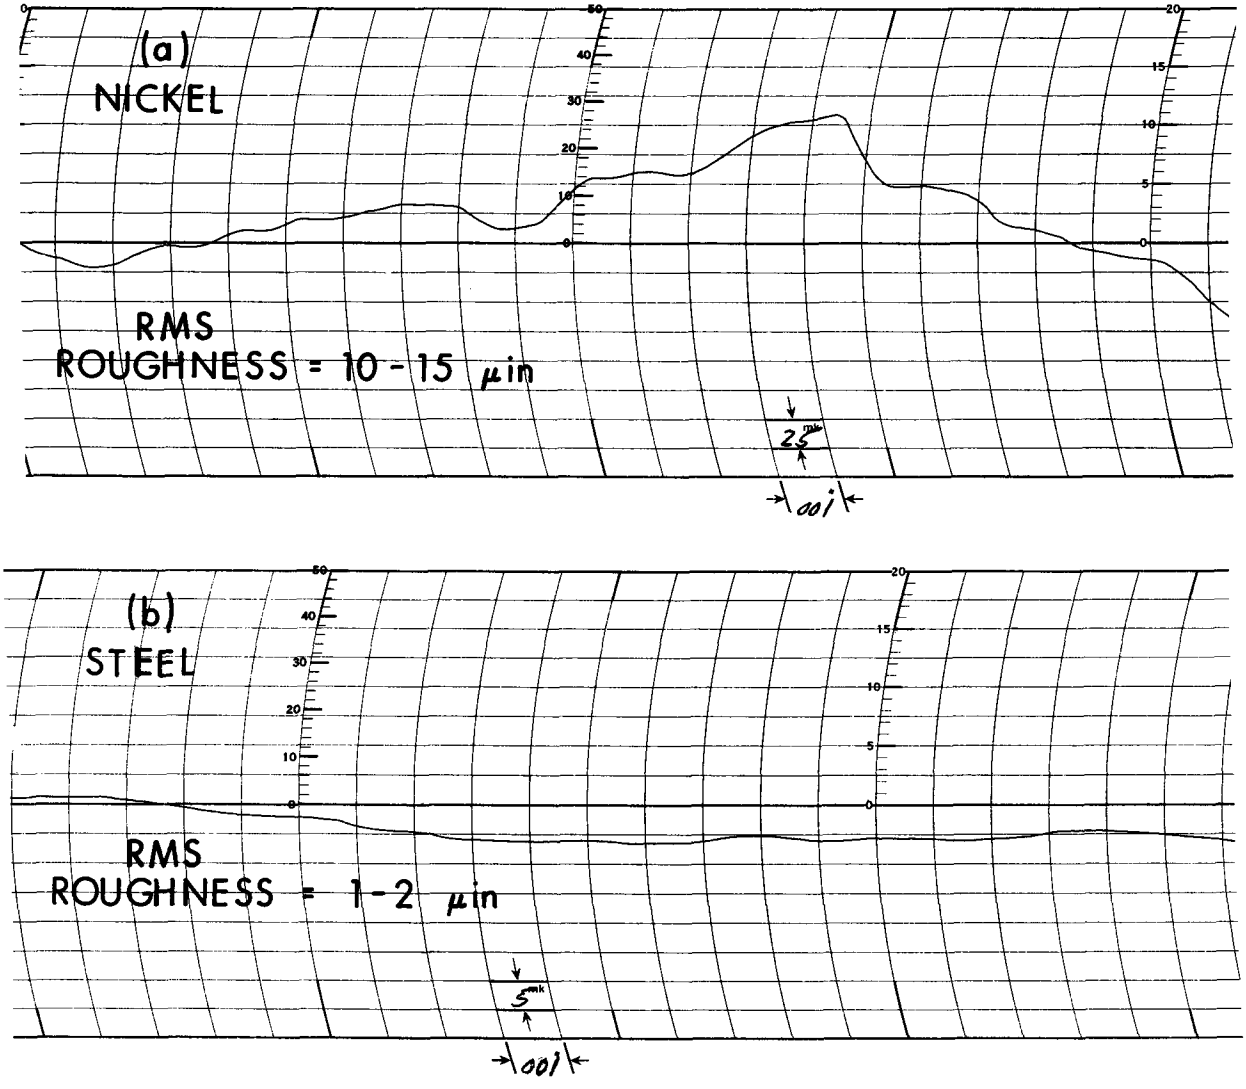

Fig. 2. Proficorder traces of the sides of holes plunge-cut by an ECM machine in nickel (a) and steel (b) samples using $NaClO_3$ solution (350 g/liter). The x-axis for both (a) and (b) is 0.001 in./div; the y-axis for (a) is 25 μin./div and for (b) 5 μin./div. RMS surface roughness is determined as 1/3 of the peak-to-valley distance.

reason, one would expect the machining rate of Ni to be slower than that of steel in the $NaClO_3$ electrolyte. In Table II is listed the highest machining rate obtained during the plunge-cutting of a sample in the laboratory ECM machine without the automatic cutoff being activated. As noted, steel can be machined almost twice as fast as Ni under the same experimental conditions in $NaClO_3$ electrolytes.

With increasing potentials, the anodic film on steel becomes uniformly thinner and highly porous producing an electropolishing of the metal surface (7). On the contrary, the anodic film on Ni anodes thickens

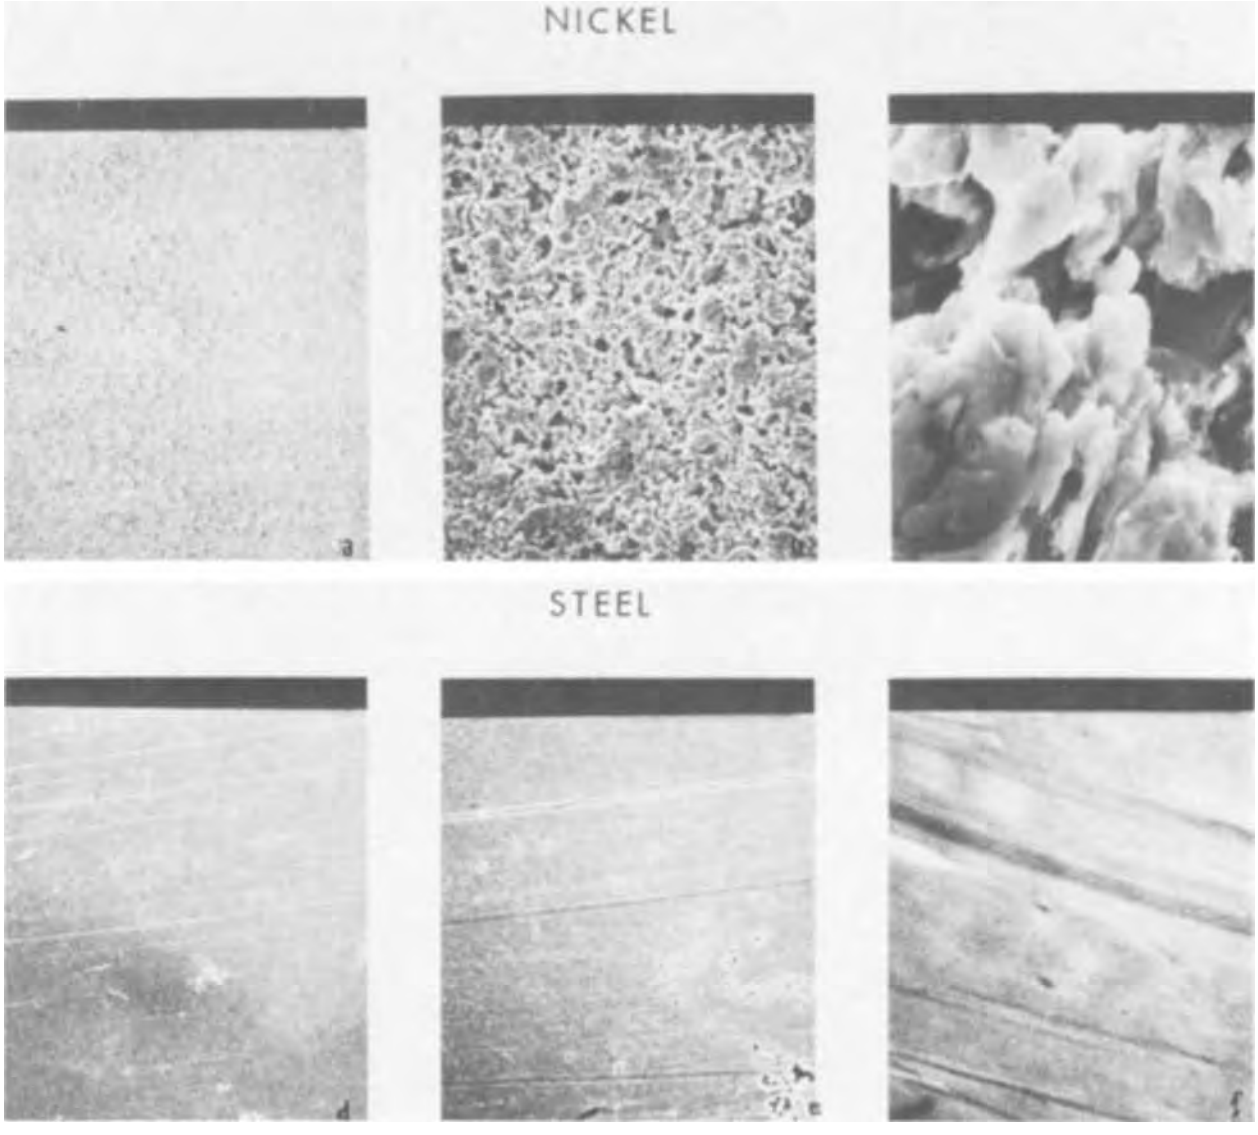

Fig. 3. Scanning-electron micrographs of the machined surface of the side of a hole plunge-cut by an ECM machine in nickel (a, b, and c) and steel (d, e, and f) samples using $NaClO_3$ solution (350 g/liter). Magnification of (a) and (d) is 100×; of (b) and (e) 1000×; of (c) and (f) 10,000×. Angle of incidence was 12°.

with increasing potential, and a less smooth surface is obtained on Ni anodes. The Proficorder traces along the sides of a hole plunge-cut in the sample by the ECM laboratory machine are reproduced in Fig. 2. It is seen that there is nearly an order of magnitude difference in the degree of surface roughness recorded on the machined surfaces of Ni and steel samples. Confirmation of this observation is obtained in Fig. 3 which shows scanning electron micrographs of the machined surfaces of plunge-cut Ni and steel samples at three magnifications.

These data confirm the contention that the ECM behavior of a given metal in a given electrolyte is highly dependent on the type and nature of the anodic films formed on the metal surface and on the interaction of the film with the anions in solutions as a function of potential. A good understanding of these two conditions can be obtained from polarization, film stripping, and mass balance studies of the given system. To obtain acceptable results from ECM, the choice of electrolyte and experimental parameters must be determined for each kind of metal under consideration.

Table I. Current efficiency for nickel and steel tubes machined in $NaClO_3$ (350 g/liter) electrolyte

Solid-State Ionics: A New High Ionic Conductivity Solid Electrolyte $Ag_6I_4WO_4$ and Use of This Compound in a Solid-Electrolyte Cell

Takehiko Takahashi,* Shoichiro Ikeda, and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

A new high ionic conductivity solid $Ag_6I_4WO_4$ has been found in the system AgI-Ag_2WO_4 at ambient temperature. This compound has a silver ion conductivity of 0.047 $(ohm \cdot cm)^{-1}$ at 25°C and an activation energy for conduction of 3.6 kcal/mole between 20° and 293°C. The transport number measurement using Tubandt's method shows that the transport number of silver ions in this compound is 1.00 within the experimental error. A $Ag/Ag_6I_4WO_4/I_2$ solid-electrolyte cell shows an open-circuit voltage of 687 mV which agrees well with the value of 686.7 mV calculated from $\Delta G°$ of the cell reaction at 21°C. Characteristics of the solid-state cells using $Ag_6I_4WO_4$ as the electrolyte have been investigated. The phase diagram of the system AgI-Ag_2WO_4 has been determined also.

In a previous paper (1) the phase diagrams of the systems AgI-Ag_3PO_4 and AgI-$Ag_4P_2O_7$ were reported, and the solid ionic conductors $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$ were described. The compounds $Ag_7I_4PO_4$ and $Ag_{19}I_{15}P_2O_7$ are more stable than the MAg_4I_5 group ($M = K$, Rb, or NH_4) (2, 3) in iodine atmosphere and in moisture. In this paper, a new high ionic conductivity solid in the silver-iodide and silver-tungstate system is described which has better stability in iodine atmosphere than the other high ionic conductors previously known.

The system AgI-Ag_2WO_4 has been examined by the same procedure as previously mentioned (1) to determine its phase diagram, and the performance of the solid-state silver-iodine cell has been investigated using this system as the electrolyte.

Experimental

Preparation of samples.—G.R. grade $AgNO_3$, KI, and $Na_2WO_4 \cdot 2H_2O$ were used as starting materials. Silver tungstate was prepared by precipitation from aqueous solutions of silver nitrate and sodium tungstate. The precipitate was washed seven or eight times with distilled water and dried under nitrogen flow at 120°C for several hours. The preparation method of AgI was described in the previous paper (1).

Weighing of silver iodide and silver tungstate was followed by mixing and grinding, and the mixture was sealed in a Pyrex tube under vacuum and heated for about 18 hr at 400°C and then the resulting material was allowed to cool to room temperature.

Conductivity measurement.—In order to reduce the contact resistance in the measurements of the conductivity change with temperature, a mixture of 0.9g of the sample and 0.3g of 200 mesh silver powder was used as the electrode material. The sample of 1.2g was stacked between the electrodes and pressed into a pellet of 13 mm in diameter by a hand press under 4000 kg/cm². The electrical conductivity was measured with an 1 kHz impedance bridge (YEW, Model BV-Z-13A).

The transport number of silver ions in this new high conductivity solid was measured by Tubandt's method (4), where a cell of the type of

$$\underset{(+)}{Ag,Hg/X_1/X_2/X_3/X_4/}\underset{(-)}{Ag} \qquad [I]$$

was used, where $X = Ag_6I_4WO_4$. In order to reduce the anodic polarization, an amalgamated silver plate was used for the anode material, and the change of the mass of X_2, X_3, X_4, and cathode was measured. A solution of 10 w/o (weight per cent) silver nitrate was used as the electrolyte of the silver coulometer. A stabilized direct current was passed through the cell for about 4 hr at the current density of 1.5 mA/cm².

Galvanic cell.—A solid-state galvanic cell of the type of

$$Ag,Ag_6I_4WO_4/Ag_6I_4WO_4/I_2,\ Ag_6I_4WO_4,C \qquad [II]$$

was constructed, the schematic of which is shown in Fig. 1. In order to reduce the contact polarization effects at the anode-electrolyte interface, a mixture of 0.4g of $Ag_6I_4WO_4$ and 0.15g of 200 mesh silver powder, and 1.0g of $Ag_6I_4WO_4$ were stacked in laminar arrangement and pressed at 4000 kg/cm² into a single pellet of 13-mm diameter to form the anode and the electrolyte, respectively.

The cathode material was a mixture of iodine, $Ag_6I_4WO_4$, and graphite (0.40g:0.40g:0.07g), and pressed into a pellet of the same shape. In order to measure the anodic and cathodic polarizations of this cell, the anode layer was divided into two pieces of an

* Electrochemical Society Active Member.

Key words: silver iodide-silver tungstate, ionic conductivity, solid-state battery.

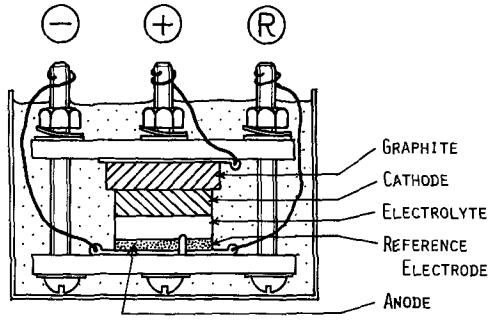

Fig. 1. Schematic diagram of the solid-electrolyte cell for polarization measurement.

original anode and a reference electrode, where the area ratio was 10:3. Silver plates 0.05-mm thick were used as the current collectors contacted directly with the anode and the reference electrode, and indirectly with the cathode via a graphite plate. The cell was sealed with polyester resin to prevent the sublimation of iodine.

X-ray diffraction.—Geigerflex D-3F (Rigaku Denki Company, Ltd.) was used for the x-ray diffraction analysis. A copper anode tube was operated at 15 mA and 35 kV. The shape of each sample was a pellet of 13 mm in diameter and about 1.5-mm thick pressed by a hand press under 4000 kg/cm^2.

Differential thermal analysis (DTA).—A sample of 0.8g was sealed in a Vycor tube under vacuum, and an α-alumina powder sealed in a Vycor tube of the same size was used for the standard material. The heating rate was 3.5°C/min, controlled by a PID controller (YEW, Model EGC 5-10) and a programmer (YEW, Model PGE-12).

Results and Discussion

Electrical conductivity of the system AgI-Ag_2WO_4.—A plot of the electrical conductivity of the system AgI-Ag_2WO_4 at room temperature against the Ag_2WO_4 content is shown in Fig. 2. The conductivity curve suggests that an intermediate compound with high electrical conductivity may be present in this system, because the curve shows a maximum at about 20 m/o (mol per cent) Ag_2WO_4 when the conductivity is of the order of 10^{-2} (ohm · cm)$^{-1}$. The conductivity of Ag_2WO_4 shown in the figure was obtained from an extrapolation of the Arrhenius plots of Ag_2WO_4 shown in Fig. 3 to 25°C.

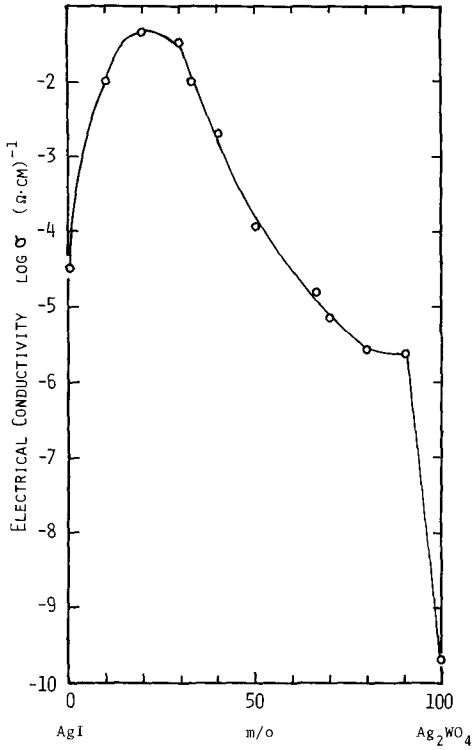

Fig. 2. Electrical conductivities in the system AgI-Ag_2WO_4 vs. the composition of Ag_2WO_4 at 25°C.

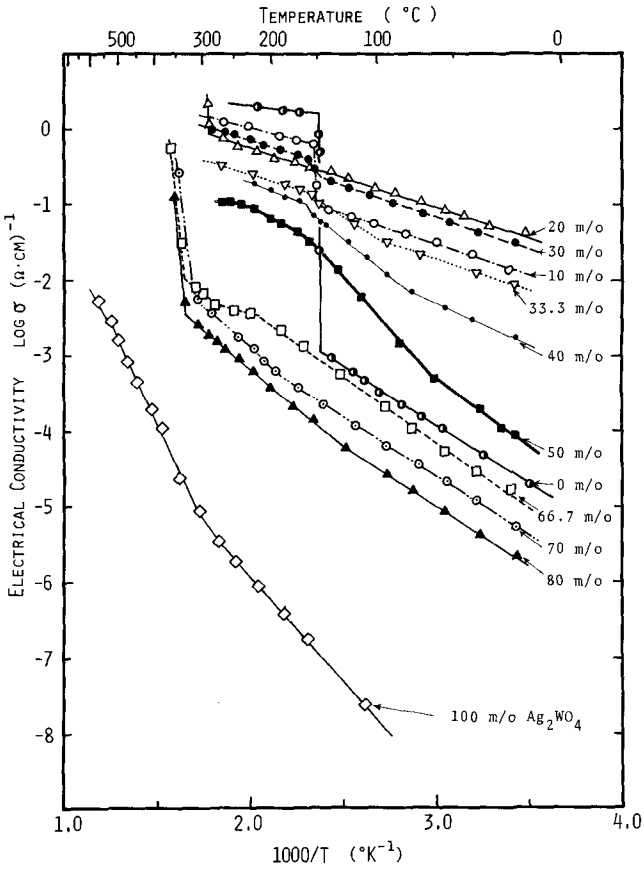

Fig. 3. Electrical conductivities of the system AgI-Ag_2WO_4 vs. the reciprocal of the absolute temperature.

The electrical conductivities of the system AgI-Ag_2WO_4 plotted as a function of the reciprocal of the absolute temperature are shown in Fig. 3. The conductivity curves of the samples containing 0 and 10 m/o of Ag_2WO_4 show abrupt change at 147°C, corresponding to the transition of silver iodide from β to α phase. The curves of the samples of 30 and 33.3 m/o of Ag_2WO_4 show the small bends near 150°C.

The conductivity curve of 20 m/o of Ag_2WO_4, however, shows no abrupt change and bend near these temperatures, and increases linearly up to 293°C, which corresponds to the incongruent melting point described in a later section. This result indicates that a new high conductivity compound, which may be written as $Ag_6I_4WO_4$, would be present at the composition of 20 m/o Ag_2WO_4-80 m/o AgI.

In order to determine the charge carrier of this compound, Tubandt's method was used. It was found that the total charge passed through cell [I] corresponded to the quantity of silver deposited at the cathode as shown in Table I, and the transport number of the silver ion is unity within the experimental error. Therefore, the electrical conductivity of

Table I. Transport number in $Ag_6I_4WO_4$

	Change in mass (mg)
Ag-Hg anode	—
X_1	—
X_2	+0.01
X_3	±0.00
X_4	+28.12
Ag cathode	±0.00
Ag deposited in coulometer	+28.30
Transport number of Ag^+	0.994

$Ag_6I_4WO_4$ shown in Fig. 3 is a silver ion conductivity and is 0.047 ± 0.001 $(ohm \cdot cm)^{-1}$ at 25°C. The activation energy for conduction obtained from the Arrhenius plot is 3.6 kcal/mole, which is comparable to the values of the other high ionic conductivity solids (1). The high ionic conductivity and low activation energy suggest that the silver ions in this new compound may be statistically distributed in the lattice taking an averaged structure.

X-ray diffraction.—The results of the x-ray diffraction of the samples carried out at room temperature using nickel filtered Cu-Kα radiation are listed in Table II. In the composition range of 0-18 m/o Ag_2WO_4, the diffraction peaks due to γ-phase silver iodide appeared. The lines due to Ag_2WO_4 were observed in the samples containing 67 m/o or more Ag_2WO_4. The lines due to β-AgI and Ag_2WO_4 were not observed in the samples containing 20-67 m/o Ag_2WO_4. The patterns of the samples containing 20, 33, and 67 m/o Ag_2WO_4 showed that the new phases were formed in these compositions. These patterns, however, are too complex to determine the crystal structure only by the powder x-ray diffraction analysis.

Phase diagram of the system AgI-Ag_2WO_4.—The results of the DTA of the system AgI-Ag_2WO_4 in the temperature range of 20°-200°C are shown in Fig. 4. Although the DTA of this system showed an endothermic peak at 147°C in the heating process in the composition range of 0-17.5 m/o of Ag_2WO_4 which is due to the transformation of silver iodide from β to α phase, the peak did not appear at this temperature in the samples of 20 and 22.5 m/o Ag_2WO_4. Another endothermic peak at 150°C appeared in the composition range of 25-60 m/o Ag_2WO_4. These results correspond to those of the electrical conductivity measurements shown in Fig. 3. In the samples containing more than 67 m/o of Ag_2WO_4, however, no peaks were observed near these temperatures. The endothermic peaks at 293°, 290°, and 348°C were also observed in the composition ranges of 0-20, 20-67, and 50-90 m/o of Ag_2WO_4 in the heating process.

Figure 5 shows the phase diagram of the system AgI-Ag_2WO_4 determined by the x-ray diffraction measurements and the differential thermal analysis. In this system, there are three intermediate compounds at the compositions of 20, 33, and 67 m/o of Ag_2WO_4, which may be written as $Ag_6I_4WO_4$, $Ag_4I_2WO_4$, and $Ag_5IW_2O_8$, respectively, at room temperature. $Ag_6I_4WO_4$ and $Ag_5IW_2O_8$ incongruently melt at 293° and 348°C, respectively. $Ag_4I_2WO_4$ decomposes to $Ag_6I_4WO_4$ and $Ag_5IW_2O_8$ above 150°C. The melting

point of Ag_2WO_4 is 620° ± 5°C, and the eutectic composition is estimated to be 25 m/o Ag_2WO_4, at 290°C.

Galvanic cell.—The high ionic conductivity solid electrolytes have been mainly used in solid-electrolyte galvanic cells (5-10). In these applications, the solid electrolyte should have a high ionic conductivity, high stability for the cathode material, and low electrode polarization. Figure 6 shows the result of the change of the internal resistance of the cell, Graphite/$Ag_6I_4WO_4$ + I_2/Graphite, with time. A mixture of 1.3g of the electrolyte and 0.3g of iodine was used. The

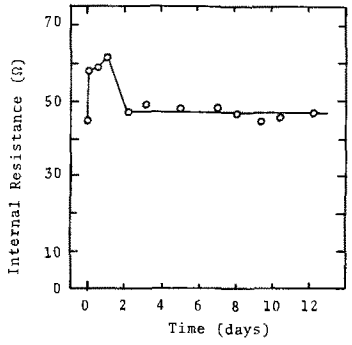

Fig. 6. Change of internal resistance of the cell; Graphite/$Ag_6I_4WO_4$ + I_2/Graphite.

resistance of the cell has been maintained at a constant value of about 50 ohm for two years.

$Ag_6I_4WO_4$ has the best stability in an iodine atmosphere among the high ionic conductivity compounds of silver previously known, such as Ag_3SI (11, 12, 13), $Ag_7I_4PO_4$, $Ag_{19}I_{15}P_2O_7$ (1), $RbAg_4I_5$ (1, 2, 3, 14), and $Ag_6I_4WO_4$, and is a promising material for solid-state silver-iodine batteries.

As $Ag_6I_4WO_4$ has been found to be a high ionic conductivity compound and stable in an iodine atmosphere, the silver-iodine solid-state cell of type [II] was constructed with $Ag_6I_4WO_4$ for the electrolyte material. This cell shows an open-circuit voltage of 687 mV at 21°C, which agrees well with the value of 686.7 mV calculated from the change of free energy of the formation of silver iodide according to the equation

$$Ag(s) + \tfrac{1}{2}I_2(g) = AgI(s) \qquad [1]$$

indicating that the ionic transport number of this compound is unity. This is confirmed with the result of the transport number measured by Tubandt's method.

Figure 7 shows the result of the measurement of the anodic and cathodic polarizations of the cell in the temperature range of −20° to 68°C. The polarization was recorded 1 min after passing the current. At 30°C, the anodic and cathodic overvoltages were 31 and 44 mV, respectively, at the current density of 1 mA/cm^2; and they were 50 and 60 mV, at 100 μA/cm^2 at −20°C, respectively. These values were relatively lower than those of the solid ionic compounds except for $RbAg_4I_5$ at ambient temperature.

Figure 8 shows the discharge curves of the cells at constant load measured at room temperature. The cell loaded 7.5 kohm showed a terminal voltage of 550 mV at 50% anode efficiency.

In Fig. 8 and 9, abbreviations E_o and E_c mean the open-circuit voltage and the cell voltage immediately after the beginning of discharge, respectively.

In order to measure the performance at low temperature, the discharge curve of the cell was measured

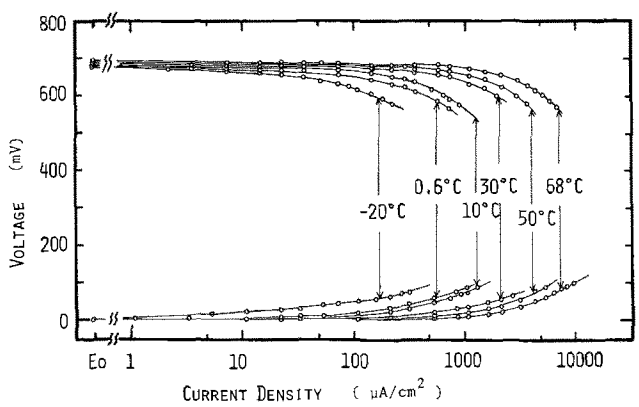

Fig. 7. Anodic and cathodic polarizations of the cell Ag, $Ag_6I_4WO_4/Ag_6I_4WO_4/I_2$, $Ag_6I_4WO_4$, C at various temperatures.

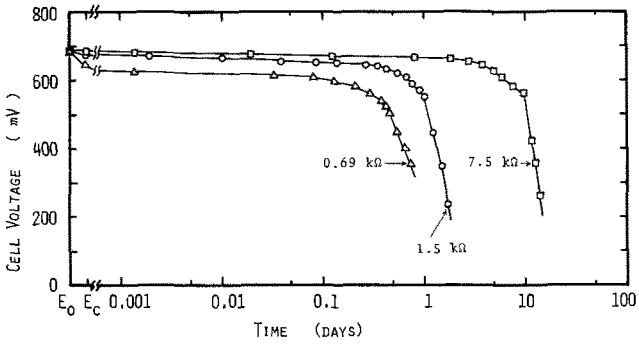

Fig. 8. Time dependence of the voltage of the cell Ag, $Ag_6I_4WO_4/Ag_6I_4WO_4/I_2$, $Ag_6I_4WO_4$, C at various constant load discharges at room temperature.

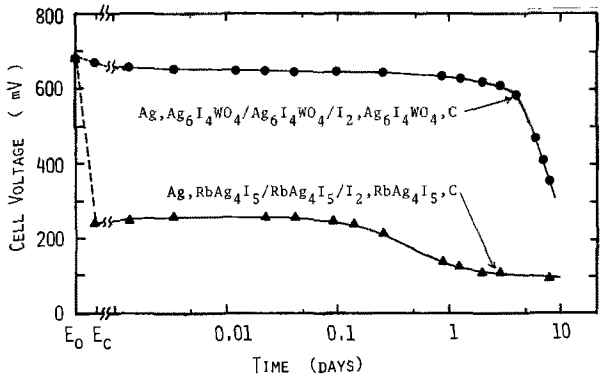

Fig. 9. Time dependence of the voltage of the cell Ag, $Ag_6I_4WO_4/Ag_6I_4WO_4/I_2$, $Ag_6I_4WO_4$, C at constant load discharge of 7.5 kohm at 0°C.

at constant load of 7.5 kohm at 0°C, and the result is shown in Fig. 9. The cell showed the open-circuit voltage of 681 mV and the terminal voltage of 668 mV at the initial stage of discharge. It showed a terminal voltage of 575 mV at 21% anode efficiency at 0°C.

Conclusion

In an investigation to find a new high ionic conductivity solid electrolyte, which was carried out on the system $AgI-Ag_2WO_4$, it has been found that $Ag_6I_4WO_4$ has a pure silver ion conductivity as high as 0.047 $(ohm \cdot cm)^{-1}$ at 25°C and an activation energy for conduction of 3.6 kcal/mole. $Ag_6I_4WO_4$ is a stable yellow-colored solid in the temperature range of 20°-293°C, and extremely stable in an iodine atmosphere. The transport number of silver ions in $Ag_6I_4WO_4$ is 1.00 within the experimental error. The silver-iodine solid-state battery using $Ag_6I_4WO_4$ as the electrolyte material showed the open-circuit voltage of 687 mV at 21°C, which is in good agreement with the value, 686.7 mV calculated from $\Delta G°$, the free energy of formation of silver iodide(s) from silver(s) and iodine(g) at 21°C. The anodic and cathodic overvoltages of this cell are 31 and 44 mV at the current density of 1 mA/cm^2 at 30°C, and 50 and 60 mV at 100 μA/cm^2 at −20°C, respectively. This cell showed the terminal voltage of 550 mV after the discharge of 50% anode efficiency at room temperature, and 575 mV after discharging 21% at 0°C.

The phase diagram of the system $AgI-Ag_2WO_4$ has been determined. There are three intermediate compounds of $Ag_6I_4WO_4$, Ag_4IWO_4, and $Ag_5I_2WO_8$ at room temperature.

The Interaction of Some Atmospheric Gases with a Tin-Lead Alloy

Harland G. Tompkins

Bell Telephone Laboratories, Columbus, Ohio 43213

ABSTRACT

A study is made of the interaction of O_2, SO_2, NO_2, H_2S, Cl_2, CO, and NH_3 with a tin-lead alloy (50-50% by weight). Studies were made at both high (10-100%) and low (0.1-100 ppm) concentrations. At the high concentrations, some interaction is observed for all except CO and NH_3. At concentrations below 100 ppm, only NO_2 and Cl_2 interact with the tin-lead to any extent. Products formed are $Pb(NO_3)_2$ for NO_2 and $SnCl_2$ and $PbCl_2$ for Cl_2. Kinetic data are presented for the interaction of these two gases with SnPb along with the effect of relative humidity. Relative humidity is shown to have a strong effect on the interaction, with high relative humidity enhancing the interaction for Cl_2 but inhibiting the interaction for NO_2.

Most of the investigations of tin-lead alloys have been concerned with degradation of appearance, solderability, and wettability (1), etc. Very little has been done in the area of kinetic studies of the interaction of gases with tin-lead, particularly at room temperature. Two of the few works available are oxidation studies made on tin (2) and lead (3) individually. A previous paper (4) deals with the interaction of NO_2 with tin-lead. This work is a continuation of that previous paper and deals with the interaction of several additional gases sometimes found in the atmosphere. Gases studied were O_2, SO_2, H_2S, Cl_2, NH_3, and CO. The results of the work on NO_2 are summarized for completeness.

From a corrosion point of view, studies should be carried out at a low concentration in order to more closely approximate the actual atmosphere conditions. Accordingly most of the present studies were done at concentrations of 0.1-100 ppm. Prior to this study, however, an exploratory investigation was made at high concentrations to determine which gases affected tin-lead appreciably. This study was to indicate the area of most fruitful effort in research. The exploratory investigations at high concentration were much less exact than the low-concentration studies. In the high-concentration studies, the concentration is estimated, and some of the film thickness values are lower limits rather than actual values. The purpose of including the high-concentration studies in this paper is not to provide kinetic data, but to indicate roughly which gases interact appreciably with tin-lead, and which do not.

Although it is an accepted rule of thumb that high relative humidity accelerates corrosion, the mechanism of this acceleration is not understood in many cases. Accordingly, the effect of relative humidity is included in the low-concentration study. Both the high-concentration exploratory study and the low-concentration study were conducted at room temperature.

Key words: corrosion, lead-tin alloys.

Experimental Setup

Low concentration.—The experimental setup for the weight gain measurements at low concentrations has been described previously (4). Briefly, weight gain was measured under various gaseous environments. The microbalance setup is shown schematically in Fig. 1. The output from a Cahn microbalance, which is used to measure weight gain continuously as the corrosive gas was passed over the sample, is presented on a chart recorder. The samples were solid tin-lead coupons having an area of about 9 cm^2. The tin-lead, nominal composition 50-50 by weight, was purchased in 0.1 cm sheets, rolled to 0.018 cm, and then annealed at 125°C in mild vacuum for 30 min.

The coupons were ultrasonically degreased in trichloroethylene and rinsed in acetone prior to annealing. This surface preparation appears adequate to obtain reproducible data.

The corrosive atmosphere was obtained by flowing a carrier gas, dry air, over a permeation tube (5) which releases the corrosive gas (*e.g.*, Cl_2) at a constant rate. The permeation tubes were purchased from

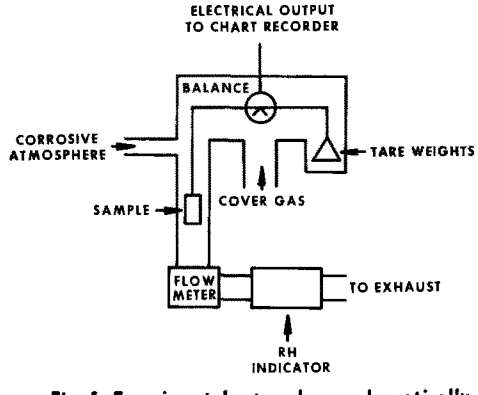

Fig. 1. Experimental setup shown schematically

Analytical Instrument Development, Inc., and consisted of liquid Cl_2 (or NO_2, H_2S, SO_2) in FEP Teflon tubes. The Cl_2 permeates out through the walls of the tube at a rate which is dependent only on the size of the tube, and temperature. Moist air was added after the carrier gas had passed over the permeation tube in order to give the desired relative humidity. Relative humidity was measured with an hygrometer indicator manufactured by Hygrodynamics, Inc., which has a quoted accuracy of ±3% RH. The permeation rates were determined by weight loss of the tube. The flow rate of the gas over the sample was 100 ml/min (0.4 cm/sec) and a typical permeation rate was 3 μg/min of Cl_2 (3 μg of Cl_2 in 100 ml corresponds to approximately 10 ppm). Concentration was varied by varying the temperature of the permeation tube. This in turn changed the permeation rate which changed the amount of corrosive gas being put into the carrier gas.

High-concentration exploratory study.—For the high-concentration work, the samples were exposed by flushing the appropriate atmosphere through a closed glass container which held the sample. The stopcocks were then closed and the sample was allowed to sit in the chosen atmosphere for the allotted time. The samples were again solid tin-lead coupons.

The dry atmospheres were obtained by flowing the appropriate gas from a lecture bottle directly into the sample chamber. The relative humidity was not measured but is estimated to be between 0 and 20%. The wet atmospheres were obtained by bubbling the gas through water and then flowing it through the sample chamber. Flow was continued for several minutes to insure saturation of the water. Relative humidity was estimated to be between 80 and 100%.

The presence or absence of film growth was noted by using cathodic reduction (6). This is an old technique whereby the film is reduced electrically and the amount of charge required is a measure of the film thickness. This method does not give accurate results for films which are soluble in water, so for these films, the value obtained from cathodic reduction is lower than the actual thickness.

Results

High-concentration exploratory study.—No film growth was observed for concentrations of approximately 100% CO or 100% NH (wet), for times of several days.

The oxygen in air causes a limiting film of tin oxide and/or lead oxide to form. Under normal room conditions, this film is of the order of 30-60Å. If excessive relative humidity (100%) or temperature (168°C) are used, films up to 300Å are obtained. These data agree with the results of Anderson and Tare (3) and Britton and Bright (2) who indicate that the oxide formed is limiting.

Sulfur-containing gases used were SO_2 with concentrations from 10 to 100%, both wet and dry, and wet H_2S (concentration 80-100%). Results were very erratic but in no case did a film thicker than 1600Å form (thickness calculated by assuming SnS with density 5.08 g/cm³). Exposure varied from 16 to 76 hr and longer times did not generally give thicker films. The conclusion is that these films are limiting.

Chlorine and oxides of nitrogen caused films to grow in excess of 10,000Å calculated by assuming $SnCl_2$, density (3.39 g/cm³) and these films appear to be nonlimiting. Concentrations from 20 to 100% were used, both wet and dry. In Cl_2, a liquid film formed on the sample. When removed from the sample chamber, the sample dried leaving a white deposit of lead chloride and hydrated tin chloride as determined by x-ray diffraction. The low-concentration section deals with the liquid film more extensively.

When the samples were viewed with an optical microscope, the surface roughness of the films grown in SO_2 and H_2S did not appear significantly different from the unexposed sample. The films grown in NO_2 and Cl_2, on the other hand, appeared very rough and grossly rearranged. These films were undoubtedly very porous.

Low concentrations.—Based on the results of the study at high concentrations, SO_2, H_2S, NO_2, and Cl_2 were used for the low-concentration study.

NO_2.—The results for NO_2 have been reported previously (4). They are summarized here for completeness. The reaction product was determined to be $Pb(NO_3)_2$ by x-ray diffraction. Presumably no interaction occurs with the Sn. The weight gain *vs.* time curves are linear indicating that a nonprotective film is being formed. The film is undoubtedly porous, but no loss of adhesion was noted, even on very thick films.

Curves were obtained with various concentrations at 32% relative humidity. In all cases, the curves were linear. The slope of these curves is the rate of the weight change. The rate of weight gain *vs.* concentration is shown in Fig. 2.

The linearity of this curve (above 10 ppm) indicates that when the concentration is doubled, the film growth rate is doubled. This is to say that when more gas arrives at the surface, more gas reacts with the surface, and the relationship is linear. The limiting process would then be the gas phase diffusion of the NO_2 to the gas-solid interface.

Curves were obtained using various relative humidities and a constant concentration (42 ppm). The slopes of these curves are plotted in Fig. 3. Here we see that high rates of film growth are obtained for intermediate relative humidities and low rates of film growth for low and for high relative humidities. The implication of the decrease in rate for higher RH values is discussed in the previous work and the conclusion was that the mechanism probably involved a simultaneous chemisorption of NO_2 and H_2O with each species competing for adsorption sites.

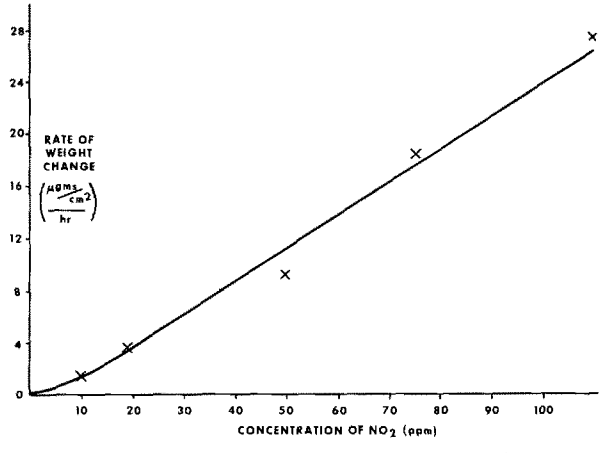

Fig. 2. Rate of weight change *vs.* concentration of NO_2 (RH is 32%).

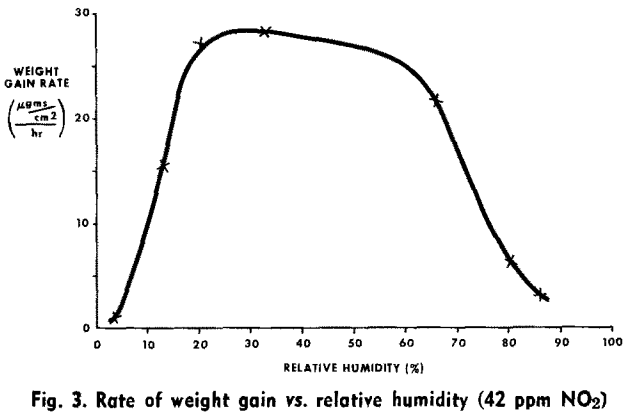

Fig. 3. Rate of weight gain *vs.* relative humidity (42 ppm NO_2)

H_2S and SO_2.—For SO_2, a concentration of 37 ppm and relative humidities of 40, 72, and 90% were used. No film growth was observed in three days for 40 and 90%. For 72% RH a slight film growth (0.15 $\mu g/cm^2$-hr) was observed. This was not repeatable and subsequent exposures of different SnPb coupons to the same conditions gave no film growth. For H_2S, concentrations of 40 ppm and relative humidities of 59 and 88% gave no film growth.

Summarizing the sulfur-containing gases, we see that we get some film growth for extremely high concentrations (10% and up) but with concentrations of less than 100 ppm we get very little, if any, film growth.

Cl_2.—Coupons of SnPb were exposed to various concentrations of Cl_2 from 0.2 to 10 ppm and relative humidities of 25 to 90%. The weight gain *vs.* time curves were linear in all cases. The reaction products observed with x-ray diffraction were $SnCl_2$ and $PbCl_2$. Visibly, the film growth was not particularly uniform, but seemed to grow from nucleation sites. For the larger weight gains, a visible liquid film formed on the sample.

A peculiar phenomenon was observed for the samples which had developed the liquid film. We would expect that, if we removed the Cl_2 and H_2O from the gas stream, a weight loss might occur. It is not at first obvious what would happen if we removed only one of these gases. It was found that if the H_2O is removed, but the Cl_2 remains, a weight loss of about 10% of the total weight gain occurred. This is not particularly surprising and is basically in agreement with the results of growth rate *vs.* relative humidity (see below). At low relative humidity the film growth stops and some of the water evaporates. The surprising phenomenon is that when the relative humidity was left unchanged and the Cl_2 was taken out of the gas stream, weight losses from 14 to 45% of the total weight gained were observed.

In the previous section we have shown that the reaction of NO_2 with SnPb appears to be simply a gas-solid interaction. We see here that the reaction of Cl_2 with SnPb is much more complex and involves at least a liquid-solid interaction and a gas-liquid interaction.

The gas-liquid interaction is simply the establishment of equilibrium of the H_2O and Cl_2 going into and coming out of the liquid from the gas phase. Since $SnCl_2$ and $PbCl_2$ are soluble in water, the liquid probably contains Sn^{+2}, Pb^{+2}, Cl^-, H_2O, H^+, and OH^-.

The weight loss might be due to a reaction which first causes tin and chlorine to form a tin chloride which then reacts with the water to form an oxide or hydroxide. HCl could then come off as a gas. The oxide or hydroxide does not show up in x-ray diffraction patterns, but this might be due to its being amorphous. This reaction, if it occurs, does not go to completion since some $SnCl_2$ is observed in x-ray diffraction patterns.

It would seem that the loss of whatever gas is going off probably occurs even while the film is growing. Because of the rather complex interaction the quantity which we call weight gain is the difference between what is going onto the sample and what is coming off the sample. We cannot directly relate the weight gain to "film growth" as in the case of NO_2, unless we were able to determine the reaction mechanism and the stoichiometry. On the other hand, weight gain does give an indication as to the conditions which cause "something to happen." Accordingly, then, weight gain *vs.* time curves were obtained for various concentrations at a constant relative humidity. The slopes of these curves are plotted in Fig. 4, taken with 80% relative humidity. It should be noted that the concentrations of Cl_2 are much lower than the concentrations of NO_2 studied.

The effects of relative humidity are shown in Fig. 5. Rate of weight gain *vs.* relative humidity is plotted for two concentration levels. It is not clear why the

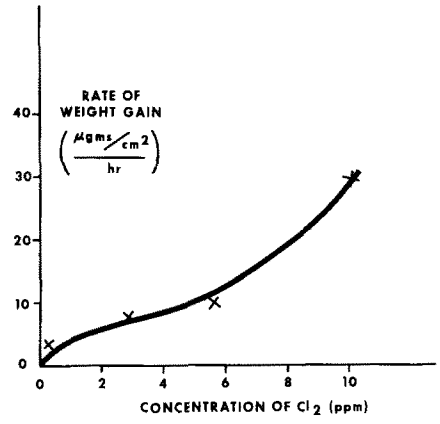

Fig. 4. Rate of weight gain *vs.* concentration of Cl_2 (RH is 80%)

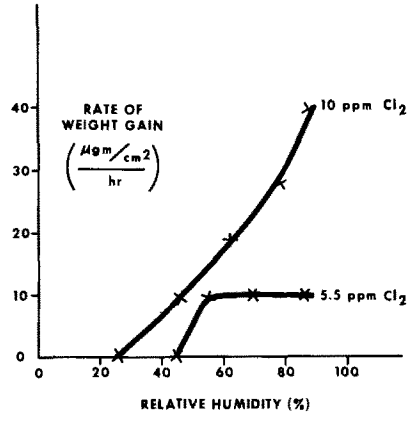

Fig. 5. Rate of weight gain *vs.* relative humidity

curve for 5.5 ppm levels off while the curve for 10 ppm continues to increase. It is, however, obvious that films will not grow in low relative humidities, and that intermediate and high relative humidity enhances film growth.

These curves, along with the weight gain-weight loss phenomenon (and the liquid film) show that relative humidity has a very complicated effect on the reaction of Cl_2 with SnPb.

Summary

The room temperature interaction of NO_2, Cl_2, H_2S, SO_2, O_2, CO, and NH_3 with a tin-lead alloy was investigated at high concentrations. No interaction was observed using CO and NH_3. The interaction of O_2 was a normal oxidation as described in the literature. A significant interaction was observed using SO_2, H_2S, NO_2, and Cl_2. This high-concentration study stimulated the low-concentration study where the interactions of NO_2, Cl_2, H_2S, and SO_2 with a tin-lead alloy at levels of 0.2-100 ppm were studied. The interaction of H_2S and SO_2 is negligibly small (below the limits of detectability of the microbalance), and the interaction of NO_2 and Cl_2 is significant with $Pb(NO_3)_2$, $SnCl_2$ and $PbCl_2$ being the reaction products.

At constant relative humidity, the interaction increases for higher concentrations for both NO_2 and Cl_2 with no sign of leveling off. At constant concentrations, the effect of relative humidity on the interaction is different for NO_2 than for Cl_2. Very high relative humidity enhances the interaction of Cl_2 but inhibits the interaction for NO_2.

A Study of Eu^{3+} Fluorescence in Some Silicate Oxyapatites

T. J. Isaacs

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Five silicate oxyapatites were activated with Eu^{3+} and their emission and excitation spectra were determined, as well as their peak emission intensities relative to $Y_2O_3:Eu^{3+}$.

The mineral apatite ($Ca_{10}(PO_4)_6(F,Cl)_2$), when doped with Mn^{2+} and Sb^{3+} is a well-known phosphor, and it is used extensively in present-day fluorescent lamps. Silicates having the apatite structure have been reported (1, 2), and the fluorescence of several oxyapatites when activated with Eu^{3+} was studied (1). An intense red luminescence was seen when $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$, $Sr_2Y_8(SiO_4)_6O_2:Eu^{3+}$ and $NaYb_8(SiO_4)_6O_2:Eu^{3+}$ were excited with 3130Å radiation. The strongest line was at approximately 6190Å, with moderate lines at approximately 7050, 6500, 6260, 5980, and 5850Å for each of these compounds.

Silicate apatites are hard, stable materials and lend themselves to a variety of compositional substitutions. In this work, we studied emission and excitation of five silicate oxyapatites [including $Ca_2Gd_8(SiO_4)_6O_2$] when activated with Eu^{3+}. The other compounds were $Ca_2Y_8(SiO_4)_6O_2$, $Ca_2La_8(SiO_4)_6O_2$, $Mg_2Y_8(SiO_4)_6O_2$, and $Mg_2La_8(SiO_4)_6O_2$.

Experimental Details

Spectrographic grade [99.99+ weight per cent (w/o)] starting materials which consisted of the oxides of yttrium, lanthanum, magnesium, silicon, and europium, and the carbonate of calcium were used. They were weighed out in stoichiometric proportions and were mixed for 15 min in a SPEX mixer mill. These mixes were then fired in air at approximately 1300°C, and the runs were of 4 hr duration.

The products of the experiments were examined under the polarizing microscope and by x-ray diffraction using the Debye-Scherrer technique to ascertain that the desired compound had been made and that the material was single phase. The radiation used was CuKα, and the exposure times were in the order of 9 hr.

Emission and excitation spectra were determined at room temperature on a double beam monochrometer system of the type described by Riedel (3). The relative intensities of the main emission peaks were also determined on this instrument.

Results and Conclusions

The optimum concentration of Eu^{3+} was found to be between 5 and 7 mole per cent (m/o) of the trivalent ion. The samples discussed below all had a 7% concentration of Eu^{3+}.

1. $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$ had a complex emission spectrum with the main peak at 6147Å, moderate peaks at 6120, 6240, 6270, and 7075Å, and numerous lesser peaks (Fig. 1a). Its excitation spectrum showed two main bands between 2100 and 2850Å and several lesser bands to 4200Å (Fig. 1b).

2. $Ca_2La_8(SiO_4)_6O_2:Eu^{3+}$ had its main emission peak at 6261Å, with moderate peaks at 5870, 5960, 6140, 6862, and 7079Å (Fig. 2a). Its excitation spectrum showed two bands, one from approximately 2100 to 2400Å and the other from approximately 2600 to 3100Å (Fig. 2b).

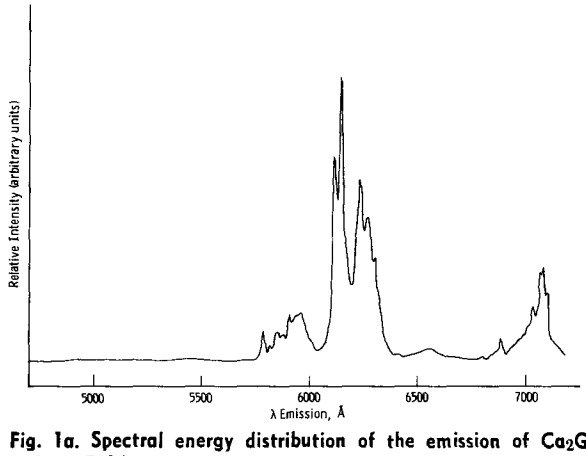

Fig. 1a. Spectral energy distribution of the emission of $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$

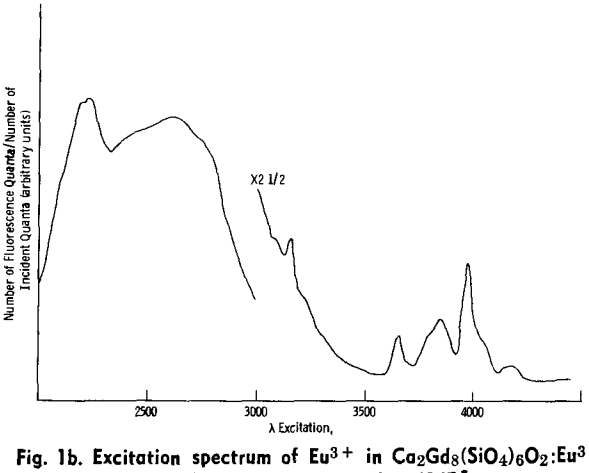

Fig. 1b. Excitation spectrum of Eu^{3+} in $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6147Å.

Key words: oxyapatites, europium, emission, excitation.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

A Study of Eu^{3+} Fluorescence in Some Silicate Oxyapatites

T. J. Isaacs

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Five silicate oxyapatites were activated with Eu^{3+} and their emission and excitation spectra were determined, as well as their peak emission intensities relative to $Y_2O_3:Eu^{3+}$.

The mineral apatite ($Ca_{10}(PO_4)_6(F,Cl)_2$), when doped with Mn^{2+} and Sb^{3+} is a well-known phosphor, and it is used extensively in present-day fluorescent lamps. Silicates having the apatite structure have been reported (1, 2), and the fluorescence of several oxyapatites when activated with Eu^{3+} was studied (1). An intense red luminescence was seen when $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$, $Sr_2Y_8(SiO_4)_6O_2:Eu^{3+}$ and $NaYb_8(SiO_4)_6O_2:Eu^{3+}$ were excited with 3130Å radiation. The strongest line was at approximately 6190Å, with moderate lines at approximately 7050, 6500, 6260, 5980, and 5850Å for each of these compounds.

Silicate apatites are hard, stable materials and lend themselves to a variety of compositional substitutions. In this work, we studied emission and excitation of five silicate oxyapatites [including $Ca_2Gd_8(SiO_4)_6O_2$] when activated with Eu^{3+}. The other compounds were $Ca_2Y_8(SiO_4)_6O_2$, $Ca_2La_8(SiO_4)_6O_2$, $Mg_2Y_8(SiO_4)_6O_2$, and $Mg_2La_8(SiO_4)_6O_2$.

Experimental Details

Spectrographic grade [99.99+ weight per cent (w/o)] starting materials which consisted of the oxides of yttrium, lanthanum, magnesium, silicon, and europium, and the carbonate of calcium were used. They were weighed out in stoichiometric proportions and were mixed for 15 min in a SPEX mixer mill. These mixes were then fired in air at approximately 1300°C, and the runs were of 4 hr duration.

The products of the experiments were examined under the polarizing microscope and by x-ray diffraction using the Debye-Scherrer technique to ascertain that the desired compound had been made and that the material was single phase. The radiation used was CuKα, and the exposure times were in the order of 9 hr.

Emission and excitation spectra were determined at room temperature on a double beam monochrometer system of the type described by Riedel (3). The relative intensities of the main emission peaks were also determined on this instrument.

Results and Conclusions

The optimum concentration of Eu^{3+} was found to be between 5 and 7 mole per cent (m/o) of the trivalent ion. The samples discussed below all had a 7% concentration of Eu^{3+}.

1. $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$ had a complex emission spectrum with the main peak at 6147Å, moderate peaks at 6120, 6240, 6270, and 7075Å, and numerous lesser peaks (Fig. 1a). Its excitation spectrum showed two main bands between 2100 and 2850Å and several lesser bands to 4200Å (Fig. 1b).

2. $Ca_2La_8(SiO_4)_6O_2:Eu^{3+}$ had its main emission peak at 6261Å, with moderate peaks at 5870, 5960, 6140, 6862, and 7079Å (Fig. 2a). Its excitation spectrum showed two bands, one from approximately 2100 to 2400Å and the other from approximately 2600 to 3100Å (Fig. 2b).

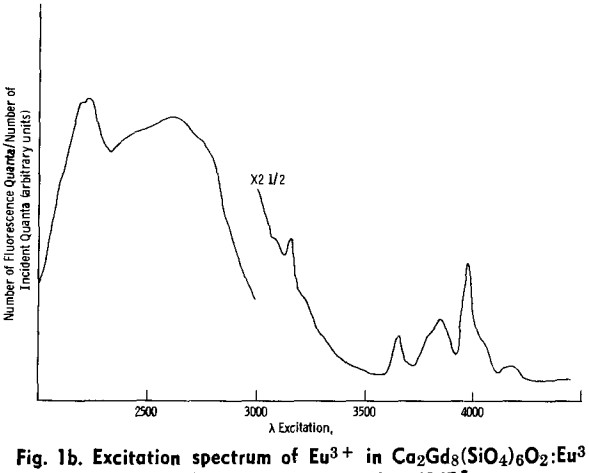

Fig. 1b. Excitation spectrum of Eu^{3+} in $Ca_2Gd_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6147Å.

Key words: oxyapatites, europium, emission, excitation.

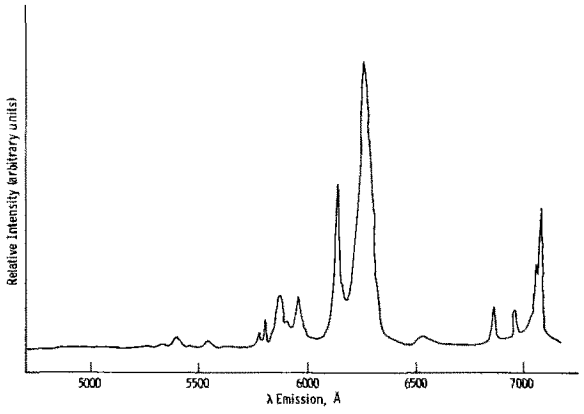

Fig. 2a. Spectral energy distribution of the emission of $Ca_2La_8(SiO_4)_6O_2:Eu^{3+}$

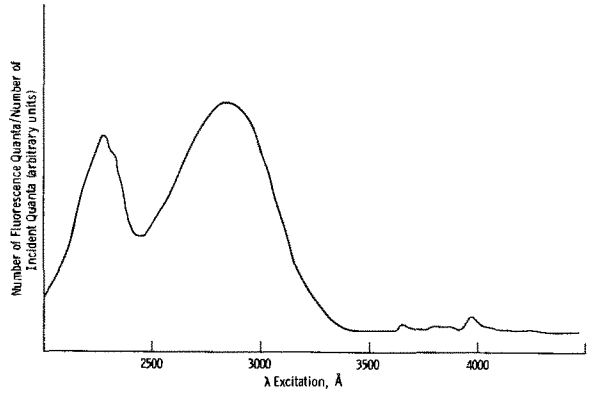

Fig. 2b. Excitation spectrum of Eu^{3+} in $Ca_2La_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6261Å.

3. $Ca_2Y_8(SiO_4)_6O_2:Eu^{3+}$ had its main emission peak at 6114Å, a moderate peak at approximately 6150Å, and a number of lesser peaks from 5800 to 7100Å (Fig. 3a). Its excitation spectrum showed one broad band from below 2000 to approximately 2500Å (Fig. 3b).

4. $Mg_2La_8(SiO_4)_6O_2:Eu^{3+}$ had a complex emission spectrum with the main peak at 6260Å and numerous moderate to small peaks throughout the spectrum (Fig. 4a). Its excitation spectrum showed two main bands between 2100 and 3100Å, with several small bands to 4200Å (Fig. 4b).

5. $Mg_2Y_8(SiO_4)_6O_2:Eu^{3+}$ had its main emission peak at 6112Å, a moderate peak at 6145Å, and a number of small peaks from 5800 to 7100Å (Fig. 5a). The excitation spectrum showed a large two-humped broad band extending from approximately 2000 to 2600Å, and some small bands to 4200Å (Fig. 5b).

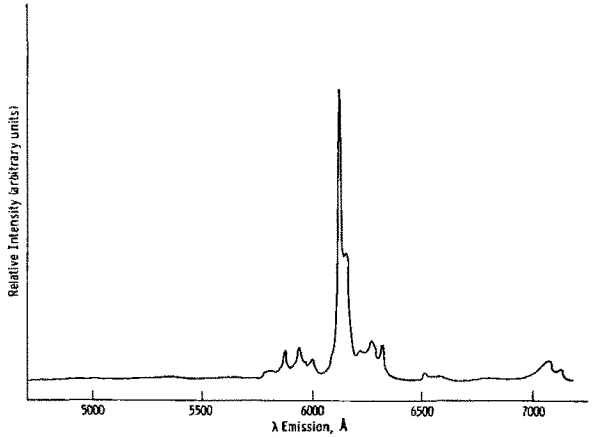

Fig 3a. Spectral energy distribution of the emission of $Ca_2Y_8(SiO_4)_6O_2:Eu^{3+}$.

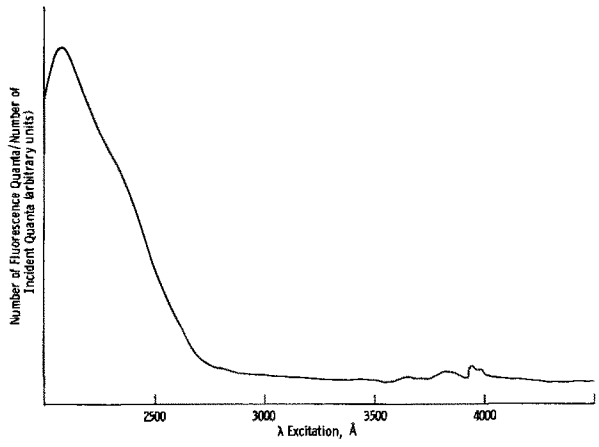

Fig. 3b. Excitation spectrum of Eu^{3+} in $Ca_2Y_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6113Å.

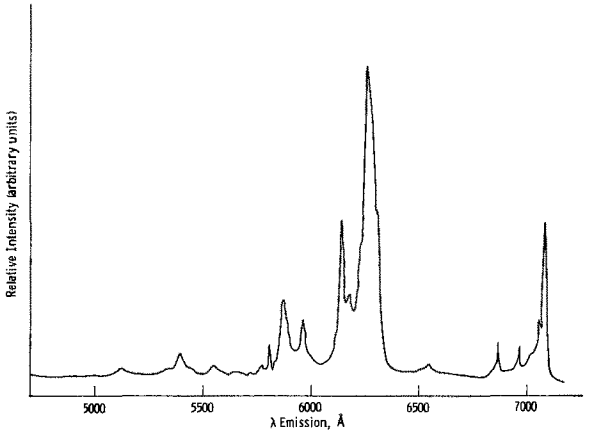

Fig. 4a. Spectral energy distribution of the emission of $Mg_2La_8(SiO_4)_6O_2:Eu^{3+}$.

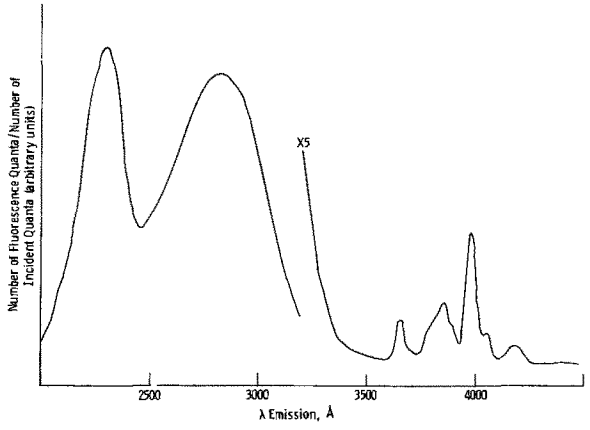

Fig. 4b. Excitation spectrum of Eu^{3+} in $Mg_2La_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6260Å.

In order to compare emission intensity among these samples, we measured the luminescence intensity of the main peak in each of the compounds against a standard $Y_2O_3:Eu^{3+}$ which contained 7% Eu_2O_3. The results are given in Table I. We can see that the two

Table I. Relative intensities of emission of the main peaks compared with $Y_2O_3:Eu^{3+}$ at 2537Å excitation

(The Eu^{3+} content was 7% for all the compounds)

Compound	% intensity *vs.* $Y_2O_3:Eu^{+3}$
$Ca_2Gd_8Si_6O_{26}:Eu^{3+}$	10
$Ca_2La_8Si_6O_{26}:Eu^{3+}$	4
$Ca_6Y_8Si_2O_{26}:Eu^{3+}Si_6$	20
$Mg_2La_8Si_6O_{26}:Eu^{3+}$	4
$Mg_2Y_8Si_6O_{26}:Eu^{3+}$	20

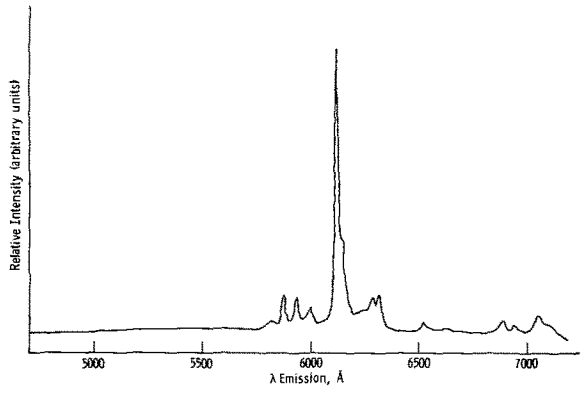

Fig. 5a. Spectral energy distribution of the emission of $Mg_2Y_8(SiO_4)_6O_2:Eu^{3+}$.

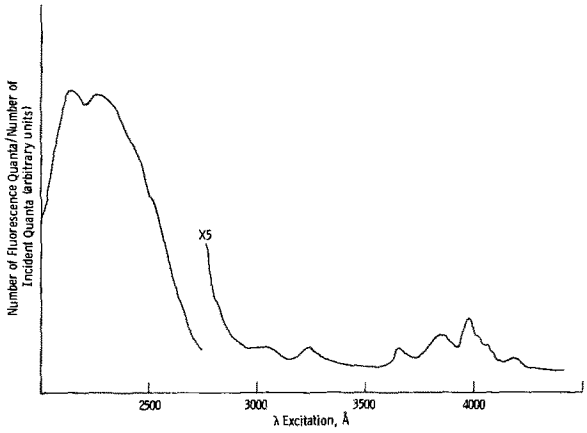

Fig. 5b. Excitation spectrum of $Eu^{3+}Mg_2Y_8(SiO_4)_6O_2:Eu^{3+}$. The fluorescence wavelength was monitored at 6112Å.

materials which had yttrium as the trivalent cation had the best relative intensities, and their emission spectra showed them to have a large part of their emission concentrated at approximately 6110Å. Their excitation spectra showed them to be poorly excited at 2537Å, with the intensity being approximately 20% that of the highest part of the curve for $Ca_2Y_8(SiO_4)_6O_2:Eu^{3+}$, and approximately 35% for $Mg_2Y_8(SiO_4)_6O_2:Eu^{3+}$.

The spectra of these compounds depends upon the trivalent cation and were independent of the divalent cation. The yttrium members had better spectral energy distributions as more of their emission was concentrated in one peak, but the lanthanum members were sensitive to excitation at longer wavelengths.

It is known that there are two sites available for cation substitution in Y_2O_3, and that there also are two sites for divalent cation substitution in the normal apatite. The materials reported on in this work are all modifications of the apatite structure and they would have at least two such sites. Spin resonance studies of fluorapatites used as laser materials show that there are more than two sites, and may be as many as eight (R. Warren, private communication). We did not attempt to interpret our spectra in terms of the symmetry of sites because of the complications involved.

Acknowledgments

I wish to thank Andrea Price for helping to make the compounds and taking the x-ray photographs, and Roy Williams for taking the emission and excitation curves and determining the relative intensities.

Epitaxial Growth and Characterization of Pyrolytic-Grown $GaAs_{1-x}P_x$ for Electroluminescent Diodes

Tadashi Saitoh and Shigekazu Minagawa

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Epitaxial layers of $GaAs_{1-x}P_x$ on GaAs substrates were prepared using trimethylgallium, arsine, and phosphine. The growth was primarily mass transport limited and the phosphorus content in the layers increased linearly with the phosphine content in the vapor and the substrate temperature. Growth pyramids appeared at high phosphine content in the vapor and were brighter than flat regions in the cathodoluminescent image. A diode, fabricated by diffusing zinc into $GaAs_{0.6}P_{0.4}$ layers, showed brightness of 43 ft-L at 8 A/cm^2 with an external quantum efficiency of about 0.01%. The external efficiency has been found to depend strongly on the generation-recombination current and the deep level impurity concentration in the depletion layer.

The method most commonly used to prepare $GaAs_{1-x}P_x$ for electroluminescent devices is a vapor transport system using a halide (1). Manasevit and Simpson (2) have reported on the use of organometallics in the preparation of III-V compounds. This method has two advantages over the conventional process. The one is that compound semiconductors can be grown in a rf-heated furnace, which requires only a short time for heating up or cooling down, and the other is that it can avoid autodoping from a substrate, because it does not include any halogen atoms which react with a substrate.

Key words: $GaAs_{1-x}P_x$ pyrolytic growth, light-emitting diodes, growth pyramids, cathodoluminescence.

Although various compound semiconductors have been prepared using organometallics (2-9), no efficient visible electroluminescence has been reported for the diodes fabricated from these crystals. The present

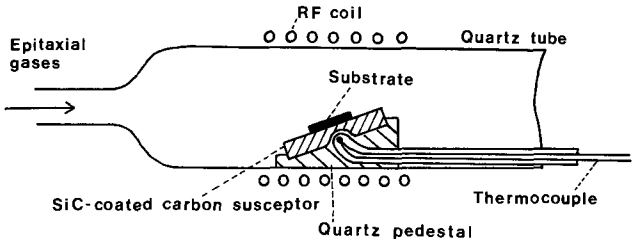

Fig. 1. Schematic representation of an epitaxial reactor

paper describes the epitaxial growth of $GaAs_{1-x}P_x$ on GaAs substrate by the pyrolytic method, and also describes morphological and cathodoluminescent characterization of these layers. Finally, several features of electrical and optical properties of pyrolytic-grown $GaAs_{0.6}P_{0.4}$ diodes are discussed.

Experimental

Apparatus.—A schematic representation of a horizontal epitaxial reactor is shown in Fig. 1. A substrate was placed on a SiC-coated carbon susceptor inclined by 20°. The substrate temperature was measured by an optical pyrometer and was controlled by an electronic control system whose thermocouple was inserted into the susceptor.

Trimethylgallium, contained in a stainless steel bubbler cooled by a thermoelectric element, was transported by passing hydrogen through it.

Procedure.—The substrates were n-type (100) GaAs with an electron concentration of 1.3×10^{18} cm^{-3}. They were mechanically polished and chemically etched (etchant; $4H_2SO_4$: $1H_2O_2$: $1H_2O$) prior to growth.

After the growth of an initial layer of GaAs, the phosphorus content of the layer was gradually increased by increasing the PH_3/AsH_3 ratios in the vapor to obtain a final composition of $x = 0.4$. The total thickness of the epitaxial layers were normally about 70μ.

Typical growth parameters are given in Table I. A higher flow rate of H_2 was adopted to prevent $GaAs_{1-x}P_x$ crystals from depositing before the substrate unlike the hitherto reported experiment (2). H_2Se was added to obtain n-type epitaxial layers with the carrier concentration of 10^{17} cm^{-3} to 10^{18} cm^{-3}.

Evaluation of epitaxial layers.—Surface morphology of the epitaxial layers was examined by a conventional optical microscope. Thickness of epilayers was measured by examining stained sections of the layers. The phosphorus content of the layers was determined by the electron microprobe analysis. Cathodoluminescence of the layers excited by 30 kV electrons was analyzed with a Hitachi Model S-12B monochrometer and a S-10 photomultiplier.

Diode fabrication and characterization.—The p-n junctions were made by diffusing Zn into the Se-doped $GaAs_{0.6}P_{0.4}$ epilayers with the electron concentration of 3×10^{17} cm^{-3} at the temperature ranges of 700°-850°C for 30 min. An array of small Au contacts was evaporated and alloyed to the Zn-diffused p-type $GaAs_{0.6}P_{0.4}$ surface, and a continuous Sn contact was evaporated and alloyed to the n-type GaAs substrate. The wafer was cleaved into chips, which were mounted on TO-18 transistor headers to measure junction characteristics and luminescent properties. The concentration of deep level impurities in the depletion layer was calculated from the difference of the junction capacitance (10) at 300° and 77°K.

Table I. Growth parameters

Substrate temperature	650°-800°C
Total flow rate	5 liters/min
Gas concentration	
$(CH_3)_3Ga$	0.056% (calc.)
AsH_3	0-0.24%
PH_3	0-0.11%
SeH_2	2 ppm
Growth rate	0.7 μ/min
Substrate	Te doped, (100) $n \simeq 3 \times 10^{18}$ cm^{-3}

Results and Discussion

Deposition reaction.—The principal parameters which affect the deposition reaction of $GaAs_{1-x}P_x$ by pyrolysis were the flow rate of H_2, the growth temperature, the PH_3/AsH_3 ratio, and the concentration of reaction gas. The growth rate as a function of temperature indicated in Fig. 2, shows that the rate is almost independent of the substrate temperature. It was also found that the growth rate is proportional to the $(CH_3)_3Ga$ concentration in the vapor. These results suggest that the growth is most probably mass transport limited.

Compositions.—Another quantity of interest is the composition of the epitaxial layer, *i.e.*, an effective vapor-solid distribution coefficient for the group V element. PH_3 mole fraction in the gas, x_g, is defined as

$$x_g = \frac{p_{PH_3}}{p_{AsH_3} + p_{PH_3}} \quad [1]$$

where p is the partial pressure of the subscript molecule in the gas. GaP mole fraction in the solid, x_s, is defined as

$$x_s = \frac{n_P}{n_{As} + n_P} \quad [2]$$

where n is the number of moles of the subscript element in the solid.

Then, the distribution coefficient for phosphorus is given by

$$k_p = \frac{x_s}{x_g} \quad [3]$$

Figure 3 shows the relation between the GaP mole fraction in the epitaxial layer and the PH_3 content in the gas. The composition increases in proportion to

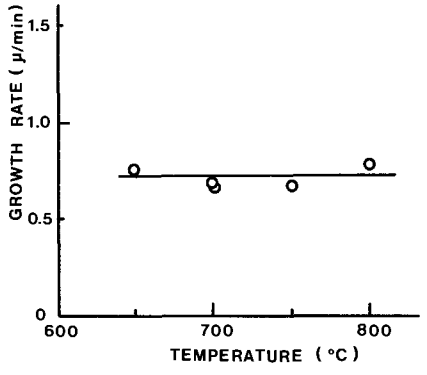

Fig. 2. Growth rate of $GaAs_{1-x}P_x$ as a function of substrate temperature.

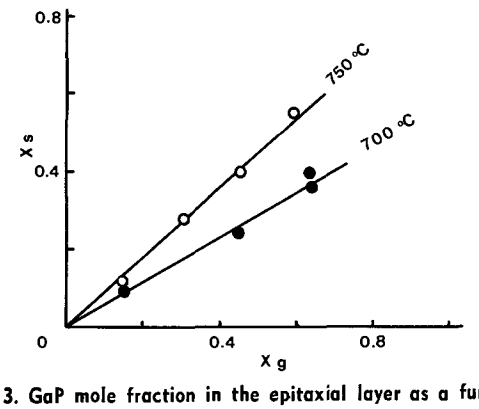

Fig. 3. GaP mole fraction in the epitaxial layer as a function of PH_3 content in the gas.

the PH_3 content in the range of $x_g = 0$ to $x_g = 0.6$, and the slope, k_p, depends on the growth temperature. The temperature dependence of the slope at $x_g = 0.54$ in the temperature range of 650°-850°C is given by

$$k_p = 3.7 \times 10^{-3} T - 2.9 \quad [4]$$

where T is the growth temperature in the absolute unit.

The equation indicates that GaAs is more easily deposited at low temperatures, and the GaP mole fraction increases with the growth temperature. The pyrolytic growth is a dynamic system in which a thermodynamical equilibrium state is not expected. A recent mass spectrometric study of $GaAs_{1-x}P_x$ system (11) showed that the vapor resulting from the thermal decomposition of AsH_3 and PH_3 mixtures has a very complex composition and the temperature variation of reactivities of P- and As-containing species reflects itself in the composition of $GaAs_{1-x}P_x$ layers. In the pyrolytic growth, dependence of the composition on the growth temperature may be explained also by the temperature variation of the reactivities of P- and As-containing species.

Structural characteristics.—The appearance of the epitaxial layers was primarily dependent on growth temperature and AsH_3/PH_3 ratios in the gas. Structural imperfections were found to be growth pyramids shown in Fig. 4. The ranges of growth pyramids generally run in the [110] direction parallel to the surface. Examination of cross sections of the layers indicated that the pyramids generally originate in the graded layer and develop with the increase of the thickness of the epitaxial layer. A few cracks, probably consisting of the [110] {111} slip system (12), were observed at the epitaxial layer-growth pyramid interface.

To evaluate crystallinity of the epitaxial layers, cathodoluminescence was studied on the surface of the epilayers and on the cross sections. Figure 5 shows the variation of the cathodoluminescent intensity and the composition with the thickness of the layer. The intensity which is almost constant in the GaAs epitaxial layer, decreases rapidly in the graded layer, but increases with the thickness. The decrease of the intensity in the graded layer is probably caused by the misfit dislocations. It seems to us that the grading rate at the initial layer should be low enough to minimize

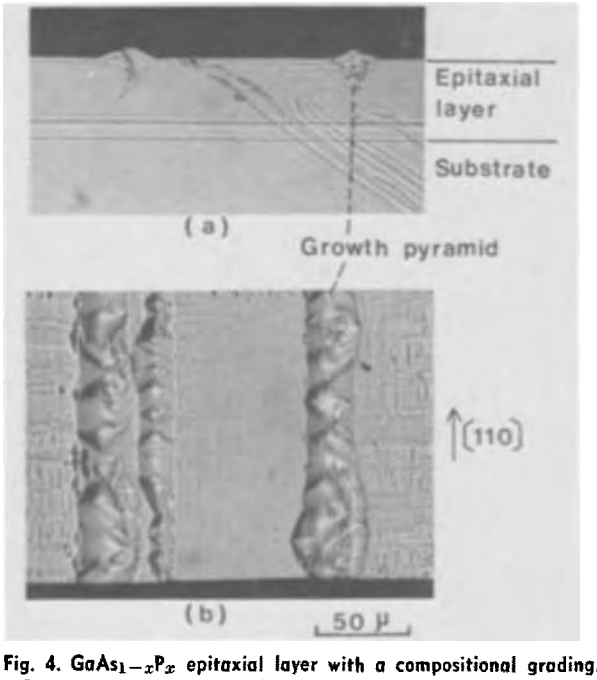

Fig. 4. $GaAs_{1-x}P_x$ epitaxial layer with a compositional grading. (a) Cross section (stained), (b) as-grown surface. Growth temperature 700°C.

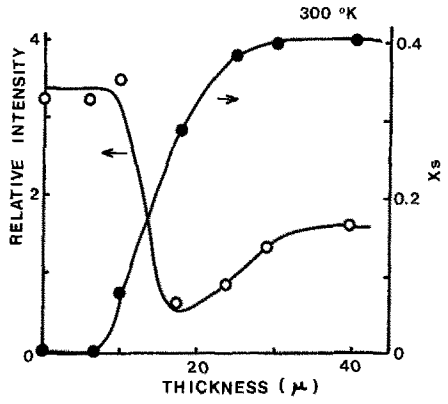

Fig. 5. Cathodoluminescent intensity or composition vs. epitaxial layer thickness.

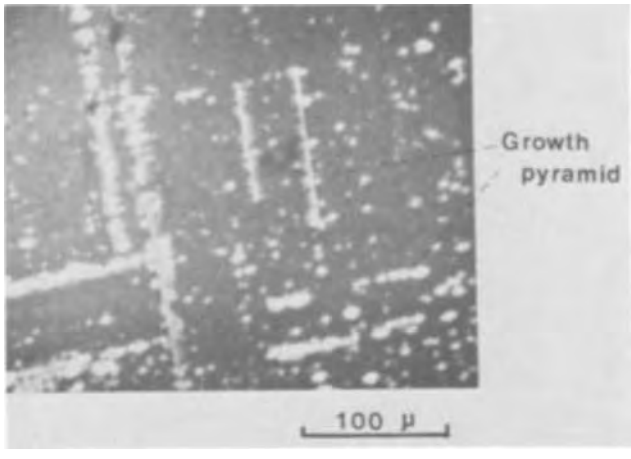

Fig. 6. Cathodoluminescent image of a $GaAs_{0.6}P_{0.4}$ surface

the misfit dislocations. A cathodoluminescent image of the epitaxial surface shown in Fig. 6 consisted of bright areas and dark areas. The bright areas where radiative recombination occurs more efficiently than the dark areas, correspond to the growth pyramids such as those shown in Fig. 4. The good crystal quality of the pyramids may be interpreted as a result of the reduction of misfit dislocations, which is caused by the stress-relaxation through the introduction of cracks at the bottom of the pyramids.

Diode characteristics.—Junction properties such as I-V and C-V characteristics were examined. The log I-V plot is linear for forward bias up to 1.3V with current varying as exp $(qV/2.3\ kT)$. The value 2.3 which is larger than 1.5 of commercial $GaAs_{0.6}P_{0.4}$ diodes, shows that almost all the carriers are consumed in the depletion layer and is not effective to produce electroluminescence. The C^{-2}-V plot is linear for reverse bias of 0-3V, indicating that the junction is abrupt. The built-in voltage and the depletion layer width calculated from the plot are 1.6 ~ 1.9V and 0.08 ~ 0.11μ, respectively.

A luminance of 43 ft-L at 8 A/cm^2 with an external quantum efficiency of 9×10^{-5} was obtained for a diode whose emission peaked at 6600Å. The efficiency was about an order of magnitude lower than the commercial $GaAs_{0.6}P_{0.4}$ diodes.

In order to examine the factors leading to reduced quantum efficiencies of the diodes prepared by pyrolysis, the forward current at 1.0V in the linear regions of log I-V plot, and the deep level impurity concentration (N_{TT}) in the depletion layer were measured. Figure 7 shows the relation between the forward current in the depletion layer and the quantum efficiency. The decrease of efficiency with the forward current means that the efficiency is reduced by the waste current, *i.e.*, the generation-recombination current in the depletion layer. The results for the deep

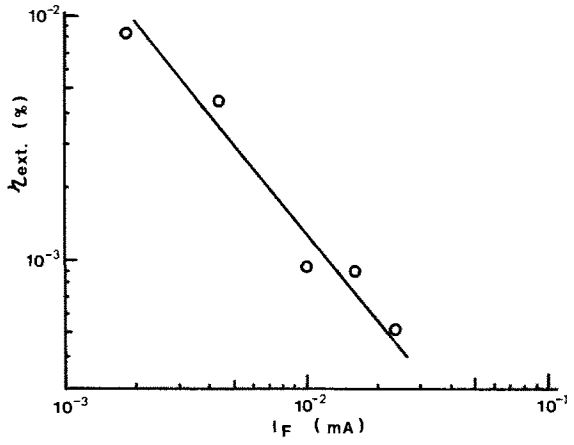

Fig. 7. External quantum efficiency vs. forward current at 1.0V. Diode area 0.25 mm².

level impurity concentration are shown in Fig. 8. The efficiency decreases rapidly with deep level impurity concentration. Deep levels may consist of lattice defects or impurities segregated at the lattice defects, related to the surface inhomogeneities shown in the cathodoluminescent image of the $GaAs_{0.6}P_{0.4}$ surface.

Conclusions

The $GaAs_{1-x}P_x$ epilayers to fabricate light emitting diodes were successfully prepared by the pyrolytic method. The main conclusions are as follows:

1. The epitaxial growth is primarily mass transport limited because the growth rate is independent of temperature and proportional to the $(CH_3)_3Ga$ concentration.
2. The phosphorus content in the epitaxial layer increases linearly with the increase of the phosphine content in the gas and the substrate temperature.
3. Apparent structural imperfections are found to be growth pyramids which generally originate in the graded layer and develop with the increase of the layer thickness.
4. The bright areas in the cathodoluminescent image of the layers correspond to the growth pyramids. The efficient cathodoluminescence may be ascribed to the reduction of lattice defects in the pyramids.
5. The external efficiency of the diodes is about an order of magnitude lower than the commercial diodes. The relatively low efficiency can be understood in view of the relatively large generation-recombination current and the substantial amount of the deep level impurity in the depletion layer.

Acknowledgments

The authors wish to thank Dr. Y. Otomo for his encouragement, Mr. S. Hosoki for measuring the cathodoluminescent spectra, and Dr. J. Umeda for his helpful suggestions and discussions.

Fluorescence Properties of Alkaline Earth Tellurates

S. Natansohn*

The Waltham Research Center of GTE Laboratories, Inc., Waltham, Massachusetts 02154

ABSTRACT

The emission characteristics of phosphors based on alkaline earth tellurates as host lattice are described. The fluorescence of hexavalent uranium in compounds of the formula M_nTeO_{3+n} with $n = 2$ or 3, was studied. The spectral energy distribution of the fluorescence is affected by the cationic species and crystal structure of the compound. Two of the more interesting phosphors are $Ca_3TeO_6:U^{6+}$ and $Ba_2TeO_5:U^{6+}$ which emit in the blue-green and orange region of the spectrum, respectively. The effect of structural variations on the nature of the emission center in uranium-activated phosphors is discussed.

The voluminous literature describing the fluorescence properties of a great number of inorganic compounds is conspicuous in its lack of reports on compounds based on oxyanions of hexavalent tellurium; yet these compounds are particularly suitable for the study of the fluorescence of hexavalent uranium in solids. The uranium activator is readily incorporated in the tellurate host lattice. Furthermore, in the course of this and previous work (1) it was found that the fluorescence intensity of U^{6+}-activated tellurates is significantly greater than that of the analogous tungstates or molybdates. The fluorescence characteristics of activated rare earth tellurates, R_2TeO_6, were reported previously (1). The current discussion is concerned with U^{6+}-activated alkaline earth tellurates of the formula M_3TeO_6 (M = Mg, Ca, Sr) and with Ba_2TeO_5. The synthesis of these materials was reported by Merz (2).

Experimental

These compounds were readily prepared by reacting the stoichiometric amounts of the appropriate reagent-grade alkaline earth carbonates with reagent-grade orthotelluric acid, $Te(OH)_6$, at elevated temperatures. The U^{6+} activator was added as the uranyl acetate. The reagents were reacted in silica crucibles in an oxidizing atmosphere at temperatures in the range of 1100°-1300°C for the Mg, Ca, and Sr compounds, and 800°-900°C for the Ba phosphors. Single-phase products were obtained after two or more heating steps with intervening mortaring.

The presence of the desired phases was confirmed by x-ray diffraction using Ni-filtered Cu-Kα radiation at a scanning speed of 1° (2θ)/min. Selected diffractograms used to establish the crystal class of the compounds were obtained at a scanning speed of ¼° (2θ) and ⅛° (2θ)/min and a silicon standard was used to calibrate the instrument. The chemical composition of certain compounds was established by analysis. The metal ion content was determined by gravimetric and/or x-ray fluorescence techniques while the oxygen content was determined by neutron activation analysis.

The method described by Amster and Wiggins (3) was used to obtain corrected emission and excitation spectra which are given in terms of relative energy *vs.* wavelength. The diffuse reflectance spectra were obtained on the Cary 14 spectrophotometer using $MgCO_3$ as a standard.

Results and Discussion

Compound identification.—The host compounds thus synthesized are well-crystallized, optically inert, and stable under ordinary conditions. The x-ray powder diffraction pattern of Ba_2TeO_5 (Table I) can be satisfactorily indexed on the basis of an orthorhombic unit cell or, by doubling one of the cell parameters, on the basis of a tetragonal unit cell of twice the volume (Table II). In the former case, the observed reflections are consistent with the space groups $Pna2_1$ or Pnma, while in the latter case the space group $P4_12_12$ is possible. Single crystals of Ba_2TeO_5 were not available to permit the unambiguous determination of the space group of the compound.

The crystal structure of Mg_3TeO_6 was recently the subject of study by several investigators (4) and it has been established as rhombohedral with the space group $R\bar{3}$. An earlier publication (5) reported that the crystal class of Ca_3TeO_6 is monoclinic with a space group $P2_1$ and that Ca_3TeO_6 is isostructural with Ca_3UO_6. The structure of Sr_3TeO_6 is related to that of Ca_3TeO_6. In the orthotellurates,[1] as in the Ca_3UO_6, the hexavalent ion is at the center of an octahedron formed by six oxygen ions.

The results of chemical analyses were consistent with the desired formulations. The amounts of constit-

[1] The nomenclature of Scholder (6) is used here which defines an oxyanionic "ortho" compound as one containing as many oxygen ions as the valence of the central ion in the anion complex.

Key words: luminescence, phosphors, uranium, calcium orthotellurate, barium pentaoxotellurate.

uents found in Ca_3TeO_6 were (weight per cent): 35.1% Ca, 37.0% Te, and 27.8% of O which is in excellent agreement with the calculated values of 34.97, 37.12, and 27.91% for the respective elements. The analysis of Ba_2TeO_5 showed this material to contain 56.6% Ba and 26.9% Te as compared to the calculated amounts of 56.96% for Ba and 26.46% for Te.

Luminescence properties of U^{6+}-activated M_3TeO_6.— Most intense fluorescence in these compounds is observed in uranium-activated calcium orthotellurate and barium pentaoxotellurate. The calcium orthotellurate, $Ca_3TeO_6:U^{6+}$, phosphor fluoresces brightly under a variety of excitation modes. Its emission spectrum at room temperature (Fig. 1) consists of a single band peaking at 501 nm with a halfwidth of 30 nm. The excitation spectrum (Fig. 2) shows a broad band peaking at 340 nm and another peaking at 280 nm so that the phosphor is responsive to both long and short wavelength uv radiation. The photoluminescent response of $Ca_3TeO_6:U^{6+}$ is among the most intense observed in uranium-activated phosphors and compares favorably with other uv-excited phosphors having similar emission spectra. The cathodoluminescent response of $Ca_3TeO_6:U^{6+}$ is about 40% that of Zn_2SiO_4:Mn. This is substantially better than that of other U^{6+}-activated phosphors, which are generally inefficient under cathode-ray excitation. The threshold voltage for cathodoluminescence is low, about 50V, and the luminescence decay time to 1/10 of I_0 is of the order of 1 msec.

The concentration dependence of the fluorescence intensity (Fig. 3) shows the critical concentration for quenching to be 2 a/o (atom per cent) for the phosphor in which the activator was formulated to substitute for the tellurium in the lattice ($Ca_3Te_{1-x}U_xO_6$)

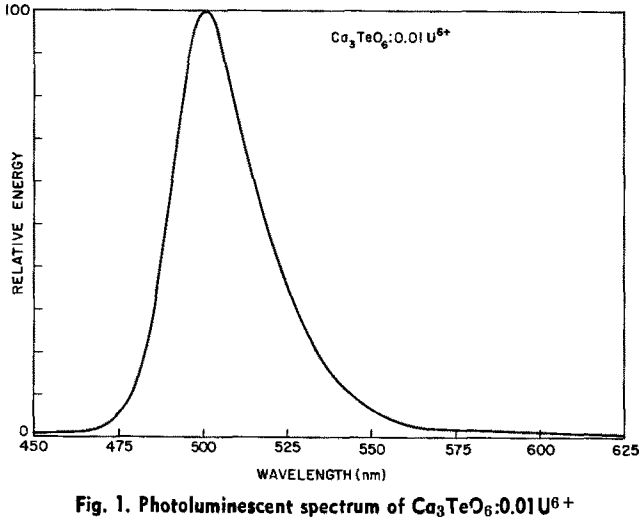

Fig. 1. Photoluminescent spectrum of Ca_3TeO_6:0.01 U^{6+}

and 0.75 a/o for the phosphor where no stoichiometric compensation was provided ($Ca_3TeO_6:xU^{6+}$). The former phosphor maintains the high efficiency of the photoluminescence response over much wider concentration range than $Ca_3TeO_6:xU^{6+}$, the luminescence of which is strongly dependent on activator concentration. The observed trends are consistent with the prevalent considerations of concentration quenching. Dexter and Schulman (7) and later Blasse (8) relate this phenomenon to the presence of quenching centers in the lattice, such as imperfections or impurities, at which the absorbed excitation energy is dissipated radiationlessly. The $Ca_3Te_{1-x}U_xO_6$ phosphor is likely to provide fewer lattice imperfections to serve as traps for the excitation energy and therefore its maximum fluorescence intensity is less concentration dependent than the noncompensated $Ca_3TeO_6:xU^{6+}$.

The green fluorescence of uranium-activated phosphors has been ascribed to the molecular uranyl ion UO_2^{2+} whose identity in a crystalline matrix may be preserved by having the uranium coordinated by two oxygen ions at a distance distinctly closer than that of the other oxygen ligands (1). Runciman (9) and then Blasse (10) state that the green emission can also be ascribed to an octahedrally coordinated uranium in a UO_6 emission center. In an attempt to elucidate the nature of the luminescence center in the compounds under investigation, the emission and excitation spectra were obtained at room and liquid nitrogen temperatures for Mg, Ca, and Sr orthotellurate and for calcium orthouranate, Ca_3UO_6, which is isomorphous with Ca_3TeO_6. As mentioned earlier, in each of these compounds the uranium activator is surrounded by six oxygen ligands in an octahedral configuration.

The fluorescence spectra of these compounds at room and liquid N_2 temperatures are shown in Fig. 4. At room temperature they all emit in the green spectral region; Mg, Ca, and Sr orthotellurates have reasonably symmetric emission bands peaking at 545, 501, and 530 nm, respectively, with the respective halfwidths of the emission band being 55, 30, and 35 nm. The fluorescence intensity of Mg and Sr orthotellurates, however, is only a fraction of that of the $Ca_3TeO_6:U^{6+}$. Calcium orthouranate, on the other hand, has a broad emission band skewed toward the red which peaks at 515 nm with a halfwidth of 50 nm. At liquid N_2 temperature the fluorescence spectra of the alkaline earth orthotellurate phosphors show sharp structure superimposed on the broad emission band. These sharp bands are most distinct in the $Mg_3TeO_6:U^{6+}$ phosphor and are similar to those observed by Blasse (10) in the $Y_6WO_{12}:U^{6+}$ compound. In fact, Newnham *et al.* (4c) established that the crystal structure of Mg_3TeO_6 is closely related to that of Y_6UO_{12} which in turn is isomorphous with Y_6WO_{12}. The space group of these compounds is $R\bar{3}$, with the hexavalent ion (U, Te, or W) being coordinated by six equispaced oxygens. This structural similarity is the probable reason for the close analogy between the de-

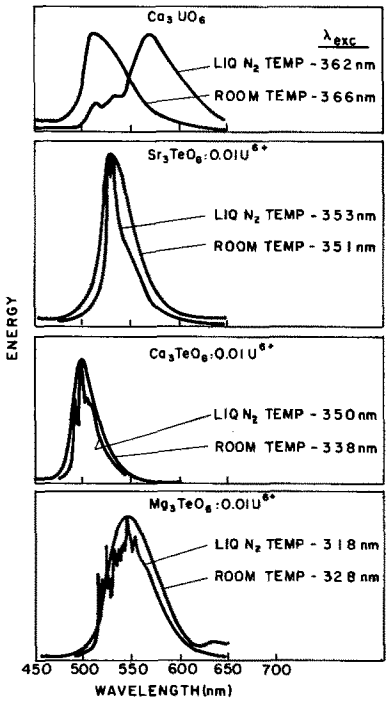

Fig. 4. Emission spectra of Ca_3UO_6 and of U^{6+}-activated M_3TeO_6 phosphors at room and liquid N_2 temperatures.

tail structure of the spectral energy distribution of U^{6+}-activated Mg_3TeO_6 and Y_6WO_{12} at liquid N_2 temperatures except that the emission of the latter is shifted toward lower energies.

The fluorescence spectra of the U^{6+}-activated alkaline earth tellurates at liquid N_2 temperature are resolved into a number of sharp bands, whose spacing is in most cases in the range of 40-210 cm^{-1} (Table III). Thus, $Mg_3TeO_6:U^{6+}$, has 12 clearly distinguishable spectral bands in the region of 515-558 nm. Blasse (10) identifies the emission center of $Y_6WO_{12}:U^{6+}$ as the UO_6 octahedron and in view of the aforementioned similarity of the spectra of $Y_6WO_{12}:U^{6+}$ and $Mg_3TeO_6:U^{6+}$, it is plausible to make the same assumption for the latter compound, the related alkaline earth orthotellurates and the calcium orthouranate. However, if one assumes a UO_6 luminescent center, then it is difficult to explain the drastic difference in the spectrum of the Ca_3UO_6 at liquid N_2 temperature when compared to those of the alkaline earth orthotellurates, particularly to that of the isostructural $Ca_3TeO_6:U^{6+}$. While there is no shift in the emission bands of the alkaline earth tellurates at liquid N_2 temperatures, the principal emission band of Ca_3UO_6 shifts from 515 nm at room temperature to 570 nm at liquid N_2 and the observed splittings are broader and more widely spaced. It has been established (11) that the uranium is in an octahedral coordination in Ca_3UO_6 although the six U-O coordinate bonds are not of equal length. If the green emission center of the aforementioned compound is the UO_6 group, then the spectral characteristics of the $Ca_3TeO_6:U^{6+}$ (or of the spectrally undistinguishable $Ca_3Te_{1-x}U_xO_6$) should be very similar to those of Ca_3UO_6, because Ca_3TeO_6 is isostructural with Ca_3UO_6 with the Te site being equivalent to the U site. But there is considerably more similarity among the spectral characteristics of the alkaline earth tellurates, although they are not all isostructural, than between Ca_3UO_6 and $Ca_3TeO_6:U^{6+}$.

543	18420						
549	18220						
551	18150						
557.5	17940						

It is possible to reconcile this difference by assuming a UO_2^{2+} emission center in the M_3TeO_6 compounds and a UO_6 emission center in Ca_3UO_6. An indication of the presence of a uranyl linkage may be obtained from an examination of the fluorescence spectrum of $Mg_3TeO_6:U^{6+}$ at liquid N_2 which resembles somewhat the series of strongest fluorescence bands of $CsUO_2(NO_3)_3$ obtained at 20°K (12). There are 14 of these bands between 479 and 571 nm and they have been interpreted as combinations of the resonance frequency ν_F and the frequencies ν_s, ν_a, and ν_b which represent, respectively, the symmetric, antisymmetric, and bending vibrations of the uranyl ion (13). A simple analysis of the observed splittings in the spectra of $Mg_3TeO_6:U^{6+}$ and $Ca_3TeO_6:U^{6+}$, such as done by Rabinowitch and Belford (12), can lead to $\nu_s \simeq 760$ cm^{-1}, $\nu_a \simeq 850$ cm^{-1}, and $\nu_b \simeq 200$ cm^{-1} for the two compounds. This is not unreasonable when compared to typical values of $\nu_s \simeq 810$-890 cm^{-1} and $\nu_a \simeq 860$-960 cm^{-1} measured on solid uranyl salts at 20°K (14). The ratio of ν_a/ν_s arrived at for Mg_3TeO_6 and Ca_3TeO_6 is 1.1 as compared to the theoretical value of 1.065 (15).

Luminescence properties of U^{6+}-activated Ba_2TeO_5.— The U^{6+}-activated Ba_2TeO_5 phosphor has an intense photoluminescent response in the orange-red spectral region. Its emission spectrum (Fig. 5) consists of a broad-band skewed toward the longer wavelength in which two maxima are discernible, at 590 nm and at 605 nm, with a composite halfwidth of 55 nm. Under cathode-ray excitation it is possible to distinguish a weak emission band in the green peaking at 520 nm in addition to the characteristic luminescence in the orange-red.

The red emission of uranium-activated compounds has been ascribed by Gobrecht and Weiss (16) and more recently by Blasse (10) to uranium tetrahedrally coordinated by oxygen, for example in a UO_4 complex. Although detailed structural data are not as yet available, it is possible that in the Ba_2TeO_5 compound the uranium, which is assumed to occupy a tellurium site in the lattice, is in the center of a UO_4 coordination tetrahedron.

The dominant excitation band of Ba_2TeO_5 is in the near ultraviolet, peaking at 375 nm, and therefore the phosphor is excited primarily by long wavelength ra-

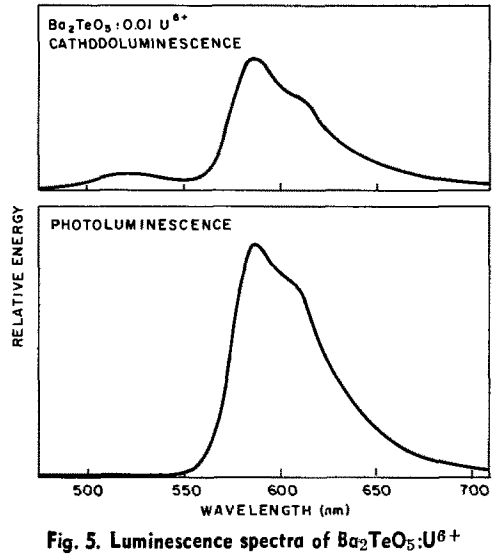

Fig. 5. Luminescence spectra of $Ba_2TeO_5:U^{6+}$

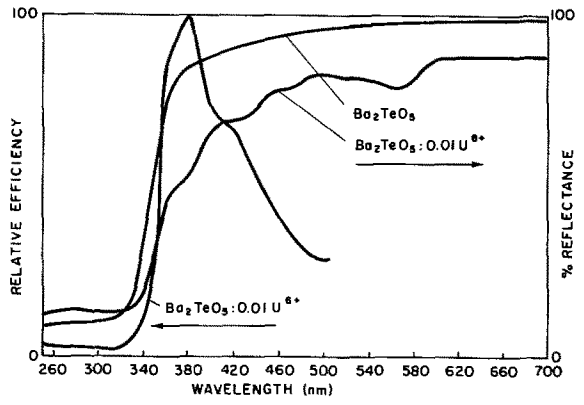

Fig. 6. Excitation and diffuse reflectance spectra of Ba_2TeO_5: U^{6+}.

diation. The comparison of the diffuse reflectance spectra of the unactivated and activated Ba_2TeO_5 (Fig. 6) shows that the presence of uranium results in several absorption bands in the visible and near ultraviolet region, the most intense of which is at 375 nm, the main excitation band of the phosphor. Thus it appears that the fluorescence results from direct excitation of the activator center rather than through energy absorption by the lattice and subsequent transfer to the activator site. The host compound absorbs strongly throughout the uv region where no excitation bands for the phosphor are found.

There are two experimental facts which indicate the strong effect of the crystalline environment on the spectroscopic properties of the U^{6+} emission. There is the substantial difference in the intensity of fluorescence between compounds in which the U^{6+} is formulated to substitute for the Te^{6+} ($Ba_2Te_{1-x}U_xO_5$) and those in which no stoichiometric compensation is provided (Ba_2TeO_5:xU^{6+}). The latter formulation is substantially brighter throughout the concentration range evaluated (Fig. 7) even though the excitation and emission spectra at room temperature are identical for the two formulations. The dependence of the fluorescence intensity on activator concentration shows concentration quenching at rather high U^{6+} content (2-5 a/o) in the Ba_2TeO_5:xU^{6+} phosphor, a concentration which is one to two orders of magnitude greater than that found in other red-emitting uranium activated phosphors.

It is noteworthy that the dependence of the fluorescence intensity on activator concentration in the barium pentaoxotellurate phosphor is contrary to that observed in the calcium tellurate and thus not consistent with the argument advanced earlier. As a first approximation one could assume fewer lattice imperfections in $Ba_2Te_{1-x}U_xO_5$ phosphor than in Ba_2TeO_5:xU^{6+} and thus one would expect higher efficiency and a higher value of critical concentration in the former material. However, the data show the Ba_2TeO_5:xU^{6+} phosphor to be substantially more efficient. The large difference in fluorescence intensity between

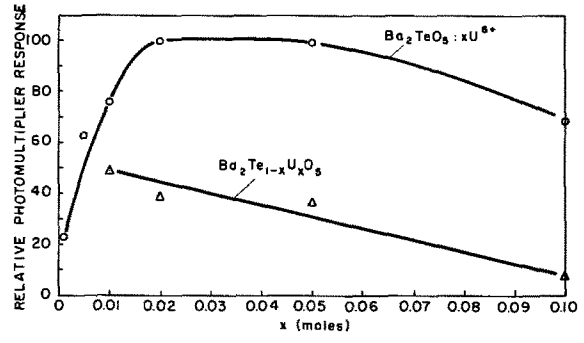

Fig. 7. Concentration dependence of the fluorescence intensity in U^{6+}-activated Ba_2TeO_5 phosphors.

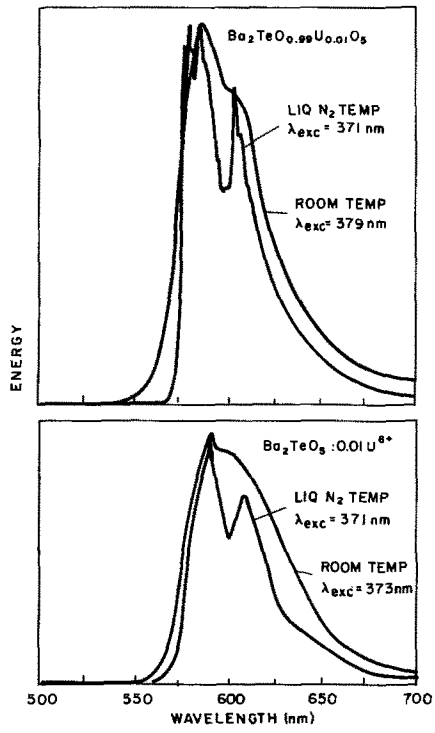

Fig. 8. Emission spectra of U^{6+}-activated Ba_2TeO_5 phosphors at room and liquid N_2 temperatures.

$Ba_2Te_{1-x}U_xO_5$ and Ba_2TeO_5:xU^{6+} phosphors implies a small variation in the nature of the activator center in the two compounds. This is also evident in the fluorescence spectra taken at liquid nitrogen temperature. While the spectroscopic data at room temperature are identical for the two materials, the emission spectra at liquid N_2 are slightly different (Fig. 8). The asymmetric RT emission curve of Ba_2TeO_5:$0.01U^{6+}$ is split at liquid N_2 into two bands whose peaks are separated by ~500 cm^{-1}. The fluorescence band of $Ba_2Te_{1.99}U_{0.01}O_5$ at liquid N_2 temperature also consists of two major bands separated by ~500 cm^{-1}; however, each of these has a distinct vibrational structure. Thus, there seems to be a tangible difference in the properties of these two virtually identical phosphors which probably is related to small changes in the ligand arrangement around the uranium activator. It is possible that some of the U^{6+} ions in Ba_2TeO_5:xU^{6+} are located in sites coordinated in a slightly different manner than the Te in Ba_2TeO_5 or may even be in interstitial positions. Such an arrangement would explain the absence of structure in the liquid N_2 spectrum of Ba_2TeO_5:xU^{6+}, because the contributions from various sites would tend to be superimposed; but it still would not account for the difference in the observed fluorescence intensities.

The conclusion reached here is that the knowledge of the spectroscopic behavior of uranium-activated phosphors is too scant to permit the unambiguous identification of the nature of the emission center. Such identification would necessarily have to reconcile all available experimental evidence which may superficially appear to be in conflict. It is hoped that the present work has contributed to stimulating this effort by posing some of the apparent questions.

Acknowledgment

The author gratefully appreciates the assistance of R. Francis in much of the experimental work, the spectroscopic measurements of S. Mosca, the analytical measurements of C. Persiani, W. Shelby, and R. Weberling, the diffuse reflectance spectra of E. Lanning, the helpful discussions with J. Baglio and the critical comments of F. Avella, T. Peters, F. Palilla, and O. Sovers.

Selective Silicon Epitaxy and Orientation Dependence of Growth

P. Rai-Choudhury* and D. K. Schroder

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15253

ABSTRACT

Silicon was grown epitaxially on oxidized silicon substrates in which the oxide was removed over selected areas. Both planar substrates and etched pedestals standing above the substrates were used. (110) oriented substrates had the highest growth rates, followed by (100), (115), and (111). (110) also had the grown surfaces with best planarity. Pattern displacement was very noticeable on (115) substrates. Alignment of the patterns with major crystal axes had a significant influence on the growth perfection. Some of the experimental observations can be explained by surface energy considerations.

Epitaxial layers of silicon are either grown over the entire wafer surface (nonselective growth) as in the case of the collector and/or base of a transistor, or grown selectively through an oxide mask as in the case of the silicon photodiode array (1, 2). In the past, device designers have paid little attention to the orientation of the starting substrate. For example, when compared with the (111) substrates, the deposition temperature could be lowered considerably by using (100) substrates without producing any increase in the defect density (3). We have succeeded in growing device quality epitaxial silicon on (100) substrates at temperatures as low as 900°C. One of the implications of this is to produce a very abrupt junction on degenerate substrates. In most transistor or integrated circuit applications the layer thickness is very much less than the substrate diameter and any faceting due to edge effects can be neglected. However, even for thin layers, selective buried layer resolution often becomes a problem due to pattern translation from faceting.

When the layer thickness becomes comparable to the size of the growth pattern, as in the case of silicon photodiode arrays, then faceting becomes very important. For example, the orientation of the substrate and hence the faceting determine the width-to-height ratio of the epitaxially grown material. In the application of this technique to diode arrays it is advantageous to have these "mushrooms" grow high with relatively little lateral growth, for good electron beam acceptance. Other applications may demand a high width/height ratio. The planarity of the surface and the geometric shape may be important for some device applications, and we show that the orientation has a major influence on these.

Key words: faceting, surface energy, alignment, silicon dioxide, masking.

Energetics and Nucleation Considerations

When epitaxial silicon is deposited from hydrogen reduction of $SiCl_4$ at about 1150°C in a conventional horizontal reactor, the orientation dependence of growth is not pronounced. For example, at a $SiCl_4$ partial pressure of 7×10^{-3} atm the growth rates on unmasked wafers varied as (111) : (110) : (115) : (100) :: 1.0 : 2.3 : 1.9 : 2.2. The relative growth rates on different orientation substrates do not change noticeably when HCl gas is injected for selective epitaxial growth, although a considerable decrease in the deposition rate is observed. The presence of excess HCl tends to favor the reverse reactions and probably causes the system to approach thermodynamic equilibrium. Thus, the selective epitaxial growth may be considered to be under isothermal and quasi-equilibrium conditions. It is well known that the crystals formed under these conditions are bounded, as much as possible, by the slowest growing surfaces (4). Therefore, in silicon, layers on different orientation substrates will eventually develop {111} facets under unconstrained growth.

Before presentation of the experimental results, a brief summary of the growth habits of different crystal faces and their relative stabilities is helpful. The main driving force in the development of different facets is the tendency for the crystal surface to approach minimum free energy configuration. The enthalpy, ΔH^{SV}, of the (111) face of silicon has been measured at liquid nitrogen temperature by Jaccodine (5) to be 1230 ergs/cm^2. From the measured enthalpy (which is equal to the energy, ΔE^{SV}, in this case), the Si-Si bond strength, and hence the surface energies of other orientations can be calculated. The surface energy values

for the orientations of interest here are given below:

Orientation	Surface energy, ergs/cm^2
(111)	1230
(110)	1510
(115)	1650
(100)	2130

Thus, at low temperatures, growth in the <111> direction will be minimized whereas in the <100> direction growth will be maximized. However, at the temperatures of interest here (T = 1400°-1500°K) the entropy term (ΔS^{SV}) becomes very significant and the observed order of stability of these planes is most likely to change. In fact, with a reasonable guess at the entropy values and considering the number of broken bonds per atom, it can be shown that at the growth temperature of 1500°K, (110) would be the plane of highest surface-free energy. The plane with high surface-free energy will tend to grow faster along its axis rather than generate new surfaces.

Recently, Sangster (6) has treated the crystal growth phenomena in III-V compounds in a qualitative manner much of which applies to the present case. If the growth is not constrained (by mass transfer rates and other operator variables), surfaces like the diagonal faces would grow very rapidly. When the face diagonal is perpendicular to the growth front, the growing interface would possess a great multitude of growth steps so that nucleation and growth could occur anywhere on the surface.

{110} surfaces.—Atoms in {110} surfaces are arranged in planar zigzag chains, each atom being bonded to two nearest neighbors in the chain with the remaining two bonds extending diagonally out on each side. Thus, each surface atom has one unsatisfied bond. The first deposited atom to start the formation of a new layer makes only one bond to the existing surface creating three dangling bonds. The net increase of two unsatisfied bonds forms a potential energy barrier for nucleation of growth of a new layer. Once the first atom is in place, other atoms can deposit adjacent to it without change in the number of unsatisfied bonds. Some inherent tendency towards maintenance of surface planarity exists, since deposition of part of a second new layer requires the presence of adjacent portions of two chains in the first layer. (110) plane might be relatively difficult to extinguish by the slow growing {111} faces since four of the six {111} planes are at right angles to the (110), while the other two {111} are at 35.26° from the (110). Thus, there are only two planes to extinguish the fast growing face.

{100} surfaces.—In a (100) surface, each atom is bonded to two atoms in the bulk and has two unsatisfied dangling bonds. A depositing atom can approach the surface and bond to two surface atoms leaving unsatisfied the other two bonds. Thus, atoms can be added to the surface without an increase in the surface energy. The four bounding {111} faces are at 54·74° from (100) and under optimum growth conditions (as will be shown later) will extinguish the (100) face in a rather well-defined manner.

{111} surfaces.—The {111} surfaces consist of two closely spaced planes of atoms. Each atom in one plane is bonded to three nearest neighbor atoms in the other plane. The fourth bond extends normal to the plane of this "double layer" and connects with an atom in the next such layer. Three-fourths of the crystal binding energy or cohesive energy is involved in the internal bonding of these double layer units. This is why the {111} face has the lowest surface energy. The depositing atoms can form only one bond each to a specific {111} surface. Addition of one atom causes the net creation of two unsatisfied bonds. Since no atom can bond both to this first one and to the existing layer, deposition of one atom does not allow subsequent barrier-free growth. For such to be possible, a second atom must attach itself to the existing layer as a second nearest neighbor of the first, again with a net increase of two unsatisfied bonds. Then a third atom can bond to the two nucleus atoms, and one of the first type from this one back to the underlying surface, without any increase in the number of dangling bonds, to generate a triangular structure. This two-dimensional nucleus is the smallest portion of the {111} double layer that can be stable. Thus, the difficulty of nucleation and the low surface energy of {111} faces are responsible for its slow growth rate and high stability.

{115} surfaces.—The (115) face makes an angle of 15 · 8° to (001). With $l \geqq 5$, (l is one of the Miller indices), the axes rapidly become indistinguishable from [001]. Thus, (115) face has two unsatisfied bonds per surface atom and can be treated very similar to the {100}.

Experimental Procedure

Epitaxial layers were deposited by hydrogen reduction of $SiCl_4$ in an rf heated horizontal reactor. In order to prevent growth over the oxide masked regions, a controlled amount of HCl was injected into the main gas stream (2). The substrates used were of (111), (110), (115), and (100) orientations, polished chem-mechanically to a damage-free surface. The substrates for the selective growth were prepared to provide two basically different geometries. One geometry consisted of small raised pedestals with oxide-passivated sides and these substrates were prepared by a process described by Appels *et al.* (7). Si_3N_4 was deposited on the silicon wafer and etched into square patterns. With the nitride as the etch mask, the silicon was etched to a depth of 4 μm. The etched regions were then oxidized and the nitride subsequently removed. This resulted in pedestals of dimensions 8 μm × 8 μm, which were oxide-passivated except for the top surface. In addition to these pedestals, there were some of the size 40

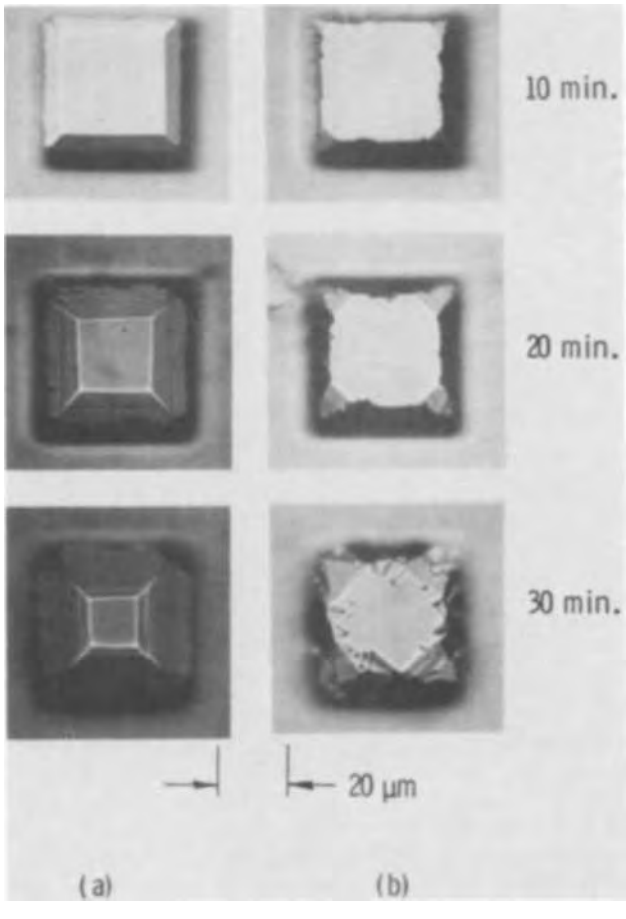

Fig. 1. Growth of silicon on 40 μm × 40 μm pedestals on a (100) substrate as a function of time. (a), sides of the square patterns aligned with {110} faces; (b), sides 45° off the {110} faces.

μm × 40 μm (see Fig. 1 and 2). Some of these pedestals were deliberately aligned with other crystal planes, *e.g.*, the sides of the square patterns on (100) wafers aligned with the {110} faces.

Substrates with the second type of geometry were prepared by simply oxidizing the silicon slices to a thickness of 1 μm and photolithographically opening windows in the oxide. No attempt was made here to align the patterns with any particular crystal faces.

Results

In conventional epitaxial growth, the layer thickness (typically 10-20 μm) is very much smaller than the substrate diameter (typically 3 × 10^4 μm) so that the boundary conditions of a semi-infinite body apply. That is, any growth facets that normally develop near the wafer edges can be neglected for all practical purposes. However, in selective epitaxy, the layer thickness is often comparable to the diameter of the growth plane, and therefore, the facets that normally initiate from the edges of the pattern cannot be overlooked. The relative stability of the different faces depend on their surface-free energies as mentioned earlier. In the following discussion, some results are presented showing how the initial growth planes are modified and the development of the low energy faces.

Figure 1 shows some photomicrographs of layers grown on etched square pedestals raised above the oxide-masked (100) surface, as shown in the insert of Fig. 3. When the sides of the square pedestals are aligned with {110} planes, four well-defined {111} facets develop from the four sides of the pedestal, as shown in Fig. 1(a). These {111} planes make an angle of 54·74° with the initial (100) plane. It can be seen from the photomicrograph of the layers grown for 30 min that a new set of faces is developing from the edges where the previous adjacent {111} faces failed to join. This type of faceting is also seen in Fig. 2(b),

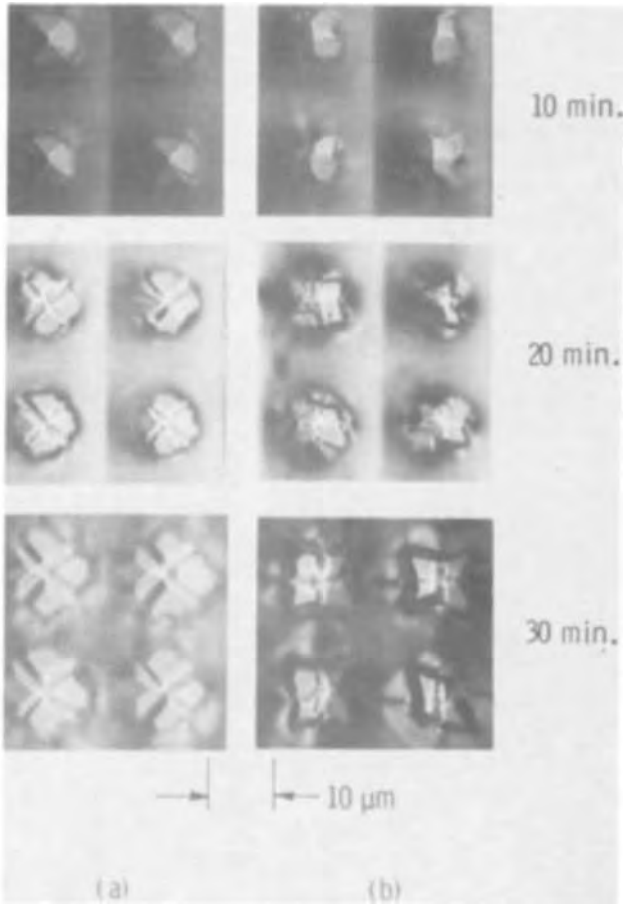

Fig. 2. Patterns on the same wafer as in Fig. 1, except that the dimensions are 8 μm × 8 μm. Alignment, same as in Fig. 1.

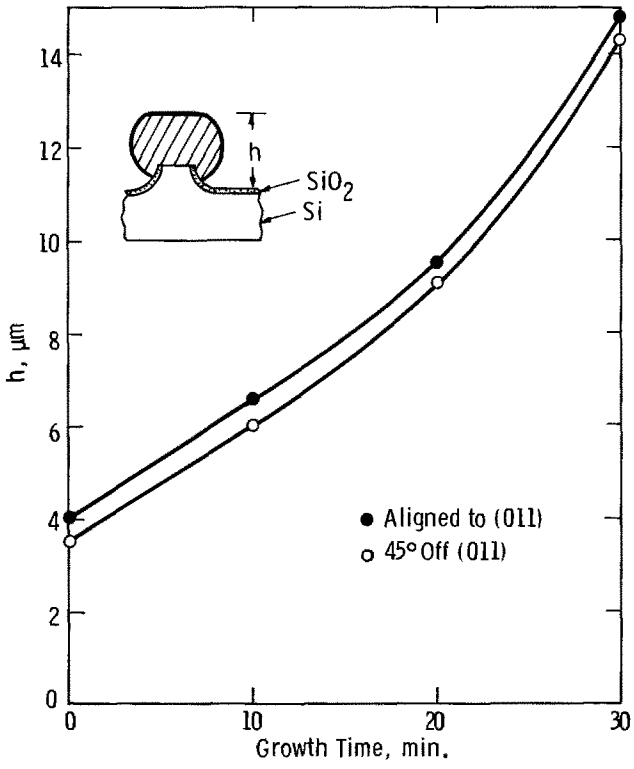

Fig. 3. Height of etched pedestal plus grown "bump" for the wafers of Fig. 1 and 2 as a function of growth time.

where here, the sides of the square are aligned 45° off the {110} planes.

The effect of multiple well-defined {111} facet development becomes more significant as the ratio of layer

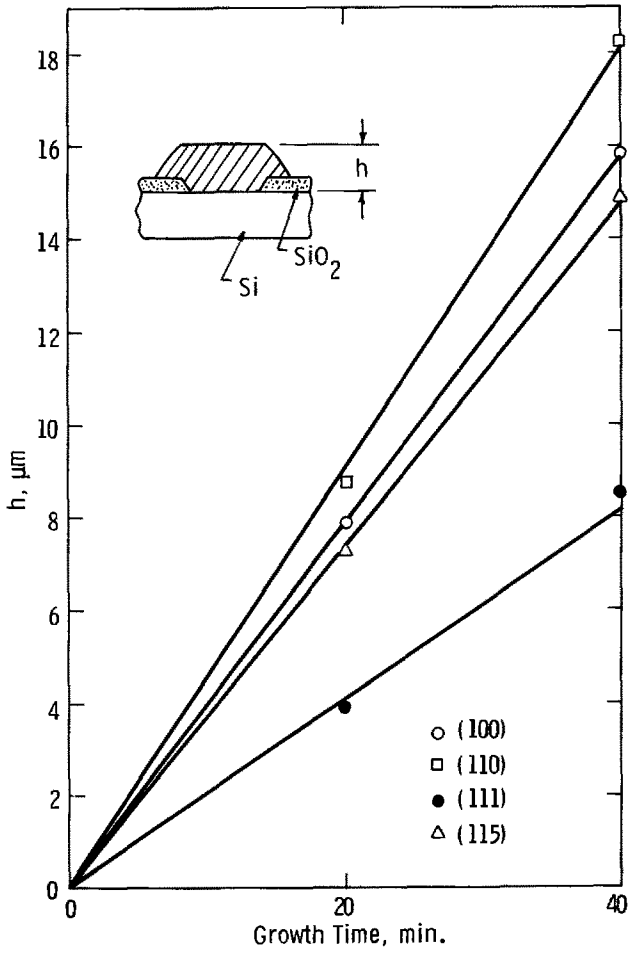

Fig. 4. Height of grown "bumps" on planar wafers as a function of time for 4 different substrate wafer orientations.

thickness to pedestal or pattern size increases. This is observed in Fig. 2, where the size of the pedestals is 8 μm $\times$ 8 μm, instead of 40 μm $\times$ 40 μm as in Fig. 1. Even for only 10 min growth time, we see the new sets of faces developing in the corners. These faces become much more obvious in the 30 min photograph in Fig. 2(a).

The random development of numerous facets is seen on the wafer where the sides of the squares are not aligned to the {110} planes [see Fig. 1(b) and 2(b)].

The growth rate of the patterned structures is not affected by the pattern alignment on a given substrate orientation. This is shown in Fig. 3 where the total pedestal height is plotted as a function of growth time. The heights of the small area structures (Fig. 2) were approximately the same as those of the larger area ones shown in Fig. 1. Note that at zero time the height corresponds to that of the etched, oxide-passivated pedestal alone. It appears that the growth rate increases as the pedestals grow higher. One possible explanation for this is that the high density of the small pedestals (1.5×10^5 cm^{-2}) in this pattern might be effective in increasing the turbulence near the wafer surface, in thinning the boundary layer for mass transfer, and/or making available higher concentration of $SiCl_4$ for growth by virtue of their raised position. These pedestals grow larger in diameter as well as reach further into the gas stream as the growth progresses. The growth rates on the pedestals were generally found to be somewhat less than that on similar density patterns on planar structures in which the patterns are etched windows in thermally grown oxide. This is expected since the pedestals form potential barriers for surface migration of any depositing species landing on the valleys. Thus, the results of growth on (100) wafers indicate that the surface planarity and the orientation of the initial pattern are lost at a very early stage of growth, which is consistent with the large difference in the surface energies between {100} and {111}. This has implications for some device applications where the growth height plus the initial etched pedestal height allow the top of the grown structure to be significantly above the oxide in the valleys.

With the objective of determining an orientation which grows further above the substrate surface without losing its identity and without touching its neighbors (to preserve the discrete nature of the structures), experiments were carried out on four different substrate orientations, namely, (100), (115), (111), and (110). Figure 4 shows a comparison of growth behavior on these four different orientations where the patterns for selective growth were formed by etching windows of the various shapes into the oxide of plane, thermally oxidized Si wafers, as opposed to raised pedestals. Also the sizes of the unmasked regions were much larger than those of the pedestal pattern. The ratio of the unmasked to oxide masked areas is 0.1 compared to 0.25 for the earlier "etched pedestal" wafers. As can be seen, no enhancement of growth with time is observed. (111) is the slowest growing plane which is consistent with its lowest surface energy and the associated nucleation difficulty. Because of the ease of nucleation

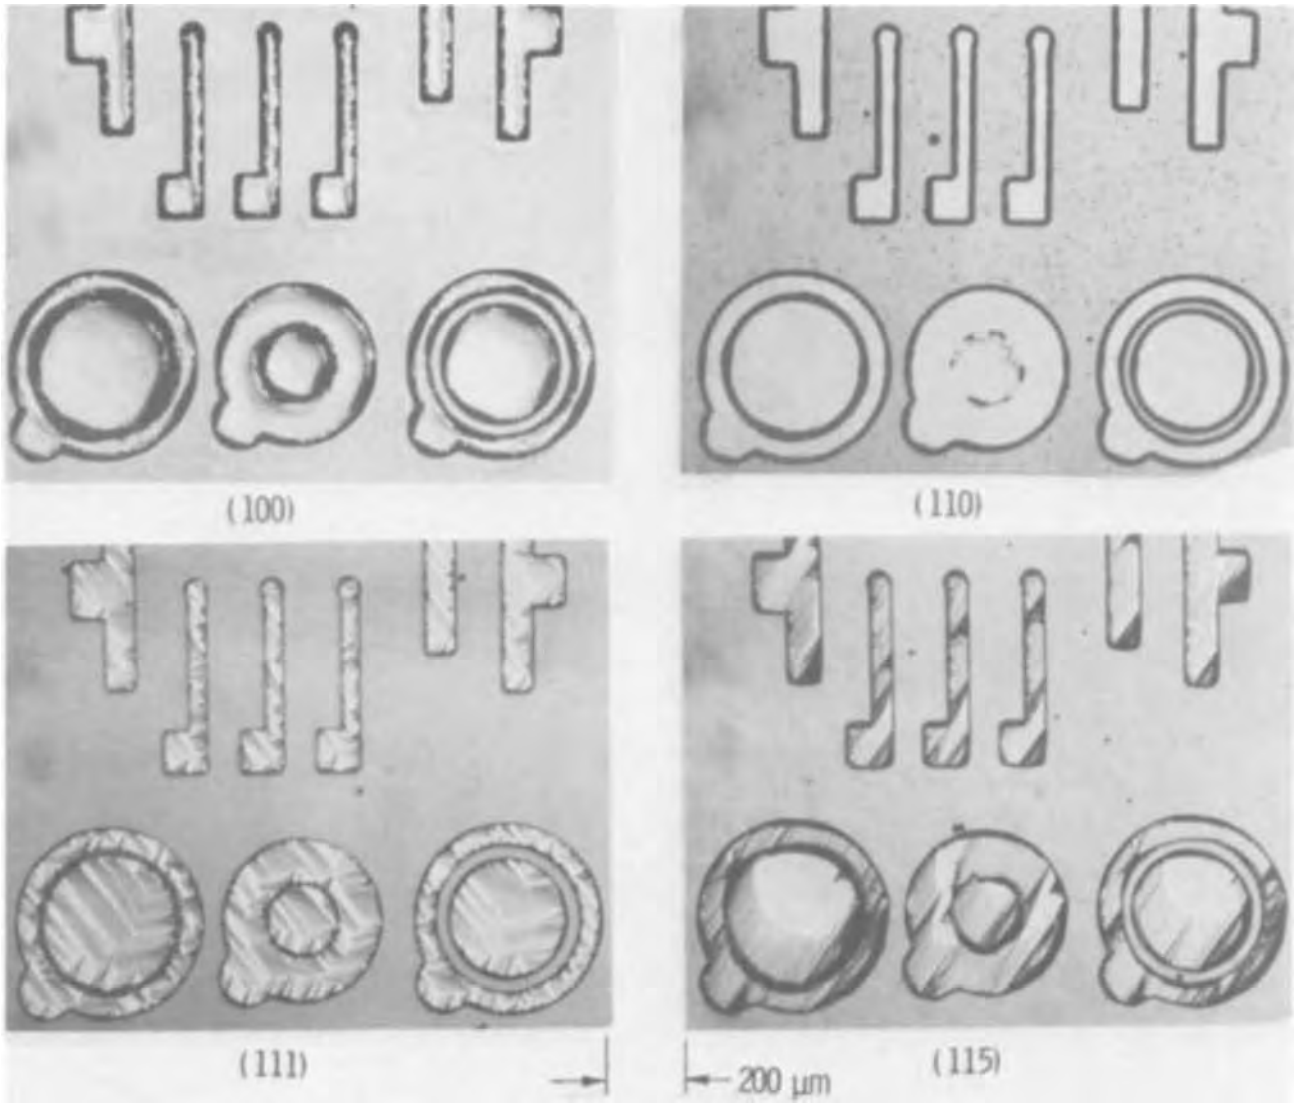

Fig. 5. Growth patterns on planar wafer of different orientations for a growth time of 40 min

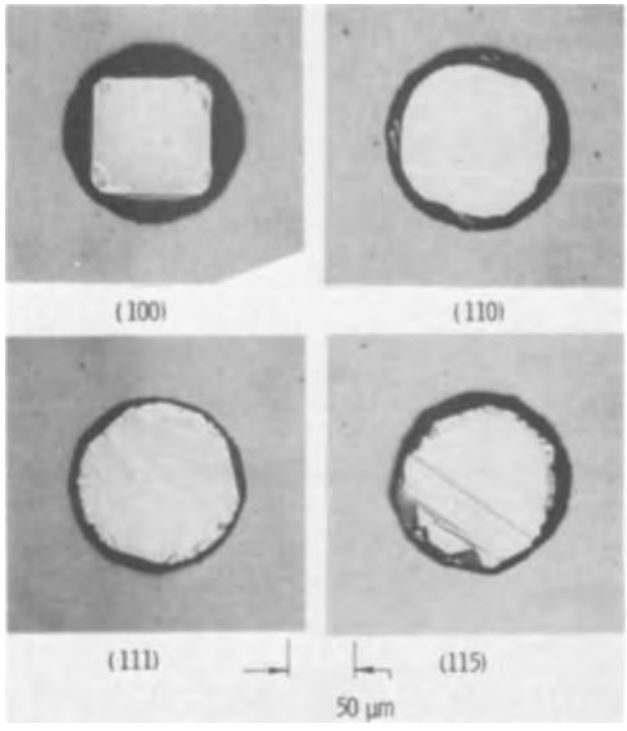

Fig. 6. Growth patterns on the same wafers as in Fig. 5 in circular oxide openings for a growth time of 40 min.

and high surface energy of the (100) plane, the growth rate on this plane is higher than that on (111). The (115) plane, being close to (100), encounters no nucleation difficulties and the growth proceeds at a rate slightly under that for (100). It is not obvious why (110) has the highest growth rate. The (110) plane has considerably lower surface energy than (100), and the nucleation is energetically not as favorable as in (100). One conjecture is that the {111} facets develop very early during the growth on (100), thus decreasing its effective growth rate. Whereas in (110) the {111} facets take considerably longer time before a significant portion of the growing (110) surface is transformed.

Figure 5 shows photomicrographs of the growth facets on the four orientations. It is noteworthy that the most planar growth occurred on the pattern on the (110) plane. This may be expected from the nucleation constraints and the availability of only two {111} faces that could extinguish the growing (110) as discussed earlier. The growth on (111) loses its planarity completely and new sets of {111} facets initially originating from the oxide-silicon interface are formed. The growth on (115) plane develops numerous {111} facets and a very distinct lateral translation of the patterns is noticeable. Therefore, in terms of pattern stability, their heights above the initial surface, and minimum interference from facet growth, (110) substrates are preferred.

The facet formation is especially evident in the photographs of Fig. 6. Here, the pattern was a 5 mil diameter circular window in the oxide. Note the square shape of the (100) orientation and the beginnings of the typical triangular configuration for the (111) substrate. The (110) again has the most planar top surface with the (100) next. As in Fig. 5, both (111) and (115) have very irregular top surfaces.

Summary

Silicon was epitaxially deposited selectively on silicon substrates, by using thermally grown SiO_2 as the mask. Both raised silicon pedestals with oxidized sides and planar surfaces were used. The effect of various substrate orientations and crystal face alignment on growth were studied with the following results:

1. The growth rate on planar structures is highest on (110) wafers and decreases in the order (100), (115), and (111).
2. The size of the area in which Si is grown has no noticeable influence on the growth rate.
3. The planarity of the growth surface is best for (110) and deteriorates in the order (100), (115), (111).
4. Alignment of the pattern with major crystal axes has an effect on the perfection of the grown patterns.
5. Pattern displacement is very noticeable for (115) oriented devices.

Acknowledgment

The authors would like to thank G. A. Gruber for the preparation of the silicon nitride films, W. Cifone and R. A. Wickstrom for assistance with the experiments.

Manuscript submitted Sept. 25, 1972; revised manuscript received Dec. 15, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Electrical Properties of a Native Oxide on Gallium Phosphide

S. M. Spitzer,* B. Schwartz,* and M. Kuhn*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A vitreous native oxide can be grown on GaP by oxidation in a concentrated solution of hydrogen peroxide, and this oxide effectively passivates GaP light-emitting devices. This paper reports the first electrical characterization of this native oxide. Electrical measurements were performed on MOS structures prepared by growing a native oxide film 500-1000Å thick on the $(\bar{1}\bar{1}\bar{1})$ face of an n- or p-type GaP wafer and evaporating an Au field plate on the oxide. The refractive index of the oxide film was 1.58. Current-voltage and capacitance-voltage characteristics show that the native oxide is an electrical insulator, with a low frequency dielectric constant $\epsilon \approx 5.5$, and a dielectric breakdown strength of 6-8 $\times$ 10^6 V/cm after annealing in nitrogen at 250°C. Current-voltage behavior shows a linear dependence of ln J on $E^{1/2}$, typical of field-enhanced thermionic emission. The I-V characteristics are nonsymmetric with respect to field plate polarity, suggesting the conduction mechanism to be surface-barrier-controlled emission, with a barrier height $\phi_b \approx 1.2$ eV, as determined from the temperature dependence of the I-V characteristics. The dielectric constant determined from the slope of the I-V characteristics by using a field-enhanced thermionic emission model agrees with the value obtained from capacitance measurements. Capacitance-voltage characteristics show accumulation and deep depletion behavior. Analysis of deep depletion curves yields a surface charge density $Q_s \approx 4 \times 10^{12}/cm^2$ for both p- and n-type GaP samples. Values of $|N_D - N_A|$ for the GaP substrates obtained from deep depletion data are in good agreement with the values obtained from Hall measurements on the substrate material.

Development of a technology for the fabrication of gallium phosphide light-emitting diodes requires a reliable method for the formation of insulating layers on the processed surface. Such insulating layers serve to electrically isolate and passivate active junctions, as well as to insulate metalization required for device interconnections. These layers should be pinhole-free, have good adherence to the GaP substrates, and be able to act as a processing mask, while being inert to subsequent processing steps. In addition such layers should have low optical absorption in order to be used in light-emitting diode structures.

The importance of electrically insulating layers has been amply demonstrated in the silicon planar device technology. For compound semiconductors, insulating layers of such materials as SiO_2 or Si_3N_4 may be deposited but these layers typically have had poor uniformity, high pinhole density, and poor adherence.

A native oxide has been grown on GaP (1) which exhibits good adherence, acts as a mask for the etching of GaP (2) and for metalization, and is transparent in the visible region. This oxide can be grown on p- and n-type material (3) by a relatively simple process occurring at ~100°C.

The electrical properties of the native oxide are reported in this paper. It is shown that this oxide is a good insulator, satisfying the electrical requirements for GaP processing. The sample preparation and oxidation procedure are described, as well as the electrical measurements and resulting experimental data. The electrical data are analyzed and the results discussed.

Sample Preparation and Oxidation

Gallium phosphide wafers were cut with a diamond saw from n-type Te-doped and p-type Zn-doped liquid-encapsulated-Czochralski-grown crystals of {111} orientation. Carrier concentrations were 1-4 $\times$ 10^{17} cm^{-3} for the n-type and 4-5 $\times$ 10^{17} cm^{-3} for the p-type samples. The wafer surfaces were prepared by lapping with 0.3 μm alumina and then etching 75 μm off the P $(\bar{1}\bar{1}\bar{1})$ face with a bromine-methanol solution for a final wafer thickness of 0.3 mm. A full-surface back contact was made to the Ga (111) face by evaporating 5000Å layers of Si-Au and Be-Au on n- and p-type wafers, respectively; a 10,000Å overlay of Au was subsequently deposited. These contacts were then alloyed at 600°C for 10 min to form ohmic contacts to the substrate.

A galvanic oxide was then grown on the $(\bar{1}\bar{1}\bar{1})$ faces of the GaP samples by boiling them in a concentrated solution of hydrogen peroxide for several hours and subsequently baking them in dry nitrogen at 250°C for 2 hr (3). This glassy oxide was found to be an amorphous mixture of Ga_2O_3 and P_2O_5. The thickness and refractive index of the oxide were determined by ellipsometry. The films used in this study ranged in thickness from 500 to 1000Å and after baking had an index of refraction $n \approx 1.58$ independent of thickness.

Electrical Characteristics

The electrical properties of the oxide films were investigated by means of measurements on metal-oxide-semiconductor structures prepared by evaporating 15-mil diameter Au field plates on the oxide. Contact was made by a W probe to the Au field plate and by a Pt base to the full-surface alloyed Si-Au or Be-Au back contact.

The dielectric breakdown strength of the oxide film at room temperature was measured by increasing the voltage across the MOS structure until the current underwent a sharp increase-limited only by external series resistance. For as-grown, unbaked films, breakdown occurred at electric fields of 0.5-2 $\times$ 10^6 V/cm. Since the oxide was grown in aqueous solution, water of hydration incorporated in the films was expected to reduce the dielectric strength. In order to verify this effect, the oxides were annealed in dry nitrogen at 250°C for 2 hr. During annealing the film thickness decreased by approximately 20% (3), the dielectric breakdown strength increased to 6-8 $\times$ 10^6 V/cm, and the index of refraction decreased slightly. Additional annealing at 250°C caused no further changes. The

physical properties of the oxide films before and after annealing are summarized in Table I.

Current-voltage measurements were taken on the MOS structures with the samples shielded from the light in a specimen holder flushed with dry nitrogen, in order to avoid photo-excited and surface-leakage current components. The *I-V* data were collected using a Keithley 602C electrometer and Lambda LS-515 digital voltage source in series with the MOS structure. Point-by-point, rather than continuous, measurements were taken to minimize any error due to lengthy response time of the electrometer and to conveniently cover the large range of current.

At room temperature the current through the oxide for applied voltages below breakdown is too small for detection ($<10^{-13}$ A/cm^2). However, the conductivity was found to be strongly temperature dependent, and *I-V* characteristics could be measured at temperatures in the range of 75°-150°C. The data were checked for reproducibility on the same sample and on different samples. All results in this temperature range were found to be consistent, indicating that sample hysteresis or drift was not a serious problem. A typical family of *I-V* curves obtained for an MOS structure incorporating an annealed oxide film is shown in Fig. 1. The current is asymmetric with respect to bias polarity and depends strongly on voltage and temperature. Analysis of these data to determine the mechanism for current transport through the oxide are given in the Section on Discussion. *I-V* measurements were not made at temperatures above 150°C owing to an experimental limitation. This limitation has now been overcome, and the results of higher temperature measurements will be reported later.

The properties of the oxide films, as well as those of the GaP oxide interface, were also investigated by capacitance-voltage measurements on the MOS structures. The *C-V* characteristics at 1 mHz for MOS structures on both n- and p-type GaP substrates show accumulation and deep depletion behavior. A typical *C-V* curve at room temperature for an n-type substrate is shown in Fig. 2. The low-frequency dielectric constant calculated from the accumulation capacitance and film thickness is $\epsilon = 5.4$. Surface inversion due to minority carrier generation could not be observed at room temperature using voltage sweep rates (4, 5) as low as 10 mV/sec, unless the sample was illuminated with a tungsten lamp. Pulsed capacitance measurements were made at room temperature in an attempt to determine bulk and surface minority carrier generation rates by using the Zerbst (6) analysis technique. Generation rates on the order of tens of hours were measured. While such slow minority carrier generation is to be expected with wide bandgap semiconductors, additional analysis of the temperature dependence of pulsed capacitance will be required to relate these generation rates to bulk minority carrier lifetimes and surface recombination velocities at the semiconductor-oxide interface.

Ramp measurements (7) were made at 250°C to determine whether the oxide exhibits ionic instabilities similar to those caused by Na or K in SiO_2 (8), which give rise to well-defined ionic current peaks about zero bias in SiO_2-on-Si MOS structures (7). Such peaks were not observed in the present experiments, suggesting that this kind of fast ionic drift does not occur in the oxide on GaP at temperatures below 250°C. In addition, *C-V* curves were measured before and after bias-temperature stress experiments performed at 200°C and ±15V for 30 min. No significant changes in flatband voltage were observed, again suggesting that the oxide is relatively free of mobile ion contamination.

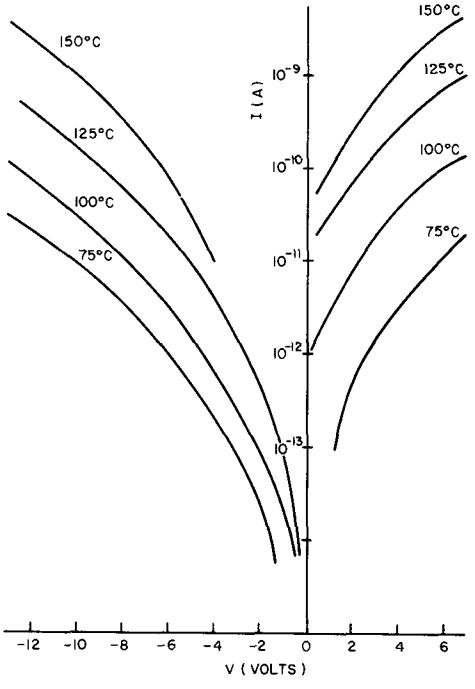

Fig. 1. Current-voltage characteristics of Au-native oxide-GaP structure. Substrate is Te-doped $\approx 3 \times 10^{17}$/cm^3 with a 500Å thick native oxide. (Sample RD269-2E, Table I).

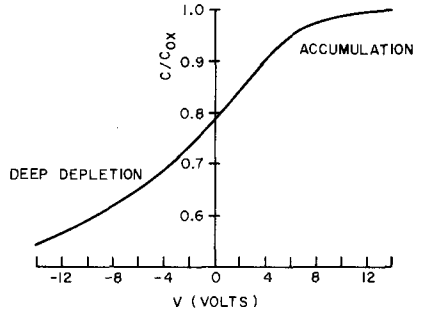

Fig. 2. Capacitance-voltage characteristics of Au-native oxide-GaP structure at room temperature. Oxide capacitance is 112 pF for 15 mil diameter Au field plates. (Sample RD269-2E).

Discussion

Current-voltage characteristics.—Current flow through an insulating oxide can take place by several different conduction mechanisms (9). These mechanisms include ionic conduction, ohmic conduction, tunneling, field emission, and field-enhanced thermionic emission either over an interfacial barrier (Schottky-Richardson mechanism) or from localized coulombic traps in the oxide (Frenkel-Poole mechanism).

In the Section on Electrical Characteristics, the discussion on ionic drift suggests that ionic conduction is not significant here. Furthermore, an ionic current would be expected to decay in time with constant applied bias, but no such decay is observed. Ionic conduction can therefore be eliminated as a significant transport mechanism for these samples.

The nonlinear, asymmetric *I-V* characteristics (Fig. 1) preclude ohmic conduction, and their strong temperature dependence precludes tunneling. The relationship between current and voltage calculated for the Schottky-Richardson (SR) and Frenkel-Pool (FP) (10) mechanisms are given by Eq. [1] and [2], which are quite similar in form, but the barriers are different, *i.e.*, an interfacial barrier and a coulombic potential well, respectively.

$$J_{SR} = A^*T^2 \exp\left[-q(\phi_b - \sqrt{qE/4\pi\epsilon_{ox}})/kT\right] \quad [1]$$

$$J_{FP} = CE \exp\left[-q(\phi_b - \sqrt{qE/\pi\epsilon_{ox}})/kT\right] \quad [2]$$

where A^* = effective Richardson constant, ϕ_b = barrier height, ϵ_{ox} = dielectric constant of oxide, and C = constant, independent of field and temperature. The experimental *I-V* data are consistent with the form of either equation, as shown by the linear plots of *I/V* and *I vs.* $E^{1/2}$ shown in Fig. 3 for one of the MOS structures.

FP emission is a bulk process and would be expected to exhibit symmetric *I-V* characteristics, while the SR mechanism is dependent on the barrier height at the metal-oxide or semiconductor-oxide interface, and the current would then be quite polarity dependent. The observed, asymmetric *I-V* characteristics suggest that conduction occurs via the SR mechanism.

Equations [1] and [2] can be used to obtain alternative values of the high frequency dielectric constant, ϵ_{ox}, from the slopes of the two lines in Fig. 3. Using the SR model (*I vs.* $E^{1/2}$), $\epsilon_{ox} = 5.53$ is calculated, a value one-fourth that determined from the FP model (*I/E vs.* $E^{1/2}$), $\epsilon_{ox} = 22.12$. It is expected that the high frequency value of ϵ_{ox} should approximate $(n)^2$, *i.e.*, 2.5, according to the Maxwell relation. The fact that the calculated ϵ_{ox} for the SR mechanism is closer to the high frequency value than ϵ_{ox} for FP emission, along with the observation that the SR value of ϵ_{ox} is close to the 1 mHz (low frequency) value of ϵ_{ox} as determined from *C-V* data, provides another indication that conduction through the oxide occurs via the SR mechanism.

The effective barrier height (assuming SR) controlling current flow, *i.e.*, the interfacial barrier ϕ_b reduced by the applied electric field due to Schottky lowering, was determined from an Arrhenius plot of ln I/T^2 *vs.* $1/T$ as shown in Fig. 4, at applied electric fields of 2 and 10 $\times$ 10^5 V/cm, by using Eq. [1]. By adding the estimated Schottky lowering, $(qE/4\pi\epsilon_{ox})^{1/2}$, the interfacial barrier was found to be $\phi_b \approx 1.2$ eV (for the sample of Fig. 4) for both positive and negative field polarity. This apparent discrepancy between symmetric barrier height and nonsymmetric *I-V* characteristics is explained in terms of the experimental uncertainty in determining ϕ_b ($\pm$40 meV) and the relatively small difference in barrier heights (5-20 meV) required to produce such *I-V* data. For a barrier height of ~1.2 eV, the incremental room temperature resistivity would be expected to be on the order of 10^{19} ohm-cm. Thus any current measured at room temperature would result from surface leakage or from the measurement instrument.

Capacitance-voltage characteristics.—As discussed in the Section on Electrical Characteristics, the capacitance-voltage characteristics show both accumulation and deep depletion behavior. Deep depletion results from the very long minority carrier generation times, while the more familiar inversion behavior is observed in semiconductors with fast generation rates (Ge, Si, GaAs). The relation between capacitance and voltage for deep depletion (11) is given by

$$(C_{ox}/C)^2 - 1 = (C_{ox}/A)^2 \frac{2}{qN\epsilon_s}(V - V_{fb}) \quad [3]$$

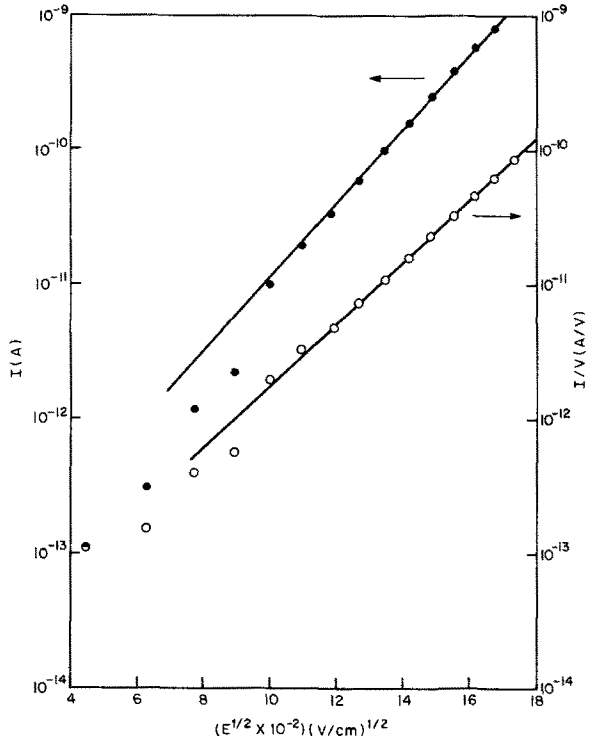

Fig. 3. Plot of *I* and *I/V* vs. $E^{1/2}$ obtained from *I-V* data of Fig. 1 with negative voltage applied to field plate at 125°C.

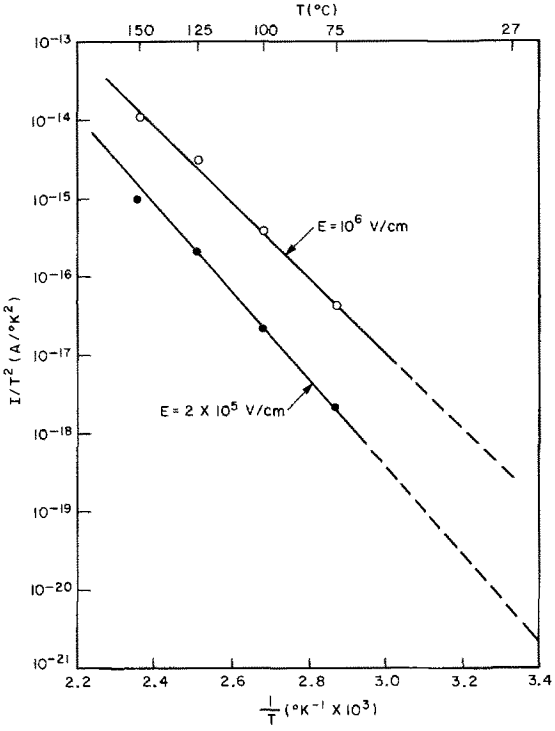

Fig. 4. Plot of I/T^2 vs. $1/T$ obtained from *I-V* data of Fig. 1 with —5V and —1V applied to field plate.

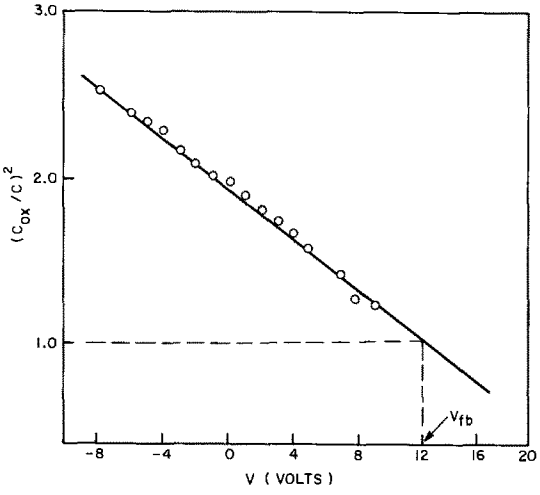

Fig. 5. Plot of $(C_{ox}/C)^2$ vs. V obtained from C-V data of Fig. 2

where C_{ox} = oxide capacitance as determined from MOS capacitance-voltage measurement in the accumulation region, A = field plate area, N = net carrier concentration $|N_D - N_A|$ in the semiconductor, ϵ_s = low-frequency dielectric constant of the semiconductor, and V_{fb} = flatband voltage.

If a plot of $(C_{ox}/C)^2$ *vs.* V is constructed from experimental C-V data, Eq. [3] can be used to obtain values of $|N_D - N_A|$ and V_{fb}. This determination of $|N_D - N_A|$ is independent of Hall data, and thus provides a consistency check. The surface charge density, Q_s, may be calculated from

$$Q_s = CV_{fb}/Aq \qquad [4]$$

A typical plot of $(C_{ox}/C)^2$ *vs.* V for a MOS structure on an n-type GaP substrate (sample RD269-2E, Table I) is shown in Fig. 5. The value of $|N_D - N_A|$ obtained from this plot, $3.17 \times 10^{17}/cm^3$, agrees within 20% with the value determined by Hall measurements on the GaP substrate material. From this plot V_{fb} is found to be 12V, corresponding to a surface charge density, Q_s, of $7 \times 10^{12}/cm^2$. Similar values were found for structures on p-type substrates (see Table I). With such large V_{fb} values, only MOS structures incorporating oxide films with relatively high dielectric breakdown strength can be biased into accumulation. If the breakdown strength is too low, as in films that have not yet been annealed, the devices go into breakdown before accumulation is obtained, making surface-state analysis quite difficult. The similarity in V_{fb} values (with a polarity change) for p- and n-type samples and the constancy of V_{fb} under temperature and bias stress suggest that the rather large surface charge density may be due to interface states rather than to mobile ions or fixed charge. It should be noted that the presence of interface states could influence the polarity dependence of the I-V characteristics. Such effects will be reported in future efforts.

Conclusions

This paper describes the electrical properties of a galvanic native oxide grown on n- and p-type GaP. This oxide is an electrical insulator, having a relative dielectric constant $\epsilon \approx 5.5$, which exhibits a dielectric breakdown strength of $6\text{-}8 \times 10^6$ V/cm after annealing in nitrogen at 250°C. Conduction in MOS structures incorporating the oxide appears to proceed via field-enhanced thermionic emission over a barrier $\phi_b \approx 1.2$V, which is believed to be an interfacial barrier at the oxide-semiconductor interface. A large surface charge density, $Q_s \approx 4\text{-}8 \times 10^{12}/cm^2$, has been found; it is attributed to interface states rather than mobile ion contamination or fixed charge. These initial findings suggest that the native oxide should serve a valuable function in GaP device technology.

Acknowledgments

We are grateful to R. C. Manz, R. A. Furnanage, and A. J. Sayko for sample preparation and oxidation. We wish to thank G. D. Weigle for his help in performing some of the electrical measurements and W. J. Sundburg for measurements of film thickness and index of refraction.

Manuscript submitted July 25, 1972; revised manuscript received Dec. 27, 1972. This was Paper 292 presented at the Miami Beach Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Etch Pit Studies of GaP Liquid Phase Epitaxial Layers

G. A. Rozgonyi* and T. Iizuka[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In investigations of the influence of defects on the luminescence properties of compound semiconductors, the relative importance of purely structural defects, *e.g.*, dislocations, *vs.* imperfections of a chemical or stoichiometric nature, such as impurities, vacancies, etc., is invariably discussed. Recent photoluminescence studies on GaAs and GaP have shown that dislocations are an important factor only if they are decorated with impurities. For GaP the decorated dislocations only occur when there is also present another type of etch feature called a saucer or S-pit. In the present report further comparisons of dislocations and S-pits are made in GaP material typical of that used in electroluminescent devices made by liquid phase epitaxy (LPE). The etch pit studies on LPE material have been examined in terms of using S-pits as an observable in evaluating the device potential of different LPE layers.

A continuing area of study in semiconductor device materials has been in evaluating the relative importance of purely structural defects, *e.g.*, dislocations, *vs.* imperfections of a chemical or stoichiometric nature, such as impurities, vacancies, etc., or complexes of different types of these defects. This question has arisen often recently by workers describing possible nonradiative recombination centers which affect the electroluminescence (EL) and photoluminescence (PL) efficiencies (η) of GaP liquid phase epitaxial (LPE) layers (1-3) and liquid encapsulated Czochralski (LEC) (4-6) and solution grown (SG) substrates. With the advent of the chemical etch pit-optical microscopy studies first described by Iizuka (7), and subsequently used by Rozgonyi and co-workers (5, 6), it has been possible to differentiate between dislocation, or D-pits, and another type of etch feature which is referred to as a saucer or S-pit. Although the nature of the defect or defect-impurity complex responsible for the formation of the S-pits has not been identified, it has been demonstrated that a reduction in S-pit density can be correlated with improved PL η, while the D-pits play a secondary role in the evaluation of GaP LEC substrates (5, 6). The object of the present report is to make a similar comparison of S- and D-pits in GaP LPE layers and LEC and SG substrates to see if the correlation with EL η is the same. Thus, by using the S-pits as an observable in characterizing the luminescence behavior of GaP, further information about the possible behavior of nonradiative centers will be described.

Experimental Procedures and Etch Pit Characteristics

The samples used in this study consisted of LPE layers grown by Saul (8) on the $(\bar{1}\bar{1}\bar{1})$ P-face of LEC substrates pulled by Nygren *et al.* (9), or on SG platelets provided by L. Derick. Both n (Te-doped) and p (Zn, O doped) type layers and substrates were examined. Initially, all the optical studies were performed on $(\bar{1}\bar{1}\bar{1})$ P-surfaces which had been chemically polished. However, angle lapping at 2° to the $(\bar{1}\bar{1}\bar{1})$ P-face was later found to be more advantageous since the layer and substrate could be studied simultaneously on the same sample. Damage due to lapping was removed by etching the sample for 30 sec in chlorine-saturated methanol prior to the actual pit delineation etch. The etching solutions used were the same as those previously described by Saul (10) and by Iizuka (7). Table I describes the solutions, etching times, and temperatures, and range of applicability of each etch. The AB and RC designations are used since these solutions are modifications of etches originated by Richards and Crocker (11) and Abrahams and Buiocchi (12). Examination of the etch pits was carried out in a Zeiss interference contrast microscope, and occasionally in a scanning electron microscope (SEM).

Table I. Etching solutions used for delineating S- and D-pits in GaP

Etch, Ref.	Solution	Temp and Time	Comments
RC, Ref. (11)	8 ml H_2O, 4 ml HF, 6 ml HNO_3, 10 mg $AgNO_3$	4 min at 65°C	Can be used on $(\bar{1}\bar{1}\bar{1})$ P face of either p- or n-type GaP
Ref. (10), (12)	10 ml H_2O, 8 ml HF, 5g CrO_3, 40 mg $AgNO_3$	50 min at 65°C	Best for $(\bar{1}\bar{1}\bar{1})$ P face of p-type material, or for delineating dislocation grooves on $(1\bar{1}0)$ cleavage faces of both p- or n-type GaP

The difference between S- and D-pits is illustrated in Fig. 1. The identification of the pits is quite straightforward, D-pits have an apex or point and tend toward a triangular shape typical of {111} surfaces, while S-pits are shallow, round, and flat-bottomed, see arrows D and S in the optical photomicrograph shown in Fig. 1a. The D-pits are generally ~10μ in diameter while the S-pits vary in size from ~1μ to slightly less than the size of the D-pits. Figure 1b is an SEM

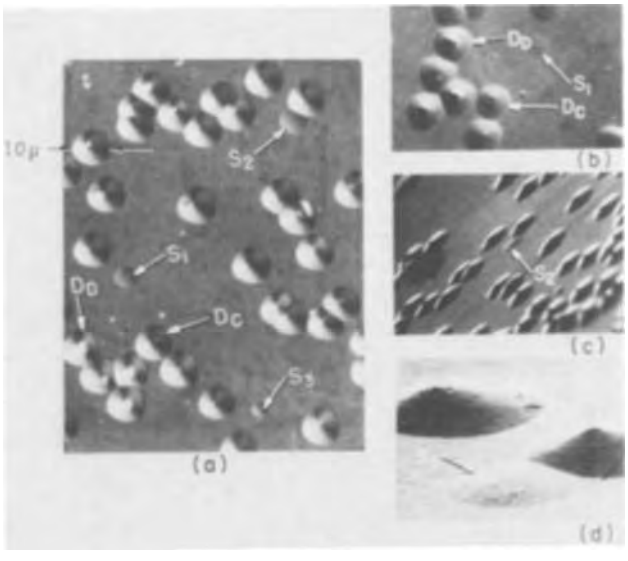

Fig. 1. Identification of saucer and dislocation pits in a GaP LPE layer. (a) Optical photomicrograph illustrating S-pits, see arrows S, and clean and decorated D-pits, D_c and D_d, respectively. (b) SEM photo with field of Fig. 1a rotated ~60° clockwise. Incident beam ~80° to surface. (c) SEM photo of S_2 with incident beam ~10° to surface. (d) Higher magnification SEM view of S_2.

photomicrograph of the same area taken at an incident beam angle of ~80° to the surface. Note that because the S-pits are shallow and the local secondary electron yield does not differ from the host crystal the contrast at the S-pits is very poor. However, using an incident beam angle of ~10° shadows the pits quite nicely as shown in Fig. 1c and d. Actually, the SEM photographs do not give any more information about the S-pits than can be obtained with interference contrast microscopy. However, the SEM does enable us to look inside the D-pits. It has, therefore, been possible to distinguish between what we have designated as a clean D-pit, *i.e.*, one that has smooth sides and undergoes no geometric discontinuities from the edge of the pit down its walls to the apex, see arrows D_C; and a decorated D-pit, see arrows D_D for the somewhat knobby and irregular appearance of decorated D-pits. It has been shown (6) that decorated D-pits are generally found in material containing a high density of S-pits, while clean D-pits occur when the S-pits are reduced or eliminated. These simple etch features will now be compared in GaP material typical of that used to fabricate red-emitting EL diodes.

Experimental Results

N-type LEC substrates and LPE layers.—The results of the etch pit analysis of an LEC substrate, tellurium doped to 3×10^{17} cm^{-3}, are presented in Fig. 2a. Three classes of surface features are to be found in this photomicrograph; they are: (*i*) a moderately high ($\sim 1 \times 10^5$ cm^{-2}) density of deep, tripyramidal-shaped, decorated dislocation etch pits, see arrows D, (*ii*) a high density (greater than 1×10^7 cm^{-2}) of shallow, flat-bottomed, saucer-shaped etch pits, see arrow S, and, (*iii*) regions surrounding D-pits which are denuded of S-pits, presumably due to depletion of impurities by incorporation into nearby dislocations (5, 7).

Figure 2b is the etched surface of an LPE layer grown on a substrate from an adjacent wafer of the same LEC ingot shown in Fig. 2a. The LPE layer was n-type, tellurium doped to $\sim 1 \times 10^{18}$ cm^{-3} at its outer surface. Note that the density of S-pits has been reduced by three orders of magnitude compared to that in the substrate. In addition, a comparison of the D-pits in Fig. 2a and b shows that the pits in the LPE layer are definitely of the clean variety. Of the more than 20 n-type LPE layers examined the great majority had an S-pit density of $\sim 1 \times 10^3$ cm^{-2}, however, several had a zero or vanishingly small number of S-pits. Note that the S-pit density in the LPE layer has been reduced even though the tellurium concentration was increased by a factor of three or four over that in the LEC substrate. This is to be contrasted to the results of Iizuka (7) who studied n-type LEC substrate material and found that the S-pit density was reduced only in undoped LEC samples.

P-type LEC substrates and LPE layers.—The etch pits typical of zinc-oxygen doped p-type LEC material with a carrier concentration of $\sim 1 \times 10^{18}$ cm^{-3} is shown in Fig. 3a. Whereas the S-pit density in n-type LEC substrates was always greater than 1×10^7 cm^{-2} the p-type material varied from 1×10^5 to $\sim 2 \times 10^7$

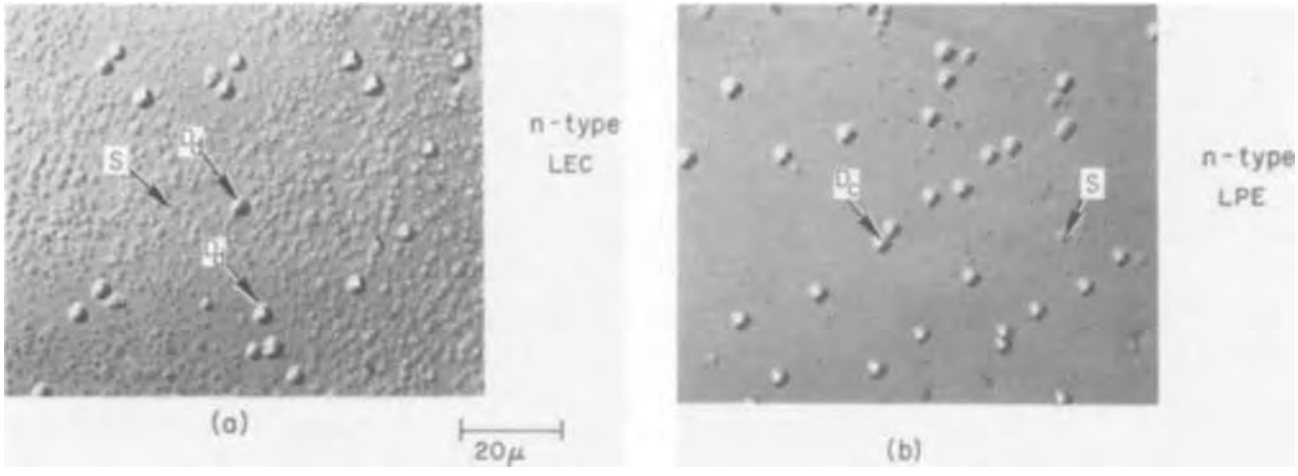

Fig. 2. Optical photomicrographs of S- and D-pits in n-type (a) LEC substrate with $|N_D\text{-}N_A| \simeq 2\times10^{17}$ cm^{-3}, and (b) LPE layer with $|N_D\text{-}N_A| \simeq 1\times10^{18}$ cm^{-3}.

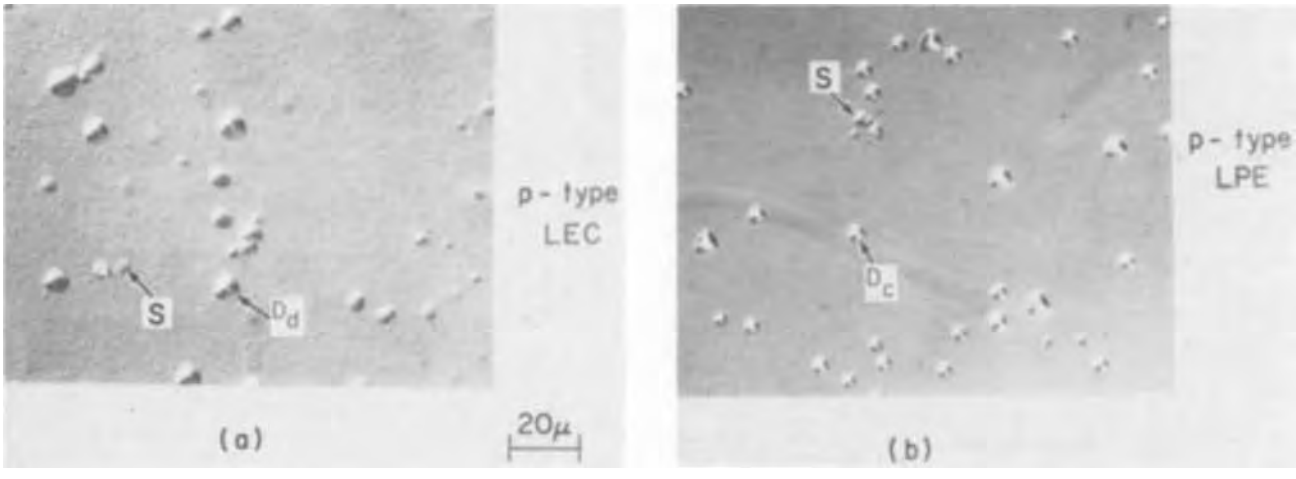

Fig. 3. Optical photomicrographs of S- and D-pits in p-type (a) LEC substrate with $|N_D\text{-}N_A| \simeq 2\times10^{17}$ cm^{-3}, and (b) LPE layer with $|N_D\text{-}N_A| \simeq 2\times10^{17}$ cm^{-3}.

cm^{-2}. Again, the D-pits are of the decorated variety and occur at a density of $\sim 1 \times 10^5$ cm^{-2}.

For p-type LPE layers very smooth and clean looking D-pits are found, see arrow D in Fig. 3b, while the S-pit density is reduced to zero. A zero S-pit density was always observed in p-type LPE layers unless there were inclusions or some other growth anomaly. The layer in Fig. 3b was (Zn,O) doped to $\sim 2 \times 10^{17}$ cm^{-3} and grown on the n-type LEC substrate shown in Fig. 2a.

Another aspect of the etched p-type material, both substrates and layers, was a generally rough or coarse texture of the surface between the different etch pits. This background feature is uniformly distributed and does not appear to be depleted in the vicinity of dislocation etch pits. Whether these features are related to a unique type of crystal defect has not been established. It should be noted, however, that in certain LEC crystals pulled from nonstoichiometric melts (6) which have high PL η, a very smooth background surface is obtained. In the present report we limit our discussion of p-type material to the previously identified S- and D-pits.

P-type LPE layers on n-type SG substrates.—The materials system which has consistently yielded electroluminescent diodes with the highest efficiencies is one consisting of a p-type LPE layer grown on an n-type SG substrate (1, 8). If the S-pits were playing an active role in the electroluminescence process we would expect their density to be a minimum for this material. This was, in fact, found to be the case as can be seen in the two optical photomicrographs shown in Fig. 4. These should be compared to the p-type LPE layer/n-type LEC substrate combination shown in Fig. 2a and 3b. It was not possible to locate any etch feature which could be identified as an S-pit in the LPE layer, Fig. 4b or in the SG substrate, Fig. 4a.

Note that the dislocation etch pit density of the LPE layer was as high as 3×10^5 cm^{-2}, which is more than three orders of magnitude higher than that in the SG substrate on which the LPE layer was grown. This large increase in structural, *i.e.*, purely geometric, defect density actually puts the LPE layers grown on LEC or SG substrates, see Fig. 2b and 3b, at the same level. However, they differ considerably in terms of chemical, *i.e.*, impurity, vacancy, etc., defect density as determined by the saucer etch pit counts. The approximate range of D- and S-pits in these two samples is given in Table II along with data on the relative device performance, which is discussed in the next section.

Relative electroluminescence efficiencies.—Electroluminescence data on red-emitting p-n junctions fabricated from adjacent pieces of the samples discussed in Fig. 2b and 3b are presented in Table II along with etch pit data. Three LPE layer-substrate combinations have been evaluated. They are the p/n (LEC), p/n (SG), and n/n (LEC), *i.e.*, the buffer layer

Table II. Etch pit and device efficiency data for GaP LPE layers and LEC substrates

Surface	Property $\lvert N_D - N_A \rvert$* (cm^{-3})	D-pit density (cm^{-2})	S-pit density (cm^{-2})	Diode efficiency** (%)

situation. First, we note that the range of D-pit densities is approximately the same in all the layers and is a factor of two to five below that in the LEC substrate material. This reduction in D-pit density is typical of that previously reported for III-V LPE systems (13, 14), but is in marked contrast to the many orders of magnitude difference in the S-pit density for both n- and p-LPE/LEC substrates. Recall also that the D-pits were of the clean variety once the S-pit density was reduced, indicating that it is the crystal defect responsible for the formation of S-pits that is of main concern and not the dislocations. This is confirmed by comparing the peak external quantum efficiencies of point contacted unencapsulated diodes shown in Table II for the p-type LPE layers on LEC and SG substrates. The factor of four difference in efficiency is typical of that previously reported (1) for single LPE layers grown on LEC or SG substrates, while the absolute values are within a factor of two of data typical of "single tipped" material.

It should be noted that if a p-type LPE layer is grown on an n-type buffer layer, thereby moving the p/n junction away from the high S-pit density LEC substrate, then the EL η jumps a factor of three or four and is comparable to devices fabricated on SG substrates. This "double tipping" approach is what is almost universally used in GaP light emitting diode technology. For these p/n/n structures the LEC substrate functions as a large area "breadboard" for the active p/n device which consists of two LPE layers.

Analysis of angle lapped LPE junctions.—In discussing the D- and S-pit densities in EL device material it was shown that "double tipping," or moving the active p/n junction away from a region of high S-pit density, *i.e.*, the LEC substrate, results in improved EL η. In this section an example will be given of how the S-pits can be used as an observable in the evalua-

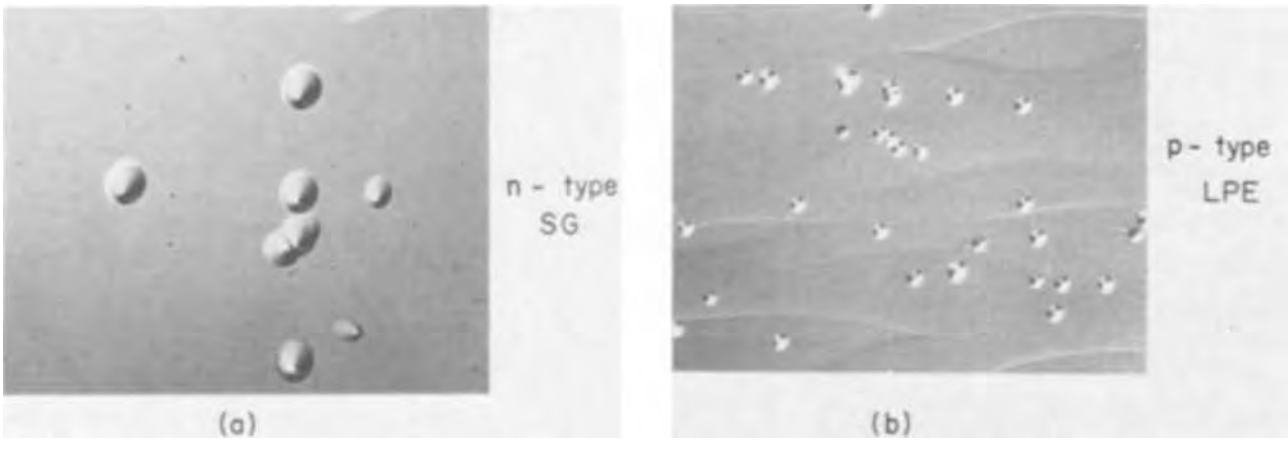

Fig. 4. Optical photomicrographs of D-pits in (a) n-type SG substrate, and (b) p-type LPE layer grown on SG substrate

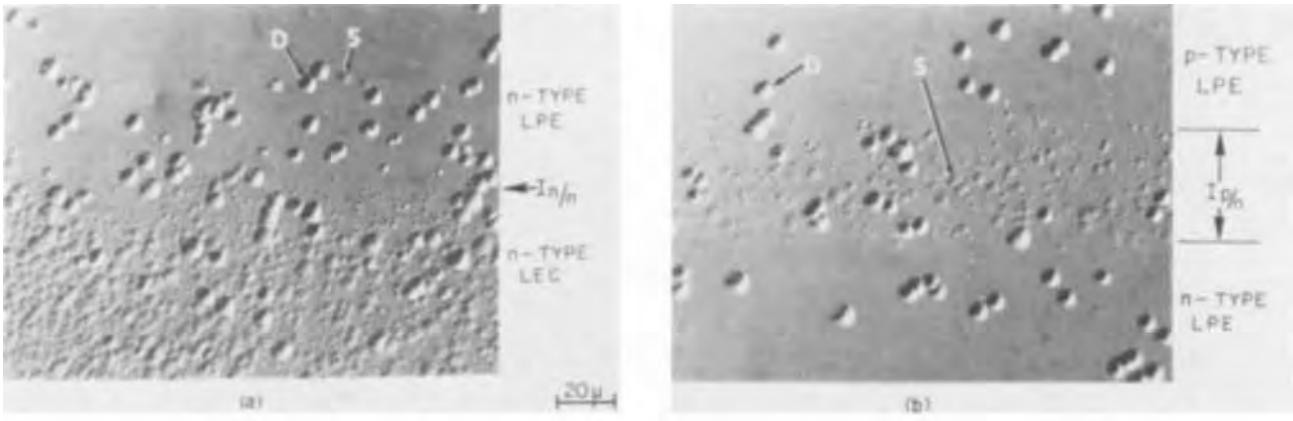

Fig. 5. Optical photomicrographs of angle-lapped sample showing (a) abrupt reduction in S-pit density at LEC substrate-LPE layer interface, $I_{n/n}$, and (b) band of S-pits localized at LPE p/n junction interface, $I_{p/n}$.

tion of p/n junctions where the junction lies between two LPE layers. For junction or interface studies it has been found that angle lapping the sample at ~2° to the $(\bar{1}\bar{1}\bar{1})$ P growth face, which enhances the depth resolution by a factor of ~30, provides an extremely useful approach to this problem. The delineation of the two interfaces on a double tipped p/n/n sample is shown in Fig. 5. The previously described reduction in S-pit density on going from an LEC substrate to an LPE layer is shown in Fig. 5a.[2] The transition is extremely abrupt and occurs within a thickness of ~1μ. A simultaneous change in the character (but not necessarily the density) of the D-pits occurs and they assume a smooth, clean appearance. The n-type LPE layer is then quite uniform until the interface with the p-type LPE layer is reached, see $I_{p/n}$ in Fig. 5b. At this point a localized band of S-pits is observed at a density of $\sim 1 \times 10^6$ cm^{-2}. The p-type layer then immediately reverts to a zero S-pit density situation. Localized bands of S-pits at p/n junction interfaces have only been observed in material which yields very poor EL device efficiencies. Similar results have been recently described by Asao and Akasaki (20) who found that the η of vapor grown LED's depends primarily on the S-pit density at the p/n junction.

The occurrence of interfacial layers containing high concentrations of residual impurities at GaAs epi-substrate junctions has recently been described by DiLorenzo *et al.* (15). Using an ion-probe mass analyzer with imaging capabilities, in conjunction with a depth profile of the active device carrier concentration, they demonstrated that a correlation exists between the occurrence of a high resistivity, or *i*-layer, and the presence of impurity contamination, most notably silicon, which was highly localized at the epi-substrate interface. Subsequent work by DiLorenzo (16), also on GaAs, gave procedures for reducing or eliminating the localized impurities by a combination of careful substrate cleaning, *in situ* vapor etching, and the growth of a "buffer" layer of epi-GaAs.

Cleavage face analysis of D- and S-pits.—In the etch pit data presented above we have assumed that the S-pits were not associated with the emergence of a dislocation line at the sample surface, but could be used to characterize the presence of an impurity or defect-impurity complex. Because of the importance of this assumption in our subsequent discussion, additional work on the nature of the D- and S-pits was carried out. Specifically, a p-type LEC crystal with isolated D- and S-pits was cleaved and examined at the intersection of the cleavage edge and the isolated pits. In this way, it was possible to examine the defect in-depth, first by identifying either a D- or S-pit on the $(\bar{1}\bar{1}\bar{1})$ P face, and then looking around the corner of the sample down the cleavage face. Although chemical etchants do not reveal individual dislocation pits on the {110} cleavage faces of GaP, Iizuka has shown (6) that etch grooves corresponding to dislocation line segments are revealed by the AB etching solution described in Table I.

The results of this type of analysis are shown in Fig. 6 which gives two composite photomicrographs of adjacent regions on a $(\bar{1}\bar{1}\bar{1})$ P surface and $(01\bar{1})$ cleavage face. Note that the S-pits, designated by the arrows S in Fig. 6a, are only revealed by a very slight depression on the matching $(01\bar{1})$ cleavage face, as shown by the arrows S' in Fig. 6a. However, the dislocation etch pit in Fig. 6b has a deep, sharply faceted profile with a dislocation etch groove, see arrow DG, extending from the apex of the pit on down the cleavage face. It was found that each D-pit which was intercepted by the cleavage has a corresponding $(01\bar{1})$ dislocation groove associated with it. Therefore, we can conclude that the crystal imperfection responsible for S-pit formation is not linear in extent, but is associated with a defect that perturbs the crystal in a limited volume with a spherical or possibly disk-shaped symmetry.

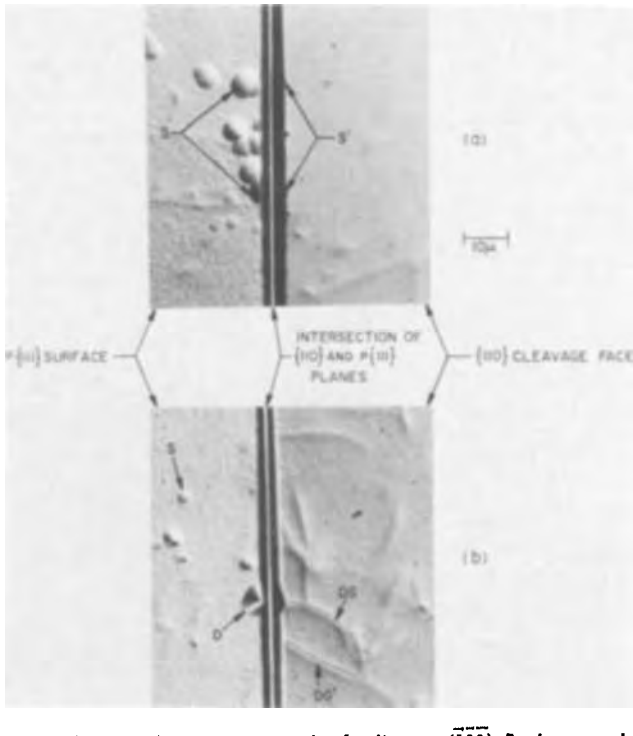

Fig. 6. Optical photomicrograph of adjacent $(\bar{1}\bar{1}\bar{1})$ P planes and {110} cleavage face showing (a) S-pits, and (b) D-pits and dislocation grooves.

[2] The lower half of this figure is labeled (a) in order to retain the actual sequence of substrate-layer growth.

Note that in Fig. 6b there were several dislocation grooves, see arrow DG', which appeared to terminate at the surface without the appearance of a D-pit. The failure of a D-pit to be revealed at the point of emergence of a dislocation line on the $(\bar{1}\bar{1}\bar{1})$ P surface could be related to whether the dislocation is of the α-(Ga) or β-(P) variety as described by Haasen (17). Abrahams and Buiocchi (12) have previously shown that for {111} surfaces of GaAs their etch will only reveal β-(As) type dislocations, unless the dislocations are decorated with an impurity. Similar behavior for GaP would help explain the observations shown in Fig. 6b. However, since it has previously been established that the D-pits in doped GaP LEC crystals are mainly of the decorated variety, see Fig. 2a and 3a, there appears to be an additional factor involved in the GaP case.

Discussion of Results

In discussing the etch pit observations on LPE layers presented above, along with the complementary information previously obtained by photoluminescence mapping (5) of LEC substrates pulled from stoichiometric melts and by etch pit comparisons on LEC material pulled from nonstoichiometric melts (6) several definite conclusions can be made about the nature of the S-pits and their ability to classify that material which is best for EL devices. For example, in dealing with the possible effects of dislocations on EL and PL (5) device performance, it has been shown that dislocations, by themselves, are of secondary importance in correlating luminescence efficiency. However, decorated dislocations, which only occur when there is a corresponding high density of S-pits, can be a significant factor. Similar conclusions have been arrived at by Stringfellow and Green (18) for defects in Ga(As, P). In addition to the association of S-pits with decorated dislocations, it has been found that very localized, high density layers of S-pits occur at p/n junction interfaces of material with poor device performance. These observations are consistent with ion probe mass analysis results on GaAs (15, 16) which have revealed the presence of high resistivity impurity layers at epi-substrate interfaces. Preliminary ion-probe studies on GaP (19) indicate that the interfacial impurity problem is very similar to that in GaAs and in fact the "buffer" layer approach used by DiLorenzo is somewhat equivalent to "double tipping" in LPE growth. However, in the vapor phase epitaxial system used by DiLorenzo the final active device layer was immediately grown on the "buffer" layer, whereas in LPE systems the p-and n-layer growth are usually separate procedures. Therefore, the elimination of *i*-layers, interfacial impurities, and ultimately S-pits at GaP p/n junctions is expected to be a more difficult procedure than it was in GaAs vapor growth.

Although we have de-emphasized the importance of dislocations and implied that an impurity is at least partly responsible for the formation of S-pits it should be noted that the dopant itself, *e.g.*, tellurium or zinc, does not appear to be a dominant factor. This is supported by the fact that the density of S-pits in tellurium-doped LPE layers is greatly reduced even though the doping level is usually a factor of four higher than that in the substrate. Iizuka (7) had previously attributed a decrease in S-pit density in certain undoped substrates to the lower doping level. However, it now appears that if Te is involved it is most likely either associated with another element, *e.g.*, Si, O, C, or B, or possibly with a native defect such as a Ga vacancy (4), or a small structural defect like a dislocation loop. Since the LPE growth temperature (as well as that for SG platelets and certain LEC crystals pulled from nonstoichiometric melts), is several hundred degrees below that of the LEC substrates it is very likely that all three possibilities, *i.e.*, impurity incorporation, defect chemistry, and dislocation mechanics, will have to be considered in finding the origin of the S-pits in LEC substrates. Although the problem of a positive identification of the imperfection responsible for formation of S-pits in GaP is not an insurmountable one, it appears that analytic tools more powerful and versatile than the optical microscope will most certainly have to be used. Foremost among these would be the transmission electron microscope for structural and precipitation information, and the direct imaging ion-probe mass analyzer for chemical identification.

In terms of using the S-pits as an observable in evaluating GaP EL material two important points are to be stressed. The first is that moving the active p/n junction away from a substrate containing a high density of S-pits, *i.e.*, double tipping; or tipping directly on substrates with low or zero S-pit density, *i.e.*, SG or LEC pulled from a nonstoichiometric melt (6), produces superior device material. Second, maintaining proper processing conditions such that interfacial layers of S-pits are not present also leads to improved device results.

Summary

The results of the above discussion can be summarized as follows:

(*i*) The dislocation density is of secondary importance when comparing the luminescence η of LPE layers with other layers or with SG and LEC crystals,

(*ii*) The association of S-pits with the presence of decorated dislocations, and with *i*-layers at p-n junction interfaces indicates that the S-pit formation mechanism is associated with some form of impurity precipitation, or defect-impurity complex,

(*iii*) The η of EL devices is considerably improved if the active p/n junction is removed from a substrate containing a high density of S-pits,

(*iv*) Conversely, the presence of a band of S-pits at the interface of an otherwise S-pit free p/n LPE layer device results in reduced EL η,

Acknowledgments

The authors would like to thank R. H. Saul for providing the LPE layers and EL device η data, G. W. Kammlott for the SEM photos, T. J. Ciesielka and F. A. Thiel for assistance with the angle lapping and optical microscopy, and R. B. Marcus for comments on the manuscript. S. E. Haszko also participated in some of the early optical microscopy work.

Manuscript submitted Oct. 26, 1972; revised manuscript received Dec. 21, 1972. This was Paper 86 at the Washington, D. C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Defects in Garnet Substrates and Epitaxial Magnetic Garnet Films Revealed by Phosphoric Acid Etching

D. C. Miller

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Phosphoric acid between 140° and 170°C has been used to reveal strain and chemical heterogeneities in nonmagnetic garnet substrates and magnetic garnet epitaxial films, principally $Gd_3Ga_5O_{12}$ and $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$, respectively. Dislocations, growth striations, and residual polishing damage have all been observed. Dislocations perpendicular to the film-substrate interface in (111) films were shown to be generated by inclusions whether at the interface or in the interior of the film. Dislocations in the substrate will also propagate into the layer. Interface or misfit dislocations were not observed either by etching or x-ray transmission and reflection topography.

Magnetic garnet films grown by liquid phase epitaxy (1-3) on nonmagnetic garnet substrates (4,5) must be essentially free of crystalline defects to be suitable for use in magnetic bubble domain devices (6, 7). To aid in the defect analysis of both the rare earth gallium garnet substrates and rare earth iron garnet films, an etchant was sought in which the dissolution rate of the garnets would be altered by the presence of strain and chemical heterogeneities such as dislocations and growth striations, respectively. Since phosphoric acid has been used successfully to chemically polish a number of other oxide single crystals at high temperatures (8-11) it seemed likely that it could also be used to etch the rare earth gallium and iron garnets selectively at lower temperatures, and this proved to be true. Many other etchants were investigated including phosphoric-sulfuric acid mixtures, and phosphoric acid containing chrome trioxide, potassium permanganate, and other additions. Some of these mixtures had higher etch rates, but none had any advantage over pure orthophosphoric acid (H_3PO_4) between 140° and 170°C, which was used throughout this investigation. Polarized light microscopy and x-ray reflection and transmission topography were used to verify the results of the etching experiments.

Experimental

Commercial 85% orthophosphoric acid with an initial density of 1.68 g/cm^3 was used for all of the etching experiments reported here. The acid was contained in platinum beakers. However, below about 200°C Teflon and Pyrex (which dissolves at the rate of approximately 0.05 μm/min at 150°C) may also be used. Specimens were held with Teflon forceps.

Samples to be etched for defects were dipped directly into the acid at 165°C for 1-15 min depending on the size of features desired and the composition of the material. The acid bath temperature was monitored with a platinum-encased Chromel-Alumel thermocouple immersed in the bath. Control of the bath temperature to within ±3° is adequate for defect delineation. Very large specimens such as whole boules were preheated to avoid the possibility of cracking due to thermally induced stresses. Following etching, the samples were quenched in heavy oil at 70°C to reduce thermal shock, then dipped in consecutive hot Alconox solutions, the first containing about 15 w/o (weight per cent) KOH to aid in neutralizing any acid remaining on the specimens. The specimens were then rinsed in distilled water and blown dry.

Key words: growth striations, topography, polishing damage.

Etch Pits

The etch rate of the garnet in phosphoric acid in the 140°-170°C temperature range is extremely sensitive to the presence of strain and chemical heterogeneities in the crystals and is edge preserving. Variations in the acid composition which occur on heating affect the etch rate (12) but do not change the etching characteristics of the acid, which remains selective up to about 270°-280°C. Therefore, the shape of pits that are formed due to the presence of inclusions or dislocations will enlarge as etching continues while maintaining their over-all initial shape even though the cause of the pit, such as an inclusion, has been etched away. This has been found to be the case with all orientations and a number of the rare earth gallium and iron garnets including solid solutions, although the pit shapes and rates of formation differ. Most of the garnet films now being produced are grown on $Gd_3Ga_5O_{12}$ {111} surfaces and thus most of the data reported here is for this material and orientation, but the techniques apply equally well to other compositions and orientations.

On {111} surfaces, pits formed in the presence of strain fields, which were detected using birefringence prior to etching, have six sides with over-all three-fold symmetry, while those formed without observable strain fields are purely triangular. This is illustrated in Fig. 1. None of these pits are dislocation etch pits. All have been generated due to the intersection of an inclusion (or possibly a void) with the surface. Dirt on the substrate may also cause this type of pit if it reacts with or becomes firmly bonded to the surface. The pit with six sides was caused by an inclusion with a strain field and has the same shape as a dislocation etch pit. However, the strained inclusion pit has a flat bottom. Upon further etching this pit will enlarge while maintaining the same cross-sectional shape near its intersection with the surface even though the strain field had been etched away. The bottom will remain flat or assume a triangular morphology as in the case of a pit formed in the absence of a strain field.

Dislocation etch pits, however, will continue to deepen on further etching, maintaining a sharp pointed tip, and thus if there is doubt about whether pits are caused by dislocations or inclusions with strain fields, continued etching will enable the two to be distin-

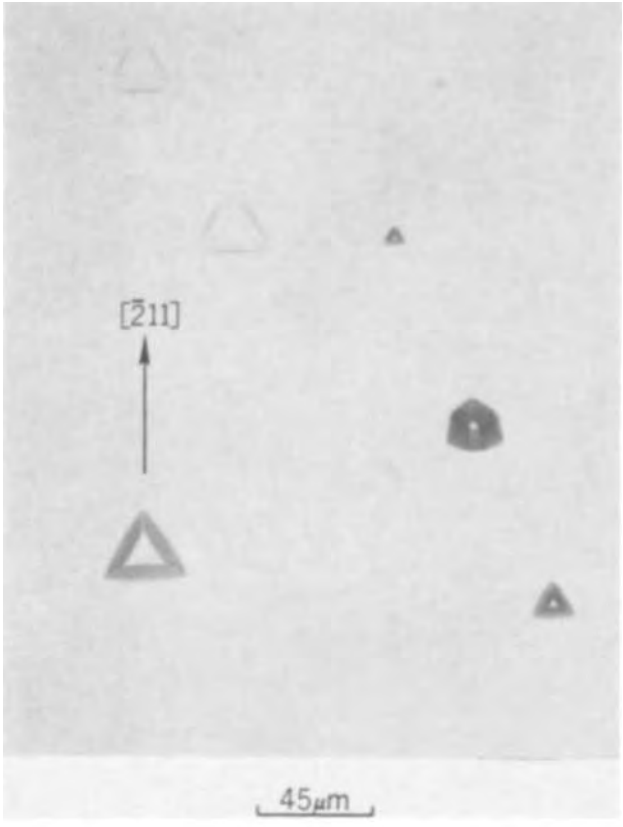

Fig. 1. Etch pits produced by phosphoric acid at 165°C in 10 min on the (111) surface of $Gd_3Ga_5O_{12}$.

guished. Roughly 15 min in H_3PO_4, at 165°C, is sufficient time to develop pits easily visible under 200X magnification. Dislocation pits formed in the (111) surface of a $Gd_3Ga_5O_{12}$ substrate are shown in Fig. 2. The extraordinary length of the pits can be used to determine the orientation of the dislocations. Their paths as well as Burgers vectors can also be determined using birefringence in the case of edge dislocations, but pure screw dislocations cannot be seen in this way (13-15). In the $Gd_3Ga_5O_{12}$ boule of which a slice is shown in Fig. 2, roughly 15% of the dislocations present are of the spiral type denoted by the arrows, and these dislocations are not visible when viewed between crossed polarizers. The Burgers vectors of the edge dislocations in $Gd_3Ga_5O_{12}$ determined using birefringence appeared to be similar to those observed in $Y_3Al_5O_{12}$ (15) (i.e., a/2<111>, a<100>, and a<110>) and all appeared to etch in the same way. No preferred orientation of the dislocations has been observed.

Having determined the shape of pits formed by various defects, the etching technique can now be used to analyze more complicated types of defects, a great variety of which occur in the garnet crystals. For example, two different variations of a type observed in some garnet boules whose analysis is aided by the use of phosphoric acid are shown between crossed polarizers in Fig. 3a and b. Both appear to consist of an inclusion, perhaps a post-growth precipitate, surrounded by dislocation loops. Normally, inclusions which generate enough stresses to cause plastic deformation punch out small loops of the order of the particle size (16). However, in this case the dislocation loops appear to surround the central inclusion, with the planes of the loops inclined to the (111) surface.

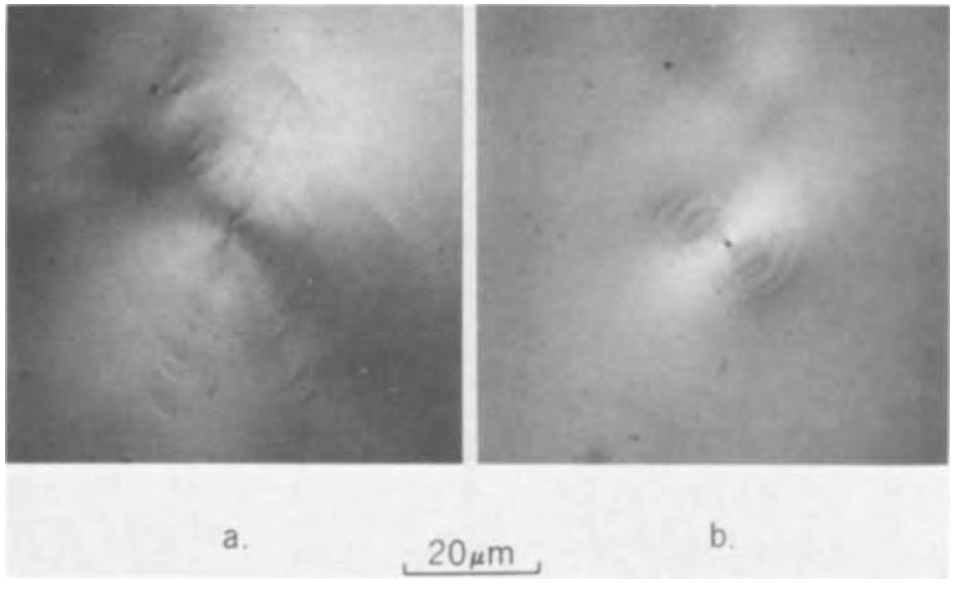

Fig. 3. A defect within $Gd_3Ga_5O_{12}$ between crossed polarizers: (a) with central inclusion only, (b) with central inclusion and an array of small inclusions or voids.

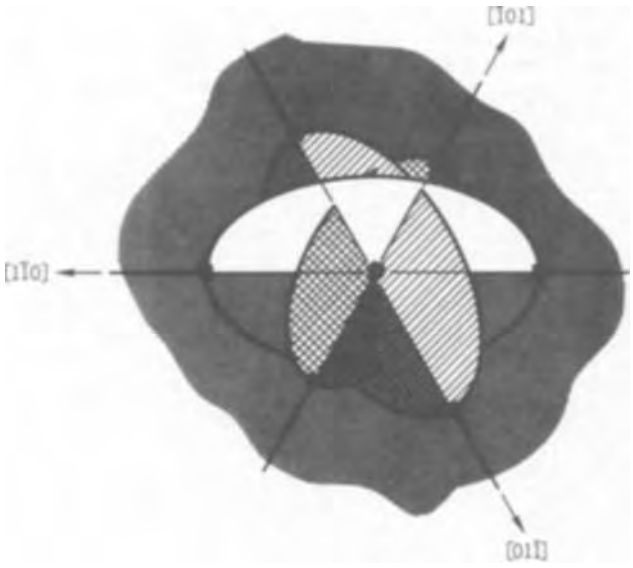

Fig. 4. Schematic illustration of a possible configuration of the defect shown in Fig. 9a.

The cluster in Fig. 3a appears to consist entirely of dislocations while the cluster in 3b appears to have associated with it an array of small (<0.2 μm) inclusions or voids lying in the planes of the loops, not along the line of the loops themselves. A possible configuration for the loops is shown schematically in Fig. 4. If sectioned through the central precipitate and etched, pits should develop at the intersection of the loops with the plane of section, here parallel to the (111) surface and through the center of symmetry of the defect. This was done on defects similar to those of Fig. 3a and b and the results are shown in Fig. 5a and b, respectively. The strong correlation in both cases of an equal number of pits on either side of the center strongly supports the view that large loops are present. The array of nondislocation pits in Fig. 5b are identical to those generated by inclusions without strain fields and are consistent with the array of small particles or voids present in Fig. 3b.

It would be very difficult for a defect of this configuration to be entirely grown into the crystal. Thus, it must form after solidification while the temperature and stress are great enough for plastic deformation to occur. A defect with a structure similar to that suggested above could result from small dislocation loops which form by vacancy coalescence and collapse or by inclusion generated stresses, and then grow due to the effect of thermal induced stress near the interface. The particle in the center of the structure, which appears to be a gadolinium gallium suboxide crystallite (5), may either have formed in the melt and been included into the crystal or have precipitated after growth from the solid which had become supersaturated with suboxide. This supersaturation would be brought about by an oxygen deficiency and a decreasing temperature associated with continued growth of the crystal. The temperature profile in the crystal and supersaturation of the precipitating species, which govern the formation and growth rate of precipitates, are in turn controlled by the thermal geometry of the apparatus, growth rate, crystal rotation rate, stoichiometry of the melt, and many other variables. Since some inclusions have strain fields and some do not and others are associated with the prismatic loop clusters, it is clear that a variety of defect generation mechanisms operate during growth. In no instance, however, have straight dislocations been observed to have been generated by isolated inclusions with or without strain fields.

In any case, all bulk defects which intersect the surface of the substrate will cause defects in an epitaxial layer subsequently grown on the substrate, and this will be discussed below. First, however, surface defects in the substrates arising from processing must be considered.

Residual Polishing and Handling Damage

Residual surface damage, such as polishing induced damage and handling scratches cause defects in films grown over them. Often, the topological result of a

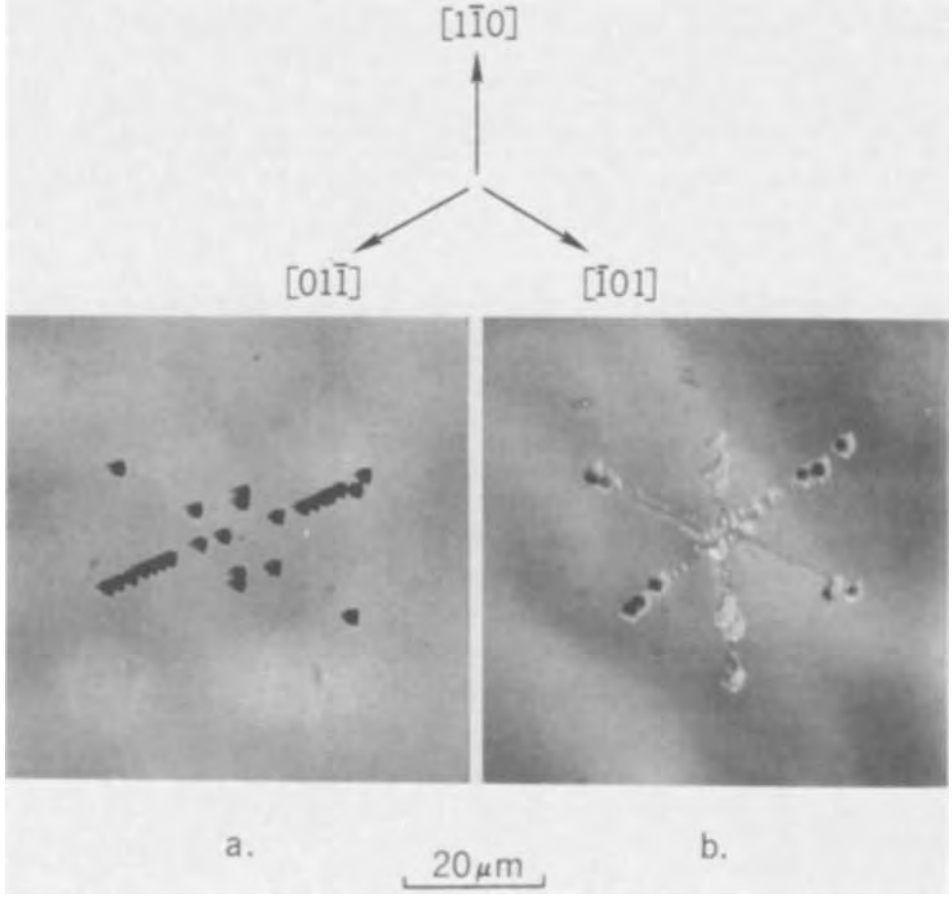

Fig. 5. Defects similar to those of Fig. 9a-b, respectively after sectioning and etching.

Fig. 6. (111) surface of a $Nd_3Ga_5O_{12}$ crystal etched in phosphoric acid at 165°C for 30 sec to reveal residual polishing damage.

scratch resulting from contamination of the polishing compound with larger grit or dirt will be polished off leaving only the subsurface residual damage which will be invisible, even under careful microscopic examination. Yet, this too will cause magnetic defects (17, 18) in the subsequently grown magnetic layer. Such residual damage will be preferentially etched during a 30-45 sec exposure to phosphoric acid at 165°C, and a groove will form at the location of the surface damage. Any other scratches present will be enlarged. The brief etch is also a cleaning step, since polishing compound, dirt, grease, etc., adhering to the specimen are removed by the acid. The grooves produced as a result of etching can be easily seen with an interference contrast microscope and even with the naked eye under sufficiently intense illumination. An example of a $Nd_3Ga_5O_{12}$ crystal that has had an inadequate amount of Syton[1] polishing to remove all of the residual damage from previous diamond polishing steps is shown in Fig. 6. The intermittent nature of some of the damage tracks suggests that the particle which caused the damage was rolling over and of irregular shape. The black spots are dislocation etch pits. $Nd_3Ga_5O_{12}$ etches much faster than any of the other gallium garnets and such pits of microscopic size will not form during the 30-40 sec etch times used to reveal polishing damage on $Gd_3Ga_5O_{12}$. The brief etch also does not affect the substrate in any deleterious way as no differences in the magnetic properties could be observed on films grown on etched and unetched substrates.

Film Defects

Crystalline defects which locally retard magnetic domain wall motion in the magnetic garnet films are caused by inclusions and dislocations in the substrate which intersect the surface, residual surface damage such as scratches, dirt which remains on the substrate surface after immersion in the flux, and inclusions, dislocations, and scratches in the films themselves.

Dislocations in the substrates will propagate into the epitaxial layers, and this is illustrated in Fig. 7. The large pits (Fig. 7a) are on the $Gd_3Ga_5O_{12}$ side of a substrate which has an LPE layer on only one side. The small pits (Fig. 7c) are on the film side. The dislocations in the substrate which have caused the pits and have propagated into the film can be seen by birefringence within the substrate in Fig. 7b. The small size of the pits on the film side relative to those on the $Gd_3Ga_5O_{12}$ side is due to the much lower etch rate of the $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ film.

Having thus established that dislocation etch pits also form in the films, phosphoric acid etching can be used to further analyze the defect structure of the epitaxial layers. For example, shown in Fig. 8b is an etched $Y_1Ga_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ film containing many dislocations. However, by observing the substrate side (Fig.

[1] Product of Monsanto Chemical Company.

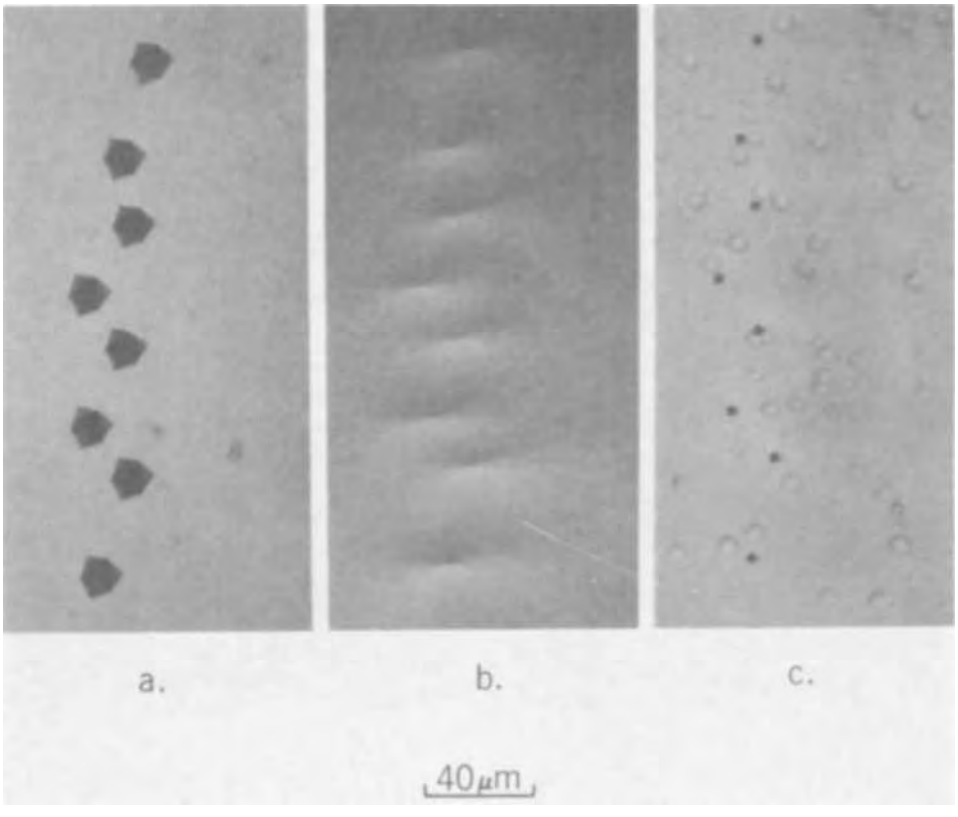

Fig. 7. (a) Dislocation etch pits on the surface of a $Gd_3Ga_5O_{12}$ crystal with a magnetic film on one side only. (b) The dislocations causing the pits as seen between crossed polarizers in the interior of the substrate. (c) The corresponding dislocation etch pits in the $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ magnetic film.

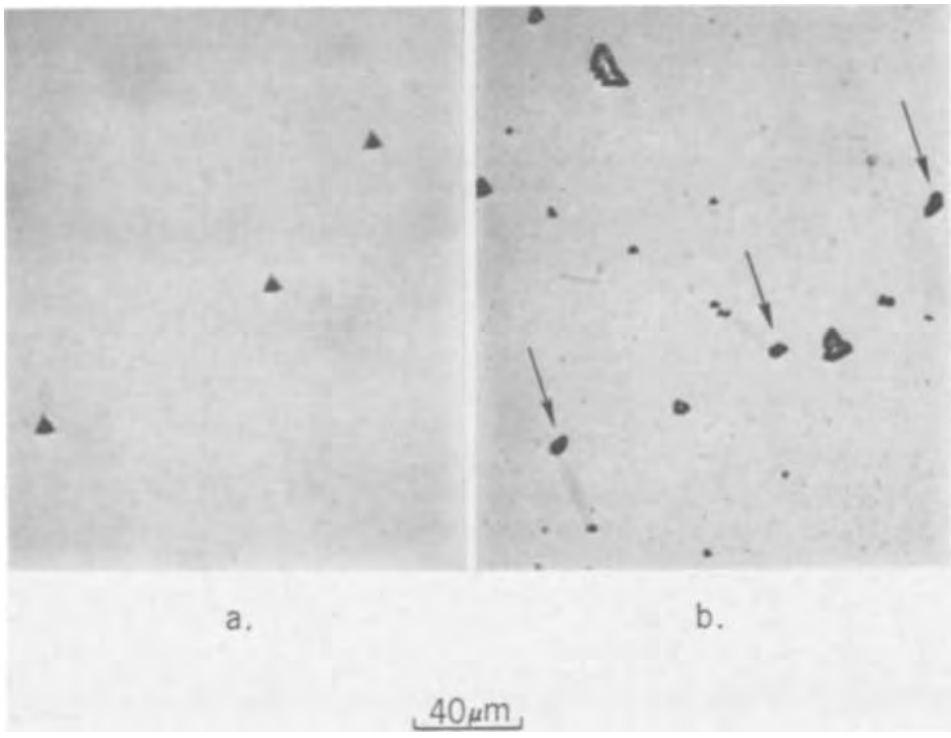

Fig. 8. (a) Dislocation etch pits on the $Gd_3Ga_5O_{12}$ side and (b) on the magnetic film side of a substrate with a $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ layer on one surface only.

8a), it can be seen from the etch pits present that only three of the dislocations, marked with arrows in Fig. 8b, arose from bulk dislocations in the substrate. The remainder originated at the film-substrate interface. The large pits are formed by the coalescence of the etch pits of clusters of dislocations generated by large inclusions at the interface. Such large inclusions can be easily observed, but the cause of every dislocation originating at the interface cannot always be so conclusively established. However, it has been established that dirt, microinclusions, and surface damage can cause dislocations in the films when they are present at the interface. For example, it was found that previously, easily moved dirt and grease drops reacted with and became bonded to the surface of the substrate during a 1-hr anneal at 1000°C in O_2, a treatment somewhat analogous to the conditions a substrate encounters when being lowered into the furnace prior to dipping into the flux. Approximately one third resulted in dislocations in the subsequently grown magnetic layer.

Inclusions within the films themselves may or may not cause dislocations, but in either case domain wall motion will be impeded. The presence of an inclusion and whether or not it has generated dislocations can be ascertained by observing the surface of the epitaxial layer using interference contrast microscopy. For example, shown in Fig. 9a is the as-grown surface of a $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ film which contains a group of depressions or pits. The outlined region in Fig. 9a is shown in transmission in Fig. 9b with the microscope focused about 5 μm down into this 9 μm thick film. Precipitates can be seen corresponding to the pits observable in Fig. 9a. Next, this film was etched for 3 min in phosphoric acid at 170°C in order to reveal dislocations. The outlined region in Fig. 9b is shown in Fig. 9c, after etching. In this case, only one of the inclusions generated dislocations (two). This corresponds to the type "A" growth pits so labeled in Fig. 9a. Thus, the deep conical pits are formed over inclusions which have generated dislocations, and the shallow "saucer" shaped pits form over inclusions which have not gen-

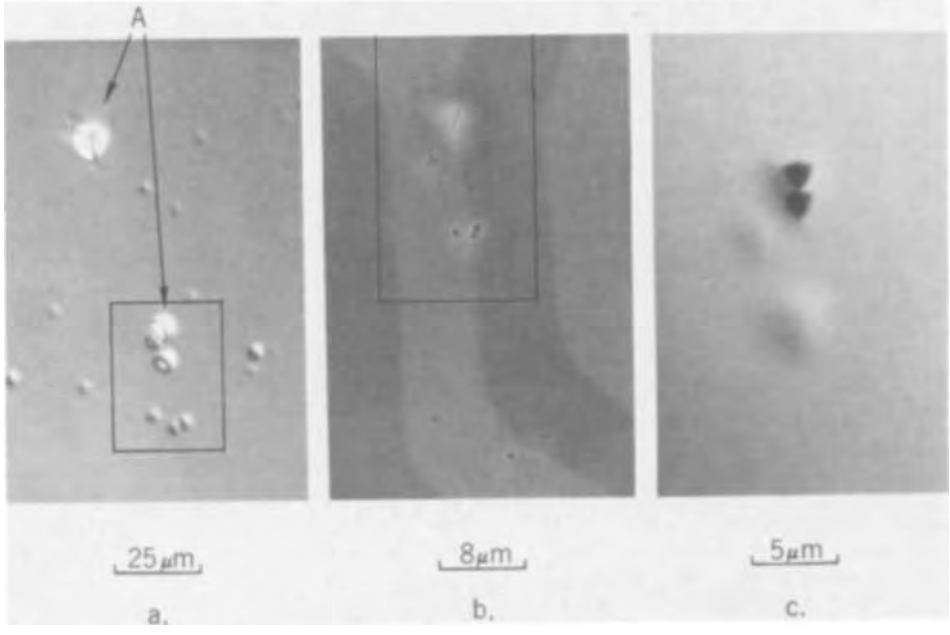

Fig. 9. The as-grown surface of a $Y_1Gd_1Tm_1Ga_{0.8}Fe_{4.2}O_{12}$ film, (b) the interior of the region of the film outlined in (a), and (c) the surface of the region of the film outlined in (b) after etching.

erated dislocations. Often, as in the case of dislocations originating at the interface, these types of surface features may be observed where no inclusions can be detected in the films. Presumably, the inclusions causing the defects in these instances are too small to be observed using optical microscopy. Even when visible, however, it is difficult to identify the inclusion unless its shape, color, and other features can be ascertained. For example, red, "cubic" inclusions which display extinction every 90° between crossed polarizers can be identified as being most probably orthoferrite crystallites which had been floating in the flux. Inclusions such as these have not been observed to generate dislocations other than perpendicular, or nearly so, to the interface.

The much greater depth of the growth pits which form over inclusions with dislocations may indicate that the presence of dislocations reduces the growth rate. This result may be explained by a plausible argument based on the observed growth behavior of the garnets. Because <111> growth facets do not form on Czochralski grown $Gd_3Ga_5O_{12}$ and other rare earth gallium garnets it can be concluded that little undercooling is required for the nucleation of new layers on {111} planes, and thus the growth of garnet in the [111] direction should also require little undercooling. Therefore, the growth rate of $Gd_3Ga_5O_{12}$ should vary directly with undercooling (19) in the [111] direction. Epitaxial films grown on {111} surfaces should behave in the same way, except for the possible influence of diffusion boundary layer effects, and this has been observed (3). However, the strain field which surrounds a dislocation is a higher energy nucleation site than a perfect (111) surface. In general, then, for any given growth temperature, the growth rate should be inversely proportional to the amount of strain associated with the site of attachment of an adatom. An inclusion which does not generate dislocations will be surrounded by a relatively weak strain field, and thus according to the above reasoning, a reduced growth rate will result until the inclusion is well covered by many atomic layers and the strain diminishes. Therefore, the size of the growth pit associated with an inclusion without dislocations should be directly proportional to the size and magnitude of its strain field. However, if dislocations are generated by the inclusion, then a larger growth pit should form than would otherwise be the case. This occurs because even though the dislocations may reduce the over-all stress in the vicinity of the inclusion, dislocations grow through the layer and thus the reduced growth rate will persist for the duration of film growth.

The situation will be different in the case of a growth plane on which the nucleation of new layers requires substantial undercooling, such as the {211} planes in garnet. Depending on the relative magnitude of the strain energy associated with a dislocation and lattice parameter mismatch, the presence of a dislocation with a Burgers vector other than parallel to the interface may increase the growth rate of the film for a given amount of undercooling. This occurs because the step produced when the dislocation intersects the interface becomes a growth step, obviating the need for the high undercooling necessary for the nucleation of new layers (20, 21).

Whether or not the above arguments can be applied to other than localized strain, *i.e.*, to the possible effect of lattice mismatch strain on the growth rates of epitaxial layers, will be investigated.

Growth Striations

The etch rate of the various garnets studied is very sensitive to small variations in composition. This can be used effectively qualitatively to study compositional fluctuations caused by growth rate variations as in the case of semiconductor crystals (22, 23). The growth rate fluctuations essentially span the entire growth front and thus can be used to study the interface shape as influenced by changes in growth parameters.

Fig. 10. $(\bar{2}11)$ surface of a sectional $Gd_3Ga_5O_{12}$ boule etched in phosphoric acid for 10 min at 165°C. The growth direction is vertically downward.

Shown in Fig. 10 is the $(\bar{2}11)$ surface of a $Gd_3Ga_5O_{12}$ boule sectioned lengthwise perpendicular to the growth direction, polished, and etched for 10 min in phosphoric acid at 165°C. The (112) faceted growth region is to the right and the nonfaceted region to the left while the pulling direction was vertically upward.

The closely spaced striations appear to have resulted from rotation of the crystal in the presence of thermal asymmetry in the apparatus. Since the rotation rate is constant, the spacing of these striations can be used to detect and analyze growth rate fluctuations arising from other sources. For example, in the off-facet region many fewer striations with greater spacing can be counted than in the core region, indicating that the crystal grew much faster in this region and that part of the crystal was remelted with each cycle. Thus, it can be calculated that the growth rate in the off-facet region is about four times greater than the pull rate of 0.18 in./hr or about 0.7 in./hr. The widely spaced "remelt" striations in the off-facet region, which have a period of about 40 sec, may result from regular low frequency fluid flow fluctuations in the melt (24, 25). It should be noted that the effective average growth rate will always be greater than the pull rate in the presence of growth rate fluctuation (26).

In this crystal the interface in the center of the boule (to the left in the figure) is almost flat, and therefore the striations will intersect the surfaces of substrates cut from this boule at a shallow angle. Thus, the lattice parameter changes associated with the striations are diffused enough so that no strain gradients large enough to interfere noticeably with bubble motion in an LPE layer grown over them will be generated. This flattened interface can be produced by using high crystal rotation rates (27), which will pump more hot liquid up the center of the crucible, thus raising the temperature there and counteracting the loss of heat by radiation up the center of the crystal. Under conditions of slow rotation the [211] facets become grouped at the center of the boule due to the highly convex interface shape. The intersection of the [211] facets with the (111) surface of a substrate cut from a boule grown with a highly convex interface is shown in Fig. 11. This also illustrates that the acid is equally selective on the {111} surfaces.

Striations may also be observed between crossed polarizers due to the strain birefringence generated by the compositional variations. This technique lacks the resolution of etching methods but, along with topography, is a useful tool.

The sensitivity of the acid to impurity or compositional heterogeneities can also be used to study growth fluctuations in the magnetic garnet films, as is shown in

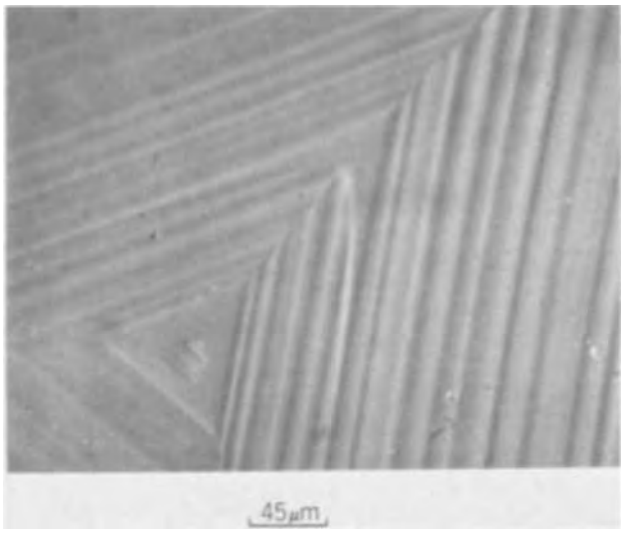

Fig. 11. (111) surface of a $Gd_3Ga_5O_{12}$ substrate after etching

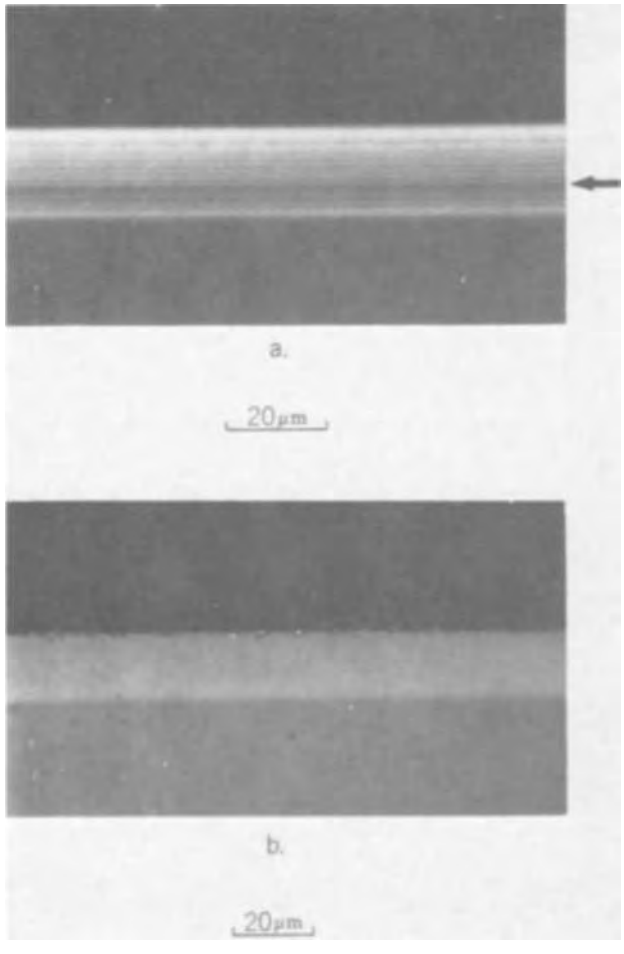

Fig. 12. Cross section of a $Er_2Eu_1Ga_{0.7}Fe_{4.3}O_{12}$ film after (a) and before (b) etching.

Fig. 12a. Figure 12b is the sectioned (by scribing and fracturing) view before etching. The origin of the striations in this film are related to boundary layer thickness changes caused by intermittent rotation of the substrate during film growth. The periods of rotation are regular, thus the variations in their spacing, as well as other topological variations produced by the etchant, can be used to measure growth rate changes during film growth and relative changes in film composition, respectively. In the film shown, after 3.5 μm of growth marked by the arrow, the over-all growth rate dropped by 15%. From the change in shading, which indicates a difference in height in interference contrast, it can be concluded that this lower part also etched faster than the upper part. This is caused by a difference in composition which is probably related to changes in the effective distribution coefficients of the constituents due to the higher growth rate. The cause of the abrupt change in rate is not known.

It is important to note here as well that there is no preferential etching at the interface as would be the case if a network of dislocations were present there. In fact, misfit or interfacial dislocations or dislocations parallel to the interface within the films have not been observed on any LPE film thus far examined which was not faceted. Dislocations have been observed parallel to the interface around the entire periphery of an LPE layer, indicating that pits form equally well on all orientations. However, these dislocations do not penetrate into the LPE layer itself, but rather are entirely contained in the material which grew epitaxially on to the outer edge of the substrate. Films in tension will crack before enough stress is generated for dislocation generation, at a mismatch of about 0.015Å. The defect structure of films grown under large compressive stress are currently being investigated.

Topography

In order to confirm the absence of interface dislocations and learn more about the strain state of the films, x-ray reflection (Berg-Barrett) (28, 29) topographs were taken. For example, an $Er_2Eu_1Ga_{0.7}Fe_{4.3}O_{12}$ film grown in tension with about 0.012Å mismatch in which cracks have formed around the periphery of the crystal was taper etched and a topograph taken. A schematic diagram of the diffraction conditions is shown in Fig. 13 and the resulting topograph in Fig. 14. Copper $K\alpha_1$, radiation and {10, 4, 0} reflecting planes were used and the image recorded on an Ilford L-4 nuclear plate. The light areas correspond to reduced intensity because a double negative was made during reproduction. The light area near the top is the substrate surface, while the lower ¼ of the crystal is unetched. The reduced intensity reflected from the substrate results because the crystal was aligned using the film and the different d spacing in the substrate renders it slightly out of alignment. There are many contrast features observable in the topograph which arise from topological variations, such as mesas resulting from flux retention, ridges due to contact with the platinum wire holders, etch pits, as well as defects in the emulsion. However, no dislocations can be resolved parallel to the interface throughout the thickness of the film or at the interface. Furthermore, no contrast (darkening) is present near the interface either (save for one weak pendellosung fringe), as would be the case if there were a network of dislocations present there too close together to be individually resolved. The cracks present can also be seen on the topograph due to the strain caused by stress relief near the crack edges.

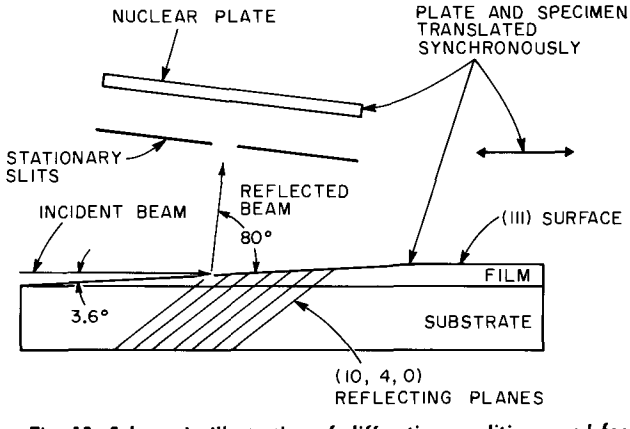

Fig. 13. Schematic illustration of diffraction conditions used for reflection topography.

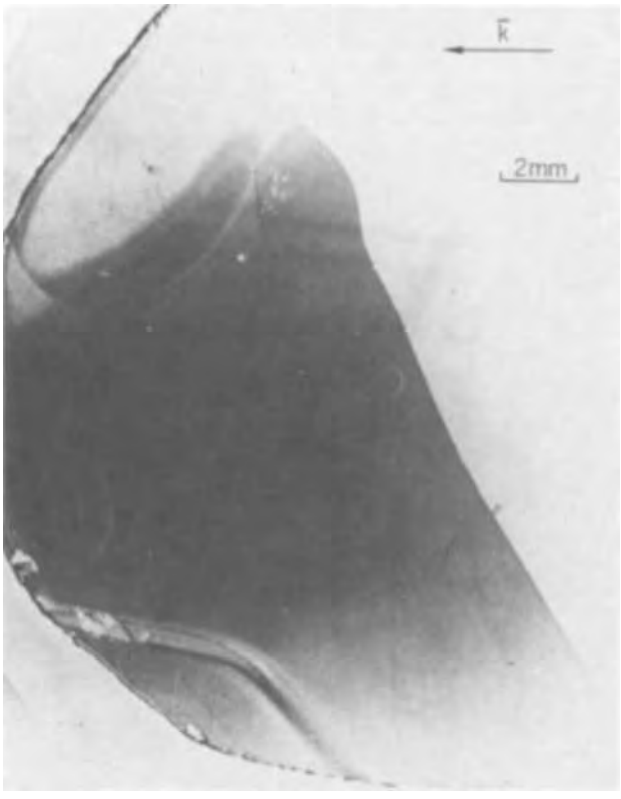

Fig. 14. Berg-Barrett reflection topograph of a taper-etched $Er_2Eu_1Ga_{0.7}Fe_{4.3}O_{12}$ film.

Such cracks when etched as grooves into the substrate due to the masking effect of the film do not have contrast since there is no strain or bending of planes.

Summary

Phosphoric acid etching combined with optical microscopy and x-ray topography can be used to study many properties of the garnet substrates and films, both qualitatively and quantitatively. An overview has been presented here of the use of these techniques to study defects found in both the substrates and epitaxial layers. Through the use of these techniques the occurrence of the defects can be related to preparation and growth conditions and then successfully eliminated, as has now been accomplished with the defects known to limit the utilization of epitaxial magnetic garnet films in large bubble domain devices. Other aspects of these materials such as growth striations in the films and substrates, the effects of strain on the growth rate, and the structure of mixed defects have also been revealed using phosphoric acid and will be studied in more detail. Even though operation of magnetic bubble circuits does not now appear to be limited by some of these phenomena, a knowledge of them may become important as work progresses and more subtle relationships between the magnetic and structural properties of these materials are revealed.

Acknowledgments

The author wishes to thank C. D. Brandle for growing the substrate crystals, and S. L. Blank and B. S. Hewitt for growing the LPE layers. Helpful comments and suggestions made by J. W. Nielsen and L. J. Varnerin are also gratefully acknowledged.

Manuscript submitted Oct. 17, 1972; revised manuscript received Dec. 15, 1972. This was Paper 5 presented at the Houston Meeting of the Society, May 7-11, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1973 JOURNAL.

Note added in proof: A detailed analysis by J. W. Matthews of the type of defect shown in Fig. 3 appears in the March 1973 issue of *Acta Metallurgica.*

Chemical Vapor Deposition of Thin-Film Platinum

Myron J. Rand*

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

Chemical vapor deposition of platinum for microelectronic applications has been studied with the aim of avoiding the radiation damage to dielectrics caused by sputter or e-gun deposition. Two known CVD methods—the pyrolysis of Pt acetylacetonate and the reduction of $Pt(CO)_2Cl_2$—were tried and judged unsatisfactory for either purity or adherence. A novel method of Pt deposition using the trifluorophosphine complex is reported. The process is simple and reliable, and produces adherent bright films of ~100Å Pt crystals on a variety of substrates at 200°-300°C in 1 atm hydrogen. The Pt contains small amounts of residual phosphorus, mostly concentrated at the surface. Resistivity of 750Å films is 1.8 times that of bulk Pt. MOS capacitors with CVD Pt field plates on both Al_2O_3/SiO_2 and SiO_2 alone have shown good stability under bias-temperature aging. CVD Pt and Si interdiffuse readily to form ohmic or Schottky diode PtSi contacts.

Thin films of platinum are used extensively in semiconductor device processing in making platinum silicide ohmic and Schottky diode contacts to silicon. Platinum is also the best diffusion barrier metal in the Ti-Pt-Au metalization scheme for beam leads. For these uses Pt thicknesses range from as little as 100Å (for some contacts) to about 2000Å. Unfortunately Pt is difficult to filament-evaporate; its vapor pressure is low, and it alloys rapidly with tungsten. Pt is usually deposited by electron-beam evaporation or by sputtering.

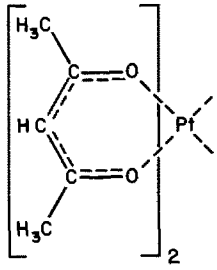
In addition to the relatively complex—and sometimes temperamental—equipment required by these vacuum operations, there is the more serious disadvantage of radiation damage to thin insulating films by x-rays, energetic electrons, and far uv radiation. The charge injected into the dielectric results in shifts of the MOS characteristic, especially during bias-temperature aging. Since stability of threshold voltage is the *sine qua non* of IGFET's, platinum is seldom used in their metalizations.

The obvious way to avoid radiation damage is to use chemical vapor deposition (CVD), which employs only thermal energy, and which is usually done in relatively simple apparatus. The prospects for platinum CVD have been reviewed by Powell *et al.* (1). They suggest two classes of volatile platinum compounds: organometallics such as the acetylacetonate (acac), and the carbonyl chlorides, especially the dicarbonyl dichloride, $Pt(CO)_2Cl_2$. It is probably significant that no articles on the acac as source could be located in the primary literature, and that the last papers on the carbonyl chloride appeared in 1934 (2-4). There is no literature specifically on thin film CVD Pt, to say nothing of films of a quality useful for microelectronics.

This paper first reports experience using both the sources given above for the CVD of Pt thin films. Next a novel deposition method will be described, the pyrolysis of the trifluorophosphine complex of platinum. This reaction employs a liquid source and has decided advantages in simplicity and temperature requirements. It has been studied in detail not only for its own sake but also because volatile PF_3 complexes of most of the transition metals have now been synthesized but as yet have been little investigated for suitability as CVD sources.

Platinum from the Acetylacetonate

The acetylaceton of zero-valent platinum is prepared from potassium chlorplatinite and acetylacetone in aqueous solution made strongly alkaline in order to displace the β-diketone equilibrium toward the enol form. The chelate may be formulated



on the assumption that Pt is bonded to oxygen. While metal-oxygen bonding is usually the case in these complexes, Lewis *et al.* (5) have shown that in some Pt(II) acac derivatives there is Pt-C bonding. The distinction is important to the pattern of pyrolysis of the compound.

$Pt(acac)_2$ is an air-stable yellow powder, available commercially (6). For CVD its vapor pressure becomes significant at about 150°C. Powell *et al.* (1) recommend vaporization at 180° *in vacuo* and a substrate temperature of 350°-450°C. Hydrogen ambient may often be used instead of vacuum to accomplish a clean pyrolytic decomposition of organometallics, but we find $Pt(acac)_2$ heated in hydrogen turns black without vaporizing. The black powder persists at red heat, in air; evidently hydrogen reduces the compound to platinum.

For vacuum CVD experiments the apparatus of Fig. 1 was used. Heating the pedestal by hot gases from a torch flame is unconventional but should not be scorned. The method permits rapid attainment of any temperature up to 700°C, constancy to ±5°, and flexible temperature adjustment by control of the size and gas mixture of the flame.

With the $Pt(acac)_2$ pressure 20-200μ Torr, deposition of Pt at 10-100 Å/min occurred at substrate temperatures of 500°-600°C. On Si substrates one would therefore expect PtSi, but reflection electron diffraction gave only the pattern of randomly oriented fcc Pt. The metallic deposit had a distinct tan or bronze cast, and it was resistant to aqua regia etching. Electron beam microprobe analysis revealed heavy carbon contamination, in fact about one carbon atom per Pt atom. The codeposition of carbonaceous residue was not suppressed by adding CO_2 to the ambient to act as oxidizer. The carbon was completely removed by oxygen-baking the deposit at 550° for a few minutes, but ohmic contact to the 0.01 ohm-cm n-Si substrate was still not achieved. No case of low-resistance ohmic contact to Si has been observed with Pt deposited from the acac, with or without a deliberate siliciding step.

Carbon has little solubility in solid Pt. Considering the electron diffraction result, the probe analysis, the

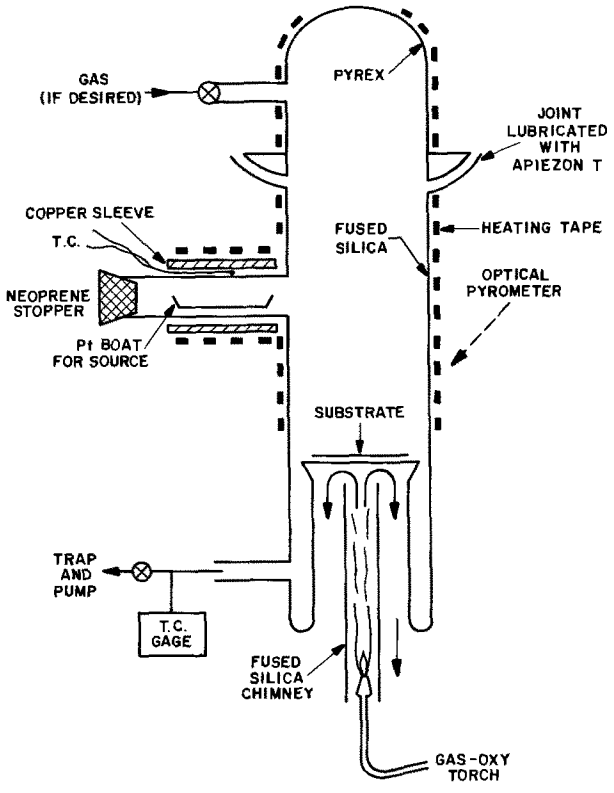

Fig. 1. Apparatus for vacuum pyrolysis of Pt acetylacetonate

result of oxygen-baking, and the failure of Pt-Si interdiffusion, the picture that emerges is one of small crystallites of Pt surrounded by heavy concentrations of carbon, very probably at grain boundaries. We conclude that Pt from the pyrolysis of the acetylacetonate contains too much codeposited carbon to be of interest for most device purposes.

Platinum from the Carbonyl Chloride

For volatile inorganic platinum sources for CVD, Powell *et al.* (1) recommend the carbonyl chlorides, especially the dicarbonyl dichloride, $Pt(CO)_2Cl_2$, as having the greatest difference between the sublimation and decomposition temperatures. They state that deposition may be carried out at 600°C at low pressures (10-20μ), or at 1 atm in hydrogen at much lower temperatures, using carbon monoxide as $Pt(CO)_2Cl_2$ carrier gas to suppress premature decomposition. Saturator temperatures were 100°-150°C. The discussion mentions problems with nonadherent or acicular deposits.

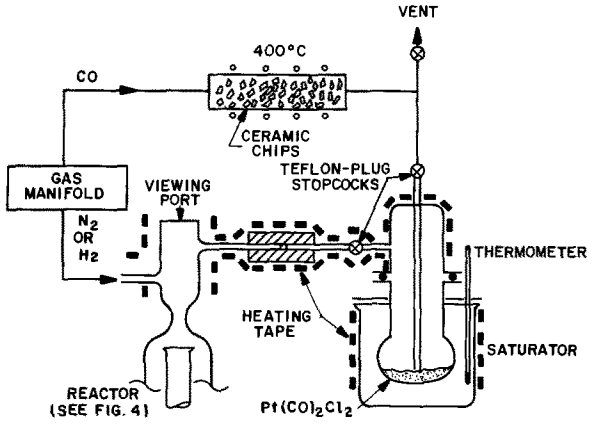

Fig. 2. Schematic diagram of apparatus for the deposition of Pt from the carbonyl chloride.

$Pt(CO)_2Cl_2$ occurs as colorless needles when pure, but is usually dark because of Pt liberated by reaction with atmospheric moisture. Our material was prepared by the method of Lutton and Parry (7) by the Pressure Chemical Company, Pittsburgh, Pennsylvania, and stored under carbon monoxide. Pt depositions were carried out both in the vacuum apparatus of Fig. 1 and the apparatus shown schematically in Fig. 2 and 4. A summary of typical conditions and results appears in Table I; available analytical data are collected in Table II.

Bright films of Pt on Si were obtained without difficulty at low pressures, but adherence was invariably poor. Characteristically, the film suddenly turned from bright to frosty in appearance during deposition, usually not long after it had become opaque, *i.e.*, 300-400Å thick. Often the rough zone continued to spread after the sample was cold. Under the microscope a dense network of folds, puckers, or wrinkles was visible, and there is little doubt that Pt had separated from the substrate. Scoring a smooth area caused instant peeling. The failure of the film to adhere is surprising; at these deposition temperatures considerable Pt-Si interdiffusion should occur. The electron beam microprobe was unable to detect either C or Cl in the Pt, and the electron diffraction pattern was normal.

In depositions in 1 atm hydrogen the necessity for a carbonyl scavenger for the carbon monoxide carrier soon became evident. The CO was research grade (Matheson Company, 99.9% min.), but at 1500 psi there is probably reaction with the tank materials, so that iron and nickel carbonyl contaminants are pyrolyzed on the substrate and Fe and Ni end up in the Pt. A 400°C tube packed with porcelain chips took care of this problem.

Hydrogen-ambient depositions also produced bright Pt films, and for the first time some of these could be alloyed into Si to produce good ohmic contacts. Adherence was still marginal. Proper dispersion of the gas flow over the substrate surface was troublesome, as it is with many CVD reactions, and keeping the $Pt(CO)_2Cl_2$ from condensing out in cool places requires careful attention to the heated saturator lines, since they cannot be permitted to be hot enough to decompose the compound.

The substrate definitely influenced the Pt film morphology in these depositions. In run 9 (Table II) relatively large islands composed of randomly oriented 150Å Pt crystals formed on a deposited silica surface giving a sheet resistance of >20-Kohm/□, while an adjacent deposited alumina surface accumulated a continuous film of ~2000Å crystals of 1.8 ohm/□. In run 10, done at 485°C, four different substrates were deposited simultaneously, but only Pt on the Al_2O_3 substrate gave the expected electron diffraction pattern. The others gave a much more complex, and somewhat variable, pattern with many d-spacings larger than any in fcc Pt. Among these were two strong reflections at about double the spacing of the two most intense fcc lines, the (111) and the (200). We have seen these anomalous patterns also on several e-gun evaporated films and two 3 kV-sputtered Pt's, but not on low voltage triode-sputtered samples. The glancing angle electron beam penetrates only ~50Å in Pt; x-ray diffraction has shown normal fcc structures for Pt with anomalous surface patterns. The existence of superlattice surface structures on Pt has been reported (8); it is not known whether they are impurity-stabilized. At 485°C, the disproportionation of CO to give some carbon is a distinct possibility, especially on Pt.

The source temperatures in Table I are to be noted. Over the course of only seven runs it was necessary to raise the $Pt(CO)_2Cl_2$ temperature from 125° to 155°C (which is above the melting point) to maintain reasonable deposition rates. This suggests that in spite of the CO atmosphere the compound was decomposing to one less volatile. After the last run of Table I the cake of source material was analyzed, with the following results:

$Pt(CO)_2Cl_2$	78.6%
$PtCl_2$	19.0%
Pt	0.63%
Fe, Ni, Cr oxides	0.1-0.2%

It seems clear that the material in the saturator was slowly decomposing to nonvolatile $PtCl_2$, which coated the solid particles and made the volatile carbonyl chloride inaccessible. The elemental Pt may have been present originally or have resulted from further decomposition.

While the carbonyl chloride process in hydrogen can produce pure Pt films, the limited source life, corrosive vapor, necessity for heated lines, and poor adherence combine to make the method unattractive. Furthermore, it is probably more than ordinarily sensitive to the various deposition parameters, owing to the complicated equilibria existing among the various carbonyl chlorides, $PtCl_2$, CO, Cl_2, and Pt (7).

Platinum from the Trifluorophosphine Complex

Phosphorus trifluoride resembles carbon monoxide, at least formally, in forming a wide variety of stable complexes with transition metals. Although $Ni(PF_3)_4$ has been known for twenty years (9), it has been only since 1965 that Thomas Kruck and his co-workers have achieved the preparation of the complexes of all the metals of Groups VI-VIII of the periodic chart. Nixon (10) has tabulated the known PF_3 complexes, and Schmutzler (11) gives a useful review of the properties of PF_3 itself.

In spite of the good volatility of the metal-PF_3 compounds, there is only one mention of their use for CVD, a patent (12) teaching the use of $W(PF_3)_6$ to deposit W on Si at 450°C in making Schottky barrier contacts.

The PF_3 complex of platinum is of particular interest because no stable carbonyl of platinum is known. Tetrakistrifluorophosphine platinum, $Pt(PF_3)_4$, was first prepared by Kruck and Baur (13). Our samples were made using their procedure by PCR, Incorporated, Gainesville, Florida, and Pressure Chemical Company, Pittsburgh, Pennsylvania. The compound is a colorless, mobile liquid boiling at 87°C, apparently stable to dry air but hydrolyzed by moisture to Pt, H_3PO_3, and HF. The compound appears to be a good solvent for simple halogenated organics and for various mixed halides of phosphorus, and it is advisable to check its purity by infrared spectra. Arsenic trifluoride (bp 65°C) is another common impurity, originating in the manufacture of the PF_3, and can contaminate Pt deposits with as much as 1% As.

In considering $Pt(PF_3)_4$ for the CVD of Pt, the hope is of course that simple pyrolysis will occur, with selective rupture of the Pt-P bond and liberation of the thermally-stable PF_3. In considering the results reported below, however, one should keep some additional chemistry in mind: that PF_3 is reported to attack SiO_2 at elevated temperatures, forming P_2O_3 and SiF_4 (both gases at the deposition temperatures); and that freshly formed Pt will certainly be a strong chemisorber and highly catalytic. In other words, the reactivity of the products may complicate the pyrolysis, degrade the Pt purity, or result in attack on the substrate.

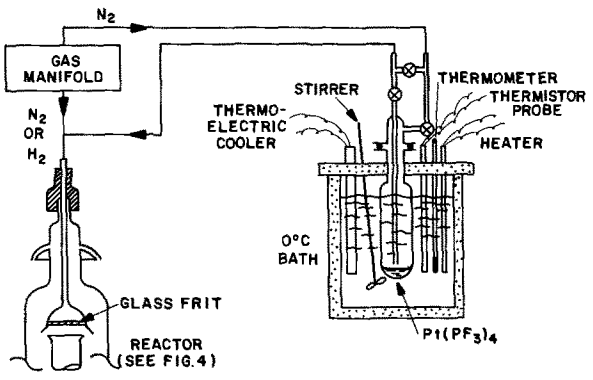

Fig. 3. Schematic diagram of source system and apparatus for the deposition of Pt from $Pt(PF_3)_4$.

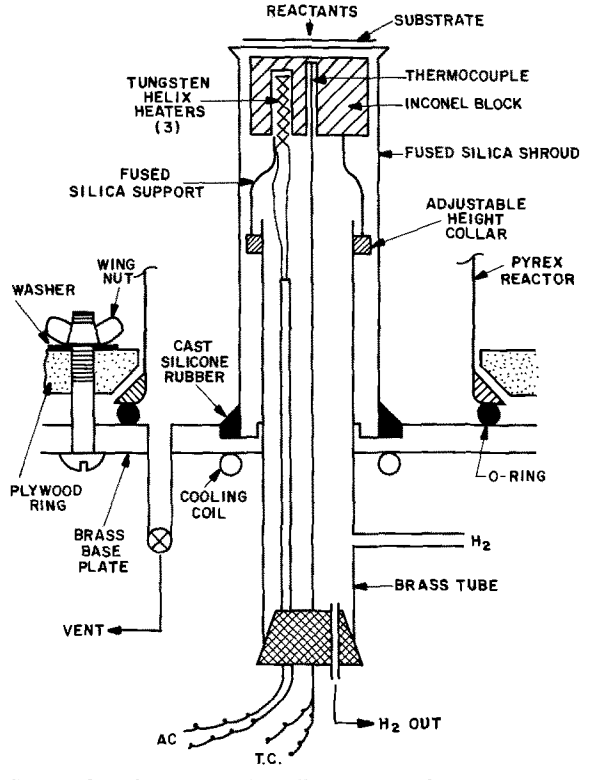

Fig. 4. Detail of the cold-wall reactor with resistance-heated silica pedestal for the substrate.

The apparatus used for Pt deposition from the PF_3 complex is shown schematically in Fig. 3 and 4. The complex is stored under dry nitrogen in a saturator at 0°C, at which temperature its vapor pressure is estimated to be ~15 Torr. After dilution by the main gas stream (usually hydrogen) its concentration is 0.01-0.1%. The total gas flow displaces the reactor volume 1-5 times a minute. A coarse glass frit distributes the reactants over the substrate wafer; deposit thickness uniformity of ±10% is easily obtained. The resistance-heated pedestal (Fig. 4) is preferred to tube furnace or rf-heated equipment because the reactor wall remains fairly cool. A hot wall would soon become opaque. The temperatures quoted in this report are not readings of the heater block thermocouple but estimated substrate temperatures derived from measurements of the temperature difference between the heater thermocouple and the horizontal surface of the fused silica shroud.

Results—Deposition of thin-film Pt.—With optimum deposition conditions the pyrolysis of $Pt(PF_3)_4$ produces a uniform, smooth, continuous, adherent layer of mirror-bright Pt indistinguishable in appearance from sputtered or e-gun-evaporated Pt. The following substrates have been coated: Si, thermal and deposited SiO_2, deposited Al_2O_3 and Si_3N_4, fused silica, soft glass, sapphire, Ta_2N, evaporated Ti, CVD tungsten, GaP, and GaAs. The preferred ambient is hydrogen, and the preferred temperature range 200°-300°C. At 175°C and below nonspecular rough deposits indicate incomplete pyrolysis; at 350°C and above a brown fume in the gas phase suggests decomposition before the vapor reaches the hot substrate. A deposition rate of 50-100Å Pt/min is most convenient.

Glancing angle or transmission electron diffraction has invariably shown only the pattern of fcc Pt. The as-deposited grain size, as seen by transmission electron microscopy, is 90-120Å, whether on Si or SiO_2. Only on single-crystal sapphire has strong preferred orientation been observed. When CVD Pt on SiO_2 is heated to 500°C or so, as would happen when PtSi contacts were being formed, rapid growth to grains several microns across occurs.

CVD Pt resistivity has been measured on 750 ± 25Å films using a four-point probe. The films were deposited on thermal silica at 225°C. The result was 18 μohm-cm. The accepted value for bulk Pt is 10 μohm-cm. Sputtered or e-gun Pt films also are in the range 1.5—2 times bulk resistivity. CVD Pt films heated to 525°C for 30 min had resistivities of 11 μohm-cm.

Adherence.—This property is always of particular interest for microelectronic applications, especially with a noble metal where adhesion is not expected to be aided by chemical bonding with the substrate. For a quick comparative adherence measurement we have used a Kentron microhardness tester with a 5 mil radius diamond stylus which could be loaded with from 1 to 1000g. The sample was moved by a micrometer stage while in contact with the stylus, and the resulting scratch was examined under the microscope. Any exposure of the substrate anywhere along the track, or any detached metal debris, was called an adherence failure. In Table III typical results for a number of films are given, so that CVD Pt may be located on a scale with other common film-substrate combinations.

Considering the mild deposition conditions, the adherence of CVD Pt is remarkably good. Adherence to insulators is comparable to that of active metals such as Al or Ti. Pt on deposited Al_2O_3 (where double-dielectric IGFET's now use Ti as a "glue" for metalization) is especially tenacious; we have not seen a sample which failed at less than 500g. At such loads the silicon is as likely to fail as the Pt-insulator bond. In fact, such a failure occurred in attempting a gold "nailhead" pull test (1 mm diam 90° thermal compression bond) on the structure Au/CVD Pt/Al_2O_3/SiO_2/Si. At 10 lb the Si ruptured. The Pt samples of Table III were remeasured 3 months later with no substantial changes.

All adherence testing is empirical and often ambiguous and subjective. Scratch testing does not predict beam lead adherence. Certainly the most meaningful adherence test is one which most closely mimics the conditions the actual structure is subject to. But CVD Pt does appear to stick very well, as well as sputtered Pt does; indeed, no case of spontaneous peeling from

Table III. Scratch tests for adherence

(5 mil radius diamond stylus)

System	Approx. failure load (g)
Metal film marginal for Scotch tape pull test	5-10

on evap. Ti/dep'd. Al_2O_3	>100 (Ti/Al_2O_3 failed first)
on CVD W/dep'd. Al_2O_3	>500

any substrate has ever been observed. Possibly conditioning of the substrate by PF_3 plays a role in this adherence.

Analysis of the Pt.—The deposited Pt films have been analyzed by two techniques: electron beam microprobe analysis and Auger electron spectroscopy combined with argon or xenon ion sputtering (14). Microprobe results must be based on the assumption that the film is homogeneous, whereas the Auger analysis can establish a profile.

The only foreign element detected in significant amount by the microprobe is phosphorus, with the reported content varying with deposition parameters. The actual figure is meaningless, since the Auger spectra have repeatedly shown that the phosphorus is concentrated in the outer 50Å of the Pt film. At the surface it is a major component; in most of the film it is undetectable, *i.e.*, <0.5 atomic per cent (a/o). The phosphorus content is four or five times higher if the deposition is carried out in nitrogen instead of hydrogen—not a recommended procedure, although there is little change in the appearance of the film.

Trace amounts of fluorine, oxygen, or carbon have been detected irregularly by the electron microprobe.

Whether there is phosphorus enrichment at the Pt-substrate interface is still moot at this writing. It is certainly much less than at the Pt surface. The question is not trivial because of the possibility of n-doping of Si during PtSi formation. The Auger spectra also show that the Pt-Si interface is not sharp after 225°C deposition: there is a zone roughly 300Å thick with major amounts of both elements (14). This result agrees with the conclusions of Hiraki *et al.* (15) that Si diffuses rapidly through some metal films at temperatures far below the eutectic.

Auger spectra have confirmed the presence of small amounts of carbon scattered through some of the CVD Pt film samples. The source is probably a volatile organic impurity in the $Pt(PF_3)_4$. There is evidence from the infrared absorption spectrum for an impurity absorbing at 1026 cm^{-1}, but it cannot be identified.

Film stress.—Stresses in deposited Pt films are of interest because they must be balanced by stresses induced into the substrate, and because they influence the interdiffusion of Pt and other metals or Si. Average film stress on (111) Si was measured by interferometric determination of beam bending (16), with results as given in Table IV. Two PtSi samples are included. All the films were under considerable tension, with the CVD Pt, at 4.7×10^9 dynes/cm^2, only about a quarter of the stress of a low-voltage sputtered Pt. It can be calculated that the thermal expansion mismatch between Pt and Si in cooling from 225°C to room temperature can account for about 2.8×10^9 dynes/cm^2; the remainder must be "intrinsic" stress.

The tensive stresses in Table IV are far above those that pure bulk Pt could sustain without plastic flow. The shear modulus μ of Pt is 6×10^{11} dynes/cm^2, and for single-crystal metals the flow stress is of the order of $10^{-4}\mu$. It is well known that much higher stresses may be observed in films of very small randomly oriented crystals. Chaudhari *et al.* (18) have presented a mechanism accounting for stresses of $1\text{-}2 \times 10^{-2}\ \mu$ for crystallite sizes of 100-200Å. For Pt this would allow flow stresses of $\sim 10^{10}$ dynes/cm^2, in close accord with our measurements. The data of Table IV thus very likely represent the elastic limits of the films, and differences can be accounted for by small amounts of Pt-Si alloying. In fact, the Auger spectra showed considerably more Si in as-deposited sputtered Pt than in CVD Pt—and, of course, very similar amounts in the silicides made from them.

Table IV. Average film stress on (111) Si at room temperature

Film	Thickness (Å)	Substrate temp (°C)	Stress (10^{10} dynes/cm²)
E-gun evaporated Pt[a]	1000	225	+1.2
Low-voltage sputtered Pt	500	?	+1.8
CVD Pt	600	225	+0.47
PtSi, l.v. sputtered	1000[b]	625[c]	+1.9
PtSi, CVD	2000[b]	525[c]	+1.0

[a] Calc. from Ref. (17).
[b] PtSi assumed twice Pt thickness.
[c] Sintering temp.

The high stress in deposited Pt films may be implicated in what we observe when Pt is deposited over films of active metals. When CVD Pt was deposited on evaporated Ti or CVD tungsten a dendritic crystal pattern developed on the surface within a few days, appearing to the eye as haze. Reflection electron diffraction gave complicated patterns whose only certain interpretation was that the crystals were not merely Pt. Some of the spacings agreed with those for Ti (or W) oxides, or with intermetallics like Ti_3Pt. In any case, there is a strong hint that at the 225°C deposition temperature the underlying metal diffused into or through the Pt. There is other evidence that at such temperatures Ti may diffuse through Pt and form rutile at the surface (19).

The crystallization may be stress-nucleated. Figure 5 shows crystals growing from the edges of a stylus trace in CVD Pt on ~1000Å CVD W (from $WF_6 + H_2$) on deposited Al_2O_3. In areas where the W was masked against Pt deposition there were no crystals along the stylus mark.

CVD Pt for field plates.—Pt electrodes of various sizes for MOS testing have been delineated on both SiO_2 and Al_2O_3 using Shipley AZ 1350H resist. The etch was 4 H_2O: 3 HCl: 1 HNO_3, 1-2 min at ~85°C. Resist adherence appeared good; there was no difficulty with edge lifting.

The first question to be answered is whether the CVD Pt process is in any way detrimental to the IGFET Al_2O_3/SiO_2 double insulator. Typical IGFET material was Pt-deposited, heated to 600°C (as would be done to form the PtSi contacts), cooled, and the Pt stripped off with aqua regia. The C-V characteristic was taken with a mercury probe before and after this procedure. A portion of each slice received the temperature cycling but not the Pt deposition, and therefore served as control.

Results of these tests are summarized in Table V. The 600° heating has caused some shift in the flatband voltage. In all cases, however, the shift is virtually identical for the Pt-deposited samples and the controls. The changes in Si doping level are also insignificant. We conclude that the CVD Pt process could be used for IGFET's without harm to the gate insulation.

Limited stress-aging experiments using CVD Pt field plates have been carried out on both the Al_2O_3 (500Å)/SiO_2 (1000Å) double dielectric and on 1150Å dry-oxygen-grown SiO_2 annealed at 1100°C. For the former the conditions were: 300°C, 24 hr, ±10V; for the latter, 200°C, 30 min, ±10V. For most of the work, controls were available in the form of evaporated Al dots on another portion of the same slice used for the Pt tests. (In any case, there is a considerable history on bias-temperature aging of these insulators with Al electrodes.) C-V curves were taken with ±20V sweeps. Electrodes were contacted with gravity probes with Pt tips; these have been superior to any others in maintaining reliable contact, especially on Al, without serious damage to the metal film.

A summary of conditions and results appears as Table VI. In general, the Pt diodes aged very well, and clearly outperformed their Al controls. In only one case, with positive bias on the Pt with the double dielectric, was ΔV_{FB} >0.2V. Results were very reproducible—note the tight statistical distribution of V_{FB}'s. On occasion shifts of 0.1-0.4V were observed on heating the diodes without bias, or shorted, but this behavior is also characteristic of Al or Au metalization. There was no instance of peeling of Pt dots as a result of B-T aging.

Interface state density determinations are available on the second sample of Table VI. Diodes which had been heated without bias showed N_{fs} in the high 10^{10} cm^{-2} eV^{-1} range near midgap, while B-T aged diodes showed $N_{fs} = 4\text{-}7 \times 10^{10}$. These are slightly high; for Al, $N_{fs} < 5 \times 10^{10}$ is expected, but no Al controls for this run were available. Judging solely by the shapes of the C-V curves, Pt metalization and B-T aging never degraded interface state density, and in some cases (notably with the SiO_2 capacitors) definitely improved it. A CVD Pt deposition represents a 225° hydrogen bake.

With (100) n-Si, Pt field plates on the double dielectric give $V_{FB} \sim +1.6$V, V_T (calc.) $\sim +0.8$V. Pt on SiO_2 shows $V_{FB} \sim +0.2$V, with V_T (calc.) ~ -0.8V.

While the data of Tables V and VI are inadequate to establish firmly the aging behavior of CVD Pt-metalized diodes, there is certainly no evidence that phosphorus or fluorine impurities in the Pt are diffusing into the dielectric or drifting under bias. So far CVD Pt has been a stable, reproducible, adherent noble metal electrode, and one which should have a useful place in stress aging. Pt should not react with the dielectric, it will not react with atmospheric moisture and produce hydrogen, and the instability of Pt oxide at elevated temperatures keeps its surface clean and easy to maintain contact to.

Ohmic contact.—Generally the first Pt deposited on a device is interdiffused with Si in selected areas, forming PtSi (probably with some Pt_2Si) contacts to the underlying Si. These may be ohmic or Schottky diode contacts, depending mostly on the doping level of the Si. In any case, Pt deposited by any process must interdiffuse readily and reproducibly with Si at 400°-600°C, and Pt deposited on insulator areas must then be removed without damaging the silicide.

There has been extensive investigation of the formation of PtSi between Si and Pt from the $Pt(PF_3)_4$ process. It is planned to present information on the electrical characteristics of the resulting contacts in a separate report. For present purposes it is sufficient to say that CVD Pt has invariably alloyed readily with Si under identical time-temperature conditions used for sputtered Pt. A smooth silicide of normal appearance results. Under all conditions where a PtSi-Si contact is expected to give an ohmic characteristic, the contact using CVD Pt infallibly has done so. This includes n-Si of $N_D > 10^{18}$, and practically all levels of p-Si, since here the PtSi-Si barrier height is only 0.25 eV (20).

PtSi made from CVD Pt shows a somewhat greater susceptibility to attack by aqua regia than does conventional silicide. We believe this is due to the relatively high phosphorus content at the surface, which degrades the integrity and chemical resistance of the thin film of SiO_2 which ordinarily protects PtSi (21).[1] However, the silicide may be made immune to attack by deliberate superficial oxidation, for example by heating in air to ~500° for a few minutes. The oxide may be removed afterwards by a brief HF treatment.

The behavior of a CVD Pt film on an insulator when it is heated ≥600°C is believed to be another conse-

[1] Platinum silicide made in even the purest available inert ambient is covered with about 100Å of silica. If this protection is removed, the PtSi is rapidly and completely dissolved by the aqua regia used to strip unreacted Pt from the insulator areas of a circuit pattern.

Table VI. Bias-temperature aging with CVD platinum field plates

Sample	Dielectric	Field plate	Conditions[a]	V_{FB}	ΔV_{FB}	No. of diodes
6 ohm-cm (As) bulk (100) Si	500Å Al_2O_3/1000Å SiO_2	Pt	As deposited	1.77 ± 0.08[b]		9

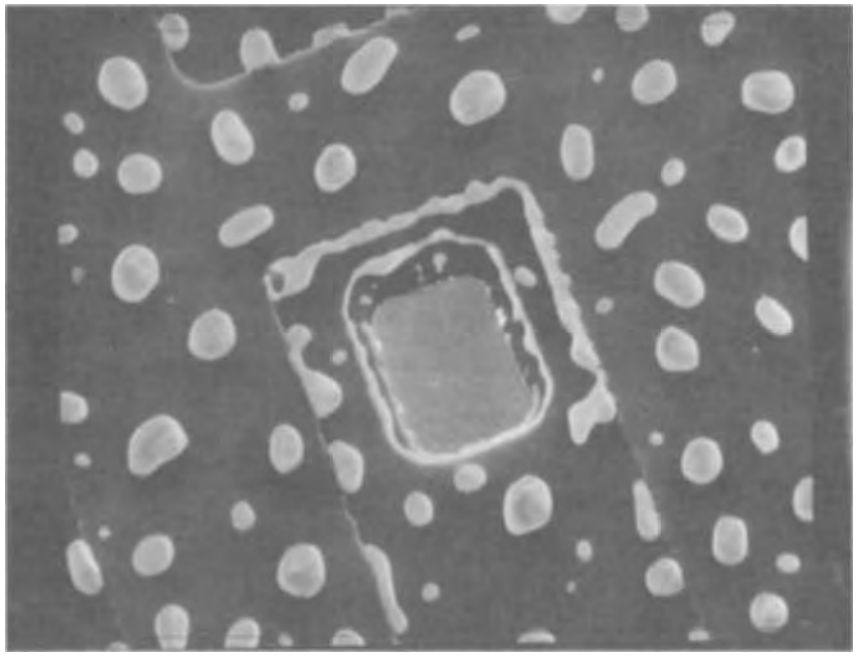

Fig. 6. Scanning electron microscope photograph of 0.3 x 0.4 mil PtSi contact formed from CVD Pt at 625°C, showing separation of Pt film on insulator into islands. The picture was taken at 45° tilt, 5000X.

quence of phosphorus segregation at the interfaces. The Pt-P system has a eutectic at 588°C. As this temperature is approached the film breaks abruptly into islands of metal with bare insulator in between. We suspect localized melting occurs where the Pt contacts the insulator, allowing strong surface tension forces to contract the film. The phenomenon is shown in Fig. 6, a 5000× scanning electron micrograph of a 0.3 × 0.4 mil contact hole in the Al_2O_3/SiO_2 double insulator. The smooth PtSi contact is seen near the center of the picture; note also the adherence of the Pt to the exposed edge of the Al_2O_3 layer. If the Pt-Si interdiffusion is carried out at temperatures below the Pt-P eutectic the film on the insulator remains smooth and unbroken.

The islanding phenomenon may impose limitations on the use of CVD Pt in some multilevel structures, since the better insulators are usually deposited at >600°C. It may be possible to find deposition conditions which will reduce the phosphorus content, or alternatively to remove most of the P from the surface chemically. Neither of these approaches has been tried as yet; doubtless it would be simpler to avoid temperatures over 550°C after the application of CVD Pt if the Pt, as such, is to remain a permanent part of the structure.

Conclusions

In solid-state device and integrated circuit technology, platinum has important applications in contacts and in metalization systems. However, present deposition methods cause radiation damage to insulating layers which may be unacceptably severe for some unipolar devices. Chemical vapor deposition of thin film Pt has consequently been studied. The two known methods were both found unsatisfactory. Pyrolysis of platinum acetylacetonate yields a film heavily contaminated with carbon. Reduction of platinum dicarbonyl dichloride yields a pure film, but adherence is poor, the source life is short, and the reaction is difficult to control.

A new method of Pt deposition, pyrolysis of $Pt(PF_3)_4$, has been studied in detail. The process is simple and reliable, and produces adherent bright films of very small crystals on a variety of substrates at 200°-300°C in hydrogen. Adherence to deposited Al_2O_3 and Si_3N_4 is particularly tenacious. The Pt contains small amounts of residual phosphorus, most of which apparently accumulates at the outside surface during deposition, or else is deposited last. Resistivity is normal for Pt thin films. The film is under tensile stress, but less so than those from e-gun evaporated or sputtered Pt.

MOS structures with CVD Pt field plates have shown good stability under bias-temperature aging, in fact better than their Al-metalized controls. CVD Pt on the usual IGFET $Al_2O_3/SiO_2/(100)$ Si gives $V_{FB} \sim +1.6$V, and on $SiO_2 \sim +0.2$V. The corresponding calculated threshold voltages are +0.8 and −0.8V, respectively. The stress-aging stability is considered evidence that residual phosphorus in CVD Pt does not permeate the dielectric, at least not in any electrically active form.

CVD Pt films behave like sputtered Pt in alloying readily with Si at 400°-600°C to form a smooth layer of PtSi. A low-resistance ohmic contact to Si is produced in all cases where theory predicts such a contact.

Finally, there is an important area of potential usefulness of the $Pt(PF_3)_4$ process which this report has not considered but which will be obvious to chemists. This is the platinum coating of particulate solids, porous materials, screens, irregularly shaped objects, plastics, etc., for corrosion resistance or catalytic activity.

Technical Notes

An Optical Study of the Chemistry of Mn^{2+} During the Formation of Calcium Fluorophosphate Phosphors

A. Wachtel*

Westinghouse Lamp Division, Bloomfield, New Jersey 07003

and F. M. Ryan*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

In 1967, Parodi (1) reported a study which was concerned with the distribution of Mn between different phases which can form in the course of solid-state synthesis of Ca-fluorophosphate. One of the important findings was that one of the phases, namely CaO, has a very high affinity for Mn, so that a large fraction of the total Mn is found in CaO during early stages of the reaction. Parodi used electron-spin resonance to identify the Mn activated phases, and therefore the total Mn concentration had to be kept very low, typically about 1/100 of that normally employed in commercial halophosphate phosphors.

In order to avoid this difficulty, we used the excitation spectra to identify the phases. This enabled us to dope the halophosphates with the higher manganese concentration of 0.085 Mn/3P such as is used in typical cool-white formulations. The excitation spectra of the d^5 configuration of Mn^{2+} consists of a combination of sharp lines which involve transitions between energy levels whose separations are independent of crystal field strength, and broad lines which involve transitions between energy levels whose separations are strongly dependent on crystal field strength. In addition, the spectra are influenced by the site symmetry in which the Mn is located. These variations are sufficient to yield excitation spectra which are unique for each of the compounds.

In addition to higher Mn concentrations, we also included Sb or Cl or both in some of our preparations, since these compounds are normal constituents of Ca halophosphate phosphors. Raw mixes consisted of $Ca_2P_2O_7$, $CaCO_3$, and CaF_2 with the Mn incorporated in solid solution in one of these three compounds for each sample. Cl containing phosphors were prepared with NH_4Cl as usual, and Sb, where used, was added as Sb_2O_3. In order to follow the formation of intermediate phases, firings which lead to equilibrium conditions (*e.g.*, 1150°C for several hours) were avoided in most cases. Thus, most of the firing times were shorter and firing temperatures lower than are commonly used in preparing halophosphate phosphors. Under these conditions it was important to avoid oxidation of Sb which reaches a maximum in air at 900°C (2), as this would prevent its incorporation into the apatite phase. All firings were therefore conducted in a purified nitrogen atmosphere. In view of the limited firing conditions it was also important to avoid any possibility of incomplete mixing which could allow some local excesses in the ratio of total metal ions to phosphorous over the stoichiometric ratio of 5/3. Although Rabatin, Gillooly, and Hunter (3) have shown that the luminescent phase in halophosphate phosphors is stoichiometric apatite, it is well known that deviations from stoichiometry in which the metal to phosphorous ratio exceeds 5/3 are disastrous to luminescence efficiency, while ratios below 5/3 have a much smaller effect (4). We, therefore, deliberately employed formulations calculated to yield the slightly nonstoichiometric metal to phosphorous ratio of 4.95/3. The second phase of $Ca_2P_2O_7$ which could form due to this nonstoichiometry was considered to be a small effect compared to the large amounts of second phases present due to the limited firing conditions.

Results

Table I summarizes the twelve major variables investigated, and also presents relative line heights of the major reflections for apatite, $\beta Ca_2P_2O_7$, and $\beta Ca_3(PO_4)_2$ (in the order shown) as obtained by x-ray powder diffraction analyses. It can be seen that in most cases, preparations in which the Mn is added in solid solution to $Ca_2P_2O_7$ showed somewhat stronger apatite lines; however these differences are not very great. The only appreciable influence due to the form of Mn addition was noted in the 254 nm excited luminescence of fluoroapatite containing Sb but no Cl. In no case were we able to detect free CaO by x-ray powder diffraction analyses where present in appreci-

able quantity (top row). It was, however, easy to demonstrate its presence by the high pH of an aqueous slurry of the phosphor.

Figure 1 shows the excitation spectra of Mn activated phases which one might encounter during solid-state reactions leading to fluoroapatite. It was easy to identify those of $Ca_2P_2O_7$, $CaCO_3$, and CaF_2 in our raw mixes, but we found no more evidence of these in the mixtures after firing at 900°C. At least in the case of $\beta Ca_2P_2O_7$ that may be due to the similarity of its excitation spectrum with that of apatite. To detect it, one relies on the sharp line at 4025Å. We estimate that 5% of $\beta Ca_2P_2O_7$ would be undetectable in apatite, provided that the distribution coefficients of Mn are the same in both compounds and that equilibrium conditions exist. Among the remainder, only the excitation spectra of Mn in apatite and in CaO could be clearly identified in phosphors fired at 900°C or higher. This is shown in Fig. 2 where we see the effect of the source of Mn and of firing temperature. The top spectrum is that of a phosphor obtained at 900°C from a raw mix which contained the Mn in solid solution

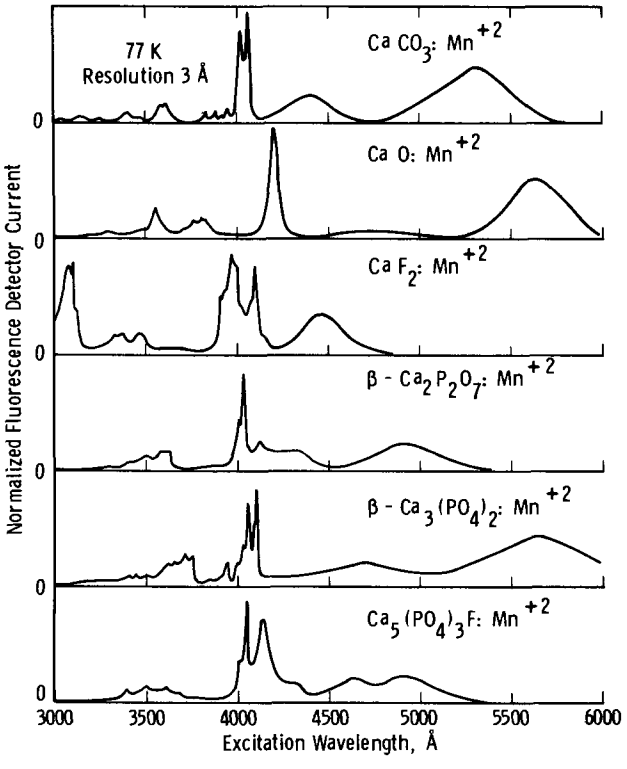

Fig. 1. Excitation spectra of Mn in raw materials and intermediates formed during solid-state reaction leading to fluoroapatite.

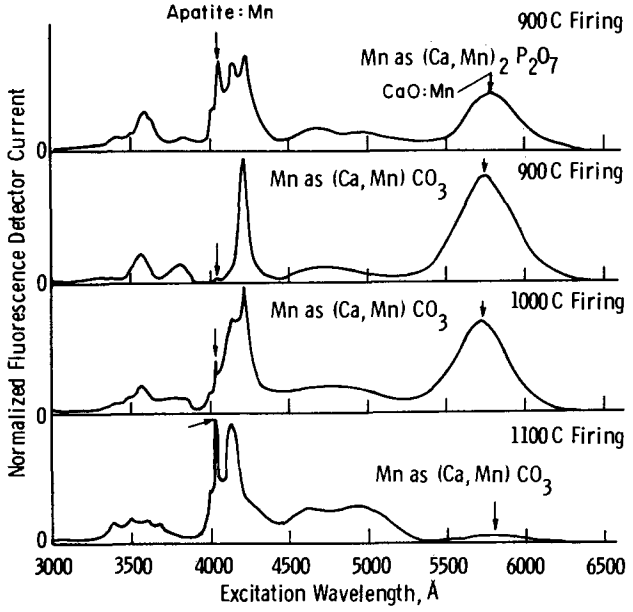

Fig. 2. Excitation spectra of Mn in fluoroapatite phosphor compositions. Detector currents of the individual spectra have been normalized to make them appear of equal height. No correction has been applied for the wavelength-dependent response of the system as a function of source of Mn and firing temperature. The arrows indicate the presence of Mn in the apatite phase as evidenced by the dominant sharp line in its excitation spectrum at 4037Å.

in $Ca_2P_2O_7$ (top left in Table I). It consists of fairly strong lines due to apatite, as well as evidence of strong fluorescence due to CaO:Mn. On the other hand, the fluorescence, if any, of the $\beta Ca_2P_2O_7$ and $\beta Ca_3(PO_4)_2$, shown to be present by x-ray powder diffraction analysis, could not be identified over the background. Phosphors derived from a mix containing the Mn in solid solution in CaF_2 show essentially the same spectra. The remainder of the figure shows the excitation spectra of phosphors derived from a mix containing the Mn in solid solution in $CaCO_3$. Here we note that at 900°C, the spectrum consists almost entirely of that of CaO:Mn. Only with increasing firing temperature does the excitability of Mn in apatite gain in strength, so that after firing at 1100°C, almost all of the CaO has disappeared.

Figure 3 shows the excitation spectra of phosphors containing Cl and Sb after firing at low temperatures. The spectra are restricted to a region near 3500Å because the fine structure there is suitable for showing

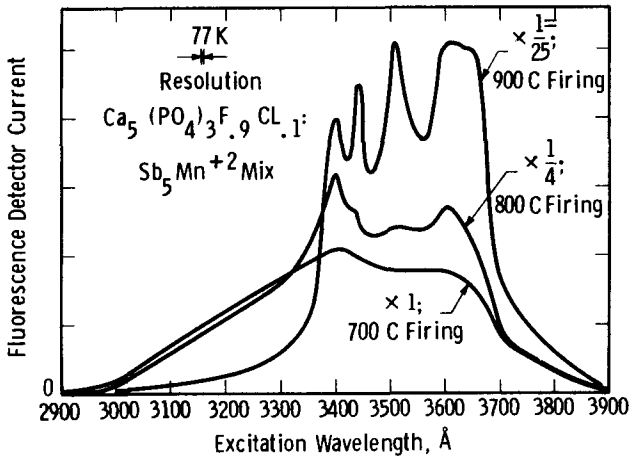

Fig. 3. Excitation spectra of Mn in fluoro-chloroapatite composition containing Sb, as a function of firing temperature.

the formation of a well-defined matrix. As one goes from 700° to 900°C, we note a very rapid rise in signal strength which is entirely due to Mn activated apatite. Although these phosphors were also derived from a mix containing the Mn in solid solution in $CaCO_3$, there was no evidence of CaO:Mn after firing at any temperature, or in any other region of the excitation spectrum.

Inasmuch as the presence of either Sb_2O_3 or NH_4Cl in the raw mix seemed to inhibit the formation of a separate CaO phase at low temperatures, we investigated these phenomena further by means of additional preparations. The effect of Sb was studied on a fluoroapatite containing 5.1 metal/3P, *i.e.*, designed to form with a separate phase of CaO even after firing to equilibrium conditions. This was accomplished by firing at 1200°C for 3 hr. Excitation spectra of a phosphor prepared without Sb did, indeed, show luminescence of Mn in apatite and in CaO of approximately equal intensity. However, the same phosphor, also doped with Sb, showed only a strong excitability of Mn activated apatite with no trace of CaO:Mn luminescence evident. This was so in spite of the fact that at this high metal/P ratio, there was none of the characteristic energy transfer from Sb to Mn, and indeed no Sb fluorescence could be observed.

The mechanism whereby NH_4Cl inhibited the formation of CaO may be twofold and was tested by (*i*) preparing chloro-fluoroapatite with $CaCl_2$ instead of NH_4Cl, and (*ii*) preparing fluoroapatite with 10% of the F addition as NH_4F instead of CaF_2, both followed by firing at 900°C for 30 min. The previous observations were now reversed, *i.e.*, the Cl containing phosphor showed free CaO, while the Cl-free phosphor contained no second phase of CaO. However, the amount of CaO in the chloro-fluoroapatite was appreciably lower than that observed in fluoroapatites prepared with CaF_2 as the sole source of F (*e.g.*, Table I and Fig. 2).

Discussion

The appearance of strong CaO:Mn luminescence in materials consisting mainly of apatite and containing less CaO than can be detected by x-ray powder diffraction analyses suggests that the apatite contained very little Mn, otherwise its signal would have swamped that of the CaO:Mn luminescence. Therefore, the affinity of CaO for Mn is very high, and concentration quenching is not pronounced. In particular, the high affinity of CaO for Mn is demonstrated by the fact that much of the Mn diffused from its original location in solid solution in $Ca_2P_2O_7$ or CaF_2 into freshly formed CaO, while in the case where it was originally located in $CaCO_3$, essentially all of it remained associated with the CaO which was formed by decomposition of the $CaCO_3$. Release of Mn for incorporation into apatite occurs only with the disappearance of the CaO, either by completing the apatite-forming reactions at higher temperatures, or by other means, *e.g.*, by reaction with excess ammonium halide to form the corresponding calcium halide.

The fact that phosphors prepared with 0.9 CaF_2 + 0.1 $CaCl_2$ contained less CaO than phosphors prepared with 1.0 CaF_2 is probably due to fluxing by the relatively low-melting $CaCl_2$ or $CaCl_2$-CaF_2 eutectics; the effect of excess ammonium halide (Cl or F) was considerably more pronounced.

The mechanism by which Sb_2O_3 inhibits the formation of free CaO is almost certainly due to formation of Ca-antimonites or antimonates (5) not only because the effect is obtained also at equilibrium conditions (prolonged high-temperature firing), but also because, at high metal/P ratio, there is no Sb luminescence, *i.e.*, the Sb does not seem to enter the apatite lattice. The fact that at 5.1 metal/3P one obtains the normal excitability of Mn in apatite also suggests that the generally observed dependence of halophosphate phosphor luminescence on the metal/P ratio is primarily governed by the efficiency of Sb luminescence.

Emission Color of Y_2O_2S:Eu Phosphor

Harvey Forest

Zenith Radio Corporation, Melrose Park, Illinois 60160

Since the introduction of narrow-lined, red-emitting phosphors such as YVO_4:Eu, Y_2O_3:Eu, and Y_2O_2S:Eu into the color-television industry there has been a constant need for fast and accurate color measurements. Simple colorimetric techniques employing a combination of three or four filters cannot be used for narrow-lined emitting phosphors because the filters only approximate the gross features of the C.I.E. tristimulus curves and may be in considerable error at particular wavelengths. The need has become even greater with the increasing use of Y_2O_2S:Eu, since the emission color and brightness of this phosphor depends upon Eu concentration and synthesis procedure to a greater degree than Y_2O_3:Eu or YVO_4:Eu. Accordingly, samples of Y_2O_2S:Eu from various phosphor manufacturers show significant variations in color which are important when evaluating the brightness of a phosphor lot.

The color coordinates of Y_2O_2S:Eu at different Eu concentrations under cathode-ray excitation are shown in Fig. 1, indicating the well-known shift of the emission color from yellow to red with increasing Eu concentration. The color shift has been attributed to the sequential quenching of the $^5D_2$, $^5D_1$, and $^5D_0$ emitting states (1). The emission spectrum consists of many narrow lines from all three emitting states resulting in a composite color. The dominant emissions from $^5D_2$ fall in the blue-green region, $^5D_1$ in the green-yellow region, and $^5D_0$ in the yellow-red region so that as the $^5D_2$ and $^5D_1$ emissions are quenched with increasing Eu concentration, the emission color becomes more red. At commercial Eu concentrations [~3.6 mole per cent (m/o)] the $^5D_2$ emissions are not important and the emission color of the phosphor is determined by the relative amounts of $^5D_1$ and $^5D_0$ emissions.

In this paper, it is shown that the color of Y_2O_2S:Eu phosphors can be routinely determined by measuring the $^5D_0/^5D_1$ line intensity ratio (LIR) from the emission spectrum. Since $^5D_1$ and $^5D_0$ emissions belonging to the $^5D_1 \rightarrow {}^7F_3$ and $^5D_0 \rightarrow {}^7F_0$ transitions occur be-

Key words: phosphor, color, spectrum.

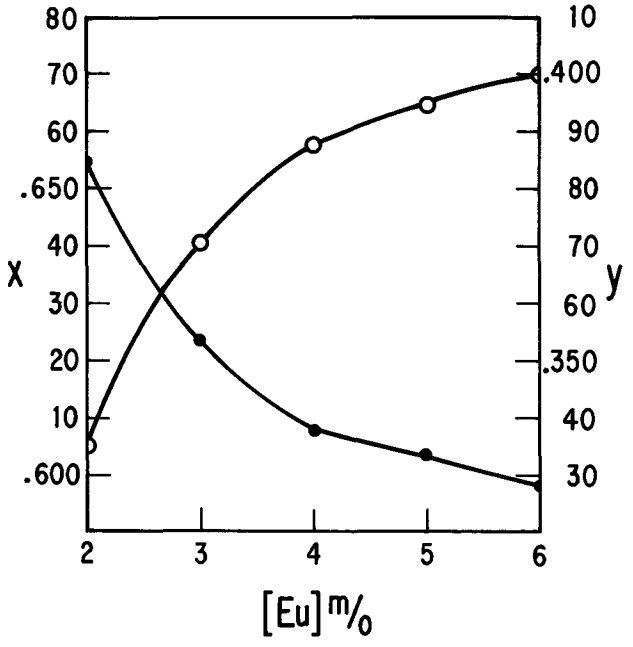

Fig. 1. Color coordinates (x,y) of Y_2O_2S:Eu under cathode-ray excitation for different Eu concentrations expressed in mole per cent. The open circles refer to the left ordinate (x) and the closed circles refer to the right ordinate (y).

tween 5800 and 5900Å, it is necessary to scan only this narrow wavelength range to determine the emission color of the phosphor. The emission spectrum can be obtained using shortwave ultraviolet excitation which eliminates the need for special sample preparation and vacuum techniques necessary for cathode-ray excitation. The entire measurement can be done in less than 5 min.

Since the $^5D_0 \rightarrow {}^7F_0$ transition is unsplit by the crystal field, the emission occurs as a narrow singlet, but the $^5D_1 \rightarrow {}^7F_3$ transition can be resolved into several emission lines. For all our measurements, a 0.25M Jarrell-Ash Monochromator with a 6Å bandpass was used which is sufficient to resolve the $^5D_1 \rightarrow {}^7F_3$ transition into two emission lines, although more lines can be resolved by decreasing the bandpass. The wavelengths of the $^5D_0 \rightarrow {}^7F_0$ and $^5D_1 \rightarrow {}^7F_3$ emissions are shown in Table I. The line intensities are measured directly from the emission spectrum after a baseline is drawn. No corrections are made for spectral sensitivity of the monochromator or phototube. Ratios are then determined from the line intensity of the $^5D_0 \rightarrow {}^7F_0$ emission line to either of the $^5D_1 \rightarrow {}^7F_3$ lines. So expressed the $^5D_0/{}^5D_1$ ratio would numerically increase as the emission color of the phosphor becomes more red.

A series of Y_2O_2S:Eu phosphors were prepared with varying Eu concentration from 2.5-6.0 (m/o) by the usual Na_2CO_3 + S flux synthesis procedure which directly converts Y_2O_3:Eu into Y_2O_2S:Eu with greater than 99% yield (3). The $^5D_0/{}^5D_1$ LIR were measured as described above and are plotted (open circles) in Fig. 2 *vs.* Eu concentration in mole per cent. A smooth curve can be drawn through the points and reproducibility of the ratio for different samples at the same Eu concentration is ±3%. The curve in Fig. 2 formed a working calibration curve for all our synthesis and color monitoring procedures.

Table I

Transition	Wavelength[a] (A)
$^5D_0 \rightarrow {}^7F_0$	5830
$^5D_1 \rightarrow {}^7F_3$	5865 5885

[a] Measured at 6A bandpass.

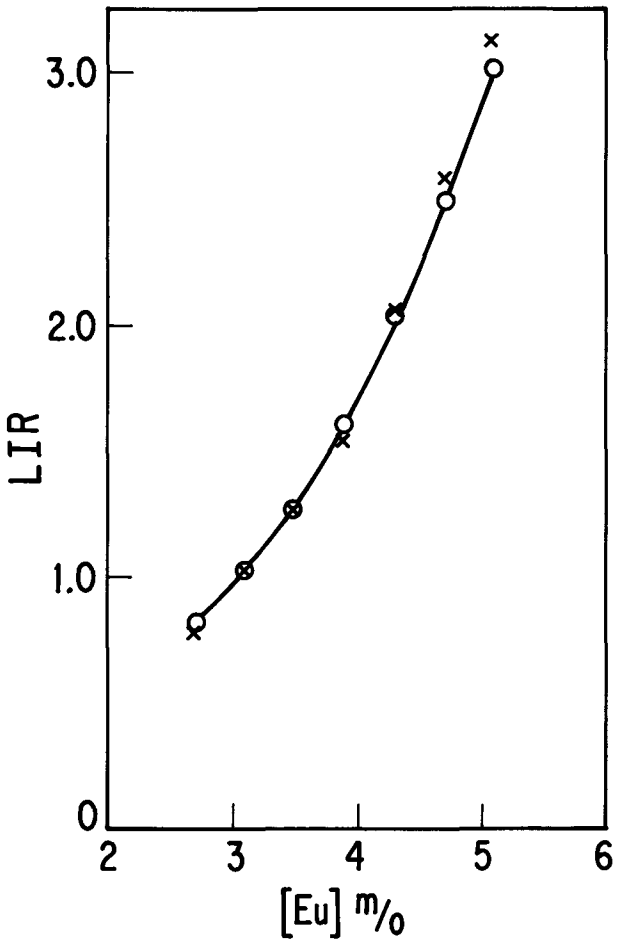

Fig. 2. $^5D_0 \rightarrow {}^7F_0/{}^5D_1 \rightarrow {}^7F_3$ line intensity ratio (LIR) *vs.* Eu concentration expressed in mole per cent. The open circles refer to Y_2O_2S:Eu phosphors made and measured at Zenith and the crosses refer to phosphors made and measured at Sylvania.

It now becomes a simple matter to determine quantitatively how close a particular sample of yttrium oxysulfide phosphor agrees with a standard color. The standard yttrium oxysulfide phosphor used by Rauland Tube Division has an LIR equal to 1.37 (3.63 m/o) while the phosphors manufactured domestically tend to fall in the range of 1.0-1.5. The more useful relationship between LIR and color coordinates (not shown) can be obtained by combining Fig. 1 and 2.

The curve in Fig. 2 has also been used by us as an analytical method for determining Eu in Y_2O_3 by converting an unknown Y_2O_3:Eu into Y_2O_2S:Eu and obtaining the mole per cent from the LIR. The reproducibility of the synthesis is within 3% so that the accuracy of the Eu determination using Fig. 1 is about 1.5% in the range of 2-6 m/o. It is possible to extend the range to either higher or lower concentrations. At the lower concentrations the $^5D_1$ emission lines can be used in some ratio combination with $^5D_1$ or $^5D_0$. A complete investigation comparing this procedure with other analytical methods for Eu is beyond this paper but we have used it in preference to atomic absorption (4).

A similar series of yttrium oxysulfide phosphors was synthesized at Sylvania Electric Products. The LIR were measured using their spectrometer and the normalized data (crosses) are plotted in Fig. 2. The agreement of their data with our data is very good. The average discrepancy between the two sets of data points is about 2% which seems to be greatest at the higher concentrations. Both sets of data points are listed in Table II. It is a little surprising that the proportionality between the data is linear even though the synthesis procedure and spectrometer used by each laboratory are not identical. This means that the

Table II. $^5D_0/^5D_1$ line intensity ratios

Photoluminescence of Gel-Grown Pb(OH)I Single Crystals

A. Schwartz and J. C. O'Connell

U. S. Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

Crystalline growth in gels containing a lead cation source and an iodine anion source will produce predominantly lead hydroxy-iodide with some lead iodide for gel *p*H greater than 7.0. Dennis *et al.* (1) have reported the growth of lead hydroxy-iodide in alkaline sodium metasilicate gels along with a few basic properties of the material. The purpose of this paper is to report some recent photoluminescent measurements on this double salt.

The method of growth which is essentially the same as in previous work has been modified somewhat resulting in increased crystal size. Acidified sodium metasilicate gels were prepared at room temperature in glass U-tubes in the *p*H range 6.0-7.3. The cation source was a 0.2-0.4M lead nitrate or lead acetate solution. The anion source was a 0.1-0.3M potassium iodide. The reaction was allowed to proceed at room temperature with crystal growth beginning in approximately 2 weeks.

The resulting crystals were rods up to 30 mm in length and 2 mm^2 cross section. Hexagonal lead iodide and its spherulitic polymorph were also present (Fig. 1). The clarity of the lead hydroxy-iodide crystals varied considerably with most having some occluded regions. A representative spectrographic analysis averaged over a number of crystals shows that Si is incorporated in the crystal from the gel (Fig. 2). Iron and other impurities are present in lower concentration.

Lead hydroxy-iodide has been reported to be a p-type semiconductor with an optical absorption edge at room temperature of 430 nm as determined from absorption and photoconductivity measurements (1). It was felt that investigation of the photoluminescence at liquid nitrogen temperature would provide additional information on crystalline growth and structure.

Lead hydroxy-iodide single crystals were mounted in an optical dewar and coated to liquid nitrogen temperature. Monochromators were used to provide u.v. excitation and to analyze the luminescent emission. The resulting emission curves were corrected for source, monochromator, and photomultiplier response.

The lead hydroxy-iodide emission spectrum is a broad band whose peak wavelength occurs at 560 nm (Fig. 3). Measurements were made for the *E* vector perpendicular and parallel to the *c*-axis of the crystal with the curves differing by a factor of three. Excitation for these curves was 350 nm.

Excitation spectra are shown for three crystals in Fig. 4. A sharp absorption edge occurs at 355 nm in all crystals. Variations in response at shorter wavelengths are large most probably due to surface influences.

Key words: lead hydroxy-iodide, photoluminescence, gel-growth, single crystals.

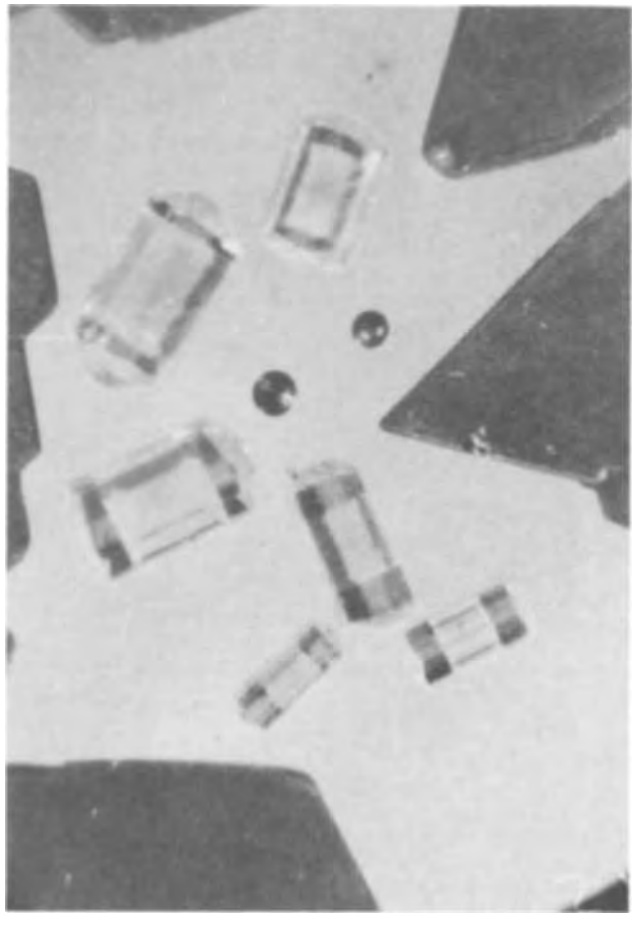

Fig. 1. Lead hydroxy-iodide crystals in which lead iodide and its spherulitic polymorph were also present.

Element	Wt. %
Pb	Major
Si	0.07
Fe	0.02
B	0.01
Mg	0.002
Ag	0.001
Ca	0.001

Sn	0.0001

Fig. 2. Averaged spectrographic analysis of lead hydroxy-iodide showing that Si is incorporated in the crystal from the gel.

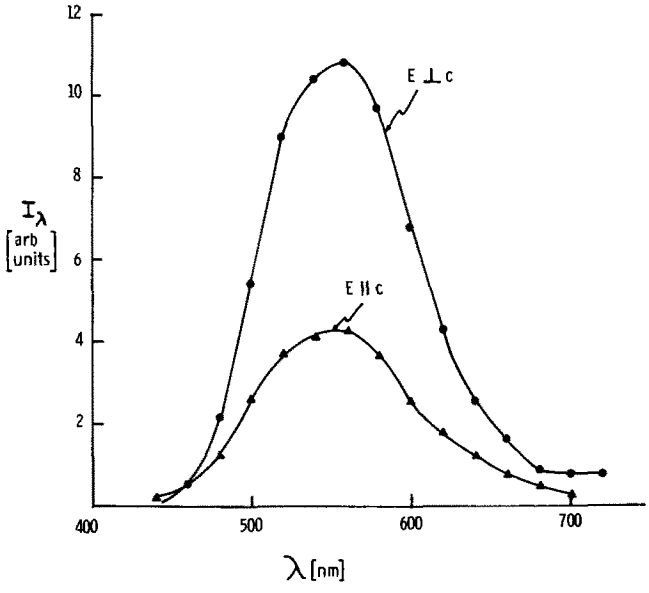

Fig. 3. Photoluminescent spectra of Pb(OH)I single crystals at 77°K.

While monitoring the peak emission of the lead hydroxy-iodide crystals the temperature was increased to room temperature (Fig. 5). Above 200°K the luminescence was thermally quenched with an activation energy of 0.3 eV.

Microscopic examination of the crystals showed that emission is inhomogeneous and occurred near and at occluded areas.

In summary, during the growth of lead hydroxy-iodide single crystals in gels, Si as well as other impurities are incorporated in the crystal. The Si may be in the form of silicon dioxide as in the case in certain gel-grown calcite. Since emission occurs primarily at or near occluded areas rather than transparent ones, impurity activation is highly probable although no identification can be made at this time. A series of rare-earth doped lead hydroxy-iodide has been grown and photoluminescent measurements along with microprobe data on impurity distribution will be pursued.

Method for Determining the Metallurgical Layer Thickness of Epitaxially Deposited Silicon from SiH_4 down to 0.5 μm

F. C. Eversteyn and G. J. P. M. van den Heuvel

Philips Research Laboratories, Eindhoven, The Netherlands

The thickness of epitaxially deposited silicon films can be determined with different techniques. Widely used methods are bevel and stain and infrared interference on highly doped substrates. A survey of these techniques has been given by Schumann (1). Each technique results in a thickness peculiar to the method used. For epitaxial silicon layers thinner than about 5 μm especially there is a need for a simple technique with which the metallurgical layer thickness, defined as the deposited layer thickness, can be determined because: (*i*) accepted methods for thick layers (*e.g.*, more than 5 μm) become less accurate or cannot be used: (*ii*) investigation of the actual impurity profile, as affected by various processing steps, finds a well-defined reference point in the metallurgical interface; and (*iii*) quantitative knowledge resulting from (*ii*) gives a sound basis for the design of integrated circuits and discrete devices.

In this paper a method is described for determining the metallurgical layer thickness of silicon epitaxially deposited from SiH_4. To use such a method as a standard technique, specially for thin epitaxial layers (*e.g.*, less than 5 μm), it is necessary that the technique be (*i*) simple and rapid, (*ii*) accurate to the second decimal place, and (*iii*) applicable also for ultrathin epitaxial layers, *e.g.*, 0.5 μm.

It will be shown that the proposed method fulfills the above-mentioned conditions. Essentially the metallurgical layer thickness of epitaxially deposited silicon is derived from the thickness of the polycrystalline silicon layer deposited on an Si_3N_4-coated check slice simultaneously processed.

The relation between the metallurgical layer thickness of epitaxially deposited silicon and the thickness of polycrystalline silicon simultaneously deposited on Si_3N_4 has been F determined by using silicon substrates partially covered with about 1500Å Si_3N_4. The depositions have been carried out from an H_2-SiH_4 mixture in a horizontal, water-cooled, epitaxial reactor, basically without an HCl-etching treatment prior to epitaxial growth, at a temperature of 1020°-1050°C (pyrometer reading). The thickness of the polycrystalline silicon layer deposited on Si_3N_4 as well as the thickness of the epitaxially deposited silicon have been determined with a Taylor-Hobson Talystep with a conical tip of radius 12.5 μm. The polycrystalline silicon is partly removed with an etch containing 1 part HF (49%) and 1 part CrO_3 solution (500 gram CrO_3 in 1000 ml water), whereafter the thickness of the polycrystalline silicon layer can be measured. Subsequent removal of the Si_3N_4 with HF marks the original substrate surface as a reference for the measurement of the metallurgical film thickness of epitaxially deposited silicon. For the range of layer thicknesses between 0.1 and 10 μm the results of these measurements are given in Fig. 1. It turns out that the relation between the metallurgical layer thickness of epitaxially deposited silicon ($d_{\text{met.Si}}$) and the thickness of polycrystalline silicon simultaneously deposited on Si_3N_4 can be given by the relation

$$d_{\text{met.Si}} = d_{\text{poly-Si(T)}} - 0.10\ \mu\text{m}, \qquad [1]$$

in which $d_{\text{met.Si}}$ = metallurgical layer thickness of epitaxially deposited silicon and $d_{\text{poly-Si(T)}}$ = thickness of polycrystalline silicon simultaneously deposited on Si_3N_4 and measured with a Talystep.

Key words: thickness determination, epitaxy, polycrystalline silicon, SiH_4, Si_3N_4.

Equation [1] can be used to determine the metallurgical layer thickness of epitaxially deposited silicon. However, for routine operation it is too cumbersome. That is why we have looked for an alternative which would permit a rapid determination of the thickness of polycrystalline silicon on Si_3N_4. For this purpose the thickness of the polycrystalline silicon on Si_3N_4 has also been determined by infrared multiple interference. We have used a Hitachi EPI-G3 spectrophotometer (k = 400-4000 cm^{-1}). The infrared interference spectra have been interpreted according to the method proposed by Severin (2) and shown in Fig. 2. The layer thickness [$d_{\text{poly-Si(i.r.)}}$] can be derived from the wave-number difference between two extrema as indicated in Fig. 2(a). To minimize the experimental error in determining the positions of the maxima and minima a more accurate method is given in Fig. 2(b). Since the wave-number difference between maxima and minima is constant, a straight line can be drawn through the extrema when the order of the interference extrema is plotted *vs.* the wave number. The slope of this line represents $2nd_{\text{poly-Si(i.r.)}}$ with n the refractive index of silicon (=3.42). In Fig. 3 the i.r. thickness of polycrystalline silicon on Si_3N_4 [$d_{\text{poly-Si(i.r.)}}$] is plotted *vs.* the corresponding Talystep thickness [$d_{\text{poly-Si(T)}}$]. It appears from this figure that up to 10 μm the thickness of polycrystalline silicon as measured with a Talystep is equal to the thickness as derived from multiple interference.

$$d_{\text{poly-Si(i.r.)}} = d_{\text{poly-Si(T)}} \qquad [2]$$

Combining Eq. [1] and [2] we obtain

$$d_{\text{met.Si}} = d_{\text{poly-Si(i.r.)}} - 0.10\ \mu\text{m}$$

The corrective term of 0.10 μm, which has to be substracted from the thickness of the polycrystalline silicon film on Si_3N_4 is due to the roughness of the poly-

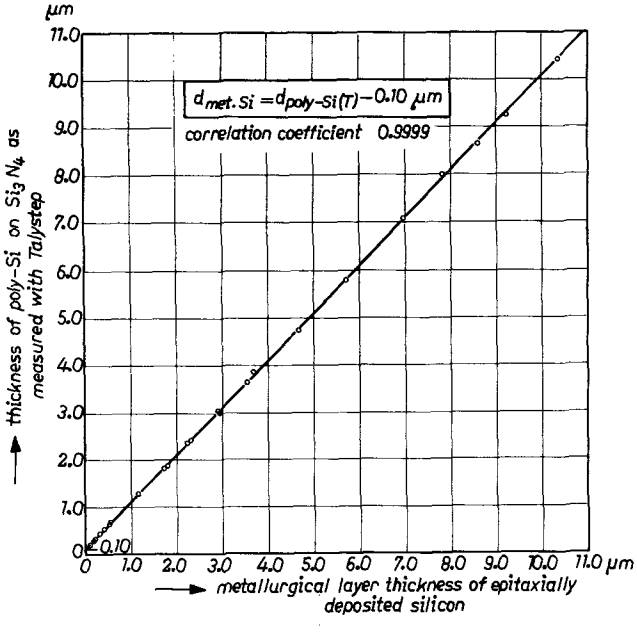

Fig. 1. Metallurgical layer thickness of epitaxially deposited silicon *vs.* thickness of polycrystalline silicon simultaneously deposited on Si_3N_4 as measured with a Taylor-Hobson Talystep.

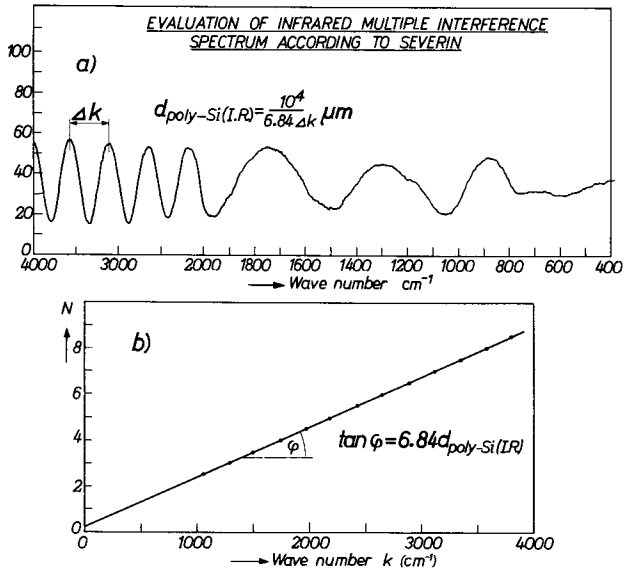

Fig. 2. (a), Infrared reflection spectrum of a 3.19 μm polycrystalline silicon layer; in this figure the way of determining the i.r. thickness is also indicated. (b), Wave number (*k*) vs. order of interference extrema (*N*) of the spectrum given in Fig. 2(a).

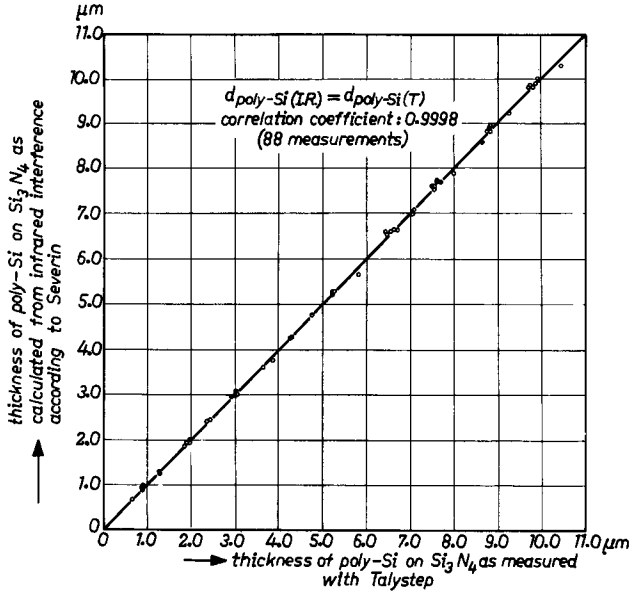

Fig. 3. Thickness of polycrystalline silicon on Si_3N_4 as measured with a Taylor-Hobson Talystep vs. thickness of polycrystalline silicon on Si_3N_4 as calculated from infrared multiple interference according to the method described by Severin.

crystalline silicon surface. Electron micrographs revealed the crystallites to have dimensions between 0.5 and 1.0 μm for the present process conditions. Because the thickness determination of the polycrystalline silicon on Si_3N_4 has been verified with a Talystep with a conical radius of the tip of 12.5 μm, the Talystep probe moves over the top of the grains of the polycrystalline silicon. In Fig. 4 a rough approximation is made of the correction necessary to derive the metallurgical layer thickness from the thickness of the polycrystalline silicon layer on Si_3N_4 in the case where the deposition rate is determined by mass transport from the gas phase. Assuming the crystallites to protrude through the surface by hemispheres, and assuming further that the bulk densities of polycrystalline and monocrystalline silicon are equal, we came to a correction value of 0.1 and 0.2 μm for crystallite sizes between 0.5 and 1.0 μm, respectively. The experimental value of 0.10 μm corresponds reasonably well to the calculated value taking the oversimplification into account.

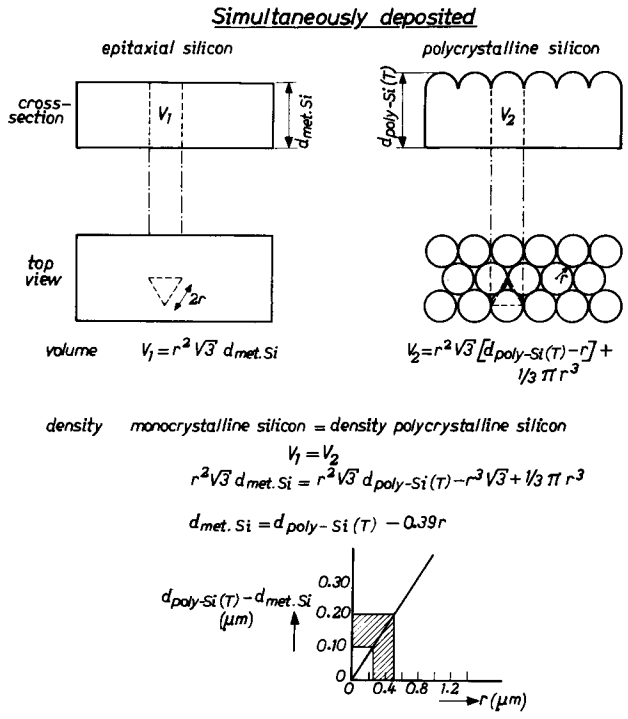

Fig. 4. Simplified model of the influence of surface roughness on correction necessary to derive the metallurgical layer thickness from the thickness of simultaneously deposited polycrystalline silicon.

It has been verified that *in situ* gas etching with hydrogen chloride does not affect the subsequent film growth and consequently this method can be used regardless of whether or not it has been applied. Also no difference has been found for (111)2-5° off and (100)1-3° off oriented substrates.

An SiO_2 coated check slice might be an obvious alternative for Si_3N_4, but the latter is preferable for the following reasons: (*i*) SiO_2 is less resistant to an HCl-vapor etch prior to epitaxial growth than Si_3N_4; and (*ii*) with SiO_2 near its edges a nonuniform deposition occurs, resulting in separately positioned crystallites, while with Si_3N_4 uniform deposition is observed all over the slice.

The influence of the thickness of Si_3N_4 on the value of the i.r. thickness of polycrystalline silicon on Si_3N_4 has been investigated. In Table I measurements are presented of polycrystalline silicon deposited on Si_3N_4 of various thicknesses. It turns out that up to 3000Å Si_3N_4, the i.r. thickness is equal to the Talystep thickness.

The proposed method for determining the metallurgical layer thickness can be used down to thicknesses of 0.5 μm. Below 0.5 μm no infrared interference fringes are obtained in the wave-number region of 400-4000 cm^{-1}.

The experimental error in the i.r. thickness is determined by the accuracy with which the positions of the extrema in the infrared-interference spectrum can be determined. This results in a final accuracy to within ±0.02 μm for silicon layers thinner than about 4 μm and ±0.5% for silicon layers thicker than 4 μm.

Chemical Composition and Electrical Properties of Tin Oxide Films Prepared by Vapor Deposition

J. A. Aboaf* and V. C. Marcotte

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

and N. J. Chou*

IBM Thomas Watson Research Center, Yorktown Heights, New York 10598

Tin oxide films have been widely used as conductive electrodes on glass substrates because of their transparency in the visible region of the spectrum. They can be prepared either by reactive sputtering (1, 2) or by hydrolysis of $SnCl_4$ in various ambients (3-5). To attain high electrical conductivity the SnO_2 films are usually doped with antimony or bismuth (1-3, 6, 7). However, highly conductive films have also been obtained by hydrolysis without intentional doping (4, 6). In the latter case, the increased conductivity was attributed to the oxygen deficiency (or excess tin) in the SnO_2 films (4). In this brief note we report the experimental evidence relating the changes in electrical conductivity and current-carrier concentration to the chemical composition of the polycrystalline SnO_2 films prepared by vapor deposition from the reaction of $SnCl_4$ with water vapor. Our x-ray and electron microprobe analyses suggest that the observed variation in these films can be attributed to a combination of the departure from stoichiometry and the incorporation of chlorine in the films. A more accurate investigative technique is, however, necessary in order to relate them quantitatively.

The SnO_2 films were vapor-deposited on oxidized Si substrates in a resistance-heated tube furnace (59 mm inside diameter) from the reaction of $SnCl_4$ with water vapor at various temperatures and ambients. About 200 cm^3/min of N_2 gas was used to transport the $SnCl_4$ vapor (high-purity grade) into the furnace tube in which either a N_2, H_2, or O_2 ambient maintained a flow of 5000 cm^3/min. Water-vapor saturated nitrogen was fed into the furnace at a rate of 400 cm^3/min through a nozzle situated at a distance of about 2 in. from the uniform hot zone. Such arrangement was essential in minimizing the reaction of $SnCl_4$ with H_2O prior to reaching the hot zone. The films obtained were clear and virtually insoluble in acids and bases.

The SnO_2 films deposited between 380° and 600°C were polycrystalline. Low-angle x-ray diffraction and reflection electron diffraction studies of the films indicated the presence of a second phase, most likely SnO, in the surface layer of the films. The thickness of this layer containing what was thought to be SnO appeared to decrease with increased temperature of deposition. The grain size of the films also increased with the deposition temperature. For 380°C, the grain size was less than 1000Å (see Table I).

The electron microprobe analysis has detected chlorine in the film deposits. Quantitative information regarding the composition of the films was obtained by using pure tin and fused quartz specimens as the standards for the analysis. The composition of the film samples was calculated from the raw intensities using Colby's MAGIC Program (8). A comparison was also made with a pure single crystal of SnO_2.[1] The results are presented in Table II. All samples including the single crystal appeared to be oxygen deficient. The oxygen content in the films was found to decrease with an increase in deposition temperature, regardless of the deposition ambient. However, the chlorine concentration was much lower for the films deposited in a hydrogen atmosphere. The reduction in Cl concentration is probably due to the effect of hydrogen in preventing the formation of intermediates containing chlorine, which cause subsequent doping of the films.

The resistivity and Hall effect measurements were made at 24° and −196°C, respectively, on films (≃2000Å thick) deposited in various ambients. The results for those deposited in a nitrgoen ambient are

	77	2.7×10^{-2}	-5.3×10^{-2}	1.95	1.2×10^{20}

shown in Table III. All films were found to be of n-type, the carrier concentration being $\sim 10^{20}$ electrons/cm^3. The electrical conductivity and carrier concentration measured at room temperature were essentially the same as measured at the liquid nitrogen temperature, implying an almost complete ionization of impurity centers at −196°C. This is in agreement with Kuznetsov's results (4), which showed that the impurity level was ≤ 0.02 eV below the conduction band edge of SnO_2. The conductivity of the films deposited in nitrogen is weakly dependent on the deposition temperature; the films deposited at 525°C are more conductive. A reduction in conductivity and carrier concentration was observed for the film deposited under comparable conditions in a reducing or oxidizing ambient.

A nitrogen-deposited SnO_2 film annealed in oxygen at 960°C for 1½ hr showed not only a decrease in oxygen content (18-16.9%), but also a reduction of chlorine concentration from 1.1 to 0.5%. The conductivity and carrier concentration of the film decreased in the process by an order of magnitude. It thus appears that the change in conductivity and carrier concentration cannot be attributed to the departure from stoichiometry alone. Our x-ray data have shown that chlorine was incorporated in the SnO_2 lattice either interstitially or substitutionally, since no chlorine-containing phases were detected. Substitutional or interstitial incorporation of chlorine should give rise to donor levels, thus increasing the conductivity and carrier concentration in n-type SnO_2 films. This is consistent with our observation that the conductivity and carrier concentration of a nitrogen-deposited film which contains 1.1 weight per cent (w/o) Cl is an order of magnitude higher than the film which was deposited at the same temperature in hydrogen but contains only 0.3 (w/o) Cl.

SnO_2 has a rutile structure; its unit cell contains four oxygen and two tin atoms, and has a volume of 71.6A^3 (9). One atomic per cent (a/o) of substitional chlorine (or singly ionized interstitial) would give rise to a carrier concentration of $\sim 8 \times 10^{20}$ electrons/cm^3. Our Hall effect data thus suggest that part of the chlorine incorporated is electrically inactive. For example, although the film deposited in nitrogen at 380°C contains 1.7 a/o Cl, it has a carrier concentration of only 1×10^{20} electrons/cm^3 (Table III). It is probable that the oxygen vacancies interact with chlorine to render the latter inactive. For the nitrogen-deposited films, the chlorine concentration decreases whereas the oxygen deficiency increases with the deposition temperature. The virtually constant carrier concentration over the same range of deposition temperatures lends further support to the contention that both the oxygen deficiency and the chlorine incorporation contribute to the carrier concentration in these films. Since the film deposits are polycrystalline, the grain boundary effect, coupled with the presence of SnO in the surface layer, makes it difficult to predict the behavior of electrical conductivity, even in qualitative terms. It is evident that a quantitative interpretation of the relationship between the chemical composition and the transport properties of the SnO_2 films would require analytical techniques of much greater accuracy than those we have used in this investigation.

The Thermal Power of the Solid Electrolytes Ag_4MI_5 and of Molten Mixtures of the Same Composition

K. E. Johnson,* S. J. Sime,[1] and J. Dudley[2]

Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan, Canada

ABSTRACT

Measurements are reported of the thermal power with reversible silver electrodes of polycrystalline samples of Ag_4MI_5 (M = K and Rb) and of molten mixtures of the same composition (M also = Cs). The Wagner-Pitzer approximation for the entropy of a single ion is extended to molten mixtures and to nonbinary solid compounds and is used to calculate the heterogeneous contribution to the thermal power of Ag_4RbI_5. Then the heat of transport of Ag^+ in Ag_4RbI_5 solid may be calculated and is found to be 2.1 kcal mole^{-1}. The term $\sum_i \frac{t_i Q_i}{z_i}$ for molten Ag_4RbI_5 is found to be 3.2 kcal mole^{-1}. This same term is estimated from the variation of the homogeneous thermal power with temperature to be 2.5 ± 0.4 for the rubidium mixture, 2.7 ± 0.4 for the potassium mixture, and 3.7 ± 0.6 for the cesium mixture. The self-consistency of the results and the agreement between the heat of transport in solid Ag_4RbI_5 and the activation energy for diffusion (of Ag^+) support the use of the extended form of the Pitzer equation.

The high-conductivity solid electrolytes Ag_4MI_5 (M = K, Rb, and NH_4) were discovered independently by Bradley and Greene (1, 2) and by Owens and Argue (3). The crystal structure of the rubidium salt (4) shows that the silver lattice is highly disordered, there being 56 sites per unit cell for 16 silver ions. Measurements have been reported of the electrical conductivity (3, 5, 6) and silver ion diffusion (7) in Ag_4RbI_5 and activation energies for these processes have been determined. Johnston, Wiedersich, and Lindberg (8) have investigated the specific heat of this compound from 5° to 350°K, and reported values of the standard entropy, entropy of silver disorder at 300°K, and the disorder contribution to the specific heat. We have recently determined the enthalpy contents of the systems Ag_4MI_5 [M = K, Rb, Cs, NH_4, and $(CH_3)_4N$] as a function of temperature (9) and reported the heats of incongruent melting of the compounds (M = K, Rb, and NH_4).

Except for the recent publication of Chandra *et al.* (10) there have been no previous investigations of the thermal power of these systems. The major problem in the analysis of thermal power is in assigning a value to the partial molar entropy of the ion to which the electrode is reversible. Single-ion entropies are not independent thermodynamic properties and thus cannot be determined by experiment. The only expression available for the calculation of a single-ion entropy is the approximation of Wagner (11), extended by Pitzer (12), and this applies only to simple binary compounds. We have extended it to nonbinary solid compounds and molten mixtures, and further modified it to allow for the disorder of the silver sublattice. Using the available thermodynamic data one is then able to calculate the heterogeneous contribution to the thermal power of Ag_4RbI_5. The measurement of the thermal power thus allows one to calculate the heat of transport of Ag^+ in the solid and this may be compared with the activation energies for diffusion and conductance.

We have measured the thermal power of Ag_4RbI_5 and Ag_4KI_5 in the solid and liquid states and also that of the molten mixture Ag_4CsI_5.

Theory

The thermal power, θ (dE/dT of the thermocell) of a system with electrodes reversible to an ion j^+ is given by (13)

$$\theta = \theta_{hom} + \theta_{het} \quad [1]$$

where θ_{het}, the heterogeneous contribution, is given, for a reversible metal electrode with reaction $J \rightleftarrows J^+ + e$, by

$$F\theta_{het} = S_j - \overline{S}_{j+} - \overline{S}_{e(j)} \quad [2]$$

and θ_{hom}, the homogeneous term, is

$$F\theta_{hom} = \sum_i \frac{t_i Q^*_i}{z_i T} \quad [3]$$

In these expressions S_j, $\overline{S}_{j+}$, and $\overline{S}_{e(j)}$ are the partial molar entropies of pure j, the ion j^+, and the electron in the metal j, respectively; t_i, z_i, and Q^*_i are the transport number, the charge, and the heat of transport, respectively, of species i, and F is the Faraday. In the expression for θ_{hom}, the values of t_i and Q^*_i are dependent on the frame of reference chosen for the ion fluxes (14, 15). In the present work the crystal lattice is chosen as the reference for the solid compounds, and the iodine ions as the reference frame in the melt [the Hittorf frame (16)].

Key words: entropy of transport, heat of transport, solid electrolyte, thermal power.

It has been shown that $\overline{S}_{e-(j)}$ is essentially zero (17) and Q^*_e may be neglected too; thus, as pointed out above, the major problem in the interpretation of thermal power data is the determination of $\overline{S}_{j+}$. The Wagner (11)-Pitzer (12) approximation assumes that short range interactions do not contribute significantly to the molar entropy of the system, or, if they do, that they are identical for each species present. In this case the configuration contribution to the molar entropy is equally divisible among the species. Thus, if classical statistical mechanics is applicable, Pitzer showed the entropy of an ion in a simple binary salt to be

$$\overline{S}_{M+} = \tfrac{1}{2}\left[S_{MX} + 3/2R \ln\left(\frac{M_{M+}}{M_{X-}} \right) \right] \quad [4]$$

where S_{MX} is the molar entropy of the salt and M_{M+} and M_{X-} are the molecular weights of the positive and negative species, respectively.

We may easily extend Pitzer's expression to the case of a molten mixture. Consider a system of $2N$ homovalent ions, N_i of species i. If x_i, the ion fraction of i, is defined as N_i/N, then the canonical ensemble partition function is given by

$$Q[2N] = \prod_i \frac{(q_i)^{N_i}}{N_i!} Z(R) \quad [5]$$

where $q_i = (2\pi m_i kT/h^3)^{3/2}$ and $Z(R)$ is the configuration integral.

The partial molar entropy of a species j is given by

$$\overline{S}_j = Nk \frac{\partial}{\partial N_j} \frac{\partial}{\partial T} T \ln (Q[2N]) \quad [6]$$

Thus the nonconfigurational contribution may be found directly to be

$$S_j^{nc} = R\left[\ln\left(\frac{q_j}{Nx_j} \right) + 3/2 \right] \quad [7]$$

We can thus determine the configurational contribution from the measured entropy for the systems S_{mes}. The expression is

$$S(Z) = \frac{S_{mes}}{2} - \sum_i \frac{x_i}{2} R\left[\ln\left(\frac{q_i}{Nx_i} \right) + 3/2 \right] \quad [8]$$

Dividing this equally among the species one obtains, noting that $\sum_i \frac{x_i}{2} = 1$

$$\overline{S}_j = 1/2\, S_{mes} - 3/2\, R \ln\left(\prod_i \frac{m_i^{x_i/2}}{m_j} \right) + R \ln\left(\prod_i \frac{x_i^{x_i/2}}{x_j} \right) \quad [9]$$

The last term in this equation arises from the entropies of mixing of the species. In the perfect crystal this term is zero (correspondingly the term $N!$ is not present in the partition function of a solid) and one obtains

$$\overline{S}_j = \frac{S_s}{n} - 3/2\ R \ln\left(\prod_i \frac{m_i^{n_i/n}}{m_j} \right) \quad [10]$$

where S_s is the molar entropy of the compound, and n is the number of ions per formula unit, n_i of species i.

In the case of solids in which one sublattice is highly disordered this expression does not apply directly. Before one can evaluate $S(z)$ from the measured molar entropy, one must subtract the part of the total entropy due to disorder of the sublattice and assign it separately to the disordered species. If this is done the final expression is, if j^+ is the disordered species

$$\overline{S}_{j+} = \frac{S_s - S_{dis}}{n} + \frac{S_{dis}}{n_j} - 3/2\, R \ln\left(\prod_i \frac{m_i^{n_i/n}}{m_j} \right) \quad [11]$$

Experimental

All the chemicals used were supplied by British Drug Houses (reagent grade). Mixtures of the correct stoichiometry were made and filtered through a sintered glass frit to remove any silver metal formed by photo decomposition of the silver iodide. The resultant solid was powdered, and stored in the dark before use.

The apparatus used for the measurements is shown in Fig. 1. It consisted of a Pyrex "H" tube (about 13 cm high, 10 cm wide), with fritted disks A, at the entrance to each arm to prevent thermal diffusion in the melts, and a central tube B. The electrodes, C, consisted of silver wire sealed inside an alumina tube so that only a small bead of silver, at the end of the tube, had contact with the melt. The Pt/Pt, 13% Rh thermocouples were mounted in Pyrex wells D so that the junction was level with the point of the electrode. The cell was wrapped in aluminum foil, the sensing elements of the temperature controllers put against each arm, and the whole wrapped in more foil. This served the dual purpose of reducing temperature gradients within each arm, and, when the foil was grounded, of isolating the electrodes from the heating elements. These were lengths of heating tape wound separately around each arm of the cell. The current through each was controlled by a separate temperature controller (Cole-Palmer Proportional 1300 series). The whole was mounted in a mass of vermiculite for insulation.

The cell was filled by heating both arms above the melting point of the mixture, filling them with the powdered solid, and then sucking the melt through the frits by applying a vacuum to the tube B.

The thermal power at a temperature t_m was determined by measuring the thermal emf at five different temperature gradients (between 0 and 17°C) with the mean temperature within ±0.4°C of t_m. These points fell in a good straight line, and the gradient was determined by linear least squares.

For convenience, within each set of five points, the temperature gradient was in the same direction across the cell. It was general practice, however, to reverse the direction before commencing the next set. Intercepts on the ΔT axis were generally less than a millivolt, and explicable in terms of thermal diffusion within the electrode compartment.

Potentials were measured with a Guildline potentiometer (Model 9174) using a preamplifier (9460 A) and a galvanometer (9461 D) as a null detector.

In any run measurements were made first on the melts, t_m being cycled between 10°C above the melting

point and 500°C. Then, for the potassium and rubidium salts the apparatus was cooled below the eutectic temperature for the system and annealed overnight. Measurements of the thermal power of these polycrystalline samples were made in the same way as the melts. For each substance studied three runs were performed, each with different batches of mixtures. Attempts were made to obtain the thermal power of single crystals and compressed pellets of Ag_4RbI_5. However, no satisfactory silver electrode could be found. Using massive silver the contact resistance was too high and the results irreproducible. Using silver paint, the silver quickly diffused into the sample and the results were highly erratic. Attempts were also made to measure the thermal power of the ammonium salt but it was found impossible to fill the cell without decomposition.

Results and Discussion

The experimental results obtained are shown in Fig. 2 through 4. Plotted there are the values of the thermal power against temperature in degrees centigrade. The error bars are the probable errors in the slopes of the experimental points at each t_m as calculated by least squares analysis. The scatter in the data for the melt is probably explained by gradual thermal diffusion within each arm of the cell, and, possibly, through the frits. The scatter in the solids is almost certainly due to strain potentials existing in the polycrystalline mass.

The results for the rubidium salt were analyzed using the equations developed above in conjunction with the data of Johnston, Wiedersich, and Lindberg (8), and of the authors (9). A list of the data used is given in Table I. θ_{het} was calculated at each t_m and subtracted from the measured thermal power. The re-

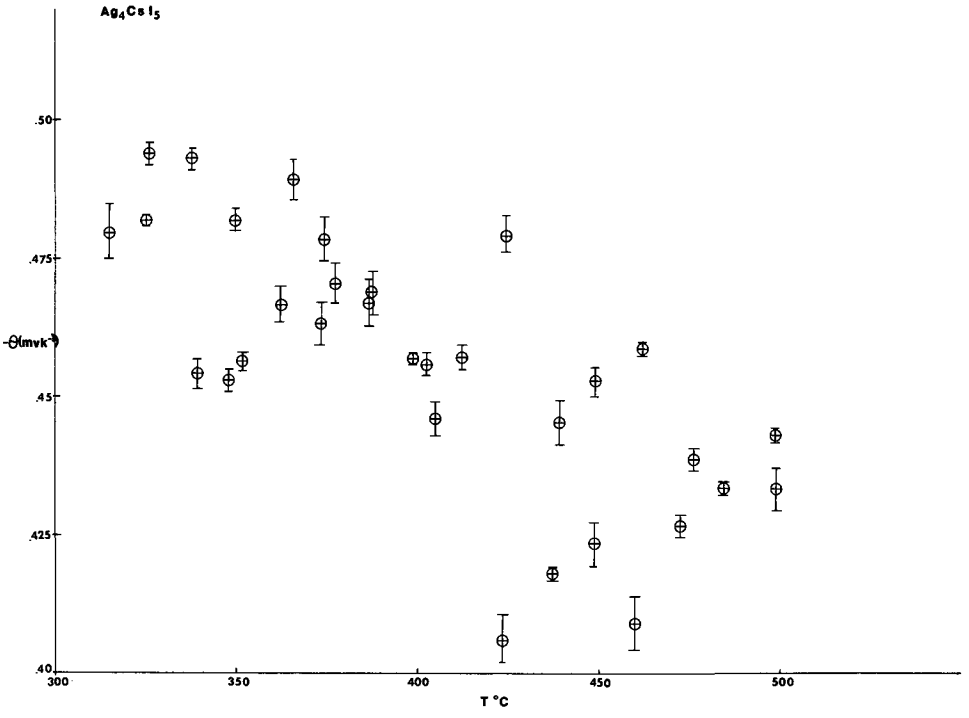

Fig. 4. Thermal power vs. temperature for Ag_4CsI_5.

sultant θ_{hom} was fitted against $10^3/T$ by least squares. For solid Ag_4KI_5 detailed analysis was not possible as the disorder contribution to the heat capacity is not known; however, if it is assumed to be in the same order as that of Ag_4RbI_5 then, as in the case of the rubidium salt, the major part of the temperature dependence of θ may be attributed to the heterogeneous term. In fact the slopes of the plots shown in Fig. 2 and 3 are in the order of 0.5×10^{-4} mV K^{-2}. The slope calculated for θ_{het} is 0.53×10^{-4} m K^{-2}.

For the potassium and cesium melts the standard entropy is not known; however, it is possible to calculate a modified heterogeneous thermal power $\theta^*_{het}(T)$ defined as

$$\theta^*_{het}(T) = \theta_{het}(T) - \theta_{het}(T^o) \qquad [12]$$

directly from the specific heats, where T^o is any reference temperature (conveniently the melting point of the mixture). If θ^*_{het} is subtracted from the measured value and the result fitted against $10^3/T$, then the slopes of such plots will be $t_{Ag} + Q^*_{Ag+} + t_{M+}Q^*_{M+}$, providing the transport numbers are not significantly temperature dependent.

The results of the least squares plots are shown in Table II. In Table III are listed the values of the heats of transport obtained from the slopes, and, for Ag_4RbI_5, by direct calculation from the magnitude of θ_{hom}. It is seen that for Ag_4RbI_5 the values calculated directly from the values of θ_{hom} are in the same order as those values predicted from the slope. This is particularly gratifying in the case of the solid in which the bulk of the temperature dependence of the measured thermal power arises from the heterogeneous term. The agreement between direct calculation and the values from the slopes in the melt indicates that the transport numbers are not significantly temperature dependent in the region studied, and allows one to place some confidence in the values predicted for the potassium and cesium mixtures.

The fact that the intercepts of the least squares plots for the rubidium system are close to zero (particularly in the case of the melt) serves to indicate that the calculated values of θ_{het} are reasonably accurate.

The calculated value for Q_{Ag+} in Ag_4RbI_5 (2.1 kcal $mole^{-1}$) is in excellent agreement with the activation energy for silver ion diffusion measured by Bentle (1.994). This agreement is predicted by the earlier theory of the heat of transport (18, 20). More elaborate theories (21) indicate that the major term in the heat of transport is the activation energy for diffusion, but that this is modified by complicated terms involving the nonisothermal friction constants. The agreement with Bentle's value would suggest that these corrections are small for Ag^+ in Ag_4RbI_5. The values for the molten systems are in the same order as Q^*_{Ag+} calculated from Kvist's (22) data for molten AgI (3.0 kcal $mole^{-1}$). The differences between the values might be understood if it is assumed that the heat of transport increases with increasing ionic radius (*i.e.*, the "activation energy" for diffusion increases) whereas the transport number, and hence its contribution to $t_{M+}Q^*_{M+} + t_{Ag+}Q^*_{Ag+}$ decreases.

Table I. Data used in the calculations of thermal powers

Quantity	Value (Cal K^{-1} $mole^{-1}$)	Reference
Standard entropy of Ag_4RbI_5	147.07	8
Entropy due to lattice disorder in Ag_4RbI_5	10.81	8
Disorder contribution to the heat capacity of Ag_4RbI_5	22	8
Heat capacities of:		
Ag_4RbI_5 solid	73.4	9
liquid	77.0	9

Table III. Values of the heat of transport terms

Substance	Phase	Term	Method	Value
Ag_4RbI_5	Solid	$Q^*_{Ag^+}$	Direct	2.07
	Solid	$Q^*_{Ag^+}$	Slope	1.2 ± 0.8
	Melt	$t_{Ag^+}Q^*_{Ag^+} + t_{Rb^+}Q^*_{Rb^+}$	Direct	3.2
	Melt	$t_{Ag^+}Q^*_{Ag^+} + t_{Rb^+}Q_{Rb^+}$	Slope	2.5 ± 0.4
Ag_4KI_5	Melt	$t_{K^+}Q^*_{K^+} + t_{Ag^+}Q^*_{Ag^+}$	Slope	2.7 ± 0.4
Ag_4CsI_5	Melt	$t_{Cs^+}Q^*_{Cs^+} + t_{Ag^+}Q^*_{Ag^+}$	Slops	3.7 ± 0.6

Chandra *et al.* (10) reported that they have measured the thermal power of compressed pellets of Ag_4KI_5 using massive silver and brass electrodes. They observed unusually large values of θ (-1.5 mV K^{-1}), and state that the potential was not a linear function of the temperature gradient. It seems likely that in their work the silver electrodes were not reversible to Ag^+. This is supported by the fact that there is little difference between the values of θ obtained with brass electrodes, which cannot be reversible, and those obtained with silver electrodes.

Hydrogen Overpotential on Zinc Containing Small Amounts of Impurities in Concentrated Alkaline Solution

T. S. Lee*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

Hydrogen overpotentials on zinc uniformly alloyed with 500 ppm Cd, Fe, Ca, and Mn, as well as 200 ppm Hg, were measured in 9*N* KOH at room temperature. Exchange current densities and transfer coefficients for each alloy for the hydrogen evolution process were obtained. Except for Cd, all the other impurities including Hg will cause zinc to be more readily corroded in alkaline medium.

Hydrogen overpotentials on zinc in alkaline solution have been measured in an open vessel (1) and in closed systems under experimentally carefully controlled conditions (2, 3). The overpotential on zinc containing electrodeposited impurities (Fe and Tl) in alkaline solution has also been measured (4). In this case, the impurities are deposited on the electrode surface and their distribution and uniformity are not well defined. The purpose of this paper is to report measurements of hydrogen overpotential on zinc containing small amounts of impurities uniformly alloyed with the zinc in highly purified 9*N* KOH solution.

Experimental

The cell used for the measurements is a closed system under a hydrogen atmosphere. It is made from epoxy-lined Pyrex so that the inner walls are highly alkaline resistant. The details of the cell, the lining technique, and tests for resistance to concentrated alkaline solution were reported previously (3).

The samples are prepared by alloying the pure elements obtainable on the market with high-purity zinc. The zinc is obtained from American Smelting and Refining Company and has a purity of 99.999+%. Analysis shows 1 ppm Cu and less than 1 ppm of Mg and Si. Other elements such as Sb, Ti, Mn, Sn, Cr, Fe, Ni, Bi, Al, Ca, In, Cd, and Ag are not detected. The purity of the alloying elements and their vendors are as follows: iron, from Battelle Memorial Institute, has a purity of 99.99+%; calcium, from J. T. Baker, has a purity of 99.0+%; mercury, from National Lead, has a purity of 99.996+%; manganese, from Foote Mineral, has a purity of 99.99+%; and cadmium, from American Smelting and Refining Company, has a purity of 99.999+%. The process of alloying is carried out by melting about 100g charges in high-purity graphite crucibles in a small resistance muffle furnace under argon. The melt is homogenized with a high-purity graphite stirrer. A graphite-coated molybdenum skimmer is used to remove the dross. Melt temperature is measured with a calibrated thermocouple adjacent to the crucible. After stirring and skimming, the melt is poured into a graphite-coated copper chill mold. Before starting, the crucible and stirrer are scraped and then cleaned with dilute HNO_3 each time. After rinsing and drying, the final cleaning is done by using a wash heat of the zinc base metal.

All alloys used in this study are made from master zinc alloy and pure zinc. The master alloys are made from pure metals which contain a higher percentage of the different alloying metals.

For the alloys of iron and mercury, the casting is followed by rolling the cast slabs from 3/8 in. to about

* Electrochemical Society Active Member.

Key words: hydrogen overpotential, hydrogen overvoltage, hydrogen evolution process in alkaline solution, electrode kinetics hydrogen evolution process, zinc corrosion.

40 mil thickness on a 35 in. diameter, 2 high flat mill with unheated rolls lubricated with 50-50 tallow-paraffin mixture. On each pass a reduction of about 10% is obtained.

To determine whether the impurities introduced into the zinc are well mixed and that no zinc oxide is introduced in the alloying process, a metallographic examination and electron-microprobe analysis of each of the specimens are done. All tests show that the small amount of impurities introduced into the zinc is evenly distributed and that no evidence of zinc oxide is present in the sample.

All the impurities introduced for this study are at a level of 500 ppm except mercury which is only 200 ppm.

The electrodes prepared for this study are made from a piece of the alloy cut from the center of the casts or rolls.

The counterelectrode is made from pure nickel and its area is about 8-10 times that of the working electrode. The reference electrode is a Hg/HgO electrode in contact with the same KOH solution. The working electrode, which has an exposed area of about 1 cm^2, is electrically insulated with the epoxy that was used to line the cell. The electrode surface is prepared and treated by following the same procedure as described before (3).

The constant current is supplied by a Harrison Laboratories' Model 855C power supply through a variable power resistor in series. The potentials are measured by a Keithley Model 630 potentiometric electrometer which has a minimum input resistance of 10^{13} ohm. All the measurements are carried out at room temperature which is controlled at 25° ± 1°C. Measurements are carried out from the high current density to the low current density region and back again; this process is then repeated.

At each current density, the steady potential is obtained in a few minutes. Once the steady potential is reached, the electrode will stay at the same potential as long as ½ hr without any change. The data presented here are the average values of at least four runs. The deviation of each run from the average value is only a few millivolts. There is no hysteresis in any of the runs. After the measurement, the electrodes are washed, dried, and examined under a microscope. The surface does not appear to have changed from its original appearance.

Results and Discussion

Hydrogen evolution on metal surfaces in alkaline solution is known to have the over-all reaction $2H_2O + 2e = H_2 + 2\,OH^-$. In the case where the rate-determining step is electron transfer and the transfer coefficient $\alpha = ½$, the hydrogen overpotential (η) for the reaction as shown before (3), is

$$\eta = \text{const.} + \frac{RT}{\mathbf{F}} \ln \alpha_{H_2O}\alpha_{OH^-} - \frac{2RT}{\mathbf{F}} \ln I$$

where α denotes activity, I is the current density, and the other symbols have their usual meaning. At constant temperature and definite KOH concentration, the above equation reduces to the Tafel equation $\eta = A + B \log I$ where A and B are constants.

In the experiments, the hydrogen overpotential is obtained by substracting the reversible hydrogen potential from the measured potential. The reversible hydrogen potential in 9*N* KOH at 25°C, as measured as well as calculated before, is −0.938V against a Hg/HgO electrode (3).

The plots of hydrogen overpotential against logarithmic current density for zinc containing 500 ppm Cd, Ca, and Fe are shown in Fig. 1, and those for zinc containing 200 ppm Hg and 500 ppm Mn are shown in Fig. 2. In each figure the overpotential for pure zinc is also plotted for comparison. (Please note that curves 3 and 4 in Fig. 1 are referred to the right-hand scale only.)

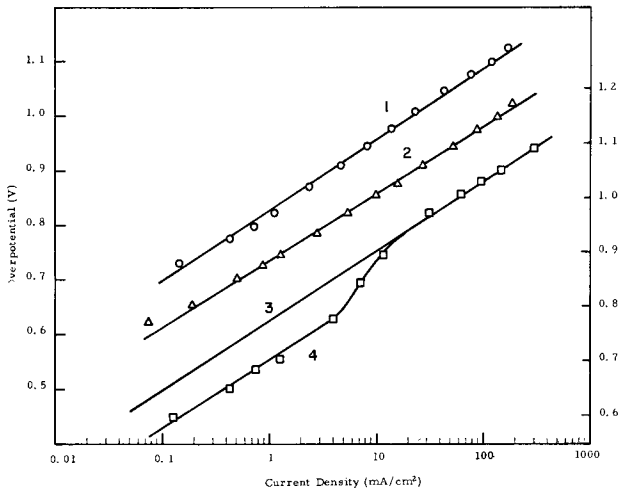

Fig. 1. Hydrogen overpotential in 9*N* KOH at 25°C: curve 1, Zn as well as Zn-0.05% Cd; curve 2, Zn-0.05% Ca; curve 3 (right-hand scale) Zn; curve 4 (right-hand scale) Zn-0.05% Fe.

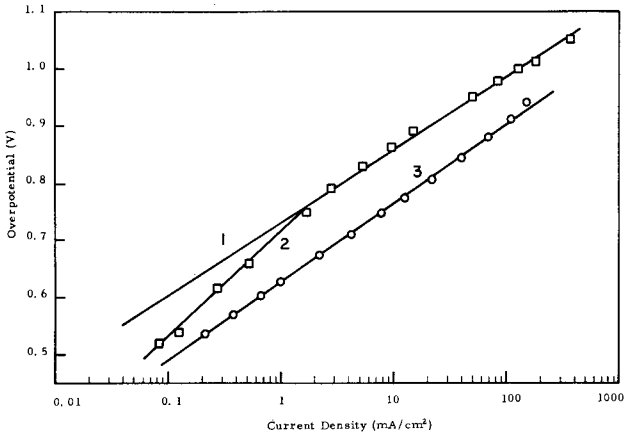

Fig. 2. Hydrogen overpotential in 9*N* KOH at 25°C: curve 1, Zn; curve 2, Zn-0.02% Hg; curve 3, Zn-0.05% Mn.

In Fig. 1, curve 1 is the hydrogen overpotential plot for Zn-0.05% Cd, which is identical to that for pure zinc. Curve 2 is the overpotential plot for Zn-0.05% Ca which is about 0.1V lower than that for zinc. Curve 3 is the plot for zinc, and curve 4 is that for Zn-0.05% Fe. Comparing curves 3 and 4, one can see that the effect of 500 ppm of Fe appears only in the low current density region, which is about 72 mV lower than that for pure zinc. In the high current density region, the small amount of iron does not have any effect. In Fig. 2, curve 3 is the plot for Zn-0.05% Mn, and the value of the overpotential is about 0.1V lower than that of pure zinc.

In Fig. 2, curve 1 is the hydrogen overpotential plot for zinc, and curve 2 is that for Zn-0.02% Hg. One can see that the small amount of mercury in zinc does not affect one way or the other the overpotential on zinc in the high current density region. However, in the low current density region, the small amount of mercury decreases the overpotential on zinc. In order to clarify the fact that the lowering of the overpotential in the low current density region is not due to impurities other than small amounts of mercury, the sample has been subjected to emission spectroscopic analysis. No impurities other than mercury have been found. Also, the measurements have been made on different samples in different purified solutions and the results are all the same. It is generally believed that amalgamated zinc is more corrosion resistant to alkaline solution than is zinc alone because mercury has a high hydrogen overpotential (5). This finding suggests that when small amounts of mercury are alloyed with zinc this belief may no longer be valid, since the hydrogen over-

potential of the alloy is lower than that of pure zinc (6). Consequently, the alloy will corrode more readily in the alkaline medium.

With the result obtained here, in conjunction with the explanation given in the preceding paragraph for the zinc-mercury alloy, one can visualize that almost all the impurities, including mercury in the zinc, will make zinc more readily corroded in the alkaline medium. Cadmium is the only exception which will not affect the zinc corrosion.

The electrochemical parameters, transfer coefficients (α), and exchange (I_0), which are derived from the Tafel slopes, are shown in Table I. For Fe and Hg-alloyed zinc, the parameters based upon the low current density region are given. Their values in the high current density region are the same as that of pure zinc. It appears that in most cases the small amounts of impurities in zinc only lower the hydrogen overpotential and do not change the mechanism of the hydrogen evolution process in alkaline solution. The Tafel slopes are in the vicinity of 120 mV per decade. The rate determining step is an electron-transfer process of the Volmer type (3), $H_2O + e = H_{ad} + OH^-$. For zinc with small amounts of mercury in the low current density region, the mechanism of hydrogen evolution in alkaline solution might be different as indicated by the high Tafel slope.

Table I. Electrochemical parameter for hydrogen evolution reaction on various Zn surfaces in 9N KOH

Electrode	Slope	α	I_0 (mA/cm^2)
Zn	124	0.48	8.5×10^{-7}

Properties of LiCl and $(CH_3)_4NCl$ Solutions in Water-Methanol Mixtures

M. H. Miles* and V. Jiamsakul[1]

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

ABSTRACT

Solutions of both 1.0M LiCl and 1.0M $(CH_3)_4NCl$ in methanol-water mixtures were investigated to determine the effect of solvent composition on viscosity, electrolytic conductance, and surface tension. The viscosity-composition curves suggest that interactions between solvent molecules attain a maximum effect at a composition of about 0.3 mole fraction methanol, and that these interactions increase as the temperature is lowered. In the methanol-rich mixtures, the conductivity of the $(CH_3)_4NCl$ solution becomes considerably larger than that of the LiCl solution. Cyclic voltammetric measurements on platinum, gold, and molybdenum electrodes indicate that oxidation of methanol is insignificant in these solutions despite favorable thermodynamics. Wide, useful potential ranges are available at all solvent compositions.

There is very little reported research on the use of mixed solvents in batteries or fuel cells. Desired properties of electrolyte solutions in mixed solvents for such applications include high electrolytic conductivity, a wide liquid temperature range, and inertness of the solution to electrochemical oxidation and reduction over a wide potential range. These properties were investigated as a function of the solvent composition for both 1.0M LiCl and 1.0M $(CH_3)_4NCl$ solutions in methanol-water mixtures. Methanol was selected due to its attractive properties of low viscosity (0.0054 poise at 25°C) and low freezing point (−98°C). The LiCl and $(CH_3)_4NCl$ salts were selected to represent the extremes of a small, highly solvated cation given by Li^+, and of a large, relatively unsolvated cation given by $(CH_3)_4N^+$. Despite numerous reported studies in water-alcohol mixtures during the past century (1-12), no literature data could be located for our selected three-component systems. However, data on the conductivity and viscosity of 0.05M LiCl solutions in methanol-water mixtures is already available (3).

Experimental

All solution preparations were made using Baker spectrophotometric reagent grade methanol and deionized distilled water. The lithium chloride used was Baker reagent grade, and tetramethylammonium chloride was obtained from Eastman. All chemicals were used without further purification.

Measurements of electrolytic conductivity were made with a Sargent conductivity bridge which had a

Properties of LiCl and $(CH_3)_4NCl$ Solutions in Water-Methanol Mixtures

M. H. Miles* and V. Jiamsakul[1]

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

ABSTRACT

Solutions of both 1.0M LiCl and 1.0M $(CH_3)_4NCl$ in methanol-water mixtures were investigated to determine the effect of solvent composition on viscosity, electrolytic conductance, and surface tension. The viscosity-composition curves suggest that interactions between solvent molecules attain a maximum effect at a composition of about 0.3 mole fraction methanol, and that these interactions increase as the temperature is lowered. In the methanol-rich mixtures, the conductivity of the $(CH_3)_4NCl$ solution becomes considerably larger than that of the LiCl solution. Cyclic voltammetric measurements on platinum, gold, and molybdenum electrodes indicate that oxidation of methanol is insignificant in these solutions despite favorable thermodynamics. Wide, useful potential ranges are available at all solvent compositions.

There is very little reported research on the use of mixed solvents in batteries or fuel cells. Desired properties of electrolyte solutions in mixed solvents for such applications include high electrolytic conductivity, a wide liquid temperature range, and inertness of the solution to electrochemical oxidation and reduction over a wide potential range. These properties were investigated as a function of the solvent composition for both 1.0M LiCl and 1.0M $(CH_3)_4NCl$ solutions in methanol-water mixtures. Methanol was selected due to its attractive properties of low viscosity (0.0054 poise at 25°C) and low freezing point (−98°C). The LiCl and $(CH_3)_4NCl$ salts were selected to represent the extremes of a small, highly solvated cation given by Li^+, and of a large, relatively unsolvated cation given by $(CH_3)_4N^+$. Despite numerous reported studies in water-alcohol mixtures during the past century (1-12), no literature data could be located for our selected three-component systems. However, data on the conductivity and viscosity of 0.05M LiCl solutions in methanol-water mixtures is already available (3).

Experimental

All solution preparations were made using Baker spectrophotometric reagent grade methanol and deionized distilled water. The lithium chloride used was Baker reagent grade, and tetramethylammonium chloride was obtained from Eastman. All chemicals were used without further purification.

Measurements of electrolytic conductivity were made with a Sargent conductivity bridge which had a

* Electrochemical Society Active Member.
[1] Present address: Faculty of Science, Prince of Songkla University, Haadyai, Songkla, Thailand.
Key words: activation energy, conductivity, electrostability, surface tension, viscosity.

specified accuracy of ±1% over the experimental range of resistances. The cell constant was determined using 0.1000M KCl. An Ostwald viscosimeter was used to determine solution viscosities. Kinetic-energy corrections were negligible in each case. The capillary rise method was used to determine the surface tension of the solutions. Experimental details of these various measurements are given by Shoemaker and Garland (13).

Measurements at 25° and 35°C were performed in a Sargent thermostatic water bath controlled by a thermistor sensor to ±0.01°C of the stated temperature. A distilled water-ice bath was used for measurements at 0°C.

Cyclic voltammetric measurements were made with a Beckman Electroscan 30 using a potential sweep rate of 100 mV/sec. These experiments were conducted in a 50 ml beaker containing the working electrode (platinum, molybdenum, or gold), counterelectrode, and solution. The potential was measured with respect to an aqueous saturated calomel electrode (SCE) contained in a separate compartment by using an aqueous 1.0M KCl salt bridge to establish electrolytic contact. Solution contamination was minimized by restricting the contact between the salt bridge and solution to a narrow strip of filter paper. From the Henderson equation, the liquid junction potentials were estimated to be less than 10 mV for all solution compositions.

Results

The viscosities of 1.0M LiCl solutions in water-methanol mixtures are shown in Fig. 1 for temperatures of 0°, 25°, and 35°C. Results for 1.0M $(CH_3)_4NCl$ solutions (TMAC) are also shown for the temperature of 25°C. Maxima on the viscosity-composition curves occur in each case at about 0.3 mole fraction methanol. These maxima in viscosity become more intense as the temperature decreases.

The conductivity measurements, shown in Fig. 2, reflect the influence of the viscosity. There is an initial marked decrease in conductivity on adding methanol due largely to the increase in viscosity. As the methanol content of the solution increases beyond 0.3 mole fraction, the change in conductivity becomes much more gradual. For the TMAC solution, the conductivity passes through a flat minimum at about 0.5 mole fraction of methanol. At high methanol concentrations, the TMAC solutions have much greater conductivities (and lower viscosities) than the LiCl solutions.

Figure 3 illustrates that addition of methanol causes an initial marked decrease in surface tension. Changes in this property become more gradual as the methanol content increases.

Cyclic voltammetry was used to obtain the current *vs.* potential traces shown in Fig. 4. These results were produced using a platinum electrode in 1.0M LiCl solutions at 24°C. The dashed line shows the trace for an aqueous solution, the dotted line for a methanol solution, and the solid line for the mixed solvent containing 0.5 mole fraction methanol.

The horizontal line segments shown in Fig. 4 represent an arbitrary limit where the current density exceeds 10 mA/cm² (geometrical area) using a potential sweep rate of 100 mV/sec. Within the potential region established by these anodic and cathodic limits, electrochemical oxidation or reduction of the solvent,

electrolyte, or electrode is relatively insignificant. This defines the electrostability region for the selected solvent-electrolyte-electrode system (14).

The electrostability limits for 1.0M LiCl solutions in methanol-water mixtures at room temperature (24°C) are shown in Fig. 5 for platinum, gold, and molybdenum electrodes. Thermodynamically, methanol can be electrochemically oxidized to formaldehyde or to carbon dioxide at potentials considerably lower than the potential at which water is oxidized (15). Experimentally, however, the potential at which appreciable electrochemical oxidation is observed is virtually unaffected at room temperature by the addition of methanol. Similarly, the potential at which significant reduction of the solutions is observed shows only slight change as the mole fraction of methanol is increased. At all solvent compositions there are wide useful potential ranges available for fundamental electrochemical investigations.

For 1.0M TMAC solutions, somewhat erratic changes in the electrostability regions are observed as the mole fraction of methanol increases (Fig. 6). Nevertheless, wide useful potential ranges are also available in these solutions.

Discussion

Properties of water-methanol mixtures are characteristic for systems with strong interactions (6). The maxima on the viscosity-composition curves in Fig. 1 can be explained by hydrogen bonding between methanol and water molecules. Theoretical studies of seven open-chain trimers in water-methanol mixtures show that the methanol-water-water trimer is the most stable (16). The viscosity maximum at about 0.3 mole fraction methanol suggests that the strongest interactions occur when two or three water molecules are available for each methanol molecule. Other studies on pure water-methanol mixtures (5) and on $LiClO_4$, $NaClO_4$, and NaCl solutions in water-methanol mixtures (12) also show viscosity maxima at about this composition. The large increase in the viscosity maximum as the temperature decreases suggests increasing interactions between methanol and water molecules with decreasing temperatures.

From Stokes' viscosity law, the product of specific conductivity, k, and viscosity, η, is given approximately by

$$k \cdot \eta = C^+ \left(\frac{1}{r^+} + \frac{1}{r^-} \right) \times \text{constant} \qquad [1]$$

where C^+ is the ionic concentration of the cation, r^+ is the radius of the cation in solution, and r^- is the radius of the anion in solution. If the extent of ionization of the 1.0M salt solutions and the radii of the solvated ions are independent of the solvent composition, and if the viscosity experienced by the moving ion is the same as the measured bulk viscosity, then the product, $k\eta$, should remain constant for all solvent compositions. Figure 7 shows this $k\eta$ product as a function of solvent composition for LiCl solutions at 0°, 25°, and 35°C, and for $(CH_3)_4NCl$ solutions at 25°C. Slight maxima in the $k\eta$ product are often observed in the predominantly aqueous regions (9, 11, 17). This is usually attributed to the viscosity experienced by the moving ion being less than the measured bulk viscosity (9, 17).

The large decrease in the $k\eta$ product at higher alcohol concentrations is usually attributed to either decreasing ionization of the electrolyte (11, 17) or to the increasing size of the ionic radii with increasing mole fraction of alcohol (3, 4, 9). Since both $(CH_3)_4N^+$ and Cl^- ions are believed to be only slightly solvated in water (18), it is difficult to rationalize that this decrease in the $k\eta$ product is due entirely to enlargement of the solvated radii as methanol is added. However, the decrease in $k\eta$ is noticeably less for $(CH_3)_4NCl$ than for LiCl. Probably both decreasing ionization and increasing solvated radii as methanol is added contribute to the decreasing $k\eta$ product. The decrease in the $k\eta$ product with increasing temperature in the predominantly aqueous solutions suggests that the ions become more highly solvated as the solvent structure is destroyed by the increased temperature (18).

The activation energies for conductivity (E_k) and for viscosity (E_η) can be calculated from the well-known equations

$$k = Ae^{-E_k/RT} \text{ and } \eta = Be^{E_\eta/RT} \qquad [2]$$

by assuming that A and B are constants which are in-

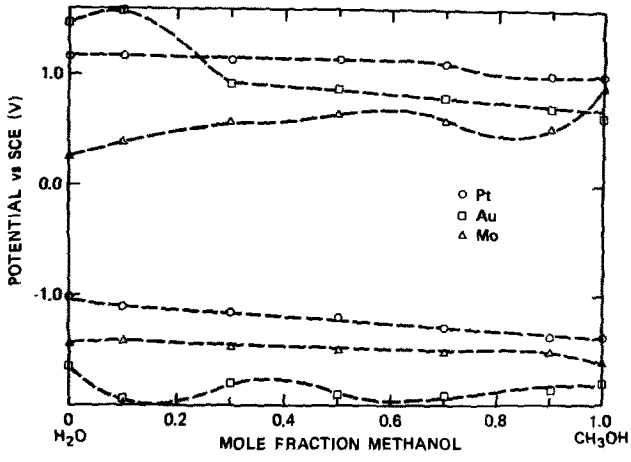

Fig. 6. Variation of the anodic and cathodic electrostability limits with mole fraction methanol for platinum, gold, and molybdenum electrodes in 1.0M $(CH_3)_4NCl$ solutions at 24°C.

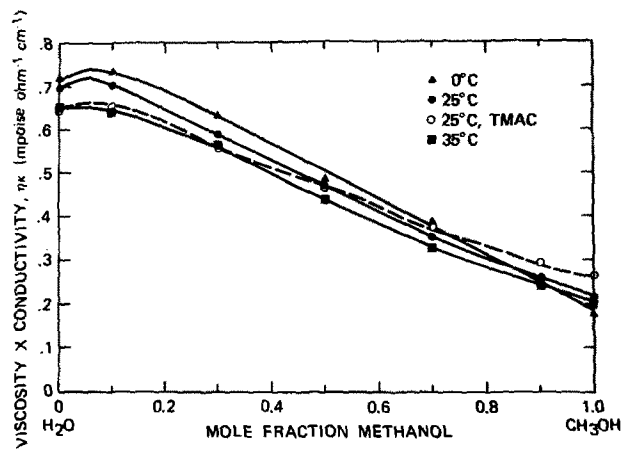

Fig. 7. Variation of the product of viscosity times conductivity with mole fraction methanol for 1.0M LiCl solutions at 0°, 25°, and 35°C and for 1.0M $(CH_3)_4NCl$ solutions at 25°C.

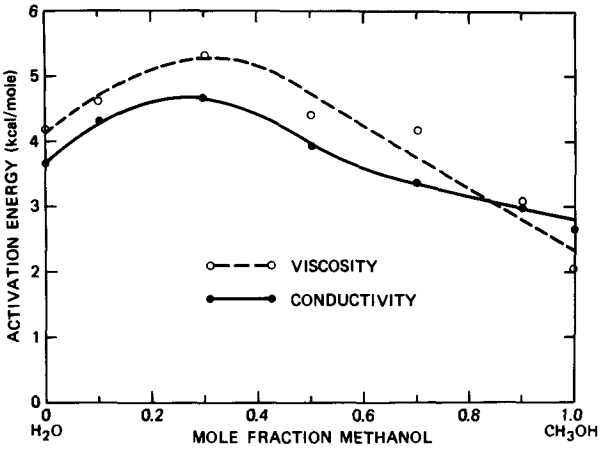

Fig. 8. Activation energies for viscosity and conductivity as a function of the solvent composition for 1.0M LiCl solutions.

dependent of the temperature. The results for such calculations are shown in Fig. 8 for the 1.0M LiCl solutions.

Two interesting features of Fig. 8 are the maxima in activation energies and differences in activation energies for the two processes. Since the energy barriers for both ionic motion and viscous flow are determined largely by solvent molecules exchanging positions (19), it is reasonable that the maxima in activation energies for these two processes are observed at about the composition of maximum interactions between water and methanol molecules. The generally lower activation energies for conductivity indicate that the intense electric field of the ions tends to loosen the solvent structure in the vicinity of the ions, which reduces the required activation energy for movement of solvent molecules (9). At high methanol concentrations, the activation energy for conductivity exceeds that for viscosity. Increasing ionization of LiCl with increasing temperature at high methanol concentrations would result in the calculated activation energy being larger than the true value determined solely from ionic mobility. Another possible factor is that the structure of the methanol-rich solutions is less influenced by the electric field of the larger, methanol-solvated ions (9).

Gibbs isotherm

$$\Gamma_2 = -\frac{1}{RT}\frac{\partial\gamma}{\partial \ln a_2} \qquad [3]$$

relates the surface concentration, Γ_2, and activity, a_2, of component 2 to the surface tension, γ, of the solution (20). This equation indicates that a component such as methanol which decreases the surface tension of the solution (Fig. 3), will tend to accumulate strongly at the surface. Rapid changes in surface potentials of LiCl solutions in water-methanol solutions observed at small methanol concentrations (21) verify this tendency of methanol to accumulate at surfaces in these solutions. Therefore, in electrochemical studies in this mixed solvent, the concentration of methanol molecules at the electrode surface will be considerably greater than the bulk concentration. Despite favorable surface concentrations and favorable thermodynamics, significant oxidation of methanol does not occur in these solutions.

Recent studies of LiCl solutions in methanol have established that the limiting anodic potential on platinum is controlled by oxidation of the chloride ion to chlorine gas (22). Due to the high overvoltage for oxygen evolution, the evolution of chlorine is likely the predominant anodic reaction on platinum in the aqueous solutions as well (23). For molybdenum, and possibly also for gold, the limiting anodic potential is likely controlled by surface oxidation of the electrode metal.

The limiting cathodic potentials on Pt, Au, and Mo for all solution compositions unquestionably represent reduction of the solvent to hydrogen gas (21). The addition of methanol generally tends to shift the cathodic limit toward slightly more negative potentials.

Summary

Favorable electrostability regions are available for the use of water-methanol mixtures in batteries or fuel cells. However, strong interactions between water and methanol molecules will limit the usefulness of such solutions at low temperatures. These interactions between solvent molecules attain a maximum effect at a composition of about 0.3 mole fraction methanol. The main differences observed between the LiCl and $(CH_3)_4NCl$ solutions are a slightly lower viscosity and a markedly higher conductivity for the $(CH_3)_4NCl$ solutions in methanol-rich mixtures.

Electrodeposition of Coherent Boron

Jordan D. Kellner

United Aircraft Research Laboratories, East Hartford, Connecticut 06108

ABSTRACT

Pure coherent boron has been electrodeposited from a fused fluoride mixture. A eutectic mixture of LiF and KF is used as the electrolyte, with BF_3 gas dissolved to form the tetrafluoborate ion which reacts at the cathode to produce boron. The boron as plated is of 95% or better purity, and is homogeneous and uncracked, up to 25 mils thickness. The substrates plated include steel, copper, graphite, tungsten, and molybdenum. Temperatures of plating range from 600° to 700°C, with plating rates up to 6 mils/hr.

Pure boron has been produced electrolytically in fused salts by Cooper (1) and others (2). However, these methods for producing boron electrolytically have produced spongy, dendritic, or compacted powder deposits. These deposits were crushed and treated with hot water and acid to leach out salts and other impurities. In contrast, the method presented in this paper produced 95+% pure boron as a single homogeneous material, dense, and structurally coherent. Boron is of interest as a coating due to its high hardness, low rate of corrosion, and high specific strength and modulus. Due to the hardness and brittleness of the material, it is difficult to machine, and electroforming offers an attractive technique to prepare useful parts made of boron. Substrates that have been plated include copper, graphite, steel, tungsten, and molybdenum.

Experimental

The electrolyte consists of a 50-50 mole per cent (m/o) mixture of reagent grade LiF and KF melting at about 495°C. These salts are partially dried by exposure for two weeks in an argon-filled dry box and then weighed and mixed mechanically. The BF_3 gas is 99.9% pure obtained in a 1400 psi cylinder. The melt is contained in a graphite crucible machined from UCAR Grade CS graphite rod obtained from Graphite Products Corporation. Figure 1 shows the crucible in its stainless steel can. The stainless steel cover is welded and provides threaded openings for fittings through which various electrodes are placed in the melt. Boron nitride inserts are used in the fittings to electrically insulate the electrodes from the can.

Key words: boron, electrodeposition, fused salts.

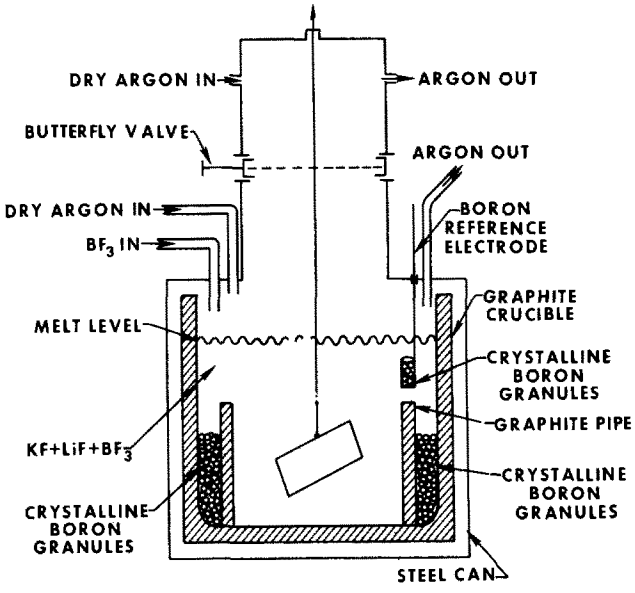

Fig. 1. Diagram of cell

The 6 in. opening at the top is fitted with a 6 in. nickel butterfly valve to provide an argon antechamber. This prevents air and moisture from reaching the melt surface, when the cathode is put in place and removed.

The dried mixed powder is held for 4-5 days in the crucible at 450°C under a stream of argon to remove residual moisture, then brought to 650°C for BF_3 addition.

A nickel tube held at ½ in. above the melt surface is used to add pure BF_3 gas for solution into the melt until the concentration reaches approximately 25 g/100 cm^3. Flow rates for gas addition are about 100 cm^3/min. Concentrations up to 100g BF_3/100 cm^3 of melt can then be obtained by immersing this tube and again flowing 20-50 cm^3/min. We have found that if the tube is below the liquid surface at low BF_3 concentrations it will become clogged easily, due to a partial vacuum being formed and forcing the liquid up the tube. The BF_3 concentration in the melt falls by about 0.5g BF_3/100 cm^3/day due to the appreciable vapor pressure of the gas above the melt, and necessitates the further addition of BF_3 periodically. The BF_3 concentration in the melt is monitored weekly by dissolving a small melt sample in water and determining fluoborate ion with an Orion specific ion tetrafluoroborate electrode.

The carbon electrodes used were all spectroscopic grade graphite rod obtained from Ultracarbon Corporation.

A power supply is used to establish a constant current between cathode and cell while the cathode-reference potential is monitored. An integrator using a Keithley 301 differential operational amplifier is used to determine the charge passed during an experiment. A Duffers Model 600 potentiostat was used to obtain constant voltage potentiograms recorded on a Mosely X-Y recorder.

Results

Plating conditions and coating appearance.—Coating appearance and purity are affected by three parameters: concentration of BF_3, current density, and temperature. Concentration of BF_3 has been varied from 3 to 25 g/100 cm^3, current density from 15 to 500 mA/cm^2 and temperatures from 550-750°C. At the lower temperatures, high BF_3 concentration and low current density are necessary for good deposits, while at high temperature, high current densities must be used. Some typical plating parameters are shown in Table I. Figure 2 shows typical coating surfaces with hemispherical nodules formed on the surface.

In general, the nodules were flatter at the high current densities, resulting in a shiny surface, while at

low currents, the relatively large nodules produced a dull "matte" finish.

Coulometry and chemical analysis.—The number of electrons transferred in the deposition reaction, n, can be calculated according to

$$n = \frac{MC}{WF}$$

where M is the molecular weight of boron, 10.81, C is coulombs passed, W is weight of coating, and $\mathbf{F}$ is Faraday's constant. Table II shows the n numbers obtained from weighed cathodes at various current densities and temperatures. Each of these n numbers is the average of at least 10 determinations with a variation of ±2%. These data indicate an n number of 3 at lower current densities and higher temperatures, with numbers lower than 3 at high current densities and low temperatures.

Table III presents data on the boron content of some of the coatings used to obtain Table II.

Chemical analyses were performed by a modified Cooper technique where the coating and the copper foil substrate was dissolved in a mixture of HNO_3, HCl, and H_2SO_4 with refluxing. After removal of copper by precipitation of $Cu(OH)_2$ with NaOH, and adjusting pH, the solution was titrated with mannitol and NaOH. Table III shows that when the n number is close to 3, the boron content of the coating is close to 100%,

Table II. n Numbers

3.01	98
3.02	98.5
2.97	100
2.83	88
2.71	87
2.02	65

while lower n number coatings produced at high rates of deposition or low temperatures showed a corresponding low boron content.

This value is consistent with the cathode reaction

$$BF_4^- + 3e^- \rightarrow B + 4F^-$$

Since KF, from free energy calculations, (Janaf Thermochemical Data) would have a decomposition potential differing by about a volt from that of BF_3 (4.7 for KF, 3.7 for BF_3) one would suspect a small amount of potassium to codeposit with boron, especially at high overpotentials. If potassium were codepositing, only 1 mole of electrons would be necessary to reduce a mole of potassium weighing 39.1g whereas 3 moles of electrons are required to reduce a mole of boron weighing 10.81g. Thus a little current used for a potassium reaction goes a long way toward reducing the purity of the boron coating. The total weight of the deposit is

$$W = \frac{M_B C_B}{3F} + \frac{M_K C_K}{F}$$

For a total of 1000 coulombs

$$W = \frac{10.81\ (1000 - C_K)}{3\ (96{,}487)} + \frac{39.1\ (C_K)}{96{,}487}$$

The number of coulombs used to deposit potassium is

$$C_K = 2718W - 101.5$$

In the limit when $W = 37.3$ mg, C_K is zero, and the deposit is all boron. The value of C_K can be used to determine the weight of potassium in the deposit

$$W_K = \frac{M_K C_K}{F}$$

and the boron purity is

$$\%\ \text{boron} = \frac{W - W_K}{W} \times 100$$

Table IV shows results for seven samples that were analyzed for boron. The boron content of these samples as calculated by the above method is shown in the last column. These calculated values show good agreement with the actual values shown in the third column. It is interesting to note that in the fourth sample only 10.21 coulombs out of 1000 coulombs can be attributed to potassium deposition, and yet this is enough to limit the boron content of this sample to 87%. A spectral analysis qualitative test on a few of these samples showed potassium was present as a major impurity.

Table IV

[a] These negative values of C_K are the result of an experimental error of 0.1 Mg in weighing the deposit.

Apparently, although the appearance of specimens plated was good, pure boron was obtained only at temperatures of about 700°, current densities below 50 mA/cm², and BF_3 concentrations above 20 g/100 cm³. Since there was good correlation between n numbers and boron purity, this can be used as a check on the quality of deposit.

Physical properties.—Samples of electroplated boron were exposed to Cu radiation for 12 hr in a Debye Camera 114.6 mm, and no crystalline peaks were observed. The pattern was typical of what has been called "amorphous" boron showing 2 diffuse rings similar to the pattern formed by high-strength vapor-deposited filament boron.

Strength and modulus of elasticity in bending was measured for copper and steel foil plated strips on a "Rigidometer" made by Galileo, Incorporated. The modulus is calculated from

$$E = \frac{M_O L}{3I \tan \theta}$$

where M_O is moment in lb-in., L is length of strip in inches, I is moment of inertia (for a flat rectangular beam $I = 1/12\ bh^3$, where b is the width and h is the thickness of the beam), and θ is the angle of deflection. The moment and the angle of deflection are read directly from the instrument. The stress at which the stress-strain curve becomes nonlinear was taken as the breaking stress of the coating, given by

$$S = \frac{6M_O}{bh^2}$$

These measurements yielded moduli for the boron coating of 57-70 $\times$ 10^6 psi and strengths of 30,000-95,000 psi.

Plating stress.—Qualitative measurements of plating stress were obtained from boron plating a bimetallic strip. A stainless steel 5 mil foil strip was copper plated on one side only, since the boron does not adhere to the steel but does adhere to the copper. Observations of the strip after coating with boron, and before cooling have shown a large compressive stress at low current densities, and a large tensile stress at high current densities. By measuring the curvature of the strip prior to cooling, effects due to differential thermal expansion were eliminated. An intermediate current density could be found where the plating stress was zero; however, this produced a coating of only 90% purity. In other words, plating for maximum purity of boron at low current densities always produced coatings with a high compressive stress. It is interesting to note that the boron produced by vapor deposition in BCl_3-H_2 gas mixture also exhibits expansion and resulting compressive stress. In vapor deposition on tungsten wires, the boriding and subseqeunt expansion of this wire tends to relieve this stress.

Hardness.—Figure 3 shows an eleven mil boron coating on graphite. Hardness measurements, using a Reichert microhardness tester at 100g load yielded a value for five impressions of 2505 ± 150 D.P.H. The same operator on the same apparatus obtained a value of 3027 ± 150 for vapor deposited boron fiber. It is apparent that the hardness of the electrodeposited boron is very dependent on the purity obtained, since lower hardness values were obtained for less pure boron deposits.

Chronopotentiometry.—Electrodes of small surface area were used to generate chronopotentiometric curves. A boron reference electrode was used, and proved to be extremely stable over long periods of time. This reference is properly called a "quasi" reference electrode (3) because its potential is not precisely defined. At BF_3 concentrations of 5 g/100 cm³ and 700°C, current densities of about 1 A/cm² produced a plateau at −0.52 and then a shallow decrease to −1.3,

Fig. 3. Boron coating on graphite rod (200×) showing five impressions of a diamond pyramid.

with a transition time of about 1 sec. This transition is too slow to be caused by diffusion control limiting the reaction, and it is probably caused by a series of reactions in which alkali borides and borates are deposited along with boron.

Voltammetry.—Current voltage curves using a copper working electrode, boron reference electrode, and a boron indicator were run with the results shown in Fig. 4. The sweep rate was 1 V/min, and little change was noted at slower sweep rates. The figure indicates the boron deposition potential is −0.55V relative to the boron reference, with a limiting current extending

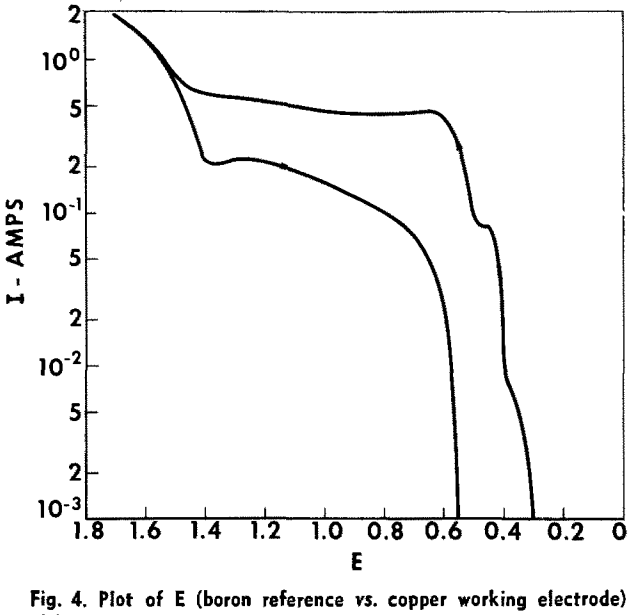

Fig. 4. Plot of E (boron reference vs. copper working electrode) vs. I (total current).

to −1.5V where alkali metal begins to deposit. Chronopotentiometric curves discussed previously indicate this is not a diffusion-limited current but a reaction-limited current. Thus, it is likely that a small amount of alkali metal deposits along with the boron at all potentials, while increasing amounts are deposited at more negative potentials.

Discussion

The essential feature of the present method for depositing boron is the low level of oxygen contamination that is necessary. After the KF-LiF mixture is melted, and before BF_3 is added, the oxygen-moisture contamination is checked by voltammetry. Two carbon rods are used, with a third carbon rod acting as a "quasi-reference." An anodic sweep at 20 mV/min produced a consistent current maximum at about +1.5V the height of which could be related to the oxide contamination level. Assignment of the current to oxygen discharge was possible from the observed evolution of carbon dioxide and carbon monoxide from the working carbon electrode as measured in the argon purge gas. Good boron deposits could be obtained only if the peak current due to the oxyanions was less than 10 mA/cm^2 and the best deposits were obtained when this current was less than 1 mA/cm^2. Boron deposited in a clean melt was of high purity (95%+) without any further purification treatment, and had a smooth surface. The thickness of the coating was varied from 0.5 to 25 mils with the thicker coatings being somewhat less pure and prone to cracks. There was no difference in the quality of the coating deposited on steel, graphite, copper, molybdenum, niobium, tungsten, titanium, or nickel. Of these substrates titanium required a thin protective coat of electroplated copper because of its corrosion by the melt. Both steel and nickel substrates required the presence of a boride layer before the boron would adhere to the surface. The boride layer would form if low current densities were chosen so that the cathode potential *vs.* a boron reference electrode was about −0.1V, *i.e.*, much less than the −0.55V necessary for boron to accumulate on the surface. Cook (4) in his boriding patent states that one should avoid the accumulation of boron on the surface which occurs at high deposition rates because the boron so obtained is crystalline, dendritic, or powdery. Numerous authors (1, 2) in the patent literature have described methods for producing this salt-boron composite mixture. The author can only conclude that the prime requisite in the present method is nearly complete absence of oxyanion contamination. Mellors and Senderoff (5) have discussed the undesirable high vapor pressure of BF_3 in fluoride melts, and the difficulties encountered by rapidly changing melt composition. The author has found that BF_3 composition changes are very small at temperatures of 600°-700°C in the KF-LiF eutectic mixture. Also, the melt can dissolve up to 50% by weight of BF_3 and still remain a single liquid phase. In melts that do not contain KF, it was found that BF_3 is nearly insoluble in this temperature range. On the other hand, attempts to use other sources of boron such as boric oxide do not produce smooth coherent pure boron deposits.

Photoconductivity in Anodic Oxide Films on Bismuth

S. Ikonopisov,* L. Andreeva, and Ts. Nikolov

Department of Physical Chemistry, Higher Institute of Chemical Technology, Sofia 56 (Darvenitsa), Bulgaria

ABSTRACT

Photoconduction of bismuth anodic films in different contacting and forming electrolytes is studied as a function of formation voltage, U_f, (film thickness, l_f); electrode potential, U_a; light intensity, L_o; and wavelength, λ. Oscillations of the photocurrent, I_{ph}, were observed when the film is obtained by galvanostatic anodization, these oscillations being eliminated by prolonged constant voltage anodization. Photoconduction is observed only under anodic polarization of the oxide-covered electrode. I_{ph} was found to be proportional to U_a and L_o, and to increase with U_f (or l_f). The spectral distribution I_{ph} (λ) is independent of the contacting electrolyte and for films anodized in a glycol-borate electrolyte or in dilute aqueous solutions shows an optical activation energy $W_{opt} \sim 2.8$ eV. For films anodized in a phosphate electrolyte [$(C_2H_5)_3PO_4 + H_3PO_4 + H_2O$] W_{opt} decreases to *ca.* 2.5 eV. This is attributed to the incorporation of ions from the electrolyte into the film. An attempt to explain the properties of the photoconduction is made on the assumption that a high density of trapping levels exists in the forbidden band of the structurally disordered anodic film.

De Smet and Hopper (1) have observed that visible light produces a sharp decrease in the potential of the bismuth anode during galvanostatic oxidation at low current density. This indicates that the anodic film exhibits photoconductivity in the visible region. The purpose of this paper is to clarify the origin and to study the properties of this phenomenon.

Experimental

The samples used in this study were cylinders (0.92 cm diameter) cut from a block of high purity (99.9995%) bismuth. A wire lead was soldered to the back-face of each cylinder. The specimen was then immersed in Araldite and, after curing, the front-face was uncovered by abrading with emery paper. The working surface was subsequently electropolished, brightened, and washed by the method described by Masing and Young (2). Conventional galvanostatic and potentiostatic techniques (3) were used for growing the anodic oxide films.

The precise measurements of the spectral distribution of photosensitivity requires operation at very low light intensities. In this case the photocurrent is only a small fraction of the dark current and the latter ought to be fully compensated. The compensating circuit designed to detect the photocurrents alone is given in Fig. 1. The electrode was polarized by an electronic constant voltage supply through a bleeder, the resistance (γ_b) of which was made proportional to the ratio of the applied voltage (U_a) to the formation voltage (U_f), viz., $\gamma_b = 500(U_a/U_f)$ kohms. The potential drop through the bleeder after stabilization of the dark current, was compensated by a second potentiostat. The anode potential was then measured by a vacuum tube voltmeter and overpotentials were calculated by subtracting the value of the open-circuit potential. Despite the high input impedance of the voltmeter the latter was disconnected during photocurrent measurements.

The electrode was subsequently irradiated with monochromatic light from a 100W incandescent lamp and photocurrent values were taken down only after a stabilization period of *ca.* 5 min. A monochromator with 11 nm half-width (Specol-C.Z.Jena, ± 1 nm wavelength accuracy) carefully calibrated against a Hg arc lamp, was used.

In the following the term formation voltage (U_f) is used to designate the potential up to which the electrode has been anodized under galvanostatic conditions or the overpotential at which the anodization has been carried out at a constant voltage and the term applied potential (U_a) refers to the overpotential at which the photoconductivity is measured.

All experiments were carried out at room temperature.

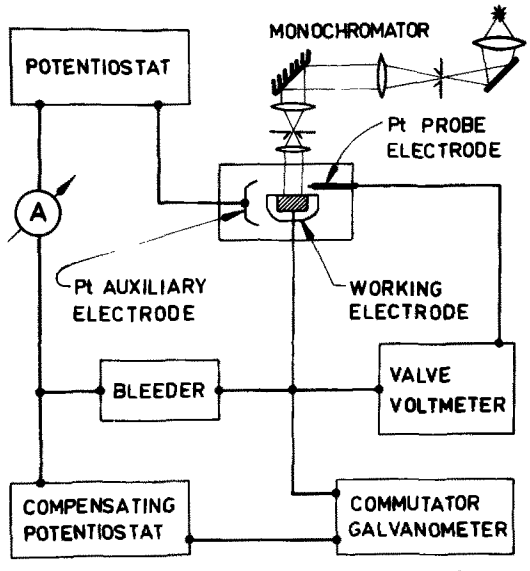

Fig. 1. Compensating circuit used for photoconduction measurements.

Results

Selection of the formation electrolyte.—Various alkaline (1, 2, 4-8) and acid (9-11) aqueous solutions are known to favor the formation of insulating anodic films on bismuth. The kinetics of anodization are strongly affected by the electrolyte composition and concentration. In many cases the dissolution of the anodic film is appreciable. Therefore investigations were carried out for the selection of an electrolyte which has no dissolution action on the film. Such appeared to be the mixture [$(H_2CO)_4B$]H + [$(H_2CO)_4B$]Na (1:1), produced by reacting appropriate amounts of H_3BO_3, NaOH, and $(CH_2OH)_2$ and removing the water obtained in the esterification by heating to 120°C. Prolonged (10 hr and more) polarization at potentials well below U_f or keeping the electrode for 100 hr in this electrolyte did not change the dielectric characteristics of the anodic film. Unless otherwise stated, the anodization and photoconductivity measurements were performed in this electrolyte, which will be designated as glycol-borate electrolyte.

* Electrochemical Society Active Member.

Key words: bismuth, anodic films, photoeffect, electronic conduction.

Influence of the film-formation method on the photoconductivity.—Preliminary experiments indicated that photosensitivity of the anodic film is strongly affected by the mode of anodization. After galvanostatic oxidation irregular oscillations of the photocurrent were observed. The amplitude of oscillation increased with the bias potential and near the formation voltage the measurements become almost impossible. A hysteresis in the photocurrent/wavelength curve was also observed.

When the galvanostatic film formation is followed by a constant voltage anodization, the current oscillations diminish the longer the anodization time. After sufficiently long (*e.g.*, 16 hr) anodization the oscillations vanish and the photoconduction can be easily measured at potentials as high as the formation voltage.

As shown in Fig. 2, all photosensitivity spectra have similar shapes and the increased duration of the constant voltage anodization results only in a reduction of the photocurrent. This is quite explicable, taking into account the increase in the film thickness (*i.e.*, the lowering of the field strength across the film) during the process.

All these results suggest the presence of imperfections in the anodic film grown under galvanostatic conditions, these imperfections being removed after a prolonged constant voltage anodization. The latter mode of oxidation was used throughout the following investigations.

Occurrence and reproducibility of photoconduction.—Photoconductivity is observed only during anodic polarization of the oxide-covered electrode. At cathodic potentials close to U_f the dark current density is very high and increases until film breakdown commences. At lower cathodic potentials the dark current decreases with time to a steady-state value, which is still many times higher than that at anodic polarization. The irradiation with visible light after current stabilization at cathodic potentials either does not cause photoconduction, or the feeble photocurrent eludes detection on the background of the very large dark current, although it is compensated.

The photosensitivity spectra have a good reproducibility and are independent of the history of the film, whether the electrode has been previously polarized at higher or lower anodic potentials or even at low cathodic potentials.

Effect of the contacting electrolyte and the film thickness on photosensitivity.—Photoconductivity was found to be independent of the nature of the contacting electrolyte. As shown in Fig. 3, the change of the glycol-borate electrolyte (after the anodic film formation) with an aqueous acid or alkaline solution has no influence over the spectral sensitivity curve.

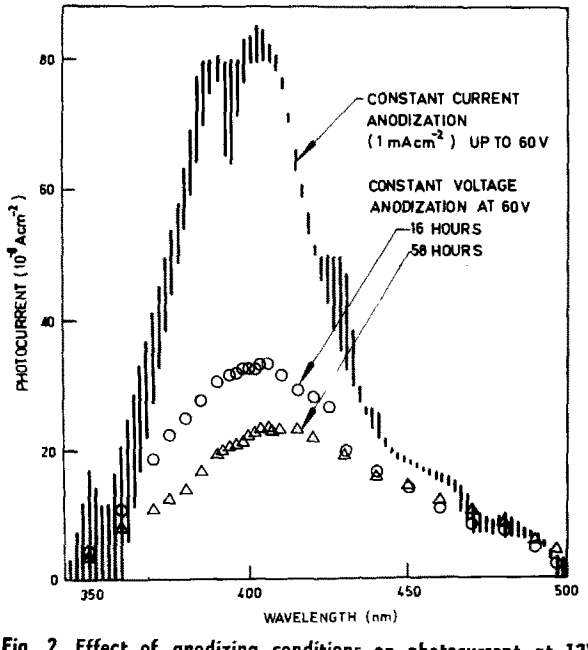

Fig. 2. Effect of anodizing conditions on photocurrent at 12V bias of anodic films formed to or at equal potentials.

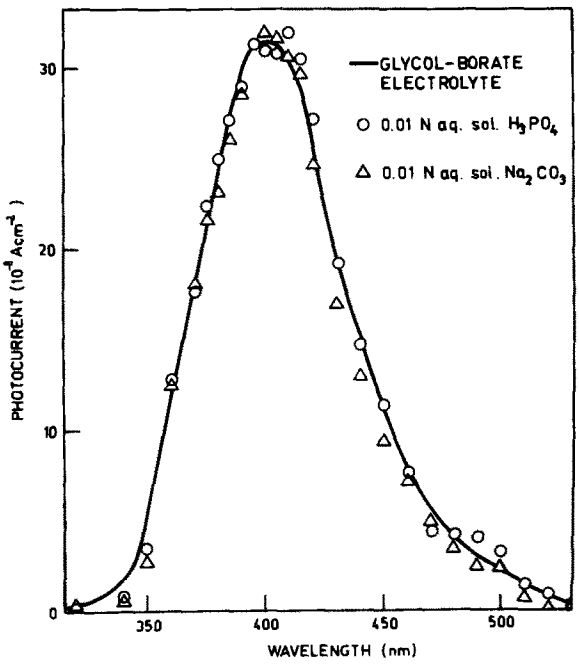

Fig. 3. Spectral distribution of photoconduction at 12V bias in various electrolyte solutions. (Film formed 16 hr at 48V in the glycol-borate electrolyte.)

The photocurrent increases with the film thickness. Figure 4 shows a plot of the peaks of the photosensitivity spectra against U_f, which is approximately proportional to the film thickness, and at $(U_a/U_f) = \text{const}$, providing for an almost constant field strength in the anodic film.

Potential and light intensity dependence of photocurrent.—The photocurrent (I_{ph}) increases with the bias potential (U_a). The shapes of the spectral response curves (Fig. 5) are, however, identical for various U_a, having a peak at $\lambda_p \sim 400$ nm. The peak photocurrent for a given film thickness was found to be proportional to U_a, and consequently to the field strength across the film. This is illustrated in Fig. 6.

As shown in Fig. 5, the wavelengths at half-maximum sensitivity ($\lambda_{1/2}$), determined as the wavelengths where I_{ph} has fallen to half its maximum value, were found to lie very close ($436 < \lambda_{1/2} < 442$ nm) for vari-

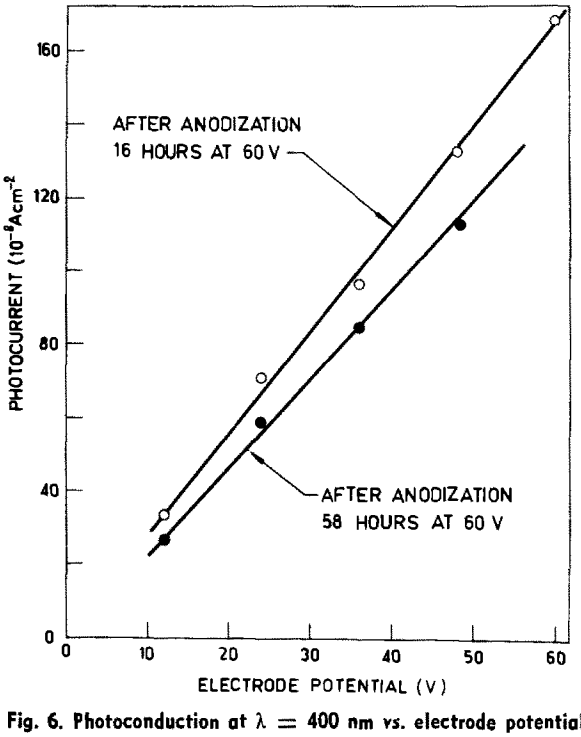

Fig. 6. Photoconduction at $\lambda = 400$ nm vs. electrode potential

ous U_a. By the way, for all runs in glycol-borate electrolyte the mean value of $\lambda_{1/2} = 445 \pm 10$ nm.

Intensity dependence of photoconduction was measured with monochromatic light of λ_p (400 nm). The light intensity (L_o) was changed by placing various numbers (N_f) of equal neutral filters between the monochromator and the electrolytic cell. The diminution of L_o was determined by the relation $L_o \propto \exp(-\text{const } N_f)$. In this way the photocurrent was found to be proportional to the intensity of illumination within the range of intensities employed (Fig. 7).

Effect of the forming electrolyte on the spectral distribution of photocurrent.—The galvanostatic anodization in sufficiently diluted aqueous acid or alkaline

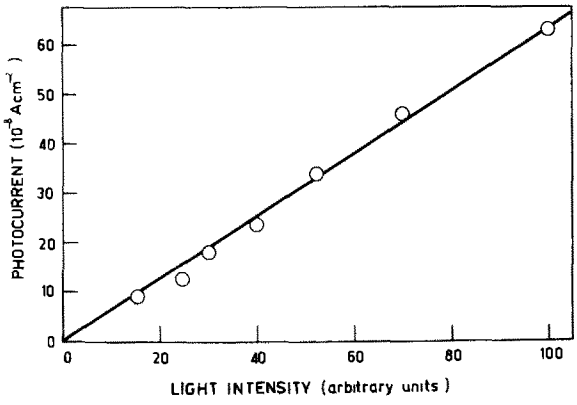

Fig. 7. Intensity dependence of photoconduction. Film formed 58 hr at 60V and tested at 24V. $\lambda = 400$ nm.

solution is known to proceed according to quite identical kinetics (8, 11). Some preliminary investigations revealed that the anodization kinetics in the glycol-borate is similar. The spectral sensitivity curves of anodic films obtained in various dilute aqueous solutions have similar shapes as for anodization in glycol-borate electrolyte and almost the same characteristic wavelengths (λ_p and $\lambda_{1/2}$). As an example the spectral distribution of photocurrent for an anodic film obtained in dilute citric acid solution is shown in Fig. 8. In spite of the great difference in the electrolyte composition and the forming conditions, the values $\lambda_p = 412$ nm and $\lambda_{1/2} = 437$ nm lie very close to the mean values for the glycol-borate electrolyte (*ca.* 400 and *ca.* 440 nm, respectively).

The case where the anodic film is formed in a phosphoric acid + triethyl-phosphate mixture with a low water content is different. For this electrolyte abnormally high rates of galvanostatic anodization are reported (11), which can be twice the rates for the dilute aqueous solutions or the glycol-borate electrolyte. This high apparent current efficiency (up to 200%) has been attributed to the incorporation of ions from the electrolyte into the film (11). Corresponding differences in the film properties, including photosen-

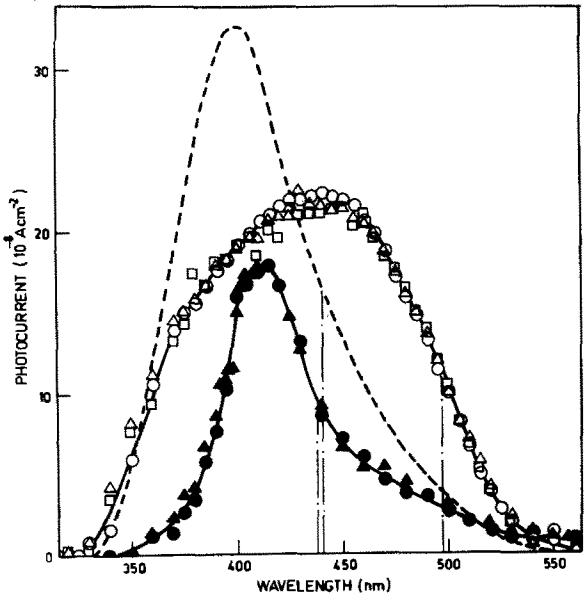

Fig. 8. Photoconduction data for anodic film formed in various electrolyte solutions and tested in glycol-borate electrolyte. Open symbols: formation in phosphate electrolyte 16 hr at 48V, testing at 12V; closed symbols: formation in 0.01*N* aqueous solution citric acid at 0.5 mA/cm^2 up to 200V, testing at 60V. For comparison the spectral sensitivity curve of anodic film formed in glycol-borate electrolyte at the same conditions as in the phosphate electrolyte is shown with dashed line. Dotted lines represent the value of $\lambda_{1/2}$.

sitivity, are to be expected. Such differences in the spectral sensitivity curves were actually observed. Thus, as shown in Fig. 8, in the case of anodization in an electrolyte of 62 w/o (weight per cent) $(C_2H_5)_3PO_4$ + 20 w/o H_3PO_4 + 18 w/o H_2O both λ_p and $\lambda_{1/2}$ are shifted by more than 50 nm to longer wavelengths as compared to the mean values of λ_p and $\lambda_{1/2}$ for oxides formed in the glycol-borate electrolyte.

Discussion

Origin of photoconductivity.—The film-thickness dependence of photoconduction indicates that the investigated phenomenon should be regarded as a bulk-limited (internal) photoeffect. This is also strongly supported by the lack of dependence of photocurrents on the nature of the contacting electrolyte. Hence the electrolyte/oxide interface does not take part in the photoexcitation process, and yet the electrolyte contact appears to be indispensable for the establishing of photoconduction, because the latter is observed only during anodic polarization of the oxide-covered electrode, *i.e.*, in the case of electron transfer from the electrolyte to the metal.

The lack of photoconduction under cathodic polarization of the metal, as well as the rectification effect of the system in question could be explained admitting a difference in the work functions of the electrolyte and the metal. The electron energy of anions in electrolytes is known to lie several electron volts below the Fermi level of metals and thus electrolytes realize one of the most blocking contact with semiconductors (12).

Thanks to the blocking electrolyte contact under anodic polarization of the metal, it is possible to apply electric fields sufficiently high to pull the photoelectrons before trapping. Conversely, the comparatively low potential barrier for electron emission from the metal gives rise to a high dark-current density at such a low cathodic potential (low field strength across the film), which are insufficient for detection of any photoconductivity. The different height of the potential barriers at the metal/oxide and the electrolyte/oxide interface presents, of course, an explanation also of the rectifying effect of the system Bi/anodic film/electrolyte, but this point is beyond the scope of the present paper.

The rectification and photoeffects for some valve metals have been related to p-n or p-i-n junctions within the oxide film (13-18). The existence of space charge in the anodic film of these metals is strongly supported by the observed corresponding variation of the film capacity with applied bias potential (17-19). But the capacity of anodic films formed on bismuth is known to be independent of potential (19), thus indicating the lack of space charge. This fact and the described independence of photosensitivity from the film history leads us to conclude that the model of p-n or p-i-n junction, which is applicable in some instances, is unacceptable in the case of anodic films on bismuth.

Photoconductive spectra and optical activation energy for films obtained in glycol-borate electrolyte.—The spectral sensitivity curves exhibit a peak, characteristic of materials with high surface recombination velocities (20, 21). At higher wavelengths the photocurrent rapidly decreases. An exponential fall of I_{ph} at longer wavelengths with photon energy, $I_{ph} \propto \exp(-\text{const } h\nu)$, was found to give a good fit to all experimental results, in accordance with theory (20).

It is known that the "absolute" threshold wavelength, that is, the wavelength at which the sensitivity vanishes completely, is condition-dependent and gives only a rough idea of the optical activation energy (W_{opt}), but nevertheless, it has been frequently used for the purpose. For the anodic film on Bi we estimated the absolute threshold wavelength to vary between 520 and 575 nm, the corresponding energies being *ca.* 2.4 and 2.15 eV.

An exact method of determining W_{opt} is proposed by Moss (20). By this method W_{opt} is determined from the spectral sensitivity curve as a point (wavelength $\lambda_{1/2}$) where the sensitivity has fallen to half its maximum value. Actually, this method is derived and regarded as valid only in the case where thermal (W_{th}) and optical (W_{opt}) activation energies are equal, *i.e.*, for nonpolar monatomic crystals (20). Nevertheless, it appeared that for sufficiently thin films (*e.g.*, $\lesssim 10$ μm) this method gives correct values of both W_{th} and W_{opt} for highly polar (even structureless) inorganic (21) and organic (22) materials.

In our case the threshold wavelength was found to be $\lambda_{1/2} = 445 \pm 10$ nm, corresponding to $W_{opt} = 2.78 \pm 0.06$ eV. The shape of the spectral response curves and the lack of sensitivity in the near uv region suggest an intrinsic photoconduction and that the energy of 2.78 eV corresponds to the energy gap (E_g) of the oxide.

Two values for E_g of Bi_2O_3 are known to the present authors. One of them, $E_g = 3.2$ eV (23), is considerably higher and probably pertains to a crystalline structure of Bi_2O_3. Nevertheless, this discrepancy could not be attributed to the glassy structure of the anodic film. It is known (24) that a band model is applicable and remains valid for amorphous structures also, the energy gap being similar in respect to the crystalline condition, or broader because of the larger interparticle distances. The outer value, $E_g = 2.7$ eV [see (25)], is quite close to the one found here.

Photoconductive properties.—Generally under an applied voltage U_a the photocurrent density I_{ph} is

$$I_{ph} = N_e(l_f, L_o)\, e\mu U_a / l_f \qquad [1]$$

where N_e is the number of photoelectrons per square centimeter in steady state, l_f is the film thickness, L_o is the intensity of the incident light, e is the electronic charge, and μ is the electron mobility.

At constant l_f, if the irradiation excites N photoelectrons per square centimeter per second, the increase of photoelectron density (n) in the conduction band with time (t) is given by

$$(dn/dt) = N - \beta n(n + M) \qquad [2]$$

where β is the recombination coefficient and M is the number of the trapped electrons (or of the trapping levels for sufficiently deep traps). Assuming a great number of trapping levels ($M >> n$) because of the amorphous structure of the film, when equilibrium is attained [*i.e.*, $(dn/dt) = 0$ and $n = N_e$], we may write

$$N_e = N/\beta M \qquad [3]$$

For monochromatic light with appropriate wavelength, taking into account the exponential decay of the light intensity with the depth into the film, we have

$$N = AL_o \int_0^{l_f} \exp(-\alpha l_f)\, dl_f \qquad [4]$$

where A is the number of photoelectrons per unit absorbed radiation and α is the absorption coefficient.

Combining Eq. [1], [3], and [4] relationship $I_{ph}(L_o U_a l_f)$ is obtained

$$I_{ph} = \frac{Ae\mu L_o U_a}{\beta M l_f} \int_0^{l_f} \exp(-\alpha l_f)\, dl_f \qquad [5]$$

Hence at constant L_o and l_f

$$(I_{ph})_{L_o, l_f} \propto U_a \qquad [6]$$

and at constant U_a and l_f

$$(I_{ph})_{U_a, l_f} \propto L_o \qquad [7]$$

Equations [6] and [7] are in accordance with the relationships found experimentally (Fig. 6 and 7).[1]

[1] Relation [7] is of course valid only at very low L_o where condition $M >> n$ is satisfied. At higher L_o Eq. [2], [4], and [5] lead to $(I_{ph})_{U_a, l_f} \propto L_o^f$ where $1 > f > 1/2$.

We have no data about the dependence $[I_{ph}(l_f)]_{U_a,L_0}$, but, if l_f is approximately proportional to the formation voltage (U_f), the observed nonlinearity of $[I_{ph}(U_f)]_{U_a,L_0}$ (see Fig. 4) becomes comprehensible from Eq. [5].

Production of donor impurity levels by incorporation of ions from the anodizing electrolyte.—The anodic film obtained by anodization in sufficiently diluted aqueous solutions or in glycol-borate electrolyte give similar photoconduction spectra, implying that the films have similar structure and composition.

This is not the case when a phosphate electrolyte is used for anodization. The threshold wavelength is shifted from *ca.* 445 nm to *ca.* 495 nm, the activation energy becoming $W_{opt} = 2.5$ eV. This indicates the appearance of new donor impurity levels reducing the optical activation energy by about 0.3 eV. This is in accordance with the assumption concerning the incorporation of ions in bismuth anodic films formed in phosphate electrolyte. The assumption was proposed to explain the higher (up to two times) rate of potential rise during galvanostatic anodization in a phosphate electrolyte (11). Incorporation of ions from the electrolyte into the oxide during anodization of other valve metals in phosphoric acid or phosphate solutions has been experimentally observed in several cases (26-30). Our results indicate that the incorporated ions from the phosphate electrolyte give impurity levels in the forbidden band of the bismuth anodic films.

Summary

It has been found that the photoconduction of the anodic films on bismuth is thickness dependent and hence is a bulk-effect. It is observed only at anodic polarization of the oxide-covered electrode and increases linearly with the applied voltage and light intensity. The spectral distribution of photoconduction is independent of the contacting electrolyte and for films obtained by anodization in glycol-borate electrolyte or dilute aqueous solutions shows an optical activation energy of *ca.* 2.8 eV. When the anodization is carried out in phosphate electrolyte, this activation energy decreases to *ca.* 2.5 eV, due in all probability to the incorporation of ions from the electrolyte into the film. An attempt to explain all these properties of photoconductivity is made on the assumption that a great number of trapping levels exists in the forbidden band because of the disordered structure of the film.

Space-Charge and Concentration-Gradient Effects on Anodic Oxide Film Formation

A. T. Fromhold, Jr.[1] and J. Kruger*

National Bureau of Standards, Washington, D. C. 20234

ABSTRACT

Numerical computations illustrate the effects of space charge and a concentration gradient on the steady-state mobile-defect concentration profile and the kinetics of anodic film formation. The position-dependence of the concentration of mobile defects producing growth is shown to vary with current density and film thickness. Of especial interest is a series of curves illustrating the total electrostatic potential developed across the oxide as a function of thickness for growth under constant current conditions. Space charge is shown to have the capability of being a critical factor in retarding the growth rate of the anodic film.

Background

Introduction to the problem.—The approach of considering forward and reverse currents over discrete energy barriers within a diffusion medium was first proposed by Verwey (1) in 1935. Since that time Mott (2) and Cabrera and Mott (3) have extended the concept by emphasizing the possibility of a rate-limiting barrier located at the interface of a growing, anodically formed (or thermally formed) metal oxide. Dewald (4) extended the model of Verwey by an approximate analytical development which included the space-charge electric field, with the major emphasis placed on the Tafel slope (5) in the high-field limit. The primary purpose of the present work (6) is to evaluate numerically the effect of space charge on the kinetics in the intermediate-field regime; simultaneously the specific role of the concentration gradient is examined (7, 8).

Physical origin of the concentration gradient.—The first question is whether or not there is a concentration difference in the diffusing species across the anodic film, and if so, whether or not it provides a driving force for mass transport through the film. In the case of equilibrium of a given species in an anodic film, the electrochemical potential for the species must be uniform in the film and there will be no particle current of that species through the film. If there is no electric field in the film, then the uniformity of the electrochemical potential may require that the concentration be uniform also, in which case there will be no concentration gradient in the film. On the other hand, if the electric field in the film is nonzero, the electrostatic potential within the film will be position-dependent. Since the electrochemical potential is made up of contributions due to electrostatic potential and defect concentration, the uniformity of the electrochemical potential then requires in general that the concentration be position-dependent. That is, a concentration gradient is to be expected even in equilibrium when the electric field is nonzero. In addition to illustrating that the equilibrium case can involve concentration gradients, the conclusion is reached that concentration gradients and electric fields do not necessarily produce any net current.

Suppose that we perform a *gedanken* experiment in which we attempt to go from the equilibrium condition of zero current with some given electric field to a nonequilibrium condition of nonzero current by changing the value of the field. There can likewise be equilibrium with some different value of the electric field, provided that the concentration profile of the defect species is allowed to rearrange itself to maintain uniformity of the electrochemical potential. Does the change in electric field then drive a net current through the film, or does the concentration profile readjust itself with the change in field in order to maintain a uniform electrochemical potential for that species in the film? The answer is intuitive: the concentration of the diffusing species is constantly depleted at the reaction interface, so that the concentration profile cannot adjust itself arbitrarily to maintain a uniform electrochemical potential. The interfacial reactions play an important role in determining the boundary concentrations, so these concentrations are more or less fixed independently of the electric field. Thus by changing the electric field, an accompanying change in the species current can be produced. This qualitative argument should not be misconstrued as a statement that the boundary concentrations are entirely independent of the electric field. Instead, it merely represents an argument that the concentration profiles are determined in accordance with conditions imposed by the interfacial reactions as well as by the electric field, and hence the profiles are not entirely free to adjust arbitrarily with the electric field. Thus we arrive at an idealized picture of the metal-oxide-solution system as an asymmetrical system with boundary concentrations of the defect species determined to a large extent by the interfacial reactions. In the absence of a particular model for the interfacial reactions, or merely for reasons of simplicity, we can choose the boundary concentrations of the diffusing defect species to have arbitrary fixed values at the interfaces. This will serve to give an indication of the general effect of the concentration gradient in anodic film growth.

The asymmetry of the metal-oxide-oxygen system as described above means that there will be a built-in electrochemical potential gradient for the ionic species which tends to give rise to film growth even before an external electrostatic potential is superimposed onto the system from some external source. To the extent that the built-in electrochemical potential is undisturbed by an applied electric field, it can be considered to be added algebraically to the externally applied electrostatic potential in order to obtain the total driving potential for mass transport. This essentially is a thermodynamic argument, which does not aid us directly in obtaining the rate constant for film growth.[2] A self-consistent solution of the relevant microscopic equations does lead to the rate constant. Numerical evaluation of the appropriate microscopic equations is the essence of the presently described work.

[2] Such electrochemical potential gradients can produce large stresses in the growing anodic films, as shown theoretically (9). This may account for the amorphous nature of many anodic oxides.

Discrete hopping model including space charge.—Figure 1 in Ref. (7) illustrates the model utilized to ascertain both concentration-gradient and space-charge effects. Let us consider a particular barrier in the oxide located at position x_k. The net current J_k is the difference between the forward current $J_k^{(f)}$ and the reverse current $J_k^{(r)}$. The concentrations at the endpoints O and N are considered in the present work to have fixed values which are determined entirely by the interfacial reactions. If these two boundary concentrations are different, then there will be a net transport current even in zero electric field [cf. upper curve in Fig. 1 of Ref. (7)]. With an applied electric field, the electrostatic potential is position-dependent. In the usual manner of illustrating applied potentials, we superimpose this potential energy variation on the periodic (or aperiodic) potential of the crystalline (or amorphous) diffusion medium, so the barriers slope downward under forward bias [cf. lower curve in Fig. 1 of Ref. (7)]. The energy difference between forward and reverse motion is noted to be (at least to lowest order) equal to $2\Delta W = 2Z|e|E_k a$, where $Z|e|$ is the charge on the diffusing defect and E_k is the field at the kth barrier. We generally denote the electronic charge magnitude $|e|$ by e. The hopping distance is $2a$. The thickness $L = 2Na$ is the product of the number of barriers and the distance $2a$ between barriers.

Let us now summarize the pertinent equations which have been described in greater detail in Ref. (7) and (8). Denote by n_{k-1} the number of charged particles of a given species per unit area in a planar slice of thickness $2a$ which is perpendicular to the hopping direction and in front of the barrier labeled k; denote by n_k the corresponding number located just beyond the same barrier. Then the number J_k surmounting the barrier in unit time is

$$J_k = J_k^{(f)} - J_k^{(r)}$$
$$= \nu \exp(-W/k_BT)\,[n_{k-1}\exp(ZeE_k a/k_BT) - n_k \exp(-ZeE_k a/k_BT)] \quad [1]$$

where ν is the attempt frequency for the particle and W is the corresponding zero-field activation energy for diffusion. This quantity J_k is the net particle current at the position of the kth potential barrier. The major assumption inherent in this equation is that of the applicability of Boltzmann statistics; this assumption should be very good for the presently considered situation of ionic diffusion, although it might not always be such a good assumption for smaller mass particles such as electrons or electron holes.

The second important equation which we utilize is

$$J_{k+1} = J_k \quad (k = 1, 2, \ldots, N-1) \quad [2]$$

This constitutes the steady-state approximation, which is premised on the assumption that there is little or no build-up (or depletion) of the diffusing species in comparison to the number diffusing through at any point within the anodic film. It is not difficult to show that this assumption is generally quite good.[3] Transients (10) are neglected in the present computations.

The third equation which we utilize is based on Poisson's equation relating the electric field in the medium to the charge density

$$E_{k+1} = E_k + \frac{4\pi Zen_k}{\epsilon} \quad (k = 0, 1, 2, \ldots, N-1) \quad [3]$$

This expression determines the electric field everywhere within the medium in terms of the surface-charge field E_0 and the diffusing defect densities n_k. The surface-charge field E_0 is determined by the net charge density per unit area on the parent metal crystal at the metal-oxide interface. It can be negative, corresponding to an electron excess, or it can be positive, corresponding to an electron deficit. This is distinct from the quantity n_0 which is the ionic charged defect density within the oxide adjacent to the metal interface.

Finally, the electrostatic potential is given in terms of the electric field

$$V_k = V_{k-1} - 2aE_k \quad (k = 1, 2, \ldots, N) \quad [4]$$

The potential V_0 is arbitrary, and thus it is conveniently chosen to be zero. The total potential V_N across the film is thus determined in terms of E_0 and the space charge densities. For a constant applied potential, V_N is given and the current J_k is determined from numerical evaluation of the above equations; for a constant applied current, J_k is given and the total potential V_N is determined from numerical evaluation of the above equations. In both cases straightforward iterative schemes are utilized to achieve self-consistency with the chosen values for the boundary concentrations.

Coordinate system conventions.—If cation interstitials or anion vacancies (positively charged ionic species) are the primary mobile species, then the boundary concentrations can be expected to be larger at the metal-oxide interface than at the oxygen-solution interface. It is then convenient to choose the origin ($x = 0$) of the coordinate system at the metal-oxide interface. The corresponding positive x-direction is from metal to oxide to solution, which is the direction of flow of the primary mobile species.[4]

For growth by the transport of negatively charged ionic species, we choose to utilize the alternate coordinate system in which the origin ($x = 0$) is located at the oxide-solution interface. Then the positive direction is from solution to oxide to metal, which is the direction of flow of the primary mobile species. The surface-charge field [viz., $E(x)$ at $x = 0$] is in this case determined by the interfacial charge density at the oxide-solution interface instead of by the interfacial charge density at the metal-oxide interface.

The convention chosen for the coordinate system will of course have no bearing on the actual species and charge distributions in the system. Thus a simple mathematical transformation can be devised to convert from one coordinate system to another. This coordinate-system transformation is not developed herein since it is not essential to our primary purpose.

The results deduced for a physical model in which the mobile species is negatively charged can be readily transformed to corresponding results for a physical model in which the mobile species is positively charged. This second type of transformation (namely, a species transformation) is especially easy in the case of the presently utilized convention of choosing the origin of the coordinate system at the particular interface having the larger boundary concentration. Then the species transformation is effected simply by reversing the sign of the charge of the species, together with making the corresponding reversals in sign for the electric field and potential.

At this point it may be evident that we do not attempt to answer by means of our numerical computations the important physical question of which ionic species is responsible for growth in any given metal-oxide-solution system. Instead, we deduce results illustrative of concentration-gradient and space-charge effects which are (apart from incidental details such as directions and signs) generally applicable to any mobile ionic species.

For our model numerical calculations we choose a negatively charged mobile ionic species, with the origin

[3] The total build-up of defect species within the film when the film increases in thickness by one monolayer is much less than the amount of defect species which must be transported to build the monolayer. Thus a minor departure from Eq. [2] allows the profiles and electric fields to adjust continuously to new steady-state values as the film increases in thickness.

[4] For the alternant situation for which the primary mobile species are either cation vacancies or anion interstitials (negatively charged ionic species) the coordinate system could be chosen to be the same if desired, in which case the boundary concentration at the origin would be lower than at $x = L$. Flow of ionic species would then be in the negative direction. We do not choose to utilize this convention in the present work.

Table I. Values utilized for parameters in numerical computations

Symbol	Units	Definition	Value
n_0	No./cm²	Defect density at position $x = 0$	10^{11}
n_N	No./cm²	Defect density at position $x = L$	10^{10}
W	eV	Activation energy for diffusion	0.3
T	°K	Temperature	300
ν	sec⁻¹	Attempt frequency	10^{13}
$2a$	A	Lattice parameter	4
Z	—	Valence of diffusing species	−1
ϵ	—	Relative dielectric constant	10

of the coordinate system located at the oxide-solution interface and the positive direction from solution to oxide to metal. The results as they stand will be immediately applicable to either cation vacancy motion or anion interstitial motion. The results can be easily converted by the above species transformation to cation interstitial or anion vacancy motion.

Scaling of the numerical results.—It can be seen from the basic Eq. [1] that

$$J \propto \nu \exp(-W/k_BT) \quad [5]$$

If a quantity Υ is defined

$$\Upsilon \equiv J/[\nu \exp(-W/k_BT)] \quad [6]$$

then the basic Eq. [1] can be looked upon as a difference equation dependent on Υ but not otherwise dependent on the specific values of the parameters J, ν, and W. For a given value of Υ, the numerical solution deduced will be generally applicable to all possible combinations of J, ν, and W consistent with the given value of Υ. In particular, the results of the present numerical calculations with W chosen to have the value 0.3 eV (cf. Table I) will be equally valid for a different value of W (*e.g.*, $W = 0.8$ eV), provided only that the currents are changed accordingly (*e.g.*, for $W = 0.8$ eV the currents will reduce by a factor of $e^{-0.8/k_BT}/e^{-0.3/k_BT} = e^{-0.5/k_BT}$, which at room temperature is approximately $e^{-20} \simeq 2 \times 10^{-9}$). The currents scale linearly with the value of ν, with no change in the profiles. The time scale dilates reciprocally as the currents, so our numerical results in actuality cover the range from large currents (corresponding to rapid growth on a laboratory time scale) to extremely small currents (corresponding to a growth rate which may be negligible on a laboratory time scale). Of course, we exclude situations in which the currents are so large that appreciable heating of the sample might occur.

Numerical Results

Diffusing defect concentration profiles.—The distribution of defects in an anodic oxide film which is growing under various applied currents is shown as a function of thickness N (in monolayers) in Fig. 1-3. The curves were produced by drawing straight lines between the numerically computed values at discrete points separated by one monolayer in the lattice. (The discrete model yields only one point per monolayer.) The values chosen for the microscopic parameters are listed in Table I. In all figures the numbers 1 through

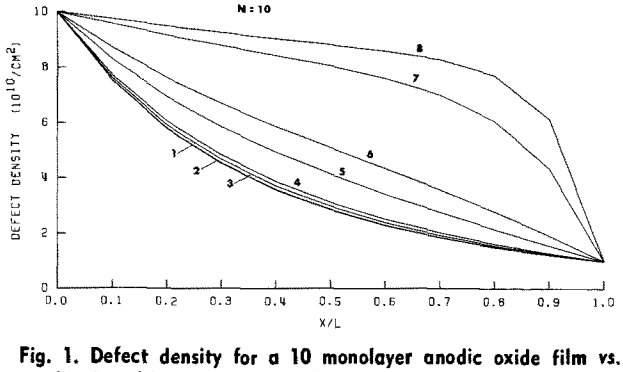

Fig. 1. Defect density for a 10 monolayer anodic oxide film vs. normalized position for several values of the current.

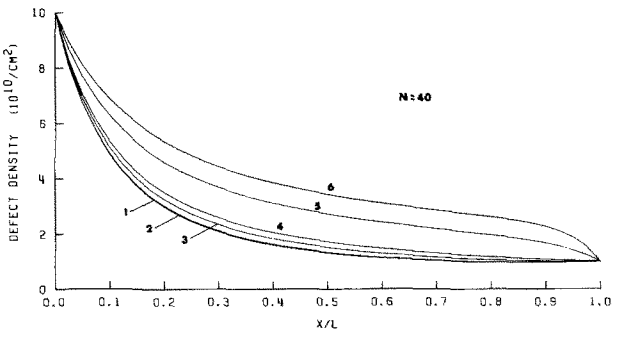

Fig. 2. Defect density for a 40 monolayer anodic oxide film vs. normalized position for several values of the current.

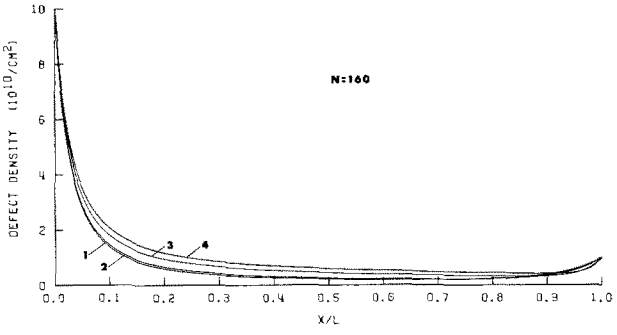

Fig. 3. Defect density for a 160 monolayer anodic oxide film vs. normalized position for several values of the current.

10 correspond respectively to currents of 5×10^{15}, 1×10^{16}, 5×10^{16}, 1×10^{17}, 5×10^{17}, 1×10^{18}, 5×10^{18}, 1×10^{19}, 5×10^{19}, and 1×10^{20} particles/cm²-sec, respectively, as listed for reference purposes in Table II.[5] Fixed boundary concentrations are chosen for simplicity in performing the numerical computations, since the purpose of the present work is to examine the general effects of concentration gradients and space charge.

A factor of 10 is chosen for the difference in the two boundary concentrations, as is evident from Fig. 1-3. This difference will in practice vary with the system in question, being larger in general for anodic films having a larger free energy of formation. The effects of the concentration difference across the film are quite apparent in these figures; this factor can be expected to influence markedly the concentration profiles found experimentally in such anodic films.

It is interesting to note (cf. Fig. 1-3) that a relatively high density of defects prevails throughout most of the film of a given thickness whenever the current is relatively large. Note especially in Fig. 1 that curve 8 has a defect density at the midpoint of the film which is at least a factor of 3 larger than curve 1. (The ratio of the currents for these two curves is $1 \times 10^{19}/5 \times 10^{15}$

[5] It can be noted from Fig. 1-3 that the higher current density curves for the thicker films are missing. These cannot be computed accurately by means of the present computer program. The curves which are shown meet a very stringent criterion for accuracy. The presently considered field and voltage range is of interest from the standpoint that it illustrates the interplay of electrostatic-field effects and concentration-gradient effects.

Table II. Currents associated with a given curve number in the figures

Curve number	Current J (No./cm²-sec)
1	5×10^{15}
2	1×10^{16}
3	5×10^{16}
4	1×10^{17}
5	5×10^{17}
6	1×10^{18}
7	5×10^{18}
8	1×10^{19}
9	5×10^{19}
10	1×10^{20}

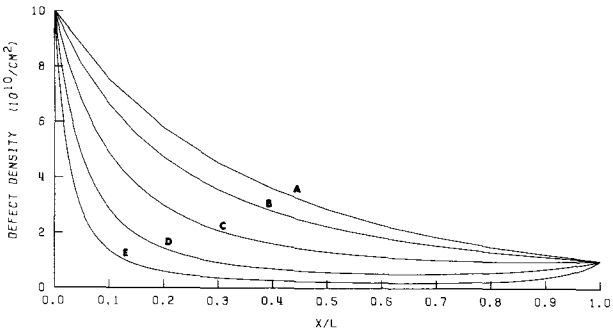

Fig. 4. Defect density for a given current vs. normalized position in growing anodic oxide films for various film thicknesses in monolayers. ($J = 5 \times 10^{15}$ particles/cm^2-sec.)

= 2000.) An important general conclusion can thus be drawn from this set of three figures: (*a*) Larger current densities for a given thickness are accompanied by greater numbers of diffusing defects in the growing film.

It is quite interesting to compare Fig. 1 through 3. It can be seen that the defect densities for a given current density become relatively lower throughout the film as the thickness increases. This effect is associated specifically with the space charge. It can be understood qualitatively somewhat as follows. Increasing the thickness tends to yield a greater total space charge and correspondingly larger space-charge fields, which requires in turn a modification in the concentration profiles to decrease the space charge in order that the concentration difference across the film may be maintained. The general conclusion to be drawn is: (*b*) Larger film thicknesses are accompanied by decreasing concentrations of diffusing defects at a given normalized position within the film for a given current density. This can also be looked upon from the standpoint that the regions of large space-charge density become relatively more confined to the interfaces as the film thickness increases.

Figure 4 illustrates quite clearly the lowering of the diffusing defect concentration with increasing thickness at a given current density. Curves A through E in all figures represent thicknesses of 10, 20, 40, 80, and 160 monolayers, respectively, as listed for reference purposes in Table III. The usefulness of plotting as a function of normalized position x/L, where x is the position in the film and L is the film thickness, is evident in this figure.

Space-charge density and electrical conductivity profiles.—The charge density is given by the product of the defect density with the charge per defect. In addition, the ionic conductivity is given by the product of the charge density with the mobility. Thus Fig. 1-4 are also representative of the charge density profile and ionic conductivity profile in growing anodic films.

Total space charge.—The total charge located in the region of the film between the origin $x = 0$ and a given normalized position x/L in the film is given by an integral of the charge density from zero to x. Figure 5 illustrates this quantity (in units of the electronic charge magnitude) as a function of normalized position for five different film thicknesses, and Fig. 6 illustrates this quantity for four different current densities. From

Table III. Thicknesses associated with a given curve symbol in the figures

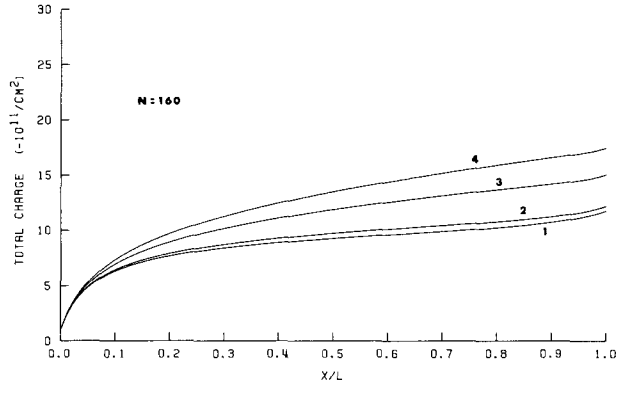

Fig. 6. Total charge up to position x within a growing anodic oxide film 160 monolayers in thickness vs. normalized position for various applied currents.

Fig. 5 we can draw the following conclusion: (c) Larger thicknesses contain greater total amounts of space charge for a given current density. From Fig. 6 we can conclude that higher current densities yield more space charge for a given thickness, which is in accord with our previously stated conclusion (*a*). A comparison of our previously stated conclusion (*b*) with conclusion (c) shows us that even though the defect concentration at a given normalized position decreases with increasing thickness at a fixed current density, the total number of defects still increases somewhat with increasing film thickness.

Figure 7 is an extensive plot for the total space charge within the growing film which serves to delineate sharply conclusions (*a*) and (c) drawn from the intensive plots discussed above. (An intensive plot contains curves for some given quantity *vs.* normalized position x/L in the film, whereas an extensive plot contains curves for some given quantity *vs.* film thick-

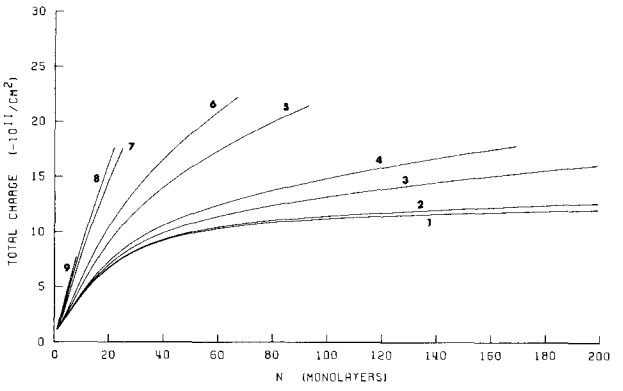

Fig. 7. Total charge within a growing anodic oxide film vs. thickness in monolayers with different applied currents.

ness.) Each curve (corresponding to a given current density) shows, for example, the increase in total space charge in the film with increasing thickness. This is basically stated in conclusion (c). A comparison of the curves in Fig. 7 shows that the total space charge at a given thickness increases with current density, which is essentially conclusion (*a*). In addition, a new conclusion can be drawn from this figure: (*d*) For growth under constant current conditions, the total space charge in the film has a tendency to level off with increasing thickness to a constant value characteristic of the current density. For lower current densities this is found to occur at smaller thicknesses. This effect can be attributed entirely to space charge, since corresponding homogeneous-field computations predict a total number of defects which increases almost linearly with thickness without any tendency to level off with increasing thickness.

Electric fields.—The electric field is nonhomogeneous in the film due to the large space-charge concentrations. Figure 8 illustrates the electric field *vs.* position in a 10 monolayer film and in a 160 monolayer film for various current densities. The increased curvature evident at 160 monolayers is indicative of the increased amount of space charge for thicker films. This effect is emphasized in Fig. 9 where the electric field *vs.* normalized position is shown for the five thicknesses at a given current density. The decreasing field with increasing x shows that the space charge happens to be of opposite sign to the surface-charge field for this particular current density.

Also it is of interest to note in Fig. 8 the algebraically decreasing electric fields associated with increasing current densities. This is simply a matter of the requirement of a larger electric driving force to produce larger current densities. The fact that the electric field has the opposite polarity for different values of the current (*e.g.*, compare curves 1 and 7 for $N = 10$ in Fig. 8) is also of interest. This is readily explained as follows. The concentration gradient in the absence of an electric field will produce a certain particle current, the exact value of which depends on the film thickness. Whenever the particle current due to the concentration gradient alone is larger than the net particle current in question, then the field has the polarity needed to retard charged particle transport. On the other hand, the field must have the polarity required to aid charged particle transport when the current produced by the concentration gradient alone is insufficient to yield the net particle current under consideration.

Figures 10 and 11 are very illuminating extensive plots illustrating the electric field at the two oxide interfaces as a function of thickness. A comparison between the two figures leads us to the following conclusion: (*e*) With increasing thickness the surface-charge field at the higher defect-density interface levels off to some constant value characteristic of the current

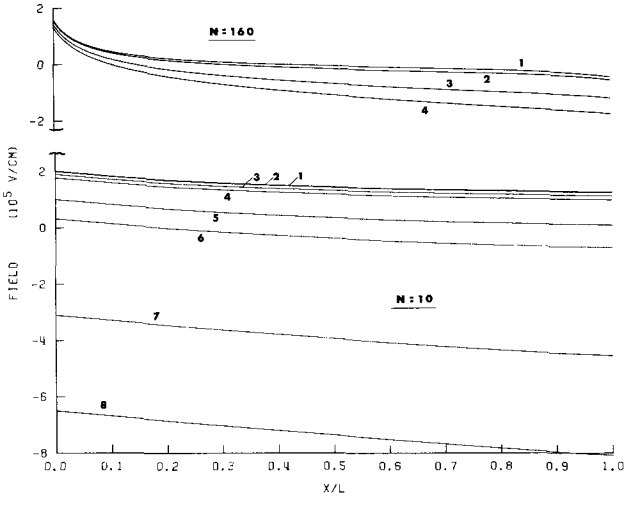

Fig. 8. Electric field *vs.* normalized position in growing 10 monolayer (lower set) and 160 monolayer (upper set) anodic oxide films for several currents.

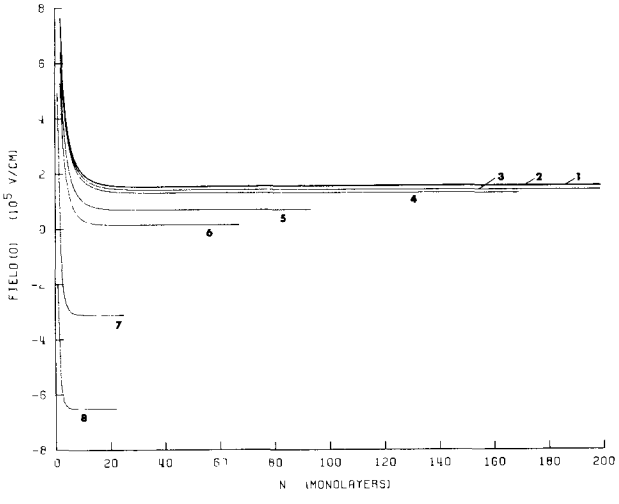

Fig. 10. Electric field at the larger defect-density interface *vs.* thickness in monolayers for a growing anodic oxide film with different applied currents.

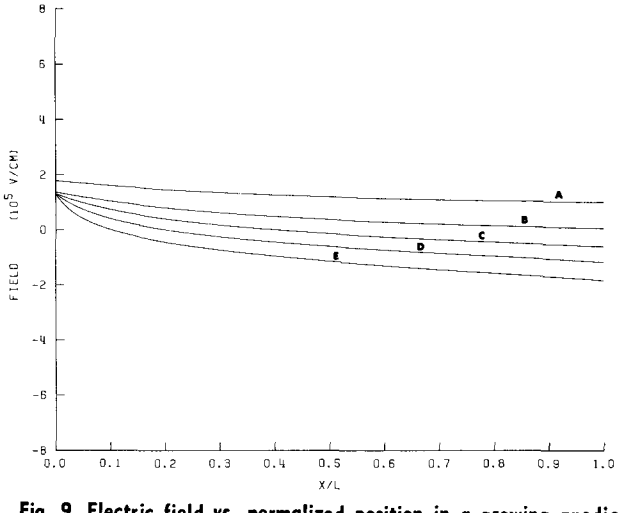

Fig. 9. Electric field *vs.* normalized position in a growing anodic oxide film with $J = 1 \times 10^{17}$ particles/cm^2-sec for several thicknesses.

density quite rapidly as compared to the electric field at the opposite interface. The difference between the electric fields at the inner and outer interfaces can be attributed of course to the total space charge within the film. (Without space charge, the electric fields at the two interfaces would be the same.) Note the similarity between the curves in the two figures for very small values of thickness. This reflects the fact that the total space charge within the film approaches zero as the thickness of the film approaches zero, so the electric fields at the inner and outer interfaces approach one another in this limit. The change in polarity of the field with increasing thickness is also very apparent in these curves. For thin enough films, the currents produced by the concentration gradient can be very large, so an opposing electric field is required to balance the current density to a given net value. With increasing thickness, the concentration gradient becomes a lesser driving force, so the electric field must gradually change from an opposing to an aiding polarity to maintain the fixed current density.

Electrostatic potentials.—The electrostatic potential $V(x)$ is generally obtained from an integral of the macroscopic electric field

$$V(x) = -\int_0^x E(x)\,dx \qquad [7]$$

or in the present model of a discrete lattice, from Eq. [4]. In the absence of space charge, $E(x)$ would have a constant value E_0 throughout the film and $V(x)$ would be a linear function of position x. With space charge, however, $E(x)$ varies with position as was noted in Fig. 8-9. Therefore space charge causes $V(x)$ to be a nonlinear function of position x. The potential is shown as a function of normalized position in Fig. 12 and 13. A comparison of the curves for a 20 monolayer thickness with corresponding curves for a 160 monolayer thickness in Fig. 12 shows an increased curvature appropriate for the thicker films. It therefore can be stated: (*f*) The electrostatic potential as a function of normalized position within the film is more nonlinear for thicker films. Another interesting feature illustrated in Fig. 12 is the larger potentials associated with the higher current densities. Also in Fig. 12 it is especially evident at $N = 160$ that: (*g*) The curvature in the potential *vs.* normalized position curves is greater at higher current densities, which reflects the greater amount of space charge in the film at higher current densities.

Figure 13 illustrates a set of different thickness curves (A through E) at two given current densities differing by a factor of five. Note that the potential (for a given current density) in the thicker films has

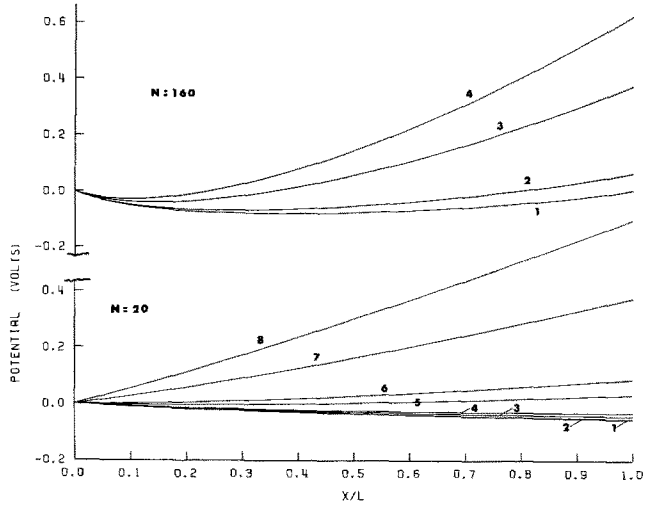

Fig. 12. Electrostatic potential *vs.* normalized position in growing anodic oxide films 20 monolayers (lower set) and 160 monolayers (upper set) in thickness for several currents.

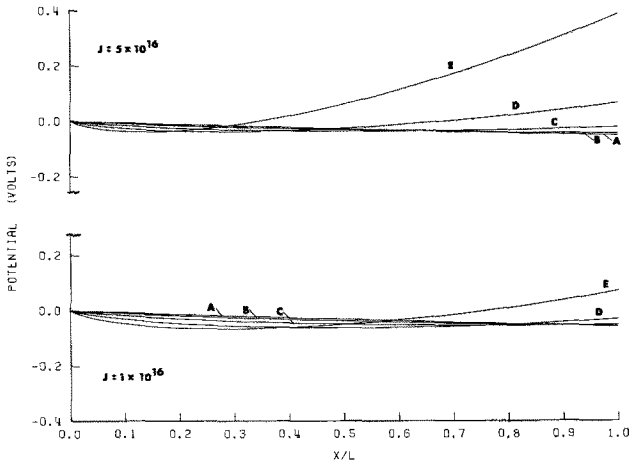

Fig. 13. Electrostatic potential *vs.* normalized position in a growing anodic oxide film with $J = 1 \times 10^{16}$ (lower set) and $J = 5 \times 10^{16}$ (upper set) particles/cm^2-sec for several thicknesses.

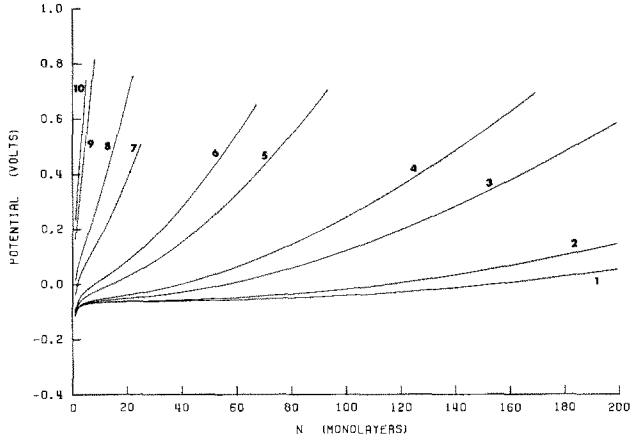

Fig. 14. Electrostatic potential *vs.* thickness in monolayers for a growing anodic oxide film with different currents.

an increased curvature which is directly associated with the greater total amount of space charge in the thicker films. Note also the increased curvature for the potential in a film of given thickness when the current density is increased.

Figure 14 represents some of the most important results of the numerical computations. The total electrostatic potential[6] $V(L)$ developed across the anodic film is shown as a function of thickness for ten different current densities. It can be noted that: (*h*) There are two separate regions of interest in the potential *vs.* thickness curves, the very thin-film region (convex curvature) where concentration gradient effects predominate, and the thicker film region (concave curvature) where space-charge effects predominate. The potential increases with thickness, as illustrated, since a greater total driving potential is needed at thicker films to maintain a fixed value for the current. It is also clear from the figure that higher current densities require considerably higher potentials at any given thickness.

Figure 15 gives the total electrostatic potential as computed as a function of thickness in the homogeneous-field limit (*viz.*, when space charge is ignored). Note that the curves are essentially linear in the thick-film region. A comparison with the corresponding curves of Fig. 14 shows that a given current at a given thickness is obtained at a significantly lower potential when space-charge effects can be ignored. Thus it can

[6] This quantity represents the electrostatic potential difference (or voltage drop) across the anodic film exclusive of any electrostatic potential differences developed within the solution phase and excluding the driving force contribution given by the concentration gradient.

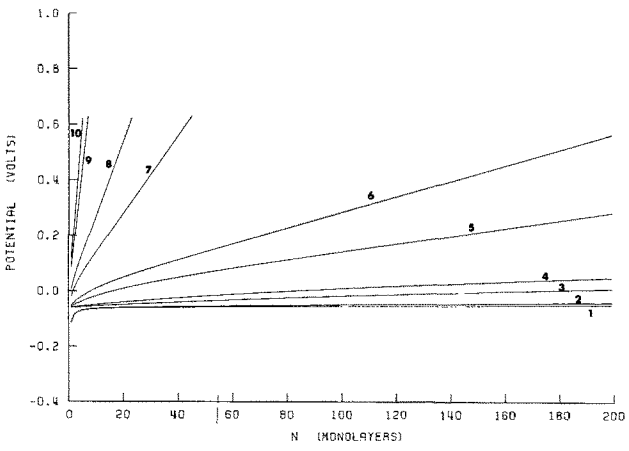

Fig. 15. Homogeneous-field results for the electrostatic potential vs. thickness in monolayers for a growing anodic oxide film with different currents.

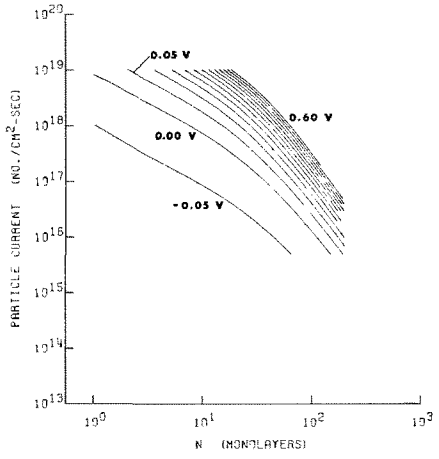

Fig. 16. Logarithm of the particle current vs. logarithm of the thickness for growth under constant electrostatic potentials ranging from −0.05 to 0.60V in increments of 0.05V.

be concluded that: (*i*) Space charge retards the rate of anodic film growth, and (*j*) Space charge gives rise to curvature in the potential *vs.* thickness characteristics.

The curvature in Fig. 14 therefore represents a measure of the effects of space charge. This plot should be quite useful in a correlation with appropriate experimental results. Unfortunately there appear to be no available experimental data in the thin-film low-voltage range to provide more than a qualitative comparison (11) with the predictions of this work. Experiments designed to yield such data are to be greatly encouraged, since the results would be most useful in delineating the possible role of space charge in anodic film formation.

Kinetics of film growth.—An examination of the range of electric fields (*cf.* Fig. 10-11) shows them to be of the order of or below 10^6V/cm. The quantity $\delta \equiv ZeEa/k_BT$ consequently has values which lie between 0.0 and 0.8 in magnitude. The fields thus reach large enough values so that the exponentials $e^{\pm\delta}$ cannot be accurately approximated by $1\pm\delta$ (for example, $e^{\delta} \simeq 2.23$ and $e^{-\delta} \simeq 0.45$ for $\delta = 0.80$). On the other hand, the fields are not so large that $e^{-\delta}$ can be neglected with respect to e^{δ}, which is the usual high-field limit. Therefore, neither of the commonly used constant potential plots of log(current) *vs.* log(thickness) and log(current) *vs.* reciprocal thickness could be expected to yield straight lines even in the absence of space-charge and concentration-gradient effects.

In order to interpret to some extent the kinetics at constant voltage, the following commonly used semi-empirical plots were made: (*a*) ln J *vs.* $1/N$, (*b*) ln J *vs.* ln N, and (c) ln J *vs.* N. In the absence of space charge and concentration gradients, the first of these would yield a straight line in the high-field limit, whereas the second would yield a straight line if growth occurred according to some empirical power law (*i.e.*, $J \propto 1/L^n$, where L denotes thickness). The third of the possibilities would yield a straight line if growth were logarithmic.

Perhaps not surprisingly, none of the three types of plot yielded good straight lines. Plots of the type (*a*) turned out to provide the poorest representation of a straight line, while plots of type (c) were somewhat better but still quite poor. Plots of type (*b*), while by no means perfectly linear as can be noted from Fig. 16, were at least quasilinear over certain thickness regions for the case of the higher potentials. At the lower potentials, the curves can be noted to be affected markedly by the presence of the concentration gradient.

The choice of the type (*b*) plot as providing the best empirical representation of the kinetics is at best somewhat arbitrary due to the fact that a log-log plot has an innate tendency to minimize variations. It does have the distinct virtue, however, that the slopes give some indication of whether or not the growth curves are severely rate-limiting in character. The slopes of the higher potential curves in Fig. 16 range between −1 and −3, so that an empirical power law for growth would be of the form

$$L \propto t^{1/n} \quad (2 \lesssim n \lesssim 4) \qquad [8]$$

This tells us that growth is more sharply rate-limiting than would be expected on the basis of a parabolic law.

Corresponding computations (cf. Fig. 17) have been carried out in the homogeneous-field limit to ascertain specifically the effects of space charge. The curves can be noted to be more linear than those in Fig. 16. In addition, the slopes are generally found to be much less than the slopes of the corresponding curves in Fig. 16 (not greatly exceeding the value $n = 2$), so that growth is more nearly parabolic. Thus it can be concluded that: (*k*) Space charge gives rise to growth kinetics curves which have a greater limiting-thickness character than the corresponding homogeneous-field growth kinetics curves. In addition, the currents in the thick-film homogeneous-field limit are as much as an order-of-magnitude larger than the corresponding currents in Fig. 16. To summarize the results of our present numerical computations, then, we can state that: (*l*) Under constant potential conditions space charge severely retards the growth rate and gives rise to growth curves which have a marked limiting-thickness character.

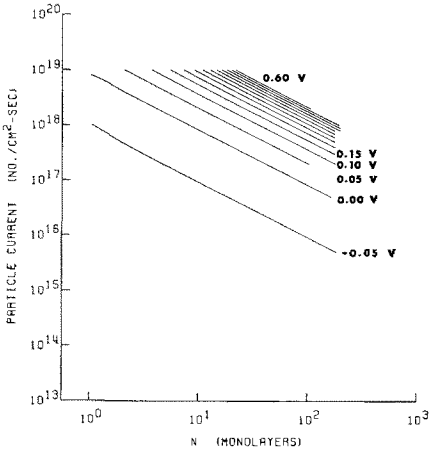

Fig. 17. Homogeneous-field results for the logarithm of the particle current vs. logarithm of the thickness for growth under constant electrostatic potentials ranging from −0.05 to 0.60V in increments of 0.05V.

Summary and Conclusions

A space-charge-gradient model computation for anodic oxidation has been carried out to delineate the effects of the concentration gradient and space charge of an arbitrary diffusing ionic species on the kinetics of film formation. The fundamental transport equation (8) is based on the concept of a thermally activated hopping (1) of charged point defects obeying Boltzmann statistics; a net mass transport takes place because of the built-in concentration gradient and the net electric field in the film due to space charge and the externally applied potential. An iterative technique has been employed to obtain extensive numerical solutions as a function of thickness and current density for reasonable values of the microscopic physical parameters involved in the model. Our major observations are summarized as follows:

1. With respect to corresponding curves computed in the homogeneous-field limit, the kinetic growth curves under constant voltage conditions are without question severely rate-limited by relatively moderate space-charge concentrations. Plots of the logarithm of the current *vs.* thickness, reciprocal thickness, and logarithm of the thickness have been made in an effort to deduce an empirical growth law, but none of the curves were found to be entirely linear. Space charge causes the growth kinetics to have an increased limiting-thickness character.

2. For growth under constant current conditions, the potential *vs.* thickness curves possess a concave curvature region which is most pronounced at low voltages. This constitutes a promising region to explore from the standpoint of verifying experimentally the existence of space-charge effects.

3. The potential *vs.* thickness curves under constant current conditions exhibit in addition a region of convex curvature which is most pronounced for thin films and very low voltages where the concentration gradient produced by the chemical reaction of film formation at the interface competes with the externally applied potential.

4. Under constant current conditions, the total amount of space charge within a film increases with thickness with a tendency to level off toward some constant value with increasing thickness. This takes place at smaller film thickness for the lower current densities.

5. Under constant current conditions, the surface-charge field at the higher defect-density interface approaches a characteristic asymptotic value very rapidly with increasing thickness. The electric field at the opposite interface levels off at a rate more in accordance with the behavior of the total space charge in the film.

6. At a given current density, the regions of large space charge become relatively more confined to the interfaces as the film thickness increases. The ionic carrier density in the central region of the film can thus become quite low for thick films.

7. For a given thickness, the order of the current density profiles shows that the total amount of space charge contained in the anodic film increases with increased current levels. The corresponding point defect density at a given position thus tends to be lower for films grown to the same thickness under low current conditions.

8. The computed electrostatic potential *vs.* position within the film is more nonlinear for thicker films due to the greater amount of space charge. In addition, at a given film thickness the electrostatic potential is more nonlinear at higher current densities due to the greater amount of space charge.

Effect of Metaphosphate and Temperature on Silver Deposition

Richard J. Roethlein*[1]

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

Effects of metaphosphate and temperature on the electrodeposition of silver from a phosphoric acid electrolyte were investigated by both steady-state and transient electrochemical techniques. Electron-microscope and x-ray diffraction techniques were used to study the morphology and structure of the electrodeposited silver. The addition of metaphosphate and the lowering of electrolyte temperature were found to change the morphology and crystal orientation of the electrodeposited silver. Possible explanations as to the cause of these changes are discussed.

Recently interest was generated in the use of silver coulometers in electronic circuits for a variety of timing applications. The device makes use of the voltage rise associated with the removal of a predetermined quantity of silver from an inert electrode (anode) which is then used to activate a relay. Due to the wide temperature span needed in many applications, a concentrated solution of phosphoric acid is used for the electrolyte system. Electroplating silver from a silver phosphate/phosphoric acid electrolyte produces rough granular deposits with poor adherence. It was found that when small quantities of metaphosphoric acid were added to the electrolyte, smoother silver deposits were obtained having better adhesion to the underlying substrate. Electrodeposition of silver at low temperature in the absence of metaphosphate was also found to have a pronounced effect on deposit texture.

Metaphosphoric acid was first used as a leveling agent for the electrodeposition of silver by Mathers (1) in an acidified silver nitrate electrolyte. Early studies indicated that the presence of this additive in silver nitrate solutions caused the formation of complex cations with silver which the authors (2) deduced were responsible for the reduction in crystal grain size. Later studies (3) have shown that although complexing may take place between the additive and cation, there is no direct correlation between complex ion formation and reduction in crystal size. Presently, the view is held that most addition agents are adsorbed on the electrode surface and thus cause modifications in the steps of the electrocrystallization process (4). Fischer (5) maintains that some form of inhibition is present in every electrode process.

Previous studies by a number of authors (6-12) on the mechanism of silver deposition in other electrolytes have revealed the presence of several alternate paths that can be rate controlling. Bockis and co-workers (7, 8) have presented evidence that at low overvoltage the rate-controlling process is surface diffusion of silver adions to lattice-building sites, which gradually changes to a charge-transfer controlled reaction at higher overvoltages. Studies (13-15) of the effects of electrode pretreatment have shown that the rate-controlling step is extremely dependent on the number of dislocations and the active growth sites present on the electrode surface. Fleishmann and Thirsk (16, 17) have maintained that the path in metal deposition would be better represented by a mechanism which would involve direct transfer to a growth site preceded by diffusion through solution. Rangarajan (18) has also shown that if the rate-controlling step was slow lattice incorporation, it would exhibit similar characteristics, such as long rise time, as predicted for a slow surface-diffusion model. Studies made by Budevskii *et al.* (10) on dislocation-free monocrystals of silver have supported the view that crystal growth involves the formation of two-dimensional nuclei and propagation by monoatomic layers. This view has also been supported with metal deposition studies employing a vitreous carbon electrode substrate (19).

In the present study, an attempt was made to investigate the steady-state and transient kinetics associated with the deposition of silver from phosphoric acid at low temperatures and in the presence of various concentrations of metaphosphoric acid. Morphology studies of the electrodeposit under various conditions have also been examined.

Experimental

A standard Pyrex glass test cell was used in making all electrochemical measurements. The cell had a separate reference compartment which could be isolated by means of a stopcock and a Luggin capillary tip extending to the edge of the study electrode. The cell also contained appropriate gas inlet and outlet ports and was cleaned before each run with a sulfuric-chromic acid mixture and then rinsed several times in doubly distilled water. The silver phosphate/phosphoric acid electrolyte was prepared by dissolving silver metal (99.97%) into a two-to-one mixture of concentrated phosphoric acid and 30% hydrogen peroxide, both reagent grade. After dissolution of the metal, the solution was heated for several hours at 125°C to remove all traces of hydrogen peroxide, which has the added benefit of oxidizing any organic impurities in the electrolyte. The electrolyte was then diluted to its appropriate concentration and stored in a taped flask, all operations being carried out in a dimly lit room to prevent formation of colloidal silver. Metaphosphate was obtained from colorless crystals of analytical reagent-grade quality containing 40% HPO_3 and 60% $NaPO_3$. Molar concentrations were calculated by averaging the molecular weight of each compound.

The reference and counterelectrodes used in these experiments were 99.99% silver. The study electrode consisted of a section of 20 mil diameter silver wire (99.99%) which was sealed to Pyrex tubing by a special Teflon tubing, Flotite. All electrodes were thoroughly cleaned before immersion into the electrolyte by rinsing in acetone, distilled water, nitric acid, and finally distilled water.

All measurements were taken immediately after the addition of metaphosphate since in phosphoric acid it slowly converts to the ortho form. A 10^{-4}M concentration will be entirely converted to the ortho form after several hours. The electrolyte was thoroughly purged by bubbling nitrogen through the system before and during each experimental run. Prepurified

Key words: deposition, silver, crystal morphology, mechanism.

nitrogen was further scrubbed before entering into the cell by passing it through a gas train containing columns of ascarite, copper filings at 300°C, and finally a liquid nitrogen cold trap. Low temperature experiments were carried out in either a cold box containing ethylene glycol as the coolant or by immersing the test cell in a Dewar flask which contained freezing mixtures of dry ice and either carbon tetrachloride or chlorobenzene. Electrical measurements were carried out after the test cell had come to a constant temperature which did not vary by more than ±0.5°C during the course of the experiment.

Steady-state polarization measurements were made using a Wenking potentiostat or an electronic measurement constant-current power supply, and potentials were recorded with a Hewlett-Packard digital voltmeter having an input impedance of 10^{10} ohms. Galvanostatic transients were obtained using an electronic circuit containing a mercury-wetted relay system that has been described previously in the literature (20). Overpotential-time measurements were recorded on a Tektronix Oscilloscope, Model 535, and photographed with an attached Polaroid camera. An electron-probe analysis for phosphorous on electrodeposited silver samples was carried out at 21 keV, and x-ray diffraction analysis for crystal orientation was done with a Phillips diffractometer using a Cu tube at 1°/min scan rate. Morphology studies of the electrodeposit were made with an American Optical 2400-P Metallograph and an electron microscope employing the carbon replica method.

Results

Effect of temperature.—The steady-state deposition and dissolution of silver was studied at various temperatures and silver ion normalities in a concentrated phosphoric acid electrolyte. At room temperature, a semilog plot of the current-potential characteristics of this reaction are almost symmetrical and do not exhibit a hysteresis effect, Fig. 1. Current-voltage data for the deposition reaction at several silver ion concentrations when plotted on rectangular coordinates exhibit linear slopes which are proportional to the silver ion concentration, Fig. 2. Curves taken in the presence of stirring show a marked reduction in overvoltage while the electrolyte is being agitated.

With decreasing temperature electrode polarization increases and a large hysteresis is observed to occur between the ascending and descending current-potential values. At a temperature of approximately −10°C or less, an inflection in the current-potential curve appears which seems to indicate a shift in the electrode process is occurring. Figure 1 reveals that under potentiostatic conditions, the initial ascending cathodic portion (curve 2) of the current-potential curve has a pronounced inhibition inflection at approximately 25 mV polarization. Further increases in polarization

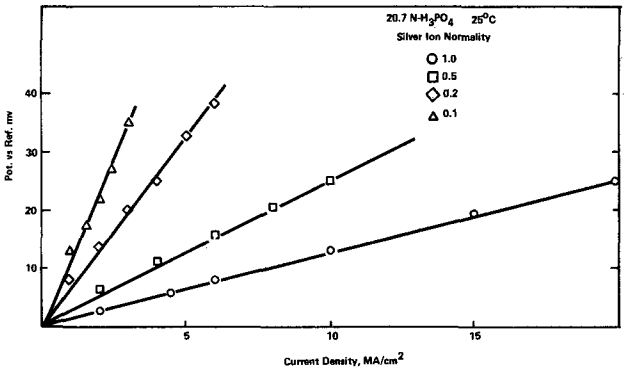

Fig. 2. Steady-state deposition of Ag

indicate that a subsequent electrode process takes place at higher overvoltages. After the transition region has been passed, descending cathodic potentials (curve 3) follow the second curve and at low current densities exhibit a higher overvoltage than the ascending cathodic portion of the curve (curve 2). Further decreases in potential produce an anodic current and the dissolution (curve 4) of the electrodeposited layer exhibits a large hysteresis when compared to the original dissolution curve (curve 1) until enough charge has been passed to remove the quantity of silver deposited during the cathodic portion of the curve. After removal of the electrodeposited layer, current-potenital parameters follow the original dissolution curve (curve 1).

A coulometric study of the potential variation between the dissolution of the silver substrate and the electrodeposited silver layer at −22°C has shown that the potential difference exists only until the electrodeposited silver has been removed from the silver-electrode substrate, Fig. 3. A stable dissolution potential was first established for a given current density; the current was then reversed and silver deposited for a given period of time. The rest potential after electrodeposition is approximately 25 mV more cathodic than the silver-reference potential and has been observed to be stable over 24 hr. Upon reversal of the same current in the anodic direction, a potential plateau is observed which is approximately 35 mV more cathodic than the initial dissolution potential. The potential remains at this value only until the amount of time corresponding to the deposition of silver has elapsed; the potential then drops to its original anodic value. At 25°C, no potential variation between the dissolution of the silver substrate and an electrodeposited layer was observed.

Morphology studies of the electrodeposited silver obtained at different temperatures and overvoltages, Table I, are shown in Fig. 4. At room temperature,

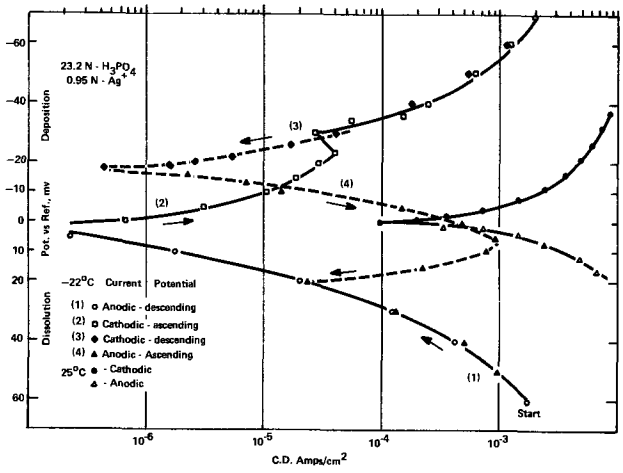

Fig. 1. Steady-state dissolution deposition of Ag

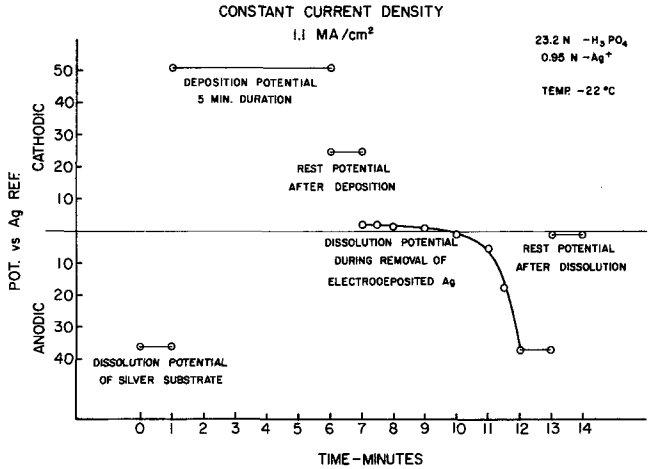

Fig. 3. Silver-dissolution potentials at low temperature

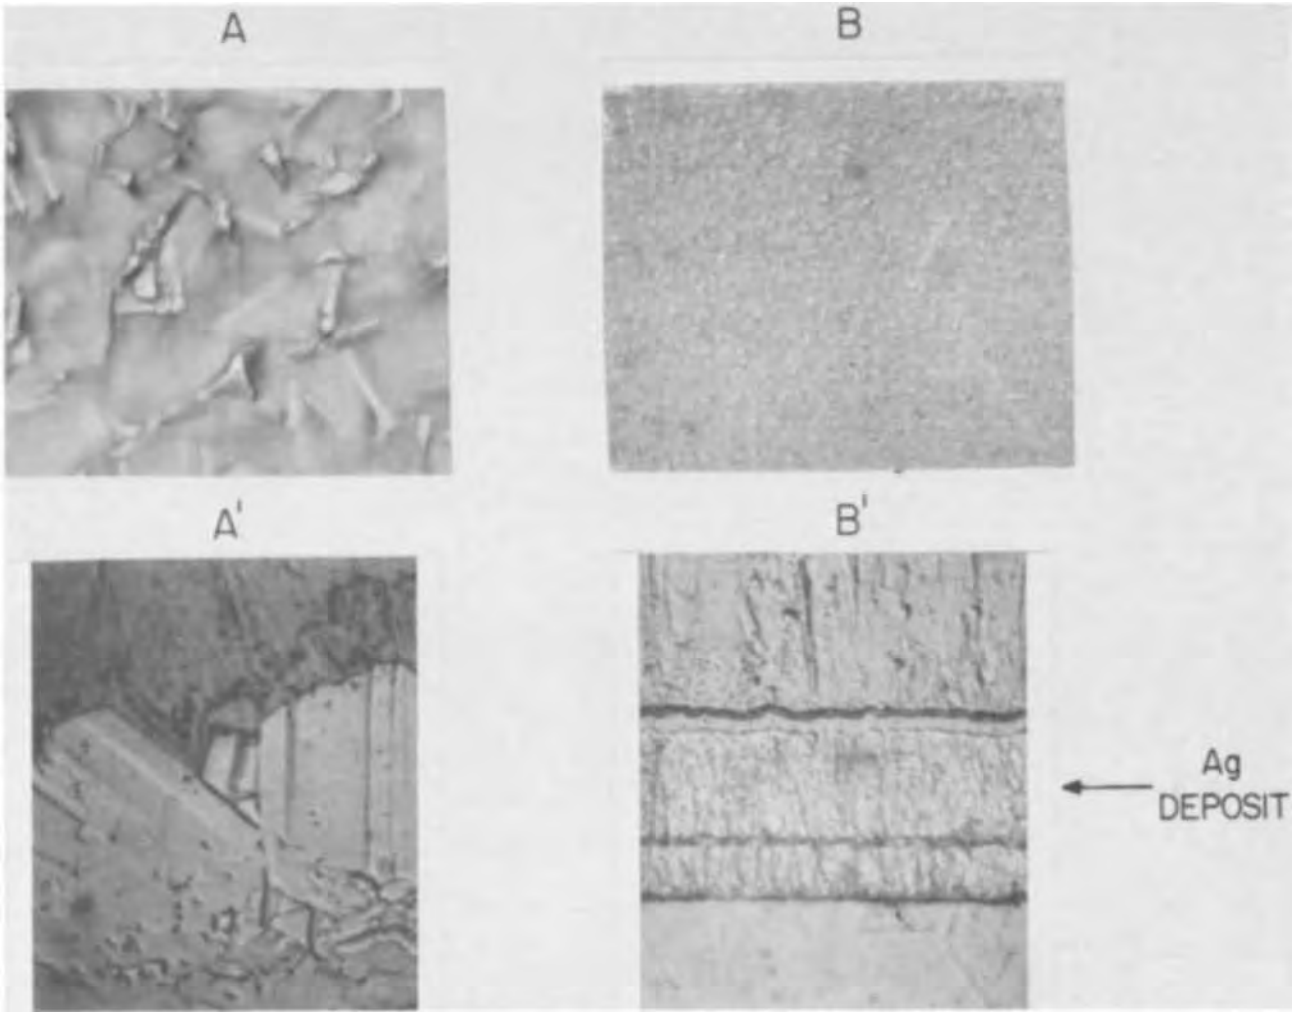

Fig. 4. Silver crystal growth as a function of temperature. A', cross section of A; B', cross section of B. Magnification 1200×

silver tends to grow large polyhedral crystals; a cross section of these crystals also indicates that a large amount of twinning occurs. These large crystals have been observed to grow over a large current-density range. Electrodeposition carried out for prolonged periods of time, up to 1 month, at low current density, 10 μA/cm^2, have produced large platelike crystal structures. Deposits obtained at lower temperatures (−20°C) are composed of much smaller crystals having a white matlike appearance. Cross section indicates the deposit is finer grained and is composed of a large amount of columnar-type structure.

The preferred orientation of electrodeposited silver also changed with decreasing temperature. X-ray diffraction studies were made of the crystal orientation of the electrodeposit at room temperature and low overvoltage. The orientation is predominantly with the <111> plane parallel to the surface with only small contributions from other planes. With decreasing temperature and higher overvoltages, a larger proportion of the crystal orientation is in the <110> plane. Examination of crystal orientation as a function of overvoltage at −20°C showed that the <110> plane was a major orientation for electrodeposited silver over the range of potentials investigated, 20-70 mV.

Table I. Morphology studies of the electrodeposited silver obtained at different temperatures and overvoltages

	23.8N $-H_3PO_4$, 1.08N $-Ag^+$ (see Fig. 4)		
C.D.	Deposition time (min)	η (mV)	Temp
A, 1 mA/cm^2	150	6.8	25°C
B, 1 mA/cm^2	150	70	−20°C

Nonsteady-state transient studies of the electrode process were made employing the galvanostatic-pulse method. Activation polarization was found to increase with decreasing temperature and an analysis of the initial portion of the charging curve supplied a value of the silver adion concentration. At 25°C, the silver adion concentration has an average value of 3.4 × 10^{-10} mole/cm^2 for a 1.0N silver ion concentration, which is in agreement with previously obtained values of this parameter (6-9). For an equivalent bulk-silver ion concentration, values of the silver adion concentration declined slightly with decreasing electrolyte temperature; at −20°C values of silver adion concentration were 50% lower. Values of the rise time to reach activation overvoltage were also obtained from the charging curve and were compared to calculated values of the rise time assuming charge-transfer control. Experimental rise times were found to be slower, up to an order of magnitude, than the calculated value of 10 μsec.

Figure 5 is a semilog plot of activation overvoltage *vs.* current density for the deposition of silver at two different temperatures. At 25°C, very little activation polarization is associated with the process up to current densities the order of 1 A/cm^2 and a linear slope is observed over the range of current densities investigated having a value the order of 10 mV/decade. At −20°C, two consecutive slopes are observed with an inflection occurring at approximately 25 mV polarization. The slope occurring in the low current-density region has a value of 10 mV/decade which increases to 30 mV/decade in the higher current-density range.

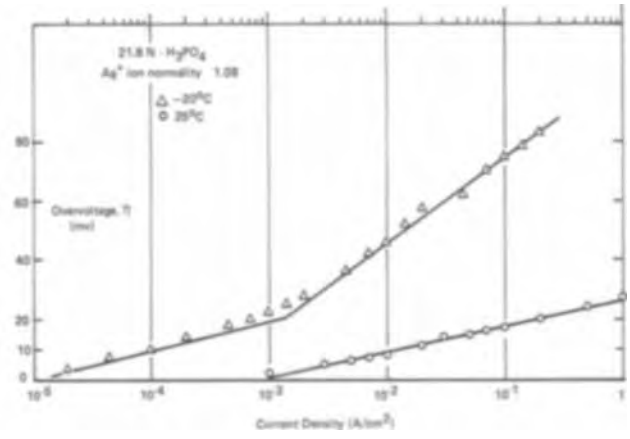

Fig. 5. Activation overvoltage for Ag deposition

Effect of metaphosphate.—Steady-state polarization curves for silver deposition show a successive increase in overvoltage with increasing metaphosphate concentration and exhibit linear current-potential behavior, Fig. 6. In the presence of metaphosphate, there is no appreciable change in slope until the metaphosphate concentration is greater than the silver ion concentration. Since metaphosphate does form weak complexes (21) with silver ions, the amount of silver ion complexing can be estimated from a reduction in the amount of silver ions present in solution. In the absence of metaphosphate, the potential difference between a silver study and reference electrode immersed in a $0.1N$-$Ag^+/20N$-H_3PO_4 electrolyte is essentially zero. With the addition of 0.1M metaphosphate to the study electrode compartment, there is a potential change of 1.5 mV indicating a very small degree of complexing is occurring. A large amount of complexing is not indicated until the metaphosphate concentration is at least an order of magnitude greater than the silver ion concentration.

Steady-state polarization curves taken on silver electrodes show that in the presence of metaphosphate, a shift in anodic (dissolution) overvoltage occurs, similar to that obtained at low temperatures in the absence of metaphosphate. Similarly, it was found that the hysteresis observed during the dissolution of silver corresponded exactly to the amount of silver deposited on the electrode during the cathodic section of the curve. A coulometric study revealed that the dissolution of an electrodeposited layer is approximately 20 mV more cathodic than the initial dissolution potential of the substrate. The potential remained at this value only until the amount of time corresponding to the deposition of silver had elapsed. The potential then dropped to its original anodic value.

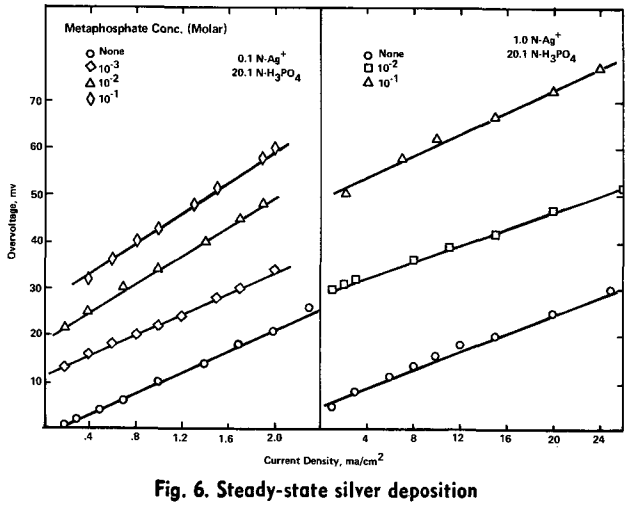

Fig. 6. Steady-state silver deposition

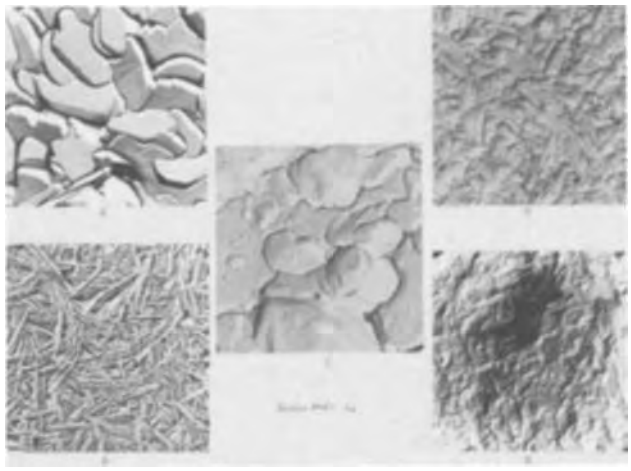

Fig. 7. Silver-crystal growth in the presence of metaphosphate

Electron-microscopy photographs were taken, Fig. 7, of electrodeposited silver surfaces under varying conditions, Table II. At the higher magnification, the samples plated in the absence of metaphosphate showed a granular structure with well-defined growth of crystal faces; the lower silver ion concentration still retained the large-grain structure but with less individual crystal definition. Growth in the presence of metaphosphate produced a smooth structure, consisting of fine needles in the presence of a $1.0N$ silver ion concentration. At the lower silver ion concentration, the grains, which ranged in size from 1.5 to 4.0μ, had little texture. For purposes of comparison, a silver deposit obtained in a cyanide bath shows the smooth, layered, crystal growth that occurs under these conditions. A comparison of deposit texture with electrode overvoltage indicates an increasingly smoother deposit is obtained with higher cathodic polarizations. The texture or crystal orientation of electrodeposited silver in the presence of metaphosphate revealed that for overvoltages greater than 20 mV the preferential orientation is mainly in the <110> plane.

In order to obtain more direct evidence for the adsorption of metaphosphate an electron-probe analysis for phosphorous was carried out on silver deposits that had been electrodeposited on gold in the presence of the additive. Table III shows that in the presence of metaphosphate, there is a large increase in the amount of phosphorous found in the deposit, which increases with a higher additive concentration. The values obtained, less than 1%, are in the range generally found for the inclusion of additives in an electrodeposit.

Metaphosphate conc.	Weight per cent
—	0.02
10^{-2}M	0.40
10^{-1}M	0.75

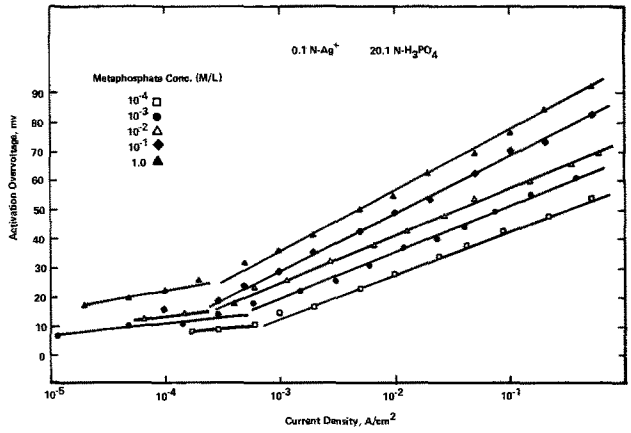

Fig. 8. Activation overvoltage vs. log C.D.

Transient potential-time traces indicate a successive increase in activation overvoltage with higher metaphosphate concentrations. A semilog plot, Fig. 8, of these values for the deposition of silver shows that at each metaphosphate concentration, a linear region exists over a considerable portion of the current-density range investigated. Values of the slope for this linear region range from 16 to 20 mV/decade. Examination of the voltage-time characteristics of the traces revealed that the rise time to an activation-controlled potential decreased with increasing metaphosphate concentration. Values of the amount of charge, Q_A, required to reach the activation potential showed little variation with current density but did decrease with increasing metaphosphate concentration; representative values are shown in Table IV. The overpotential-time transients were analyzed by the same procedure mentioned previously for silver adion concentration; the values did not show much variation with current density but do decrease with the addition of metaphosphate, remaining fairly constant for additive concentrations greater than 10^{-3}M, Table IV.

Discussion

Previous studies of the silver-deposition reaction have shown that the reaction mechanism is composed of several steps; mass transport of silver ions to the interface, discharge to the electrode surface, and the surface diffusion of silver adions to lattice-building sites. The above steps are also accompanied by losses of several waters of hydration associated with the various stages of silver ion crystallization. There has been some disagreement over the role surface diffusion plays in the over-all electrochemical process, but we have found in this study that this is an important step under certain conditions.

For the steady-state deposition and dissolution of silver in phosphoric acid the over-all rate-controlling step is the mass transport of silver ions from the bulk electrolyte solution. This is indicated by the decrease in overvoltage accompanying electrolyte agitation, the linearity observed between the current-potential curves at low overvoltages, and the slopes of these curves being proportional to the bulk-silver ion concentration. For reactions with high exchange currents linear steady-state, current-potential behavior has previously been shown to be due to concentration polarization (12). Although the over-all electrochemical reaction rate is mass-transport controlled, the rates of individual steps in the reaction mechanism can vary.

Table IV. Values of charge, Q_A to an activation overvoltage and silver adion concentration

$20.7N - H_3PO_4$, $1.0N - Ag^+$

Metaphosphate conc. molar	—	10^{-4}	10^{-3}	10^{-2}	10^{-1}	1
Q_A, μcoul/cm²	87	36	25	19	15	14
$C_o \times 10^{10}$, mole/cm²	3.4	1.27	0.27	0.24	0.27	0.23

Studies (6-9) of the silver-deposition mechanism in aqueous electrolytes have shown that at low overvoltages, the surface diffusion of silver adions is an intermediate step in the over-all reaction mechanism. In the present study, the results obtained from galvanostatic pulsing also indicate that at ambient temperatures and low overvoltages, surface diffusion is a slower intermediate step than charge transfer. Values of the silver adion concentration are similar to those observed by Bockris, activation polarization is extremely low, and the rise time is greater than that calculated for a charge-transfer controlled step. Slow adion diffusion would also be consistent with the type of deposit obtained at ambient temperatures, where deposit morphology indicates crystal growth occurs on a relatively limited number of nucleation sites with the eventual formation of large crystal structures. Under these conditions, partially hydrated silver adions migrate over the surface in a random walk manner until they collide with an active site such as a kink position where the growth via a step or screw dislocation can be maintained.

At lower temperatures, $<-10°C$, deposit morphology, along with crystal orientation, changes accompanied by a large increase in the number of nucleation sites on the electrode surface. Steady-state, current-potential curves indicate a change in the electrode process occurs at overvoltages greater than 25 mV and a large hysteresis is observed between the removal of the electrodeposited species and the polycrystalline-electrode substrate. This variation in current-potential behavior can be related to the change in crystal orientation obtained at higher overvoltages. Since changes in crystal orientation will give rise to different bond strengths between adions and surface metal atoms, a shift in the amount of energy needed to remove them will be required. Piontelli (22) has also shown that the current-potential relationships for metal deposition and dissolution vary considerably on different crystal faces.

A shift in electrode process at low temperatures is also suggested from the nonsteady-state plot of current *vs.* activation overvoltage. The two linear slopes with an inflection at 25 mV indicates that another consecutive reaction is rate controlling at higher overvoltages. Since electrochemical rate constants, for various steps in a reaction, depend on potential it would be reasonable to assume that some other reaction such as the direct transfer of silver ions becomes more rate controlling at higher potentials. At higher overvoltages, sufficient energy would be realized to nucleate more energetic deposition sites; concurrently the rate of silver adion diffusion would increase to where it is no longer the slowest intermediate step in the reaction. Due to the high dislocation density of the etched silver-electrode surface used in these experiments, the possibility of deposition occurring via two-dimensional nucleation would be unlikely.

In the presence of metaphosphate, a change in silver-deposit morphology is also accompanied by a large increase in overvoltage. Linear steady-state, current-potential behavior in the presence of metaphosphate indicates the over-all reaction rate is mass-transport controlled. Evidence of metaphosphate adsorption on the electrode surface is indicated by the decrease in silver adion concentration and the amount of charge required to reach activation overvoltage. Electron-probe analysis also indicates metaphosphate coverage increases with larger additive concentrations. Similar values of the slope obtained from the nonsteady-state plot of current *vs.* potential indicate a consistent rate-controlling step over the range of metaphosphate concentrations investigated. These facts tentatively suggest that with the adsorption of metaphosphate, low energy sites become blocked and deposition is forced to occur on higher energy sites with a subsequent increase in overvoltage. This would gradually make direct transfer of silver ions from solution to nuclea-

tion sites a more favorable intermediate reaction step in the over-all electrochemical process. With increasing overvoltages, more nucleation sites for silver deposition become available, resulting in an over-all more fine-grained electrodeposited surface.

A Study of Surface Chromium on Tinplate

S. E. Rauch, Jr. and R. N. Steinbicker

Homer Research Laboratories, Bethlehem Steel Corporation, Bethlehem, Pennsylvania 18016

ABSTRACT

The reactions occurring during the anodic polarization of tinplate passivated cathodically in a dichromate solution (CDC tinplate) were ascertained by applying Faraday's law to analyses of the oxidation products generated. It was found that a large portion of the CDC passivation film consists of chromium in the metallic state.

Most of the tinplate used for making cans and other containers, particularly containers for foods and beverages, is produced commercially by the electroplating of steel strip with a thin coating of metallic tin. After the strip has been plated, the tin coating is flow-brightened to convert the tin from a condition in which it presents a matte surface to a condition in which it presents a bright surface. The flow brightening is accomplished by melting and subsequently solidifying the tin coating. If the tin surface were permitted to remain in the flow-brightened condition, it would be susceptible to the formation of an oxide film during storage that is very detrimental to lacquer or enamel adhesion if the tinplate is subsequently coated. In addition, untreated tin surfaces are susceptible to discoloration or yellowing when heated during the enamel-drying process and to sulfide staining when sulfur-containing foods are packed in such tinplate. Such discolorations are objectionable from an esthetic standpoint.

For these reasons and also to improve the corrosion resistance of the tin surface, it is customary to electrochemically treat the flow-brightened tin surface in a dilute solution of sodium dichromate. The tinplate is made cathodic in this solution maintained at a temperature of approximately 80°-85°C, about 4 coulombs/dm^2 being passed at a current density of 5-10 A/dm^2.

This treatment applies a layer of chromium amounting in weight to 60-100 $\mu g/dm^2$ to the surface of the tinplate. The nature and composition of such a passivation film has been a subject of controversy for many years, but it has generally been felt that the film consists of various hydrated and/or unhydrated oxides of chromium. Although the solution to the problem is complicated by the extreme thinness of the film ($\simeq$10 Å), recent evidence has indicated the possibility that some portion of the film might consist of chromium in the metallic form (1). Along these lines the anodic polarization at constant current (galvanostatic) of cathodic dichromate (CDC)-treated tinplate and the relationships of the resulting potential-time (charge) curves to various surface properties have been independently explored and reported by several investigators, notably Rocquet and Auburn (1), Britton (2), and Becker (3).

Britton's investigations provided the basic work in this field, and his general procedure was used by most of the other investigators. Using Britton's electrolyte (0.75% Na_2HPO_4, adjusted to pH 7.4 with H_3PO_4), engineers in Bethlehem Steel's Research Department examined the procedure and attempted to correlate the results with plain plate and underfilm sulfide stain ratings. However, the correlations were poor and the lack of a clearcut relationship between the test and total surface chromium prevented Britton's procedure from being used as a routine analytical method.
