The peak at Si_4^+ in silicon probably results from the large number of four-bonded nearest neighbors. If the number of nearest neighbors is changed, one would expect, by these arguments, a change in the cluster distribution. Baun *et al.* (8) have, in fact, observed large differences in cluster distribution between amorphous carbon, diamond, and graphite corresponding to changes in nearest neighbor structure. Similar unreported results on carbon have been observed with the sputter-ion source mass spectrometer at GCA. Impurities in silicon which serve to break the Si-Si bond should then alter the polyatomic ion distribution. This is observed in samples 42 and 63F in Fig. 2.

The similarity in cluster distribution between the amorphous and crystalline phase is thus a consequence of their similar nearest neighbor environments. The slight diminution of clusters, particularly the Si_6^+ peak in the sample deposited at low temperature, may be significant. Curves, not shown here, carried out to Si_8^+ confirm this diminution of higher order clusters in amorphous samples. The amorphous samples studied here are about 8% less dense than the corresponding crystallized samples (12). The diminution of the higher order cluster peaks may thus be due to the presence of voids or to changes in the second and third nearest atomic neighbor distances.

The influence of the defocused bombarding argon beam on film structure and consequently cluster distribution is believed to be small in view of the cluster changes observed in the carbon system and the cluster sensitivity to impurities in silicon.

Impurity Spectra

Analysis of the atomic impurity fraction (f_X^+) was obtained from spectra such as shown in Fig. 1, and spectra using the 100 eV window shown in Fig. 5. The absence of the polyatomic peaks is evident in Fig. 5 Quantitative data is obtained according to the following relation

$$f_X^+ = \frac{I_{X+}/Y_{X+}}{I_{X+}/Y_{X+} + I_{Y+}/Y_{Y+} \ldots I_{Z+}/Y_{Z+}}$$

where I_{X+}, I_{Y+}, and I_{Z+} represent the ion peaks of species X, Y, and Z, and Y_{X+}, Y_{Y+}, ... Y_{Z+} their respective sputter yields. In dealing with pure silicon, the following approximate relation was used

$$f_{X+} = \frac{I_{X+}\ Y_{Si+}}{I_{Si+}\ Y_{X+}}$$

where I_{Si+} and Y_{Si+} are the measured silicon peak ion current and yield, respectively.

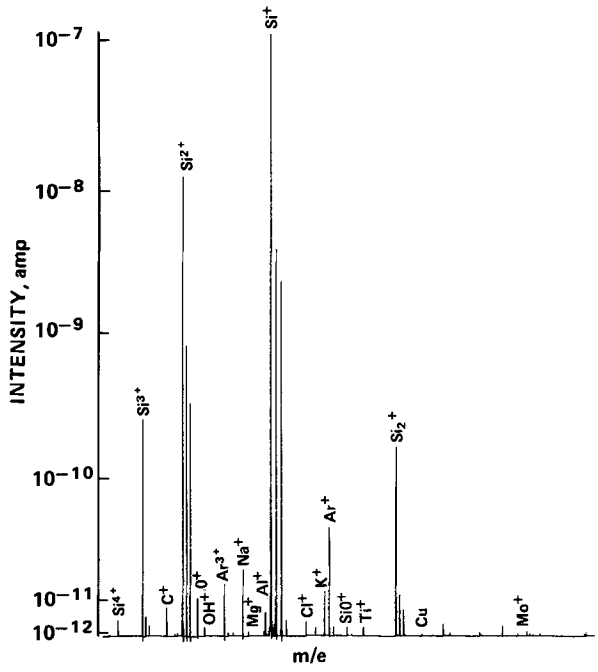

Fig. 5. Sputter-ion source mass spectra, 100 eV window, silicon film No. 93C.

A knowledge of the yields for each ion is thus necessary in order to obtain quantitative results. A specific calibration of impurity yields from the silicon matrix has not yet been made. Approximate yields based on prior work on elements and compounds (14) were therefore used in the present study. The yield figures, based on impurities being present in the oxidized state, are indicated in Tables II and III. Yields on a relative basis for 0 eV energy window are different in some cases from those for the 100 eV window. Comparison among samples does not, of course, depend on accurate yield values.

The impurities in representative silicon films are given in Tables II, III, and IV. The impurities present in quantities greater than approximately 1 ppm are listed. The spectrometer sensitivity to each impurity depends, of course, on the sputtering yields. The amount of oxygen present is probably the most questionable figure in the tables. Oxygen is present in the spectrometer background and in the substrates (SiO_2) as well as in the sample.

Discussion of Origins of Impurities

On comparing the data in Tables II, III, and IV with the fabrication conditions (Table I), one may infer the sources of impurities in the samples. In Table III, for example, the large quantity of tantalum and oxygen in sample 86E arose from the use of a tantalum substrate. The Ag and Cu impurities in sample 52

came from the use of a silver-plated crucible. Samples 63C and 63F were heated at 850° and 975°C, respectively, in the vacuum and may be compared with the unheated film 63A. One sees that lithium, sodium, and potassium impurities were picked up at 850°C but were lost (re-evaporated) at 975°C. The carbon, oxygen, magnesium, chromium, and boron content increased, however, with firing temperatures. Chromium was present in extremely large quantities at 975°C and probably arose from the stainless steel supports, etc., in the system.

On examining samples 86F and 86B in Table III, it can be seen that lithium and oxygen were picked up in sample 86B during the firing in argon. There was little change in sodium or potassium content. In comparing series 63 and 86, one sees that firing in argon resulted, in general, in purer films than firing in vacuum. Somewhat more boron seemed to be present when the Pyrex bell jar was used than when the stainless steel one was used. The Pyrex bell jar was not water cooled and became warm during the vacuum heating. This may account for the large boron concentration in sample 63F. Na and K content appeared to be lower when the deposition was carried out on hot substrates as in sample 52. In all samples, the impurities introduced from the crucible material (Cu, Ag, Mo) were small and may, with proper precautions (*e.g.*, cooling as in series 89), be kept to a minimum (< 1 ppm). Since the titanium pump was not operated during the deposition, the small amount of Ti present may come from the substrate.

In order to ascertain the extent of the impurities introduced from fused silica substrates, depositions were made on "semiconductor" grade fused-silica[2] and Suprasil[3] fused-silica substrates. Results are shown in Table IV. Impurities listed in 89A and 89B-2 were those found close to the substrate. Impurity concentrations in the films and substrate were determined using yields listed in Table III. As can be seen from Table IV, Suprasil substrates introduced generally less impurities than the fused-silica substrate. The sample on fused silica contained very high quantities of Li, C, Al, and Ti, conforming to the higher quantity of these impurities in the substrate. Oxygen diffused in from both substrates.

Impurities that were occluded in the layer from the residual gases during deposition may be estimated in the usual fashion from the partial pressures of the residual gas during deposition and the deposition rate (15). The partial pressures during deposition of sample 89 are listed in Table V for those gases which may contribute O, C, and Cl impurities to the sample. Total hydrocarbons were estimated from the 43 ($C_3H_7^+$) peak (17). Note that the CO_2 partial pressure accounts

[2] Silica was obtained from U.S. Fused Quartz Company, Inc., Fairfield, New Jersey.
[3] Suprasil was obtained from Amersil, Inc., Hillside, New Jersey.

Table V. Residual gasses during deposition (Sample 89)

Gas	Mass	Partial pressure during deposition, Torr	ν molecules striking substrates, cm^{-2} sec^{-1}	$\frac{\nu_g}{\nu_{Si}} \times 100$
CH_4	16	1×10^{-7}	5×10^{14}	13
H_2O	18	9×10^{-9}	4×10^{13}	1.1
$CO + N_2$	28	5×10^{-7}	2×10^{15}	51
O_2	32	9×10^{-10}	3×10^{12}	0.086
HCl	36	2×10^{-9}	7×10^{12}	0.18
C_nH_m	43	6×10^{-9}	2×10^{12}	0.049
CO_2	44	1×10^{-6}	3×10^{15}	81
Si	—	—	4×10^{15}	—

for a large portion of the pressure increase from 5×10^{-9} to 2×10^{-6} Torr during deposition. The ratio of gas atoms (ν_g) striking the substrates per square centimeter/second to silicon atoms (ν_{Si}) being deposited per square centimeter/second is listed in the table. As can be seen, this ratio easily accounts for the O, C, and Cl impurities shown in sample 89B-1 (Table IV). The results indicate that the sticking coefficients for the residual gases at the substrate temperature of 290°C were small.

Ordinary laboratory dust contains 5% (weight) or more of O, Mg, Al, Si, C, and Fe; many other impurities are present in the 1-5% range such as Na, P, and Pb (13). If the sample is fired some of these impurities, in spite of precautions, may diffuse into the interior. Contaminants may also be picked up during handling and transferral from APL to GCA for the mass analysis. Some surface contaminants are removed during the initial sputtering process. Particles too large to be sputtered away contribute, however, to the film impurity analysis. The impurities quoted in this paper unless stated otherwise, were those found below the surface layer of the samples.

In summary, one may divide the major impurities found in the interior of the Si films into the following broad categories: (*i*) residual gas related: O, C, Cl, F; (*ii*) bell jar and system related: B, Cr; (*iii*) crucible related: Cu, C, Ag, Mo; (*iv*) substrate related: Li, B, C, Na, Mg, Al, Ti, Fe, Cu, O; and (*v*) tube furnace related: Li. Impurities in categories (*ii*), (*iv*), and (*v*) are found primarily in crystallized or fired samples.

Conclusions

Sputter-ion source mass spectrometry has provided a great deal of information on the nature of thin silicon films. Both the cluster spectra and the impurity spectra were useful in analyzing samples. There appeared to be little difference in the cluster distribution fall off or structure between amorphous and crystalline samples. This is believed due to the fact that the nearest neighbor environment in both phases was essentially the same. In order to determine possible effects of voids, dangling bonds, and more distant neighbors, cluster regions of Si_6^+ to Si_8^+ must be carefully examined using extremely pure samples. As in the case of the spark source, the sputter-ion source cluster distribution is sensitive to impurities.

The silicon cluster spectra of amorphous SiO and SiO_2 showed large differences in both fall off and structure. This suggests the possibility of distinguishing between SiO, SiO_x, and SiO_2 layers. This is a difficult task by other techniques.

The impurity spectra provided a great deal of information on techniques for fabricating pure silicon that may have only been suspected in the past. The purest films were fabricated at elevated temperatures (~500°C). This temperature limits the introduction of high vapor pressure impurities. Processing the films for annealing or crystallization purposes in the vacuum chamber at high temperatures (>700°C) brings about the introduction of impurities unless suitable precautions are taken, such as avoiding hot stainless steel supports. Crystallization of the films in an inert gas atmosphere in a fused silica tube furnace generally

appears preferable to vacuum heating. The use of ultra-pure fused silica substrates is important in limiting impurities in crystallized samples.

As a result of this study, vacuum-deposited silicon films on fused-silica substrates have been crystallized and doped n- or p-type in a standard diffusion furnace with considerable success. This work will be described in a subsequent report.

Current Gain Mechanism in Arsenic Emitter Transistors

R. D. Lillard, J. L. Saltich, and C. E. Volk*

Motorola, Inc., Semiconductor Products Division, Phoenix, Arizona 85008

ABSTRACT

The effect of arsenic and arsenic-phosphorous mixed emitters on current gain in bipolar transistors is discussed. Experimental data for doping profiles and output admittance tests are correlated with emitter efficiency. It is conclusively shown that emitter efficiency is greater for arsenic-type devices, and that base recombination limits the gain when arsenic is used as the emitter dopant.

The use of arsenic as an emitter dopant in bipolar transistors has received considerable attention during the past year (1-3). The primary advantages of arsenic over phosphorus for emitter diffusions are the steeper doping gradient at the emitter-base junction and the absence of the "push ahead" or "emitter dip" effect. The published work on arsenic emitters during the past year has treated the diffusion characteristics of arsenic in silicon and the resulting improved high-frequency performance of arsenic emitter devices.

In the previous work, the limiting gain mechanism in an arsenic emitter bipolar transistor has been assumed to be emitter efficiency. Ghosh *et al.* (1) have demonstrated that the emitter efficiency is higher when arsenic is used as the emitter dopant. This paper will present data showing that the limiting gain mechanism in arsenic emitter structures is base region recombination, whereas for phosphorus emitter devices, emitter injection efficiency limits the gain. Moreover, the emitter efficiency increases as the concentration of arsenic increases in phosphorus-arsenic mixed emitters. Thus, as the concentration of arsenic increases, the emitter efficiency becomes greater and base recombination plays a more dominant role in limiting the transistor's current gain.

Key words: output admittance test, lifetime, arsenic, phosphorus, dopant profiles.

Experimental

The emitter diffusions employed in this study were made from solid sources of arsenic, phosphorus, and arsenic-phosphorus mixtures to a depth of 1 μm. The doping profiles of these emitter diffusions were analyzed by the anodic oxidation technique with a NH_4NO_3-$OCH_2CH_2CHCH_2OH$ (tetrahydrofurfuryl alcohol) anodizing solution. The concentration of NH_4NO_3 was 3.34 g/liter. The thickness of oxide grown in this manner was determined from calibrated color charts. After oxide removal with HF, the resistivity was measured with a four-point resistivity bridge.

The depth-resistivity data were then analyzed with a computer program to obtain a concentration *vs.* depth profile. The computer program simply performs the calculation

$$\frac{d\,(\rho_s^{-1})}{dx} = N_x\,\mu_x\,q \qquad [1]$$

to find the concentration N_x at the depth x. In Eq. [1], ρ_s is the sheet resistivity, q is the electron charge, and μ_x is the electron mobility at the depth x. The mobility values used were from the compilation by Irvin (4).

The transistors used to study the limiting current gain mechanism of the various emitters were devices with emitter and base areas of 1.8×10^{-4} cm^2 (28 milli-in.^{2}) and 18×10^{-4} cm^2 (280 milli-in.^{2}), respec-

tively. The transistors were built on <111>, n^+ substrates with 10 μm of 3-5 ohm-cm epitaxially deposited silicon.

Two sets of transistors were fabricated. The first set had current gains of 30 and were used for the output admittance comparison discussed below. These transistors were fabricated with the same prebase-getter and base cycles. Emitters with varying arsenic-phosphorus concentrations were then diffused to a depth of 1.0μ from a solid source. Because the different emitters required varying temperature-time cycles to obtain a depth of 1.0 μm, the base depths and consequently the integrated base doping varied somewhat from transistor to transistor.

The second set of transistors were fabricated with arsenic and phosphorus emitters. With these transistors, the same prebase-getter cycle was employed. However, the base and emitter cycles were adjusted so as to obtain the same emitter depth, base width, and integrated base doping for the arsenic and phosphorus emitter devices. The final base and emitter depths were 3.5 and 1.8 μm, respectively. The current gains were 80 and 40 for the arsenic and phosphorus devices, respectively.

The recombination mechanism dominating the current gain in these transistors was determined using the output admittance test of George and Clark (5). Briefly, they found that for emitter efficiency limited devices

$$\left.\frac{\partial I_C}{\partial V_C}\right|_{I_B} = \left.\frac{\partial I_C}{\partial V_C}\right|_{V_{BE}} \qquad [2]$$

whereas for base recombination limited gain

$$\left.\frac{\partial I_C}{\partial V_C}\right|_{I_B} \approx 2\left.\frac{\partial I_C}{\partial V_C}\right|_{V_{BE}} \qquad [3]$$

These relationships enable the determination of the mechanism limiting current gain from simple curve-tracer measurements. The result of the experiments will now be discussed.

Results and Discussion

The doping profiles obtained for arsenic, phosphorus, and a 1P:3As mixed source are shown in Fig. 1. From these profiles, the grade constants at the junction were measured as 5.7×10^{22}, 2×10^{22}, and 3.6×10^{22} cm^{-4} for the arsenic, phosphorus, and mixed source, respectively. These values are lower than those of Ghosh *et al.* (1), who observed a value of 10^{24} cm^{-4} for a sealed ampoule arsenic diffusion, and a value of 2-3 $\times 10^{23}$ cm^{-4} for open-tube $POCl_3$ and PH_3 diffusions. The emitters studied by Ghosh, however, were 0.5 μm deep, whereas the emitters of this work are 1.0 μm deep. In fact, values comparable to those of Ghosh are observed in this laboratory for 0.5 μm diffusions. A very important result, shown in Fig. 1, is the variation of the grade constant with arsenic concentration. This makes possible the tailoring of the emitter profile for specific applications.

The results of output admittance tests on transistors with various emitter dopants are tabulated in Table I, along with data for other important device parameters. The output admittance comparison and emitter sheet resistance are plotted in Fig. 2 as functions of the arsenic concentration in the emitter. From the figure, it is seen that the phosphorus device has an admittance ratio of 1 and is therefore (by the previously described test) emitter efficiency limited; the admittance ratio of the arsenic device is 2, implying base recombination limited gain. For mixed arsenic-phosphorus emitters, the ratio varies from 1 to 2 with increasing arsenic concentration. For these mixed emitters, base recombination becomes more dominant as the arsenic concentration is increased. Alternatively, one can say that emitter efficiency is increasing as the arsenic concentration is increased. In fact, increased emitter efficiency is necessary in order to realize the gain in the mixed emitter devices, because the integrated base doping is monotonically increasing as the arsenic concentration is increased. This increased emitter efficiency is occurring in spite of the lower net doping in the emitter as evidenced by the emitter sheet resistances.

To demonstrate the increased emitter efficiency of arsenic emitters, transistors were carefully processed to have identical base widths, identical integrated base

Q_b, integrated base doping; τ, minority carrier lifetime in collector.

doping, and comparable minority carrier lifetimes. Both arsenic and phosphorus emitter structures were fabricated. Some important device parameters are shown in Table II. The sheet resistance under the emitter, ρ_{sbe}, and the collector current at V_{BE} = 600 mV, I_C (600 mV), are identical for the arsenic and phosphorus devices. Series resistance effects are assumed negligible as I_C is increasing one decade for each 60 mV of applied V_{BE} from V_{BE} = 480 mV to V_{BE} = 660 mV. Both these results indicate that the integrated base doping is the same in each device. It should also be noted that the emitter depth and base widths are identical for these devices. Finally, the minority carrier lifetime is comparable for both devices, as can be inferred from the forward biased collector-base I-V data.

Equivalence of minority carrier lifetime in the emitter, base, and collector, is desirable when comparing the efficiency of different emitters in bipolar transistors. Consideration of gain controlling mechanisms implies identification of the various sources of base current. For an emitter efficiency limited device, the dominant mode of base current is the minority carriers injected into the emitter. Some of the factors important in determining the magnitude of minority carriers injected into the emitter are: (*i*) base doping, Q_B; (*ii*) emitter doping, Q_E; (*iii*) emitter-base profile; and (*iv*) minority carrier lifetime in the emitter. Thus, when comparing the effect of doping profile on emitter efficiency it is necessary to control all other parameters, such as Q_B, Q_E, and lifetime. Unfortunately, no techniques are available for directly measuring minority carrier lifetime in the emitter. The assumption has been made that collector lifetime and emitter lifetime will "track." That is, equivalent values for collector lifetime imply equivalent values for emitter minority carrier lifetime; of course, the absolute value of emitter lifetime is not known, but is much lower than the value for collector lifetime.

The significant difference between these devices is the high current gain, 80, exhibited by the arsenic emitter transistor. Because all other process parameters are identical for these devices, it is evident that the increased gain of the arsenic transistor is a direct result of increased emitter efficiency.

The arsenic emitter devices, however, are base recombination limited, as shown above. Therefore, the emitter efficiency of the arsenic emitter device has increased to such an extent that base recombination limits the gain. In the phosphorus emitter transistor, with the same base width and minority carrier lifetime, emitter efficiency limits the gain.

Increased emitter efficiency with arsenic emitters has been suggested several times in the literature (1, 2), but has not been demonstrated. These results demonstrate that emitter efficiency is greater for arsenic emitter devices, and that base recombination limits the gain when arsenic is used as the emitter dopant.

Summary

Small-signal bipolar transistors have been fabricated using arsenic, phosphorus, and mixed arsenic-phosphorus solid sources for the emitter dopant. The emitter profiles, emitter efficiency, and current gain mechanism were studied in these structures. The results are as follows.

Dopant profiles.—The grade constants for phosphorus, arsenic, and 1P:3As sources were 2×10^{22}, 5.7×10^{22}, and 3.6×10^{22} cm^{-4}, respectively. The grade constant increases as the arsenic concentration is increased.

Emitter efficiency.—The emitter efficiency increases as the concentration of arsenic in the emitter is increased.

Current gain mechanism.—Transistors fabricated with phosphorus emitters are emitter efficiency limited, whereas arsenic emitter devices are base recombination limited. For mixed arsenic-phosphorus emitter devices, base recombination becomes more dominant as the arsenic concentration is increased.

Experimental Approach to the Quantitative Determination of Dopant Segregation During Crystal Growth on a Microscale: Ga Doped Ge

A. F. Witt,* M. Lichtensteiger, and H. C. Gatos*

Department of Metallurgy and Materials Science and Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

An experimental approach was developed combining differential etching, rate striations, and spreading resistance measurements. This approach permitted the direct determination of dopant concentrations and growth rates on a microscale in gallium-doped germanium. Compositional inhomogeneities as revealed by differential etching were quantitatively related to dopant concentration variations. Rotational striations were identified as dopant concentration maxima associated with decreasing growth rates. Dopant concentration variations up to 50% were found within rotational cycles. The experimental results were subjected to a Burton, Prim, and Slichter analysis on a microscale. It was found that steady-state segregation is encountered only during increasing growth rates within each rotational cycle; the dependence of dopant segregation on growth rate became weaker in the presence of remelting. In all instances the effective diffusion layer thickness was smaller than that computed on the basis of the Cochran analysis.

Compositional inhomogeneities are encountered in virtually all solids and are the result of nonsteady-state conditions prevailing during growth from the melt, solution, or vapor phase. Thus the effective segregation of solute elements (dopants) is a complex function of experimental growth parameters. Dopant inhomogeneities have been intensively investigated (1) because of their adverse effects on materials properties and also because they reflect the conditions at the growth interface, and thus, can be used to study growth and segregation phenomena. However, both the nature and origin of dopant inhomogeneities have been the subject of controversial interpretations (2) primarily because the experimental methods available for their investigation have been limited in sensitivity and/or resolution. The use of various etching techniques has led to the identification of several types of impurity inhomogeneities (3) (striations), but the lack of quantitative correlations between etching rates and dopant concentration has limited the value of these investigations. The recently developed method of introducing rate striations permitted the determination of the microscopic growth behavior and established unambiguously the origin of certain compositional inhomogeneities (4). However, this method, based on high resolution etching, could not establish quantitative cause and effect relationships regarding compositional inhomogeneities.

The present investigation is concerned with the development of an experimental approach which permits simultaneously the quantitative determination of dopant inhomogeneities and the corresponding growth rates on a microscale by combining the rate striation technique with spreading resistance measurements (5). This approach is applied to the study of the segregation behavior of gallium in germanium grown by the Czochralski technique. The results are analyzed on the basis of the Burton, Prim, and Slichter (BPS) theory (6) on effective dopant segregation.

Experimental Procedure

Crystal growth.—The crystal used for the present investigation was grown in the <111> direction by the Czochralski method from a melt charge of 73g Ge doped with Ga (9.8×10^{19}/cm^3) at pulling rates of 7.6 and 3.0 cm/hr, with and without seed rotation. Rate striations (4) were introduced during growth by transmitting current pulses (20 A/cm^2) of 0.03 sec duration across the crystal-melt interface at a repetition rate of 0.5 sec (current direction melt to crystal). The crystal sections analyzed were 2 mm thick slices obtained by cutting the crystal along the axis of rotation (see sketch in Fig. 1).

Spreading resistance measurements.—The spreading resistance associated with a metal-semiconductor point contact has been extensively investigated (5). It has been shown that the point contact resistance for lapped germanium surfaces of moderate resistivities is predominantly given by its spreading resistance with an insignificant contribution from surface resistance due to a potential barrier. Accordingly, measurements of spreading resistance, R_s, can be used to obtain local values of resistivity. The local resistivity, ρ, of a volume element of approximately 10^{-9}/cm^3 associated with the point contact of an effective diameter, D, is given by $\rho = 2DR_s$ for a large sample with a large second ohmic contact at a relatively long distance (other side of specimen). In practice it is found that D is a complex function of several parameters and cannot readily be determined. However, R_s can be converted to ρ through calibration based on samples of known resistivity.

The apparatus (commercially available) used in the present investigation is equipped with an air-operated probe descent mechanism which gives reproducible point contacts with the specimen mounted on a traversing stage. The spreading resistance was determined by measuring the current flow through the point contact at an applied constant voltage of 10 mV.

All spreading resistance measurements were performed with the single point configuration, referred to above, on samples soldered onto a backing plate with an indium-tin alloy (large ohmic contact). Calibration of spreading resistance *vs.* carrier concentration was obtained from two gallium-doped germanium samples which exhibited the best dopant homogeneity (see nonrotated segment of curve b in Fig. 2). The resistivity and carrier concentration of the sections with the most uniform spreading resistance ($\Delta R_s < \pm 3\%$) were determined with Hall effect measurements at room temperature in the Van der Pauw configuration. The values obtained (Table I) are in excellent

Table I. Spreading resistance calibration data

Spreading resistance, R_s [ohm]	Resistivity $\times 10^{-3}$, ρ [ohm · cm]	Carrier concentration, N [cm^{-3}]	Calculated mobility, μ [cm^2 V^{-1} sec^{-1}]
4.50	13.05	8.54×10^{17}	563
1.96	2.18	1.43×10^{19}	201

agreement with earlier published results of ρ as a function of carrier concentration (7).

Surface preparation.—In view of the observed sensitivity of spreading resistance on surface preparation, several procedures were investigated. It was found that measurements on Ge surfaces prepared by "chemical lapping" with Lustrox and Syton on Polytex pads are reproducible to better than ±1%. However, since chemically polished surfaces do not reveal dopant inhomogeneities and rate striations, differential etching procedures were studied. It was observed that spreading resistance data obtained on differentially etched surfaces are completely reproducible and in quantitative agreement with measurements on chemically polished surfaces. Thus, compositional inhomogeneities, microscopic growth rates, and carrier concentrations could be determined directly on the identical surface.

The adopted surface preparation procedure was as follows: The cut Ge slices were lapped with 10 μm Al_2O_3 abrasive and subsequently polished unidirectionally with Linde "A" and Linde "B" abrasive (0.03μ). After removal from the polishing block, the samples were transferred into distilled H_2O and while still wet were subjected to etching (10 sec) in a solution of 1 part H_2O_2, 1 part HF, and 1 part CH_3COOH. After drying the etched specimens were soldered with an In-Sn alloy onto brass support blocks.

Experimental Results and Discussion

The photomicrograph in Fig. 1 (obtained with interference contrast) shows a part of the etched "off-core" region of a germanium crystal (see sketch in Fig. 1). The following features can be distinguished: (*a*) rotational striations (3) propagating from top to bottom (from the center to the periphery in the crystal with a spacing of about 0.023 cm), (*b*) rate striations, faint dark lines, introduced during growth by Peltier cooling at time intervals of 0.5 sec, and (c) equally spaced (10 μm), impact traces of the spreading resistance probe (bottom of microphotograph).

The part of the crystal shown (0.068 cm long) was pulled at a rate of 21.2 μm/sec (7.6 cm/hr) with seed-rotation (6.16 rpm). The actual growth rate and its variations, as obtained from the spacing of the rate striations with a time resolution of 0.5 sec, is shown in curve a. It is seen that the average growth rate was 26 μm/sec; the difference between the pulling and the average growth rate (in the absence of remelting) reflects the continuous lowering of the melt level at a rate of 4.8 μm/sec. During each rotational cycle the growth rate varies continuously and reaches maximum and minimum values of about 39 and 15 μm/sec, respectively. The growth rate changes are somewhat irregular and do not exhibit the generally assumed sinusoidal behavior observed in InSb crystals (3).

It is of interest to note that the rotational striations do not coincide with the location of the three growth rate minima; rather they appear under conditions of decelerating growth rate and precede the actual rate minima. It can also be seen that irregularities of the microscopic growth rate in the vicinity of their minima are not reflected as compositional inhomogeneities. The carrier concentration (Ga concentration) and its variations is recorded in curve b with a linear resolution of 10 μm obtained from spreading resistance measurements (probe impact traces are seen on the

photomicrograph). It can be seen that segregation on a microscale undergoes continuous changes with the average dopant concentration of $3.1 \times 10^{19}/cm^3$ fluctuating between 2.6 and $3.7 \times 10^{19}/cm^3$. Curve b, together with the photomicrograph, gives the first confirmation of the generally assumed direct correspondence between topographic features resulting from etching and dopant concentration on a microscale. Abrupt compositional fluctuations as low as about 2% (to the left of the center of the rotational striations) can be unambiguously detected on the photomicrograph; on the other hand, the gradual compositional changes between successive rotational striations are not revealed by interference contrast. It is important to point out that the rotational striations (as revealed by etching) are pronounced dopant concentration maxima. Thus, earlier reports for example on InSb (4a), which attributed rotational striations to compositional minima coinciding with growth rate minima, cannot be generalized.

The outstanding feature of the present approach lies in the inherent superposition of curves a and b: dopant concentration data, together with the precisely corresponding microscopic growth rates, permit now the experimental investigation of the growth rate dependence of segregation on a microscale.

As seen from curves a and b, the generally assumed dependence of segregation on growth rate is observed only in the segments of "increasing" growth rates with each rotational cycle. The dopant concentration continues to increase beyond the growth rate maxima and reaches pronounced peak values (rotational striations) under steadily decreasing growth rates. Segregation minima on the other hand, coincide in all instances with growth rate minima.

The growth and segregation behavior of another segment of the same crystal (see sketch in Fig. 1) pulled at a rate of 8.5 μm/sec (3.0 cm/hr) is shown in Fig. 2. The left part of this crystal segment was pulled with seed rotation (6.2 rpm) whereas the right part was pulled without seed rotation. The growth rate data (curve a) reveal a pronounced effect of rotation at this reduced pulling rate. Because of extensive remelting, the average microscopic growth rate in the rotated segment increased to about 30 μm/sec and thus became larger, by a factor of 3.5, than the pulling rate. This rate is higher than that in Fig. 1 although the pulling rate was here reduced by a factor greater than two. The spreading resistance measurements at spacings of 5 μm (curve b) indicate an average carrier concentration of $3.4 \times 10^{19}/cm^3$ ranging from 2.9 to $3.7 \times 10^{19}/cm^3$. The rotational "remelt" striations are readily identified as abrupt transitions of high to low dopant concentrations confirming the conclusions of earlier qualitative studies (4a). Comparing the effective segregation behavior in Fig. 1 and 2 it is seen that its growth rate dependence in the presence of remelting is noticeably decreased.

The average growth rate in the nonrotated segment is 9 μm/sec and, thus, less than expected from the applied pulling rate and the corresponding lowering of the melt level. This discrepancy is attributed to a gradual relocation of the crystal melt interface resulting from the changes in thermal conditions associated with the arrest of seed rotation.

Analysis of Segregation Behavior on the Microscale

The following analysis of microsegregation associated with rotational crystal pulling should be considered as preliminary and is primarily intended to demonstrate the potential of the present approach; *i.e.*, no special attempt was made to grow the crystals at any particular doping levels, nor were the experimental growth conditions varied in any systematic way.

Nonequilibrium segregation has been the subject of several theoretical treatments (6, 8) among which that by Burton, Prim, and Slichter has been applied with partial success to actual growth systems (9). Discrepancies between theory and experiment (tested on a macroscale) have not been as yet resolved since some of the experimental parameters could not be determined with the required accuracy. Thus, in all reported investigations the segregation controlling microscopic growth rate has been equated with the macroscopic growth rate; as was recently shown, the two rates may differ by a factor of up to 30 or more (4).

To carry out an analysis of microsegregation according to the BPS theory, it is necessary to obtain the effective segregation coefficients ($k_{eff} = C_S/C_L$). Since the exact dopant concentration in the melt (C_L) for the segments presently investigated was not known, the linear growth rate dependence of k_{eff} (and thus of C_S), indicated in the BPS theory for small growth rates under steady-state growth conditions, was used for its determination. The growth rate dependence of C_S for the third rotational cycle in Fig. 1 (curve a) is plotted in Fig. 3. The expected linear rate depen-

Curve (a) growth rates as obtained from the spacings of the rate striations introduced at 0.5 sec intervals. Growth rate analysis could not be carried out in the immediate vicinity of the remelt striations (remelt regions). Curve (b) carrier (dopant) distribution as obtained from spreading resistance measurements at spacings of 5 μm. The location of the depicted crystal segment is given in the sketch in Fig. 1. (Magnification 90X)

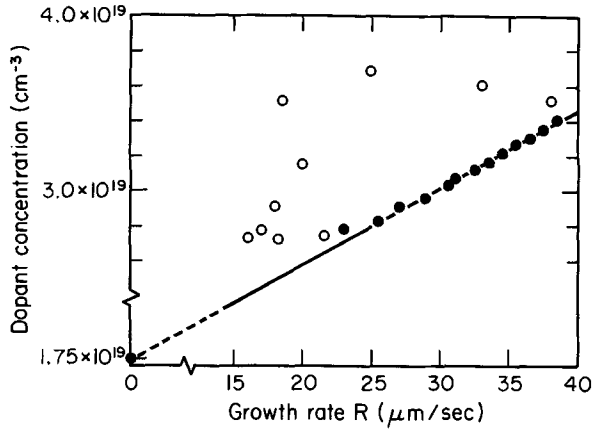

Fig. 3. Growth rate dependence of dopant concentration for the third rotational cycle of crystal segment in Fig. 1. ● dopant concentrations associated with increasing growth rates; ○ dopant concentrations associated with decreasing growth rates. Note that the linear dependence is observed only for the segment of the rotational cycle with increasing growth rates.

dence is observed only in the segment of steadily increasing growth rate. The segregation behavior in the segment of decreasing growth rate cannot at present be explained. Assuming that the linear portion in Fig. 3 reflects steady-state segregation the extrapolated value of C_{S_0}, at zero growth rate, is found to be $1.75 \times 10^{19}/cm^3$. Taking the generally accepted value for the equilibrium segregation coefficient of Ga in Ge (10) ($k_0 = C_{S_0}/C_L = 0.087$), C_L was found to be 1.97×10^{20}. This value of C_L agrees reasonably well (within about 20%) with that computed for directional solidification of 30% of the melt at an average rate of 20 μm/sec (assuming a boundary layer thickness of 0.04 cm).

To test the applicability of the BPS theory, the relationship

$$k_{eff} = \frac{k_0}{k_0 + (1 - k_0)e^{-\delta R/D}} \qquad [1]$$

is converted to the convenient form

$$\ln\left(\frac{1}{k_{eff}} - 1\right) = \ln\left(\frac{1}{k_0} - 1\right) - \frac{R\delta}{D} \qquad [2]$$

where R is the growth rate, δ the thickness of the "diffusion layer," and D the diffusion coefficient of gallium in germanium, 1.9×10^{-4} cm²/sec.

A plot of $\ln(1/k_{eff} - 1)$ against the microscopic growth rate for the third rotational cycle of Fig. 1 is shown in Fig. 4. It is seen that dopant segregation with constant "effective diffusion layer thickness" (δ/D = 180 sec/cm) takes place only during the segment of increasing microscopic growth rate within the rotational cycle. The diffusion layer thickness thus computed is 0.0342 cm. The value of δ obtained for the applied rotational rate from Cochran's analysis (11)

$$\delta = 1.8\, AD^{1/3}\nu^{1/6}\omega^{-1/2} = 0.0412 \text{ cm} \qquad [3]$$

where $A = 0.87$ (11), $\nu = 0.0025$ cgs units (11), $\omega = 0.645$ sec^{-1}.

The microsegregation behavior in the presence of "remelting" during rotation (Fig. 2) is analyzed in Fig. 5. It is seen that the "effective diffusion layer thickness" (δ/D = 90 sec/cm; δ = 0.017 cm) remains constant for all three cycles. A comparison with the segregation behavior in Fig. 1 shows that "back melting" (a result of the decreased pulling rate) leads to a reduction of the diffusion layer thickness by a factor of two and thus to a significantly weaker dependence of dopant segregation on growth rate. It is also of interest to note that the dopant concentration associated with the growth rate minima ($2.9 \times 10^{19}/cm^3$) is virtually identical with that observed for nonrotational pulling.

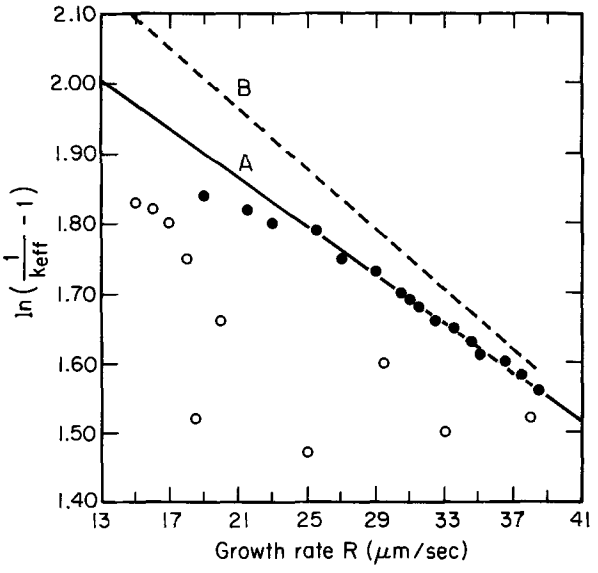

Fig. 4. Analysis of growth rate dependence of dopant segregation according to the BPS theory for the third rotational cycle shown in Fig. 1. ● dopant segregation associated with increasing growth rates; ○ dopant segregation associated with decreasing growth rates. Steady-state segregation (slope δ/D = 180 sec/cm) is indicated only for the segment of the rotational cycle with increasing growth rates (curve A). δ/D obtained from a Cochran analysis is 217 sec/cm (curve B).

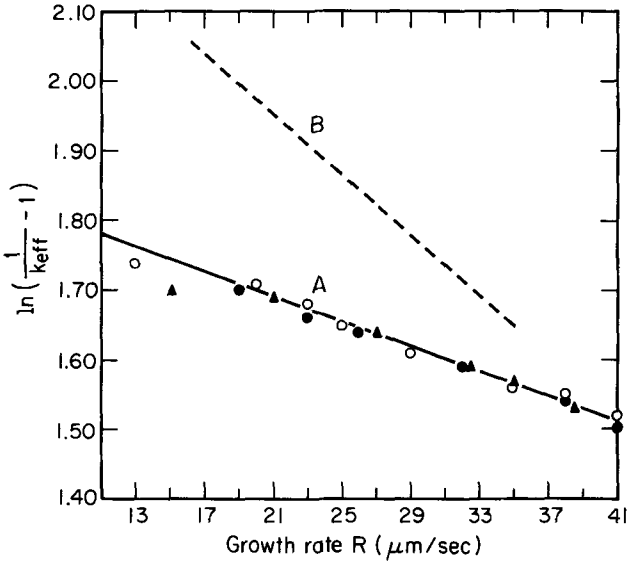

Fig. 5. Analysis of growth rate dependence of dopant segregation under remelt conditions according to the BPS theory for the three rotational cycles (○, ●, ▲, respectively) of the crystal segment shown in Fig. 2. Steady-state segregation is indicated for all three rotational cycles. The growth rate dependence of dopant segregation (δ/D = 90 sec/cm) is significantly weaker than in the case of Fig. 4. Curve B represents the growth rate dependence on the basis of a Cochran analysis (δ/D = 217 sec/cm).

Summary

An analytical approach was developed for the quantitative determination of dopant segregation and the precisely corresponding growth rates on the microscale. The approach is based on the use of rate striations in conjunction with spreading resistance measurements on differentially etched specimens. A preliminary analysis of germanium crystals pulled by the Czochralski technique from a gallium-doped melt revealed the following growth and segregation behavior: at a pulling rate of 7.6 cm/hr and seed rotation of 6.16 rpm the microscopic growth rate exhibits continuous

periodic changes (ranging from 15 to 39 μm/sec) which, however, are not sinusoidal, as generally assumed. The associated dopant segregation varies continuously (by more than 45%). Rotational striations, as revealed by etching, are identified as pronounced dopant concentration maxima which do not coincide with the growth rate maxima. Pulling at a reduced rate, 3.0 cm/hr, results in pronounced "remelt" rotational striations and an average microscopic growth rate (31 μm/sec) which exceeds the pulling rate by a factor of more than three. An analysis of the effective dopant segregation according to the BPS theory indicates the presence of steady-state conditions (constant δ/D) only for the segments of increasing growth rates within each rotational cycle. The effective diffusion layer thickness (δ) is found to be smaller than that computed from a Cochran analysis and decreases noticeably in the presence of remelting.

Diffusion from a Thin Layer into a Semi-Infinite Medium with Concentration Dependent Diffusion Coefficient. Part II

M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

A formal solution of the diffusion equation is presented for a redistribution case with an initial diffusant concentration represented by a delta function and a diffusion coefficient proportional to the concentration elevated to an integer power. The time dependence of the surface concentration and of the distance of the diffusion front from the surface is discussed and shown to be different from the familiar square root law or its inverse. An example of application of this theory is provided by the high concentration diffusion of arsenic into silicon from a finite source, for which numerical data are computed.

In a recent article (1) a transformation similar to Boltzmann's transformation was applied in the mathematical treatment of impurities redistribution in a semi-infinite medium with a diffusion coefficient dependent only on the ratio of impurities concentration to surface concentration. This case was presented more for illustrative purposes than for solving actual diffusion problems, because in a redistribution of impurities the surface concentration is changing with time and therefore the diffusion coefficient as specified above would not be truly concentration dependent. This paper is the result of further work on this subject for extending the application of the transformation method to physically meaningful cases, such as those occurring for example in the dopant diffusion into semiconductors for the formation of PN junctions.

* Electrochemical Society Active Member.

Key words: diffusion theory, Boltzmann's transformation, concentration dependent diffusion coefficient, arsenic diffusion.

Theory

Following the same terminology of the previous article (1) we assume a more general transformation for the expression of the impurity concentration, N, given by

$$N(x,t) = f(t) \cdot F(xf(t)) \qquad [1]$$

where f and F are analytical functions to be determined in such a way that N will satisfy the boundary conditions and the diffusion equation.

In the redistribution case considered here the boundary conditions are

$$N(x,t) \to \infty \text{ for } x = 0,\ t = 0 \qquad [2a]$$

$$N(x,t) = 0 \quad \text{for } x > 0,\ t = 0 \qquad [2b]$$

$$N(x,t) = 0 \quad \text{for } x \to \infty,\ t \geq 0 \qquad [2c]$$

Furthermore as the initial concentration profile is assumed to be represented by a delta function

$$Q = \int_0^\infty N(x,t)\,dx \qquad [3]$$

where Q is the total amount of impurities per unity of surface in the indiffused medium and is constant.

Let us assume that the diffusion coefficient, D, depends on the concentration, N, according to the expression

$$D = D_0\,(N/N_0)^m \qquad [4]$$

with m a positive integer including zero and D_0 the value of the diffusion coefficient at the reference concentration N_0. As both D_0 and N_0 are constants, it is convenient to conglobate them in a new constant, K, defined by

$$K = D_0/N_0{}^m \qquad [4a]$$

so that D becomes

$$D = KN^m \qquad [4b]$$

Substitution of Eq. [1] and [4b] in the diffusion equation

$$\frac{\partial N}{\partial t} = \frac{\partial}{\partial x}\left[D\,\frac{\partial N}{\partial x} \right] \qquad [5]$$

and a change of coordinates from (x,t) to (η,t), where

$$\eta = xf(t) \qquad [6]$$

yields

$$f'(t)\cdot\left[\eta\,\frac{\partial F(\eta)}{\partial \eta} + F(\eta) \right] = f(t)\,\frac{\partial}{\partial \eta}\left[Kf^m(t)F^m(t)f^2(t)\,\frac{\partial F(\eta)}{\partial \eta} \right] \qquad [7]$$

which simplifies to

$$f'(t)\,\frac{d}{d\eta}[\eta F(\eta)] = f(t)\,\frac{\partial}{\partial \eta}\left[Kf^{(m+2)}(t)F^m(\eta)\,\frac{dF(\eta)}{d\eta} \right] \qquad [8]$$

After variable separation, Eq. [8] is set equivalent to the system of equations

$$f'(t) = -Kf^{(m+3)}(t) \qquad [9]$$

$$\frac{d}{d\eta}[\eta F(\eta)] = -\frac{d}{d\eta}\left[F^m(\eta)\,\frac{dF(\eta)}{d\eta} \right] \qquad [10]$$

A simple integration of Eq. [9] subject to the boundary condition [2a] yields

$$f(t) = \frac{1}{[K(m+2)t]^{1/(m+2)}} \qquad [11]$$

As for Eq. [10], integration between η and ∞ results in

$$\eta F(\eta) = -F^m(\eta)\,\frac{dF(\eta)}{d\eta} \qquad [12]$$

because, for satisfying the boundary conditions [2c] and [3], $F(\eta)$ must be of order greater than one in $1/\eta$ and therefore

$$\lim_{\eta\to\infty}(\eta F(\eta)) = \lim_{\eta\to\infty}\left(F^m(\eta)\,\frac{dF(\eta)}{d\eta} \right) = 0 \qquad [13]$$

Integration of Eq. [12] between 0 and η finally yields

$$F(\eta) = \left[F^m(0) - \frac{\eta^2}{2}m \right]^{1/m} \qquad [14]$$

when $m \geq 1$, and

$$F(\eta) = F(0)\,\exp(-\eta^2/2) \qquad [15]$$

when $m = 0$, that is $D = D_0$.

While $F(\eta)$ as expressed by Eq. [15] is always a real positive number assuming that $F(0)$ is the same, the value of $F(\eta)$ given by Eq. [14] may be a positive real number only if the argument under the m-root sign is positive, that is for η limited to the interval

$$0 \leq \eta < \sqrt{\frac{2}{m}F^m(0)} \qquad [16]$$

Therefore for $m \geq 1$ the impurity concentration profile must be represented by a composite function as specified below

$$N(x,t) = \frac{1}{[K(m+2)t]^{1/(m+2)}}\left\{ F^m(0) - \frac{mx^2}{2[K(m+2)t]^{2/(m+2)}} \right\}^{1/m} \qquad [17]$$

for

$$0 \leq x < X(t) \qquad N(x,t) = 0 \text{ for } X(t) \leq x < \infty$$

where

$$X(t) = \sqrt{\frac{2}{m}F^m(0)}\cdot[K(m+2)t]^{1/(m+2)} \qquad [18]$$

is the transition point between the significant solution of the diffusion equation and the solution identically zero. The obvious discontinuity of $\partial N/\partial x$ for $x = X(t)$ is acceptable, because the impurities flux $J = -D\,\dfrac{\partial N}{\partial x}$ is continuous and equal to zero when computed from both sides of the transition point $X(t)$, as $D = 0$ for $N = 0$ with $m \geq 1$. A similar combination of a significant solution with the zero solution was also found by Wagner (2) to represent the concentration profile in the case of a diffusion from an infinite source with constant surface concentration and diffusion coefficient proportional to the concentration.

It is easy to verify that Eq. [17] gives an expression of N, which satisfies the boundary conditions represented by Eq. [2] and [3]. Indeed as a check and for finding the relationship between Q and $F(0)$, we substitute in Eq. [3] the expression of N given above

$$Q = \int_0^\infty N(x,t)\,dx = \int_0^{X(t)} f(t)\left[F^m(0) - \frac{m}{2}x^2f^2(t) \right]^{1/m} dx = \int_0^{\sqrt{\frac{2}{m}F^m(0)}} \left[F^m(0) - \frac{m}{2}\eta^2 \right]^{1/m} d\eta \qquad [19]$$

The independency of the integration limits from any variable is a further proof that Q is constant, as required by the boundary conditions. A formal verification that Eq. [17] satisfies the diffusion equation is given in the Appendix.

Applying the transformation

$$\eta = \xi\cdot\sqrt{\frac{2}{m}F^m(0)} \qquad [20]$$

to Eq. [19], the relationship between Q and $F(0)$ is easily found

$$Q = \sqrt{\frac{2}{m}}\cdot F(0)^{(m/2+1)}\cdot\int_0^1 (1-\xi^2)^{1/m}d\xi \qquad [21]$$

or else, by explicating $F(0)$

$$F(0) = \left[\frac{Q\sqrt{\frac{m}{2}}}{\int_0^1 (1-\xi^2)^{1/m} d\xi} \right]^{2/(m+2)} \quad [22]$$

In many applications it is useful to express the concentration profile in a normalized form, which can be obtained combining Eq. [17], [18], and [22]. The result is

$$\frac{N(x,t) \cdot X(t)}{Q} = \left\{ 1 - \left[\frac{x}{X(t)} \right]^2 \right\}^{1/m} \Big/ \int_0^1 (1-\xi^2)^{1/m} d\xi \quad [23]$$

where, using Eq. [4a] for expressing K

$$X(t) = \left\{ 2\left(\frac{m+2}{m}\right) \left[\frac{Q}{N_0 \int_0^1 (1-\xi^2)^{1/m} d\xi} \right]^m D_0 t \right\}^{1/(m+2)} \quad [24]$$

The surface concentration, N_s, decreases with time and its expression is found by setting $x = 0$ in Eq. [23]

$$N_s(t) = Q \Big/ \left[X(t) \cdot \int_0^1 (1-\xi^2)^{1/m} d\xi \right] \quad [25]$$

Plots of normalized concentration profiles are shown in Fig. 1 for different values of m, while the values of the definite integral appearing in Eq. [23], [24], and [25] are tabulated in Table I for values of m between 1 and 10.

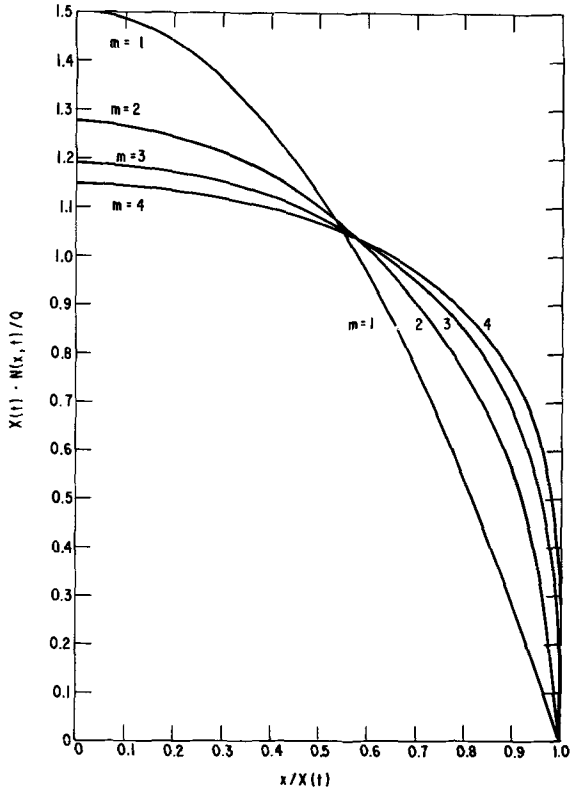

Fig. 1. Plots of normalized concentration profiles for the diffusion coefficient $D = D_0(N/N_0)^m$, with $m = 1, 2, 3, 4$, in a redistribution case with initial concentration represented by a delta function.

Table I. Values of $\int_0^1 (1-\xi^2)^{1/m} d\xi$ for m between 1 and 10

m	$\int_0^1 (1-\xi^2)^{1/m} d\xi$
1	0.6666
2	0.7852
3	0.8409
4	0.8734
5	0.8947
6	0.9098
7	0.9211
8	0.9299
9	0.9368
10	0.9425

From Eq. [24] we observe that a diffusion front advances with the $(m+2)$-root of the diffusion time and that only in the case of a constant diffusion coefficient we obtain the familiar square root law dependence. It is also important to point out that for x larger than $X(t)$ and $m \geq 1$, $N(x,t)$ is identically zero, while for $m = 0$, $N(x,t)$ is represented by an exponential function and is therefore larger than zero for any positive x at any time t after the beginning of the diffusion process. In particular for $m = 1$ and using linear scales the concentration profile is represented between 0 and $X(t)$ by a branch of a parabola, symmetrical with respect to the ordinate axis and with the concavity pointing down, while outside this interval it is coincident with the abscissa axis. As the time increases, the vertex of this parabola, which corresponds to the surface concentration at time t, decreases by a factor inversely proportional to the cubic root of time, while its curvature also decreases shifting its intersection with the abscissa axis at progressively higher x values, which are directly proportional to the cubic root of time, as seen from Eq. [24].

Often the diffusion of impurities into a semiconductor is used for the formation of PN junctions and therefore it is of paramount importance the determination of the diffusion time, τ, required for achieving a desired junction depth, x_j, when besides Q and D the background concentration, N_B, is known. For this purpose we rewrite Eq. [23] in the form

$$\frac{N(x,t) \cdot x}{Q} = \left[\frac{x}{X(t)} \right] \cdot \left\{ 1 - \left[\frac{x}{X(t)} \right]^2 \right\}^{1/m} \Big/ \int_0^1 (1-\xi^2)^{1/m} d\xi \quad [26]$$

and we plot the corresponding family of curves for the first four values of m in Fig. 2. When in Eq. [26],

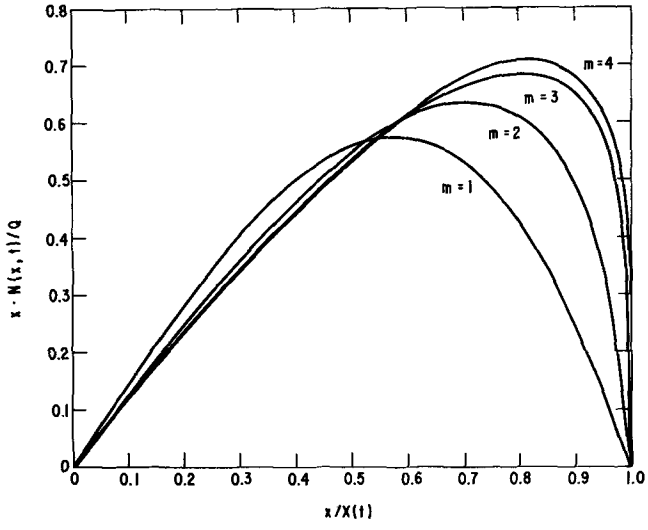

Fig. 2. Plots of $(x \cdot N(x,t))/Q$ vs. $x/X(t)$ for $m = 1, 2, 3, 4$, used in the determination of the diffusion time required for obtaining a desired junction depth, x_j.

$N(x,t)$ is replaced by N_B and x by x_j, two solutions for $x_j/X(\tau)$ are found at the intersection of the appropriate plot of Fig. 2 with the horizontal line of ordinate $(N_B \cdot x_j)/Q$. They both are physically meaningful, because as the diffusion time increases the concentration profile spreads at the expense of its peak height and therefore its intersection with a reference concentration, like N_B, occurs twice at a junction depth x_j at two different times, τ_1, and τ_2.

These two solutions coincide when $(x_j \cdot N_B)/Q$ is equal to the maximum of the plot of Fig. 2 for the corresponding value of m. This means that there is a maximum junction depth, x_{jm}, achievable for any chosen ratio (Q/N_B) and that it can be obtained only with one diffusion time, τ_m.

Equating to zero the derivative of the right-hand member of Eq. [26] we find that the relative maximum occurs at

$$\frac{x_{jm}}{X(\tau_m)} = \sqrt{\frac{m}{m+2}} \qquad [27]$$

and therefore by substituting in Eq. [26] $x/X(t)$ with its expression given by Eq. [27] we obtain x_{jm}

$$x_{jm} = \frac{Q}{N_B} \cdot \sqrt{\frac{m}{m+2}} \cdot \left(\frac{2}{m+2}\right)^{1/m} \Big/ \int_0^1 (1-\xi^2)^{1/m} d\xi \qquad [28]$$

The time τ_m is easily computed from Eq. [24], [27], and [28]

$$\tau_m = \frac{m}{4D_o} \cdot \left(\frac{2}{m+2}\right)^{2(m+1)/m} \cdot \left[\frac{Q}{N_B \int_0^1 (1-\xi^2)^{1/m} d\xi}\right]^2 \cdot \left(\frac{N_o}{N_B}\right)^m \qquad [29]$$

while the corresponding surface concentration, N_{sm} is derived from Eq. [25], [27], and [28]

$$N_{sm} = N_B \cdot \left(\frac{m+2}{2}\right)^{1/m} \qquad [29a]$$

Example

Masters and Fairfield (3) have shown that the diffusion coefficient of As in Si conforms with the relationship

$$D = D_i(n/n_i) \qquad [30]$$

where (n/n_i) is the ratio of the free electron concentration in the extrinsic sample to that of intrinsic silicon at the diffusion temperature.

In Table II the values of n_i and D_i are presented as a function of the diffusion temperature T, having used for their computation the formulas of Ref. (3). Calling N the As concentration, we write following Equation 4 of Ref. (3)

$$\frac{n}{n_i} = \frac{N}{2n_i} + \left[1 + \left(\frac{N}{2n_i}\right)^2\right]^{1/2} \qquad [31]$$

which clearly shows that

Table II. Values of intrinsic carrier concentration in Si, n_i, and intrinsic arsenic diffusion coefficient in Si, D_i, at different diffusion temperatures, T [computed from formulas in Ref. (3)]

T (°C)	n_i (cm^{-3})	D_i (cm^2/sec)
900	4.923×10^{18}	5.505×10^{-17}
1000	9.360×10^{18}	1.437×10^{-15}
1100	1.648×10^{19}	2.333×10^{-14}
1200	2.729×10^{19}	2.594×10^{-13}

$$\frac{n}{n_i} \simeq \frac{N}{n_i} \quad \text{for} \quad N >> 2n_i \qquad [32a]$$

$$\frac{n}{n_i} \simeq 1 \quad \text{for} \quad N << 2n_i \qquad [32b]$$

Therefore the theory developed for the impurity redistribution with concentration dependent diffusion coefficient is only approximate in the As case and its results are reliable in the profile region where the As concentration is larger than $2n_i$ at the diffusion temperature.

Considering for example a diffusion temperature of 1100°C we find from Eq. [24] that

$$X(t) = (9QD_it/n_i)^{1/3} = 2.335 \times 10^{-11} \times Q^{1/3}t^{1/3} \qquad [33]$$

where $X(t)$ is expressed in centimeters, Q in cm^{-2}, and t in seconds. Equation [33] shows that the high concentration region of the diffusion front is advancing in first approximation with the cubic root of the diffusion time instead of with the square root, as in the familiar case of constant diffusivity.

The profile as computed from Eq. [23] is

$$N(x,t) = \frac{3}{2}\frac{Q}{X(t)} \cdot \left\{1 - \left[\frac{x}{X(t)}\right]^2\right\} \quad \text{for } 0 \leq x < X(t) \qquad [34]$$

$$N(x,t) = 0 \quad \text{for} \quad X(t) \leq x < \infty$$

which is a parabola with the concavity facing the negative ordinate direction and with its maximum represented by the surface concentration, followed by the zero solution for values of x larger than the intersection of the parabola with the abscissa axis.

Assuming a P-type background concentration, N_B, larger than 3.296×10^{19} cm^{-3} ($= 2n_i$ at 1100°C), Eq. [28] shows that the maximum junction depth, x_{jm}, achievable for a chosen Q is

$$x_{jm} = \frac{Q}{\sqrt{3}\,N_B} = 0.578 \times \frac{Q}{N_B} \qquad [35]$$

while the time, τ_m, required for obtaining this junction depth with an As diffusion at 1100°C is according to Eq. [29]

$$\tau_m = \frac{Q^2 n_i}{9D_i N_B^3} = 7.848 \times 10^{31} \times \frac{Q^2}{N_B^3} \qquad [36]$$

where τ_m is expressed in seconds, Q in cm^{-2}, and N_B in cm^{-3}.

According to Eq. [29a] the surface concentration for this profile is

$$N_{sm} = 1.5\,N_B \qquad [36a]$$

For carrying on in more detail this example, let us further assume that $N_B = 6 \times 10^{19}$ cm^{-3} and $Q = 1.8 \times 10^{16}$ cm^{-2}, corresponding to an initial box distribution profile 0.1μ deep and with a uniform As concentration of 1.8×10^{21} cm^{-3}, that is equal to the solid solubility of As in Si at 1100°C (4). Substituting these values into Eq. [33], [34], [35], and [36] and using the same units as before unless otherwise specified, we obtain the following results

$$X(t) = 6.1 \times 10^{-6} \times t^{1/3} \qquad [37]$$

$$N(x,t) = \frac{4.42 \times 10^{21}}{t^{1/3}} \times [1 - 2.7 \times 10^{10} \times (x/t^{1/3})^2] \qquad [38]$$

for

$$0 \leq x < X(t)$$

$$x_{jm} = 1.74\mu \qquad [39]$$

$$\tau_m = 1.18 \times 10^5 \text{ sec} = 32.8 \text{ hr} \qquad [40]$$

$$X(\tau_m) = 3.00\mu \qquad [41]$$

$$N_{sm} = 9 \times 10^{19} \text{ cm}^{-3} \qquad [42]$$

It is interesting to observe that due to the small discrepancy between the actual initial distribution and the delta function assumed in the theory, Eq. [37] and [38] are not valid for very small diffusion times. This observation is more of academic interest than of practical importance, because the errors introduced in the profile calculations by random changes in the heat-up times are more relevant. Nevertheless this observation was felt necessary to avoid the impression that Eq. [38] contemplates surface concentrations larger than the solid solubility limit. Indeed a short calculation shows that this happens only in the first 15 sec according to Eq. [38], while the time errors due to the heat-up are usually larger.

Furthermore, the large diffusion time (32.8 hr) required for achieving a junction depth of only 1.74μ operating at 1100°C is somewhat surprising. This is partially due to the high background concentration (6×10^{19} cm^{-3}) assumed in this example, so as in Eq. [41] it is given also the corresponding value of the diffusion front penetration, that is 3μ, which is about twice as large as x_{jm}. But the main reason for this seemingly slow diffusion is the cubic root dependence of $X(t)$ on t, which is more effective in reducing the penetration rate of the diffusion front with time than the familiar square root law.

Summary

A formal solution of the diffusion equation was found for a redistribution of impurities from a thin layer into a semi-infinite medium with an impermeable boundary and a diffusion coefficient proportional to the concentration elevated to an integer power. This solution is represented by a combination of a significant function and by the function identically zero, so as a rigorous definition of the diffusion front is possible. The advancement in depth of the diffusion front with time is following a law, which is different from the square root law and is represented by the $(m + 2)$-root of time for D proportional to N^m. Likewise the surface concentration decreases as the reciprocal of the $(m + 2)$-root of time for a similar diffusion coefficient. Therefore the value of m can be easily inferred from redistribution experiments.

An example of application of this theory is provided by the high concentration diffusion of arsenic into silicon, for which formulas are given and numerical data are computed.

APPENDIX

Verification that $N(x,t)$ given by Eq. [17] is a formal solution of the diffusion equation when $D = KN^m$ and $m \geqq 1$.

Let us assume

$$S(x,t) = \left\{ F^m(0) - \frac{mx^2}{2[K(m+2)t]^{2/(m+2)}} \right\}^{1/m} \quad [A\text{-}1]$$

so as

$$N(x,t) = \frac{S(x,t)}{[K(m+2)t]^{1/(m+2)}} \text{ for } 0 \leqq x < X(t) \quad [A\text{-}2]$$

Therefore

$$\frac{\partial N}{\partial t} = \left(-\frac{1}{m+2}\right)[K(m+2)t]^{-\left(\frac{m+3}{m+2}\right)} K(m+2) \cdot S(x,t) + \frac{1}{[K(m+2)t]^{1/(m+2)}} \cdot \frac{1}{m} \cdot S(x,t)^{(1-m)} \left(-\frac{mx^2}{2}\right) \cdot \left(-\frac{2}{m+2}\right) \cdot [K(m+2)t]^{-\left(\frac{m+4}{m+2}\right)} K(m+2)$$

$$= \frac{KS(x,t)^{(1-m)}}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \left\{ -F^m(0) + \frac{mx^2}{2[K(m+2)t]^{2/(m+2)}} + \frac{x^2}{[K(m+2)t]^{2/(m+2)}} \right\} = \frac{KS(x,t)^{(1-m)}}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \left\{ -F^m(0) + \left(\frac{m+2}{2}\right) \frac{x^2}{[K(m+2)t]^{2/(m+2)}} \right\} \quad [A\text{-}3]$$

$$\frac{\partial N}{\partial x} = \frac{1}{[K(m+2)t]^{1/(m+2)}} \cdot \frac{1}{m} \cdot S(x,t)^{(1-m)} \cdot \left(-\frac{m}{2}\right) \cdot \frac{1}{[K(m+2)t]^{2/(m+2)}} \cdot 2x$$

$$= -\frac{xS(x,t)^{(1-m)}}{[K(m+2)t]^{3/(m+2)}} \frac{\partial}{\partial x}\left(KN^m \frac{\partial N}{\partial x}\right)$$

$$= \frac{\partial}{\partial x}\left\{ -K \frac{S^m(x,t)}{[K(m+2)t]^{m/(m+2)}} \cdot \frac{xS(x,t)^{(1-m)}}{[K(m+2)t]^{3/(m+2)}} \right\}$$

$$= -\frac{K}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \frac{\partial}{\partial x}[xS(x,t)]$$

$$= -\frac{K}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \left\{ S(x,t) + x\frac{1}{m} S(x,t)^{(1-m)} \cdot \left(-\frac{m}{2}\right) \frac{2x}{[K(m+2)t]^{2/(m+2)}} \right\}$$

$$= \frac{KS(x,t)^{(1-m)}}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \left\{ -S^m(x,t) + \frac{x^2}{[K(m+2)t]^{2/(m+2)}} \right\} = \frac{KS(x,t)^{(1-m)}}{[K(m+2)t]^{\left(\frac{m+3}{m+2}\right)}} \cdot \left\{ -F^m(0) + \left(\frac{m+2}{2}\right) \frac{x^2}{[K(m+2)t]^{2/(m+2)}} \right\} \quad [A\text{-}4]$$

The right-hand members of Eq. [A-3] and [A-4] are identical, as required for proving that Eq. [A-1] and [A-2] represent a formal solution of the diffusion equation with the diffusion coefficient specified above.

Vapor-Doped Multislice LPE for Efficient GaP Green LED's

R. H. Saul and D. D. Roccasecca

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A single-step liquid phase epitaxy process has been developed for the growth of efficient GaP green light-emitting diodes (LED's), in which all doping is accomplished from the vapor phase. The use of vapor-phase doping increases the flexibility of the LPE process since junction formation and control of doping profiles is accomplished by regulating the composition and flow rates of the doping gases. This method has been applied to multislice growth on large area substrates (up to 38 mm in diameter). Thin melts and nearly complete utilization of the GaP initially dissolved in the melt minimize the gallium usage. Encapsulated LED's with efficiencies in the 0.10-0.15% range at 7 A/cm^2 are obtained routinely. These efficiencies are comparable to the highest values reported to date for low current (~10 mA) operation. Efficiencies as high as 0.2% have been obtained at 7 A/cm^2 using this method. The short deposition time for this single-step method, reproducibility, multislice capability, and minimum gallium consumption make this method economically attractive for the high level production of efficient green LED's.

Efficient green junction luminescence in nitrogen-doped GaP has been demonstrated for p-n junctions grown by liquid phase epitaxy (LPE) (1-3). The commercial interest in this material for display devices and discrete light emitting diodes (LED's), has stimulated interest in developing inexpensive high capacity LPE systems, capable of producing efficient p-n junctions. In this paper we report on a single-step LPE technique for green LED's which employs vapor-phase doping for p-n junction formation and control of doping profiles. The vapor-doping method has been applied to growth from thin melts and a multislice system capable of producing reproducibly efficient, green LED material is discussed. The single-growth step, high production capability, and minimum Ga consumption make this method economically attractive for commercial applications. A more comprehensive account of the growth procedures and material characteristics will be given elsewhere (4).

Green LED Structure

The LED structure, schematically illustrated in Fig. 1, is similar to that described by Logan and co-workers (1). The recombination and injection processes and their relation to quantum efficiency are discussed elsewhere (5). The p-n junction is formed by LPE on {111}-oriented, n-type, liquid encapsulated Czochralski (LEC) substrates which are doped with the Se donor at a level of $N_D - N_A = 0.3\text{-}1.0 \times 10^{18}$ cm^{-3}. The n-type LPE material is doped with S typically at $N_D - N_A = 1 \times 10^{17}$ cm^{-3}, and the p-type material is doped with Zn at a level of $N_A - N_D \sim 8 \times 10^{17}$ cm^{-3}. The isoelectronic nitrogen center from which the efficient green recombination originates (6), is present in both LPE layers at a concentration of $\sim 7 \times 10^{18}$ cm^{-3}, as determined by optical absorption measurements (1). Previous studies have shown that for these doping levels, the external luminescence is generated equally in the n- and p-regions for operating current densities of 5-10 A/cm^2 (5).

Key words: crystal growth, junction formation, electroluminescence.

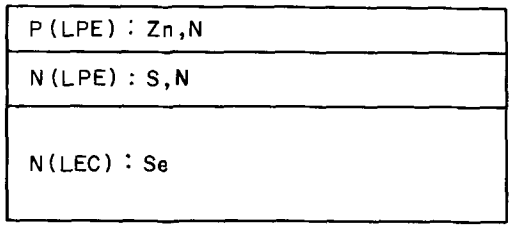

Fig. 1. Schematic representation of the p$^+$-n-n green LED structures.

Junction Formation and Control of Doping Profiles

The high efficiency junctions described by Logan and co-workers (1) were formed by a two-step LPE process involving consecutive growth of the n- and p-layers in separate growth systems. Ladany and Kressel (2) accomplished this in a single-growth system by employing a slider boat containing separate compartments for the n- and p-melts. Recently, Lorimor and co-workers (3) have successfully applied the method of overcompensation (7) to form the p-n junction. This was achieved in a vertical dipping system by growing an n-layer from a S- or Te-doped melt and then adding a pellet of metallic Zn to the melt (via a drop tube) to produce an overcompensated (*i.e.*, p-type) layer on further cooling. The single-step nature of this method and that of Ladany (2) is expected to improve reproducibility, however, the doping profiles are not readily controlled (especially for the overcompensation method) as discussed below.

In Fig. 2 we show the doping profile, variation of doping level along the growth direction, for a p-n

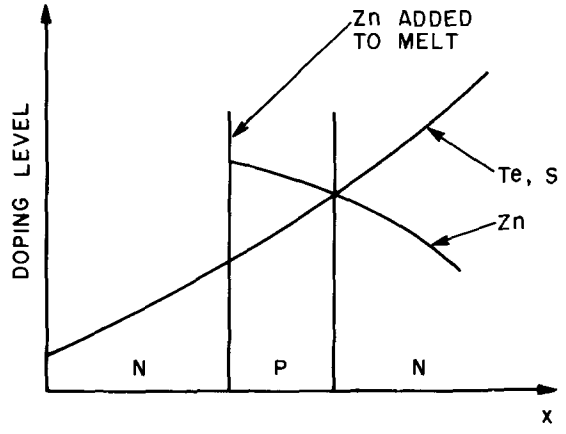

Fig. 2. Variation of doping level along the growth direction for the overcompensation method employing direct melt additions. The N concentration (not shown) is essentially constant. The substrate is located at $x = 0$.

junction formed by overcompensation employing direct melt additions. The Te (or S) concentration increases along the growth direction as a result of the increasing distribution coefficient with decreasing temperature (8). On the other hand, the Zn concentration decreases as a result of the decreasing distribution coefficient with decreasing temperature (9, 10) and volatilization of Zn from the melt in open flow systems. As shown in Fig. 2, these effects result in an increasingly compensated p-layer. Eventually, the donor concentration exceeds the acceptor concentration and the material reverts back to n-type giving a n-p-n structure. The increased compensation and formation of an n-skin will also result without intentional donor additions because of the net donor concentration associated with residual impurities (10, 11). To provide low voltage LED's, growth must be terminated not only prior to the formation of the n-skin, but before the net acceptor concentration in the p-layer is reduced to levels $N_A - N_D \lesssim 1 \times 10^{17}$ cm^{-3}, where low voltage ohmic contacts are difficult to form. These considerations become more important for growth from thin melts (next section) where a wide temperature range is required to grow layers of sufficient thickness (~25-40μ).

In this work, we have employed vapor-phase doping for both junction formation and control of doping profiles in the grown layers. Since all doping is done from the vapor phase, the geometry of the LPE system can be relatively simple and the method is readily adapted to growth from thin melts (12, 13). The donor S is introduced by passing H_2S over the growth solution, the acceptor Zn is obtained from an evaporating elemental source, and N is introduced in the form of NH_3. All constituents are added using palladium-diffused H_2 as a diluent carrier gas and controlled doping is achieved by regulating the respective gas flow rates.

The doping profile obtained using vapor-phase doping is shown in Fig. 3. In a typical growth run, the n-layer is first grown from a S,N-doped melt. The increasing S concentration along the growth direction can be maintained constant by reducing the H_2S flow rate during cooling; in practice, the normally obtained gradient is not detrimental so this adjustment is not made. When growth is terminated by interrupting the cooling, the H_2S is purged from the reactor tube using H_2 and the dissolved S is transformed back to H_2S. Simultaneously Zn vapor is introduced into the gas flow. After an equilibration period, cooling is continued to grow the p-layer. The overcompensation of the p-layer is virtually eliminated by the effective removal of S from the melt.

The incorporated Zn level, C^S_{Zn}, is determined by the distribution coefficient, viz.

$$C^S_{Zn} = k(T, C^l_{Zn})C^l_{Zn} \quad [1]$$

where, as discussed earlier, k decreases with decreasing T. For ideal solutions ($\gamma^l_{Zn} \approx 1$), the liquid concentration C^l_{Zn} is given by

$$C^l_{Zn} \simeq p_{Zn}(f, T_s)/p^o_{Zn}(T) \quad [2]$$

where p_{Zn}, the Zn partial pressure over the melt, is determined by the relative flow rate f over the evaporating elemental source maintained at temperatures T_s. The quantity $p^o_{Zn}(T)$ is the vapor pressure over elemental Zn at the growth temperature T. Combining Eq. [1] and [2], C^S_{Zn} is given by

$$C^S_{Zn} = [k(T, C^l_{Zn})/p^o_{Zn}(T)]p_{Zn}(f, T_s) \quad [3]$$

The Zn distribution can therefore be readily controlled by varying f or T_s during cooling. For the case of constant f and T_s, the Zn distribution in the solid is determined by the bracketed term in Eq. [3]. Using Jordan's (9) values of k and p^o_{Zn} obtained from Ref. (14), the equilibrium Zn distribution can be shown to be essentially invarient, as verified experimentally. This produces the desirable result of moderate surface doping levels ($N_A - N_D \sim 6 \times 10^{18}$ cm^{-3}) for application of ohmic contacts and minimization of current crowding under the top contact. (Free carrier absorption at these doping levels is negligible compared to the A-line self-absorption). When the p-layer is partially compensated by residual S, the same surface (net) doping level can be achieved by increasing f during cooling.

The requirements for producing the abrupt changes in doping levels needed for junction formation and control of doping profiles are: (*a*) a reactor tube which minimizes incorporation of previously used dopants (so-called memory effect); and (*b*) appropriate design of the LPE boat to permit rapid communication between the melt and (doping) vapor phase.

Reactor tube design.—In Fig. 4 we show a schematic representation of the reactor tube. The tube consists of (*i*) an active zone in which the crystal growth and doping takes place, and (*ii*) a passive zone which provides the vapor source of Zn. The two zones are isolated by a connecting capillary tube. This restriction also increases the flow velocity of the Zn vapor to the active zone when the flow of carrier gas (H_2) is initiated. All dopants are introduced in the hot zone using independent delivery tubes. This has been found to be essential to reduce system memory effects. An LPE slider boat rests on a quartz ramp of rectangular cross section and is accurately positioned in the hot zone by a depression in the ramp. The transverse motion of the slider is accomplished using a push rod fed through a Teflon O-ring seal. Loading is accomplished within a nitrogen-filled chamber and is countercurrent to the gas flow to minimize entrance of contaminants into the system. The active zone is contained in a modified diffusion furnace. The Zn boat in the passive zone is maintained at $T_s \sim 600$°C, using a

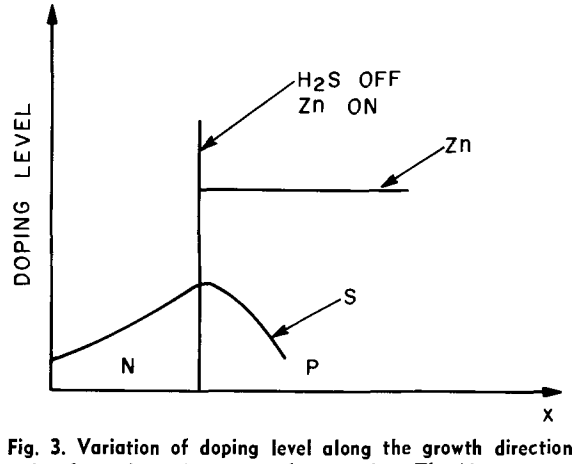

Fig. 3. Variation of doping level along the growth direction for junction formation using vapor-phase doping. The N concentration (not shown) is essentially constant.

separately controlled furnace. An evaporating sodium heat pipe is used to provide a constant temperature zone T_s (±5°C) which is independent of the active zone, as the temperature of the latter varies during the growth cycle.

LPE system.—A thin melt LPE apparatus is used for growth of the GaP layers. As in earlier (13, 15) double slider boats, the thin melts are produced by sectioning a reservoir melt into increments (aliquots) of equal thickness. The multislice LPE boat which we are currently using is schematically illustrated in Fig. 5. Six substrates up to 38 mm in diameter can be accommodated in this prototype system. The carbon boat utilizes 1-2 mm aliquot melts which are sequentially formed by passing a slider containing the substrates under the reservoir melt. The formation of thin aliquots is aided by the wetting action of the substrates and the use of a nonwetting (carbon) cover plate which confines the aliquot (13). The aliquot thickness is determined by the depth of the substrate well. As shown in Fig. 5, the aliquot cover plate is perforated to maximize communication with the gas phase. Previous double-slider boats (13, 15) utilized a second slider to confine the aliquot and to terminate growth (by wiping the melt from the substrate) for control of the surface doping levels. In the present case, the former is achieved with a stationary cover plate and the surface doping levels are controlled from the gas phase. Approximately 90% of the GaP in solution is deposited on the substrates, owing to the high deposition efficiency from thin melts (13) and cooling to low temperatures where melt depletion is nearly complete.

Discussion

The growth conditions which are most widely used are summarized in Table I. The partial pressures of H_2S and Zn are appropriate for achieving the desired doping levels (see section on Junction Formation and Control of Doping Profiles) while the NH_3 pressure is maintained below the level where solid GaN becomes an equilibrium phase (16). (The NH_3 purification as described in Ref. (1) was not utilized in this work, however extreme care was taken to eliminate air leaks and other sources of oxygen.) Growth of the n-layer occurs over the indicated temperature interval after a suitable equilibration period. Termination of the n-growth is achieved by interrupting the cooling during which time the H_2S is purged from the system and the carrier flow is started over the hot Zn source. Approximately 30-60 min are required to equilibrate the gas dopants. The p-layer is then grown by cooling to low temperatures (<865°C) where the melt is essentially depleted. A total growth time of less than 2 hr is possible, independent of the number of substrates. After completion of a run, Ga adhering to the substrates is readily removed by mechanical swabbing and/or aqueous etching. Since the melt is depleted when growth of the p-layer is terminated, the smoothness of the as-grown surface is not dictated by the effectiveness of the Ga removal, as in the usual case where growth is terminated at elevated temperatures.

Table I. Summary of growth conditions

	Partial pressure of dopants (atm)*			Growth interval (°C)**	
	H_2S	NH_3	Zn	$T_{initial}$	T_{final}
N-layer	~6 × 10⁻⁷	8 × 10⁻⁴	—	1015°	950°
P-layer	—	8 × 10⁻⁴	1.8 × 10⁻³	950°	<865°

* A hydrogen carrier gas is used for all dopants.
** The cooling rate is 3°/min.

This system has been extensively operated according to the schedule given in Table I using from one to six 25-35 mm substrates in a given run to produce a total of ~80 p-n junction slices. [During the latter stages of this work, the growth process was automated so that the entire junction formation sequence was executed without operator assistance (17).] The doping levels were found to be reproducible with no indication of memory effects even after 50 consecutive runs with the same reactor tube. The excellent surface quality and layer thickness uniformity ($\lesssim$10%) is typical of slider-grown LPE material. The green[1] electroluminescence efficiency was determined using a calibrated close-couple cavity (18) for both slurry-cut die and abrasive-honed mesas which were wire bonded and mounted on TO-18 headers, the former being used for rapid material evaluation. Measurements were made at a forward current density of ~7 A/cm² (10 mA for a 0.015 × 0.015 in. die). In a given multislice run, variations of ~±10% in slice-to-slice average efficiency have been observed, which probably represent the reproducibility of the measuring technique. The efficiencies of epoxy-coated diodes in the mesa configuration routinely ranged between 0.10-0.15%, for both d-c and pulsed measurements. These efficiencies compare favorably with the 0.09-0.14% reported by Logan (1) (using LEC substrates), Ladany (2) and Lorimor (3), for mesa diodes at this current density. Several encapsulated die mounted (without reflectors) on TO-18 headers had efficiencies of 0.2% at 7 A/cm². This is the highest efficiency reported to date for low current operation. Although extensive measurements have not been performed at high current densities where pulsed excitation is required to avoid device heating, the increase in efficiency per decade of current density is roughly a factor of two less than that indicated by Ladany (2). This difference may be associated with the higher donor concentrations and the presence of N in the p-layers for our structures.

Summary

We have described a single-step LPE process for GaP green LED's which utilizes vapor-phase doping. Vapor-phase doping substantially increases the flexibility of the LPE process since junction formation and the control of doping profiles are achieved by regulating the flow of doping gases. Termination of growth is not required to control surface doping levels as with conventional doping methods (*i.e.*, direct additions to the melt) and thus ~90% of the GaP initially dissolved in the melt is grown on the substrate. This method has been applied to multislice growth from thin (1-2 mm) melts by providing access holes so that the melt, which is confined over each substrate, can communicate with the gas ambient. The prototype LPE system described here accommodates six substrates up to 38 mm in diameter, and yielded LED's which routinely were in the 0.10-0.15% range at 7 A/cm². A total growth time (n-layer plus p-layer) of less than 2 hr is possible, independent of the number of substrates. The speed of this single-step technique, its multislice capability and its minimal Ga consumption make this method economically attractive for high level production of efficient green LED's.

[1] The measurement apparatus incorporates a filter to provide a 30:1 red to green rejection ratio. It should be noted also that the integrated green to red ratio for typical diodes is 10:1.

Acknowledgments

The authors are indebted to W. H. Hackett, Jr. and R. Z. Bachrach for providing the efficiency and N-level determinations. We also thank P. Garbinski for fabrication of the mesa diodes. We especially acknowledge the skillful assistance of C. R. Paola in designing the LPE apparatus, and helpful discussions with numerous colleagues.

Manuscript submitted Feb. 15, 1973; revised manuscript received March 30, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Technical Notes

Reduction of Carrier Concentration in $Pb_{1-x}Sn_xTe$ by Cd Diffusion and Doping with Zn

K. J. Linden

Infrared and Optical Research Laboratory, Special Microwave Devices Operation, Raytheon Company, Waltham, Massachusetts 02154

The compounds PbTe and SnTe form a complete series of pseudobinary solid solutions ($Pb_{1-x}Sn_xTe$, where $0 \leq x \leq 1$) characterized by the rock-salt crystal structure. These alloys have received considerable attention because they can be used to prepare high performance infrared detectors, operating at 77°K and above, that are sensitive in the 8-14 μm atmospheric window region of the infrared spectrum (1). The alloys of particular interest for this application are those with compositions in the range $0.18 < x < 0.25$, since their energy gaps lead to detector responsivities peaking in this region.

As is the case for PbTe and SnTe, as-grown crystals of $Pb_{1-x}Sn_xTe$ obtained from stoichiometric source materials by either melt-growth or vapor-growth techniques are strongly p-type, with carrier concentrations typically in the range between 10^{18} and 10^{19} cm^{-3}. The acceptors responsible for these high hole concentrations are native point defects that are present because the crystals are Te-rich with respect to the stoichiometric composition (2). In order to obtain material for device applications, annealing can be used to decrease the hole concentration by reducing the amount of excess Te or to convert the crystals to low concentration n-type by making them slightly Pb rich.

Reduced carrier concentrations in $Pb_{1-x}Sn_xTe$ with $x \approx 0.2$ have generally been obtained by an isothermal annealing technique (1, 3). The crystals are typically annealed in an ampoule containing a metal-rich, solid-liquid $(Pb_{1-x}Sn_x)_yTe_{1-y}$ mixture with the same x value as that of the crystals, but with y (typically 0.51) outside the homogeneity range of $Pb_{1-x}Sn_xTe$. The crystals change their composition by solid-state diffusion until they reach equilibrium with the vapor phase by becoming metal saturated. At equilibrium, their deviation from stoichiometry is therefore determined by the location of the metal-rich solidus for their particular x-value at the specific annealing temperature used.

The metal-rich solidus lines for $Pb_{1-x}Sn_xTe$ alloys with $x \approx 0.2$ cross the stoichiometric composition line, where the conductivity changes from p- to n-type, so that in principle the isothermal annealing technique could be used to obtain exactly stoichiometric material if the proper annealing temperature were used. However, near the crossover point the carrier concentration along the solidus line varies so strongly with annealing temperature that concentrations below 10^{16} cm^{-3} have not been reproducibly obtained, although a concentration of 1.8×10^{15} cm^{-3} has been reported for an n-type sample of $Pb_{0.83}Sn_{0.17}Te$ (4). Furthermore, for certain alloy compositions (namely those associated with smaller energy gaps) the lower isothermal annealing temperatures required to obtain reduced carrier concentrations necessitate the use of long annealing times.

Since as-grown $Pb_{1-x}Sn_xTe$ is normally p-type, the introduction of donor impurities can be expected to result in carrier concentration reductions. Elements from Group III of the periodic table (*e.g.*, Al and Ga) are capable of acting as donor impurities in PbTe in that when substituted for the Pb atom they provide an extra electron. These impurities may also increase the ratio of metal to nonmetal atoms and thereby lead to reduced carrier concentrations. The Group V atoms, Bi and Sb, behave in a similar manner in PbTe (5). The Group II impurities Zn and Cd have also been

Key words: lead tin telluride, infrared detectors, photoconductors, chalcogenides, ternaries.

shown to act as donor impurities, and low carrier concentrations have been achieved in $Pb_{0.83}Sn_{0.17}Te$ by annealing in the presence of these elements (6). Since these atoms have the same number of available electrons as Pb and Sn, their donor behavior is presumably the result of their increasing the metal to nonmetal ratio.

By the diffusion of vapor-grown samples of $Pb_{1-x}Sn_xTe$ with Zn and Cd, Antcliffe and Wrobel (6) obtained n-type material with carrier concentrations of 1.3×10^{17} cm^{-3} and mobilities up to 5×10^5 cm^2 V^{-1} sec^{-1} at 4.2°K. Using radioactive tracer methods, these authors found the Zn concentrations to be of the same order of magnitude as the excess hole concentrations in the material prior to diffusion, and therefore postulate that the Zn solubility is controlled mainly by the concentration of Pb vacancies. In the experiments reported here, diffusion experiments were performed on p-type vapor-grown crystals of $Pb_{1-x}Sn_xTe$ under various Cd vapor pressures. The results of attempts to incorporate Cd and Zn impurity atoms into $Pb_{1-x}Sn_xTe$ crystals during the vapor-growth process are also reported.

Cadmium diffusion experiments.—Cadmium diffusion experiments were carried out on $Pb_{0.76}Sn_{0.24}Te$ crystals grown from a stoichiometric source by a closed-tube vapor-growth technique similar to the one described by Calawa *et al.* (3). Such crystals were used since they generally have crystallographic and electrical properties superior to those of crystals obtained by melt-growth techniques such as the Bridgman method. This has been verified by cleavage experiments performed in this laboratory in which near-identically shaped and oriented samples of both Bridgman-grown and vapor-grown $Pb_{1-x}Sn_xTe$ were subjected to cleavage tests. It was found that the vapor-grown samples were characterized by cleavage faces with considerably fewer defects than those observed in the cleaved faces of Bridgman-grown samples. It was also found that photodiodes fabricated from vapor-grown material generally had higher quantum efficiencies than those fabricated from Bridgman-grown material.

Two different diffusion techniques were used: a single-zone method with elemental Cd as the source, and a two-zone technique in which the $Pb_{0.76}Sn_{0.24}Te$ crystals were held at one temperature and a Cd-In alloy source was at a lower temperature.

In the single-zone method, three to five crystals of $Pb_{0.76}Sn_{0.24}Te$ were sealed in an evacuated quartz capsule together with a weighed amount of Cd. Typical hole concentrations in the as-grown crystals varied from approximately 10^{18} to 10^{19} cm^{-3} at 77°K. Diffusions were carried out for 3 days at 600°C. Different Cd partial pressures were obtained by varying the amount of Cd in the capsule, which had a volume of about 35 cm^3. After diffusion, the capsule was removed from the furnace in such a manner that the Cd vapor condensed on one end of the capsule rather than on the crystals (which radiate efficiently and can therefore cool rapidly). The crystals were removed from the capsule, lapped to thicknesses of about 0.75 mm, polished, and etched. The resistivity and Hall coefficient of each crystal were then measured at 77°K by the van der Pauw method (7).

While it was not practical to remeasure the electrical characteristics of a given sample after repeated runs under the same diffusion conditions (since the effect of the soldered contacts at elevated temperatures would introduce an additional unknown), experiments showed that the length of the annealing times used (3 days) was sufficient to produce equilibrium for even the largest samples. This was demonstrated by annealing some samples for longer periods, and others for shorter periods. Samples annealed for longer times did not exhibit further changes in carrier concentration and mobility, but samples annealed for less than 2 days did not appear to have reached equilibrium.

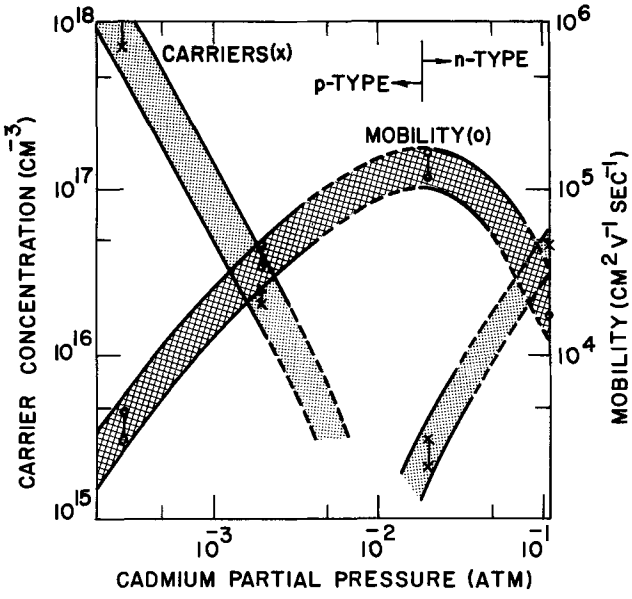

Fig. 1. Carrier concentration and mobility of $Pb_{0.76}Sn_{0.24}Te$ doped with cadmium by postgrowth diffusion using a single-zone method.

The results of the single-zone diffusion experiments are given in Fig. 1, which shows the carrier types, concentrations, and mobilities of crystals annealed under Cd partial pressures between about 3×10^{-4} and 1.1×10^{-1} atm. The pressure values were calculated by the perfect gas law from the amount of Cd introduced into each capsule. At the lowest Cd partial pressures shown in Fig. 1, the observed carrier concentrations and mobilities were similar to those of nonannealed material. As higher partial pressures were used, reduced carrier concentrations and increased mobility values were observed until, at partial pressures in excess of approximately 10^{-2} atm, the material converted from p- to n-type. The lowest carrier concentration attained by this single-zone diffusion method was 2.3×10^{15} cm^{-3}, n-type, with an accompanying mobility of 1.95×10^5 cm^2 V^{-1} sec^{-1}. From the slope of the curves in Fig. 1 it is clear that the attainment of carrier concentrations much below this value can be expected to be increasingly difficult. Further increases in Cd partial pressure lead to increased electron concentrations and reduced mobility values. Surface alloying of the Cd with the $Pb_{0.76}Sn_{0.24}Te$ was observed at the highest Cd pressure used (1.1×10^{-1} atm). At this pressure, the amount of Cd in the capsule was sufficiently large to cause condensation on the samples. In these experiments, it was assumed that the Pb-Sn ratio of the annealed crystals was the same as the ratio prior to annealing, this ratio having been initially determined by microprobe analysis.

The spread in data indicated in Fig. 1 is probably due to a combination of factors such as a variation in the carrier concentration of the as-grown crystals and differences in the total weight of the $Pb_{0.76}Sn_{0.24}Te$ crystals from one capsule to the next. The data points for a given annealing temperature were generally obtained for crystals grown in separate runs, although those at 2×10^{-3} atm were obtained for crystals from the same growth run. Each data point represents a different annealing run.

Assuming a linear relationship between density of states effective mass and energy gap, which is supported by $Pb_{1-x}Sn_xTe$ laser emission data, Melngailis and Harman (1) have calculated the intrinsic carrier concentrations for various temperatures as a function of energy gap. For material with a bandgap of approximately 0.09 eV at 77°K, the calculated intrinsic carrier concentration at 77°K is approximately 8×10^{13} cm^{-3}. Thus the lowest carrier concentration achieved in the above series of Cd diffusions was from one to two orders of magnitude larger than the cal-

culated intrinsic carrier concentration. It should be noted that, while $Pb_{0.76}Sn_{0.24}Te$ has been made n-type by annealing at 600°C in a Cd atmosphere, this cannot be achieved by isothermal annealing at this temperature in the absence of impurities since, for this composition, even metal-saturated crystals are p-type at 600°C (3).

The homogeneity of the annealed samples was studied by electron-microprobe analysis using a 1 μm diameter electron beam to scan the wafer surfaces. This analysis did not reveal any compositional inhomogeneities or precipitates to within the accuracy of the instrument (1-2%). However such microprobe analysis is incapable of revealing the presence of any microprecipitates which are considerably smaller than 1 μm in dimension or microprecipitates located more than an electron beam absorption length (on the order of a few micrometers) below the sample surface. It has been shown by Wolfe, Stillman, and Rossi (8) that inhomogeneities in semiconductors can result in anomalously high mobility values. It is therefore possible that the high value of mobility observed here could be due to the presence of some microprecipitates or microinhomogeneities in the samples.

In a second type of Cd diffusion experiment, $Pb_{0.76}Sn_{0.24}Te$ crystals and a Cd source were sealed into an evacuated quartz capsule which was then placed in a two-zone furnace. The crystal temperature was held at 500°C, while in different runs the source temperature was varied from approximately 120° to 265°C. In order to reduce the possibility of surface alloying as well as the dependence of Cd partial pressure on source quantity, an infinite alloy source of 1% Cd in In weighing approximately 0.2g was used. Since the vapor pressure of In is eight orders of magnitude less than that of Cd, and Cd readily alloys with In to form a soft, dilute mixture, the 1% Cd in In alloy proved to be a convenient diffusion source. The results of this second series of Cd diffusion experiments are summarized in Fig. 2. As in the first series of experiments, measurements on samples in the van der Pauw configuration were used to determine carrier concentrations and mobilities. As the diffusant source temperature was increased from 120°C, the hole concentration decreased and the mobility increased until, at approximately 200°C, the material converted from p- to n-type. The lowest carrier concentration achieved by this two-zone diffusion technique was 1.4×10^{15} cm^{-3} with an accompanying mobility of 1.85×10^5 $cm^2\ V^{-1}\ sec^{-1}$. This concentration is somewhat lower than the lowest obtained by the single-zone diffusion method. In connection with the high mobility value observed here, the same comments regarding the possibility of microinhomogeneities causing anomalous mobility values as noted above are relevant, even

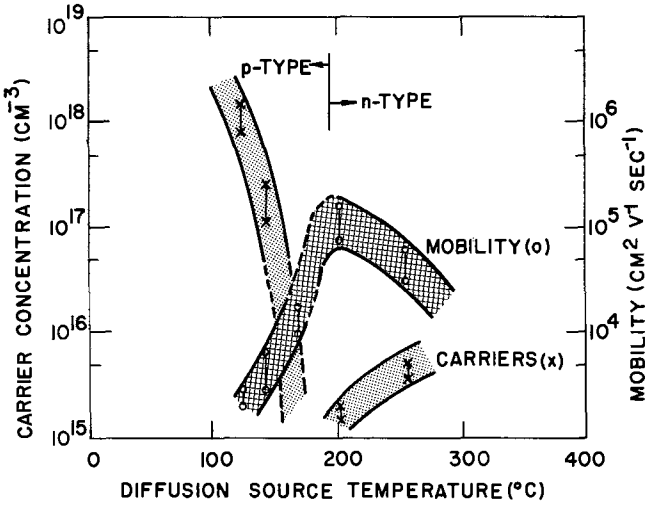

Fig. 2. Carrier concentration and mobility of $Pb_{0.76}Sn_{0.24}Te$ diffused from a 1% Cd in In source using a two-zone method.

though electron-microprobe scans of these samples revealed no inhomogeneities.

In order to determine whether any significant outdiffusion of Cd from $Pb_{1-x}Sn_xTe$ would occur under elevated-temperature vacuum conditions (such as might occur during the vacuum Dewar packaging of devices), Cd-diffused van der Pauw samples were baked at 125°C for 8 days under a dynamic vacuum of approximately 10^{-8} Torr. As might be expected for a temperature so low compared to the in-diffusion temperature, no changes in either the carrier concentrations or the mobilities were observed.

Cadmium and zinc incorporation into $Pb_{1-x}Sn_xTe$ during vapor growth.—Experiments were also performed to determine whether a reduction in carrier concentration could be achieved by incorporating Cd or Zn into $Pb_{1-x}Sn_xTe$ during crystal growth from the vapor phase. Either elemental Cd or Zn was introduced into the vapor-growth capsules, which were maintained in a horizontal position to prevent alloying of the metal with the $Pb_{1-x}Sn_xTe$. This technique is inherently less versatile than the methods described previously since the impurity can be incorporated into the crystals only at the growth temperatures, which typically range from 700° to 800°C. On the other hand, the method is in principle convenient since the impurities are introduced during growth and no postgrowth annealing is required. A range of impurity partial pressures was obtained by introducing amounts of Cd or Zn varying from 10^{-5} to 10^{-3}g into the growth capsules, which had volumes between 100 and 300 cm^3. With increasing Cd or Zn pressure the as-grown crystals changed from p- to n-type, and carrier concentrations as low as 4.4×10^{16} cm^{-3} were obtained. However, the results were so irreproducible that this method does not appear to be feasible for obtaining low carrier concentrations.

Conclusion

Experiments were carried out to explore possible methods of reducing carrier concentrations in $Pb_{1-x}Sn_xTe$ vapor-grown crystals. A significant reduction in carrier concentration accompanied by an increase in mobility has been achieved by using one-zone and two-zone annealing techniques for the diffusion of Cd into vapor-grown crystals of $Pb_{0.76}Sn_{0.24}Te$. The reduction in carrier concentration should make it possible to fabricate efficient photoconductive detectors and potentially to produce low capacitance photodiodes.

The General Problem of Rediffusion in Semiconductor Devices

M. A. Fullenwider*,[1]

Institute for Inorganic, Analytic, and Physical Chemistry, University of Bern, Bern, Switzerland

The problem of rediffusion (solution for the flux out of precharged specimens and the resulting concentration profiles) has been solved for many cases. Two cases of particular importance have been solved (1) for semi-infinite specimens. They are (*i*) the case of the uniform initial condition and (*ii*) the case of the error function complement initial condition. The expressions for the flux (J_t) at the surface are, respectively

$$J_t = C_o\left(\frac{D}{\pi t}\right)^{1/2}\left[1 - 2\sum_{n=0}^{\infty}(-1)^n e^{-(n+1)^2L^2/Dt}\right] \quad [1]$$

an equation applying to a finite specimen, with the approximation for semi-infinite specimens

$$J_t = C_o\left(\frac{D}{\pi t}\right)^{1/2} \quad [1a]$$

Note that Eq. [1] as it appears in Ref. (1) is in error by a factor of 2. And

$$J_t = \frac{D^{1/2}C_o}{\pi^{1/2}}\left[\frac{1}{t^{1/2}} - \frac{1}{(t+t_o)^{1/2}}\right] \quad [2]$$

and for the concentration profiles, $C(x, t)$, during the rediffusion process, respectively

$$C(x,t) = C_o - C_o\sum_{n=0}^{\infty}(-1)^n \operatorname{erfc}\frac{(2n+1)L - x}{2(Dt)^{1/2}} - C_o\sum_{n=0}^{\infty}(-1)^n \operatorname{erfc}\frac{(2n+1)L - x}{2(Dt)^{1/2}} \quad [3]$$

and

$$C(x,t) = C_o\left[\operatorname{erf}\frac{x}{2(Dt)^{1/2}} - \operatorname{erf}\frac{x}{2(Dt_o + Dt)^{1/2}}\right] \quad [4]$$

where: C_o is the maximum concentration within the specimen at the time rediffusion starts; D, the diffusion coefficient; t, the time of rediffusion after the surface concentration has been made zero; t_o, the time that the specimen is allowed to charge with the diffusing species; x, the distance into the specimen; and L, the thickness of the specimen.

These expressions have been of great utility. For example, Eq. [2] was used (1) to extend the evaluation of D for hydrogen in metals by a factor of approximately 10^5.

The error function complement profile is one of the two types of profiles commonly found in semiconductor devices, corresponding to a constant quantity of the impurity at the surface of a semi-infinite specimen during diffusion into the semiconductor. The other case, the problem of rediffusion, to be discussed here since it does not appear in the literature, is that of a Gaussian concentration profile, corresponding to a finite quantity of the impurity at the surface of the semiconductor. The solutions to these problems of rediffusion should be of interest to solid-state scientists since, by varying the two quantities, (*i*) time of diffusion into the specimen and (*ii*) time of rediffusion out of the same specimen, quite a variety of known profiles can be easily prepared.

The expression for the initial condition of the problem to be discussed here is (2)

$$C(x, t_o) = C_o e^{-x^2/4Dt_o} \quad [5]$$

where the symbols have the same definition as previously. Also

$$C_o = \frac{Q}{(\pi Dt_o)^{1/2}} \quad [6]$$

where Q is the amount of diffusing substance at the surface initially. To obtain a solution to the problem of rediffusion in this case we use the Green's function representation of the diffusion equation. Thus we have in one dimension (3)

$$C(x,t) = \int (u)_{\tau=0} f(x')\,dx' + D\int_o^t \phi(\tau)\frac{\partial u}{\partial n_i}\,d\tau \quad [7]$$

where $f(x')$, is the initial distribution; $\phi(\tau)$, the surface distribution; $\partial/\partial n_i$, the differentiation along the inward drawn normal to the surface; and u, the Green's function, is the concentration at x' and time t due to a unit instantaneous source at x and time τ. In this case we have (3)

$$u = \frac{1}{[4\pi D(t-\tau)]^{1/2}}\{e^{-(x-x')^2/4D(t-\tau)} - e^{-(x+x')^2/4D(t-\tau)}\} \quad [8]$$

also

$$\phi(\tau) = 0 \quad [9]$$

Thus

$$C(x,t) = \frac{C_o}{(4\pi Dt)^{1/2}}\int_o^{\infty} e^{-x'^2/4Dt_o}\, e^{-(x-x')^2/4Dt}\,dx' - \frac{C_o}{(4\pi Dt)^{1/2}}\int_o^{\infty} e^{-x'^2/4Dt_o}\, e^{-(x+x')^2/4Dt}\,dx' \quad [10]$$

and by a known definite integral we have for the concentration profile

$$C(x,t) = C_o\left(\frac{t_o}{t+t_o}\right)^{1/2} e^{-x^2/4D(t+t_o)} \operatorname{erf}\left\{x\left[\frac{t_o}{4D(t^2+tt_o)}\right]^{1/2}\right\} \quad [11]$$

and since

* Electrochemical Society Active Member.
[1] Present address: 2970 MacArthur Road, White Hall, Pennsylvania 18052.
Key words: rediffusion, concentration profiles.

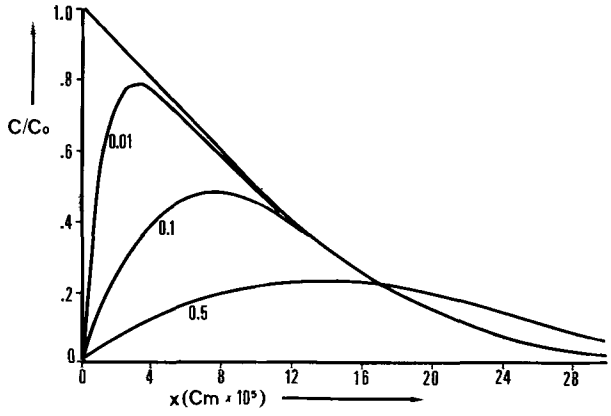

Fig. 1. Error function complement initial condition, surface concentration zero during rediffusion.

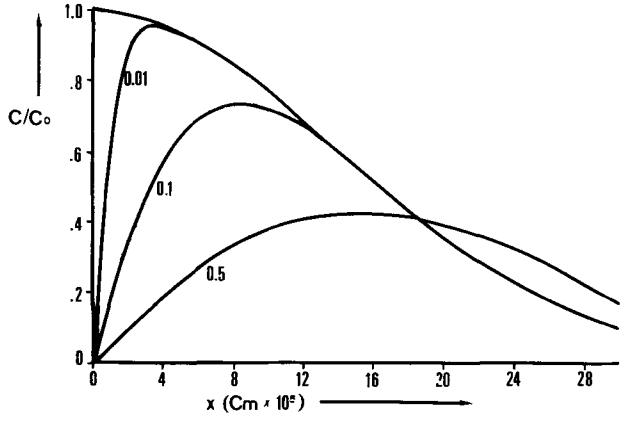

Fig. 2. Gaussian initial condition, surface concentration zero during rediffusion.

$$J_t = -D\left(\frac{\partial C}{\partial x}\right)_{x=0} \qquad [12]$$

we have for the flux at the surface

$$J_t = \frac{D^{1/2} C_o}{\pi^{1/2}}\left[\frac{t_o}{t^{1/2}(t + t_o)}\right] \qquad [13]$$

Also putting Eq. [6] into Eq. [13] we have an interesting expression involving only J_t, Q, t, and t_o

$$J_t = \frac{Q}{\pi}\left[\frac{t_o^{1/2}}{t^{1/2}(t + t_o)}\right] \qquad [14]$$

Now Eq. [4] and Eq. [11] hold only for the case of zero surface concentration during the rediffusion process. To obtain solutions for cases where the surface concentration has some constant nonzero value it is only necessary to add to these solutions the quantity (from Eq. [7] and Eq. [8] with $f(x') = 0$ and $\phi(\tau) = C_1$, the concentration at the surface during rediffusion)

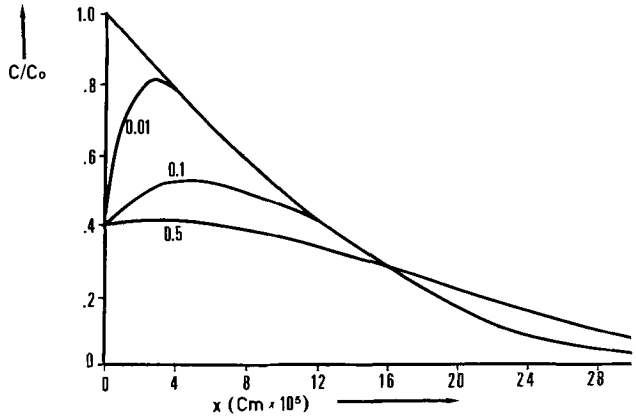

Fig. 3. Error function complement initial condition, $C_1/C_o = 0.4$ during rediffusion.

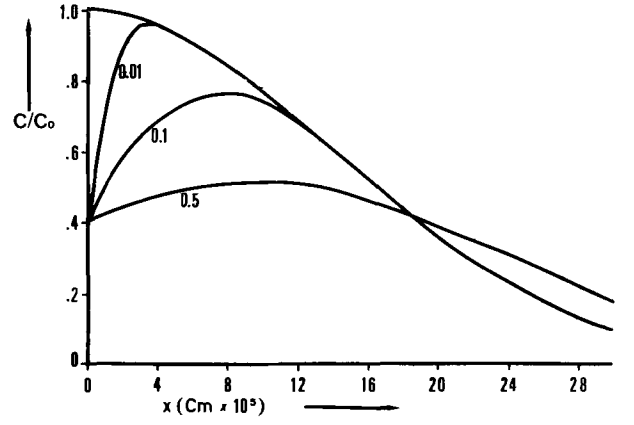

Fig. 4. Gaussian initial condition, $C_1/C_o = 0.4$ during rediffusion

$$C(x, t)_{f(x')=0} = \frac{C_1 x}{(4\pi D)^{1/2}}\int_o^t \frac{e^{-x^2/4D(t+\tau)}}{(t - \tau)^{3/2}}\, d\tau \qquad [15]$$

which is simply

$$C(x, t)_{f(x')=0} = C_1 \operatorname{erfc}\frac{x}{2(Dt)^{1/2}} \qquad [16]$$

Figures 1-4 illustrate some typical concentration profiles. The numbers on the curves are the ratios of t to t_o.

Impurity Atom Distribution Resulting from Thermal Redistribution of an Implanted Impurity Source

David S. Perloff

Research and Development Laboratory, Signetics Corporation, Sunnyvale, California 94086

The diffusion into silicon of impurities introduced by implantation is acquiring increasing significance in device and circuit fabrication (1-4). An important advantage of this method is that the implanted impurities may be thermally redistributed without concurrent oxidation if the implantation is carried out

Key words: diffusion, ion implantation, oxide, semiconductor, silicon.

through an existing oxide layer of sufficient thickness (1, 5). For such a case, a general solution of the diffusion equation may be obtained which describes the distribution of impurities within the semiconductor and, under a rather unrestrictive assumption, within the oxide layer. A related problem has been treated by Kennedy and Murley (6) for the two-step diffusion process traditionally employed for transistor fabrication.

In certain MOS applications, a significant fraction of the implantation dose is deposited within the oxide layer (7). The net transfer of impurities from oxide to semiconductor must then be considered to predict doping profiles accurately. The results of the following mathematical treatment should be found useful for determining the significance of the oxide layer as a secondary source of impurities in such cases. As an example, the behavior of boron as the implanted diffusant is treated.

Mathematical Treatment

The impurity distribution resulting from the implantation will be approximated by (8)

$$N(x) = \frac{\phi}{\sqrt{2\pi}\,\Delta R_p} \exp - \left(\frac{x + w - R_p}{\sqrt{2}\,\Delta R_p} \right)^2 \quad t = 0 \qquad [1]$$

where $N(x)$ is the impurity concentration at a distance x from the oxide-semiconductor interface, w is the thickness of the oxide layer, R_p and ΔR_p are, respectively, the projected range and standard deviation of the implanted impurity (assumed to be the same in both oxide and semiconductor), and ϕ is total implantation dose expressed in ions/cm^2.

The impurity atom distribution in the oxide (diffusion constant D_1) is then obtained by solving the diffusion equation

$$\frac{\partial^2 N_1}{\partial x^2} = \frac{1}{D_1} \frac{\partial N_1}{\partial t} \quad -\infty < x < 0 \qquad [2]$$

and that in the semiconductor (diffusion constant D_2) by solving

$$\frac{\partial^2 N_2}{\partial x^2} = \frac{1}{D_2} \frac{\partial N_2}{\partial t} \quad 0 < x < \infty \qquad [3]$$

The boundary conditions, in addition to Eq. [1], are

$$D_1 \frac{\partial N_1}{\partial x} = D_2 \frac{\partial N_2}{\partial x} \quad x = 0, \quad t > 0 \qquad [4]$$

$$N_2 = mN_1 \quad x = 0, \quad t > 0 \qquad [5]$$

$$N_1 = 0 \quad x = -\infty \qquad [6]$$

$$N_2 = 0 \quad x = \infty \qquad [7]$$

Strictly speaking, Eq. [1] is valid only when the stopping power associated with each medium is identical and effects such as channeling and enhanced diffusion are neglected. Nevertheless, a simple Gaussian distribution should provide an adequate representation of the initial distribution of impurities in many cases of practical interest.

Equation [6] implies that the external boundary of the oxide layer is sufficiently far from the oxide-semiconductor interface that it can be neglected when considering the distribution of impurities inside the semiconductor. This assumption is reasonable when the diffusion length of the impurity within the oxide is small compared with the thickness of the oxide. (For both boron and phosphorous in silicon, this condition is satisfied over a wide range of implantation and diffusion conditions for oxide thicknesses greater than 1000A.)

Solutions to Eq. [2] and [3], subject to the boundary conditions, are obtained by employing integral representations for N_1 and N_2 in the manner described by Boltaks (9). The impurity distribution in the semiconductor ($x \geq 0$) is given by

$$N_2(x,t) = \frac{1}{2\sqrt{\pi}} \frac{\phi}{\gamma_2} \left\{ \left[\exp - \left(\frac{x - \lambda}{\gamma_2} \right)^2 \cdot \operatorname{erfc} - \left(\frac{\alpha_2^2 x + \alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_2^2}} \right) + \exp - \left(\frac{x + \lambda}{\gamma_2} \right)^2 \cdot \operatorname{erfc} \left(\frac{\alpha_2^2 x - \alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_2^2}} \right) \right] - \frac{2r}{r+m} \left[\exp - \left(\frac{x + \lambda}{\gamma_2} \right)^2 \cdot \operatorname{erfc} \left(\frac{\alpha_2^2 x - \alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_2^2}} \right) - m \frac{\gamma_2}{\gamma_1} \exp - \left(\frac{rx - \lambda}{\gamma_1} \right)^2 \operatorname{erfc} \left(\frac{\alpha_1^2 rx + \alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_1^2}} \right) \right] \right\} \qquad [8]$$

where the following parameters have been introduced

$$r = \sqrt{D_1/D_2}; \quad \lambda = R_p - w$$

$$\alpha_0 = 1/\sqrt{2}\,\Delta R_p; \quad \alpha_1 = 1/2\sqrt{D_1 t}; \quad \alpha_2 = 1/2\sqrt{D_2 t}$$

$$\gamma_1 = \sqrt{1/\alpha_0^2 + 1/\alpha_1^2}; \quad \gamma_2 = \sqrt{1/\alpha_0^2 + \alpha_2^2} \qquad [9]$$

The impurity distribution in the oxide ($x \leq 0$), subject to the assumption already discussed, may be obtained by interchanging indices 1 and 2 and setting $x = -x$, $\lambda = -\lambda$, $r = 1/r$, and $m = 1/m$ in the right-hand side of Eq. [8].

Equation [8] has been structured to emphasize the influence of the oxide-semiconductor interface on the distribution of impurities in the semiconductor. The first half of Eq. [8] is the distribution of impurities when the oxide-semiconductor interface is impermeable ($-D_2\,\partial N_2/\partial x = 0$ at $x = 0$). The second half of Eq. [8] therefore describes the incremental distribution of impurities due to the segregation of impurities at the oxide-silicon interface (Eq. [5]) and the requirement that the flux of impurities be continuous at the interface (Eq. [4]).

The impurity concentration at the oxide-semiconductor interface, gotten by substituting $x = 0$ in Eq. [8], is given by

$$N_2(0,t) = \frac{\phi}{\sqrt{\pi}} \frac{m}{r+m} \left[\frac{\exp - (\lambda/\gamma_2)^2}{\gamma_2} \cdot \operatorname{erfc} - \left(\frac{\alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_2^2}} \right) + r \frac{\exp - (\lambda/\gamma_1)^2}{\gamma_1} \cdot \operatorname{erfc} \left(\frac{\alpha_0^2 \lambda}{\sqrt{\alpha_0^2 + \alpha_1^2}} \right) \right] \qquad [10]$$

$N_1(0,t)$ is immediately obtained by using the condition $N_2(0,t) = mN_1(0,t)$ specified in Eq. [5].

The impurity content of the silicon, as a function of time, is determined by evaluating the integral $\phi_2(t) = \int_0^\infty N_2(x,t)\,dx$, in which $N_2(x,t)$ is given by Eq. [8] and, by definition, $\phi_1(t) + \phi_2(t) = \phi$. Using the fact that the fractional impurity content at $t = 0$ is given by

$$\frac{\phi_2(0)}{\phi} = \frac{1}{2}\left[1 + \operatorname{erf}(\alpha_0 \lambda)\right] \qquad [11]$$

the following expression may be shown to describe the fractional impurity content at any later time t

$$\frac{\phi_2(t)}{\phi} = \frac{\phi_2(0)}{\phi} + \frac{1}{2}\frac{\exp -(\alpha_0\lambda)^2}{r+m}\left\{ r\left[\frac{\tan^{-1}(\alpha_2/\alpha_0)}{\pi/2} - \frac{\alpha_2}{\alpha_0}F(-\alpha_2)\right] - m\left[\frac{\tan^{-1}(\alpha_1/\alpha_0)}{\pi/2} - \frac{\alpha_1}{\alpha_0}F(\alpha_1)\right] - (r-m)\right\} \quad [12]$$

where, for $i = 1$ or 2

$$F(a_i) = \frac{2}{\sqrt{\pi}}\int_0^{\pi/2} a_i^3 \exp(a_i^2) \cdot \operatorname{erfc}(a_i)\frac{d\theta}{(\alpha_0\lambda\sin\theta)^2} \quad [13]$$

and

$$a_i(\theta) = \frac{\alpha_0^2\lambda\sin\theta}{\sqrt{\alpha_0^2\sin^2\theta + \alpha_i^2(1+\sin 2\theta)}} \quad [14]$$

The definite integrals in Eq. [12] represented by the functions $F(a_1)$ and $F(-a_2)$ may be numerically evaluated by routine application of Simpson's rule.

Example

As an example, the case of boron implanted through an oxide layer into an underlying silicon substrate will now be considered. In Fig. 1, the net change of impurity content of the silicon is plotted as a function of the dimensionless quantity $|R_p - w|/2\sqrt{D_2 t}$ for various values of the parameter $\phi_2(0)/\phi$. The values $m = 0.33$ and $r^2 = D_1/D_2 = 2.5 \times 10^{-4}$ used for these calculations are typical of those encountered for the diffusion of boron over the temperature range 1150°-1250°C (10, 11). In general, when $m < 1$, impurity transfer occurs first out of the silicon (to correct for the nonequilibrium distribution of impurities at the interface at $t = 0$), then into the silicon (to replenish impurities which rapidly diffuse away from the silicon interface), and finally out of the silicon (when the oxide has become depleted of impurity to the extent that Eq. [5] can no longer be satisfied). In many practical applications in device and circuit fabrication involving boron as the diffusant, the oxide will therefore behave as a secondary source of impurities. The extent to which this occurs will of course depend on the location of the implanted distribution relative to the oxide-silicon interface.

In Fig. 2, the net change of impurity content of the silicon for the case $\phi_2(0)/\phi = 0.5 (R_p = w)$ is plotted as a function of the dimensionless parameter $\alpha_2/\alpha_0 = \sqrt{2}\,\Delta R_p/2\sqrt{D_2 t}$ for $r^2 = 2.5 \times 10^{-4}$ and various values of the segregation coefficient m. According to Eq. [12]-[14], when $R_p = w$ ($\lambda = 0$)

$$\frac{\phi_2(t)}{\phi} = \frac{1}{2}\left\{1 + \frac{1}{r+m}\left[r\frac{\tan^{-1}(\alpha_2/\alpha_0)}{\pi/2} - m\frac{\tan^{-1}(\alpha_1/\alpha_0)}{\pi/2} - (r-m)\right]\right\} \quad [15]$$

As $\alpha_2/\alpha_0 \to 0$, $\phi_2(t)/\phi_2(0) \to (m-r)/(m+r)$ and consequently $\phi_2(t)/\phi_1(t) \to m/r$, a result which may also be obtained using the qualitative argument employed by Wagner (12). This behavior is illustrated in Fig. 2 for $\alpha_2/\alpha_0 \sim 10^{-4}$. Evidently, for the smaller values of the segregation coefficient m, significant transfer of impurity from the silicon to the oxide will take place when $\alpha_2/\alpha_0 \gtrsim 0.05$.

In Fig. 3 the normalized impurity concentration $N_2(x,t)/\tilde{N}_2(0,t)$ (for the case $R_p = w$) is plotted as a function of the dimensionless parameter x/γ_2 for various values of the parameter α_2/α_0. The quantity $\tilde{N}_2(0,t) = \phi/\sqrt{\pi}\gamma_2$ represents the surface concentration when the interface is impermeable, obtained by setting $r = \lambda = 0$ in Eq. [10]. For this case, $N_2(x,t) = (\phi/\sqrt{\pi}\gamma_2)\cdot\exp -(x/\gamma_2)^2$, which describes a Gaussian distribution of impurities for which the standard deviation is $\gamma_2/\sqrt{2}$ and the total impurity content $\phi/2$. The departure from a Gaussian distribution for the case of a permeable interface ($r \neq 0$) becomes quite significant when $\alpha_2/\alpha_0 \lesssim 0.05$, as suggested also in Fig. 2. It is easily shown that as $\alpha_2/\alpha_0 \to 0$, both $\phi_2(t)/\phi_2(0)$ and $N_2(0,t)/\tilde{N}(0,t)$ approach a limiting value of $2r/(m+r)$ which, for $r^2 = 2.5 \times 10^{-4}$ and $m = 0.33$, is equal to 1.91 (Fig. 2 and 3).

The curves of Fig. 1-3 are expected to provide a reasonable description of the diffusion behavior only as long as the diffusion length of boron in silicon dioxide does not exceed the oxide thickness. The parameter $|R_p - w|/2\sqrt{D_2 t}$ must, therefore, be greater than $r|R_p/w - 1|$ for each of the curves of Fig. 1. For example, according to Eq. [11], when $\phi_2(0)/\phi = 0.60$, $R_p/w = 1.065$ (assuming $R_p = 4\Delta R_p$). Thus the range of validity for the curve labeled 0.60 should be restricted to that portion of the abscissa for which $|R_p - w|/2\sqrt{D_2 t} \gtrsim 1 \times 10^{-3}$. A similar restriction applies to the use of the curves in Fig. 2 and 3. In this case, $\sqrt{2}\,\Delta R_p/2\sqrt{D_2 t}$ must be greater than or equal to $r \cdot \sqrt{2}\,\Delta R_p/R_p$. Since $R_p \approx 4\Delta R_p$ for practical applica-

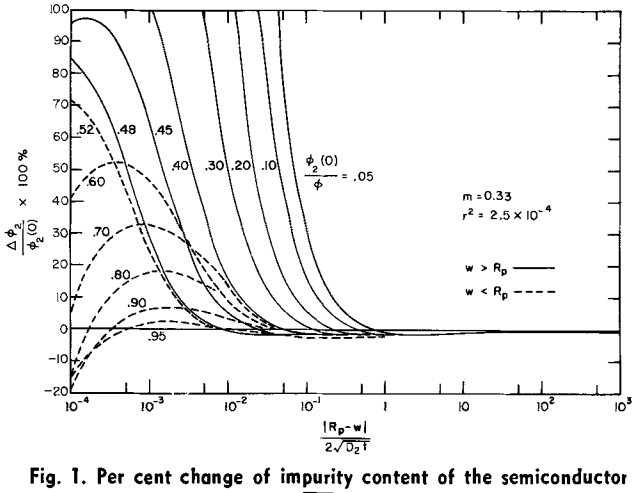

Fig. 1. Per cent change of impurity content of the semiconductor as a function of $|R_p - w|/2\sqrt{D_2 t}$ for various values of the parameter $\phi_2(0)/\phi$.

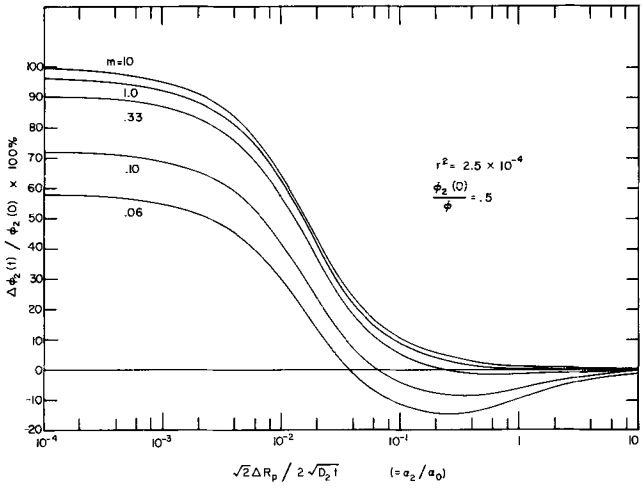

Fig. 2. Per cent change of impurity content of the semiconductor as a function of $\sqrt{2}\Delta R_p/2\sqrt{D_2 t}$ for the case $\phi_2(0)/\phi = 0.5$ ($R_p = w$). Curves are plotted for various values of the segregation coefficient m.

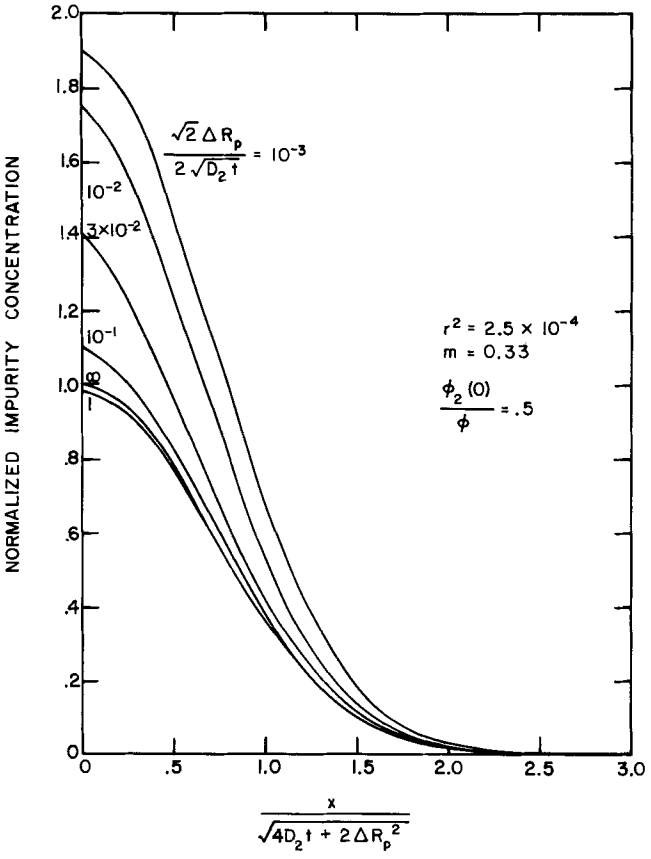

Fig. 3. Normalized impurity concentration as a function of $x/\sqrt{4D_2t + 2\Delta R_p^2}$ ($= x/\gamma_2$) for the case $\phi_2(0)/\phi = 0.5$ ($R_p = w$). Curves are plotted for various values of the parameter $\sqrt{2}\Delta R_p/2\sqrt{D_2 t}$. The curve labeled ∞ represents the normalized distribution of implanted impurities at $t = 0$, exp $- (x/\sqrt{2}\Delta R_p)^2$.

tions involving implanted boron, it follows that the range of validity for the parameter $\sqrt{2}\,\Delta R_p/2\sqrt{D_2 t}$ does not extend below values $\sim 5 \times 10^{-3}$. In order to accurately treat the diffusion behavior for those cases for which $2\sqrt{D_1 t} \gtrsim w$, it would be necessary to consider the influence of the SiO_2-ambient interface, as has been done for conventional doped-oxide diffusion sources (13).

Conclusion

An exact solution of the diffusion equation has been obtained for the impurity atom distribution which results from thermal redistribution of an ion implanted impurity source. It was assumed that the implantation was through an existing oxide layer of thickness at least comparable to the diffusion length of the impurity in the oxide. As an illustration, the behavior of a boron implanted impurity source in silicon was examined, assuming diffusion parameters typical of the temperature range 1150°-1250°C.

LIST OF SYMBOLS

α_0	reciprocal of the standard deviation of the implanted Gaussian distribution, cm^{-1}
α_1	reciprocal of the diffusion length of the impurity in the oxide, cm^{-1}
α_2	reciprocal of the diffusion length of the impurity in the semiconductor, cm^{-1}
D_1	diffusion coefficient of impurity in oxide, cm^2 sec^{-1}
D_2	diffusion coefficient of impurity in semiconductor, cm^2 sec^{-1}
λ	distance between peak of the implanted Gaussian distribution and oxide-semiconductor interface, cm
m	segregation coefficient of impurity between oxide and semiconductor
N_1	concentration of impurity in oxide, cm^{-3}
N_2	concentration of impurity in semiconductor, cm^{-3}
ϕ	total implanted dose, cm^{-2}
$\phi_1(t)$	density of impurities in the oxide after time t, cm^{-2}
$\phi_2(t)$	density of impurities in the semiconductor after time t, cm^{-2}
$\Delta\phi_2(t)$	net change of density of impurities in the semiconductor after time t, cm^{-2}
R_p	projected range of impurity, cm
ΔR_p	standard deviation of the implanted Gaussian distribution of impurities, cm
r	ratio of diffusion length in oxide to diffusion length in semiconductor
t	elapsed time, sec
w	thickness of oxide layer, cm
x	distance from oxide-semicondutcor interface, cm

Brief Communications

On the Statistics Governing the Defect Density Determination in SiO_2 Films

N. J. Chou* and J. M. Eldridge*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

In a paper by Meek and Braun that appeared in the November 1972 JOURNAL (1), reference was made to the statistical method first employed by Fritzsche (2) and then by Chou and Eldridge (3) to determine the defect density in the SiO_2 films on Si in their assessment of the oxide quality in terms of dielectric strengths. It was contended that the defects in SiO_2 films ought to be regarded as indistinguishable, and that Bosse-Einstein rather than Boltzmann statistics should have been used in deriving the functional relationship among the defect density ρ [or σ in Ref. (1)], the electrode area, F, and the fraction, P, of the MOS capacitors exhibiting primary breakdown when tested for dielectric strengths.

A parallel was drawn between the fraction of primary breakdown and the yield of integrated circuits (IC). The work of Price (4) was cited to show that different expressions for the IC yield could be obtained depending on the choice of statistics. For distinguishable defects, for which Boltzmann statistics are appropriate, the IC yield, P, [or Y_1 in Ref. (4)], is given by

$$P = \exp(-F\rho)$$

or

$$\rho = -\frac{\ln P}{F} \qquad [1]$$

where F now denotes the active area of the IC devices. In the case of indistinguishable defects, where Bose-Einstein statistics are applicable, the IC yield, P [or Y_2 in (4)], is expressed by

$$P = \frac{1}{1 + \rho F}$$

or

$$\rho = \frac{1}{F}\left(\frac{1 - P}{P}\right) \qquad [2]$$

Consequently Eq. [2] was considered to be more appropriate for determining the defect density from the breakdown distribution of the SiO_2 films. [See footnote 2, p. 1539, Ref. (1).]

In this short communication, we shall discuss why Boltzmann statistics are preferred in the evaluation of defects in SiO_2 films.

It is perhaps instructive to note that in determining the IC yield, the device failure due to various types of defects is evaluated on a "go or no go" basis. Such a proposition makes the defects statistically indistinguishable provided they are sufficiently small in relation to the active area of the devices. Be it pinholes, misalignments, or diffusion faults, they contribute equally to the device failure. The situation with dielectric strength measurements in SiO_2 films is quite different. Even though the defects in the SiO_2 films may be of a single type,[1] they should be regarded as distinguishable for the following reasons:

i) In deriving these functional relationships we have applied a two-dimensional statistical model to the three-dimensional reality. Since the defects are comparable in size to the third dimension, *i.e.*, the oxide thickness, their dimensional variation in that direction can be taken implicitly into account only when they are considered distinguishable. To be more specific, let us assume that the defects responsible for nonprimary breakdowns are devitrified spots containing crystallites of various dimensions (1-3). If the crystallite has associated with it a well-defined breakdown strength, then the spots containing crystallites of varied lengths should be distinguishable in the two-dimensional model on account of their variable dielectric strengths. A simple argument can be advanced. When the crystallite in a defective spot does not occupy the entire oxide thickness, the dielectric strength of this particular spot will be that of the composite material, *i.e.*, the crystallite plus the amorphous SiO_2 with their respective dielectric constants and breakdown strengths, and should therefore assume an apparent value between the dielectric strengths of these two materials. Considering the frequently observed zigzag paths of electrical breakdown (5), this is obviously an oversimplified picture since the interactive effect of defects in various depths of the oxide film has been completely ignored. However, it does underscore the necessity of treating the defects as distinguishable in our two-dimensional model. In fact, recent refinement in the experimental technique has shown that defect-related breakdown field in SiO_2 films can indeed assume any value between 2 mV-cm^{-1} (secondary) and 9 mV-cm^{-1} (primary). As pointed out by Osburn (6), the measuring circuit used by Chou and Eldridge (3) did not have a sufficiently fast response to detect all the "self-healing" breakdowns; therefore their breakdown strength distributions were distorted in favor of low- and high-field events. While peaks at low fields ($\sim$2 mV-cm^{-1}) were also observed with an improved measuring circuit, the defect-related breakdown events were found to constitute more than often a continuous spectrum of dielectric strengths [see Fig. 2, Ref. (6)]. Using a different form of mathematical treatment, Osburn arrived at essentially the same functional relationship as obtained by Boltzmann statistics (compare Eq. [1] with Eq. [7] in Ref. (6)).

ii) In actual defect density computations, the fraction of primary breakdowns is usually determined by arbitrarily setting a threshold field value, above which the breakdown events are considered to occur in the primary mode. This procedure is warranted by the fact that the primary breakdown strength is not a well-defined quantity. The variability of the primary breakdown strength and the spread of dielectric strengths near its peak have been frequently observed in the MOS capacitors fabricated under various conditions [see, for example, Fig. 2 and 3 in Ref. (3)]. Obviously, the said procedure differs from the "go or no go" proposition in the IC yield determinations.

* Electrochemical Society Active Member.

Key words: dielectric breakdown, silicon dioxide, reliability, statistics.

[1] For ease of discussion we shall ignore the presence of pinhole-type defects (tertiary breakdowns).

Table I. Fitting of experimental breakdown data to statistical models

Data set No.	Experimental data: Electrode area, F, mm²	Fraction of primary breakdown, P, %	$-\ln P$	$(1-P)/P$	Results of least square fitting: Defect density, ρ, defects/cm²	Intercept, c	Standard deviation, σ	Correlation coefficient, K	Reference
1	0.05	96	0.04	0.041					(3)
	0.5	72.5	0.32	0.38					
	1.3	62.3	0.47	0.60					
		Boltzmann statistics (Eq. [1]):			33	0.08	0.06	0.95	
		Bose-Einstein statistics (Eq. [2]):			43	0.08	0.06	0.96	
2	0.05	85.7	0.15	0.167					(6)
	0.5	65	0.43	0.54					
	1.3	31.9	1.14	1.94					
		Boltzmann statistics (Eq. [1]):			80	0.08	0.04	0.99	
		Bose-Einstein statistics (Eq. [2]):			146	−0.01	0.12	0.98	
3	0.05	50	0.69	1.0					(3)
	0.5	5	3.0	1.9					
	1.3	1.5	4.2	6.57					
		Boltzmann statistics (Eq. [1]):			265	0.99	0.49	0.94	
		Bose-Einstein statistics (Eq. [2]):			462	0.31	0.51	0.98	

Having advanced our argument in favor of Boltzmann statistics, it would appear appropriate, at this time, to present some experimental evidence in its support. Unfortunately, the experimental breakdown data currently available for SiO_2 films do not permit us to make a confident choice between the two statistical models. As pointed out by Meek and Braun (1), Eq. [1] and [2] yield essentially the same results at low-defect densities (or at large P's), since for $P \geq \frac{1}{2}$, $(1-P)/P$ in Eq. [2] is the first term in the series expansion of $-\ln P$ in Eq. [1]:

$$-\ln P = \frac{1-P}{P} - \frac{1}{2}\left(\frac{1-P}{P}\right)^2 + \frac{1}{3}\left(\frac{1-P}{P}\right)^3 \cdots \quad [3]$$

Thus, for $P \geq 90\%$, the difference between the calculated ρ is indeed less than 5%.

As P decreases, however, the difference becomes substantial and reaches as high as 45% at $P = 50\%$. In order to differentiate between the two models, one should therefore rely on the data for highly faulted SiO_2 films. Such data are understandably meager because defective films are neither reproducible nor of practical interest. Nevertheless, three sets of experimental data with $P \leq 0.7$ have been collected from Ref. (3) and (6). Using F as a variable, these data have been least-square fitted to Eq. [1] and [2]. The results are shown in Table I. Since $P = 100\%$ for $F = 0$, the straight lines representing Eq. [1] and [2] should both pass the origin (0,0) in a $-\ln P$ *vs.* F and a $(1-P)/P$ *vs.* F plot. For this reason, the intercepts (C's) are included as a criterion for comparison; the smaller the intercept, the better fit the model gives.

As can be seen from the tabulated results, the experimental data fit both models equally well except, perhaps, for the third set which appears to be slightly in favor of the Bose-Einstein model on account of its smaller intercept. It is clear, therefore, that much more data are needed to settle the problem experimentally.

Ellipsometry of Multilayered Dielectrics on Silicon, Applied to MNOS Structures

Leif Lundkvist

Research Laboratory of Electronics III, Chalmers University of Technology, Gothenburg, Sweden

In a recent paper, Maguire and Augustus (1) reported on the detection of a thin silicon oxynitride layer on top of silicon nitride layers fabricated by pyrolysis of silane at about 800°C. In the present communication, we want to point out that the interpretation of their ellipsometer measurements needs some modification. As ellipsometer measurements are used routinely in much solid-state device work, the results presented have a general applicability.

Maguire and Augustus used nitride layers which were originally 610Å and 1010Å thick and had refractive indices of 1.88 and 1.95, respectively. After heating in vacuum at 1140°C for up to 2 hr, the layers had decreased in thickness by about 30Å and had a refractive index of just over 2. This was interpreted to mean that the removed oxide (oxynitride) layer had had a thickness of 30Å and that the removal of 30Å oxide with a refractive index of 1.46 had increased the refractive index of the remaining layer to just over 2, a value that is characteristic of the nitride layer alone.

This interpretation is incorrect both with regard to the refractive index and the thickness for reasons given below. We believe that the refractive index increases mainly because of sintering and not oxide removal.

Key words: ellipsometry of multilayers, silicon nitride, MNOS.

Interpretation of Ellipsometer Measurements of MNOS Multilayers

In order to clearly show the correct way of interpreting the data by Maguire and Augustus (1), the two cases studied by them have been analyzed and subsequently checked by separate experiments on similar wafers. The theory of ellipsometry of multilayered di-

electrics has been treated earlier, [see for example Ref. (2) and (3)]. The problem is that knowledge of refractive indices and thicknesses of the dielectric layers makes it possible to calculate the ellipsometer readings Δ and Ψ (4), but not the inverse.

Figure 1 shows calculated ellipsometer readings for monolayers of various thicknesses and refractive indices around those found in silicon nitride [cf. Fig. 1 and 4 in Ref. (4)]. The points measured by Maguire and Augustus (1) are shown as open circles, with an arrow indicating the direction of change upon heating at 1140°C for 2 hr. The dashed line starting at the first of these points shows the direction and magnitude the change should have had if the heat treatment had resulted in removal of oxide ($n = 1.46$) from the top of the sample. This line is given by a computer program used to calculate ellipsometer readings of multilayered dielectrics, just by taking as the first layer the measured refractive index and thickness (for example $n = 1.95$ and 1010Å) and on that a layer of oxide ($n = 1.46$) with negative thickness. This method is approximate but it is simple and can be used if the oxide is not too thick (<100Å). In this case the error is always less than 0.5° for the sum of Δ and Ψ. It is important to note that removal of oxide increases the apparent refractive index on the 610Å sample, while it reduces the apparent refractive index on the 1010Å sample.

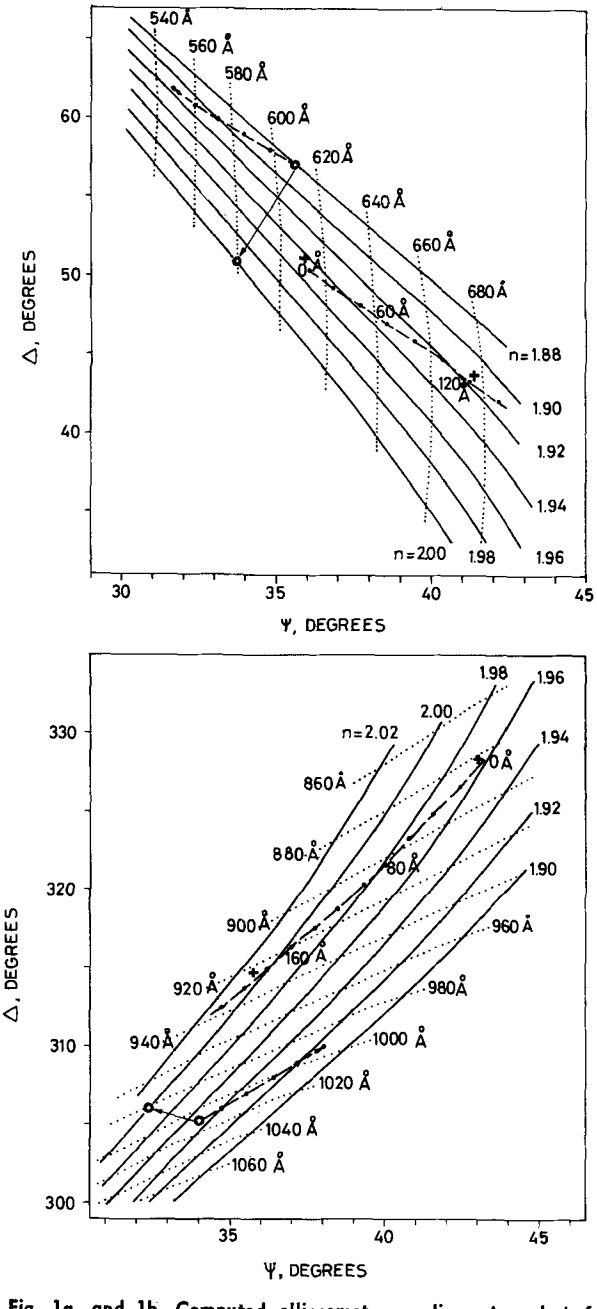

Fig. 1a. and 1b. Computed ellipsometer readings Δ and ψ for dielectric layers on silicon. The solid lines are computed for single layers with some different refractive indices. The dotted lines are lines of constant thickness. The dashed lines are computed for multiple layers, where the layer on top is oxide ($n = 1.46$) of variable thickness. These lines have a dot for each 20Å of oxide. Points measured by Maguire and Augustus (1) are marked ○. Experimental points from the present work are marked +. Angle of incidence is 70°.

Figure 2 shows that when oxide ($n = 1.46$) is added to nitride ($n = 1.96$), the apparent refractive index reduces when the nitride is 0-800Å thick, but increases when the nitride is 800-1600Å thick. The curves for oxide on nitride starts on the nitride curve and continues with an oxide branch more or less parallel with the oxide curve. A diagram similar to Fig. 2 can be drawn for other combinations of dielectrics to get the direction of change in other cases.

The correct thicknesses of the two layers are now found at the intersection of the dashed line and the line of refractive index of the nitride (see Fig. 1). Consequently, the value of the refractive index of the nitride by itself used by Maguire and Augustus, assuming identical nitride on both samples, must have been 1.915, half way between the two values found, 1.88 and 1.95. Adding 100Å (not 30Å as assumed by Maguire and Augustus) of oxide on top of both samples would then give the values found by Maguire and Augustus, as indicated in Fig. 1a and 1b by circles at the starting point of the arrows. Removal of the oxide layer by heating in vacuum, as done by Maguire and Augustus, would then give values of refractive index and thickness as indicated in Fig. 1 by dashed lines, the end points of which would correspond to complete removal of oxide. If the layer on top was oxynitride with a refractive index between that of oxide and that of nitride, removal of oxynitride would give a point on a line between the one for oxide (dashed line) and the one for nitride ($n =$ constant). This is in disagreement with the values after vacuum heating found by Maguire and Augustus as indicated in Fig. 1 by circles at the end point of the arrows. Thus a different explanation as discussed later is required.

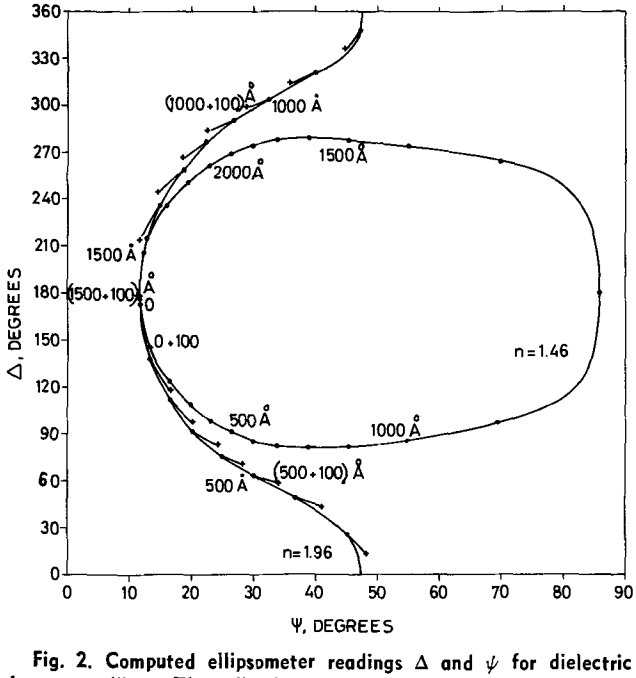

Fig. 2. Computed ellipsometer readings Δ and ψ for dielectric layers on silicon. The solid dots are for oxide ($n = 1.46$) and nitride ($n = 1.96$) on 20Å of oxide. Crosses are for 20Å of oxide + nitride + 100Å oxide. When the nitride is 0-800Å thick, the crosses are at a lower refractive index than that of the nitride, but when the nitride is 800-1600Å they are at a higher refractive index.

Table I. Present experimental results—comparison of multilayers evaluated as if they were single layers

	Sample No. and Fig. No. 1a	1b
Two layers		
Apparent refractive index	1.945	1.965
Apparent thickness, Å	610	880
Three layers		
Apparent refractive index	1.91	2.01
Apparent thickness, Å	680	920
Apparent thickness difference, Å	+70	+40
Real thickness difference = thickness of third layer (on control slice), Å	120	220

Experimental Test of the Analysis

In order to test that the analysis presented is correct, two silicon wafers were made with a nitride thickness of 590Å and 865Å. This nitride was made by pyrolysis of SiH_4 in NH_3 at about 700°C. After ellipsometer measurements, the wafers were covered by oxide made by pyrolysis of SiH_4 in O_2 at about 400°C. The thickness of the oxide was measured on clean slices of silicon on which the oxide was deposited at the same time. The ellipsometer readings before and after deposition of oxide are shown as crosses in Fig. 1 and the results are summarized in Table I. A computer program was used to calculate theoretical curves for the two slices. The parameters used for the calculation were: Fig. 1a, first a layer of oxide ($n = 1.46$) 20Å thick, then nitride ($n = 1.96$) 590Å thick, and finally oxide ($n = 1.46$) 0-140Å thick; Fig. 1b, first a layer of oxide ($n = 1.46$) 20Å thick, then nitride ($n = 1.96$) 865Å thick, and finally oxide ($n = 1.46$) 0-220Å thick. These calculated ellipsometer readings are shown in Fig. 1 as dashed lines. The experimental points correspond very closely to theory. The first layer of 20Å of oxide used in the calculations is an approximation of the oxide always left on the slice after cleaning. The effect of this layer is to change the apparent refractive index in the same direction as for the oxide layer on the top, but the apparent thickness is very close to the sum of the nitride thickness and the oxide thickness.

Conclusion and Discussion

When analyzing multilayers of dielectrics on silicon, single layer evaluation does not give a correct result. The large change in refractive index seen by Maguire and Augustus (1) cannot be explained by removal of oxide, but must have some other explanation. Our nitride, which has only a very thin oxide on the top (if any), also shows an increase in refractive index when heated at temperatures higher than the deposition temperature. This heating also reduces the etch rate, just as higher deposition temperatures do. We believe that the change in both cases is due to densification or rearrangement of the nitride. To ensure that no such changes occur, all treatments must be performed at low temperature, for example, by stepwise chemical etching of the oxide (or oxynitride) layer combined with ellipsometry.

The difference in refractive index on the samples used by Maguire and Augustus also needs some explanation. If there is 20Å of oxide under the nitride, the oxide on the top must be about 60Å if the nitride has the same refractive index on both samples. It is not probable that that much oxide can be created by oxidation of nitride during the cooldown period, as Maguire and Augustus (1) suggested. Fränz and Langheinrich (5) show that the oxidation rate of silicon nitride is lower than that of silicon, and that the result of the reaction is oxide, not oxynitride. If the oxygen content in the carrier gas is high enough to give appreciable oxidation of the nitride, it must also be high enough to give oxynitride as the result of the deposition of nitride, as this process is very sensitive to oxygen impurities. The result is an oxynitride film with refractive index lower than for nitride and with variations due to variations in oxygen impurity content from deposition to deposition. This may be the explanation of parts of the variation observed by Maguire and Augustus.

A Novel Electrolyte System: Solutions of Diethyl Ether in Concentrated Aqueous HCl + $ZnCl_2$ Mixtures

A. J. Easteal[1] and C. A. Angell

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

ABSTRACT

Electrolyte solutions with novel characteristics are formed by dissolution of ether in $ZnCl_2$ + hydrochloric acid solutions of high concentration. At 0°C ether is only slightly soluble in the "solution" $ZnCl_2 + 4H_2O$, but dissolves in the solution $HCl + 4H_2O$ until moles Et_2O:moles $H_2O \approx 1:2.8$. Its solubility increases markedly in mixtures of these solutions, reaching a maximum near the mole ratio corresponding to the formation of $ZnCl_4^=$, when moles Et_2O: moles $H_2O \approx 1:1.3$. Furthermore, the solubility in this mixture increases with decreasing temperature, down to the glass transition temperature at −124°C. Although ionic mobilities appear to increase with increasing ether content the electrical conductance at 0°C decreases, evidently due to the disruption of an efficient proton transfer mechanism in the chlorozincate acid. The strongly proton conducting solutions may have useful low temperature electrolyte applications, since the conductivity is not necessarily limited by the ionic and molecular transport mechanisms which determine the fluidity.

The extraction, with various ethers, of complex metal halide ions and/or halo acids of the form HMX_n from acidified solutions of metal halides is a well-established experimental procedure (1). We have attempted to use this procedure with diethyl ether (Et_2O), to characterize species existing in concentrated aqueous solutions of $ZnCl_2$ + HCl. From the results of a study of concentrated aqueous $ZnCl_2$ + LiCl solutions (2) it was concluded that formation of a tetrachlorozincate species has a profound effect on a variety of properties of these electrolytes. It seemed feasible that from aqueous $ZnCl_2$ + HCl electrolytes the acid H_2ZnCl_4 (probably with associated water molecules) might be extractable with Et_2O, particularly at low temperatures.

The extraction experiments did not achieve this objective for reasons which form the subject of this communication because they have led us to a study of a class of electrolytes which seem not to have been previously investigated in detail.

Experimental

In the experiments described below an aqueous electrolyte, E (0.6 HCl, 0.4 $ZnCl_2$, $4H_2O$), of fixed composition was used. When a mixture containing 20 mole per cent (m/o) E and 80 m/o Et_2O is shaken at room temperature, two liquid phases result. This was expected on the basis of analogous experiments described in the literature. When the two-phase mixture is cooled with agitation in liquid nitrogen, a single homogeneous liquid phase is formed. This was an unexpected result and was the basis of our subsequent experiments. The homogeneous solution becomes turbid and eventually completely separates into two phases on warming.

Variation of the relative proportions of E and Et_2O showed that the saturated solution of Et_2O in E at 0°C contained 74.3 ± 0.2 m/o Et_2O, while mixtures containing more than *ca.* 81 m/o Et_2O could not be induced to form a single phase on cooling in liquid nitrogen. The solubility of Et_2O in E at 23.9° ± 0.2°C was measured as 65.8 ± 0.3 m/o Et_2O. From the solubilities at 0° and 23.9°C the average heat of solution[2] of Et_2O in E between these two temperatures was calculated as $\Delta H = -2.78 \pm 0.05$ kcal mole^{-1} (and the dissolution is thus exothermic).

Electrolyte E can be regarded as a mixture of the two components

electrolyte E_H: HCl, $4H_2O$
electrolyte E_Z: $ZnCl_2$, $4H_2O$

in the mole ratio 0.6 E_H, 0.4 E_Z. At 0°C the saturated solution of Et_2O in E_H contains 59.4 ± 0.2 m/o Et_2O, and in E_Z approximately 5.8 m/o. The dissolution of Et_2O in E_Z is endothermic since the saturated solution at about 25°C contains approximately 7.5 m/o Et_2O.

A portion of the phase diagram (at 0°C) for the ternary system $Et_2O/E_H/E_Z$ is shown in Fig. 1, which has been constructed from the solubility measurements at 0°C. Qualitative experiments indicated that the maximum solubility of Et_2O, at a given temperature, should occur for mixtures of E_H with E_Z in which the Zn:Cl ratio is 1:4.

The solubilities of Et_2O in electrolytes E_H, E, and E_Z at 0°C are 1.46, 2.89, and 0.05_8 moles per mole of electrolyte, respectively. In electrolyte E this mole ratio increases to 4.27 at the lowest temperatures studied (see below). The latter ratio corresponds to 7.1 moles of Et_2O for each proton present in the solution. Since there are 4 moles of H_2O for each mole of E_E, this low temperature saturated solution contains Et_2O and H_2O

Key words: low temperature electrolytes, glass transition temperature, electrical conductance, complex ions, protonic conduction.

[2] The heat of solution measured was the differential heat of solution, defined as the heat absorbed when 1 mole of solute is dissolved in a solution which is already practically saturated.

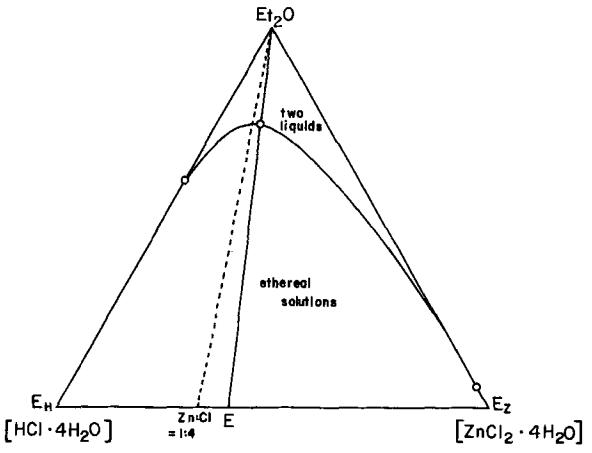

Fig. 1. Part of the phase diagram (at 0°C) for the pseudoternary system Et_2O/E_H $(HCl \cdot 4H_2O)/E_Z(ZnCl_2 \cdot 4H_2O)$. The open circles indicate experimental compositions derived from solubility measurements.

in approximately equal proportions ($Et_2O:H_2O$ = 4.27:4 = 1.07).

The homogeneous solutions of Et_2O in E are resistant without crystallization: when cooled in liquid nitrogen they form glasses which do not crystallize on warming. The solutions (especially those most concentrated in Et_2O) appear to have relatively high fluidity down to very low temperatures (*e.g.*, of the order −100°C) and for this reason may have some practical value as low temperature electrolytic media.

We have measured glass transition temperatures (denoted T_g) of vitrified solutions containing up to 70.6 m/o Et_2O, using in essence the differential thermal analysis method described previously (3). T_g decreases slowly and linearly (within experimental precision) from 0 to 70.6% Et_2O: the rate of change of T_g is −0.13°C (mole per cent $Et_2O)^{-1}$. T_g for pure Et_2O has been measured as −175°C ± 2°C.

To further characterize the ethereal solutions we have measured their electrical conductance as a function of composition at 0°C. For these measurements a simple U-shaped Pyrex glass capillary cell was used, with platinized platinum electrodes, in conjunction with a Wayne-Kerr Type B331 impedance bridge. The cell constant was 175.0 ± 0.2 cm^{-1} (measured using 0.1 demal aqueous KCl). Specific conductances, κ ohm-cm^{-1}, are listed in Table I as a function of composition.

In Fig. 2, T_g and log κ are plotted *vs.* composition expressed as mole per cent ether (lower scale), and as moles water: moles ether (R, upper scale).

Discussion

The propensity of $ZnCl_2$, a strong Lewis acid, for coordinating chloride ions to yield $ZnCl_4^{2-}$ tetrahedral complexes, is well known. The stoichiometry of the 2:1 mixture of electrolytes E_H and E_2 (Fig. 1) corresponds to $(H_3O^+)_2$ $ZnCl_4^{2-}$ diluted with 12 moles of water, while the 6:4 mixture (electrolyte E) corresponds to $(H_3O^+)_3Zn_2Cl_7^{3-}$ diluted with 16 moles of water. Although competition of water for positions in the Zn^{++} first coordination sphere will undoubtedly lead to some complicated distribution of chloro- and chlorohydrate species, it is certain that free chloride ions will not be present, and that the protons in the solution will be particularly free from anion binding interactions.

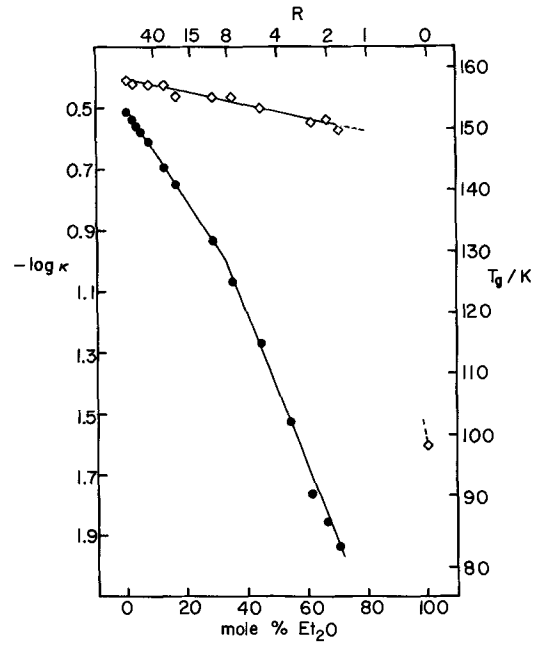

Fig. 2. Variation of glass transition temperature (T_g, unshaded diamonds) and log (specific conductance) (κ in $ohm^{-1}cm^{-1}$, shaded circles) with ether content of the pseudobinary system Et_2O/E (0.6 HCl, 0.4 $ZnCl_2$, $4H_2O$). *R* is the mole ratio H_2O: Et_2O corresponding to given solution compositions.

The increase in Et_2O solubility in electrolyte E over that in aqueous $HCl(E_H)$ is presumably to be associated with this increase in proton activity, although the extent to which ether molecules are protonated, rather than just coordinated to hydrated proton complexes, is unknown.[3] However, some rather specific structuring must be involved since the properties of the pseudobinary solutions E + Et_2O vary with composition in a highly nonideal fashion (which eventually leads to the phase separation commencing at ~70% Et_2O). In particular the cohesive energy density, indicated by the glass transition temperature, changes very slowly with ether content when viewed against the very low value of T_g characteristic of ether itself (Fig. 2).

By contrast, ether addition has a severe effect on the conductance of E. The addition to E of only 1 Et_2O molecule per 10 H_2O molecules reduces the conductance by more than 60% of its initial value. In view of the decrease in T_g with ether additions, which implies an increase in particle mobilities at constant temperature $T > T_g$ (3), the sharp decrease in conductance is best interpreted in terms of a decrease in efficiency of some Grotthus-like proton transfer mechanism which makes a major contribution to the conductance of electrolyte E. The existence of such a contribution would be expected on general grounds, and would be consistent with recent experience (5) that this substance yields a protonic semiconducting glass with conductance several orders of magnitude greater than expected from ionic mobilities alone.

Figure 2 shows that the conductance decreases exponentially with mole per cent ether, *i.e.*, the proton jump probability *P* is of the form

[3] It is noteworthy that Clark *et al.* (4) have recently isolated the anhydrous ethereal acids $[H(Et_2O)_n]^+[MCl_4]^-$ where *M* = Al(III), Fe(III), Ga(III), or In(III), and *n* can take values from 1.5 to 8.

$$P = P_o \exp(-X_{ether}) = P_o \exp\left(\frac{1}{1 + cR}\right)$$

where X_{ether} is the ether mole fraction, R is the water: ether mole ratio, and c is a constant. This form presumably reflects the probability of an ether molecule interceding between water molecules otherwise favorably orientated for a proton transfer process, but until further data on solutions of this type are available the development of a detailed model for this effect is unwarranted. The apparent break between low and high ether content behavior occurs at about $R = 8$, which corresponds to the presence of one ether molecule per $H^+(H_2O)_4$, or ($H_9O_4^+$). This is the water: proton ratio in the Pr_2O extract from $FeCl_3$-HCl-H_2O solutions suggested by Friedman (6), so the break in this plot is probably significant. Simple dilution effects must also contribute to the decrease in specific conductance with ether additions.

In two respects these solutions deserve further attention. In the first place, an electrolyte which exists at normal temperatures as a combination of highly conducting and poorly conducting layers at normal temperatures, but a single highly conducting phase at low temperatures could be useful for low temperature-activated electrolytic systems. Secondly, electrolytes in which the proton conduction mechanism is very efficient offer an in-principle method of overcoming otherwise fundamental limitations on low temperature operations of liquid electrolyte systems (7) imposed by the loss of ionic mobility approaching the glass transition temperature for the solution.

Computer Simulation of Full-Size, High-Drain, AgCl-Mg Sea Water-Activated Batteries

Duane W. Faletti*[1]

Applied Physics Laboratory, University of Washington, Seattle, Washington 98105

ABSTRACT

The predictions of a computer simulation for high-drain, AgCl-Mg batteries are compared to the observed performance of four full-size AgCl-Mg batteries: the Mk 61 (Mod 0 and Mod 2), Mk 64, and Mk 67. The Mk 61 Mod 0, like the Mk 64 and Mk 67 batteries, uses AZ61 magnesium anodes; the Mk 61 Mod 2 uses the high-voltage magnesium alloy, AP65. These four batteries differ sufficiently in their configurations and were discharged over a wide enough range of operating conditions to constitute a valid test of the capabilities of the computer simulation. The simulation gave voltage predictions accurate to within 7% for over 90% of the discharge. Predictions for other useful parameters, such as electrolyte temperature, are also given. This simulation can eliminate the need for most of the "cut and try" effort presently required in AgCl-Mg battery development and should be helpful in system studies of this battery.

Present design techniques for high-drain, sea water-activated, AgCl-Mg batteries require considerable experimentation involving the construction and testing of subassemblies as well as full-size prototypes. The operating conditions for such batteries often encompass a wide range of temperature, salinity, and pressure conditions. Because of limited discharge facilities and the expense of in-water tests, it is not feasible to test sea water-activated batteries over their entire operating range.

A computer simulation, which was developed as an aid to the design of AgCl-Mg water-activated batteries, has been described (1). Here we will compare the agreement between the predictions of that simulation and the observed behavior of four full-size, high-drain batteries. Three of these batteries, the Mk 61 Mod 0, Mk 64, and Mk 67, use AZ61 magnesium alloy for their anodes; the Mk 61 Mod 2 uses a high-voltage magnesium alloy, AP65. They differ sufficiently in their configurations and were discharged over a wide enough range of operating conditions to constitute a valid test of the capabilities of the simulation.

Characteristics of the Mk 61, Mk 64, and Mk 67 Batteries

The Mk 61, 64, and 67 are high-drain, sea water-activated batteries which use a compact, rugged, lightweight, pile-type construction (Fig. 1). Glass beads embedded in the cathodes act as separators, permitting electrolyte to pass between the electrodes of the cell. Metal foil is placed between adjacent cells to prevent unwanted electrochemical reactions and to provide electrical contact.

In the pile-type construction parasitic currents flow between cells of different potential because the cells are immersed in a continuous electrolyte. The parasitic currents act as a load in parallel to the external load, causing lower battery voltage and a reduced discharge life. The magnitude of the parasitic currents

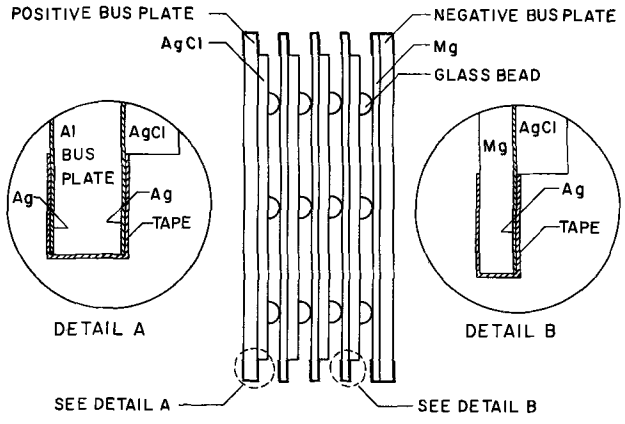

Fig. 1. Four-cell series-connected section. Current is transferred to the load by bus rods (not shown). Glass beads imbedded in the AgCl provide interelectrode spaces through which the electrolyte passes. Silver foil provides electrical contact between cells while acting as a barrier to chemical reactions between AgCl and Mg. The edges of magnesium-silver foil assemblies are taped to prevent electrolyte from reaching the back of the anodes.

increases with the conductivity and volume fraction of the electrolyte, the area of the flow passages above and below the battery, and the cross-sectional area of the flow passages within the cells.

Of the three batteries, the Mk 64 operates at the highest current density and has a parasitic-to-external current ratio of less than 0.05. The Mk 61 battery, which has the same flow passage area and cell configuration but operates at about half the current density, has a ratio near 0.08. The Mk 67 battery operates with a voltage control system which has the effect of increasing the conductivity of the electrolyte as the discharge progresses; thus, its parasitic-to-external current ratio increases during the discharge and, depending on the temperature and composition of the entering electrolyte, ranges from 0.19 to 0.25 in the early portions of the discharge, 0.25 to 0.33 when the discharge is 90% complete, and 0.67 to 0.85 at the completion of the discharge.

The cells of the battery may be connected in series as in Fig. 1, or they may be divided into two series-connected sections which are connected in parallel to the load as in Fig. 2. The Mk 64 battery has 169 cells connected electrically in series; the Mk 61 Mod 0, Mk 61 Mod 2, and Mk 67 batteries each have two sections connected electrically in parallel, each section containing 118, 104, and 230 cells, respectively.

The Mk 61 and Mk 64 batteries have cells and flow passages of the same size and shape (Table 1 and Fig. 3) and are designed to operate at near the same power level. Since the Mk 64 has a single section and the Mk 61 has two, the current density is nearly twice as high and the discharge period is correspondingly shorter for the former.

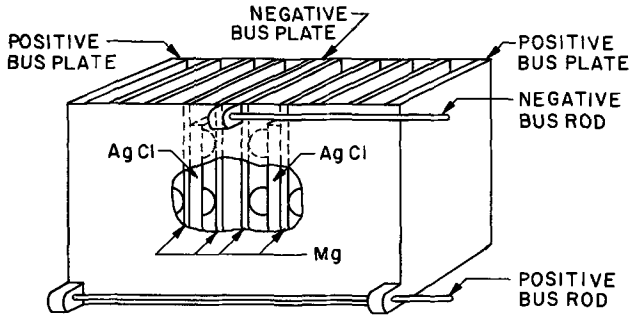

Fig. 2. Battery composed of two series-connected sections, containing four cells each, which are connected in parallel. Cell assembly is of same construction as that in Fig. 1, but there is symmetry about the negative bus plate.

Area of flow passages, cm²	10.24	10.24	10.24	67.25

The cells of the Mk 67 battery are rectangular in shape (Table I and Fig. 3) and are about two and one-half times larger than the Mk 61 and Mk 64 cells. The Mk 67 cathodes have about one-third greater capacity per unit area than those of the Mk 61 and Mk 64 batteries.

The Mk 61 and Mk 64 batteries operate with an entering electrolyte of constant flow rate. This produces battery voltages which are strongly dependent on electrolyte composition and temperature, and which fall continuously as the discharge progresses.

The Mk 67 battery is designed to operate within a few per cent of 245V over the range of sea water temperature and composition found in the world's oceans. This is accomplished by a voltage control system that recirculates a constant flow rate of effluent back into the lower flow passage and adjusts the flow rate of entering sea water to achieve the desired voltage (Fig. 4).

These particular batteries were chosen for this study because (*a*) their physical dimensions and method of manufacture and testing were well documented, and (*b*) the three batteries differed sufficiently in operating conditions and physical configurations to provide a good test of the capabilities of the computer simulation.

Results

The predictions of the computer simulation are compared to observed battery voltages, effluent electrolyte temperatures, and (for the case of the Mk 67 battery) electrolyte flow rates in Fig. 5-16. The observed values

lie within the crosshatched areas on the figures and were obtained from discharges conducted by the Quality Evaluation Laboratory of the Naval Torpedo Station, Keyport, Washington.

The manufacturing tolerances, and to a lesser extent the test tolerances of these batteries, allow a significant spread in battery performance. A measure of the maximum possible spread in performance was obtained by making three computer simulations for each test condition studied. These were (*a*) for the case where the battery was built according to the nominal specified dimensions and tested according to the nominal specified test conditions, (*b*) for the case where the battery was built with the most favorable set of dimensions allowed by the specifications and tested according to the most favorable set of operating conditions permitted by the test specifications, and (c) for the case of the least favorable set of dimensions permitted and the least favorable set of operating conditions permitted. These three conditions are referred to as the nominal, best, and poorest performance predictions, respectively, and are represented by the solid lines in Fig. 5-16.

For the sake of brevity, the computer inputs for battery dimensions and discharge conditions are given only for the Mk 67 battery (Table II). Reference (2) gives a complete listing of all computer inputs. Two other computer inputs warrant discussion. The computer simulation makes use of numerical analysis to account for spatial and temporal variations within these batteries. This is done by dividing the cells into a sufficiently large number of subcells so that spatial variations in operating conditions within any subcell are small, and by dividing the discharge period into short time intervals so that temporal variations within a time interval are small. For this study we chose 25 subcells and a 10-sec time interval. This was shown to be adequate by making checks in which the number of subcells was increased to 100 and the time intervals decreased to 1 sec. Only negligibly small changes in the computer predictions were observed.

Mk 61 battery.—The Mk 61 battery is tested under four discharge conditions which encompass four levels of temperature (0.8, 12.8, 15.6, and 31.1°C), as well as two levels of salinity (31 and 38°/₀₀), pressure (15 and 45 psig), and resistance (0.72 and 0.58 ohm). Figures 5-8 present comparisons between the predicted and observed voltages that are typical for all test conditions encountered by the Mk 61 Mods 0 and 2.

The computer simulation predicts low voltages, *i.e.*, discharge periods which are too long for both the Mk 61 Mod 0 (AZ61 anodes) and for the Mk 61 Mod 2 (AP65 anodes).

A significant number of the batteries performed better than the highest predictions of the computer simulations in all four test conditions. Thus, unless the batteries were built or tested outside of the allowed tolerances, it must be concluded that the voltage predictions for the Mk 61 battery are intrinsically low. However, the magnitude of this discrepancy is not large, especially in view of the 6% spread in observed voltages and the 5-20% spread in the observed discharge time to a cutoff voltage of 100V (0.85 V/cell). The predicted voltages are within 7% of the observed voltages (taken to be the center line of the observed voltage envelope) for 100% of the discharge period to a cutoff voltage of 100V for the low-temperature discharges, for 92% of the two sets of discharges near 15°C, and for 97% of the high-temperature discharges.

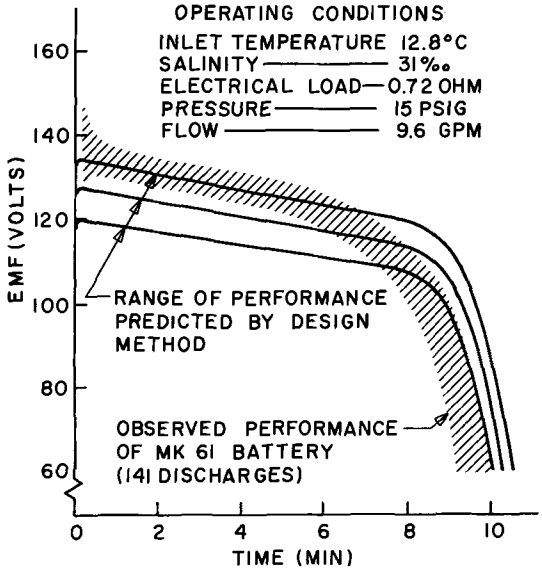

Fig. 6. Comparison of voltage predictions of computer simulation to observed performance of Mk 61 Mod 0 battery when discharged at 12.8°C.

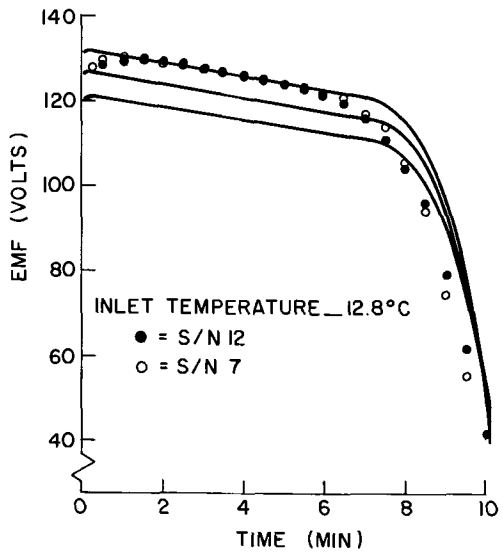

Fig. 7. Comparison of voltage predictions of computer simulation to performance of Mk 61 Mod 2 battery when discharged at 12.8°C.

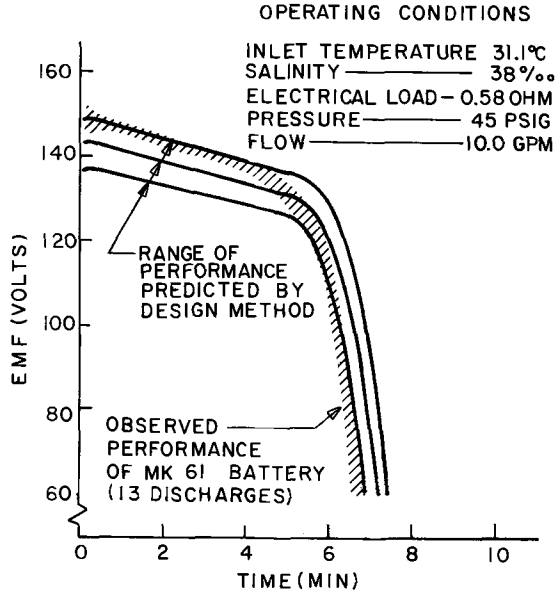

Fig. 8. Predicted voltage and observed voltages of Mk 61 Mod 0 when discharged at high temperature.

Except for starting transients caused mainly by the limitations of the test facility, the observed and predicted temperatures are in good agreement. The predicted and observed Mk 61 effluent temperatures for the discharges at 12.8°C, which are typical of all four test conditions, are compared in Fig. 9 and 10. The predicted temperatures would have to be about 1°-2°C higher to be consistent with the voltage predictions. However, this is not much larger than the uncertainties in temperature measurement and is well within the accuracy required for battery design.

Mk 64 battery.—The Mk 64 battery is designed to operate at the same power level as the Mk 61 but for a shorter period of time. Since it has only one section compared to the Mk 61's two, and since the cells are the same size (Table I), the current density is roughly twice as high.

The observed voltages (taken to be the center line of the observed voltage envelope) are within 2% of the nominal predicted voltage until the observed voltage drops to 100V (0.59 V/cell) at 3.7 min (Fig. 11). The accuracy of the simulation decreases between 3.7 and 5.2 min with a maximum error of +15% occurring at 4.5 min. The low predictions of the simulation beyond 5.4 min are the result of the higher predicted exhaustion rate during the 3.7-5.2-min period.

The errors at or below 100V result from the limitations of the semiempirical model on which the simulation is based (1, 3). Fortunately, enough is known about these limitations that the operating regions where serious errors might be expected can be identified. In practice this is not a serious consideration since the model works well over the range of operating conditions of interest in modern battery design.

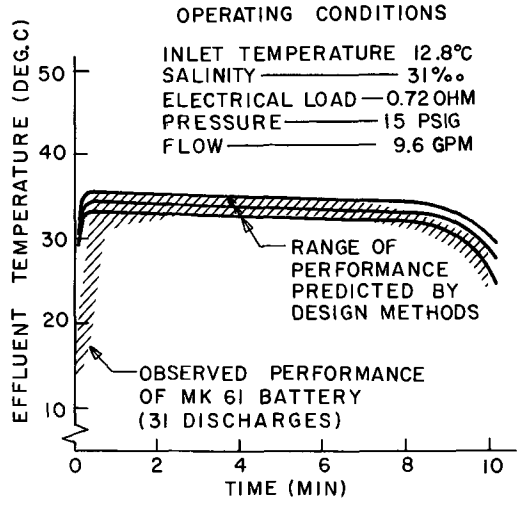

Fig. 9. Predicted and observed effluent temperatures of Mk 61 Mod 0 when discharged at 12.8°C.

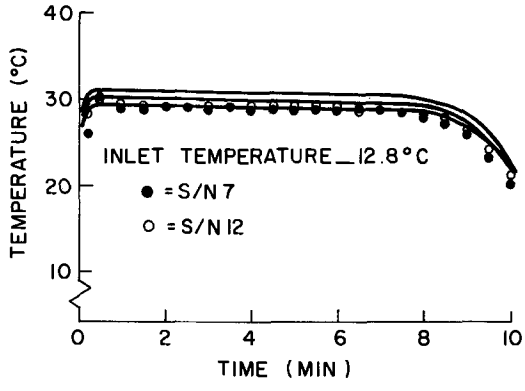

Fig. 10. Predicted and observed effluent temperatures of MK 61 Mod 2 when discharged at 12.8°C.

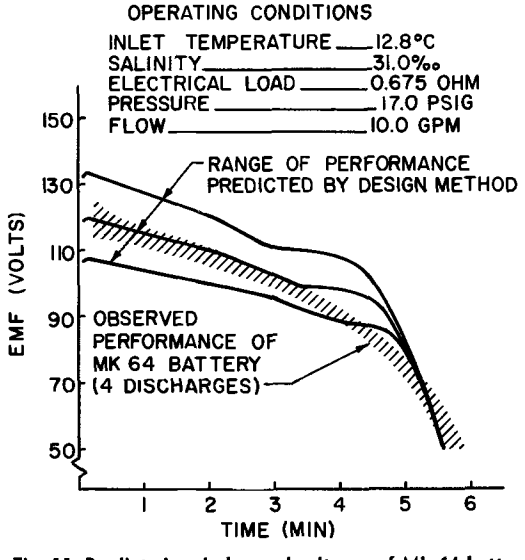

Fig. 11. Predicted and observed voltages of Mk 64 battery

Observed and predicted effluent temperatures are in excellent agreement. The slightly high temperature predictions of the computer simulation are consistent with the slightly high voltage predictions.

Mk 67 battery.—The Mk 67 battery was tested for three conditions: (*a*) high temperature, high salinity, (*b*) ambient temperature, normal salinity, and (c) low temperature, low salinity (Table II). The high-temperature, high-salinity discharges will be discussed first.

Although the Mk 67 battery is designed to operate at 245V, the performance of the battery is such that even at its maximum flow rate of 120 gal/min the voltage does not fall to 245V until the 7-9 min mark for the high-temperature, high-salinity discharge condition (Fig. 12). This permitted us to determine the adequacy of the computer simulation for the Mk 67 battery when discharged at constant flow rate. The agreement is excellent, with the simulation predicting voltages accurate to better than 1% for the first 5 min and to within 2% until the 8-min mark.

At the 8-min mark the observed voltages begin to fall approximately 0.8 min earlier than that predicted by the "low performance" predictions of the simulation. An examination of the flow rate data for this condition shows that the experimental reductions in flow rate lag behind those of the simulation. This lag in flow reduction, which is caused by equipment limitations, explains much of the discrepancy found after 8 min. Another possible source of low observed voltage, especially at low flow rates, is that significant amounts of H_2 are quite likely recirculated into the lower flow passage by the recirculation pump (4). This is most likely to occur near the end of the discharge when flow rates are low because of the increasing volume fraction of H_2 at low flow rates. In spite of this, the predicted and observed discharge life agreed to 5%, based on the "nominal" computer predictions and the average observed time to 160V (0.7 V/cell).

The predicted and observed temperatures are in excellent agreement (within about a degree centigrade) for the first 4 min of the discharge where the flow is constant at 120 gal/min. Thereafter, the observed temperatures were lower than the predicted temperatures, reflecting the high observed flow rates responsible for the low observed voltages described above.

The comparisons between the predicted and observed voltages, temperatures, and flow rates when the Mk 67 battery is discharged at 12.8°C are presented in Fig. 13, 14, and 15, respectively. The nominal voltage predictions are within a few per cent of the observed voltages for 96% of the discharge period to a cutoff voltage of 160V (0.7 V/cell).

The temperature and flow predictions are in good agreement with the observed results over most of the discharge (Fig. 14 and 15). During this period, which ends at about 7½-8 min, the computer predictions imply that the Mk 67 battery is performing between the nominal and the best expected of it. Thereafter, the observed flow rates decrease and the observed temperatures rise faster than the predictions of the computer simulation. This apparent decrease in the intrinsic voltage capabilities of the Mk 67 battery could be the result of H_2 recirculation.

Figure 16 presents the agreement between the simulation and the observed voltages for the case of low temperature and low salinity. The voltage predictions of the simulation are excellent between the 1½ and 7-min marks.

The discrepancies in the first 1½ min of the discharge are caused by starting transients. The battery is filled at a flow rate of 120 gal/min until the system pressure reaches 45 psig, whereupon the flow rate is

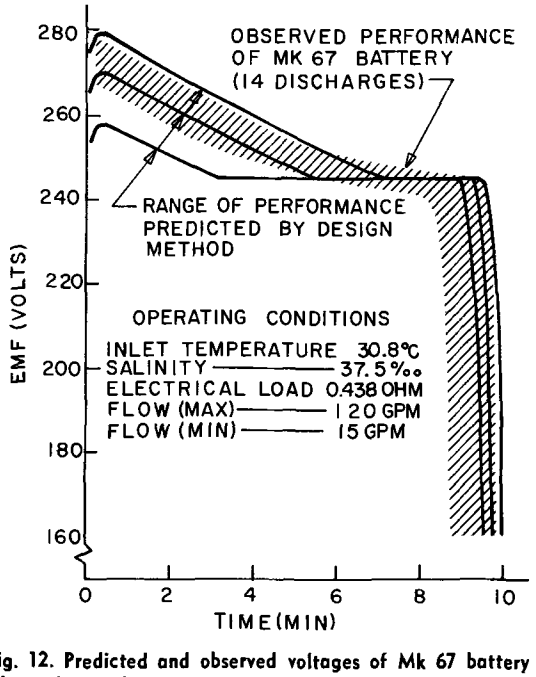

Fig. 12. Predicted and observed voltages of Mk 67 battery when discharged at high temperature.

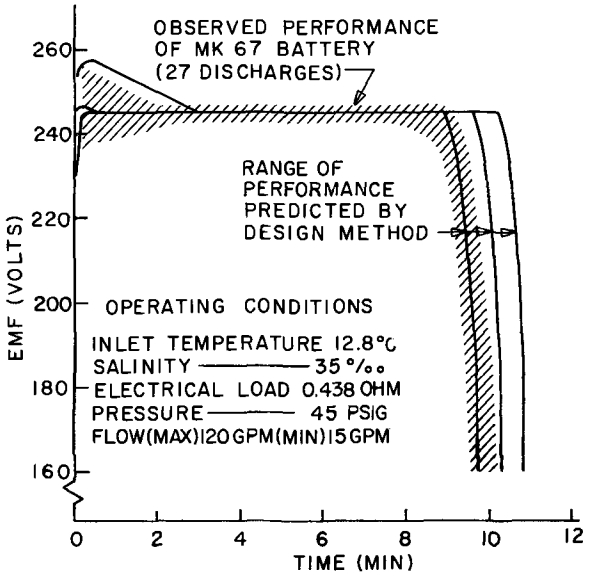

Fig. 13. Predicted and observed voltages of Mk 67 battery when discharged at 12.8°C.

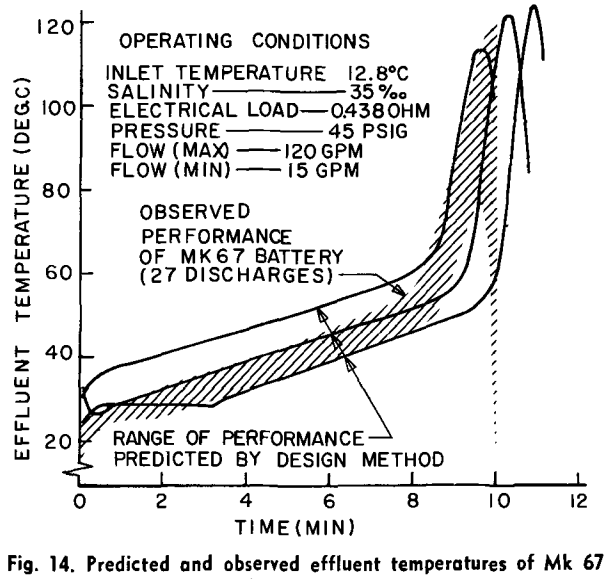

Fig. 14. Predicted and observed effluent temperatures of Mk 67 battery when discharged at 12.8°C.

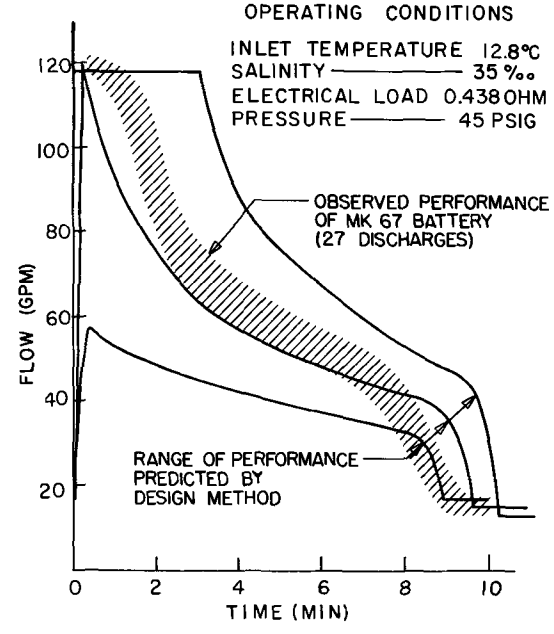

Fig. 15. Predicted and observed flow rates of sea water entering Mk 67 battery when discharged at 12.8°C.

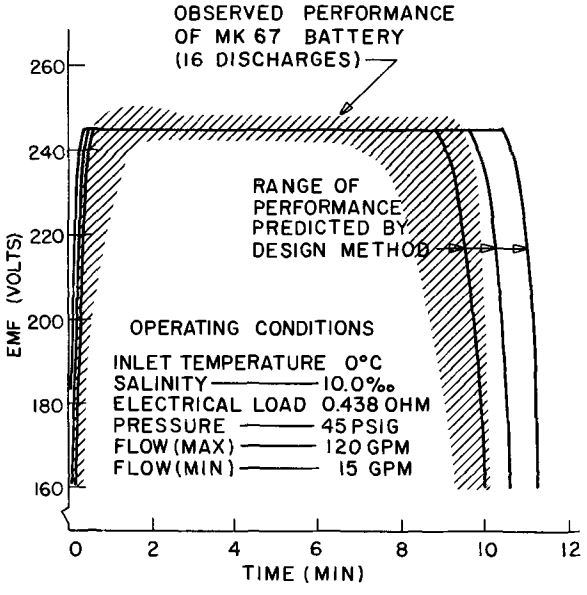

Fig. 16. Predicted and observed voltages of Mk 67 battery when discharged at 0°C.

reduced to the 30-40 gal/min required to bring the battery voltage up to the desired 245V. The wide range of observed voltages found in the first 1½ min (Fig. 16) results from variations in the time it takes to accomplish this task. In contrast, the computer simulation simulates operation in which the filling time is very short with a flow control valve with infinitely fast and accurate response. This condition is best approached by the battery behavior given by the "leading edge" of the observed voltage envelope. It is significant that the agreement between the simulation and the leading edge is excellent.

Low-temperature, low-salinity discharges of the Mk 67 battery are frequently marked by clogging and electrical arcing within the battery in the period beyond 7½ min. This, along with the probable recirculation of H_2, accounts for the poor performance during this period. Since the simulation assumes that no voltage losses from undesired effects such as arcing or clogging occur, a valid comparison during the latter portion of the discharge would be that of the trailing edge of the voltage envelope and the nominal predicted voltage line. These two lines are in good agreement, reaching the cutoff voltage of 160V (0.7 V/cell) within 0.5 min of each other.

Thus, the nominal voltage predictions of the simulation are in excellent agreement for 95% of the discharge time to a cutoff voltage of 160V if the leading edge of the voltage envelope is used during the first 1½ min of the discharge to compensate for the effects of start-up procedures and if the trailing edge of the voltage envelope is used beyond the 8-min mark to compensate for the effects of arcing and clogging.

Discussion

When limitations of the test facility and the effects of clogging and arcing are taken into account, the voltage, flow, and temperature predictions of the computer simulation are in good-to-excellent agreement with the observed performance of the Mk 61 Mods 0 and 2, Mk 64, and Mk 67 batteries. The configurations of the four batteries used in this study are sufficiently diverse that these results are applicable to all high-drain AgCl-Mg battery configurations known to this author. Furthermore, the temperature and salinity of the electrolytes used in the discharges reported here cover the extremes found in the world's oceans with the exception of a few small regions such as those at the bottom of the Red Sea where extremely warm concentrated brines are found. On this basis we conclude that the simulation is more than adequate for use in carrying out parametric studies or for the design of high-drain, sea water-activated batteries which use AZ61 magnesium alloy, the most common alloy for such batteries today.

The computer cost of simulating a battery discharge ranges from $15-$30. The cost of discharging a full-size battery ranges from $2,000 to $30,000 (1). In addition to the advantage of low cost, the simulation gives information on the spatial and temporal distributions of such quantities as temperature, electrolyte composition, and current density that are difficult or impossible to obtain from battery discharges. A further advantage of the simulation is that the range of operating conditions which can be studied is not limited by the availability of discharge facilities or by the practicality of tests conducted at sea. This latter is a significant problem, not only because of the high costs of field operations and instrumentation problems but because of the unpredictable occurrence of many of the test conditions which are of interest.

Thus, the computer simulation permits rapid and inexpensive determinations of the behavior of competing battery configurations permitting a large reduction or even the complete elimination of the "cut and try" effort previously required to design batteries. This ability to evaluate the performance of candidate battery configurations for any desired operating condition considerably reduces the technological risks of battery development. These comments apply with equal force to system studies involving the application of high-drain AgCl-Mg batteries.

Union Carbide Corporation, Consumer Products Division, Cleveland, Ohio 44101

ABSTRACT

A solid-state battery system using a powdered silver anode, a charge transfer iodine complex cathode of 2 perylene · $3I_2$, and an electrolyte of ionically conductive solid KCN-4AgI has been developed. The open-circuit voltage of single cells is 0.64V. Being totally solid, the system enjoys long shelf life and freedom from electrolyte leakage. Cell construction is such that the thickness of the highly conductive (1.4×10^{-1} ohm^{-1} cm^{-1}) KCN-4AgI electrolyte layer can be as low as 0.004 in. without sacrificing useful shelf life. This coupled with the high electronic conductance of both anode and cathode results in low impedance cells capable of delivering continuous currents as high as 50 mA/in.^{2} and pulse currents up to 1.0 A/in.^{2}. Successful operation under conditions of severe rotational spin has been demonstrated. Cell performance over the wide temperature range of $-40°$ to $+250°$F has been shown.

Solid electrolyte batteries enjoy inherent advantages over their liquid electrolyte counterparts in that the absence of a liquid extends the temperature range over which the battery is operable and permits the construction of a leakproof system. Anode corrosion and loss of solvent by drying out constitute two of the important limitations of shelf life in aqueous batteries and it is reasonable to expect that solid-state systems should show improved behavior in these respects. Solid-state batteries should also be capable of pressure packaging or hard encapsulation to yield rugged assemblies that would be capable of withstanding shock and vibration.

Within the last 20 years attempts have been made to use solid ionic conductors as battery electrolytes. Work done before 1950 was mainly of theoretical interest and consisted of measurement of single-cell potentials. During the 1950's a flurry of activity occurred within the battery industry with the resultant development of a number of solid electrolyte systems. However, the most conductive ionic solid known at that time was silver iodide whose specific conductance at 25°C was about 10^{-6} ohm^{-1} cm^{-1}.

Because of this, very thin electrolyte layers had to be employed in order to minimize internal resistance and permit the delivery of current even in the microampere range. During the period 1957-1960 pilot plant production techniques were developed usually under Industrial Preparedness Study Contracts to study design and production problems. The development work conducted by five major battery companies during this period confirmed the advantages predicted for solid electrolyte batteries (1). Miniaturization approaching 100V/cm was achieved, and shelf life was estimated at 10 years. Manufacturing techniques were amenable to a high degree of mechanization. Some of the battery systems were operational and apparently unharmed at temperatures approaching 100°C Packaging could be made exceptionally sturdy and rugged and the batteries were able to withstand shock and vibration.

The development work indicated that there were also limitations inherent in solid-state systems. All exhibited very high internal resistance and high polarization losses during discharge at room temperature. No system could be considered a useful power source for drains in excess of 10 μA/cm^2. Recently a revival of interest in solid-state systems has occurred mainly as a result of the discovery of new conducting compounds. Reuter and Hardel (2) reported Ag_3SI to have conductance of 10^{-2} ohm^{-1} cm^{-1}, and cells of the type $Ag/Ag_3SI/I_2$ built by Takahashi and Yamamoto (3) yielded currents of 1 mA/cm^2 at 25°C. Since Ag_3SI, when slightly off stoichiometry, possesses appreciable electronic conductance and reportedly reacts with iodine to form silver iodide and sulfur (4), further work to clarify the stability of this system is required.

Materials of the general formula MAg_4I_5 (where M = K, Rb, or NH_4) were described almost simultaneously by Bradley and Greene (5) and Owens and Argue (6). Ionic conductances in the region of 2×10^{-1} ohm^{-1} cm^{-1} were reported for the best of these materials, and later papers described cells in the system $Ag/RbAg_4I_5/RbI_3$ (7). Other cathodes used were iodine and the reaction product of iodine and tetrabutylammonium iodide (8). Currents in the milliampere region may be drawn continuously from these batteries.

Recent work (9, 10) has described the preparation and properties of a family of cyanide-iodide solids whose conductance is essentially ionic and again differs but little from that of aqueous battery electrolytes. For example, the specific conductance of KCN-4AgI is 1.4×10^{-1} ohm^{-1} cm^{-1} while that of the aqueous electrolyte of Leclanché cells is 2.0×10^{-1}.

The present paper describes the development of a solid-state battery (11) based on these cyanide-iodide materials and a perylene-iodine cathode. Of necessity, since these solids conduct by silver ion transport, the anode was silver metal. A large number of inorganic and organic iodine complexes were evaluated as potential cathode materials, however, the charge transfer complex of perylene-iodine was used in all cells described here.

Experimental

Materials.—The materials that were used in the cell fabrications were generally Reagent Grade or ACS grade purity chemicals. The preparation of the solid electrolytes of the KCN-AgI and RbCN-AgI systems has been previously described (10).

Cell construction.—In its simplest form the cell consists of an anode layer, an electrolyte layer, and a

* Electrochemical Society Active Member.

Key words: solid electrolyte battery, silver/perylene iodine battery system, potassium cyanide-silver iodide electrolyte, shelf life, perylene-iodine.

cathode layer. The anode can be merely a thin sheet of silver foil or a thin layer of silver metal deposited on one side of the electrolyte layer, or a silver powder-electrolyte composition. This is mechanically separated from the cathode by a thin layer of the compressed KAg_4I_4CN electrolyte. The cathode is also a pressed powder disk formed from the iodine-containing complex, 2 perylene · $3I_2$. The three layers are held together in intimate contact obtained by compression of the respective powders during cell fabrication, the cell thereafter functioning without any applied external pressure.

Figure 1 shows a partial cutaway view of a typical cell construction that utilizes an electrolyte layer that even if as thin as 0.004 in. does not shorten the useful shelf life of the cell and which at the same time results in more efficient utilization of cell volume. The anode subassembly consists of a pressed disk containing silver powder adjacent to the electrolyte layer and an anode collector that serves as an electronic contact to the anode situated on the outside surface of the anode as shown. The cathode subassembly is a disk containing the 2 perylene · $3I_2$ powder and a metallic cathode collector, for example, a thin sheet of nickel. The entire cell assembly is compressed during manufacture to establish intimate physical bonding between the various layers. A standard Adolph Buehler metallographic mounting press may be used for these molding operations in the laboratory. The cell is thereafter encapsulated in plastic, for example, Lucite or Kel-F. Cells have been made whose diameter varied between 0.4 to 1.25 in. In a cell encapsulated in plastic, holes may be drilled through the plastic at either end, filled with conductive silver epoxy cement in which are embedded lead wires, the latter serving as contacts. In a hermetically sealed (metal case) system, one electrode may be brought out through a Stupakoff seal (glass-metal) and the other may be the metal case, or both may be brought out through glass-metal seals.

Electrodes.—In general the choice of anode for a solid-state battery is dependent on the nature of the conducting ion. In the present electrolytes, one must use silver and while the anode metal may be present as a flat, thin metal foil, it is preferable for optimized performance that a large surface area of silver be provided in the anode in contact with solid electrolyte. This is accomplished by the physical blending of mixtures of silver powder and electrolyte powder. The resulting pressed powder compact not only has a large area of interfacial contact between anode and electrolyte but also provides intimate contact between the anode and the electrolyte layers when these are subsequently pressed together. A third component of the anode may be finely divided carbon black which further improves cell performance.

In all cells described here the charge transfer complex of perylene-iodine (2:3) was used as active cathode material. For a battery to possess good, high-temperature shelf life it is desirable that the iodine exert a low vapor pressure; the data of Fig. 2 obtained in this laboratory (12) shows the variation with temperature of the vapor pressure of I_2 over perylene-iodine (2:3) and over solid iodine. In addition the perylene-iodine materials are particularly well suited for use as solid-state battery cathodes because of their high electronic

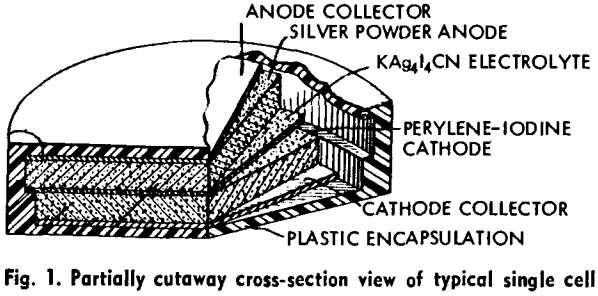

Fig. 1. Partially cutaway cross-section view of typical single cell

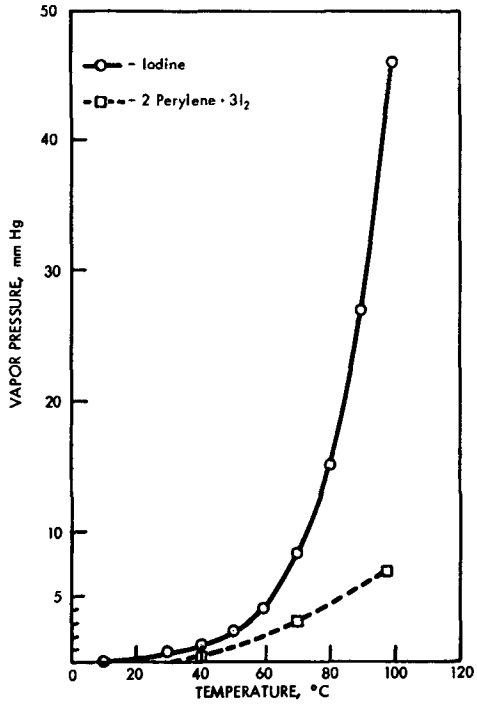

Fig. 2. Variation of iodine vapor pressure with temperature for iodine and 2 perylene · $3I_2$.

conductivities. For example, the specific resistivity of a pressed pellet of 2 perylene · $3I_2$ is 8 ohm-cm. The complex is prepared by reacting the components in a closed tube at 200°C for several hours. While in the open, iodine evaporates slowly and leaves golden-yellow perylene behind, in the sealed environment of the cell the complex is stable.

The 2 perylene · $3I_2$ complex may be powdered and compressed alone as the useful cathode, but preferably it is compounded in much the same manner as the anode, *i.e.*, starting with the dried powder form of the active cathode material, electrolyte, and carbon and physically mixing these together. Drying is again accomplished by storing the respective powders in an argon atmosphere over P_2O_5.

In Table I are shown typical electrode formulations together with capacities and silver and iodine utilizations.

While the charge transfer complex, 2 perylene · $3I_2$, was used as the active cathode material for the cells whose performance is described herein, a number of other organic and inorganic iodine-containing materials were also evaluated. A number of cell systems resulting from this work are shown in Table II.

Electrolyte.—A number of solid compositions prepared in the KCN-AgI and RbCN-AgI system have been used as the solid electrolyte. Of these, the KCN-4AgI solid (KAg_4I_4CN) is preferred because of the

lower cost of potassium salts as compared to rubidium salts. This material was ground to a fine powder in a dry argon atmosphere before being used in the compression molding of cells. The powdered solid electrolyte layer is intimately compressed into both the powdered anode and cathode layers to form a good continuous cell structure. The conductance of KCN-4AgI has been reported in an earlier publication (10) and it may be noted that the conductance is adequate, even at −80°C, to permit use in cells. A comparison of the specific conductance of this material with those of the aqueous electrolytes used in commercial systems is presented in Table III.

Results

In the following section data are reported on single cells and on batteries having a number of cells connected in series or in series-parallel.

Single-cell discharge data.—Continuous discharge data at nominal drains of 50, 150, and 300 μA are shown in Fig. 3, 4, and 5, respectively, over the temperature range of −40° to 160°F. Pulse discharge at 1A for 5

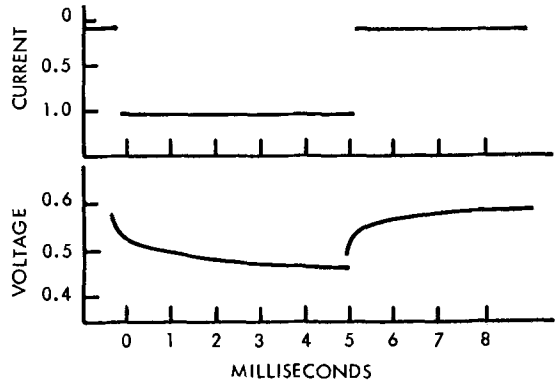

Fig. 6. 1 Ampere discharge for 5 msec $Ag/KAg_4I_4CN/2$ perylene · $3I_2$ cell.

msec is shown in Fig. 6. The ratio of silver to iodine in the electrodes was 4:1 and the formulations 1A and 1C (Table I) were used. The open-circuit potential was 0.64-0.66V and the cells were 1 in. in diameter with a nominal electrode cross-sectional area of 0.75 in^2.

In Fig. 7 is shown a photograph of a hermetically sealed single cell, where the steel container is one contact and the other lead was brought out through a glass to metal (Stupakoff) seal. This construction permitted continuous operation at the 5-6 mA level at up to 250°F in an oil bath (Fig. 8). Polarization scans at 72° and 250°F are shown in Table IV.

Another smaller size of single cell was developed and tested for a low drain-extended service application. This was 0.5 in. in diameter, used electrode formulations 2A and 2C (Table I), and the silver to iodine ratio in the electrodes was 1:1. Performance at room temperature at average currents of 12.6 and 28.3 μA are shown in Fig. 9. Other cells were made in this size with identical anodic silver:cathodic iodine ratios but using the 3A-3C combinations of electrode formulations.

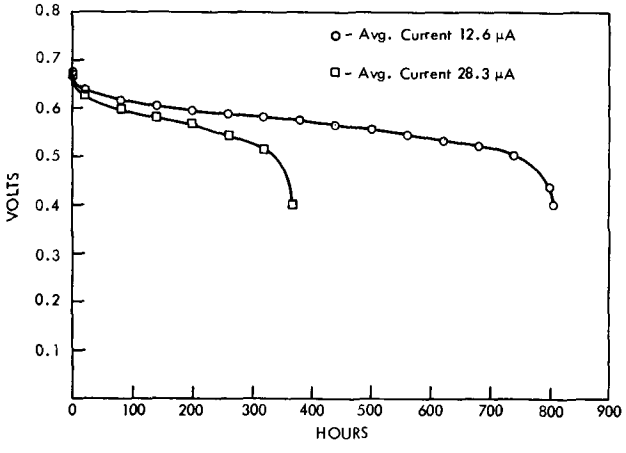

Fig. 9. Performance of 0.5-in. diameter cells using 2A and 2C electrode formulations.

trodes is shown in Table V and the performance of such a cell at room temperature and at −40°C is shown in Fig. 10.

The capability of the cell is much reduced at low temperatures but, by employing a silver reference electrode built into the cell, it was found that under these conditions the anode polarized severely and thus, by increasing the amount of anode (*i.e.*, increasing silver:iodine ratio), improved performance at low temperatures could be obtained. However, this improvement was at the expense of performance at room temperature and 160°C. Data for +23° and −40°C are shown in Fig. 10 and it was decided that the best compromise was an Ag:I_2 ratio of 4:1. One may note that, in cells that are anode-limited, the anode efficiency falls from 58% at room temperature to 12% at −40°F, while

in a cell designed to be cathode-limited the figures are 83% at room temperature and 74% at −40°F based on iodine utilization.

Multiple cell batteries.—Batteries have been made with single cells connected in series, or in parallel, or in combination. A hermetically sealed four-cell battery (two parallel pairs of two cells in series) designed to operate over the temperature range −40° to 160°F is shown in Fig. 11a while a 3.25V battery (five cells in series) is shown in Fig. 11b. The latter was intended to supply a pulse of 1A for 5 msec. A discharge curve for a single cell under these load conditions has been shown in Fig. 6.

Figure 12a shows a variety of single cells and stacks made from these cells, while Fig. 12b shows encapsu-

lations in hermetically sealed containers of some of those batteries.

Performance of three and seven cell stacks of 1/2 in. OD cells is shown in Fig. 13 with loads as indicated (anode:cathode ratio 1:1, 3A and 3C formulation). Figure 14 shows the discharge of seven cell batteries at three different temperatures.

Performance of a series-parallel battery is shown in Fig. 15. Curve A is for a battery having two cells in

series, paralleled three times, while Curve B has four series pairs in parallel. Curve A was obtained by discharging at a 500-ohm load 15 msec on, 30 msec off. The average current was 0.70 mA and the capacity 104 mA-hr to 0.8V cut-off. Curve B was obtained with an 1100-ohm load, 1.0 mA average current with capacity 64 mA-hr to 0.8V cut-off.

Impedance.—Since the electronic conductance of the anode and cathode and the ionic conductance of the electrolyte are all high, it is not surprising that at room temperature single cells of 1-in. diameter have an impedance of about 0.3 ohm. In addition after 12 months storage at 160°F, only a small increase to 0.7 ohm occurred. At −40°F, single-cell impedance is 2.1 ohms fresh and 2.5 ohms after storage. Cell discharge also results in additional small impedance increases as can be seen from Table VI.

The impedance of equivalent cells made with $RbAg_4I_4CN$ electrolyte in place of KAg_4I_4CN is essentially identical. The variation of impendance with temperature for a four-cell (series-parallel) battery using $RbAg_4I_4CN$ electrolyte (see photograph of cell, Fig. 11a) is shown in Fig. 16. The temperature coefficient is 2.9×10^{-3} ohm/°F (5.2×10^{-3} ohm/°C).

Table VI. 1000 Hz impedance of single cells. 1-in. diameter, 0.75 in.^{2} apparent area

Discharge	Temperature of discharge, °F	Impedance (ohms)	
		Fresh cells	After 12 months storage at 160°F
Before	70	0.3	0.7
After	70	0.5	1.2
Before	−40	2.1	2.5
After	−40	—	4.6

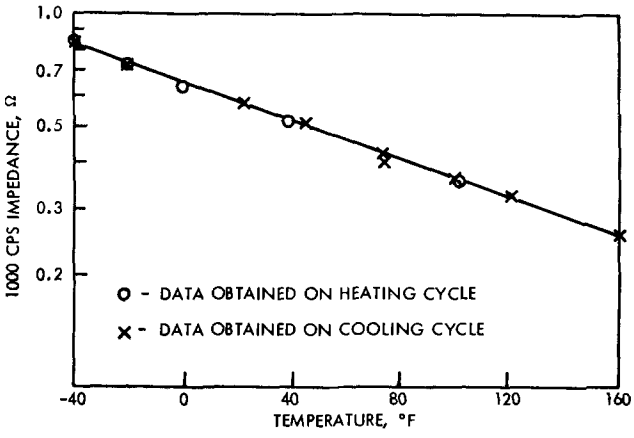

Fig. 16. Variation of impedance with temperature (for 4-cell [series parallel] battery of Ag/RbAg$_4$I$_4$CN/2 perylene · 3I$_2$ system).

Some typical values (also at 1000 cycles) of impedance for 3-, 5-, and 7-cell batteries are shown in Table VII.

Depending on the components and on the amounts of material used for example, high capacity necessitates thick electrodes and hence higher than normal impendance, the figures given in Table VIII can be quoted for impedance for single cells.

Shelf life.—Shelf-life studies were conducted with 1-in. diameter cells under conditions designed to minimize any variabilty caused by seals and moisture ingress. These cells were built as described in previous sections utilizing the design of the single cell shown in Fig. 1, with the 1A-1C electrode formulation (4:1 silver-iodine ratio). Cells were encapsulated in Lucite plastic with an additional second layer of epoxy plastic placed over the Lucite not normally placed over cells destined for hermetic battery sealing. The cells were further stored in a desiccator over P_2O_5 so as virtually to eliminate the possibility of moisture ingress during the storage period. The experimental conditions chosen for this shelf-life study simulate those that exist in the hermetically sealed construction used in later designs of this battery. The shelf-life capability of the system is evaluated by discharge of cells that have been stored for six months at 160°F and then tested over the temperature range of −40° to +160°F. A comparison of the capacities obtained under these conditions with those obtained from fresh cells may be found in Fig. 17. While some decrease in capacity was noted after prolonged 160°F storage (accelerated shelf test), a substantial and certainly useful cell capacity is obtained, and a rule of thumb common in battery technology suggests that one month of storage at 160°F is approximately equivalent to one year at room temperature.

Table VII. Battery impedance at 1000 cycles

Battery type and nominal area	Electrodes (see Table I)	Time	1000 Cycle a-c resistance (ohms)
3-cell, 0.11 in.²/cell	3A-3C	Fresh	3.68
		4 months	4.5
		1 year	4.6
5-cell, 0.11 in.²/cell	3A-3C	Fresh	5.7
		1 month	5.9
7-cell, 0.11 in.²/cell	3A-3C	Fresh	7.3
		3 months	8.3

Table VIII. Impedance of single cells

Area (in.²)	Impedance (ohms)
0.11	0.9 ~ 2.5
0.28	0.5 ~2.0
0.60	0.25 ~ 1.0

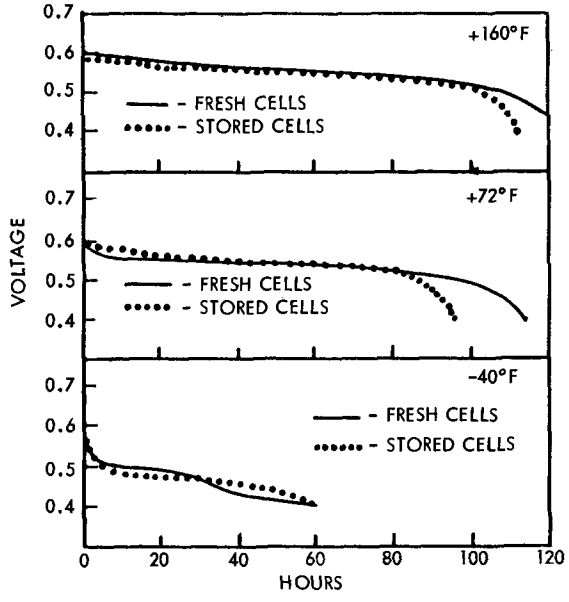

Fig. 17. Shelf-life study (capacity retention of Ag/KAg$_4$I$_4$CN/2 perylene · 3I$_2$ system) (4000-ohm load).

Storage experiments with 0.5-in. diameter cells (3A-3C electrode formulations, 1:1 silver to iodine ratio) are shown in Fig. 18. After six months storage at room temperature virtually no loss in capacity was observed on discharging at room temperature. On the other hand, some loss was observed in the room temperature capability after storage at 160°F for six months.

A loss of open-circuit voltage is seen upon storage and an attempt has been made to determine the magnitude of this decay. An examination of data from several sources indicates a continuously decreasing rate of open-circuit decay. The rate of decay is defined as the total loss in voltage from the time of manufacture divided by the number of days during which the loss occurred. Over a long period of time the loss becomes very small, as is demonstrated in Fig. 19; for example, after storage at room temperature for about one year the average decay is 0.028 mV/day.

Spin testing.—Ag/KAg$_4$I$_4$CN/2 perylene · 3I$_2$ cells have been subjected to discharge loads ranging from 47 to 10,000 ohms while being rotated at speeds of 360 rps (21,600 rpm). The cells operate essentially the same while being rotated at 360 rps as they do under normal static conditions.

Summary

Solid-state battery systems were developed using either KCN-4AgI or RbCN-4AgI as the solid electrolyte, and the charge transfer complex, 2 perylene · 3I$_2$ as cathode. This material provided iodine for electrochemical reduction at a low vapor pressure thus pre-

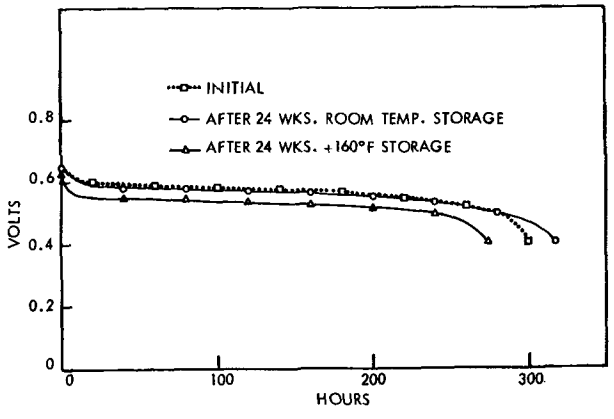

Fig. 18. Storage data with 3A-3C electrode formulations (20,000-ohm load).

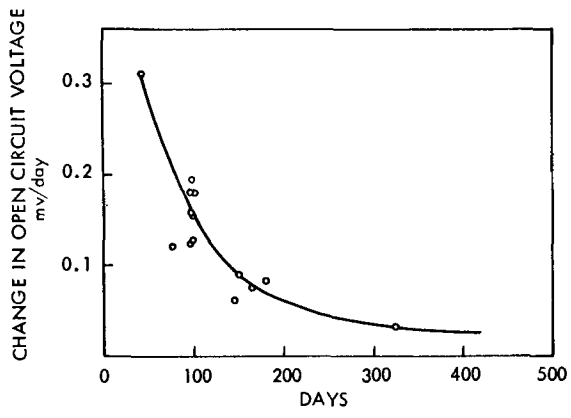

Fig. 19. Loss of open-circuit voltage on storage over extended periods at room temperature.

serving high-temperature shelf life, and was well suited for use as a cathode because of its high electronic conductivity. The use of a silver anode was dictated by faradaic experiments which established the conductance of the solid electrolytes as being due to the movement of Ag^+ ions. In its simplest form, the equation of cell discharge may be written as

at the anode

$$Ag \rightarrow Ag^+ + e^-$$

at the cathode

$$\tfrac{1}{2}I_2 \text{ (perylene complex)} + e^- \rightarrow I^- + \text{perylene}$$

over-all

$$Ag + \tfrac{1}{2}I_2 \text{ (perylene complex)} \rightarrow AgI + \text{perylene}$$

Cell construction and molding techniques were developed that permitted electrolyte thickness as low as 0.004 in. to be used without sacrificing useful shelf life. $Ag/KAg_4I_4CN/2$ perylene $\cdot$ $3I_2$ cells of 1-in. diameter (0.75-in.^{2} apparent electrode cross section) were made whose 1000 Hz impedance is only 0.3 ohm at room temperature. Useful cell discharge was demonstrated over the temperature range of $-40°$ to $+250°$F.

Acknowledgments

The authors would like to express their thanks to M. S. Soldat, R. L. Johnson, and J. T. Marshall who performed much of the experimental work.

The Silver/Silver Iodide/Silver Thermocell

Herbert F. Hunger*

Power Sources Technical Area, Electronics Technology and Devices Laboratory, United States Army Electronics Command, Fort Monmouth, New Jersey 07703

ABSTRACT

Various thermodynamic expressions for the thermoelectric effects in solid electrolytes, including silver iodide, have been reported in the literature. No attempt has been made so far to account for the contraction phenomenon occurring in γ, β silver iodide during temperature increase. Considering that we are dealing actually with a thermomechanical electrical effect, a novel equation for the thermoelectric power of silver iodide was developed which appears to account quantitatively for the experimental data.

The equation contains two terms. Discussion of the nature of these terms and their numerical values lead us to believe that the first term is identical with the heterogeneous thermoelectric effect and the second term with the homogeneous thermoelectric effect. These two effects were postulated and discussed by earlier investigators.

The equation permits computation of both effects as well as computation of the total thermoelectric power as a function of impurity ion concentration and temperature from 0° to 140°C. It appears that the heterogeneous thermoelectric effect is a function of the impurity ion concentration level. The levels in a commercial product of powdered silver iodide from which the sensor pellets were prepared were 4.95×10^{17} and 8.65×10^{17} impurity ions per cm^3. These levels correspond to an averaged thermoelectric power of 7.5×10^{-4} V/°K at room temperature.

A thermocell composed of two identical silver electrodes in intimate contact with opposite faces of a pellet made of compressed silver iodide powder can sense a temperature gradient across the cell by development of a potential difference. Thereby the warmer electrode assumes a negative potential *vs.* the cooler, positive electrode.

* Electrochemical Society Active Member.

Key words: thermomechanical electrical effect, homogeneous thermoelectric effect, heterogeneous thermoelectric effect, strain-potential effect.

The thermoelectric effect of silver iodide and of other solid electrolytes was first studied in 1928 by Reinhold (1). He reported measurements of thermovoltages of various modifications of silver iodide and developed empirical equations describing the observations.

A series of fundamental publications pertinent to the effect followed. Eastman contributed fundamentally with a thermodynamic treatment of stationary states in nonisothermal systems (2). The key to the treatment was the introduction of the heat of transfer and of the entropy of transfer. Wagner's and Reinhold's work led to the separation of the thermoelectric effect into two effects, one homogeneous and one heterogeneous (3, 4). Reinhold expected that in a system consisting of a homogeneous solid electrolyte in a nonisothermal arrangement there would be a potential difference and termed it the homogeneous thermoelectric effect. According to the theory of Wagner, the homogeneous thermoelectric effect can be related to the "elemental heat of transport." This elemental heat of transport differs from Eastman's heat of transfer (of a specie, i, in a mixture) in that only one component of a system participates in the transportation process. The heat of this migrating component is equal to its elemental heat of transport. The heterogeneous thermoelectric effect is equal to the temperature coefficient of the potential difference at the phase boundary between the two electrodes and the solid electrolyte. Reinhold computed the heterogeneous effect from thermal data.

A general theory of the homogeneous thermoelectric effect was developed by Lidiard both for the intrinsic region where Frenkel or Schottky defects prevail and also for the region of impurity-controlled conductivity at lower temperatures (5). The theory suggests that the homogeneous effect is independent of the impurity ion concentration.

In this paper, a mechanistic treatment of the Ag/AgI/Ag thermocell is presented, with the homogeneous thermoelectric effect assumed to be due to Ag^+ transport and the heterogeneous thermoelectric effect to Ag^+ concentration differences (strain-induced) at the electrodes.

Results and Discussion

Movement of ionic charge carriers in a simultaneous electrical and thermal diffusion field.—The current density I_i of an ionic specie, i, in a simultaneous diffusion and electrical field is

$$I_i = I_D + I_E = Z_i F D_i \left(\frac{-\partial c_i}{\partial X} + \frac{Z_i F}{RT} c_i \frac{\partial V}{\partial X} \right) \quad [1]$$

This equation is valid if no temperature gradient is present in the system, or in other words, if the system is isothermal. In a nonisothermal system where $\partial T/\partial X \neq 0$, a current density I_T due to the temperature gradient will be observed (5). We derived an expression for I_T, the thermal current density, from the thermal diffusion equation (6)

$$I_T = -Z_i F \Delta_i \frac{q_i c_i N_L}{C_p T^2} \left(\frac{\partial T}{\partial X} \right) \quad [2]$$

where Δ_i is the thermal diffusivity and q_i the heat of transport of a single charge carrier i.

The sign convention for the partial currents (Eq. [1] and [2] and Fig. 1) has been introduced by Lidiard (5) and has been adopted in our basic considerations. The total current density of charge carriers in a simultaneous electrical and thermal diffusion field is

$$I_i = I_D + I_E + I_T = 0 \quad [3]$$

Looking at the scheme in Fig. 1, which represents a silver iodide crystal with a thermal gradient ΔT across it, we can give proper signs to the various currents. Due to the negative thermal expansion coefficients of γ and β silver iodide, contraction, $-\Delta l$, of the crystal occurs on the warmer side. It is postulated that depletion of silver ions at the compression side causes the negative potential. The movement of silver ions to the cooler side provides ionic heat and mass transport across the crystal.

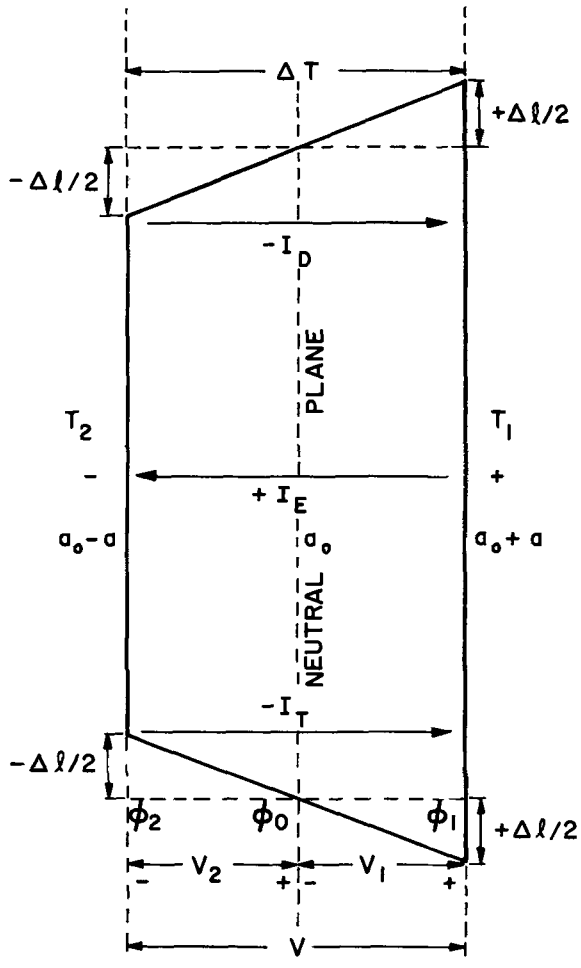

Fig. 1. Scheme of thermoelectric effect in silver iodide

The cooler side assumes a more positive potential. The increasing potential difference across the crystal causes some of the cations to move in the opposite direction, providing for the component I_E. In steady state, I_i has to become zero.

Thermoelectric power equation.—From Eq. [3] the thermoelectric power can be derived. Rearranging we obtain

$$\left(\frac{\partial V}{\partial X} \right) = \frac{RT}{Z_i F} \frac{1}{c_i} \left(\frac{\partial c_i}{\partial X} \right) + \frac{RT}{ZF} \frac{\Delta_i}{Z_i F} \frac{q_i}{C_p T^2} N_L \left(\frac{\partial T}{\partial X} \right) \quad [4]$$

Making $q_i N_L = Q_i$, and multiplying both sides with $(\partial X/\partial T)$, we obtain for the thermoelectric power θ

$$\theta = \left(\frac{\partial V}{\partial T} \right) = \frac{RT}{Z_i F} \frac{\partial \ln c_i}{\partial T} + \frac{Q_i}{Z_i f F T} \frac{\Delta_i}{D_i} \quad [5]$$

This equation contains two terms; the dimension of the two terms is measured in (g-cm^2 sec^{-2} grad^{-1} coulomb^{-1}). The first term describes the temperature dependence of the thermocell voltage caused by the change in mobile silver ion concentration with temperature. This is formally the temperature coefficient of the voltage of a concentration cell with ionic transport (cation transference number = 1) in which the concentration changes with temperature. The second term is proportional to the heat of transfer. Q_i is the elemental heat of transfer of 1 mole of charge carriers

as defined in the works of Eastman, Wagner, and Reinhold (2-4). Δ_i/D_i is the thermal diffusion ratio, whereby Δ_i is the thermal diffusion coefficient and D_i is the mass diffusion coefficient.

The thermoelectric power of silver iodide is negative in sign (1). The first term of Eq. [5] should carry a negative sign since it expresses, in the case of γ-β silver iodide, a decrease in positive electrode potential caused by a decrease in mobile silver ion concentration with increasing temperature. According to Reinhold the second term is also negative (4). Therefore, Eq. [5] can be expressed in its negative form; however, for convenience sake, we are avoiding negative signs in the following.

Thermomechanical electrical effect.—Analysis of the thermoelectric effect shows, in analogy to the pyroelectric and piezoelectric effect, that we are dealing with a thermomechanical electrical effect (7). Our effect is analogous to the "false" pyroelectric effect which is due to the deformation which accompanies a change in temperature and which is, therefore, of piezoelectric origin.

The "true" thermopotential effect, which follows path $T \rightarrow V$, could only be measured if $-\Delta l = 0$ (6). The "false" thermopotential effect, which is a secondary effect, is a sequence of the thermal contraction effect and the strain-potential effect and follows the path $T \rightarrow -\Delta l \rightarrow V$ (6). Consequently, the mechanical electrical part of the effect can be treated formally like the strain-potential effect (8, 9). The first term of the thermoelectric power Eq. [5] can be developed further by applying strain-potential calculations to the effect. The strain potential difference V_s is directly proportional to the strain (6, 8, 9)

$$V_s = 2\frac{RT}{Z_i\mathbf{F}}\frac{b \cdot \epsilon}{a_o} \qquad [6]$$

b is a constant and a_o is the original mobile ion concentration before deformation.

Since $\epsilon = \Delta l/l$, we have to relate $-\Delta l$, the contraction of the crystal, to $\Delta T = T_2 - T_1$. This can be done by using the negative thermal expansion coefficient α of γ-β silver iodide (10-14).

Equation [6] thus changes to

$$V_s = 2\frac{RT}{Z_i\mathbf{F}}\frac{b}{a_o}\alpha T \qquad [7]$$

Differentiation of V_s by T gives a new equation which corresponds to the first term in Eq. [5]

$$\frac{dV_s}{dT} = \frac{4RT}{Z_i\mathbf{F}}\frac{b\alpha}{a_o} \qquad [8]$$

The new term takes material parameters into account, such as the negative thermal expansion coefficient α and the original mobile ion concentration a_o, which was found to be practically identical with the impurity ion concentration (8, 9)

$$\theta = A + B = \frac{4R}{Z_i\mathbf{F}}\frac{b}{a_o}\alpha T_2 + \frac{q_i N_L}{Z_i f \mathbf{F} T_1}\frac{\Delta_i}{D_i} \qquad [9]$$

A and B are the heterogeneous and homogeneous components of the thermoelectric power, respectively. Equation [9] considers that the temperatures in the two terms are different, T_2 being the high temperature on the contraction side and T_1, the original lower temperature of the system, now the temperature of the heat sink.

Numerical evaluation of the thermoelectric power equation.—Equation [9] can be numerically evaluated if we rearrange the B term. The heat of transfer q_i can be estimated (6)

$$q_i = \frac{c_p \cdot \rho \cdot \overline{T}}{c_i} \qquad [10]$$

c_p is the specific heat, ρ the density, and c_i the mobile charge carrier concentration.

Since α, c_p, ρ, and consequently c_i are in themselves functions of the temperature which we can estimate, we can improve Eq. [9] to

$$\theta = A + B = \frac{4R}{Z_i\mathbf{F}} b\,\alpha_T \frac{T_2}{a_o} + \frac{1}{Z_i f \mathbf{F}}\frac{\Delta_i}{D_i} N_L \frac{(c_p)_T \cdot \rho_T}{2(c_i)_T}\left(1 + \frac{T_2}{T_1}\right) \qquad [11]$$

By our definition $T_1 = T_2 - 1$, and a_o and T_2 are real variables. The following are constants: $4R/Z_i\mathbf{F} = 3.355 \times 10^{-4}$; $b = 3.28 \times 10^{20}$; $1/Z_i f\mathbf{F} = 7.25 \times 10^{-6}$; $N_L = 6.02 \times 10^{23}$. Δ_i/D_i, the thermal diffusion ratio, is unknown and will be estimated. α_T, $(c_p)_T$, ρ_T, and $(c_i)_T$ are, within the range of temperatures considered, linear functions of T_2 or $\overline{T}$, respectively (6). $\overline{T}$ is the average bulk temperature of the electrolyte.

$$\alpha_T = 4.0 \times 10^{-6} + \frac{2.215 \times 10^{-8}}{11}(T_2 - 273) \qquad [12]$$

$$(c_p)_T = 4.48 \times 10^{-2} + 2.669 \times 10^{-4}(\overline{T} - 273) \qquad [13]$$

$$\rho_T = 5.5984 + 2.82 \times 10^{-3}(\overline{T} - 273) \qquad [14]$$

$$(c_i)_T = 1.438 \times 10^{22} + 7.07 \times 10^{18}(\overline{T} - 273) \qquad [15]$$

The thermal diffusion ratio Δ_i/D_i in the B term of Eq. [11] is unknown for the solid-state system under consideration. We are, however, able to estimate it from Eq. [11] by using experimental theta data.

A Fortran program was used to compute the thermal diffusion ratio from Eq. [11] utilizing an experimental theta value of 7.5×10^{-4} measured by Catz (15). For 274°K and experimental impurity ion concentrations a_o ranging from 4.95×10^{17} to 8.65×10^{17} ions/cm^3 in Malinchrodt silver iodide samples (9), we obtain ratio values of 7.98 and 6.61, respectively. These values are physically reasonable (6).

Another Fortran program was prepared in order to compute the first term A and the second term B of Eq. [11], and further their sum theta as a function of a_o and T_2. We varied a_o irregularly. T_2 varied from 274° up to 414°K in steps of 10°K. The upper limit was chosen to be 420°K. The data of the computer program are presented in Fig. 2. The logarithm of the thermoelectric power theta is plotted *vs.* the absolute temperature T_2 as a function of a_o. The a_o range of interest is 10^{17}-10^{20}. In the figure, the computed theta values are compared with experimental data given by Catz and Reinhold (15, 1). Over 80% of these data fall

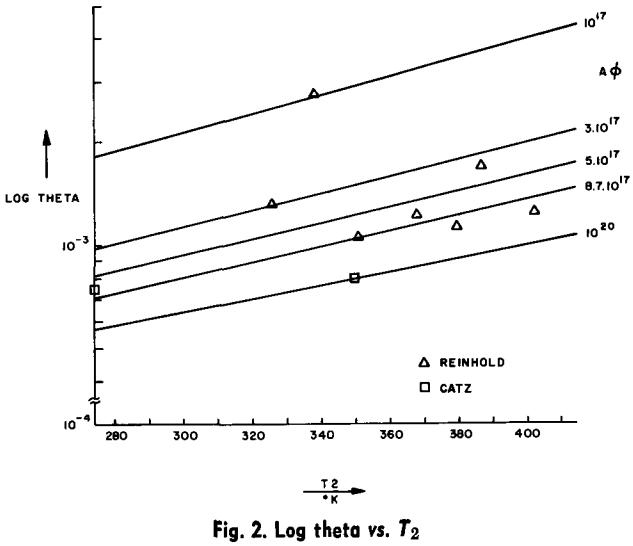

Fig. 2. Log theta *vs.* T_2

Table I. Heterogeneous and homogeneous thermoelectric effect in silver iodide

T°K	$(\partial V/\partial T)\cdot 10^3$ (V/°K)	$(\partial V/\partial T)\cdot 10^3$ hetero	$(\partial V/\partial T)\cdot 10^3$ homo
400°K (16, 17))	−1.24	−0.11	−1.13
400°K (our data, $a_0 = 10^{18}$)	−1.296	−0.31	−0.99

within the range of experimentally observable impurity ion concentrations.

In the next two figures (Fig. 3 and 4), log theta, log A, and log B are plotted *vs.* the absolute temperature T_2 for $a_0 = 10^{17}$ and 10^{18}, respectively. We can see from Fig. 3 and 4 that at $a_0 = 10^{17}$, the A effect dominates the theta data both in absolute value and slope. At $a_0 = 10^{18}$, however, the situation becomes reversed and the B effect dominates.

A more comprehensive presentation is given by a log theta, log A, and log B *vs.* log a_0 plot (Fig. 5). The two full curves, designated 274° and 414°K represent log theta *vs.* log a at the given temperatures. The interrupted lines A274 and A414 show the A effect at the two temperatures, and B274 and B414 the B effect. Figure 5 shows the influence of both T_2 and a_0 on the different terms of the thermoelectric power equation. It can be seen that the major effect can be either the

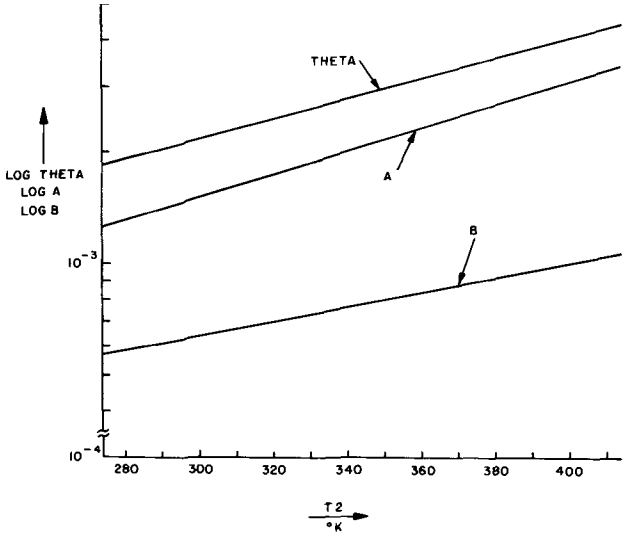

Fig. 3. Log theta, log A, and log B *vs.* T_2; $a_0 = 10^{17}$

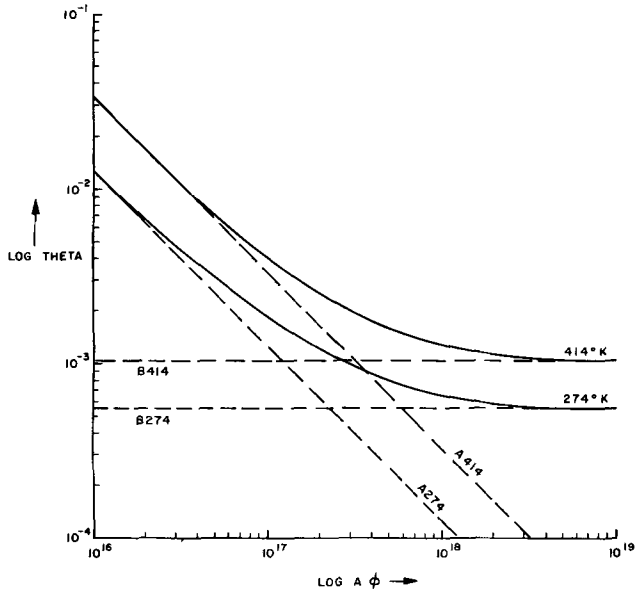

Fig. 5. Log theta, log A, and log B *vs.* log a_0

A or B effect depending upon the order of magnitude of the impurity ion concentration. An increase in thermoelectric power can be expected in silver iodide material with low impurity ion concentration.

We have found in the work of Reinhold and Blachny, summarized by Hauffe, thermodynamic treatment and estimates of the homogeneous and heterogeneous thermoelectric effects (16, 17). The data given there for the thermocell Ag/βAgI/Ag are summarized in Table I and compared with our data for the A and B effect. Reinhold and Blachny derived the homogeneous effect as the difference between the experimental thermal power and the heterogenous effect which was computed from thermal data. From the data given in Table I, it appears that our A effect is practically identical with the heterogeneous thermoelectric effect. The numerical difference can be accounted for by a slight difference in the impurity ion concentration of the two silver iodide samples. The B effect is in excellent numerical agreement with the homogeneous thermoelectric effect.

Manuscript submitted Nov. 5, 1971; revised manuscript received April 6, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Cathodic Discharge of Graphite Intercalation Compounds in Organic Electrolytes

Herbert F. Hunger* and George J. Heymach

Power Sources Technical Area, United States Army Electronics Technology and Devices Laboratory (ECOM), Fort Monmouth, New Jersey 07703

ABSTRACT

A survey of graphite intercalation compounds with cathodic depolarizer capability showed that two groups, graphite fluorides and graphite oxides, offer theoretically 900-1500 W-hr/lb of cell reactants in lithium batteries. The attractiveness of these compounds is further enhanced by their practical insolubility in the electrolytes of interest. Mechanically stable cathodes were prepared from tetracarbon monofluoride, carbon monofluoride, and graphite oxide. Galvanostatic current-potential curves of the cathodes in 1M $LiClO_4$–propylene carbonate electrolyte were measured at 30°C. The current-potential curves of the intercalation compounds were compared with that of cathodes prepared in the same fashion but containing manganese dioxide as the depolarizer. Galvanostatic discharge curves showed that 100% reduction of the cathodic depolarizers can be achieved. This is followed by solvent reduction which led to an apparent increase in utilization over 100%. By graphical integration of the cathodic and cell discharge curves, a comparison of the energy content (watt-hour/pound of depolarizer and watt-hour/pound of cell components) of the depolarizers as a function of rate, per cent utilization, electrolyte anion, and solvent was made. Considering the essential cell component weights, up to about 150 W-hr/lb of battery components can be expected in practical lithium/carbon monofluoride batteries.

There has been recent interest in the use of graphite intercalation compounds, primarily graphite fluorides, as cathodic depolarizers in organic electrolyte batteries.

Carbon monofluoride was first synthesized by Ruff and Bretschneider (1) by direct fluorination of coarse graphite in the temperature range of 420°-460°C.

Tetracarbon monofluoride, a compound with lower fluorine content, was prepared by Ruedorff and Ruedorff (2) by reacting fluorine in a fluorine-hydrogen fluoride mixture with graphite at room temperature.

The first report of utilization of graphite intercalation compounds in batteries comes from Brown (3, 4). He reports to have used and tested graphite oxides as depolarizer in Leclanché cells.

Braeuer (5-8) was the first to demonstrate and report the feasibility of lithium organic electrolyte batteries using a graphite intercalation compound, tetracarbon monofluoride, as the cathodic depolarizer. In comparing his cell with the best organic electrolyte batteries available, there appeared promise in graphite intercalation compounds as cathodic depolarizers.

Fukuda *et al.* (9, 10) have shown the usefulness of carbon monofluoride as cathodic depolarizer in experimental lithium organic electrolyte batteries. The use of intercalation compounds in a secondary, nonaqueous solvent battery was reported by Bennion (11).

The objective of this paper is to compare various potential depolarizers for primary lithium organic

* Electrochemical Society Active Member.

Key words: graphite oxide, carbon monofluoride, tetracarbon monofluoride, manganese dioxide, dimethyl sulfite.

electrolyte batteries with each other and to cite their relative merits.

After a survey of all known graphite intercalation compounds (12, 13), the following two groups of graphite intercalation compounds were considered in our experimental study as potential cathodic depolarizers: graphite oxides and graphite fluorine compounds.

In Table I a comparison is made of the theoretical energy contents of various depolarizers in lithium organic electrolyte batteries. The first three depolarizers are transition metal oxides; the next two are copper halides; the last three are graphite intercalation compounds. In computing the faradaic capacities, the following assumptions were made. In the case of V_2O_5, the reduction is assumed to occur from the +5 valency state to the +4 valency state, in the case of MnO_2 from the +4 to the +3, and in the case of MoO_3 from the +6 to the +4 state. The figures for $CuCl_2$ and CuF_2 were given by Jasinski (14). The faradaic capacities for tetracarbon monofluoride, carbon monofluoride, and graphite oxide were calculated by assuming LiF and Li_2O as end products. The emf's in Table I were computed from thermodynamic data (15, 16). In the case of CF and C_4F, emf data calculated from the free energy of the cell reaction were used (17). The measured open-circuit voltages of Li/CF and Li/C_4F cells are considerably lower than the theoretical emf's. This discrepancy could be due to the establishment of a mixed potential, CF reduction being the cathodic reaction and solvent oxidation the anodic reaction involved. The mixed potential would lie between the two corresponding redox potentials. In the fourth column of Table I, experimentally observed open-circuit voltages are recorded. It has been found that the open-circuit voltages in the cases of MnO_2 and MoO_3 exceed the theoretical emf's considerably (18). Unknown electrode processes other than those assumed in the computations must be responsible for the experimentally observed data. From the table, a theoretical watt-hour/pound ratio, ranging from 918 to 1505, can be expected for the graphite intercalation compounds. This high ratio combined with their practical insolubility in the organic electrolytes of interest makes these compounds promising candidates for depolarizers in lithium-nonaqueous electrolyte batteries.

Table II shows a comparison of theoretical energy densities of cathodic depolarizers in lithium batteries.

Table I. Comparison of theoretical energy contents of various depolarizers in lithium organic electrolyte batteries

T = 25°C

Depolarizer	A-hr/lb[a]	EMF	Open-circuit voltage	W-hr/lb[b]
V_2O_5	62.1	2.34	3.5	217
MnO_2	129.5	2.69	3.48-3.98	349
MoO_3	154.0	1.93	2.9-3.0	297
$CuCl_2$	164.0	3.06	3.1	502
CuF_2	211.0	3.55	3.3	749
C_4F	175.8	5.23	3.14-3.32	918
CF	320.0	4.66	3.14-3.3	1491
C_2O	451.4	—	3.34	1505

[a] Ampere-hour/pound of reactants.
[b] Watt-hour/pound of reactants.

Table II. Comparison of theoretical energy densities of cathodic depolarizers in lithium batteries

T = 25°C

Electrochemical couple	A-hr/cm³ of reactants	W-hr/cm³ of reactants
Zn/HgO	1.19	1.59
Li/CF	1.11	5.17
Li/C_2O	1.11	3.71
Li/CuF_2	1.07	3.80
Li/$CuCl_2$	0.81	2.48
Li/C_4F	0.59	3.08

For comparison purposes, the data for a Zn/HgO cell are added. It can be seen from the table that the theoretical enery densities to be expected from graphite intercalation compounds look highly attractive.

Experimental

Most of the experimental work was performed in a dry lab (Dri-Lab/Dri-Train/Vacuum/Atmospheres Corporation, North Hollywood, California) in pure, dried argon atmosphere.

Purification of solvents.—The solvent mainly used in this study was propylene carbonate, PC, (Eastman Kodak Company, T_B = 121°-123°C at 17 mm pressure). It was chosen because it has been widely studied and most of its data of interest are reported in the literature (19). Its purification procedures are also well described (20). After drying the PC with 5A molecular sieves, the solvent was submitted to vacuum fractionation at 7 mm Hg. The first fraction of 300 ml was discarded.

Dimethylsulfite, $DMSO_3$, (Eastman Kodak Company), was the other solvent used in the study. It was chosen because electrolytes prepared with this solvent have only about 40% of the viscosity of those containing PC. $DMSO_3$ was purified by treatment with 5A molecular sieves.

Preparation of electrolytes.—Three types of electrolytes were prepared: 1M $LiClO_4$-PC, 1M $LiAsF_6$-PC, and 1M $LiClO_4$-$DMSO_3$. Lithium perchlorate, anhydrous, (Alfa Inorganics, Inc., Beverly, Massachusetts) was vacuum dried at 150°C and 1M solutions were prepared in the dry lab; 1M solutions with $LiAsF_6$, electrochemical grade, (U.S. Steel Corporation) were prepared in a similar manner. The use of 1M $LiAsF_6$-PC electrolytes presented no problem in measuring the characteristics of the depolarizers *vs.* a lithium reference electrode; they appeared, however, to be of questionable value as practical electrolytes since the lithium anode showed random passivation phenomena in this medium.

Depolarizer materials.—The following depolarizer materials were used in the study:

1. Tetracarbon monofluoride with the actual composition $C_{5.54}F$ (Ozark-Mahoning Company, Tulsa, Oklahoma).

2. Carbon monofluoride $CF_{1.007}$ (Ozark-Mahoning Company, Tulsa, Oklahoma). Spectroscopic analysis detected further the following metals in percentage of total weight. Ni 0.01, Fe 0.1, Al 0.005, Mg 0.0005, and Cu 0.0005. The metals are probably present as fluorides.

3. Graphite oxide could not be obtained commercially and had to be prepared in-house by partial oxidation of graphite (21). In this preparation, graphite is treated with an anhydrous mixture of concentrated sulfuric acid, sodium nitrate, and potassium permanganate, followed by washing and drying procedures (P_2O_5). An analysis gave the following data: C = 54.43%, H = 2.46%, O = 40.35%, or $C_8O_{4.4}$, $H_{4.36}$. Considering the "ideal formula" of graphite oxide, $C_8O_2(OH)_2$, proposed by Hofmann (22), we recognize that our sample has a too high hydrogen content. This could mean that it contains water. Thus, we arrive from our analytical data at a composition of $C_8O_{1.48}(OH)_{1.48}\cdot 1.44\ H_2O$. Our graphite oxide thus reached about 75% of its maximum oxidation state and contains about 1.1 molecule of water per each C_6 arrangement.

4. Manganese dioxide, Type M (Manganese Chemical, Baltimore, Maryland).

5. Graphite, Microcrystalline Graphite 1651 (Southwestern Graphite Company, Burnet, Texas).

Preparation of electrodes.—*Cathodes.*—The preparation method described by Braeuer (7) was first considered, but soon discarded, since it was found that no good adherence of the cathodic mix to the copper grid

could be maintained after submersion of the electrodes in propylene carbonate.

Another preparation method, described by Watanabe and Fukuda (9), which consists in pasting a mix of the depolarizer with carbon (or graphite), Teflon powder, and propylene carbonate onto a nickel-screen, did not result in a mechanically stable electrode during discharge.

Consequently, a method was devised which resulted in mechanically stable cathodes. In this method, a cathodic mix was prepared from 1g depolarizer, 0.2g graphite, and 0.2g Teflon powder; 0.25 ml Teflon emulsion 41 BX (Du Pont)), containing 0.8g Teflon per ml, was added to 2g of the cathodic mix. Distilled water was added to form a sludge under stirring. The total Teflon content of the cathodes was 21.8%. Then, a generous amount of acetone was added. Current collectors (3.2 × 3.2 cm plus a tab) made from copper grid (Exmet 3-10) were placed on a glass plate and covered with acetone. The sludge was smeared with a spatula on the grids and rolled on with a glass tube. The product was brought between two filter papers and Teflon sheets and pressed to remove the major amount of liquid and to compact the electrodes. Pressure applied per electrode varied, but was usually around 10,000 psi for 1 min. The compressed electrodes were vacuum dried in a dessicator. In the case of the graphite fluorides, the cathodes were further dried in a vacuum oven at 140°C until the weight became constant. In the case of graphite oxide, however, it became necessary to dry the finished electrodes in a vacuum dessicator over P_2O_5, because of the low decomposition temperature of the compound (starting 70°C). The rubberlike consistency of graphite oxide also led to bending of the cathodes after drying. Careful pasting of each side and twice compressing, however, eliminated that problem. The electrodes containing MnO_2 were also vacuum dried over P_2O_5. In one experiment, graphite was used as the sole depolarizer. In this case, the mix did not form a sludge in water-acetone as in the case of the intercalation compounds. The suspension had to settle and was decanted from the liquid and then carefully pasted on the copper screen. Its adherence was extremely poor before compression.

Lithium electrodes.—A commercial lithium ribbon (4 × 0.015 in.) stored in decahydronaphthalene, was cut to size (5 × 2.5 in.) and pressed into a nickel screen (Exmet 2/0; 5 × 6 in.). Pressing was performed between two stainless steel plates greased with petrolatum (Fisher, snow white, U.S.P.). The pressure applied for a minute was 1000 psi per electrode. Then, eight electrodes were cut out. Their dimensions were about 3.2 × 3.2 cm with an attached nickel screen tab of 1.5 × 4.0 cm. Lithium anodes thus prepared contained about 0.16g lithium metal each, which corresponds to about 0.617 A-hr per electrode. The finished electrodes were stored in decahydronaphthalene. Before use, they were thoroughly washed several times in petrol ether.

Electrochemical cell.—The electrochemical cell case used was essentially of the design described by Braeuer (7) and fabricated completely from Teflon. The cathode was held in position by the center groove of the cell case, thus separating the cell in two electrolyte compartments. A U-fold paper separator (3.2 × 6.6 cm) was put around the cathode to protect against eventual flaking off of the cathodic material. The paper separator was made of Genuine Whatman Filter Paper No. 1 (W & R Balston Ltd., England). The lithium anode and the lithium reference electrode, which were identical in design to the lithium anode, were held in position by the two outside grooves in the cell case. These lithium electrodes were thus pressed with one surface against the walls of the case so that only one surface was exposed to the electrolyte. The geometrical surface areas of anode and reference electrode in contact with the electrolyte were thus about 10 cm^2 each. The anode and reference electrodes were arranged parallel to the cathode each at a distance of 5 mm from the latter. Since there were two separate electrolyte compartments, the active geometrical surface area of the cathode *vs.* the anode was about 10 cm^2. The cell temperature was monitored. The electrolyte resistance between each lithium electrode and the cathode was about 10.2 ohms.

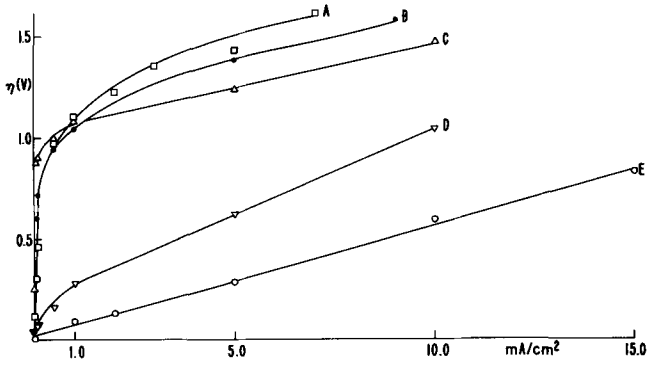

Fig. 1. Polarization curves of cathodes and anodes in Li/1M $LiClO_4$-PC/depolarizer cells. A, $C_{5.54}F$; T = 29.8°C. B, $C_xO_yH_z$; T = 29.5°C. C, CF_x; T = 29.0°C. D, MnO_2; T = 26.0°C. E, Li anode; T = 32.5°C.

Electrochemical measurements.—The open-circuit voltage of the cells was measured with a 610B electrometer, Keithley Instruments, after at least 1 hr of equilibrium in the electrolyte. In order to measure the current-voltage relationship of the total cell and of an individual electrode *vs.* the reference electrode, galvanostatic steps were applied to the cell with a precision current source, Model CS-12, North Hills Electronics, Inc., Glen Cove, New York. Voltage readings were taken with the 610B electrometer until steady state was reached. For practical purposes, steady state was defined as voltage change $\leq$ 10 mV/5 min. Since the conductance of 1M $LiClO_4$ in propylene carbonate is $\sigma = 4.9 \times 10^{-3}$ ohm^{-1} cm^{-1}, the iR drop within the electrolyte to the reference electrode $\simeq 1.5 \times 10^{-15}$V for the highest potential measured and can be neglected.

Galvanostatic discharge curves at various current densities were measured to determine the cathode utilization. Electrode potential and cell voltage readings were taken during continuing discharge mainly with a Hewlett-Packard Strip-Chart Recorder, Model 7100B, with two 1750A Input Modules.

Results and Discussion

Current-voltage relationship.—Table III compares experimentally observed open-circuit voltages of various Li/organic electrolyte/depolarizer cells with theoretical emf's. It can be seen from the table that all graphite intercalation compound-electrolyte combinations show open-circuit voltages ranging from 2.85 to 3.34V. In case of CF, data are about 1.44V lower than those thermodynamically expected. One exception occurs in the case of 1M $LiAsF_6$-PC electrolyte, where an even lower open-circuit voltage was observed.

Figure 1 shows the polarization, η, of $C_{5.54}F$, CF, graphite oxide $C_xO_yH_z$, and MnO_2 cathodes and also of a lithium anode, measured *vs.* the lithium reference electrode as a function of current density. By definition

Table III. Comparison of open-circuit voltages of various Li/organic electrolyte/depolarizer cells with emf's

Cell	Open-circuit voltage	EMF	T, °C
Li/1M $LiClO_4$-PC/$C_{5.54}F$	3.32	—	29.5
Li/1M $LiClO_4$-PC/CF	3.14	4.66	29.0
Li/1M $LiClO_4$-PC/$C_xO_yH_z$	3.34	—	28.0
Li/1M $LiClO_4$-PC/MnO_2	3.51	2.69	24.2
Li/1M $LiClO_4$-PC/C graphite	3.00	—	30.0
Li/1M $LiAsF_6$-PC/CF	2.85	4.66	30.0
Li/1M $LiClO_4$-$DMSO_2$/CF	3.22	4.66	30.0

the polarization is composed of activation polarization, concentration polarization, and internal electrode resistance polarization (*e.g.*, due to a nonconducting film, or in this specific case, due to contact resistance between graphite and the intercalation compounds or MnO_2, respectively). The curves were measured up to the current density where the voltage between lithium anode and cathode reached zero volt and started to reverse. No limiting currents were observed in that current density region. The limiting current density of a lithium anode in 1M $LiClO_4$-PC electrolyte at room temperature is around 40 mA/cm² (19).

All three graphite intercalation compounds show a polarization larger than 1V at a relatively low current density of 1 mA/cm². The kinetic reason for this behavior is unknown at the present time. Polarization-current density curves of similar shapes, however, have been observed in cases of high activation polarization due to low exchange current densities (23). One step in the reduction mechanism of the depolarizer will be rate limiting, *e.g.*, in the case of carbon monofluoride it could be

$$(CF)_n + ne^- \longrightarrow nC + nF^- \qquad [1]$$

The breaking of the covalent C—F bond and/or formation of an activated complex could be connected with a high activation energy resulting in a low exchange current density. No severe concentration polarization can be recognized in any of the three curves over the measured current density range.

It has to be noted that manganese dioxide is kinetically superior to the graphite intercalation compounds. It does not exhibit the high polarization effect. The comparison between manganese dioxide and the intercalation compounds also shows that the common slow kinetic of the latter is not a consequence of the electrode preparation or potential measurement technique since manganese dioxide cathodes were prepared and measured in the same manner.

The cathodic reaction [1] will be followed by [2]

$$F^- + Li^+ \longrightarrow LiF_s \qquad [2]$$

leading to the formation of solid lithium fluoride within the cathode. The solubility of lithium fluoride in pure propylene carbonate is less than 5×10^{-6} molar (24). Addition of lithium perchlorate to form a one molar solution should decrease the solubility of lithium fluoride further.

Cathodic depolarizer utilization.—From coulometric analysis of galvanostatic discharge curves, the utilization of graphite intercalation compounds could be determined.

Graphite fluorides.—Galvanostatic discharge curves for CF (curve A), $C_{5.54}F$ (curve C), and a graphite cathode (curve E) in 1M $LiClO_4$-PC electrolytes are shown in Fig. 2. The current density is 1 mA/cm². The cathode potentials are measured *vs.* the lithium reference electrode. The interrupted lines of curves B and D represent the corresponding cell discharge curves. The amounts of CF and $C_{5.54}F$ in the cathodic mix used at the electrodes correspond to 0.26 and 0.065 A-hr, respectively. The corresponding points on discharge curves A and C, which should give, in the absence of any side reactions, the potentials at which 100% utilization of the depolarizer has been reached, are shown. Visible gas evolution at the cathodes, marked in the figure with arrows, can be observed around these potentials and continues on further discharge.

Since utilization efficiencies above 100% can be obtained by discharging to lower potentials, another reduction process must account for a utilization exceeding 100%. It is highly probable that this is solvent reduction [3]

$$C_4H_6O_3 + 2e^- \longrightarrow CH_3 - CH = CH_2 + CO_3^{2-} \qquad [3]$$

Reaction [3] could occur simultaneously with the reduction of the graphite fluorides or successive to it. The strong bend in the CF discharge curve, just above 1.1V, suggests a change in the discharge mechanism. Electrochemical reduction of propylene carbonate at graphite rods in 1M $LiClO_4$-PC electrolyte to propylene gas and carbonate ions has been described in the literature (25). Curve E (Fig. 2) shows the potential change of a graphite cathode at 1 mA/cm².

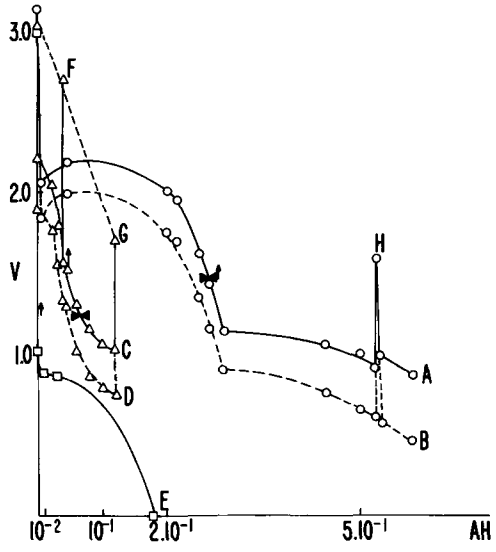

Fig. 2. Galvanostatic discharge curves of graphite fluorides in Li/1M $LiClO_4$-PC/C_xF cells. $I = 1$ mA/cm². A, CF cathode *vs.* lithium reference electrode; $T = 29°C$. B, Li/1M $LiClO_4$-PC/CF cell; $T = 29°C$: C, $C_{5.54}F$ cathode *vs.* lithium reference electrode; $T = 31°C$. D, Li/1M $LiClO_4$-PC/$C_{5.54}F$ cell; $T = 31°C$. E, Graphite cathode *vs.* lithium reference electrode; $T = 30°C$. F,G,H, Open-circuit potentials after partial or complete discharge. ↑, Gas evolution at cathode. ⋈, 100% utilization.

The discharge of $C_{5.54}F$ was interrupted and the open-circuit potential after partial discharge was measured. It can be seen that point F lies considerably below the original open-circuit potential and point G, after theoretically complete discharge, is still lower. There appears to exist a linear relationship between these "rest" potentials and the ampere-hours passed. CF showed a similar behavior (point H).

Graphite oxide.—The composition of the graphite oxide under study was $C_8O_{1.48}(OH)_{1.48} \times 1.44\ H_2O$. The following reaction was assumed to occur during its cathodic discharge

$$C_8O_{1.48}(OH)_{1.48} \times 1.44H_2O + 4.44e^- \longrightarrow C_8 \times 1.44H_2O + 1.48\ O^{--} + 1.48\ OH^- \qquad [4]$$

O^{--} and OH^- react further with lithium ions to form lithium oxide and lithium hydroxide.

Figure 3 shows the galvanostatic discharge curves of a Li/1M $LiClO_4$-PC/$C_xO_yH_z$ cell. Curve A shows the cathode potential during discharge at a current density of 1 mA/cm² and curve B the corresponding cell voltage.

The amount of depolarizer in the cathode corresponds to 0.262 A-hr. Again a utilization above 100% can be observed if the discharge is continued to lower potentials. Gas evolution at the cathode is observed just prior to 1.1V. The discharge was interrupted several times in order to measure the open-circuit potentials after partial or complete discharge (curve C). These potentials were attained after resting the electrodes overnight. It can be seen that curve C shows a linear behavior up to about 100% theoretical utilization, followed by a marked break and change in slope.

Manganese dioxide.—The cathodic reduction of manganese dioxide at 1 mA/cm² is presented in Fig. 4. Assuming a reduction of Mn^{4+} to Mn^{3+}

$$2MnO_2 + 2e^- \longrightarrow Mn_2O_3 + O^{--} \qquad [5]$$

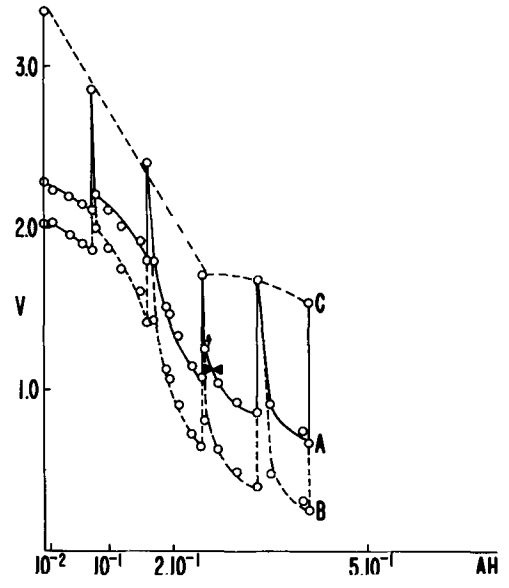

Fig. 3. Galvanostatic discharge curves of graphite oxide in Li/1M $LiClO_4$-PC/$C_xO_yH_z$ cells. $I = 1$ mA/cm^2; $T = 29.2$°C. A, $C_xO_yH_z$ cathode vs. lithium reference electrode. B, Li/1M $LiClO_4$-PC/$C_xO_yH_z$ cell. C, Open-circuit potential after partial or complete discharge. ↑, Gas evolution at cathode. ⋈, 100% utilization.

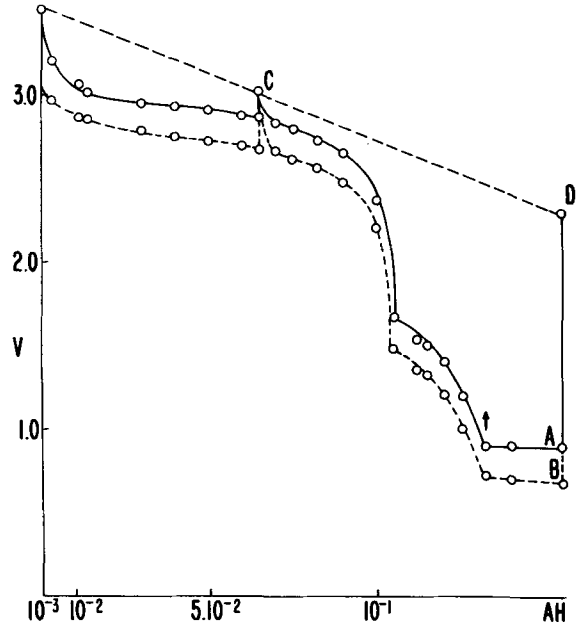

Fig. 4. Galvanostatic discharge curve of manganese dioxide in Li/1M $LiClO_4$-PC/MnO_2 cells. $I = 1$ mA/cm^2; $T = 29.2$°C. A, MnO_2 cathode vs. lithium reference electrode. B, Li/1M $LiClO_4$-PC/MnO_2 cell. C, D, Open-circuit potentials after partial discharge. ↑, Gas evolution at cathode.

the depolarizer would yield 0.194 A-hr, however, only about 0.13 A-hr are obtained, corresponding to a utilization of about 68% by discharge down to 0.9V.

The open-circuit potential and the major part of the discharge curve lies above the theoretical, reversible potentials of the assumed cell reaction

$$2Li + 2MnO_2 = Li_2O + Mn_2O_3; \quad E_o^{298} = 2.69V \quad [6]$$

The reversible potential for a 4+ and 3+ reduction lies at the end of the first plateau. A second reduction region can be recognized between 1.7 and 0.9V *vs.* lithium. Since strong gassing is observed at the cathode at the latter potential, it is probable that solvent reduction occurs at 0.9V and at lower potentials.

The disagreement between the discharge potentials and reversible potential (Eq. [6]) suggests that other unknown electrode reactions are responsible for the behavior on discharge. The open-circuit potentials after partial discharge (points C and D) exhibit again a linear relationship *vs.* time.

Comparison of cathodic depolarizers.—The depolarizers investigated were compared with each other, using the galvanostatic discharge curves in Fig. 2, 3 and 4. By graphical integration of the discharge curves from open-circuit potential to a cathode potential corresponding theoretically to 100% utilization, except in the case of manganese dioxide, a comparison was made of the energy content and the kinetics of the depolarizers. Relating this data to the grams of depolarizer used, the watt-hour/pound ratio could be computed. The results are shown in Table IV. It can be seen that carbon monofluoride yields the highest watt-hour/pound ratio under the given experimental conditions. Its $\bar{V}$ value is the highest one of the three intercalation compounds investigated, being surpassed only by the more reactive manganese dioxide.

Comparison of the energy content of Li/1M $LiClO_4$-PC/CF and Li/1M $LiClO_4$-PC/MnO_2 cells during discharge at a rate of 1 mA/cm^2.—From the results of Table IV, two depolarizers appear to be of interest. Carbon monofluoride was chosen for its high energy content and manganese dioxide because of its somewhat better kinetic characteristics. Consequently, a comparison was made of these two on the basis of their cell discharge curves and the essential component weights involved. For this purpose, curves B in Fig. 2 and 4 were graphically integrated from cell open-circuit voltage to a chosen end (cut off) voltage. The watt-hours obtained were related to essential component weights. In case of CF, the cut off voltages chosen were 1.8, 1.5, and 0.9V. The area under the curve to 1.8V was 0.344 W-hr, to 1.5V was 0.44 W-hr, and to 0.9V was 0.494 W-hr.

The actual component weights within the experimental cell in grams were:

CF cathode + Cu grid	0.467 + 0.528 = 0.995
Li anode + Ni grid	0.163 + 0.419 = 0.582
Separator (4.2 × 4.2 ×3.2 cm)	0.230
Electrolyte (10 ml) (26)	12.590
Total experimental component weight =	14.397g

Table V lists improvements in component weights that can be made in the experimental cells. It can be seen that the electrolyte accounts for about one half of the component weight. The influence of the cathode characteristics in practical cells will, therefore, not be as marked as in Table IV. No consideration was given during the conceptual redesign of the experimental cell to any changes in the ohmic cell resistance

Table IV. Comparison of cathodic depolarizers discharged in Li/1M $LiClO_4$-PC/depolarizer cells at 1 mA/cm^2 and $\bar{T} = 29.7$°C

Depolarizer	(W-hr/lb) theoretical[a]	(W-hr/lb) maximum[b]	(W-hr/lb) experimental[c]	% Theoretical[d]	% Maximum[e]	$\bar{V}$[f]	η[g]
$C_{5.54}F$		471	263		55.8	1.85	100
CF	1491	1020	804	54.0	78.8	2.05	100
$C_8O_{1.48}(OH)_{1.48}$		1500	590		39.3	1.87	100
MnO_2	349	451	241	69.0	53.5	2.52	68.3

[a] (W-hr/lb) theoretical are based on emf values computed from thermodynamic data and pounds of total cell reactants.
[b] (W-hr/lb) maximum are based on experimental open-circuit voltage and pounds of total cell reactants.
[c] (W-hr/lb) experimental are based on graphical integration of the discharge curves, up to the utilization efficiency η, and on pounds of depolarizer only. A comparison of this data with *a* or *b* gives the loss in theoretical energy content given by the cathodic polarization at the given rate. In case of CF, *e.g.*, this loss amounts to 46.0%.
[d] % theoretical = (W-hr/lb) experimental/(W-hr/lb) theoretical.
[e] % maximum = (W-hr/lb) experimental/(W-hr/lb) maximum.
[f] The average discharge potential $\bar{V}$ = (W-hr/g) experimental/(A-hr/g) theoretical.
[g] η depolarizer utilization in %.

Table V. Improvements in component weights

CF cathode + Cu grid 0.467 + 0.2[a] =	0.667	(29.0%)
Li anode + Ni grid 0.069[b] + 0.2[c] =	0.269	(11.7%)
Separator	0.100[d]	(4.4%)
Electrolyte	1.259[e]	(54.9%)
Essential component weight (in grams)	2.295	(100.0%)

[a] Shorter tab area 0.528 → 0.404g and half the copper weight by using a more open grid.
[b] 0.617 A-hr/0.16g lithium electrode yields 61.7 hr of operation at 10 mA. CF depolarizer amount, however, requires only 26.4 hr. Therefore, only 0.069g lithium metal are required at the anode.
[c] Shorter tab area and half the nickel weight by using a more open grid.
[d] Separator thinned by 50%.
[e] Electrolyte spacing decreased from 5 to 0.5 mm → 1 ml electrolyte. Practical experimental cell configurations with two lithium anodes on each side of a depolarizer cathode required about 3.06g electrolyte (27).

which would be reflected in the cell discharge characteristics. An increase in ohmic resistance due to a smaller collector-depolarizer interface will certainly be upset by a considerable decrease in electrolyte resistance due to decreased electrolyte spacing.

A comparison between cells using carbon monofluoride and manganese dioxide is given in Table VI. From these data, it can be seen that CF has a higher W-hr/lb ratio than manganese dioxide, especially at lower cut off voltages. A proper preselected cut off voltage is of greater significance in the operation of practical batteries of this type. According to Eq. [3], the cathodic reduction of propylene carbonate is accompanied by evolution of propylene gas. Although propylene shows some solubility in the electrolyte (25), continued gas evolution will lead to a pressure buildup in sealed batteries. This problem can be eliminated if the proper cut off voltage is chosen.

Energy content and depolarizer utilization as a function of discharge rate, electrolyte anion, and electrolyte solvent.—The next point of interest in this study was the influence of factors, such as rate, electrolyte anion, and electrolyte solvent, on the energy content and depolarizer utilization.

For this purpose, the following additional cell compositions were prepared and discharged at a given rate at about 30°C:

Li/1M $LiAsF_6$, PC/CF	0.46 mA/cm² to vary rate and electrolyte anion
Li/1M $LiClO_4$, PC/CF	0.50 mA/cm² to vary rate
Li/1M $LiClO_4$, $DMSO_3$/CF	1.00 mA/cm² to vary solvent
Li/1M $LiClO_4$, PC/CF	1.88 mA/cm² to vary rate

During the discharge, the cathode potential *vs.* a lithium reference electrode plus the total cell voltage were monitored.

The rate changes did not produce anything new in the discharge behavior (Fig. 5). The discharge curves are similar in shape to that in Fig. 2 with a somewhat different position in the V-A-hr plot. The open-circuit potential after partial discharge up to full discharge follows a straight line. The steep slope of the discharge curves diminishes after reaching a theoretically 100% utilization.

Table VI. Comparison of W-hr/lb of cell components[a] during discharge of Li/1M $LiClO_4$-PC/depolarizer cells at 1 mA/cm² and T = 29.7°C

	Cutoff voltage			
	0.9V		1.8V	
Depolarizer	W-hr/lb	% Utilization	W-hr/lb	% Utilization
CF	97.7	100	68.0	65.5
MnO_2	58.7	67.2	52.6	53.7

[a] Based on essential component weights.

Changing the electrolyte anion from ClO_4^- to AsF_6^- presented experimental problems with the lithium anode. After operating the cell for about 0.165 A-hr, the voltage between anode and cathode changed polarity to −2.5V. After about 15 min at this voltage level, it returned again to a positive reading. A similar phenomenon occurred after about 0.28 A-hr. The cell voltage, however, remained from then on reversed while under discharge. The first observation at the anode had the characteristics of a film formation-film removal phenomenon. The second had that of permanent passivation at the anode. The potential of the cathode *vs.* the lithium reference electrode remained always positive and showed no unusual behavior with time (Fig. 6).

In Fig. 6, we compare the discharge curves in electrolytes with different anions at about the same current density. Initially, the curves appear to be practically identical. Prior to 100% utilization, curve B exhibited a higher potential. There are marked differences, however, in the open-circuit potentials after partial and complete discharge. The initial open-circuit potential

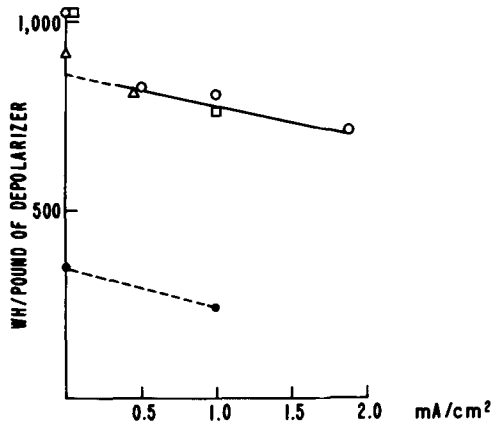

Fig. 8. Watt-hour/pound of depolarizer ratio as a function of current density, electrolyte anion, and solvent; $T \simeq 30°C$. ○, CF in 1M $LiClO_4$-PC, $\eta = 100\%$. △, CF in 1M $LiAsF_6$-PC; $\eta = 100\%$. □, CF in 1M $LiClO_4$-$DMSO_3$; $\eta = 100\%$. ●, MnO_2 in 1M $LiClO_4$-PC; $\eta = 68.3\%$.

in $LiAsF_6$-PC is lower (~2.8V) than in $LiClO_4$-PC. The open-circuit potential in $LiAsF_6$-PC after complete discharge, however, is higher than that in $LiClO_4$-PC.

The influence of solvent on the discharge is shown in Fig. 7. Propylene carbonate and dimethylsulfite are compared. A markedly different discharge behavior is observed. The open-circuit potentials are both above 3.0V. While CF in $LiClO_4$-PC shows a strong potential drop before 100% theoretical utilization, followed by a flat PC reduction curve, CF in $LiClO_4$-$DMSO_3$ continues at a higher potential level even after complete utilization. The resulting apparent utilization efficiency above 100% can be explained as in the case of propylene carbonate by solvent reduction.

Graphical integration of the discharge curves in Fig. 2, 4-7 (cathode potential *vs.* lithium reference electrode) led to a comparison of the energy content of the depolarizers as a function of discharge rate, electrolyte anion, and solvent. The results are compared in Table VII.

From Table VII it can be seen that neither a strong anion nor solvent effect on the energy density exists at 100% theoretical utilization. The average discharge potential, $\overline{V}$, shows also that neither the anion nor solvent effect is a marked one. The experiment with $DMSO_3$, however, indicates that a remarkable increase in the W-hr/lb depolarizer ratio could be obtained if solvent reduction can be utilized.

In the column of $V_{reference}$, the cathode potential at the given rate and utilization is shown. The last column contains the per cent of theoretical energy that can be obtained on discharge. The maximum theoretical value computed from thermodynamic data is 1491 W-hr/lb of depolarizer.

In Fig. 8, the W-hr/lb of depolarizer ratio is plotted as a function of current density, electrolyte anion, and

CF, $LiClO_4$-PC	1.88	—	0.0 (0.0)	68 (73)	—	83 (96)

[a] Utilization efficiency of, *e.g.*, (100 + 9) means that theoretically 100% CF discharge has occurred plus additional solvent reduction equivalent to 9% CF discharge.

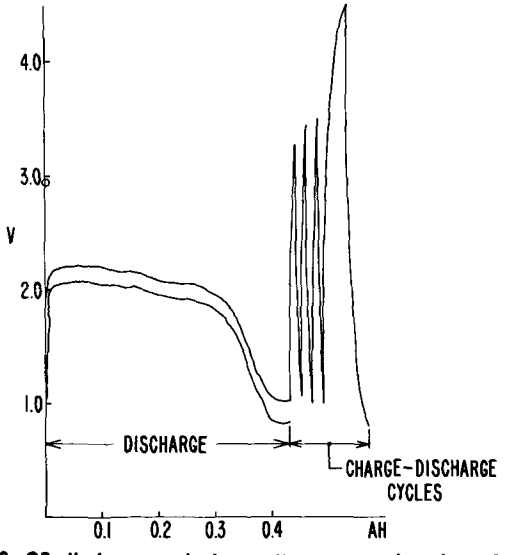

Fig. 9. CF discharge and charge-discharge cycles; $I = 1$ mA/cm^2; $T \simeq 30$°C.

solvent. It can be seen that the data points are arranged around a straight line. Neither a strong anion nor solvent effect can be noted.

By graphical integration of the cell discharge curves in Fig. 2, 4-7 and from the essential component weights, the W-hr/lb of cell components were estimated. The W-hr/lb of cell components and in parenthesis the per cent utilization efficiency for various cut off voltages are given in Table VIII.

The table shows that the approximate limit for a lithium carbon monofluoride battery, using anodes and cathodes made according to our preparation procedures, operating in the given current density range at about 30°C, would be somewhere in the range between 85 and 113 W-hr/lb of cell components at about 100% theoretical CF utilization. If additional solvent reduction can be tolerated (discharge to 1.0-0.9V cut-off voltage), then far higher energy densities can be envisioned probably even above 150 W-hr/lb. A reduction in energy density of about 20% should be considered if a battery case is included in the component weights.

Feasibility of electrically recharging the Li/LiClO$_4$-PC/CF cells.—Limited experimentation was performed to explore the feasibility of electrically recharging the Li/1M LiClO$_4$-PC/CF cells. A platinum grid was used instead of the copper grid at the cathode since the latter disintegrated during charge/discharge cycles. After regular discharge of the CF at 1 mA/cm^2, the cell was charged at the same current density. Although the cell appeared to charge and discharge well for short periods, the charge voltage was increasing and the discharge voltage was decreasing with cycles (Fig. 9). The cell was unable to hold a charge for a longer period of time. At both 4.5 and 0.9V, gas bubbles were noted at the cathode, probably connected with oxidation and reduction of the solvent.

Acknowledgment

The authors wish to thank Captain Burt Strasser for performing the preparative experimentation required to synthesize graphite oxide, one of the depolarizers investigated, and Mr. J. W. Mellichamp for performing the spectrochemical analysis of CF.

Evaluation of the Ferric Ion Sensitive Chalcogenide Glass Electrode

Raymond Jasinski* and Isaac Trachtenberg*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Further information is presented on the preparation, composition, performance, and ferric ion sensing mechanism of the chalcogenide glass $Fe_nSe_{60}Ge_{28}Sb_{12}$ (where n falls between 1.3 and 2). Properly prepared and activated electrodes respond to changes in ferric ion concentration in perchlorate, chloride, and nitrate solutions with an average Nernstian slope of 57.6 ± 2.9 mV/decade, over the concentration range of 10^{-2}-10^{-5}M ferric iron (based on 16 electrodes). Useful response is found down to at least 10^{-6}M Fe^{+3}. Details are presented on the activation and operating procedures. Although a complete evaluation of the sensing mechanism has not been made, it has been established that the activation process involves both an oxidation of the fresh surface as well as a chemical interaction of this surface with ferric iron from solution. The sensing process then involves exchange of ferric iron with this modified surface.

It has been shown (1) that electrodes formed from the chalcogenide glass, $Fe_nSe_{60}Ge_{28}Sb_{12}$, hereafter designated as Fe-1173, will develop potentials relatable to the free, uncomplexed ferric ion concentration of aqueous solutions. This effect is of practical interest in the monitoring of some process effluents and waste waters for ferric iron; application of these electrodes has also been made to the determination of sulfate ion in natural and waste waters (2, 3). This response is of scientific interest in that (*a*) the electrode potential is independent of the ferrous ion content of the solution, while (*b*) the potential response to ferric ion is a nominal 60 mV/decade concentration change, indicative of a one-electrode process rather than the expected three-electron process (20 mV/decade).

Further information is therefore presented on the preparation and composition of this unique material, its electrochemical performance, and the ion sensing mechanism.

Experimental

The iron glasses were prepared by fusing the appropriate amount of iron wire at 900°-1000°C with the glass, $Se_{60}Ge_{28}Sb_{12}$, previously synthesized directly from the pure elements. To form electrodes, disks, 1.1-1.2 cm diameter and 0.1-0.2 mm thick were cut from the melt; gold was then evaporated onto one side of the glass disk; a platinum wire lead made contact to the gold via silver micropaint; the lead side of the glass was isolated from the test solutions by sealing the glass disk into a Plexiglas[1] tube.

Resistivity and potential measurements were made as described previously (1). Potentiostatic measurements were made with a Wenking Model 6343R potentiostat. All potentials are reported with respect to the commercial Ag/AgCl electrode used as reference. In those experiments concerned with the possible influence of chloride ion on the measured potentials, this electrode was replaced with an Orion double junction Ag/AgCl reference electrode containing a potassium nitrate solution in the outer junction. All measurements were made at ambient room temperature.

Four Fe-1173 electrodes were generally immersed in the specific solutions under test, so as to separate out spurious electrode effects from the particular parameter being studied. For simplicity of presentation, only the data from one of the set will be discussed.

In order to obtain a reproducible surface, independent of the previous history of the electrode, the sensor was etched periodically in 10% KOH for 30 sec, rinsed with supporting electrolyte, re-etched, and rerinsed. The electrodes were then stored in 10^{-3}M Fe^{++} overnight before use. The significance of these etchings and equilibration steps will be discussed.

The supporting electrolytes used in this study were 1M KCl and 0.1*N* $NaClO_4$. Chloride forms weak complexes with ferric iron; perchlorate shows little tendency to complex (4). The responses in nitrate were discussed previously (1).

A motor-driven paddle stirrer was used in the experiments concerned with the effect of stirring on response time. Magnetic stirrers were avoided to obviate any possible complications from the heat so produced.

The analytical method for determining the total iron content of the various slices of Fe-1173 glasses was based on dissolution of the sample in aqua regia, followed by measurement with an atomic absorption spectrometer.

Results and Discussion

The surface of an electrode prepared as described is visibly heterogeneous, containing islands of one phase imbedded in a matrix phase. Portions of this electrode material were ground to a powder and an x-ray (Fe radiation) pattern taken under prolonged exposure. In no case could a detectable pattern be found. It must therefore be concluded that neither phase of the electrode material is crystalline.

The Fe-1173 electrodes are opaque to infrared radiation; the parent 1173 glass is transparent. It must therefore be concluded that neither phase is the original 1173 glass. It was not possible to withdraw portions of either phase individually for chemical analysis.

The homogeneity of the melts prepared as previously described (1) is indicated by the data shown in Table I for the iron contents of slices taken along the length of two melts (slice 1 is the top of the melt). There are significant variations in composition from slice to slice and it is not possible to infer the composition of slice x from that of slice $x \pm 1$. No trend in iron content could be established from the position of the slice within the melt; crushing and remelting the slices did not improve the homogeneity of melt composition.

It had been shown previously (1) that there was a dependence of resistivity on the iron concentration of the melt. The existence of a critical iron concentration, above which the resistivity decreased from the order of 10^3 ohm-cm down to the order of 50 ohm-cm, was confirmed with chemical analysis of the individual slices on which the resistivity measurements had been made. This was necessary in view of the compositional

variations shown in Table I. As a result of improved analyses, the critical concentration found was 1.3 a/o (atomic per cent) iron rather than the approximate 2.3% value previously reported.

Shown in Table II are the electrochemical performances of three high-resistance electrodes; here performance is discussed in terms of the potential-log concentration slopes between the specified concentration limits. All the high-resistance glasses showed less than the expected Nernstian slope to changes in iron concentration at low net ferric ion contents. Shown in Table III are the steady-state Nernstian slopes for 16 low-resistivity (≤50 ohm-cm) electrodes over the concentration range of 10^{-5}-10^{-2}M ferric chloride in 1M KCl, pH 2. All electrodes had iron concentrations of approximately 1.3 a/o Fe. Included in the table are the standard deviations of slope as calculated from a least squares fit of the data for each electrode. (The numbering system is such that the first number refers to a particular melt; the second number refers to a particular slice within the melt.) The average slope computes as 57.6 mV/decade with a net standard deviation of ±2.9 mV/decade. This then is a measure of the reproducibility with which electrodes can be prepared. No correlation could be found with iron content and performance, except as determined by the resistivity of the glass. Unless otherwise specified, all data discussed below were taken with low-resistance electrodes.

Shown in Fig. 1 are the response times of one such electrode to small changes in iron concentration. Steady state was achieved within 2-4 min; response time to increasing iron concentration appeared to be

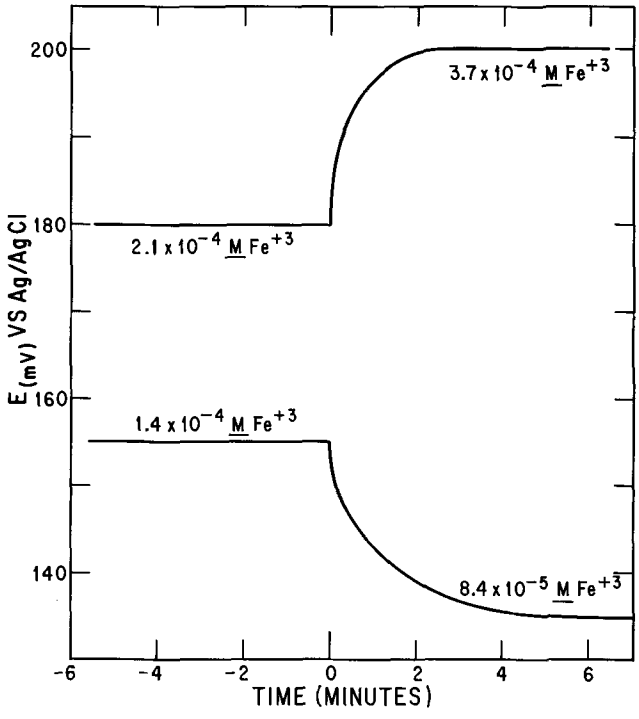

Fig. 1. Response times for a 2.39 mole per cent Fe°-1173 glass electrode to changing ferric ion concentration.

somewhat faster than responses to decreasing concentrations.

Response time increased significantly, however, (*a*) when the concentration changes were increased to order-of-magnitude increments, and (*b*) when the ambient ferric iron concentration was decreased below 10^{-4}M ferric iron. With stirring, steady state at 10^{-5}M was achieved within 20-30 min; without stirring, steady-state responses at 10^{-5}M were always quite long, taking up to 60 min to reach steady state (here steady state is defined as an electrode potential stable to within 0.1 mV/min). At steady state the electrode potentials were independent of stirring rate, over the range of 0-275 rpm. At 10^{-4}M ferric ion, steady state was achieved within 10-20 min with stirring.

This trend of decreasing response time with increasing iron concentration did not persist above 10^{-3}M; generally 20 min were required to reach steady state, as defined, and stirring had little effect. Response times were the same in perchlorate and in chloride solutions.

During the preliminary studies of electrode behavior, it was often observed that the potential changes measured at and below 10^{-3}M Fe^{+++} were smaller than expected (from a Nernstian slope of about 59 mV/decade) if the electrodes had been first exposed to 10^{-1} or 10^{-2}M ferric iron for prolonged periods of time. Furthermore, the equilibrium potentials themselves were higher than had been observed after the electrodes had been first exposed to 10^{-4}M ferric iron. This effect was found in both chloride and perchlorate solutions. The phenomenon can be illustrated and explained by the following experiment. A thoroughly washed electrode was equilibrated in 100 ml of 10^{-3}M ferric chloride after exposure for 10 min to 10^{-1}M Fe^{+++}; a steady potential of +355.7 mV was observed. The electrode was then rinsed with supporting electrolyte and the test solution was replaced with a second sample of the same 10^{-3}M concentration but which had not been exposed previously to an Fe-1173 electrode; a steady-state potential of +341.7 mV was recorded. Not only is this potential lower, but it is what was anticipated from Nernstian behavior and the potential observed at 10^{-2}M ferric iron. Placing the electrode back into the original 10^{-3}M solution restored the potential reading to its original value. This indicates that the potential difference between the two millimo-

lar iron solutions was not an artifact or electrode drift but was indeed representative of the ferric iron contents of the solutions. It would appear then that ferric ion was transferred from the surface of the electrode, previously exposed to high iron content solutions, into the first millimolar iron solution.

Thus when measuring the potential of a solution more than an order-of-magnitude different in ferric iron content than the solution previously monitored, the electrodes had to be equilibrated for at least 30 min in the test solution and then placed in a fresh portion of the test solution. This provided the most accurate representation of potentials characteristic of the ferric iron content of the particular solution under study.

A more classical source of contamination was also found with a number of the supporting electrolytes used in the study, specifically the presence of a small amount of residual iron impurity in the salt itself. The KCl and $NaClO_4$ electrolytes were analyzed for total soluble iron via an atomic absorption spectrometric method (5). The 0.1*N* $NaClO_4$ solution used contained 1.7×10^{-5}M Fe; the 1M KCl solution contained 2×10^{-7}M Fe. It was found that the KCl solutions did vary in soluble iron content according to the particular batch of KCl used; most samples contained residual iron in the 10^{-7}M range.

The lower limits-of-detection of the Fe-1173 electrodes were therefore estimated as follows. Equilibrium potentials were first measured for a KCl solution with a known, large concentration of added iron. Sufficient EDTA (at the same pH) was added to complex all iron present; potentials were recorded after 15 min. The results of one such experiment in 1M KCl are shown in Table IV. Comparing the potentials at 10^{-5}M Fe^{+3} with those of the KCl + EDTA solution (*i.e.*, no iron), it would appear that the electrodes are sensitive down to approximately 10^{-6}M ferric iron in 1M KCl.

The same experiment was carried out in perchlorate solution with substantially the same result, *i.e.*, the electrode is capable of measuring soluble ferric ion above a concentration of 10^{-6}M.

Also of interest were the observations that exposure of the electrode to EDTA did not adversely affect activity, in fact exposure may well have improved electrode performance. An example of this is shown in Table V. Listed are the steady-state potentials at 10^{-4} Fe, (*a*) initially, (*b*) after exposure to 10^{-1} Fe, and (*c*) after exposure to EDTA. (The significance of the 10^{-1} exposure will be discussed below in more detail; suffice it to say that such an exposure has a deactivating effect for subsequent exposure of the electrode to 10^{-4} solutions.)

In order to generate electrodes which showed these Nernstian responses to varying ferric ion concentrations, it was necessary to activate the sensor surface

Table IV. Determination of limit-of-detection

Solution	Electrode		
	32-5, mV	32-5, mV	32-8, mV
10^{-5}M Fe + KCl	+216	+235	+232
10^{-6}M Fe + KCl	+165	+203	+198
KCl	+147	+188	+184
KCl + EDTA	+145	+182	+180

Table V. Effect of EDTA on equilibrium potentials

Electrode	Potentials (for 10^{-4}M Fe)*		
	Initial	After 10^{-1}	After EDTA
5	231.7	223	230
6	210.8	204	211
7	232.6	208.9	230
8	226.6	209.9	227

* Obviously, there is good agreement between the "Initial" and "After EDTA" potentials.

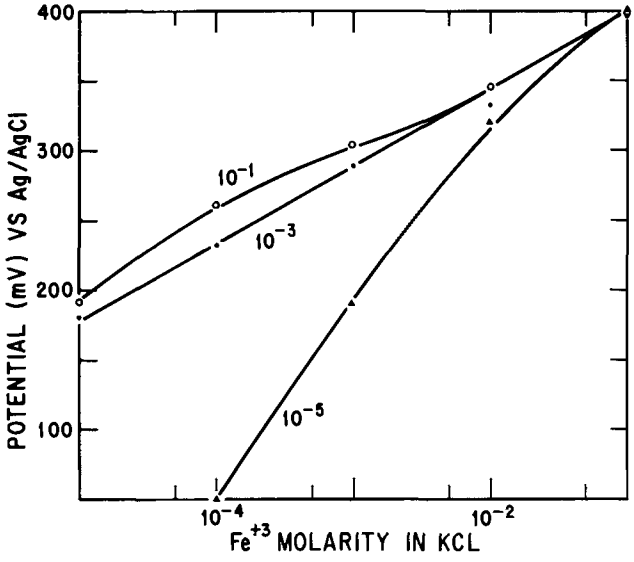

Fig. 2. Response of an Fe-1173 electrode to varying ferric ion concentrations after equilibration overnight in ferric iron solutions of the concentrations indicated.

by exposing a freshly etched electrode to a solution high in ferric ion concentration ($\geq 10^{-3}$M). This phenomenon is illustrated by the data shown in Fig. 2, in which are plotted the responses of a freshly etched electrode after equilibration overnight in three different iron solutions. In each case, measurements were first made at the 10^{-5}M concentration level and then for successively increasing iron concentrations. Chloride was the supporting electrolyte, but similar results were obtained with perchlorate ion.

Consider first the response of the electrode equilibrated in the 10^{-5}M iron solution: (*a*) potential readings were abnormally low below 10^{-3}M and (*b*) the response above 10^{-4}M was super-Nernstian, *i.e.*, greater than ~58 mV/decade change in iron concentration. After exposure to 10^{-1}M ferric ion, this electrode showed the normal Nernstian responses as obtained with properly activated electrodes (data not shown in the figure).

Consider next the electrode equilibrated overnight in 10^{-3}M ferric ion. Response was Nernstian, and little hysteresis was observed in potential on increasing and decreasing the iron concentration (data not shown in the figure). Similar behavior was observed after equilibrating a freshly etched electrode for 1 hr in 10^{-1}M ferric ion solution.

Finally consider the plot for the electrode equilibrated overnight in 10^{-1}M ferric iron. The subsequent performance at and above 10^{-3}M is normal; response below 10^{-3}M was less than would be expected from Nernstian behavior. Furthermore the potentials showed considerable long term drift. In many cases such treatment with 10^{-1}M ferric ion resulted in electrodes completely nonresponsive to changing ferric ion concentration below 10^{-4}M ferric ion.

To confirm that this deactivation involved exposure time as well as ferric iron concentration, an active electrode was exposed to 10^{-3}M ferric ion for 87 hr rather than overnight as described above. Subsequent measurements of the concentration-potential responses indicated a decrease in sensitivity of the electrode to low concentrations of ferric ion, *e.g.*, a potential change of only 35 mV was observed from 10^{-5} to 10^{-4}M iron and 53 mV from 10^{-4} to 10^{-3}, rather than the previously observed 58 mV/decade. Above 10^{-3}M ferric ion the response was still Nernstian. This result has obvious implications relative to the use of this sensor for the continuous monitoring of process streams. As with other ion-selective electrode, the best performance is obtained when the electrode is used to measure less

than order of magnitude changes in concentration around a constant ambient concentration.

In order to avoid, or at least minimize, such deactivation of the electrode when the sensor is not in use, consideration was given to storing the electrodes in the dry state, without etching and chemical reactivation between applications. Accordingly a series of four electrodes were activated overnight in 10^{-3}M ferric ion and then operated. After demonstration of the expected sensitivity to ferric ion, the electrodes were washed with supporting electrolyte, washed with distilled water, dried, and left overnight in air. The electrodes were then exposed to solutions of varying iron content and the steady-state potentials were recorded. The greatest divergence between the two sets of potentials was 20 mV; the average divergence was 10 mV. Two conclusions can be made. First dry storage does not deactivate the electrode, and, second, as with all ion-selective electrodes, recalibration is a desirable precaution.

The operational effects discussed above raise significant questions regarding the electrode mechanism for sensing ferric ion concentration. In particular it is necessary to rationalize the 58 mV/decade Nernstian slope, *i.e.*, a one-electron process, with the following: (*a*) the electrode activation phenomenon, (*b*) the electrode deactivation process, (*c*) the autocontamination of the test solutions, and (*d*) the variation in response times with the magnitude of concentration change and concentration level.

One possible explanation, consistent with previously discussed redox behavior, is that the electrode sees only the oxidation potential of the ferric ion (the reduced half of the equilibrium couple is in the electrode), but to function properly the electrode surface must first be oxidized, *e.g.*, to a potential approximating that of 10^{-1}M ferric chloride. The autocontamination effect could indicate that the solubility of the electrode material is potential dependent. Similarly the deactivation process could be explained by a competing slow and irreversible oxidation of the surface by ferric ion at potentials equal to or greater than +400 mV *vs.* Ag/AgCl.

The following experiment was carried out in an attempt to evaluate the effect of oxidation potential (this study was done in replicate, but for simplicity of presentation we will discuss the data for only one run). An electrode was etched, washed with supporting electrolyte, and placed in 1M KCl, *p*H 1.7 but with no added iron. The potential of the electrode was set to +400 mV with the potentiostat and held for 3 hr. This is approximately the potential the electrode would have reached if exposed to 10^{-1}M ferric chloride in 1M KCl, *p*H 1.7. A current flow of 2 mA anodic was observed initially, decreasing within 15 min to 0.003 mA anodic. Thus, a chemical oxidation of the electrode surface does take place during the electrode activation step.

After the anodic current had definitely fallen to zero (3 hr), the applied potential was removed and the electrode was exposed to varying concentrations of ferric ion in the same supporting electrolyte, starting with 10^{-5}M and proceeding to higher concentrations in order of magnitude increments. The potential-log concentration response so obtained was substantially identical to that shown in Fig. 2 for the freshly etched electrode exposed to 10^{-5}M ferric chloride. At 10^{-5}M Fe^{+3}, the electrode potential was of the order of 150 mV below its equilibrium Nernstian value and only slowly increased toward this potential (at ~5 mV/hr). This rate of approach to equilibrium was much slower than observed during operation of the chemically activated electrode at this concentration level. Varying the solution Fe^{+3} concentration generated a super-Nernstian response. As concentration increased, the potentials more closely approximated their "true" equilibrium values and the rate-of-approach to equilibrium increased.

It can thus be concluded that oxidation of the electrode surface does occur during the activation step, but, in itself, is not sufficient to provide an electrode responsive to changing iron concentrations in the supporting electrolyte solution. Exposure to high concentrations of ferric iron is indeed required. Since the phenomenon is observed in perchlorate solution, the important species involved in this process is ferric ion and not a chloride complex.

It had been determined previously that exposure of the electrode to 10^{-1}M ferric iron for 3 hr, *i.e.*, the time period used in the potentiostatic treatment discussed above, was sufficient to deactivate the electrode response to low concentrations of ferric iron in the solution. However, the potentiostatic treatment did not adversely affect the electrode performance. To further confirm this, a freshly etched and chemically activated electrode was put on the potentiostat at +400 mV for 3 hr. Subsequent potentiometric response to varying iron content in solution was unchanged, *i.e.*, the electrode was not detectably deactivated. Thus it can be concluded that electrode deactivation also does not solely involve surface oxidation, *i.e.*, high potential, but that high concentrations of ferric ion are required.

The next point to establish is the nature of the chemical interaction between the ferric iron in solution and the surface of a chemically, or electrochemically oxidized Fe-1173 electrode. The most likely reaction is that of equilibrium (rather than irreversible) chemisorption of Fe^{+3}. The specificity of such a process would account for the selectivity of the electrode material. The equilibrium exchange of the adsorbed iron with ferric ion in solution would account for the autocontamination effect, as the electrode is severely shifted from equilibrium by, for example, reducing the solution iron content more than an order of magnitude. The initial adsorption of ferric iron would, of course, be expected to produce a potential change and indeed after potentiostatic oxidation, the addition of ferric ions subsequently does lead to an increase in potential which, as described, is super-Nernstian, *i.e.*, is greater than expected from the effect of concentration change alone.

A series of experiments was therefore carried out in an attempt to elucidate the chemistry involved in this electrode-ferric ion interaction. The specific measurement techniques used were: (*i*) free ferric iron analysis of the equilibration solutions with an activated Fe-1173 electrode, (*ii*) total iron analysis of the equilibration solution via atomic absorption spectrometric analysis, and (*iii*) Fe^{+3}/Fe^{+2} ratio monitoring via a platinum screen electrode.

Accordingly an electrode was freshly etched and placed in a 10^{-5}M $FeCl_3$ solution (*p*H 1.7, 1M KCl) which was equilibrated with the active Fe-1173 electrode. The potential of the active electrode decreased by 7.8 mV in 60 min. Atomic absorption analysis indicated no change in total iron content. These results are rationalized by noting that a freshly etched electrode is in a reduced state (at approximately −400 mV) and is thus capable of reducing ferric ion to ferrous ion. Potentiostating such an electrode at +400 mV did result in an anodic current flow as described above.

The test electrode was therefore re-etched, potentiostated at +400 mV, for 2.5 hr, and then exposed to 10^{-5}M ferric chloride solution. The active Fe-1173 electrode again indicated a decrease in ferric iron content, but the potential change was much smaller, *i.e.*, of the order of a millivolt; the platinum screen electrode indicated a decrease in potential of 4.6 mV. Thus there is indeed a change in the composition of the equilibrating electrolyte, but it is small. Atomic absorption analysis of the solution showed no change in the total iron content. However the changes indicated by the electrodes are at the limit of reproducibility of the atomic absorption analytical method. Complicating matters, however, was the observation that in no case

during the replicate atomic absorption analysis of replicate solutions was there indicated a lower concentration of total iron in the equilibration solution compared to that for the original electrolyte.

Nevertheless it is possible to conclude that very little, if any, reduced species come off the electrode during the activation step. The potential change noted for the platinum electrode, if due solely to ferrous iron or a similar reduced specie, would be of the order of 10^{-7}M (0.006 ppm Fe). The same conclusion applied to a chemically activated electrode during ferric iron sensing. The platinum electrode was placed in a 10^{-5}M ferric chloride solution until steady state was achieved. An active Fe-1173 electrode was placed in this solution; no change in potential of the platinum electrode was observed.

These observations then are consistent primarily with the adsorption of ferric iron onto the electrode surface during the activation step. The quantities involved are proportional to solution ferric ion concentration and hence are small at low ambient concentrations of ferric iron. (At higher concentrations there would be the problem of detecting small differences between large numbers.)

However, with available data it is not possible to exclude rigorously, the desorption or dissolution of material from the electrode surface which would form a stable complex ion with Fe^{+3}, and thereby reduce the electrode potentials of the monitoring electrodes as described. Such a mechanism would be consistent with the atomic absorption results on total iron content of the solutions. However (*a*) such dissolution would have to take place only in the presence of ferric iron (or the process would have been completed during the potentiostating step), (*b*) such dissolution could not expose fresh Fe-1173 surface (or steady state would not have resulted), and (c) the Fe^{+3} complex would have to have a low equilibrium constant (log *K* of the order of 2 or 3) or the changes in ferric iron concentration would be greater than observed; this in turn would imply a solubility product not strongly influenced by the Fe^{+3} concentration and condition (*a*) would not apply.

Thus the most likely interaction is adsorption of ferric iron on the fresh electrode surface.

If the deactivation process proceeds via an irreversible, slow adsorption of ferric iron species, which may or may not be potential dependent, then it would be expected that, if the potential of the electrode were reduced, it would be possible to displace ferric iron from the electrode surface or it would be possible to reduce this adsorbed ferric iron to ferrous iron. Since ferrous iron does not evoke an electrode response, it can be assumed that it is not adsorbed onto the electrode. In both cases, soluble iron should appear in the supporting electrolyte. Accordingly, a deactivated electrode was potentiostated at +120 mV for 10 min in 1M KCl, *p*H 1.7, containing no added iron. Current flow was cathodic, but less than 0.001 mA. The solution was then analyzed for soluble iron via a sensitive atomic absorption spectrometric method (5); 0.34 mg/liter (6×10^{-6}M) iron was found. Although small, the value is nevertheless real, *i.e.*, in excess of the residual iron content found in the particular KCl solution used in this experiment. This then is evidence in support of deactivation via irreversible, but slow, adsorption of ferric iron onto the electrode surface. Consistent with such a mechanism is the fact that inactive electrodes always read high, i.e., give potentials in excess of what is expected for equilibrium with the solution being measured. Such would be the case for an electrode with an excess of iron on the surface.

We are therefore left with the following conclusion regarding the activation and sensing mechanism of Fe-1173 electrodes. A properly activated electrode will show Nernstian responses to solutions varying in ferric iron content with a slope of approximately 58 mV/decade concentration change, *i.e.*, a one-electron change process. However to function properly, a freshly etched surface must first be exposed to ferric iron solution of moderately high concentration, of the order of 10^{-3}M or higher. During this step, the electrode surface is first oxidized, after which a chemical interaction takes place between the electrode and ferric iron in the solution. It is this modified surface which is involved in the sensing of ferric iron content of solutions. This sensing mechanism does not involve the injection of reduced species into the electrolyte. This interaction of the electrode with ferric iron in solution is most likely one of specific adsorption, although the quantity of ferric iron so involved is low, at least at low ambient iron concentrations. The operational effects discussed imply that the subsequent ferric ion sensing mechanism involves the exchange of ferric ions in solution with the electrode surface.

Electrode deactivation is rationalized in terms of a slow, irreversible adsorption of ferric iron taking place simultaneously with the faster adsorption process which forms the basis of the sensing mechanism. In any event the involvement of ferric iron in the deactivation process is strongly indicated. The rate of deactivation is proportional to the average Fe^{+3} concentration seen by the electrode thus further supporting the idea of dry storage to prevent deactivation.

The remaining problem is to account, at least qualitatively, for the one-electron Nernstian slope with such a mechanism. Obviously the electrode mechanism is more complex than that originally proposed, *i.e.*, a redox couple Fe^{+3}/M^{+2}, where M^{+2} is contained in the electrode surface. That the electrode responds to oxidizing agents such as Ce^{+4} and peroxides, there is little doubt (1). However there may well be more than one mechanism depending on the species involved; work in progress is consistent with such a conclusion. To be consistent with the information discussed above relative to Fe^{+3} sensing, it is necessary to postulate a surface adsorption or chelation which involves a potential determining ion exchange with Fe^{+3} in solution. The over-all process of generating an active surface and sensing ferric iron may be represented as follows

$$\text{Fe-1173} + Fe^{+3}\ (\text{sol}) \rightarrow \text{oxidized Fe-1173} + Fe^{+2}\ (\text{sol})$$
$$\text{Fe-1173 (ox)} + Fe^{+3} \rightarrow M^*$$
$$M^* + Fe^{+3}\ (\text{sol}) \rightleftarrows M^*Fe$$

The freshly etched Fe-1173 on exposure to ferric iron in solution is first oxidized. This surface then interacts chemically with further ferric iron to form the active centers (M*) involved with the subsequent ferric iron sensing. (This process is inferred from the extremely slow approach of the oxidized electrode to true equilibrium when exposed to low concentrations of ferric ion in solution.) The active site (M*) now establishes its potential via fast, reversible adsorption-desorption equilibrium with Fe^{+3} in solution and that adsorbed on the surface. At the same time a much slower irreversible adsorption-deactivation process takes place which is dependent on the concentration of ferric ion in solution.

Summary

Properly prepared, activated and operated Fe-1173 electrodes show Nernstian responses to changing ferric ion concentration between 10^{-5} and approximately 10^{-1}M Fe^{+3}, with a nominal slope of 58 mV/decade ferric iron concentration. This slope is reproducible from electrode to electrode within ± 3 mV (1σ level). The same slopes were found in chloride and in perchlorate media. Ferrous ion is not seen by the electrode.

As presently prepared, slices of sensor material taken from a given melt can vary $\pm 10\%$ in total iron content. Fe-1173 glasses containing less than 0.9% (weight) are higher in resistivity ($\geq 10^{+3}$ ohm-cm). Electrodes of this material while responding to changes in ferric iron content in solution, are less sensitive to low ($\leq 10^{-4}$M) concentrations of Fe^{+3}. Low resistivity ($<10^{3}$ ohm-cm and preferably $<10^{2}$ ohm-cm) material

results in electrodes that are sensitive to concentrations as low as 10^{-6}M Fe^{+3} (0.06 ppm) in chloride and perchlorate solutions.

Electrode response time decreases with decreasing increment of concentration change, increasing ambient concentration of ferric iron, and with stirring. Exposure of the electrodes to strong chelating agents such as EDTA does not adversely affect subsequent electrode response.

In order to develop an active sensor for monitoring ferric ion concentration, the electrode surface must be etched in a caustic and exposed to high ($\geq 10^{-3}$M) concentration of ferric iron. This activation process involves the oxidation of the surface as well as further chemical reaction with ferric iron. The activation process is different from the sensing process in that the latter involves a fast, reversible exchange between solution ferric ions and adsorbed ferric ions. A slow chemical deactivation of the surface takes place which involves at least in part the irreversible adsorption of ferric ion. Electron life can be prolonged by dry storage and deactivated electrodes are readily reactivated by etching and exposure to ferric ion.

Electrochemical Behavior of Sodium Tungsten Bronze Electrodes in Acidic Media

J. P. Randin,* A. K. Vijh,* and A. B. Chughtai*

Hydro-Quebec Institute of Research, Varennes, P.Q., Canada

ABSTRACT

The electrochemical behavior of sodium tungsten bronze electrodes (Na_xWO_3, with x between 0.58 and 0.89) has been examined in helium-saturated 1*N* H_2SO_4. Several techniques have been employed, *e.g.*, steady-state polarization, potentiodynamic scanning, galvanostatic charging, and open-circuit decay of electrode potential. New data involving potential-*p*H, rotating-disk, and thermogravimetric measurements on the sodium tungsten bronze electrode are also reported.

The results indicate that the surface layer of a strongly anodized bronze electrode is depleted of sodium and its composition may approach WO_3. On a strongly (cathodically) reduced Na_xWO_3, formation of sodium-hydrogen tungsten bronze ($Na_xH_zWO_3$) is indicated. The reduction of a preoxidized (and hence sodium-depleted) sodium tungsten bronze electrode produces hydrogen tungsten bronze H_zWO_3.

Sodium tungsten bronzes have been proposed as electrocatalysts for the oxygen reduction reaction. Although their electrocatalytic activity has been the subject of numerous studies (1-9), relatively little information is available on the electrochemical stability of these materials.

It has been hypothesized (5-8) that on anodization the sodium diffuses out of the bronze surface, leaving a semiconducting layer of very low sodium content. Ion probe microanalysis has confirmed this hypothesis (10). The formation of hydrogen tungsten bronze and the oxido-reduction of the surface layer has been proposed (7). Finally, a model based on the existence of a nonstoichiometric, hydrated tungsten oxide-like layer at the surface has been proposed (11).

In the present study, the effect of electrode potential on the surface composition of sodium tungsten bronzes will be presented. The nature of the processes taking place on the surface layer of the bronze electrode in acidic media will be discussed. Several different techniques such as steady-state polarization, potentiodynamic scanning, galvanostatic charging, and open-circuit electrode potential decays have been applied. New data involving potential-*p*H, rotating-disk, and thermogravimetric measurements on the sodium tungsten bronze electrode will also be reported. A detailed a-c impedance investigation of the bronze-electrolyte interface, with particular emphasis on the Mott-Shottky behavior in relation to the electrode pretreatment, has been reported elsewhere (12).

Sodium tungsten bronzes are nonstoichiometric compounds of general formula Na_xWO_3 where x is a variable <1. For Na_xWO_3 in the approximate composition range $0.49 < x < 0.93$, a cubic structure is found which is intermediate between the hypothetical $NaWO_3$ and undistorted WO_3 structures and in which a fraction $(1 - x)$ of sodium atoms are missing from the cube corners of the $NaWO_3$ unit cell. The limiting structure of "$NaWO_3$" is that of the perovskite (ABO_3). The unit cell has a tungsten atom at the center of a cube octahedrally surrounded by 6 oxygen atoms at the face centers; there are 8 "interstitial" sites occupied by sodium atoms at the corners of the cube. The structure of WO_3 is a distorted version of the ReO_3 structure in which tungsten atoms are slightly off-center in adjacent unit cells such that the W-W distances are alternately long and short. As the sodium content of the bronze decreases, the cubic symmetry of the lattice is lowered and the structure passes through two tetragonal phases and one orthorhombic to the monoclinically distorted phase of pure WO_3.

Key words: electrochemical stability, sodium tungsten bronze, anodization, oxidation, hydrogen tungsten bronze.

Sodium tungsten bronzes with $x > 0.25$ behave as metallic conductors between 4° and 800°K. Detailed consideration of the Hall and Seebeck effects reveals that there is one free electron per metal atom in the host lattice and that the carrier mobility is comparable with that of free electrons in the conduction band of a typical metal (13, 14). The different models (15-18) for the conduction band of bronzes have been reviewed recently (19, 20). In the preferred model (18), the conduction band is made up predominantly of the overlap of W, 5*d* (t_{2g}) and O, $2p_{(\pi)}$ orbitals.

Rather little information is available on the electrical properties of low x values Na_xWO_3. It seems that below $x = 0.25$ sodium tungsten bronzes are semiconductors (21). For a single crystal of $Na_{0.025}WO_3$, semiconductor-type behavior has been established (22). The low sodium content Na_xWO_3 exhibits n-type semiconductivity with an energy gap expected to be about 0.5 eV (15) due to a localization of the π electrons in isolated cation-anion pairs or clusters (18). For pure WO_3, the conduction band is empty and the energy gap, *i.e.*, about 2.5 eV (23), is sufficiently large that at room temperature very few electrons are found in the conduction band.

The sodium tungsten bronzes are very resistant towards acids but are readily oxidized to tungstate in the presence of alkali and oxygen (or oxidizing agents). The chemical inertness of the tungsten bronzes is perhaps associated either with the high energy of activation for the diffusion of sodium ions in the oxide matrix [51.8 kcal/mole for Na in $Na_{0.78}WO_3$ (24)] or with the formation of a protective layer of WO_3 (25).

Experimental

The sodium tungsten bronzes were prepared by electrolysis of molten mixtures of sodium tungstate and tungsten trioxide as will be described elsewhere. Sodium tungsten bronze samples with an x value from 0.58 up to 0.89, and platinum content between 1 and 1450 ppm were investigated in the present work.

The crystals of sodium tungsten bronze were mounted in electrodes by compression moulding within a Kel-F holder. Apparent surface area of each of the electrodes used in the present study was about 0.2 cm^2. All data are given with respect to the apparent surface area of the electrode. Prior to the electrochemical measurements, the bronze electrode was mechanically polished using different particle sizes of alumina (Buehler Ltd.) down to 0.3 μm and subsequently washed thoroughly with triple distilled water.

The electrochemical cell used for linear sweep voltammetry, open-circuit potential decays, and galvanostatic charging experiments consisted of the main compartment which contained the sodium tungsten bronze electrode, and separate compartments for both the reference and the counterelectrodes. The counter compartment was separated from the main part of the cell by a solution-sealed stopcock whereas the reference compartment was connected to the main one through a coarse fritted disk via a Luggin capillary, whose tip was located approximately 3 mm below the working electrode. Gas outlets with water bubblers were used in the main and counter compartments. All connections from gas lines to the cell were made by means of glass-to-glass ground joints. A Teflon plate mounted in the rotating disk electrode assembly served as a gas tight cover when the Teflon O-ring located at the top of the cell was firmly seated against the plate. The electrode shaft seal was provided by a centrifugally induced unidirectional gas flow within the small gap between the Teflon disk on the electrode shaft and the horizontal Teflon cover plate during rotation. The volume of the electrolyte used in the main compartment was about 300 cm^3. An Hg/Hg_2SO_4 (1*N* H_2SO_4) reference electrode was used and the counterelectrode in the separate compartment was sodium tungsten bronze with a surface area of about 1 cm^2. This cell was used on an ESB Depack XLR-2 model rotating electrode system.

An all-glass three-compartment cell was used for other electrochemical measurements. Hydrogen electrode (in the same solution) and Hg/Hg_2SO_4 (1*N* H_2SO_4) were used as reference electrodes. All electrode potentials are given with respect to NHE. The counterelectrode in a separate compartment was sodium tungsten bronze or spectroscopic grade graphite (Union Carbide Corporation).

The hydrogen gas used for the reference electrode was purified by a palladium diffusion processor (Model HPD 050, Engelhard Industries, Newark, New Jersey). Helium gas used for deaeration and to provide an inert atmosphere inside all the electrochemical cells before and during all measurements was purified by passing it through a train, which included a BTS catalyst (BASF, Ludwigshafen-am-Rhein, Germany), maintained at 180°C to remove oxygen and CO, and Linde Type 3A and 13X molecular sieves to remove other impurities.

Sulfuric acid solutions were prepared by diluting H_2SO_4 (ULTREX, J. T. Baker Chemical) in deionized and doubly distilled water, both distillations being over alkaline permanganate. No pre-electrolysis was conducted in the present work since it was noted in some preliminary runs that pre-electrolysis tends to produce impurities, especially from the anode. It was observed that pre-electrolysis conducted with two platinum gauze electrodes (3 × 10 cm) at 1 mA for 48 hr in 100 cm^3 of helium-saturated 1*N* H_2SO_4 brought 10^{-6}g platinum into the electrolyte.[1] Sodium tungsten bronze and spectroscopic graphite were also found unsuitable. Although the problem of trace impurities may, in general, be of crucial importance in a kinetic study, the results of the present work have not been found to depend strongly on the impurity level; this statement excludes, of course, highly catalytic impurities such as traces of Pt.

In some potentiostatic measurements, the tungstate concentration in the electrolyte was measured spectrophotometrically (Spectrophotometer Perkin-Elmer, Coleman, Model 124D) using the thiocyanate method (26).

The potentiostats used were a Wenking Model 68TS3 or a Tacussel Type Bipad. A linear potential-time input was obtained from a Tacussel Electronic Function Generator, Type GSTP 2, or a Servovit 9, also from Tacussel. A Wenking Scanning Potentiometer Model SMP 69 was used to control and program the potentiostat in the automatic recording of steady-state current-potential curves (27). Constant current d-c power supplies (Kepco, Type CC 100-0.2M, and Hewlett-Packard, Model 6177B) were used for charging curves with mercury-wetted-contact vacuum relays for current inversion and open-circuit potential decay measurements.

Experiments were carried out at room temperature unless otherwise specified.

The thermogravimetric measurements[2] were performed in helium at a linear heating rate of 4°/min using a Thermoanalyser Mettler I (Mettler Instrumente AG, CH 8606 Greifensee-Zurich, Switzerland).

Results

Linear sweep voltammetry.—A typical voltammetry curve for sodium tungsten bronze electrodes with low platinum content in He-saturated 1*N* H_2SO_4 is shown in Fig. 1. A well-defined oxidation-reduction peak occurs around 0.2V. The effect of increasing the sweep rate on the voltammetry curve in the vicinity of the peak is illustrated in Fig. 2. The potentials of current maxima for the anodic and cathodic peaks are more separated at the higher sweep rates than at the lower ones and their difference approaches a constant value,

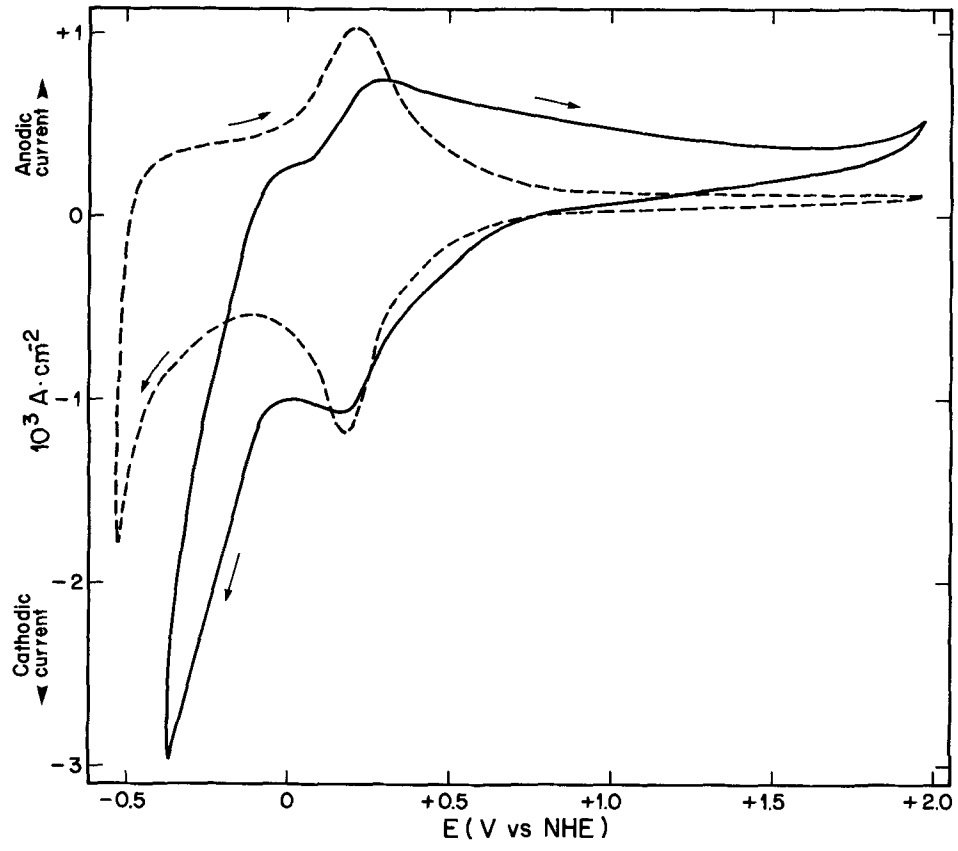

Fig. 1. Linear sweep voltammetry curve at 0.017 V/sec for $Na_{0.68}WO_3$ with 1 ppm Pt (dashed line) and 255 ppm Pt (solid line) in He-saturated 1*N* H_2SO_4. Direction of sweep indicated by arrows.

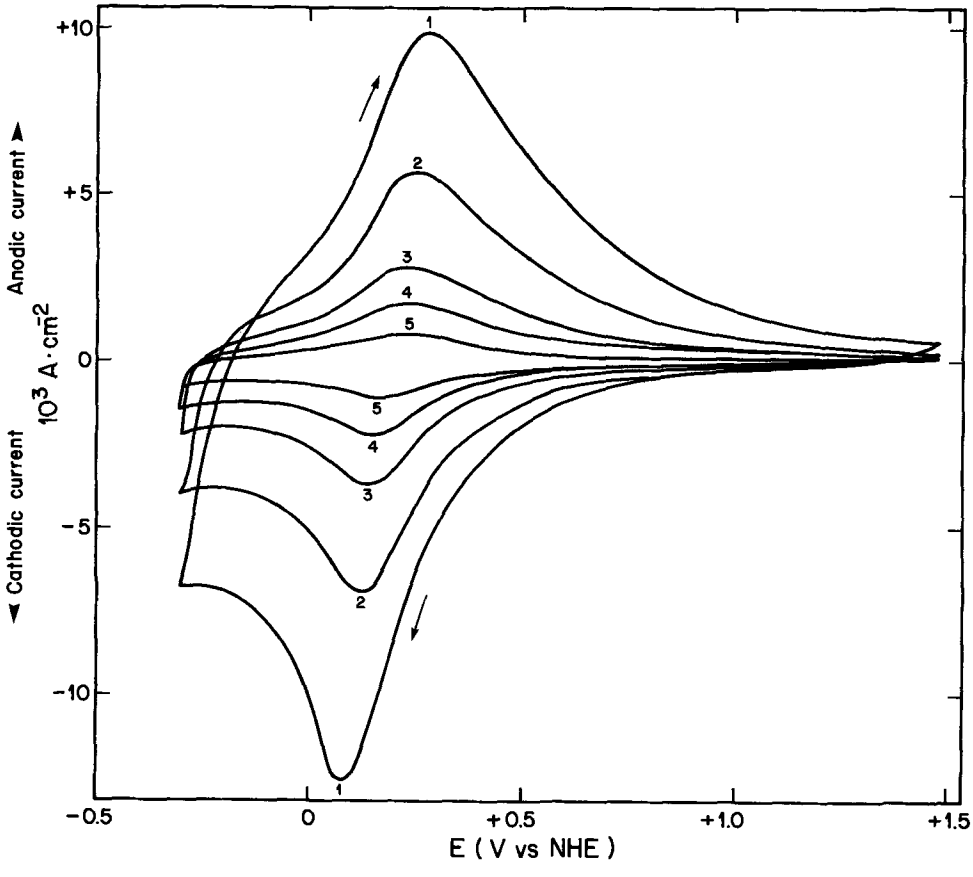

Fig. 2. Linear sweep voltammetry at various sweep rates for $Na_{0.68}WO_3$ (1 ppm Pt) electrode in He-saturated 1*N* H_2SO_4. 1, 0.720; 2, 0.360; 3, 0.180; 4, 0.090; 5, 0.036 V/sec.

i.e., about 60 mV, as the sweep rate is decreased. The 60 mV potential difference between the anodic and cathodic peaks is typical of a reversible process (28). A plot of the peak currents *vs.* the square root of the voltage scan rate, or, the voltage scan rate, shows that no linear relation passing through the origin is obtained, either in the anodic or in the cathodic direction of sweep.

This same general behavior was found for all the samples studied. The x value in the range 0.58-0.89 has no significant effect on the voltammetry curves. Samples with high platinum content exhibit some dif-

ferences with respect to samples containing only a low concentration of platinum (Fig. 1); the peak around 0.2V is still present, but it is now much broadened and overlaps the hydrogen evolution region on the cathodic sweep.

Steady-state current-potential relationships.—A typical steady-state current-potential relationship between −0.5 and 1.0V is shown in Fig. 3. Background anodic currents of the order of 10 μA cm^{-2} (apparent area), accompanied by a characteristic inhibition inflection (peak at 0.2V), a long transition region on anodic potentials, and a significant cathodic background current are the main features of the curve. The hydrogen evolution region is also shown in Fig. 3 and will not be examined in detail here. A Tafel line for the oxygen evolution reaction is observed around 2V (Fig. 4). A passivation region at potentials more anodic than 2.5V is usually quite characteristic of profound surface changes suffered by the electrode material on anodic polarization (Fig. 4).

Galvanostatic charging curves.—Anodic and cathodic galvanostatic charging curves were studied over a wide range of $i \times \tau$, where i is the charging current density and τ the duration of the transient. Normal surface conditioning performed before each galvanostatic charging curve involved a cathodic prepolarization at about 20 mA cm^{-2} for 200 sec. In a typical charging curve (Fig. 5), an arrest is obtained below 1V, followed by a plateau corresponding to the oxygen evolution reaction at about 2.3V. At low charging currents, typically 5 mA cm^{-2}, this potential remains almost constant over a long period of time. When the charging current was greater than 5 mA cm^{-2}, the voltage increased rapidly following a period during which it remained constant at about 2.3V. This transition time, τ, is shorter, the higher the applied current density. At a still higher current density, a voltage build-up as high as 40V is reached during anodization, which is an indication that some electrically limiting layer is formed on the electrode surface. It has been shown in a previous publication (29) that most likely the electrically limiting layer was an oxide. The kinetics of the oxide growth were also examined previously (29).

The transient observed at potentials below 1V was studied in detail as a function of the charging current density and the prepolarization conditions. The reverse curve was also examined and compared with the forward one.

On a freshly polished electrode, the analysis of the charging curve aimed at establishing the relative roles of diffusion and activation-controlled processes gives ambiguous relationships between the current density and $\tau^{-1/2}$ or τ^{-1}.

It was noted that a prior electrochemical treatment, especially an oxidation, had a significant effect on the shape of the galvanostatic charging curve, as well as on the charging current density *vs.* τ relationship. A preoxidized electrode gave a linear relationship between i and τ^{-1}, indicating an activation-controlled process (Fig. 6), whereas a prereduced electrode gave an i *vs.* $\tau^{-1/2}$ linear relationship, characteristic of a diffusion-controlled reaction (Fig. 7). These two different relationships have been taken as criteria of an "oxidized" and a "reduced" electrode surface, respectively.

An oxidized electrode was usually obtained after charging at about 20 mA cm^{-2} for 20 min. The reduced state of the electrode surface was much more difficult to obtain. An overnight reduction at about 20 mA cm^{-2} was sometimes not sufficient to attain the reduced state. Whereas the platinum content of the bronze had no significant effect on the time required to obtain the oxidized bronze surface, it was easier to reduce a bronze electrode containing platinum than one deprived of it. Between each series of measure-

ments the electrode surface was usually polished. If a reduced bronze electrode was subsequently oxidized without polishing, the typical behavior of an oxidized electrode was obtained. On the contrary, it was not possible to obtain the behavior of a reduced electrode with a previously oxidized electrode without polishing it thoroughly.

Typical galvanostatic charging curves obtained with strongly prereduced and preoxidized electrodes are shown in Fig. 8. At a given current density, the transition time is longer with an oxidized electrode than with a reduced one. This trend is more pronounced at higher current densities than at low ones. The anodic charging curves performed on a reduced electrode with a current density smaller than about 5 mA cm^{-2} exhibit a plateau at about 2.2V corresponding to the oxygen evolution reaction. The same measurements carried out on an oxidized electrode show only a small break at the oxygen evolution potential, followed by a rapid increase of the potential. This behavior is characteristic of an oxidized surface layer (Fig. 5). The transition times depend slightly on the extent of the pretreatment.

The transition times, τ, used in the current *vs.* τ relationship were taken from the beginnng of the transient to the minimum of the capacity-potential profile calculated from the anodic charging curve (Fig. 9). The transition time was also measured using the time between the beginning of the transient and the intersection of the tangent traced in the transition region with the continuation of the linear section of the charging curve between 1 and 2V (30). Both τ values gave the same trend in the current *vs.* τ relationship (Fig. 7.) The transition time determined by the tangent method was usually preferred to that given by the minimum of the capacity-potential profile because of the broad shape of this latter curve at potentials between 1 and 2V.

On a preoxidized electrode surface, the capacity-potential profile calculated from the anodic charging curve exhibits two maxima, suggesting the occurrence

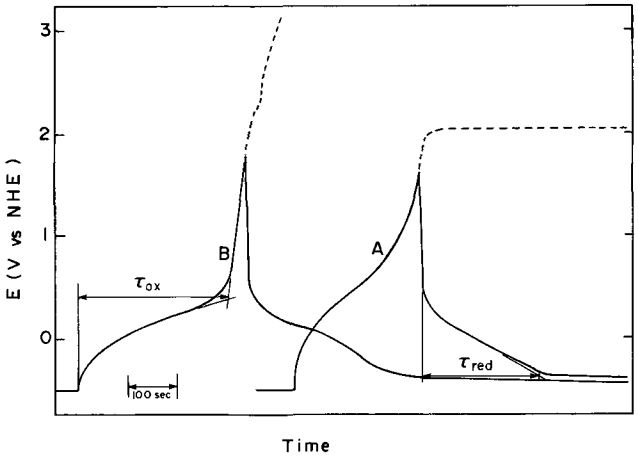

Fig. 8. Current-reversal galvanostatic charging curves for a $Na_{0.65}WO_3$ (1 ppm Pt) electrode in He-saturated 1*N* H_2SO_4. The dashed lines indicate the form of the charging curve if the current had not been reversed. $i = \pm$ 0.85 mA cm^{-2} after normal surface preparation. A, electrode prereduced at 21 mA cm^{-2} for 18 hr; and B, electrode preoxidized at 21 mA cm^{-2} for 30 min.

of two different processes (Fig. 10). These two capacity peaks overlap broadly, however, and the capacity-potential curve calculated from the cathodic charging measurements exhibits only one peak. The transition times of the two processes defined by the capacity-potential profile from the anodic charging curve have been called $\tau_{ox(1)}$ and $\tau_{ox(2)}$ and defined as indicated in Fig. 10. A linear relationship is obtained between the current density and $\tau_{ox(1)}^{-1}$, $\tau_{ox(2)}^{-1}$, $(\tau_{ox(1)} + \tau_{ox(2)})^{-1}$ and τ_{red}^{-1} (Fig. 6).

The capacitance-potential curves calculated from the galvanostatic charging curves exhibit a very high max-

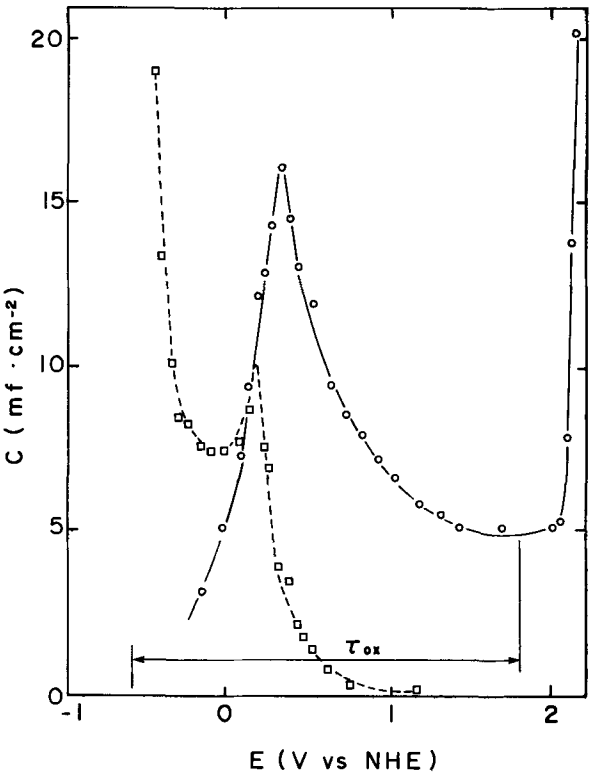

Fig. 9. Capacity-potential profile calculated from the anodic (○) and cathodic (□) charging curves for a $Na_{0.65}WO_3$ (1 ppm Pt) electrode prereduced at -27 mA cm^{-2} for 18 hr in He-saturated 1*N* H_2SO_4. Current density $i = 1.66$ mA cm^{-2} following normal surface preparation.

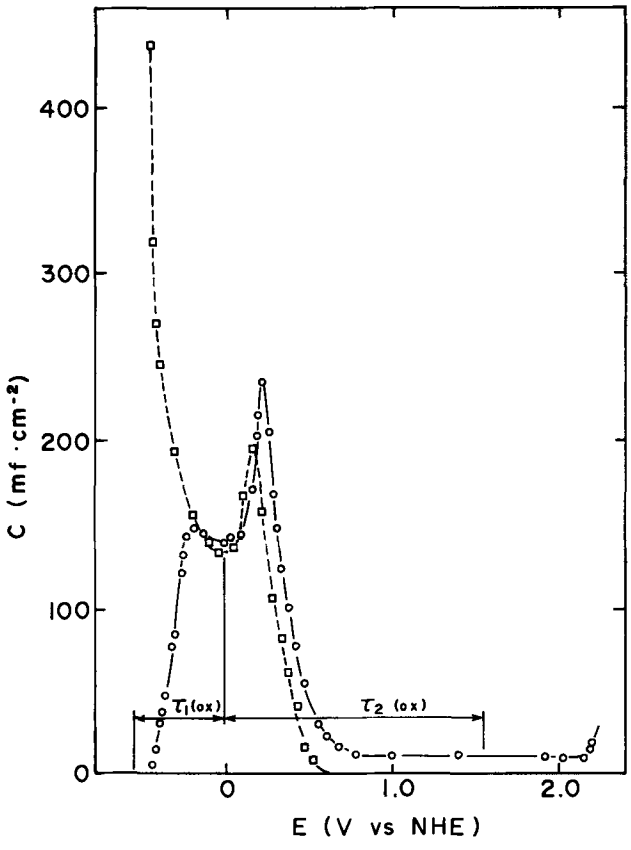

Fig. 10. Capacity-potential profile calculated from the anodic (○) and cathodic (□) charging curves for a $Na_{0.65}WO_3$ (1 ppm Pt) electrode preoxidized at 27 mA cm^{-2} for 30 min in He-saturated 1*N* H_2SO_4. Current density $i = 1.66$ mA cm^{-2} following normal surface preparation.

imum pseudocapacity. The capacitance is higher with an oxidized electrode than with a reduced one (Fig. 9 and 10). The value of the total charge given by the average slope of the anodic charging current *vs.* τ^{-1} in Fig. 6 is equal to about 120 millicoulomb cm^{-2}, whereas the charge corresponding to the cathodic charging current is equal to about 100 millicoulomb cm^{-2}.

A comparison of the ratio $\tau_{oxidation}$ to $\tau_{reduction}$ deduced from the data in Fig. 6 and 7 gives a value of about 1.2-1.3. The value of $\tau_{reduction}$ depends only slightly on the potential at which the current was reversed, *i.e.*, $\tau_{reduction}$ from a cathodic curve triggered at 1.3V (anodic) is about 15% smaller than that from a curve triggered at 2.0V (anodic) on an oxidized electrode. According to the diagnostic criteria defined by Reinmuth (31) for a diffusion controlled process, the equivalence of τ_{ox} and τ_{red} is observed only when the reduced species involved in the process is insoluble.

The general behavior of the galvanostatic charging curves has been found not to depend, significantly, on either the x value in Na_xWO_3 (for x between 0.58 and 0.89) or the platinum content of the bronze electrode (platinum content ranging from a few ppm up to 1450 ppm). The effect of platinum to achieve a reduced surface has already been pointed out.

Measurements with a rotating disk assembly.—The rotation of the electrode has no significant effect on the potentiodynamic and galvanostatic measurements carried out at intermediate potentials, *i.e.*, between -0.5 and 2V. These results indicate that diffusion in the electrolyte plays no major role in the process (es) under investigation. The electrode was sometimes rotated at low speed (about 1000 rpm) to help remove the gas bubbles from the bronze surface.

Open-circuit potential decay.—Open-circuit potential decay curves were recorded following polarizations at 1.0, 1.5, and 2.0V for times varying between 30 and 1800 sec. Each run was preceded by a prepolarization at about 5 mA cm^{-2} for 240 sec. In a given series of measurements from one particular value of the anodic electrode potential, the electrode surface was polished only before the first measurement. Three regions of potential can be distinguished (Fig. 11). First, at highly anodic potentials, a region of slow decay is observed in curves triggered after long oxidation times; this is perhaps associated with a solid-state diffusion process. Second, a more rapid region is observed whose slope, dE/d log t, is a function of both the time of polarization at a given potential (Fig. 11) and the value of the polarization potential. The more anodic the polarization potential and the longer the time of polarization, the steeper is the potential decay. This behavior is characteristic of an oxide-covered surface (32). Third, a slow potential decay is observed in the region of the rest potential, which is possibly due to a slow attainment of the equilibrium mixed potential. Neither the x value in Na_xWO_3 nor the platinum content of the electrode have a significant effect on the open-circuit potential decay.

Potential-pH relationship.—The potentials were measured in 1*N* H_2SO_4, then NaOH was progressively added to increase the pH, and inversely in NaOH with increasing amount of H_2SO_4. The rest potentials in acidic solution have low reproducibility and a long time was needed to reach a stable value. In alkaline solutions the reproducibility is better and the stable potential was reached after a shorter time than in acidic solution. Each potential-pH point was measured after allowing sufficient time (at least 24 hr) for the equilibrium to take place and the potential to stabilize.

Typical results are shown in Fig. 12. At pH values lower than about 3, the potential seems to be independent of pH, although some uncertainties exist due to the lack of reproducibility of the measurements and the long time needed to reach a stable potential. A potential-pH relationship with a slope close to 60 and

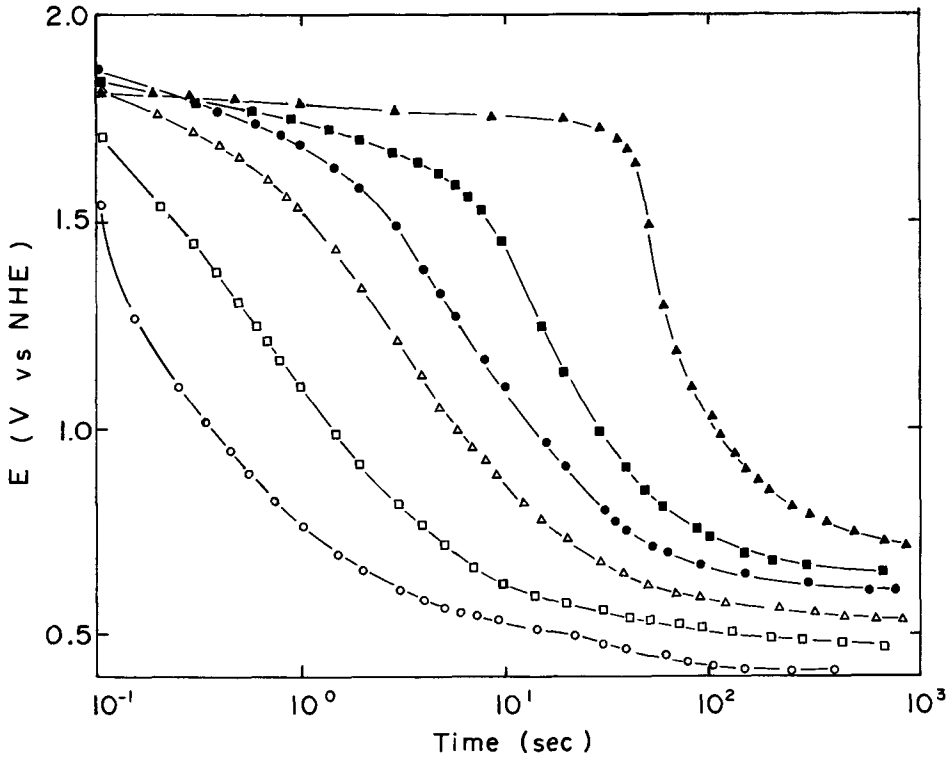

Fig. 11. Open-circuit potential decay for a $Na_{0.65}WO_3$ (1 ppm Pt) electrode in He-saturated 1*N* H_2SO_4. Galvanostatic prepolarization at −5 mA cm^{-2} for 240 sec followed by potentiostatic polarization at 2V vs. NHE for 30 sec (○), 60 sec (□), 120 sec (△), 240 sec (●), 480 sec (■), and 1800 sec (▲).

120 mV/pH in acidic and alkaline media, respectively, is indicated in Fig. 12. However, a 180 mV/pH slope in strongly alkaline solutions cannot be entirely ruled out. The presence of tungstate ions in the sulfate solution has no significant effect on the potential-pH relationship.

Tungstate dissolution upon potentiostatic polarization.—Potentiostatic polarizations at 2V were carried out on a 0.17 cm^2 polished bronze electrode in 100 cm^3 in 1*N* H_2SO_4 in the presence of He or O_2 bubbling. The amount of tungstate dissolved and the integrated charge as a function of the polarization time are given in Fig. 13. Despite scatter in these results, some general conclusions may be drawn. Roughly linear relations are obtained between the charge or the tungstate dissolved and the polarization time. However, the ratio of the tungstate dissolved to the charge passed is very low, *i.e*, of the order of 2×10^{-3}. It was also observed that this relatively low corrosion, under anodic polarization, of the bronze electrode is not appreciably enhanced by the presence of oxygen.

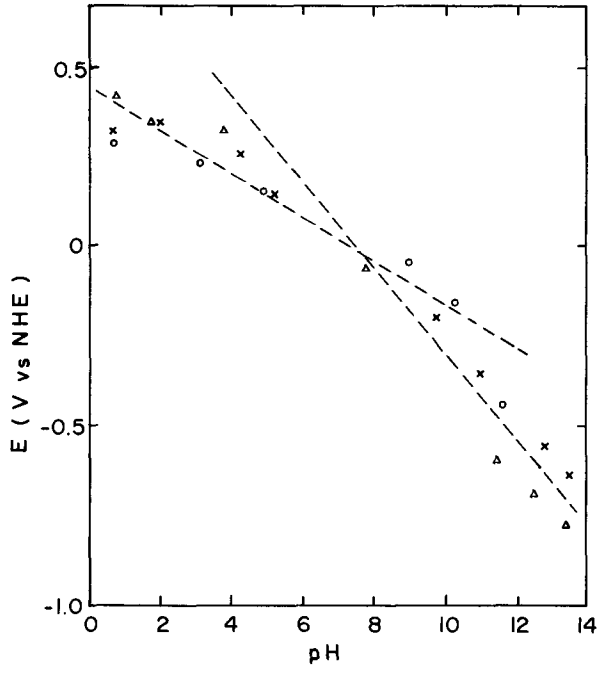

Fig. 12. Electrode potential-pH plot for a $Na_{0.65}WO_3$ (1 ppm Pt) electrode in He-saturated 1*N* H_2SO_4-Na_2SO_4 solutions [measured by going towards alkaline media (x) and towards acidic media (○)] and in 1*N* H_2SO_4 — Na_2SO_4 + 0.2 *M* Na_2WO_4 solutions [measured by going towards acidic media (△)].

The amount of tungstate dissolved at open circuit is very low, almost at the detection limit of the analytical method used, *i.e.*, 2.3×10^{-8} and 0.8×10^{-8} mole, respectively, after 170 hr in oxygen and helium saturated 1*N* H_2SO_4. These values fit reasonably well with those given by Pourbaix (33) for WO_3, *i.e.*, 10^{-8} mole/liter at pH = 3 and 25°C. These results point out the relative insolubility of the bronze in 1*N* H_2SO_4. As expected from the insolubility of tungstate in acidic media, the oxidation of W(V) into a W(VI) species does not give rise to a soluble compound since only a thousandth of the current is used for the dissolution of tungstate. It cannot be ruled out that a part of the tungstate analyzed in the electrolyte is in fact an insoluble species, such as WO_3, which erodes from the electrode surface and drops down in the electrolyte as a colloidal particle and is subsequently analyzed as a "soluble" species.

Thermogravimetric analysis.—A thermogravimetric diagram obtained with a $Na_{0.65}WO_3$ powdered sample previously immersed in water and subsequently dried at 120°C, is shown in Fig. 14. The weight loss between 100° and 400°C is only about 0.02% and a weight gain is recorded at temperatures higher than 400°C.

Discussion

The results of the present study indicate that the surface of the bronze electrode changes significantly upon electrochemical treatment. Steady-state polarization curves exhibit a significant background current in both the anodic and the cathodic direction. Potentiodynamic and galvanostatic measurements show the existence of a pseudofaradaic process at about 0.3V, which exhibits high pseudocapacitance. High pseudocapacitance values are also observed in the a-c impedance measurements (12). Steady-state potentiostatic measurements reveal a passivation region at po-

tentials more anodic than about 2.5V. Galvanostatic charging curves obtained at high current densities show a voltage build-up as high as 40V (Fig. 5). Previous work also shows capacitative behavior associated with the presence of a semiconducting surface oxide (12, 29).

Irreversibility possibly due to sodium depletion of the surface layer.—Indirect evidence described in the present study and elsewhere (6-11) indicates that the sodium tungsten bronze electrode undergoes some kind of irreversible process when anodically treated. The a-c impedance measurements reveal the presence of a semiconducting layer (10, 12). The sodium content of this surface layer is very low, *i.e.*, corresponds roughly to $x < 0.01$ in Na_xWO_3, as compared to the bulk concentration (12). McHardy and Bockris (10) have presented the only direct evidence of sodium depletion of the surface layer. This is based on ion probe analysis. The decrease, at anodic potential, of the sodium content in the surface layer can result from either the sodium depletion of the bronze surface or the growth of a sodium-free oxide on the bronze surface.

The anodic reaction for sodium depletion may be described as

$$Na_xWO_3 \rightarrow Na_yWO_3 + (x - y)Na^+ + (x - y)e^- \quad [1]$$

The occurrence of this reaction to an appreciable depth into the electrode is in contradiction with the high activation energy for the diffusion of sodium in Na_xWO_3, *i.e.*, 51.8 kcal/mole for $Na_{0.78}WO_3$ (24). [A recent study (34) indicates that sodium in tetragonal Na_xWO_3 ($x = 0.4$) diffuses much more easily than in the cubic structure. This result, however, may not be relevant to our work since it has been shown that the cubic symmetry can be extended to considerably lower x values (0.23) than the normal composition range ($0.49 < x < 0.93$) by diffusing sodium from a crystal initially in the normal cubic composition range (22)]. With such a high activation energy the diffusion of sodium is expected to occur over a few lattice dimensions only, whereas the typical depth for the sodium depleted layer found by McHardy and Bockris (10) by means of ion probe mass spectroscopy is between 500 and 2000Å for a platinum-free crystal of $Na_{0.7}WO_3$ and between 200 and 400Å for a crystal of the same bulk sodium content but containing platinum.

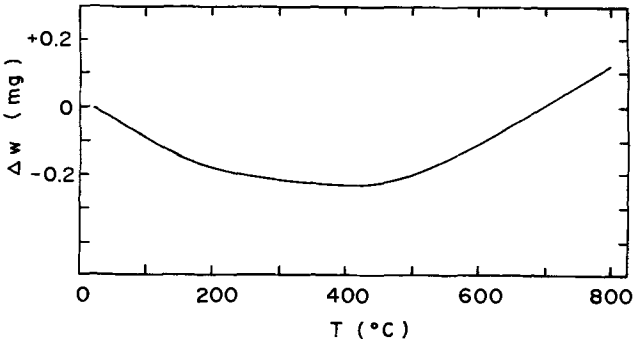

Fig. 14. Thermogravimetric diagram for $Na_{0.65}WO_3$ previously dried at 120°C. Heating rate 4°C/min, initial weight 0.60543g, He-atmosphere at 10 liter/hr.

It has been mentioned above that another possible reason for the decrease of the sodium content in the surface layer was the growth of a sodium-free oxide on the bronze surface. This alternative will be discussed below and found to be in contradiction with the experimental results.

The surface composition of a reduced electrode.—The formation of hydrogen tungsten bronzes by reduction of WO_3 with hydrogen at room temperature (35) or with zinc in boiling hydrochloric acid (36) is well documented. A synergistic effect due to platinum has been found when platinized WO_3 is reduced by hydrogen (35). The highest degree of reduction obtained at 25°C corresponds to the formula $H_{0.44}WO_3$ (35). Single crystals of H_xWO_3 in the composition range $0.3 < x < 0.6$ behave as metallic materials analogous to the corresponding sodium tungsten bronzes. The H_xWO_3 are structurally analogous to Na_xWO_3. The electronic properties of H_xWO_3 are compatible with a model in which H atoms enter the host lattice WO_3 as protons and donate electrons to a fairly wide conduction band formed from the overlapping of W_{5d} and O_{2p} orbitals (36-38). No thermodynamic data could be found for H_xWO_3.

Hence, the composition of the surface layer of the electrode during electrochemical reduction is believed to change according to the following reaction

$$Na_xWO_3 + yH^+ + ye^- \rightleftharpoons Na_xH_yWO_3 \quad [2]$$

This reaction agrees well with the conclusions drawn from the analysis of the impedance data at cathodic potential, especially the frequency dispersion of the capacitance and resistance (12).

The reaction [2] is preferred to a reaction in which the oxygen of the bronze is removed by reaction with protons, such as

$$Na_xWO_3 + 2yH^+ + 2ye^- \rightleftharpoons Na_xWO_{3-y} + yH_2O \quad [3]$$

This is because reaction [3] would require the breaking of a tungsten-oxygen bond which is expected to be energetically less probable than the introduction of a proton with the valence adjustment of tungsten.

Surface composition of an oxidized electrode.—Sodium tungsten bronze with low sodium concentration ($x < 0.25$) is known to be an n-type semiconductor with an energy bandgap of about 0.5 eV (22, 16). The a-c impedance study (12) revealed the presence of an n-type semiconducting layer with a low equivalent x value.

The injection of negative charge carriers O^{2-} into the bronze, giving a compound with an excess of anion, has been proposed recently (10, 29). This hypothesis, however, is not sustained because such a nonstoichiometric compound would exhibit a p-type semiconductivity, which is in contradiction with the experimental results. In general interstitial oxygen excess is not found in nonstoichiometric oxides because of the large size of the oxygen anion. So far, only UO_{2+x} (39) has been found to correspond to a nonstoichiometry associated with an excess of interstitial anions. A deficiency of tungsten ions would have the same effect and is also ruled out.

An alternative explanation could involve the injection of negative charge carriers into the bronze lattice whose sodium has not been completely depleted, even after a prolonged oxidation treatment. The negative charge injected as an interstitial oxygen anion should be compensated by a valence adjustment of the tungsten cations. This process could occur as long as the sodium ion is still in the lattice; *i.e.*, only half the mole content of sodium could neutralize the mole content of oxygen injected. In this process, however, the carrier concentration should decrease on going to high anodic potential; this is in contradiction with the experimental results (12).

The similarity between the a-c impedance data obtained on WO_3 single crystal electrodes by Baticle *et al.* (40) and those reported in a related study on strongly oxidized Na_xWO_3 (12) suggests that both surface layers have a similar composition. Tungsten trioxide is known to be an n-type semiconductor with a bandgap of 2.5 eV and a donor concentration equal to $2\text{-}4 \times 10^{18}$ donor-cm^{-3} (41). This compound can have various stoichiometries, due to the regular interruption of the octahedral structure by planes of discontinuity where octahedra share edges rather than corners, and not, as might be supposed, to the loss of oxygen with the concomitant ordering of vacant sites (42).

Perovskites with an oxygen deficiency (ABO_{3-x}) are also known, for example $BaNiO_{2.67}$, $BaCoO_{2.23}$ (42). However, an oxygen deficiency does not correspond to the accepted stoichiometry of the bulk Na_xWO_3. As a matter of fact, the oxygen stoichiometry in the as-grown Na_xWO_3 has been the subject of some discussion. Ingold and deVries (43) found that sodium tungsten bronzes prepared by electrolysis of molten mixture of Na_2WO_4 and WO_3 can exist with a O/W ratio as high as 3.5. More careful chemical analyses of Na_xWO_3 performed by Raby and Banks (44) indicate that the O/W ratio is 3.0. However, these data are not necessarily representative of the surface composition. The latter has not yet been analyzed.

On the basis of the preceding discussion, the most likely reaction for the oxide growth is reaction [1], which leads, in the case of strong oxidation, to a pronounced sodium depletion resulting in a very thin surface layer composed almost entirely of WO_3, *i.e.*, y in Eq. [1] is very small.

Nature of the quasi-reversible redox process at intermediate potentials.—On an electrode that has not been extensively oxidized or reduced, a quasi-reversible process occurs around 0.3V. This process is neither purely activation-controlled nor purely diffusion-controlled.

On an electrode subjected to a prolonged reduction, the quasi-reversible process is purely diffusion-controlled. Since the rotation of the electrode has no significant effect on the transition time, the diffusion is expected to occur in the solid state. The pseudocapacitance associated with this process is high and only one peak is observed in the capacity-potential profiles.

If anodic galvanostatic charging curves triggered from cathodic potentials exhibit an arrest, this would indicate that desorption of hydrogen, surface hydride formation, or hydrogen bronze formation (reaction [2]) has occurred during the cathodization. The latter process is expected to be reversible, diffusion-controlled, with diffusion occurring in the solid state. Thus the quasi-reversible reaction occurring at intermediate potentials on a reduced electrode is believed to be the hydrogen bronze formation. The potential range at which this reaction occurs, *i.e.*, about 0.2V, corresponds to the potential of the adsorption-desorption peaks for hydrogen on platinum (45).

Galvanostatic charging curves obtained with strongly oxidized electrodes reveal the occurrence of a more complex surface redox process since the capacity-potential profile calculated from the anodic charging curves exhibits two peaks. Although the process probably involves two or more steps, it can reasonably be discussed as one reaction since the reduction curve has only one peak in the capacity-potential profile (Fig. 10). On the strongly oxidized electrode the process is activation-controlled in contrast with that occurring on the reduced electrode, which appears to be diffusion-controlled. The potential of the maximum capacitance in the capacitance-potential curve is roughly the same on both the reduced and the oxidized electrodes, *i.e.*, about 0.2V. Consequently, the redox process is believed to be the same on both the pretreated electrodes; *i.e.*, the hydrogen bronze formation. On a strongly oxidized electrode the reaction may be written as

$$WO_3 + zH^+ + ze^- \rightleftharpoons H_zWO_3 \quad [4]$$

In this reaction, and in the following discussion, the composition of the oxidized electrode will be formulated as WO_3, although it is understood that a small amount of sodium may still be present in the surface layer.

The fact that the same reaction is controlled by activation on an oxidized surface and by diffusion on a reduced surface may be explained in the following way. According to Vijh (46), a rough correlation is obtained between the rate of a reaction taking place on an oxide covered electrode and the energy bandgap of that oxide. Hence, on a wide bandgap oxide such as WO_3, the electron transfer may be the rate determining step (rds) and the reaction may hence be activation-controlled. On a surface layer with a much smaller energy bandgap, such as $Na_xH_yWO_3$, the electron transfer is no longer the rds and the reaction may consequently be diffusion-controlled, as is indeed observed.

It was mentioned above that a strongly oxidized electrode subsequently reduced without polishing did not exhibit diffusion-controlled behavior typical of a reduced electrode in the galvanostatic charging curves. This fact does not necessarily imply that, once oxidized, the electrode cannot be reduced, but rather that the behavior of this reduced state does not correspond to that observed on an electrode reduced immediately after polishing. According to the preceding discussion the surface composition of an oxidized electrode may be taken as WO_3. An extensive reduction

carried out on such an electrode is expected to produce a surface layer corresponding to the composition H_zWO_3. On the other hand, an electrode reduced immediately after polishing will have a surface layer corresponding to $Na_xH_zWO_3$. The proposed explanation involves the occurrence of the same redox process in each case proceeding with different rds, depending on the composition of the surface layer. The reaction is diffusion-controlled only on a surface layer containing sodium ($Na_xH_zWO_3$). On a surface layer without sodium (WO_3 or H_zWO_3) the process is activation-controlled. The proposed reason for this behavior is that the diffusion of protons in Na_xWO_3 is hindered by the presence of sodium at the corners of the lattice, these sites being those of hydrogen in the hydrogen tungsten bronze. This interpretation is supported by the high activation energy for the diffusion of sodium in Na_xWO_3 (24). On WO_3 the interstitial sites are vacant and, consequently, protons can move easily into the canals of the octahedra. Hence, it is not surprising that the diffusion in the solid state is not the rds of the process taking place on H_zWO_3 or WO_3.

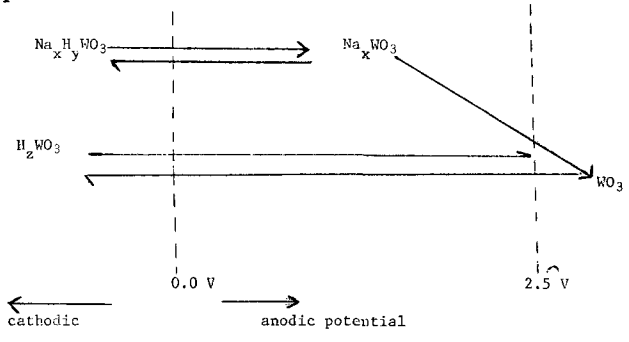
The only significant effect of platinum on the behavior of Na_xWO_3 noted in the present study involves its enhancement of the reduction process to form a hydrogen tungsten bronze. Similar enhancement has been described by Hobbs and Tseung (35) for the anodic oxidation of hydrogen. A mechanism explaining the effect of platinum to achieve a reduced surface is the following

$$x\text{Pt} + x\text{H}^+ + xe^- \rightleftharpoons x\text{Pt (H)}_{ads} \quad [5]$$

$$x\text{Pt (H)}_{ads} + Na_xWO_3 \rightleftharpoons Na_xH_zWO_3 + \text{Pt} \quad [6]$$

The rate of the over-all reaction of sodium hydrogen bronze formation would be limited by the electron transfer step on the platinum. However, it should be noted in Eq. [6] that platinum has an effect only on the forward process and not on the backward one. This is because the Pt can act only as a porter of hydrogen by providing catalytic sites for forming Pt-H during cathodization.

The foregoing discussion may be schematically represented as follows



The rate determining step for the hydrogen bronze formation is the electron transfer on a sodium-depleted electrode (WO_3 or H_zWO_3). On an electrode containing sodium ($Na_xH_yWO_3$) the process is controlled by the diffusion of protons in the solid state.

Sodium tungsten bronze electrodes as pH indicator.—Several studies on the use of bronzes in pH and other related measurements have been published recently (47-48). Koksharov *et al.* (47) report a slope of about 60 mV/pH between pH 1.5 and 13.5 for a sodium tungsten bronze ($Na_{0.8}WO_3$) prepared by the solid-state method. Tetragonal bronze ($Na_{0.3}WO_3$) and melted bronze gave no definite slope in acidic media and responded to changes in pH only in a narrow interval of pH in alkaline solutions. Wechter *et al.* mentioned (48) that the potential-pH response of sodium tungsten bronze electrodes deviates from linearity but reported no data.

Thus, it appears from the present work, as well as from the earlier studies (47), that in strongly acidic media (pH < 3) no definite equilibrium potential is reached. At intermediate pH (between about 3 and 10), a 60 mV/pH slope is suggested from Fig. 12. Such behavior is predicted from any one of the following reactions (33, 11)

$$W_2O_5 + H_2O \rightleftharpoons 2\,WO_3 + 2H^+ + 2e^-, \quad E_o = -0.029\text{V} \quad [7]$$

$$WO_2 + H_2O \rightleftharpoons WO_3 + 2H^+ + 2e^- \quad [8]$$

$$2\,WO_2 + H_2O \rightleftharpoons W_2O_5 + 2H^+ + 2e^-, \quad E_o = -0.031\text{V} \quad [9]$$

$$W_6O_{11}(OH)_8 \rightleftharpoons W_6O_{17}(OH)_2 + 6H^+ + 6e^- \quad [10]$$

In alkaline media, a 120 mV/pH slope is suggested by Fig. 12, and it may be attributed to the following reaction

$$NaWO_3 + H_2O \rightleftharpoons WO_4^{2-} + Na^+ + 2H^+ + e^- \quad [11]$$

The lack of dependence of the potential of the bronze electrode on tungstate concentration is a behavior similar to that found for a ReO_3 electrode for which no dependence of potential on ReO_4^- concentration was indicated (49). These results may be contrasted with those obtained with MnO_2 electrodes for which Mn^{+2} concentration influences the potential-pH relationship (50).

Hydration characteristics of the sodium tungsten bronze electrode.—Vojnovic, Sepa, and Ovcin (11) have recently proposed a model of the surface of the bronzes in acidic solution based on the existence of a nonstoichiometric hydrated tungsten oxide-like layer at the surface. This model is based mainly on the findings of Spitzin and Kaschtanoff (51) concerning the bonding of water at the bronze surface. These authors (51) claim that a bronze sample previously dried at 120°C releases water below 300°C. This result is in contradiction with the more recent thermogravimetric measurements in which Polaczkova (52) has shown that a $Na_{0.11}WO_3$ sample gains about 0.2% weight upon heating between 200° and 300°C and the weight remains stable between 300° and 800°C.

If the structurally bonded water is removed from the surface sites upon heating as claimed by Vojnovic *et al.* (11), a sudden weight loss should be recorded around 300°C. The DTG diagram is devoid of such a peak. The small weight loss between 100° and 400°C followed by a small increase in weight between 400° and 800°C shown in Fig. 14 may be due to some gas adsorption or desorption. Thus the results of Polaczkowa (52) and those of the present study put in serious doubt the earlier work of Spitzin *et al.* (51) and would, consequently, invalidate the model proposed by Vojnovic *et al.* (11) for the surface of bronzes in acidic solution.

Acknowledgments

The authors thank Mr. R. Bellemare for his assistance in the experimental work, Dr. G. Bélanger for helpful discussions, and Dr. P. Lenfant for his interest and encouragement. The cooperation of the Materials Science and Electronics Departments of the Hydro-Quebec Institute of Research is gratefully acknowledged. One of the authors (A.B.C.) thanks the Canadian International Development Agency, Ottawa, for the award of a training fellowship.

Manuscript submitted Feb. 12, 1973; revised manuscript received April 11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Thermal Effects During the Formation and Dissolution of Anodic Tantalum Oxide

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Anodic films formed on tantalum at 10 mA/cm² were found to be thicker at the top of the specimen than at the bottom. The effect has been traced to a temperature difference resulting from the presence of convection currents in the electrolyte; these currents are powered by the heat released during anodization. The oxide thickness is thus very sensitive to changes in the anodizing temperature, and this sensitivity has been used to determine the temperature rise within the film itself. Convection currents during the dissolution of the oxide in buffered HF give rise to similar thickness variations, from which it has been concluded that the oxide dissolves exothermically.

A highly precise sectioning technique (1) has recently been developed for the purpose of measuring concentration profiles in anodic tantalum oxide (2, 3). The technique is based on slow dissolution of the oxide in HF almost saturated with NH_4F, and its extreme precision is due to the uniformity of the dissolution. In verifying this precision (1), it was shown that the anodization kinetics must necessarily give rise to oxide films of uniform thickness. Measurements showing that the oxide film was thicker at the top of a specimen than at the bottom therefore came as a surprise!

* Electrochemical Society Active Member.
Key words: tantalum, anodic oxidation, oxide dissolution, convection currents.

Fortunately, the explanation was soon apparent. The film thickness depends, *inter alia*, on the anodizing temperature; the higher the temperature, the greater the thickness formed. A greater thickness at the top of the specimen implies a higher anodizing temperature, and this could be due to convection currents in the electrolyte. Since the anodization of tantalum proceeds with the evolution of heat (4), such convection currents will inevitably be present unless action is taken to eliminate them. The observed thickness variations therefore act as a sensitive thermal probe, and some additional investigations were suggested thereby. In particular it seemed reasonable to suppose that if thickness variations resulted from thermal changes during anodization, they might also result from thermal changes during the dissolution of the oxide in buffered HF; appropriate experiments showed that this was indeed the case.

Anodization

Consequences of the anodization kinetics.—At constant temperature, the anodization kinetics may be represented approximately by

$$i = C \cdot \exp(DV/h) \qquad [1]$$

where i is the current density and V the potential across the oxide film of thickness, h; C and D are positive constants. Suppose that at a certain point on the surface the oxide thickness is less than h; then from Eq. [1], the current density at that point will be greater than i. If the current density is greater than i, the oxide will thicken more rapidly, and so the thickness irregularity will disappear as anodizing is continued. The oxide thickness must therefore remain extremely uniform throughout the anodizing process (1).

This argument is valid even though the anodization kinetics are much more complex than indicated by Eq. [1]; in particular, they vary with temperature. The best description (5) appears to be Young's (6) equation

$$i = i_o \cdot \exp[-(W - A \cdot (V/h) - B \cdot (V/h)^2)/kT] \qquad [2]$$

where i_o, W, A, and B are constants, k is the Boltzmann constant, and T the absolute temperature. This equation may be rearranged thus

$$h/V = 2B/[-A + \sqrt{(A^2 - 4B \cdot (-W + kT \cdot \ln(i_o/i)))}] \qquad [3]$$

On inserting appropriate values obtained from a least squares fit of Eq. [2] to the original data of Ref. (6)

$$h/V = 9.851/[1 - \sqrt{(0.001091T - 0.2056)}] \quad [\text{Å/V}] \qquad [4]$$

where i is taken as 10 mA/cm², the current density used in the present experiments. The left-hand side defines the "angstrom/volt" parameter, which measures the oxide thickness formed per volt of anodizing potential at the specified current density; the right-hand side shows that this value increases with the anodizing temperature, T°K.

Angstrom/volt values can easily be calculated from measurements of applied voltage and oxide thickness, but the results obtained here agreed only qualitatively with those computed from Eq. [4]. The reason for this is obscure, but it may perhaps be due to idiosyncracies in the apparatus used; the present anodizing apparatus (7) was intended merely to control the process, not to make accurate measurements on the kinetics.

On differentiating [4] with respect to temperature

$$d(h/V)/dT = 0.0363 \quad [\text{Å/V/°C}] \qquad [5]$$

for 25°C, the temperature at which the present experiments were performed. Hence if two tantalum specimens are anodized by 10 mA/cm² to 200V, and at temperatures close to 25°C but 1°C apart, the oxide thicknesses formed will differ by approximately 7Å. Such a difference can readily be detected by the spectrophotometric method for measuring oxide thickness (1, 8).

Thus although [4] could not be applied satisfactorily to measure the anodizing temperature itself, it was possible to apply [5], with good confidence, to measure differences in anodizing temperature. Fortunately, it was these differences that were of the greatest interest.

Heat liberated during anodic oxidation.—The resistive heat generated by the current flow is given by $V \cdot i/4.2$ cal/cm²/sec, where V is the potential across the oxide film in volts, and i is the current density in amperes/square centimeter. If V is 100V and i is 10 mA/cm², the heat liberated is 0.24 cal/cm²/sec, which is very large in relation to the small volume in which it is generated; the heat generation per unit volume is in fact of the order of 50 kW/cm³. Unless this heat is dissipated very quickly, therefore, the temperature of the oxide will rise substantially.

This problem has been considered by Young (4), who noted that while some of the heat would be dissipated by conduction to the underlying tantalum, most of it would be lost by convection currents in the electrolyte. He concluded, on both theoretical and experimental grounds, that the temperature rise would be appreciable only at current densities greater than a few milliamperes/square centimeter; and then only if the metal specimen were thin, the stirring of the electrolyte inefficient, and the anodization carried out continuously to high voltages. These general conclusions have been confirmed by others (9, 10) and also by experience in these laboratories.

Experimental results and discussion.—Rectangular coupons, 35 mm long by 10 mm wide, were cut from 0.37 mm (0.015 in.) tantalum sheet supplied by the Fansteel Metallurgical Corporation. A tantalum wire, 1.25 mm (0.050 in.) in diameter, was spot welded on one corner to provide electrical contact, and the coupons were then cleaned and chemically polished as described elsewhere (1). All anodizations were performed in 0.1M H_2SO_4 electrolytes maintained at 25°C by means of a water bath, using the apparatus devised by Walker (7). Oxide thicknesses were measured with a precision of 2Å or 0.15% of the thickness, whichever was greater (1), by means of the spectrophotometric method due to Young (8).

Four coupons were set in unstirred electrolyte with their long axes vertical, and anodized to 55, 110, 165, and 220V, respectively, at 10 mA/cm². Average oxide thicknesses over areas 8 × 2 mm (1) running across the coupons were then measured for the mean positions listed in Table I. The anodic films were all found to

Table I. Effect of thermal convection currents in the electrolyte on the thickness of the anodic oxide formed on rectangular tantalum coupons, 35 mm long by 10 mm wide. Temperature differences calculated from [5]. Anodizing conditions: 10 mA/cm², 0.1M H_2SO_4, 25°C

Distance from bottom or end of foil, mm	Oxide thickness, Å					
	Vertical orientation				Horizontal orientation	
					Upper side	Lower side
29.5	872	1750	2633	3549	3563	3566
17.5	871	1743	2628	3531	3574	3584
5.5	869	1734	2609	3498	3570	3574
Maximum potential applied (V)	55	110	165	220	220	220
Maximum temperature difference across coupon (°C)	1	4	4	6	1	2
Temperature increase at mid point relative to first coupon (°C)	—	0	2	6	11	12

be thicker at the top of the coupons than at the bottom, exactly as predicted from the convection current hypothesis. Angstrom/volt values were calculated for each end of the coupons, and the difference divided by 0.0363 [5] to obtain the maximum temperature differences. These are also listed in Table I, from which it can be seen that they increase with final anodizing voltage.

As already noted, the heat generated during anodization is proportional to $V \cdot i$, and therefore increases linearly with voltage under the constant current conditions used here. More heat is generated at the larger voltages, and, because the anodization takes longer, there is more time in which the convection currents can be set up. Increased temperature differences at the larger voltages are thus readily explained. By the same token, the average temperature of the electrolyte in contact with the coupon will increase, and so the mean anodization temperature will also be greater. Temperature differences calculated from the angstrom/volt values at the midpoints of the various coupons confirm this hypothesis also.

Further proof that convection currents are responsible for these nonuniformities was provided by changing the orientation of the coupons in the electrolyte. When a coupon was aligned horizontally, the results shown on the right-hand side of Table I were obtained. The greatest thickness now occurred in the middle of the coupon, as might be expected from the nature of the convection currents set up. The latter would, however, be so much weaker than for the vertical orientation that the temperature differences across the coupon would be less, and the electrolyte in contact with it would heat up more. The result in Table I shows that this is indeed what happens.

A convection current can be destroyed by stirring the electrolyte, and so the following experiment was performed. Two coupons, oriented with their long axes vertical, were placed in different anodizing cells immersed in the same water bath. The electrolyte was well stirred in one cell, but not at all in the other, and both coupons were anodized simultaneously to 220V at 10 mA/cm^2. Film thicknesses on the coupon in the unstirred cell were within 10Å of those for the similar specimen in Table I, which illustrates the reproducibility attained in these experiments; those in the stirred cell averaged 3398Å, with no significant variation across the foil. From the corresponding angstrom/volt values, the temperature difference at the midpoints was no less than 16°C, so that the way in which the heat is dispersed in the electrolyte has significant consequences for the anodizing process.

This ability to measure small temperature differences suggested that it might be possible to detect an effect when only one side of a coupon was anodized. A suitable specimen was prepared by masking one side with Apiezon N grease (1), and then anodizing the other to 170V at 1 mA/cm^2. On dissolving the Apiezon N in trichlorethylene, the first side was available for further anodization, while the second was protected by the anodic film already formed. The specimen was then anodized to 150V at 10 mA/cm^2 in a well-stirred electrolyte; simultaneously, an ordinary specimen was anodized in the same well-stirred electrolyte on both sides. The thickness of the film formed on the one side was 2290 ± 2Å (range of three measurements), while that formed on both sides was 2299 ± 2Å (range of six measurements, three on each side); repetition of the experiment gave exactly the same results. There is no doubt, therefore, that a temperature difference does exist under these conditions, and that its magnitude is of the order of 1.5°C.

If the presence of the second anodizing film raises the temperature of the first by 1.5°C, this implies that the first is already 1.5°C above the ambient electrolyte temperature; always assuming that the temperature gradient in the metal is negligible, as has been demonstrated theoretically (10). Such a result is of some significance for precise measurements on the anodization kinetics [*e.g.*, Ref. (6)] Obviously, the temperature increase will depend on the conditions of the experiment, and will be greater at larger current density and final voltage.

Dissolution

As discussed in Ref. (1), the dissolution of anodic tantalum oxide in concentrated HF almost saturated with NH_4F is normally just about as uniform as the anodization. Thus a tantalum coupon of the usual size was anodized at 220V at 1 mA/cm^2 and the thickness measured at 4 mm intervals across each face, starting 5.5 mm from one end. The fourteen measurements thus obtained ranged from 3588 to 3592Å, with a mean of 3590Å. The specimen was then stripped, with agitation, in 200 ml 48% HF + 80g NH_4F for four 10-min periods, being washed in water and acetone at the end of each period (1). Remeasurement of the oxide thickness at the same fourteen positions gave results ranging from 1907 to 1914Å, with a mean of 1911Å. A layer of oxide 1679 ± 2Å (rms deviation) thick had therefore been removed from every part of the specimen surface.

A second specimen was anodized and measured in exactly the same way, the fourteen thicknesses ranging from 3595 to 3597Å. This specimen was then placed in the same sample of stripping reagent and held stationary, with its long axis vertical, for 40 min. After washing and drying, remeasurement of the oxide thicknesses on one side gave 1811, 1812, 1814, 1818, 1820, 1827, and 1831Å for 4 mm intervals starting 5.5 mm from the bottom; the corresponding positions on the second side gave 1808, 1812, 1815, 1821, 1819, 1826, and 1829Å. More oxide had been dissolved from the bottom than the top, and more oxide had been removed overall, compared with the agitated sample. Convection currents were obviously present.

To establish the nature of these convection currents, two additional pieces of information were needed. As in anodization, the influence of temperature had to be established. Three anodized specimens were stripped in the same sample of reagent at three different temperatures (3.1°, 26.4°, and 46.9°C) whereupon the stripping rates were found to be 17, 81, and 479 Å/min, respectively. The dissolution rate therefore increases very markedly with temperature.

Second, the dissolution of oxide presumably weakens the reagent's ability to dissolve further oxide. To confirm this, approximately 1g of tantalum metal was dissolved in 20 ml concentrated HF, and then 8g of NH_4F added to make up the reagent; simultaneously, another 8g of NH_4F were added to 20 ml of the same concentrated HF to act as a standard. After equilibrating to the same temperature, the stripping rates were found to be 35 and 47 Å/min respectively, so that the presence of the dissolved tantalum had indeed decreased the stripping rate.

The convection currents can then be interpreted as follows. The oxide dissolves exothermically in the HF-NF_4F reagent, and the solution in contact with the surface becomes warmer. As it warms, it starts to rise; and as it dissolves the oxide, so its ability to dissolve further oxide is reduced. The two effects are in opposition, and hence the observed result depends on the outcome of the competition between them. The faster over-all dissolution is obviously a consequence of the temperature effect, while the slower dissolution at the top of the specimen is due to the weakening of the dissolving agent. The alternate possibility, that the oxide dissolves endothermically, can be dismissed, for the two effects would then reinforce one another to leave the greatest thickness at the bottom of the coupon.

Duplicate experiments confirmed these observations and showed that they were surprisingly reproducible, apart from the single occasion, noted in Ref. (1), when the interference colors indicated spots of thinner oxide. To study the formation of the convection currents, four specimens were anodized simultaneously at 1 mA/cm^2 to a thickness of 3565Å, and then stripped in a sta-

tionary vertical position for 10 × 4, 5 × 8, 2 × 20, and 1 × 40 min, respectively; after each strip, the specimens were washed and dried in the usual way (1). All four specimens were thus stripped for the same total time, and in the same sample of reagent at the same temperature; the effect of the convection currents was expected to become greater as the stripping periods lengthened. This was precisely what was observed. The thicknesses at the midpoints were found to be 1058, 1011, 942, and 950Å, respectively, which demonstrates the increase in dissolution rate due to local heating of the reagent. At the same time, the oxide thickness at the top was found to be 7, 13, 20, and 14Å greater than that at the bottom, thus demonstrating the onset of the convection currents.

Conclusions

1. Tantalum coupons anodized at 10 mA/cm² in unstirred electrolytes developed a greater oxide thickness at the top than at the bottom. These thickness variations have been related via the known kinetics of anodization, to differences in anodizing temperature.
2. The differences in anodizing temperature have been attributed to the presence of a convection current resulting from the heat liberated during the anodic oxidation.
3. The relation between oxide thickness variations and anodizing temperature differences has been used to measure the temperature rise in an oxide film during anodization in well-stirred electrolyte. For anodization at 10 mA/cm² to 150V, it was found to be about 1.5°C.
4. Thickness variations that developed when the oxide was dissolved in concentrated HF almost saturated with NH_4F were also attributed to convection currents.
5. From the nature of these currents, the oxide must dissolve exothermically.

Magnetic Plating on Nonconductors

John R. DePew*

General Products Division, International Business Machines Corporation, Boulder, Colorado 80302

ABSTRACT

Thin magnetic films of Co-P were autocatalytically deposited on two different plastic substrates. A polycarbonate and a polyimide plastic were chosen as the nonconductive substrates because of their thermal stability and flatness. The conditioning, sensitization, activation, and autocatalytic deposition of these nonconductors are described. A citrate hypophosphite bath was used with variations in the ratio of cobalt salts to citrate salts. The magnetic properties (coercive force, remanence, and squareness) of the thin (250-4000Å) films were analyzed, and the most promising concentration ratio and substrate were chosen for further experimentation. Variations in reductant concentrations were made at a constant ratio of cobalt to citrate. For each concentration of reductant, films of different thicknesses were prepared, and the effects of composition and thickness on the crystallographic and magnetic properties of the deposits were studied.

With the coming of the computer age, magnetic recording media consisting of thin films of magnetic material on substrates such as tape, drums, disks, or loop surfaces became indispensable to the complete data processing system. The most extensively used magnetic coating over the last ten years or so has been a finely divided ferric-oxide dispersion in a thermoplastic binder. In recent years, considerable effort has been spent on developing autocatalytic metal deposition. This technique deposits thin ferromagnetic metal films on conducting and nonconducting substrates by catalytic reduction of metal salts from aqueous baths. The thin films used are particularly suitable for very high-density digital magnetic recording because of their thinness, high coercivity, and high magnetic-moment density.

This paper deals with autocatalytically plating a thin cobalt-phosphorus magnetic film from a citrate-hypophosphite bath onto polycarbonate and polyimide nonconductive substrates. The effect of metal-ion concentration to citrate-ion concentration on the respective substrates (relative to magnetic properties) was evaluated in order to choose the optimum ratio for varying the reductant concentration. The resulting crystallographic and magnetic properties were examined.

Experimentation

The substrates chosen to receive an autocatalytic deposit of cobalt-phosphorus had to meet the following criteria: thermal stability, smoothness or flatness, nonconductivity, and flexibility (plasticity). These criteria are dictated by the requirements of the magnetic recording medium and its application in the computer industry.

Some previous work has been reported in which Mylar[1] was used as a substrate. Although somewhat more expensive than Mylar (a polyester), Kapton[1]

* Electrochemical Society Active Member.

Key words: plating, autocatalytic deposition, Co-P deposition, magnetic films, nonconductive substrates.

[1] Registered trademark, E. I. du Pont de Nemours Company.

(a polyimide) and Lexan[2] (a polycarbonate) were the substrates chosen for the experiments described in this report.

The following procedures were developed to obtain good coverage and adhesion by the metal. The Lexan and the Kapton were first ultrasonically cleaned in a detergent and a chlorinated solvent. Next the Lexan was soaked for 1 min in N, N dimethyl foramide, and then for 10 sec in a dichromate solution at 95°C (1, 2). The Kapton was soaked for 15 sec in a dichromate solution at 95°C, followed by a 15-sec dip in a 4M solution of NaOH at 90°C. The substrates were then given the usual sensitization (stannous chloride) and activation treatment (palladium chloride) (1). After each step, the substrate was rinsed in distilled water. The substrates were then ready for the autocatalytic deposition of the magnetic coating.

The deposition was carried out in a one-liter beaker. The general and the experimental formulations for the baths are given in Table I (3, 4). An expanded-scale pH meter was used to constantly monitor the pH. An ammonium-hydroxide solution was added to the bath to raise the pH as needed. The temperature of the bath was maintained by a thermostatically controlled hot plate. The agitation of the solution during deposition was kept at a level merely sufficient to ensure uniformity of temperature and concentration.

A fresh bath was prepared for each set of experimental conditions. To minimize the effects of the gradual depletion of the solution, only six samples were plated in each bath.

Photomicrographs were obtained by using an optical microscope and a scanning electron microscope. The percentages of cobalt and phosphorus in the films were determined by x-ray fluorescence. Standards of Co-P films that had been previously analyzed by wet chemical means were used to establish a graph of counts *vs.* mass per unit area (milligrams/square centimeter).

The percentage of phosphorus in the deposits was calculated by using the mass-per-area values of cobalt and phosphorus obtained by fluorescence. The thicknesses of the films were calculated by using the bulk density of cobalt (about 8.9 at 20°C) and assuming that the cobalt was the main constituent of the deposit. A diffractometer was used to trace the x-ray diffraction patterns of select plated samples to establish the particle size and the cobalt orientation in the experimental films.

Orientation with respect to the substrate of the films can be predicted from the intensity ratio of planes

$$\frac{I_{(0002)}}{I_{(10\bar{1}0)}}$$

Cullity (5) holds that a ratio of less than one indicates a preferred orientation of the (0002) planes to the surface of the substrate, whereas a ratio greater than one indicates (0002) planes, or c-axis, normal to the substrate. Values close or equal to one after normalization indicate a random c-axis orientation in the films.

All plated samples were placed on a vibrating sample magnetometer in order to measure the magnetic hysteresis. The two magnetic parameters measured were the coercivity and the squareness. A nickel standard of five-nines purity, accurately weighed, was used to calculate the saturation moment and the remanent moment. A calibrated x-axis on the recorder was used to calculate the coercivity of all samples.

Table I. Formulations

General	Experimental Series 1 (g/liter)	Experimental Series 2 (g/liter)
$CoSO_4 \cdot 7H_2O$ (35 g/liter)	2.5-35.0	17.5
$Na_3C_6H_5O_7 \cdot 2H_2O$ (35 g/liter)	35.0	35.0
$NaH_2PO_2 \cdot H_2O$ (20 g/liter)	20.0	10.0-30.0
$(NH_4)_2SO_4$ (66 g/liter)	66.0	66.0
Temperature = 178° ± 4°F		
pH = 8.6 ± 0.1		

Results

As was previously noted, the first experiments were done on Lexan and Kapton substrates. The first plating bath (series 1) used to deposit a magnetic coating on these substrates was a modified Brenner bath that had been used by others (4, 5). The pH, temperature, reductant concentration, buffer concentration, and complexing agent concentration of the bath were held constant. The only variables were time and the cobalt-ion concentration. Since the ratio of the cobalt ion to the complexing agent controls the amount of free cobalt available for reduction, it was this relationship that was examined and represented graphically in Fig. 1 for the Lexan and the Kapton substrates. Since the requirements for high-density media for digital recording are high coercivity, high squareness, and reasonable plating rates, the graphic results were examined to determine the optimum substrate and concentration ratio.

Figure 1 also shows that the squareness is quite linear and high over most of the range for Kapton, whereas the coercivity is somewhat erratic except in the range of 15-35 g/liter. The plating rate appears flat and reasonable (1250 Å/min) in the same range.

The results obtained by using Lexan as the substrate show very low coercivities and high squareness, initially. A peak in coercivity is reached at a concentration of 27.5 g/liter, but corresponding low squareness makes it unsatisfactory for high-density media. Adhesion between the deposits and the Lexan became very poor with thicknesses above 1700Å. The deposit blistered and tended to flake off in the bath.

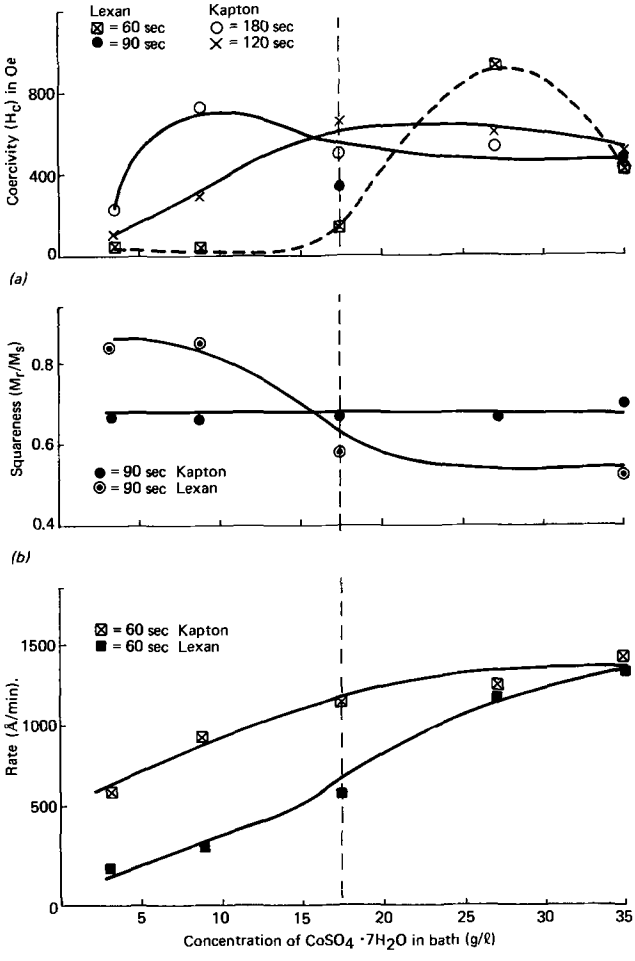

Fig. 1. Properties of deposit at different cobalt-ion concentrations on Kapton/Lexan substrates. (a) Coercivity, (b) squareness, (c) rate.

The reasons for choosing the 0.50 concentration ratio (represented by the vertical broken line) for further study become more apparent on examination of Fig. 1. The unusual relationship between the coercivity and the cobalt-ion concentration is an extension of the work disclosed by Wright (6), but contradicts his conclusion that the coercivity increases with decreasing cobalt-cation concentration.

After the initial experimental results were examined, further efforts were centered on the Kapton substrate, using a bath concentration ratio of 0.50. The pH, temperature, buffer concentration, complexing agent concentration, and cobalt-ion concentration were kept constant. The time and the reductant concentration were the only independent variables in this phase of the experiment (series 2). The reductant was chosen as the main variable since it had pronounced effects [discussed by others (7)] on rates of deposition, the amount of phosphorus in the deposit, and the crystallography, coercivity, and squareness.

The weight of the cobalt and the phosphorus deposited, determined by x-ray fluoresence, is shown in Fig. 2 as a function of deposition time with the reductant concentration as a variable. The total weight of the deposit is a linear function of the deposition time for each concentration of reductant; hence the deposition rate must be constant for each composition. If we assume a bulk density for cobalt (the main constituent of all deposited films) of 8.9 g/cm^3, we can calculate the dependence of the plating rate on the reductant concentration from Fig. 2. The average rate of deposition is a linear function of the reductant concentration over the range covered, and is probably the result of the optimum ratio of the cobalt ion to the complexing agent (0.50). Figure 3 supports the conclusion that the thickness of the deposit is a linear function of time and the reductant concentration.

The phosphorus in the films greatly influences their crystallographic and magnetic properties. The structure-sensitive property of hysteresis (and hence the coercivity and squareness) is greatly determined by phosphide-forming elements and particle size. According to Amendola *et al.* (8), the phosphorus content of a film is also a criterion for resistance to wear; cobalt thin films containing more than 2% phosphorus are abrasion-resistant.

The weight of the phosphorus deposited depends on the total weight of the deposit. There is no apparent change in the percentage of phosphorus over this thickness range in which the average percentage of phosphorus is independent of the weight of the deposit. The average phosphorus content remained quite constant throughout the concentration range of the reductant. Another noteworthy influence of increased film thickness is a decrease in the phosphorus content of the

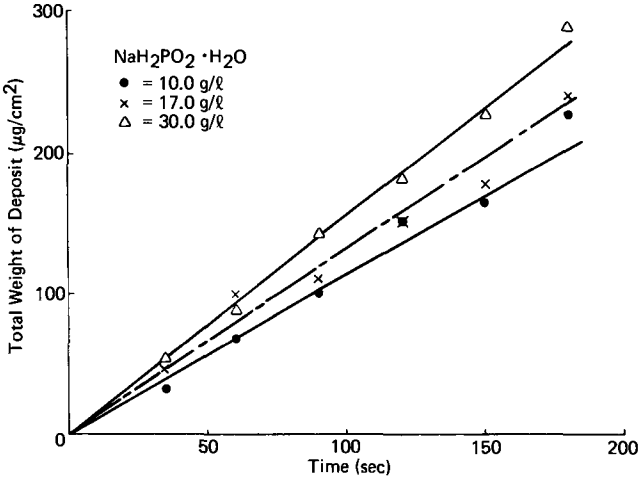

Fig. 2. Total weight of cobalt and phosphorus deposit vs. plating time.

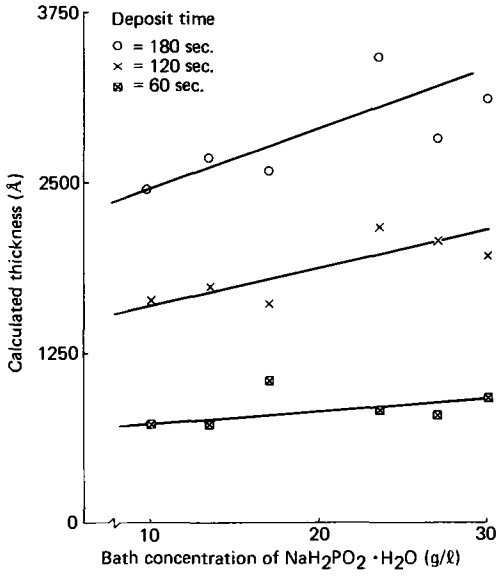

Fig. 3. Calculated thickness vs. reductant concentration in bath

deposits (see Fig. 4). Much of the phosphorus is co-deposited in the initial stages of the autocatalytic reaction. Some deposits in the lower thickness range achieved a phosphorus content of nearly 10%.

The effects of these varied amounts of phosphorus on the relative smoothness of the deposit are shown in Fig. 5. This figure shows the results obtained by examining various film samples with a scanning electron microscope. The film with 0.6% phosphorus appeared to have a crevice pattern; it also appeared less bright to the naked eye. The film with 6.5% phosphorus was cracked through to the substrate, probably because of the high stress associated with the high phosphorus content. Even though it contains twice as much phosphorus as the film with 3.1%, it looks only slightly smoother. All these effects have been observed by others (8, 9) except that no one has reported the cracking with high percentages of phosphorus, no doubt because only films containing up to 3% of phosphorus were studied.

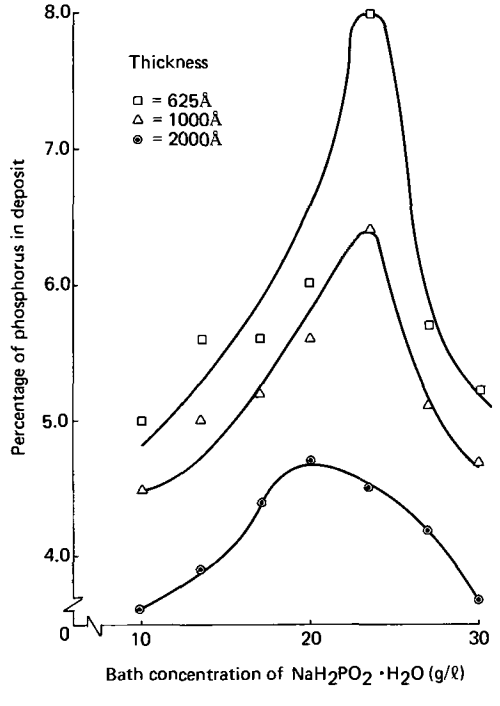

Fig. 4. Percentage of phosphorus vs. reductant concentration in bath.

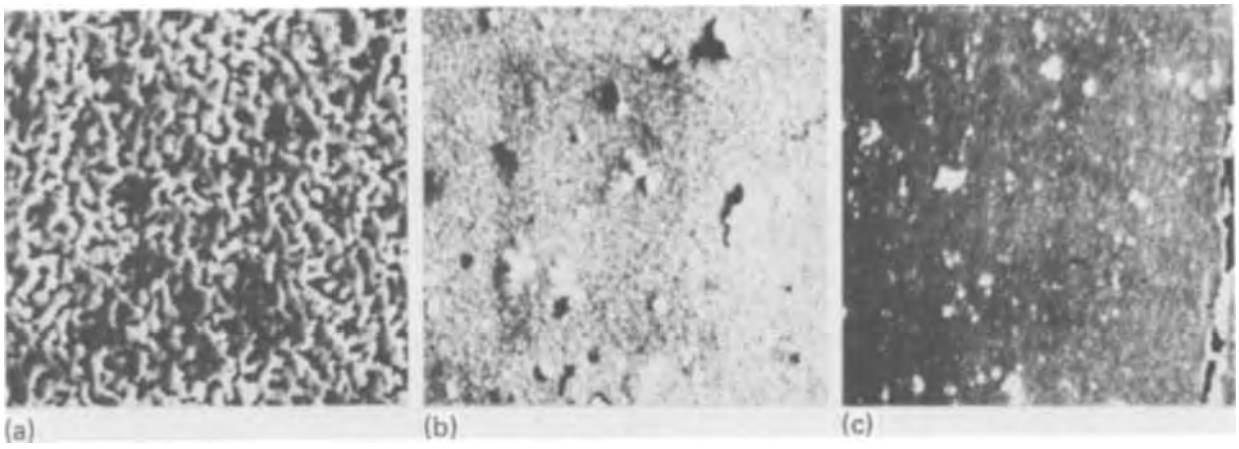

Fig. 5. Scanning electron micrographs of Co-P plated surfaces over a range of phosphorus content (4000×). (a) 0.6% phosphorus, (b) 3.1% phosphorus, (c) 6.5% phosphorus.

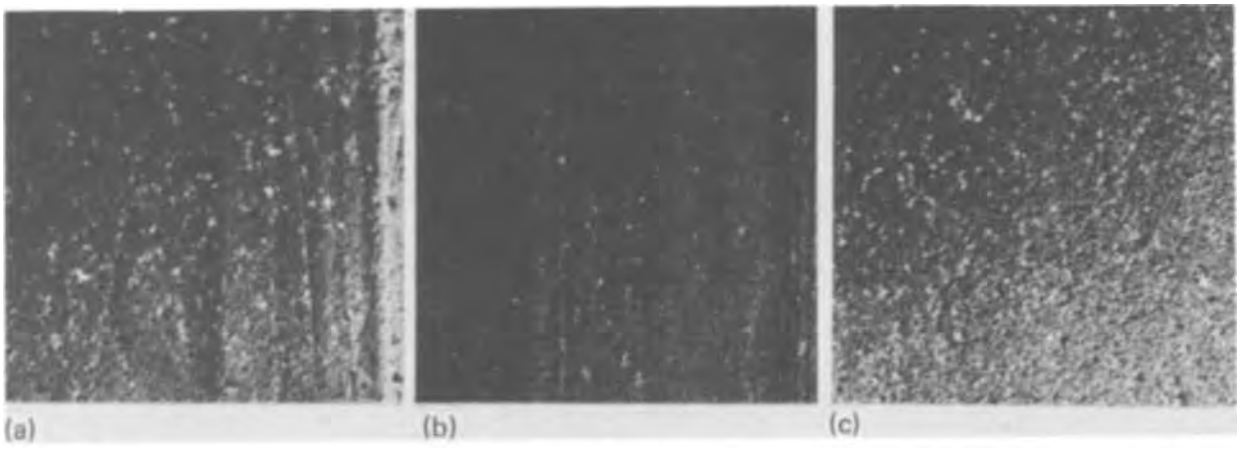

Fig. 6. Photomicrographs of Co-P plated surfaces at various hypophosphite concentrations (800×). (a) 10 g/liter, 3.6% phosphorus, (b) 17.0 g/liter, 4.8% phosphorus, (c) 30.0 g/liter, 4.0% phosphorus.

Figure 4 shows that the percentage of phosphorus in the deposit depends on the hypophosphite content of the bath. Note that the phosphorus content of the deposits reaches a peak and then decreases as the reductant content of the bath increases. Note also that there are large variations in the percentage of phosphorus in the thinner deposits, whereas linearity is approached in the thickest deposit. Films approximately equal in thickness and in phosphorus content were examined for relative surface roughness. As Fig. 6 shows, the films containing a bit more phosphorus than others were only slightly smoother. No deposits that contained medium amounts of phosphorus were cracked.

The saturation magnetic moments of the deposits were measured with a vibrating sample magnetometer, relative to a five-nines-purity nickel standard that was accurately weighed. The moments so obtained were dependent on deposit thickness but only slightly affected by hypophosphite concentration (Fig. 7). The saturation magnetic moment density (σ_s) of the films, calculated from the slope of the line, was 128 electromagnetic units/g. If we assume that the phosphorus exists as nonferromagnetic Co_2P, an average weight of 4.2% P would correspond to about 18% by volume of Co_2P. Therefore, a theoretical calculation of σ_s is about 132 electromagnetic units/g. Although phosphorus was quantitatively detected by x-ray fluorescence, its presence as Co_2P was never conclusively shown. At any rate, the nonmagnetic diluents in the deposits are assumed to be Co_2P and other phases of cobalt and phosphorus. These other phases may account for the discrepancy between the experimental and the theoretical values of σ_s.

For the two extreme reductant concentrations, the squareness of the deposits decreased with increasing thickness and tended to level off in thicker deposits, as is shown in Fig. 8. The median concentration of hypophosphite tended to give a linear relationship between squareness and thickness throughout the range covered.

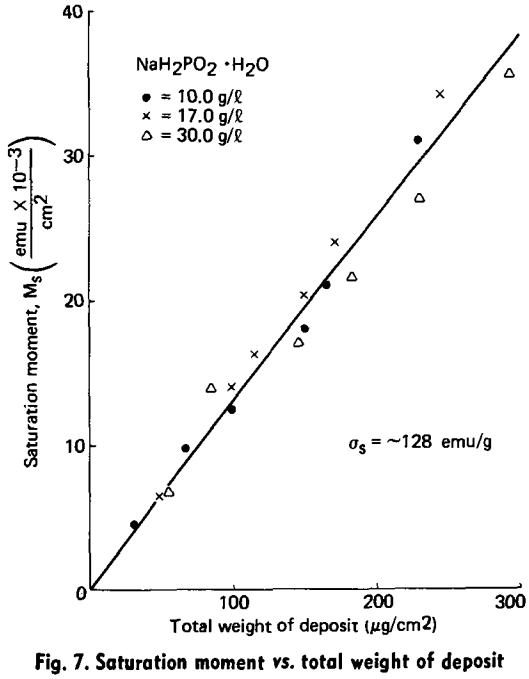

Fig. 7. Saturation moment vs. total weight of deposit

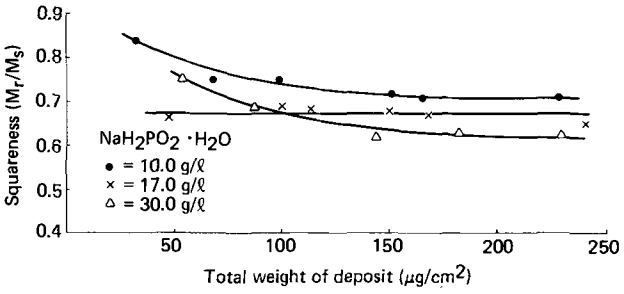

Fig. 8. Squareness vs. total weight of deposit

This finding is in direct conflict with earlier work (5, 10) in which a ratio of 0.3 cobalt to 1.0 citrate ion in the bath was used. The apparent discrepancy can be explained by observing the linear relationship that gives an average of 4.2% phosphorus, independent of thickness and hypophosphite concentration. The content of phosphorus, and therefore the occurrence of single-domain regions, are presumably constant throughout the deposits.

The structure-sensitive property of coercivity is a complicated function of many variables. One of these variables, thickness, is plotted against coercivity in Fig. 9. Here we see that thickness greatly influences the coercivity of the deposited film, particularly with lower concentrations of reductant, say 10.0 g/liter. This curve follows the usual relationship of monotonically decreasing coercivity with increasing thickness (7, 11, 12). However, the high concentration of reductant monotonically increases with thickness and tends to level off to 700 oe at 2300Å. This is about the same level of coercivity at which the 17.0 g/liter concentration of reductant levels off after decreasing from 1000 oe. The linearity of the coercivity at thicknesses greater than 2000Å is further substantiated by the results obtained with 23.5 g/liter of hypophosphite in the bath. At this concentration, coercivity is independent of thickness.

Attempts to induce anisotropy in the films were made in the early experiments by autocatalytically plating in a strong field. These attempts were unsuccessful as were those of previous investigators. All deposited films were isotropic in the film plane.

The influence of the sodium hypophosphite in the bath on the coercivity of the film is shown in Fig. 10. With short deposit times (and hence thin deposits), the coercivity decreased very rapidly with increasing hypophosphite. With longer deposit times, no sharp

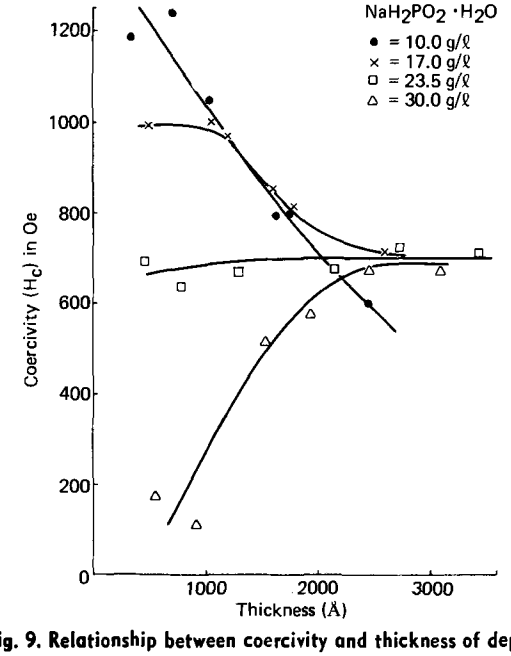

Fig. 9. Relationship between coercivity and thickness of deposit

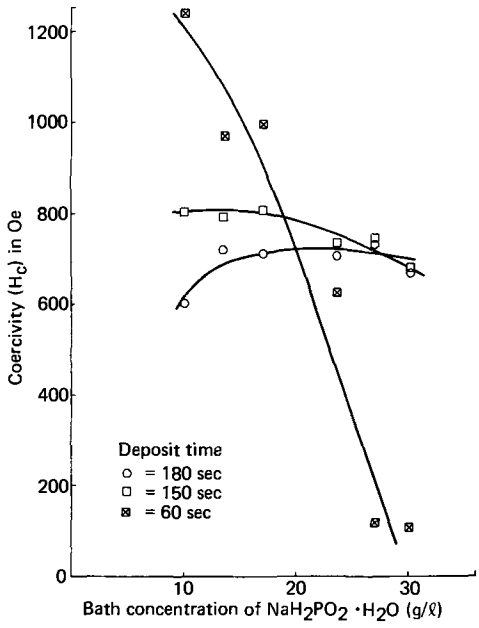

Fig. 10. Coercivity vs. hypophosphite in bath

changes in coercivity were observed. Linearity was approached at 700-800 oe. Figure 10 represents two different effects: film thickness and concentration of reductant. Therefore the changes in coercivity shown seem to be the results of increases in film thickness caused by the reductant concentration, as shown in Fig. 3. The similarity of Fig. 9 and 10 further substantiates the conclusion that the true influence of the reductant concentration on coercivity is masked by the thickness of the deposit. Figure 11 is included merely to show the effect of the reductant concentration in the bath on the coercivity of the deposit at two different ratios of cobalt ions to citrate ions in the solution. The reductant concentration has a larger effect on coercivity at the 1.0 ratio than at the 0.5 ratio, even though a linear relationship is evident in both cases. This relationship indicates that coercivity is more reproducible in the 0.5-ratio bath because the slope approaches zero.

X-ray diffraction revealed that all deposits were predominantly hexagonal-close-packed (hcp) cobalt.

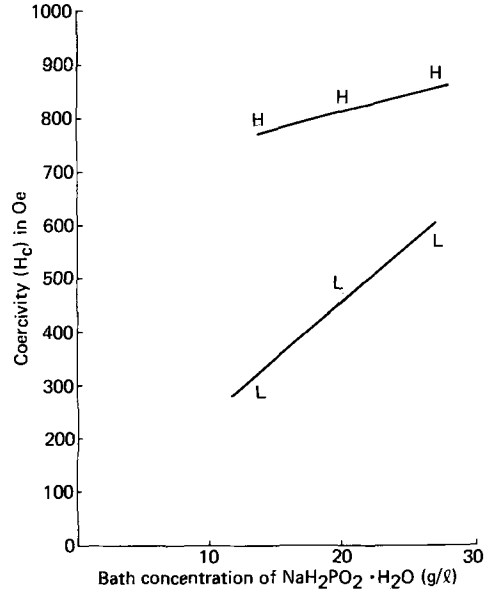

Fig. 11. Coercivity vs. hypophosphite at different concentration ratios. *H* = 0.5 ratio, (high citrate) at 2100Å; *L* = 1.0 ratio, (low citrate) at 2500Å.

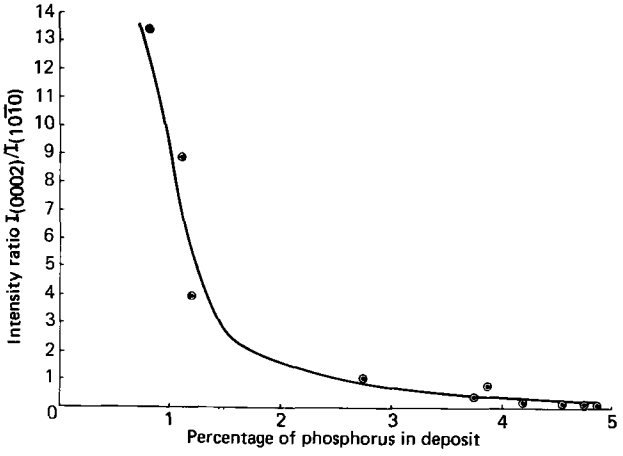

Fig. 12. Intensity ratio vs. percentage of phosphorus in deposit

X-ray line broadening was used to estimate the crystallite sizes in the deposits. Most estimates were from 200-400Å. A few films appeared to have either very small crystallites (20-60Å) or an amorphous structure. However, these estimates of crystallite size are actually the lower limit, since the stresses and faults in the deposit also contribute to the line broadening. In most cases, the estimates of crystallite sizes showed no correlation with thickness, phosphorus content, or magnetic properties. Figure 5 shows an example of a change in crystallite size with a change in phosphorus concentration; (b) and (c) are 300Å, whereas (a) is only about 50Å. Figure 6, on the other hand, maintains the same crystallite size in the range of 3.6-4.8% of phosphorus. Films with coercivities of 200-800 oe had the same relative crystallite size, whereas the samples with coercivities greater than 800 oe tended to have smaller crystallites. It appears that since most of the crystallite sizes were in the 200-400Å range, the magnetic properties of the experimental thin films were a result of single-domain behavior.

Diffracted x-ray intensities of the (0002) and the $(10\bar{1}0)$ planes of the deposits were measured. Calculating the normalized value of these ratios

$$\frac{I_{(0002)}}{I_{(10\bar{1}0)}}$$

enables us to predict the c-axis orientation in the films. If the intensity ratios are plotted against the percentage of phosphorus in the films, as in Fig. 12, a clear relationship can be shown between crystal orientation and phosphorus content. The plot nearly duplicates that of Amendola *et al.* (8), except that it shows the percentage of phosphorus from less than 1.0 to more than 5.0. Since the films under study here contain an average of 4.2% phosphorus, it is apparent that these deposits exhibited a preferred orientation of the c-axis in the plane of the substrate. The raw data imply no relationship between coercivity and intensity ratios.

Summary and Conclusion

Preliminary experiments were made on two kinds of nonconductive substrates. The magnetic and physical properties of the deposits were examined in order to formulate an autocatalytic solution to improve these properties. Kapton, the most promising substrate on the basis of adhesion and appearance, was chosen for further study. The independent variables of time and reductant concentration were examined, and the resulting physical and magnetic properties of the deposits were evaluated. The average plating rate was linear, increasing with increasing reductant concentration. The average amount of phosphorus in the deposits remained constant over the range of reductant concentrations, and had little effect on the roughness or the coercivity of the deposit. The saturation magnetic moment density for the deposits agreed closely with the theoretical value. This led to the conclusion that the nonmagnetic diluent was chiefly Co_2P. The squareness was high and linear throughout the range; the coercivity depended greatly on thickness and hypophosphite concentration. Crystallite sizes of 200-400Å were found in most of the films, independent of phosphorus content, with smaller crystallites appearing in the films with coercivities above 800 oe. Intensity-ratio calculations showed that most of the films had their c-axes oriented in the plane of the substrate.

Others have shown that in the autocatalytic deposition of a magnetic film, the thickness and the hysteresis of the film can be controlled by varying the deposition time, the *p*H of the bath, the temperature, and the reductant concentration. Proper combination of these variables will produce a coating that has excellent properties for recording. One such combination has been given in this paper. It is a bath with a 0.50 ratio of cobalt ion to citrate ion (with other conditions as previously given), and a reductant concentration of about 23 g/liter of sodium hypophosphite. Metal deposition is carried out on a specially prepared Kapton substrate for approximately 2.5 min. The resulting deposit is an excellent reproducible medium for high-density digital magnetic recording.

ABSTRACT

The electrochemical reduction of Ti(IV) in molten LiF-NaF-KF [46.5-11.5-42.0 mole per cent (m/o)] at 500°C was studied by means of linear sweep voltammetry, chronopotentiometry, and chronoamperometry. The reduction of Ti(IV) to Ti(III) was found to proceed reversibly at both platinum and pyrolytic graphite electrodes; further reduction of Ti(III) to the metal was shown to be a reversible process involving alloy formation with the platinum electrode. Standard electrode potentials for the processes, Ti(IV) + e = Ti(III) and Ti(III) + $3e$ = Ti, are −0.058 and −1.798V, respectively (both *vs.* a unit mole fraction Ni(II)/Ni electrode).

The electrochemical oxidation of Ti(III) at unsheathed platinum and sheathed glassy carbon electrodes was studied in molten LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o) at 500°C. Evidence for a reversible electrode reaction was obtained from voltammetric and chronopotentiometric studies. A standard potential of +0.197V (*vs.* a unit mole fraction Ni(II)/Ni electrode) was determined for the process Ti(III) = Ti(IV) + e.

The more anodic value of the standard potential of the Ti(IV)/Ti(III) couple in LiF-BeF_2-ZrF_4 in comparison to LiF-NaF-KF reflects the higher acidity (Lewis concept) of the LiF-BeF_2-ZrF_4 melt.

In this paper we describe electrochemical studies of titanium solute species in molten LiF-NaF-KF [46.5-11.5-42.0 mole per cent (m/o)] and LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o). Interest in molten fluorides stems from their importance in nuclear reactor technology and use in production of aluminum and fluorine, electrodeposition of refractory metals, formation of corrosion-resistant diffusion coatings, and preparative electrochemical fluorination.

Most of the studies of electrode reactions in molten fluorides have been rather recent. The status of this subject through 1968 has been summarized by Mamantov (1). Recent reviews of molten salt electrochemistry (2-4) contain much more information pertaining to molten fluorides than did earlier reviews on the same topic (5-8).

The electrochemistry of titanium has been studied to a much greater extent in molten chlorides than in any other molten halide system. The usual solvent is LiCl-KCl eutectic. The results of voltammetric studies in this solvent have been summarized in two reviews (6, 7). In polarographic studies of the reduction of Ti(III) in molten LiCl-KCl eutectic at 400°-550°C, two reduction steps, Ti(III) to Ti(II) and Ti(II) to Ti, were observed.

Baboian, Hill, and Bailey (9) have reported $E°$ values for the reversible couples, Ti(III)/Ti(II) and Ti(II)/Ti, *vs.* the Pt(II)/Pt reference electrode in the LiCl-KCl eutectic at 450° and 550°C. Flengas (10) was able to measure the standard potential of the Ti(IV)/Ti(III) couple in addition to the above two couples in NaCl-KCl at 700°C.

Senderoff (11) has reviewed the methods of obtaining titanium metal by electrolysis of molten halide solutions. Barksdale (12) has discussed the commercial production of titanium including the electrolytic methods in fused salt baths. However, little information exists regarding the nature of the electrode reactions involved in these electrolytic processes. Nevertheless, the two reviews (11, 12) serve to point out the importance of lower-valent species to the over-all current efficiency, the nature of deposits obtained, and the cell design considerations. Most of the electrolytic methods employ a fluoride-chloride process with tetravalent titanium as solute (K_2TiF_6 in LiCl-KCl, NaCl-KCl, or NaCl) or an all-chloride process with reduced titanium ($TiCl_3$ or $TiCl_2$) as solute (12). One all-fluoride process was described by Stetson (13) in which coherent titanium deposits were obtained at 850°C on selected substrates from a fluoride bath (NaF-KF) containing K_2TiF_6. It was noted that a layer of insoluble lower-valent titanium salts remained in contact with the cathode during the entire operation. This coating proved to be advantageous in preventing attack of the deposited titanium by the Ti(IV) solution and by the anode gases. The lower-valent salts so described were likely composed of Ti(III) since, according to Wurm, Gravel, and Potvin (14), the formation of insoluble Ti(III) double fluorides of sodium and potassium always precedes the production of metallic titanium during electrolysis of molten NaCl-KCl mixtures containing K_2TiF_6 or Na_2TiF_6. These double fluorides of Ti(III) were identified as K_2NaTiF_6, K_3TiF_6, and Na_3TiF_6 by Bright and Wurm (15). Furthermore, no divalent titanium compounds were detected by chemical analysis in the chloride melts where fluoro complexes of titanium were present (14).

Thus, previous work indicates that there are differences in behavior between the two solvent systems, chlorides and fluorides, notably the nonexistence of an intermediate reduction step involving Ti(II) in fluoride or chloride-fluoride melts.

Experimental Section

Materials

Two fluoride salt mixtures were used as solvents in this investigation. Their compositions and melting points are as follows: (*i*) LiF-NaF-KF (46.5-11.5-42.0 m/o, eutectic temperature 454°C) (16); and (*ii*) LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o, liquidus temperature 434°C) (17). The LiF-NaF-KF and LiF-BeF_2-ZrF_4 solvents and anhydrous nickel(II) fluoride were obtained from the Reactor Chemistry Division of the Oak Ridge National Laboratory (18).

High-purity K_2TiF_6 was prepared by D. E. LaValle of the Oak Ridge National Laboratory. TiF_3 was used as received from Research Inorganic Chemicals. The single crystals of LaF_3 used to fabricate reference elec-

trode compartments (19, 20) were obtained from Optovac, Incorporated. ATJ graphite was used for container fabrication.

All salts and active metals were stored in an inert-atmosphere dry box prior to their use.

Apparatus and Procedure

Electrolytic cell assembly.—The experimental setup employed for these studies is similar to that described earlier (21). The melts were contained in a graphite or platinum cell approximately 2 in. diam and 4½ in. long. To maintain a vacuum or controlled atmosphere, the cell was enclosed in a Pyrex outer jacket approximately 2½ in. diam and 10 in. long. The top of the Pyrex jacket was sealed to a removable Pyrex cap by means of a 102/75 O-ring joint. The joint was secured with an adjustable clamp; Viton or Teflon O-rings were employed. On the cap were located six ¼-in. Cajon Ultra-Torr fittings which provided access to the melt for the various electrodes, thermocouples, and helium bubbling line. Vacuum and inert atmosphere connections were through a three-way vacuum stopcock located on the side of the cap. The lower part of the cell assembly was heated in a 3-in. ID resistance furnace (725W Hoskins Model). The temperature of the furnace was controlled to about ±2°C by means of a Wheelco Model 407 temperature controller. The actual temperature of the melt was monitored with a shielded Chromel-Alumel type thermocouple inside a platinum sheath.

The metal wire electrodes (platinum and nickel) consisted of 2-in. long wires (1 mm diam or less) which were arc-welded to the end of ⅛ × 12 in. nickel rods. The tops of the nickel rods were fitted with ¼-in. Teflon sleeves (about 3 in. long) to provide a leak-tight connection when the electrodes were inserted through the adjustable Cajon fittings. The platinum indicator electrodes (0.5 and 0.8 mm diam) were immersed to depths of 6-8 mm (typical electrode area 0.08-0.12 cm^2). Platinum quasi-reference electrodes (22, 23) (1.0 mm diam) were adjusted to depths of 1-2 in. as were larger diameter (⅛ in.) platinum or graphite counterelectrodes.

The pyrolytic graphite indicator electrode (1 mm diam) consisted of an unsheathed pyrolytic graphite rod (prepared by the Metals and Ceramics Division of the Oak Ridge National Laboratory) which was attached to the ⅛-in. nickel rod by means of a threaded connection. Details of the construction of this type of electrode have been given previously (24). The glassy carbon indicator electrode was sheathed in boron nitride. A description of the fabrication of a similar type of sheathed planar electrode is available (25). Since the entire surface of the glassy carbon is immersed below the melt, a more accurate determination of the electrode area is possible. The area of the glassy carbon electrode used was 0.08 cm^2.

The reference electrode used in the three-electrode measuring system consisted of a $NiF_{2(sat.)}$/Ni couple contained in a single-crystal lanthanum fluoride compartment for isolation from the bulk melt. The utility of the Ni(II)/Ni couple as a reference electrode in molten fluorides was demonstrated earlier (26, 27). A reference electrode for molten fluorides employing a single-crystal LaF_3 membrane for separation has been described recently (19, 20).

Instrumentation.—The controlled potential-controlled current cyclic voltammeter used in this study has been described in detail (28). With this instrument, scan rates from 0.01 to 500 V/sec are available and cell currents up to 100 mA can be measured. In the controlled current mode, currents from a few microamperes to 500 mA can be passed through the electrolytic cell. The built-in time base allows the measurement of transition times from 400 sec to 4 msec.

Cyclic voltammograms and chronopotentiograms were recorded either on a Moseley Autograph X-Y recorder (Model 2D-2A) or on a Tektronix Type 549 storage oscilloscope equipped with a Tektronix Type C-12 camera attachment. Photographs were made using Type 42 Polaroid film (ASA 200 speed).

The details of the experimental procedure are described elsewhere (20).

Results and Discussion

Electrochemical Studies of Titanium(IV) in Molten LiF-NaF-KF

Voltammetric studies.—Initial voltammetric studies of the reduction of titanium(IV) in molten LiF-NaF-KF (46.5-11.5-42.0 m/o) at 500°C were carried out in a graphite beaker using platinum and pyrolytic graphite (PG) working electrodes, a large Pt wire counterelectrode, and a platinum wire quasi-reference electrode (QRE). However, it became apparent that Ti(IV) could not be kept in solution for more than one to two days in the graphite beaker and all subsequent experiments on titanium were done in a platinum crucible. In the platinum container, Ti(IV) solutions were found to be stable; no appreciable change in concentration was observed voltammetrically during a three-week period. Ti(IV) was added to the melt as K_2TiF_6 in all cases. Potentials were measured with respect to a Ni(II) (saturated)/Ni reference electrode (LaF_3 membrane type) unless otherwise stated. Concentrations are expressed in terms of molarity. Conversion to mole fraction, X, can be made by use of the following equations (27): in LiF-NaF-KF (46.5-11.5-42.0 m/o) at 500°C, M(molarity) = $52.6X$; in LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o) at 500°C, M = $62.2X$.

Linear sweep voltammograms (scan rate = 0.1 V/sec) obtained at a Pt electrode prior to the addition of K_2TiF_6 are shown in Fig. 1. Two small reduction waves occur at −0.55 and −0.85V [*vs.* Ni(II) (saturated)/Ni reference electrode]. Similar reduction waves were also obtained at the PG electrode. These waves are probably due to residual amount of iron and chromium impurities, respectively, which are commonly found in the LiF-NaF-KF eutectic (21). A larger wave was observed at the Pt electrode at −1.70V, which was very broad and irreversible in nature. Although this wave was not identified, it is probably caused by the predeposition of alkali metal as a result of alloy formation with the platinum electrode (6). The cathodic limit at about −2.0V corresponds to the reduction of alkali metal cations (probably potassium ions); the anodic limit at ~+1.5V is due to oxidation of platinum (21).

Additions of K_2TiF_6 resulted in a well-defined, peak-shaped reduction wave [$E_p \approx +0.01$V *vs.* Ni(II) (saturated)/Ni reference electrode] at both Pt and PG electrodes. A typical linear sweep voltammogram for Ti(IV) reduction at a Pt electrode is shown in Fig. 2. A similar voltammogram was obtained at the PG electrode. At the Pt electrode a second reduction wave, larger and steeper than the first one, was observed with

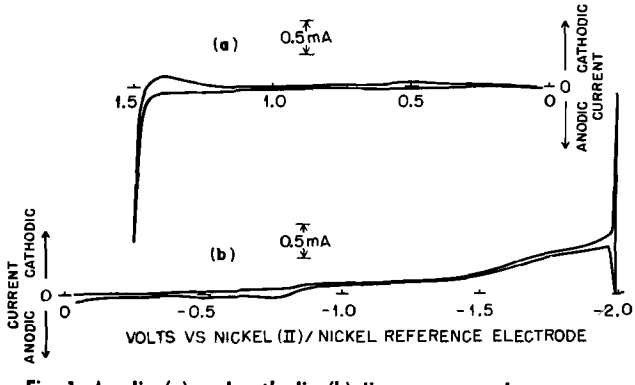

Fig. 1. Anodic (a) and cathodic (b) linear sweep voltammograms of the LiF-NaF-KF melt at 500°C. Platinum electrode area: 0.10 cm^2; scan rate: 0.1 V/sec; Ni(II)(saturated)/Ni reference electrode (LaF_3 membrane type).

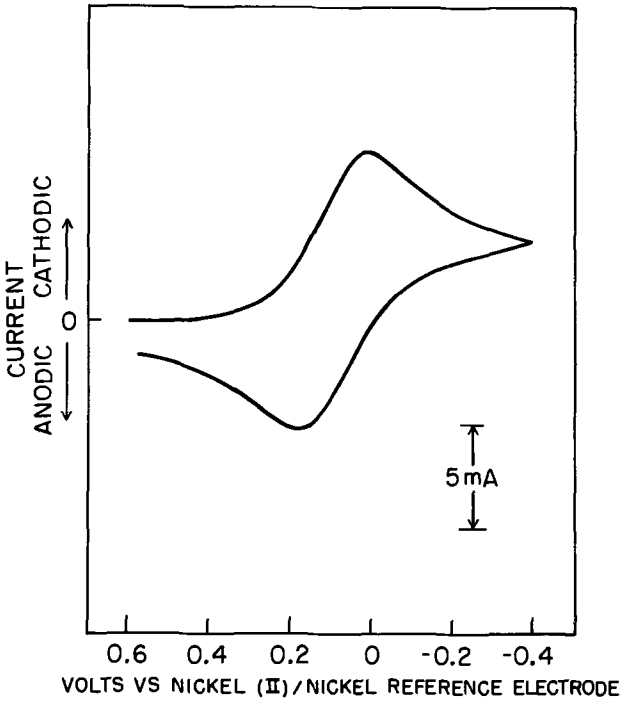

Fig. 2. Linear sweep voltammogram at platinum electrode for the reduction of Ti(IV) to Ti(III) in molten LiF-NaF-KF at 500°C. Scan rate: 1.0 V/sec; electrode area: 0.10 cm².

a well-defined peak located at about −1.69V. On the reverse cycle an anodic stripping peak clearly associated with this second wave was observed at −1.18V. A linear sweep voltammogram for the second reduction step at Pt electrode is shown in Fig. 3. The voltage span extended from +0.6 to −2.0V *vs.* the Ni(II) (saturated)/Ni reference electrode; however, only the potential region of interest is shown since no other reduction waves [other than Ti(IV) to Ti(III) wave] were observed. The second wave could not be studied at a PG electrode because with this electrode a large reduction peak at about −1.2V *vs.* the Ni(II) (saturated)/Ni reference electrode is observed in LiF-NaF-KF (1); this peak is probably caused by the predeposition of potassium and the formation of a graphite-potassium intercalation compound (29).

The voltammograms for the two-step charge transfer process observed in the reduction of Ti(IV) can be treated as independent waves since the separation between the half-wave potentials is greater than the minimum value required, $(T/298)(118/n)$ mV (true for reversible waves) (30). The data for half-wave potentials, anodic to cathodic peak potential separation ($\Delta E_p = E_{ap} - E_{cp}$), and half-peak to peak potential separation ($\Delta E = E_{p/2} - E_p$) are given in Table I. The $E_{1/2}$ values were measured at potentials corresponding to 0.85 i_p (31). The expected values for peak potential separation and half-peak to peak potential separation are 2.22 $RT/n\mathbf{F}$ and 2.20 $RT/n\mathbf{F}$, respectively, (31) for the first wave. Half-peak to peak potential

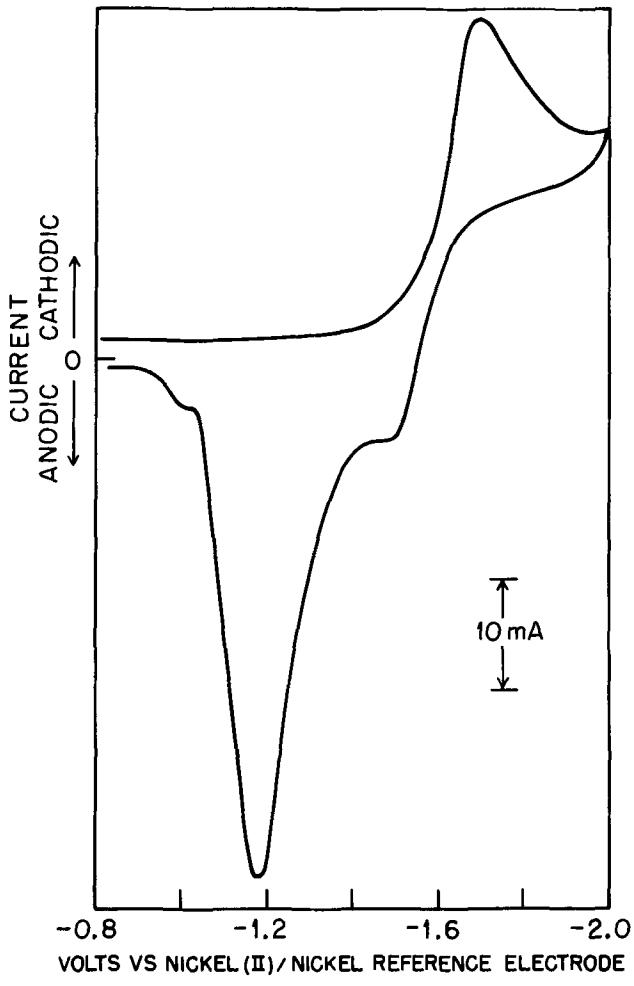

Fig. 3. Linear sweep voltammogram at platinum electrode for the reduction of Ti(III) to Ti in molten LiF-NaF-KF at 500°C. Scan rate: 0.5 V/sec; electrode area: 0.10 cm².

separation ΔE for the second wave should be 2.2 $RT/n\mathbf{F}$ (31), if the product of the reversible electrode reaction (presumably titanium metal) is soluble in the electrode, and 0.77 $RT/n\mathbf{F}$ (32), if reversible deposition of an insoluble product occurs. The experimental ΔE obtained (Table I) clearly favors formation of a soluble product (assuming that the electrode reaction is reversible).

The ratio of anodic to cathodic peak current (i_{ap}/i_{cp}) calculated using Nicholson's semiempirical formula (33) is 0.95 for the first wave. A ratio of one is expected for simple reversible electron transfer (31). A plot of log $(i_p - i)/i$ *vs.* potential for the first reduction wave was linear in the approximate range 0.35-0.70 i_p. The expected (32) slope of the line for a reversible charge transfer where both reactants and products are soluble is 0.58 $n\mathbf{F}/RT$. An n value of one was calculated from the slope. A plot of log $(i_p - i)/i$ *vs.* potential for the second wave resulted in a slope corre-

Table I. Half-wave potentials, anodic to cathodic peak potential separation, and half-peak to peak potential separation (theoretical values in parentheses) for the processes Ti(IV) + e = Ti(III) (process I) and Ti(III) + 3e = Ti(process II) at platinum electrode at 500°C.

Process	Melt	Concentration (M)	$E_{1/2}$ (V)[a]	$\Delta E_p = E_{ap} - E_{cp}$ (mV)	$\Delta E = E_{p/2} - E_p$ (mV)

[b] For reversible reduction yielding a soluble product.
[c] For reversible deposition of an insoluble product.

sponding to $n = 3$. The solubility of titanium metal in the Pt electrode is probably responsible for the agreement of this type of plot with that expected for a three-electron reversible reaction involving soluble reactants and products.

The peak current i_p for the first wave was found to be directly proportional to concentration of Ti(IV) in the range 8.97×10^{-3} to 3.39×10^{-1} M and to the square root of the scan rate v (up to ~2.0 V/sec) at the Pt electrode. The variation of i_p with $v^{1/2}$ at a Pt electrode for a given concentration of Ti(IV) is shown in Fig. 4. According to Nicholson and Shain (31) the parameter $i_p/v^{1/2}$ is independent of the scan rate for a simple reversible charge transfer reaction. The nonlinear increase of i_p with $v^{1/2}$ in Fig. 4 starting at ~5 V/sec indicates weak adsorption of the reactant (24, 30).

A scan rate study of the second reduction wave which is believed to be due to Ti(III) reduction to the metal, resulted in a linear plot of i_p *vs.* $v^{1/2}$. The results indicate that, at the scan rates studied, diffusion is the predominant mass transfer process since the Randles-Sevcik equation (34) is obeyed. The Randles-Sevcik equation at 500°C becomes

$$i_p = 1.67 \times 10^5 n^{3/2} A D^{1/2} v^{1/2} C \qquad [1]$$

The diffusion coefficient of Ti(IV) in molten LiF-NaF-KF at 500°C was calculated from Eq. [1] using the slope of the linear portion of the i_p *vs.* $v^{1/2}$ plot (Fig. 4). Because of the uncertainty in the area of the unsheathed platinum wire electrode employed, the value of D, is reported as approximately $2.6 \pm 0.5 \times 10^{-6}$ cm²/sec.

These voltammetric results indicate that the two reduction waves at platinum for Ti(IV) in LiF-NaF-KF correspond to one-electron and three-electron reversible charge transfer processes involving the reduction of Ti(IV) to Ti(III) and Ti(III) to the metal, respectively. Similar voltammetric behavior at pyrolytic graphite was observed for the reduction of Ti(IV) to Ti(III) in LiF-NaF-KF at 500°C; however, no reduction of Ti(III) could be observed at pyrolytic graphite in this melt.

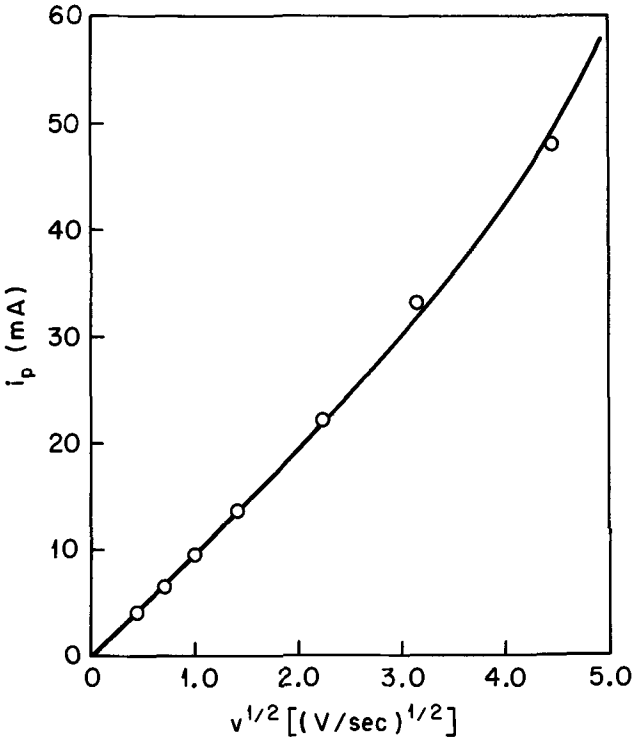

Fig. 4. Plot of i_p *vs.* $v^{1/2}$ for the first wave, Ti(IV)→ Ti(III), in molten LiF-NaF-KF at 500°C. Ti(IV) concentration: 0.339M; Pt electrode area: 0.10 cm².

Polarographic analysis using current-time curves.—The polarogram constructed from current-time curves for the reduction of Ti(IV) in molten LiF-NaF-KF at a Pt electrode is shown in Fig. 5. This polarogram has been corrected for the residual currents measured from current-time curves obtained prior to addition of K_2TiF_6 at the same electrode. Two cathodic waves with a limiting current ratio of 2.9 were obtained. The corresponding log $(i_d - i)/i$ *vs.* potential plots (35) were straight lines with the theoretical slopes, 2.3 $RT/n\mathbf{F}$ (35), for a one-electron and three-electron reversible process, respectively.

Thus, the polarographic results support voltammetric evidence that the reduction of Ti(IV) at platinum in LiF-NaF-KF proceeds reversibly to Ti(III) which in turn is reduced to the metal alloying with the platinum electrode.

Chronopotentiometric studies.—Chronopotentiograms were obtained for the reduction of Ti(IV) in LiF-NaF-KF at 500°C at both Pt and PG electrodes using a platinum quasi-reference electrode. The definition of the potential-time curves was reasonably good for the first step; however, the poor definition and reproducibility of the second step (seen only at platinum) prevented any meaningful analysis of this subsequent reduction reaction. The variation of $i\tau^{1/2}$ with current for chronopotentiograms at platinum is shown in Fig. 6. The observed increase of the product $i\tau^{1/2}$ with increasing current is generally indicative of adsorption (24, 36, 37), in agreement with the voltammetric i_p *vs.* $v^{1/2}$ plot (Fig. 4) at higher scan rates. No attempt was made to arrive at a theoretical model for adsorption since the limited utility of chronopotentiometry for the study of adsorption has been pointed out (38).

The diffusion coefficient for Ti(IV) in LiF-NaF-KF at 500°C calculated using the Sand equation (34) is $1.9 \pm 0.4 \times 10^{-6}$ cm²/sec, in fair agreement with the value obtained from voltammetry. The value of $i\tau^{1/2}$

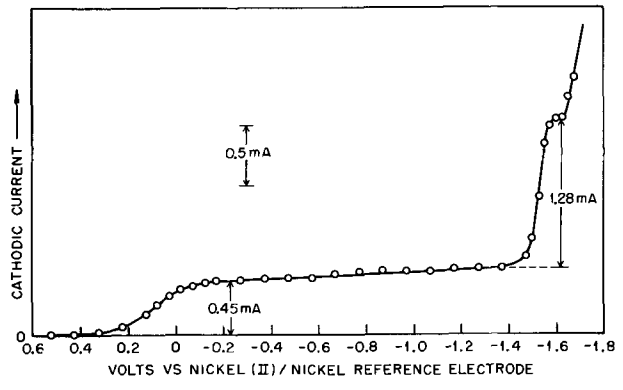

Fig. 5. Polarogram constructed from current-time curves for the reduction of Ti(IV) at platinum electrode in molten LiF-NaF-KF at 500°C. Ti(IV) concentration: 7.62×10^{-2}M; electrode area: 0.12 cm²; time at which current was measured: 5 sec.

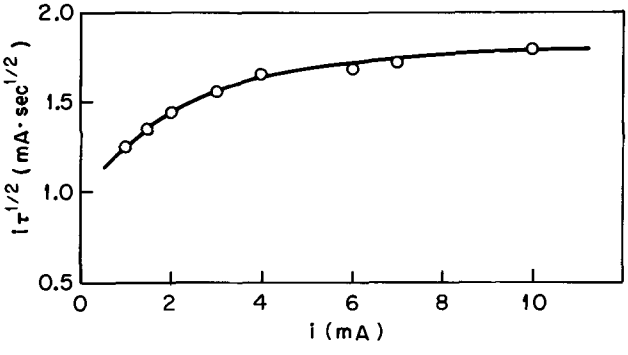

Fig. 6. Plot of $i\tau^{1/2}$ *vs.* current for the chronopotentiometric reduction of Ti(IV) in LiF-NaF-KF at 500°C. Ti(IV) concentration: 7.62×10^{-2}M; platinum electrode area: 0.12 cm².

used in the calculation was obtained from the intercept of a plot of $i\tau^{1/2}$ *vs.* $1/\tau^{1/2}$ using the data shown in Fig. 6. Such a plot has been proposed (39) as a semiempirical correction for the effects of charging of the double layer, oxidation or reduction of the electrode, and adsorption of the electroactive species on the electrode. Transition times were in the range 0.03-1.5 sec.

Excellent verification of $n = 1$ for the first Ti(IV) reduction step in LiF-NaF-KF was achieved from the ratio of voltammetric $i_p/v^{1/2}$ to chronopotentiometric $i\tau^{1/2}$. For this determination of n, concentration, diffusion coefficient, and electrode area do not need to be known. The ratio is obtained by dividing Eq. [1] by the Sand equation (34) and is given by the following expression

$$\frac{i_p/v^{1/2}}{i\tau^{1/2}} = 1.96\, n^{1/2} \qquad [2]$$

Using values for $i_p/v^{1/2}$ and $i\tau^{1/2}$ determined under identical experimental conditions, n is calculated to be 1.01.

Standard electrode potentials of the titanium(IV)/titanium(III) and titanium(III)/titanium couples.—The half-wave potential $E_{1/2}$ for a reversible process $O + e \rightleftarrows R$ may be taken as the voltammetric equivalent of the standard electrode potential $E°$, assuming that diffusion coefficients and activity coefficients for O and R are equal (31). $E_{1/2}$ for the reversible process Ti(IV) + $e \rightarrow$ Ti(III) was found to be +0.080V with respect to a Ni(II) (saturated)/Ni reference electrode (Table I). By extrapolating the Nernstian plot for the Ni(II)/Ni couple in LiF-NaF-KF (20) to unit mole fraction of nickel(II), $E°$ for the Ti(IV)/Ti(III) couple is estimated to be −0.058V.

A similar estimate of the standard electrode potential for the Ti(III)/Ti couple in LiF-NaF-KF can be made assuming that Ti is soluble in the platinum electrode. Experimental evidence for titanium solubility in platinum is obtained from the fact that the peak potential for the Ti(III) reduction wave is independent of concentration as predicted for a reversible electrode reaction yielding a soluble product (31). In the case of reversible deposition of insoluble (unit activity) titanium metal, ΔE should decrease by about 0.05V for a ten-fold change in concentration (34).

Other experimental evidence in favor of titanium solubility in the platinum electrode is (*i*) the observed adherence of the polarographic wave [Ti(III) + $3e \rightleftarrows$ Ti] to the Heyrovsky-Ilkovic equation (40), (*ii*) the half-peak to peak potential separation for the Ti(III) voltammetric reduction wave (Table I), and (*iii*) the unusually large separation between the anodic and cathodic peak potentials for the Ti(III) + $3e \rightleftarrows$ Ti process (Fig. 3). It is also of interest to note that titanium is known to form several alloys with platinum, such as $TiPt_3$, TiPt, and Ti_3Pt (41). Thus, on the basis of titanium metal solubility in platinum, an $E_{1/2}$ for the Ti(III) + $3e \rightleftarrows$ Ti process can be calculated from the following expression (31)

$$E_p = E_{1/2} - 1.11\, RT/nF \qquad [3]$$

using the experimental E_p given in Table I. An $E_{1/2}$ of −1.660V [*vs.* Ni(II)(saturated)/Ni reference electrode] is obtained which corresponds to an $E°$ of −1.798V [*vs.* a unit mole fraction Ni(II)/Ni electrode] for the Ti(III)/Ti couple in molten LiF-NaF-KF at 500°C.

Electrochemical Studies of Titanium(III) in Molten LiF-BeF_2-ZrF_4

Voltammetric studies.—Initial voltammetric studies of titanium in molten LiF-BeF_2-ZrF_4 (65.4-29.6-5.0 m/o) at 500°C were undertaken using K_2TiF_6 as the solute. However, these studies of titanium(IV) reduction were greatly complicated by the observed instability of Ti(IV) in the melt. White deposits were found to collect in the cooler part of the electrolytic cell after K_2TiF_6 was added to the melt. The volatilization of titanium tetrafluoride from the melt was confirmed in a separate experiment in a closed stainless steel vessel provided with a cold trap; the volatile product collected was identified as TiF_4 by x-ray diffraction. These observations are not too unexpected since the formation of TiF_4 may occur in this fluoride-deficient melt at 500°C by virtue of the following reactions

$$TiF_{6(l)}^{2-} + 2ZrF_{x(l)}^{4-x} \rightleftarrows 2ZrF_{x+1(l)}^{3-x} + TiF_4(g) \qquad [4]$$

$$TiF_{6(l)}^{2-} + ZrF_{x(l)}^{4-x} \rightleftarrows ZrF_{x+2(l)}^{2-x} + TiF_4(g) \qquad [5]$$

Since TiF_4 volatilizes at 284°C (42), its removal from the melt serves as a driving force to shift the above equilibrium reactions to the right even if TiF_4 were to be a stronger Lewis acid than ZrF_x^{4-x}.

Preliminary results indicated the presence of a single reduction wave for Ti(IV) at about −0.2V (*vs.* a platinum quasi-reference electrode); however, the continuously changing wave height prevented a meaningful study of this wave. Voltammetric studies of the oxidation of titanium(III) in molten LiF-BeF_2-ZrF_4 at 500° were then initiated since TiF_3 was expected to be stable in the melt at this temperature. The sublimation point of TiF_3 is 930° *in vacuo* (42).

Linear sweep voltammograms for molten LiF-BeF_2-ZrF_4 containing Ti(III) at a sheathed glassy carbon electrode are shown in Fig. 7. Similar but less well-defined waves were obtained at an unsheathed platinum electrode. This was the only wave observed upon addition of TiF_3 within the potential limits of the melt, +1.5 to −1.5V, measured at platinum *vs.* the nickel(II)(saturated)/nickel reference electrode (LaF_3 membrane type). These potential limits correspond to anodic dissolution of platinum and the reduction of Zr(IV), respectively. The plot of i_p *vs.* $v^{1/2}$ is also shown in Fig. 7. The resulting straight line is indicative

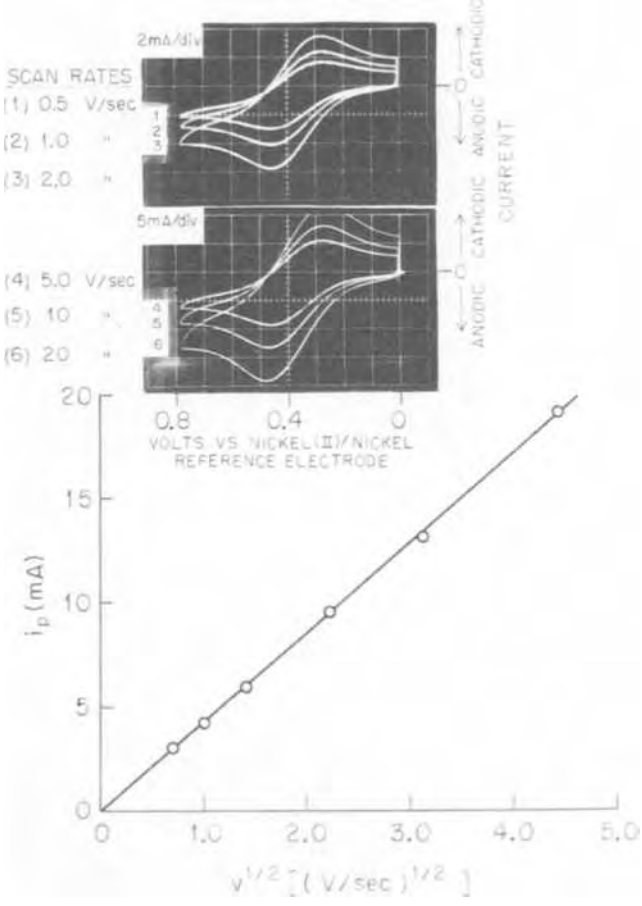

Fig. 7. Voltammograms for the oxidation of titanium(III) at glassy carbon electrode in molten LiF-BeF_2-ZrF_4 at 500°C; plot of i_p *vs.* $v^{1/2}$ for the voltammograms shown. Ti(III) concentration: 0.319M; electrode area: 0.08 cm².

of a simple charge transfer reaction. The concentration dependence of i_p is linear in the concentration range 0.05-0.32*M*.

The data for half-wave potential, peak potential separation, and half-peak to peak potential separation for the Ti(III) oxidation wave are given in Table I; theoretical values are given in parentheses. The value of i_{ap}/i_{cp} (33) for the wave at a scan rate of 1.0 V/sec is 0.98. The plots of log $(i_p - i)/i$ *vs.* potential for the wave at several scan rates are linear for the range $i = 0.35\text{-}0.70\ i_p$ and yield a slope in the same region corresponding to an n value of 1.

The diffusion coefficient of Ti(III) in molten LiF-BeF_2-ZrF_4 at 500°C obtained from the slope of the straight-line i_p *vs.* $v^{1/2}$ plot of Fig. 7 is $1.0 \pm 0.1 \times 10^{-6}$ cm²/sec. A more precise value of D was obtained in this case since a planar glassy carbon electrode ($A = 0.08$ cm²) sheathed in boron nitride was used.

Chronopotentiometric studies.—Chronopotentiograms for the oxidation of Ti(III) at a sheathed glassy carbon electrode in LiF-BeF_2-ZrF_4 at 500°C were reasonably well-defined. The product $i_o\tau^{1/2}$, essentially constant in the current density range 0.025-0.100 A/cm², was found to be 0.038 ± 0.002 A·sec$^{1/2}$·cm^{-2}. Transition times were in the range 0.1-2.3 sec. The diffusion coefficient for Ti(III) was calculated to be $1.9 \pm 0.2 \times 10^{-6}$ cm²/sec. No explanation is available for the poor agreement with the value obtained by voltammetry.

Verification of $n = 1$ for Ti(III) oxidation was accomplished using the ratio of voltammetric $i_p/v^{1/2}$ to chronopotentiometric $i\tau^{1/2}$. The n value determined by this method was 0.90.

In chronopotentiometry the half-wave potential for a reversible electrode reaction corresponds to the potential at one-fourth of the transition time (34). Thus, the value of $E_{1/2}$ obtained from chronopotentiograms for the oxidation of Ti(III) in LiF-BeF_2-ZrF_4 at 500°C is +0.40V *vs.* the nickel(II)(saturated)/nickel reference electrode. This chronopotentiometric $E_{1/2}$ compares well with the corresponding $E_{1/2}$ obtained from voltammetry (see Table I).

Standard electrode potential of the titanium(IV)/titanium(III) couple.—The standard electrode potential $E°$ for the Ti(IV)/Ti(III) couple may be estimated from the $E_{1/2}$ for the process Ti(III) $\rightleftarrows$ Ti(IV) + e in molten LiF-BeF_2-ZrF_4 at 500°C. The $E_{1/2}$ is given as +0.380V with respect to the Ni(II)(saturated)/Ni reference electrode in Table I. By extrapolating the Nernstian plot for the Ni(II)/Ni couple in LiF-BeF_2-ZrF_4 (20) to unit mole fraction of the nickel(II), $E°$ for the Ti(IV)/Ti(III) couple is estimated to be +0.197V.

The difference between $E°$ values in LiF-NaF-KF and in LiF-BeF_2-ZrF_4 is a good indication of the greater stability of Ti(III) relative to Ti(IV) in the latter solvent. In LiF-BeF_2-ZrF_4, the standard potential of the Ti(IV)/Ti(III) couple is 0.255V more anodic than its value in LiF-NaF-KF. Thus, Ti(III) is 0.255V or 5.81 kcal more stable relative to Ti(IV) in LiF-BeF_2-ZrF_4 than in LiF-NaF-KF. Such an effect may be caused by the formation of stable BeF_4^{2-} and ZrF_x^{4-x} complexes which would make LiF-BeF_2-ZrF_4 a more acidic solvent (using the Lewis concept) than LiF-NaF-KF by the reduction of the activity of the basic species, free F^-. Acidic solvents tend to stabilize lower oxidation states as pointed out previously (43). A similar acid-base effect was observed for the Fe(III)/Fe(II) couple (27) on the basis of measured electrode potentials in LiF-NaF-KF (46.5-11.5-42.0 m/o) and LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o).

ABSTRACT

The electrochemical reduction of Ti(IV) in molten $NaBF_4$ at 420°C was studied by voltammetry, chronopotentiometry, and chronoamperometry. The process, Ti(IV) + e = Ti(III), at both platinum and pyrolytic graphite electrodes was found to be reversible. No further reduction steps were observed. A standard electrode potential for this couple of −0.358V (*vs.* a unit mole fraction Fe(II)/Fe electrode) was obtained.

Use of molten fluoroborates as solvents for electrochemical investigations has been quite limited. Fluoroborates have been used as electrolytes for the electrodeposition of boron metal (1) and boron-silicon alloys (2) and for the preparation of KBF_4 (2). Although their potential use as coolants for molten-salt nuclear reactors (3) has necessitated a number of fundamental studies of these systems (4-8), electroanalysis in molten fluoroborates apparently has not been explored previously. The relatively nonhygroscopic nature, the convenience of high-purity preparation (4), and the low melting points of alkali-metal tetrafluoroborates (5) make fluoroborates attractive as molten salt solvents; unfortunately, slow decomposition of fluoroborates in the molten state produces boron trifluoride (6), creating certain experimental problems in containment and handling (7, 8).

An iron(II)/iron reference electrode utilizing a single-crystal lanthanum trifluoride membrane was recently employed by us (9) for potential measurements in molten $NaBF_4$ at 420°C. In this paper, we report on the use of the above reference electrode to study the electrochemistry of titanium in molten $NaBF_4$ at 420°C by means of linear sweep voltammetry, chronopotentiometry, and chronoamperometry. The electrochemical behavior of titanium in this medium is of particular interest because titanium is the least noble constituent of the Hastelloy N alloy used to contain the coolant in molten salt reactors.

Experimental

Reagent grade $NaBF_4$ was obtained from the Harshaw Chemical Company and was further purified by a recrystallization procedure described previously (4). The procedure involved a double recrystallization from 0.12M HF (aqueous) solution, air-drying at 110°C, crushing, and redrying. All-plastic ware was used throughout.

The electrolytic cell assembly and the instrumentation employed for this study was the same as that used in our previous electrochemical study (10) of titanium in molten fluorides. The Fe(II)/Fe reference electrode contained in a lanthanum fluoride compartment was described recently (9).

Results and Discussion

Background voltammograms of the $NaBF_4$ melt at platinum and pyrolytic graphite electrodes are shown in Fig. 1. The residual currents observed are reasonably low within the potential range of interest. A small impurity wave (25-30 μA) located at about −0.1V *vs.* Fe(II) (saturated)/Fe reference electrode (LaF_3 membrane type) is due to the presence of iron(II) at a concentration of about 200 ppm ($M = 7.16 \times 10^{-3}$). Its

Key words: titanium, molten fluoroborates, voltammetry, chronopotentiometry, melts.

identity was confirmed by additions of FeF_2 to the melt which resulted in proportionate increases in the height of this wave. The anodic stripping wave for the iron impurity was more pronounced at the pyrolytic graphite electrode. The anodic and cathodic potential limits are believed to be due to anodic dissolution of the platinum electrode and reduction of boron(III), respectively. A small unidentified wave was observed at about +0.8V. The possibility of an extraneous metallic impurity was excluded on the basis of emission spectroscopic analyses of the melt. However, the wave may be due to oxidation of oxide impurities since chemical analyses (performed by General Analyses Laboratory, Oak Ridge National Laboratory) revealed a total oxygen content of about 200 ppm.

Linear sweep voltammograms for Ti(IV) (added as K_2TiF_6) in molten $NaBF_4$ at a platinum electrode are shown in Fig. 2. The plot of i_p *vs.* $v^{1/2}$ for those voltammograms is linear as is also shown in Fig. 2. Peak currents at the Pt electrode were observed to increase linearly with increasing concentration of Ti(IV) in the range 1.01×10^{-3} to 1.59×10^{-1}M. Similar well-defined voltammograms were obtained at a pyrolytic graphite electrode. No other reduction waves were obtained in this system.

The half-wave potential, peak potential separation, and half-peak to peak potential separation for the Ti(IV) reduction wave are −0.150 ± 0.01 (*vs.* an Fe(II)saturated/Fe reference electrode), 0.140 ± 0.01, and 0.130 ± 0.01V, respectively. The log $(i_p - i)/i$ *vs.* E plot yielded a straight line of theoretical slope (11) corresponding to an n value of 1. Further evidence for a simple reversible electrode reaction is provided by the semi-empirically calculated (12) value of i_{ap}/i_{cp} equal to unity in agreement with the theoretical value (13).

The diffusion coefficient for Ti(IV) in molten $NaBF_4$ was determined from the Randles-Sevcik equation (14) which at 420° is given by

$$i_p = 1.77 \times 10^5 n^{3/2} A D^{1/2} C v^{1/2} \quad [1]$$

Using the slope of the i_p *vs.* $v^{1/2}$ plot (Fig. 2), $A = 0.12$ cm², $C = 0.140$M, D was calculated as $2.6 \pm 0.5 \times 10^{-6}$ cm²/sec.

The polarogram constructed from current-time curves for the reduction of Ti(IV) at a platinum electrode is shown in Fig. 3. The corresponding log $(i_d - i)/i$ *vs.* potential plot is shown in Fig. 4; the straight line drawn through the data points has the theoretical slope for a one-electron reversible process.

A series of chronopotentiograms for the reduction of Ti(IV) in molten $NaBF_4$ is shown in Fig. 5. The value of $i_o\tau^{1/2}$ of 13.7 ± 0.3 mA · cm^{-2} · sec$^{1/2}$ obtained from these chronopotentiograms was reasonably constant over the current density range studied. Transition times were in the range 0.06-0.52 sec. From the $i_o\tau^{1/2}$ value, D was calculated as $1.3 \pm 0.3 \times 10^{-6}$ cm²/sec. As in the case of Ti(III) in $LiF\text{-}BeF_2\text{-}ZrF_4$ (10), the agreement between D values obtained by voltammetry and chronopotentiometry was not good. Additional evidence for the electrode reaction being simple and re-

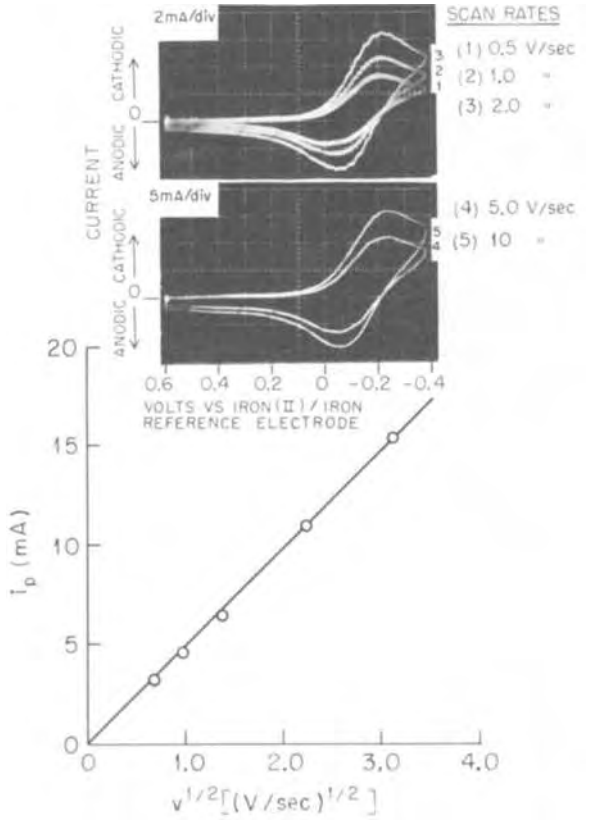

Fig. 2. Voltammograms for the reduction of Ti(IV) at platinum electrode in molten $NaBF_4$ at 420°C; plot of i_p *vs.* $v^{1/2}$ for the voltammograms shown. Ti(IV) concentration: 0.140M; electrode area: 0.12 cm².

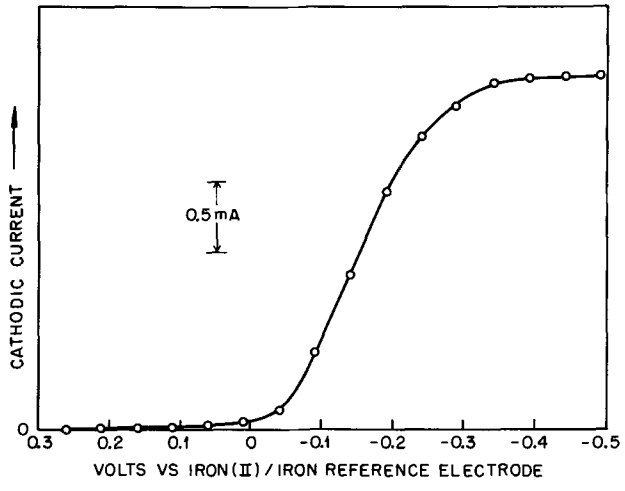

Fig. 3. Polarogram constructed from current-time curves for the reduction of Ti(IV) at platinum electrode in molten $NaBF_4$ at 500°C. Ti(IV) concentration: 0.178M; electrode area: 0.20 cm²; current measured at 5 sec.

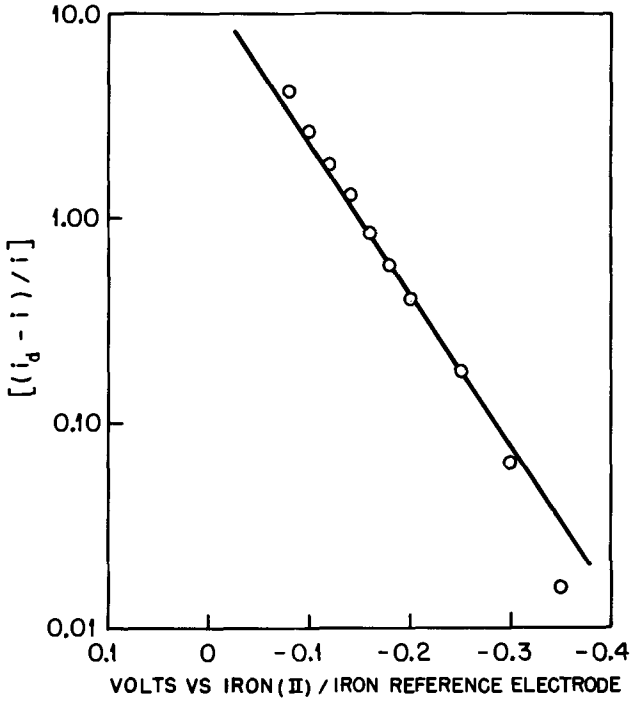

Fig. 4. Plot of log $(i_d - i)/i$ *vs.* potential for the polarographic wave of Fig. 3.

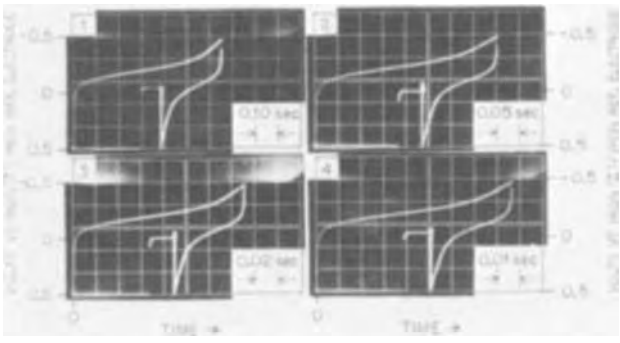

Fig. 5. Chronopotentiograms for the reduction of Ti(IV) in molten $NaBF_4$ at 420°C. Platinum electrode area: 0.08 cm^2; Ti(IV) concentration: 0.140M; currents: 1, 1.5 mA; 2, 2.0 mA; 3, 3.0 mA; 4, 4.5 mA.

versible was obtained from measurement of the reverse transition time τ_r for the chronopotentiograms in Fig. 5. According to Reinmuth (15), τ_r should be equal to one-third of the forward transition time τ for a simple reversible electron transfer. The experimentally determined ratios of 0.35 to 0.37 were in good agreement with theory.

Direct comparison of the chronopotentiometric $E_{1/2}$ with the voltammetric $E_{1/2}$ for the Ti(IV) reduction wave can be made since the same iron(II) (saturated)/iron reference electrode (LaF_3 membrane type) was used in both measurements. From Fig. 5 an $E_{1/2}$ (determined from the potential at $\tau/4$) of -0.15 ± 0.01V was obtained, in excellent agreement with the voltammetric $E_{1/2}$.

The half-wave potential for the reversible process $Ti(IV) + e \rightleftarrows Ti(III)$ of -0.150V [*vs.* the Fe(II) (saturated)/Fe reference electrode] was used to estimate the standard electrode potential of the Ti(IV)/Ti(III) couple. Extrapolation of the Nernstian plot for the Fe(II)/Fe couple in molten $NaBF_4$ (9) to unit mole fraction of iron(II) gives an $E°$ for the Fe(II)/Fe couple which is about 0.208V more anodic than the potential of the Fe(II) (saturated)/Fe reference electrode. Thus, $E°$ for the Ti(IV)/Ti(III) couple in $NaBF_4$ at 420°C is estimated to be -0.358V (with respect to a unit mole fraction Fe(II)/Fe electrode).

Interpretation of the Impedance Properties of the Anode-Surface Film in the Electropolishing of Copper in Phosphoric Acid

K. Kojima and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The frequency dispersion of the impedance measured by Ohashi *et al.*, between a vertical copper anode and a reference electrode during electropolishing in concentrated phosphoric acid, is analyzed in terms of linear combinations of resistors and capacitors. The frequency dependence of the anode under electropolishing conditions may be satisfactorily represented by an analogue circuit consisting of a resistor and a capacitor connected in parallel. The resistivity is in the range of 4.5-5 ohm · cm^2 while the capacitance is 5-8 $\mu F/cm^2$. The contribution of the solution-side resistance to the total impedance is small. Assuming that the solid film layers on the anode surface are composed of oxides of copper, depending on actual composition, the measured impedances are consistent with a thickness range of 13-124Å.

The question of the presence of an invisible anode solid film during copper electropolishing in concentrated phosphoric acid has been a subject of investigation by many researchers in recent years. The mercury test by Hoar and his co-workers (1, 2) and an ellipsometric study of the anode *in situ* by Novak *et al.* (3) provide strong evidence of the existence of a solid film on the surface.

Electrical properties of the anode-electrolyte interface during electropolishing have been explored by Ohashi, Murakawa, and Nagaura (4) by means of a-c impedance measurements. A reinterpretation of these experimental impedance data allow inferences about the nature of the invisible solid film.

Impedance of Anode Film in Electropolishing Region[1]

The a-c impedance between a vertical anode and a reference electrode during electropolishing was measured by Ohashi *et al.* (4) in the frequency range of 400 Hz to 10 kHz. They have interpreted their experimental results in terms of a resistor, R_s, and a capacitor, C_s, connected in series. The series resistance R_s decreases sharply while C_s decreases only slightly with increase of frequency. However, for this analogue to represent the experimental impedance values, both the series resistance, R_s, and capacitance, C_s must be independent of frequency. Obviously, the series connection of a resistor and a capacitor does not represent the measured impedance properly.

The wavelength range of a.c. used by Ohashi *et al.* (400 Hz to 10 kHz) is many orders of magnitude larger than the dimensions of the anode specimen. This allows an equivalent circuit to be represented by linear elements. We exclude here nonlinearity caused by roughness of the surface on the microscale. One of the equivalent circuits to be considered for nonporous films of uniform properties along the anode surface is shown in Fig. 1. It is assumed that there is no special adsorption of ions affecting the anode impedance. The Warburg impedance is probably negligible in the high frequency range.

Assuming that either the solid side or the solution side is the controlling factor of the over-all anode impedance, one greatly simplified equivalent circuit is the parallel connection of a resistor and a capacitor with series resistors as shown in Fig. 2.

The total impedance across points A and R, Z_{ar}, for the equivalent circuit shown in Fig. 2 is given by

$$Z_{ar} = \frac{R_x}{1 + \omega^2 R^2{}_x C^2{}_x} + R_{ar} + R_{sc} - j\frac{\omega R^2{}_x C_x}{1 + \omega^2 R^2{}_x C^2{}_x} \quad [1]$$

in which ω is the angular frequency. For the series connection of a resistor and a capacitor, used by Ohashi, the following relation holds

$$Z_{ar} = R_s - j\frac{1}{\omega C_s} \quad [2]$$

Comparing Eq. [1] with Eq. [2], we get

$$R_s = R_{ar} + R_{sc} + \frac{R_x}{1 + \omega^2 R_x{}^2 C_x{}^2} \quad [3]$$

and

$$\frac{1}{\omega C_s} = \frac{\omega R_x{}^2 C_x}{1 + \omega^2 R_x{}^2 C_x{}^2} \quad [4]$$

From these equations we obtain [5]

[1] Section of the current plateau below the onset of the transpassive region.

$$\left(\frac{R_x}{1+\omega^2R_x^2C_x^2}-\frac{R_x}{2}\right)^2+\left(\frac{\omega R_x^2C_x}{1+\omega^2R_x^2C_x^2}\right)^2=\left(\frac{R_x}{2}\right)^2 \quad [5]$$

or

$$\left(R_s-R_{ar}-R_{sc}-\frac{R_x}{2}\right)^2+\left(\frac{1}{\omega C_s}\right)^2=\left(\frac{R_x}{2}\right)^2 \quad [6]$$

Equation [6] is the equation of a circle which is centered at $(R_x/2,0)$ with radius $R_x/2$, if the measured reactance, $1/\omega C_s$, is plotted against resistance, $R_s - R_{ar} - R_{sc}$. The values of R_{ar} and R_{sc} have been estimated in two ways: (*i*) from extrapolating the measured values of R_s *vs.* $1/f$ [Ref. (4)] to infinite frequency, and (*ii*) from the measured values of the resistance between the anode and the reference electrode when the anode dissolves in the active region.

Figure 3 shows the impedance loci of the Cu/solid film/solution/reference electrode system, when the anode potential is $1.0V < E_n < 1.3V$ and the frequency is in the range of 400 Hz to 10 kHz. The experimental data points fall close to a circle of 16-ohm diameter. This suggests that the analogue circuit of a parallel resistor and a parallel capacitor is approximately correct. In Fig. 4 and 5, the parallel resistance $R_{x,o}$ (ohm · cm²) and parallel capacitance $C_{x,o}$ (μF/cm²) of the analogue circuit per unit area of the apparent surface are plotted as functions of frequency. $R_{x,o}$ is nearly independent of frequency, although it slightly decreases with the increase of anode potential. Figure 5 shows that $5\ \mu F/cm^2 < C_{x,o} < 8\ \mu F/cm^2$.

The foregoing analysis indicates that the impedance of the anode surface under electropolishing conditions can be satisfactorily represented by the parallel connection of a resistor and a capacitor, instead of the series combination suggested by Ohashi *et al.* (4).

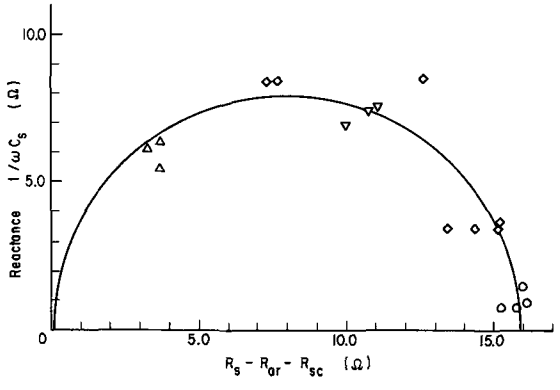

Fig. 3. Impedance loci of the copper/solid film/solution/reference electrode system (calculated by Eq. [6]). $1.0V < E_h < 1.3V$. Data by Ohashi *et al.* (4). ○, 400 Hz; ▽, 3 kHz; ◇, 1 kHz; △, 10 kHz.

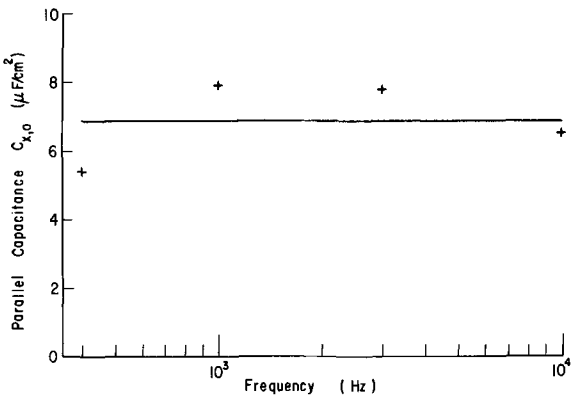

Fig. 5. Effect of frequency on the parallel capacitance $C_{x,o}$. $E_h = 1.04$-$1.24V$ (this work).

Effect of Solution-Side Impedance

We shall now examine whether the impedances, R_x and C_x, are predominantly determined by the solution-side impedance, R_w, C_w, and Z_{F2}. The fact that $R_{x,o}$ and $C_{x,o}$ are nearly independent of frequency suggests that under Ohashi's experimental conditions the effect of the diffusion impedance on the over-all impedance is small.

Assuming the diffusion impedance to be negligible, we get

$$\frac{1}{R_x}\simeq\frac{1}{R_w}+\frac{1}{R_T} \quad [7]$$

and

$$C_x\simeq C_w \quad [8]$$

The reaction resistance R_T may be calculated by the following relation (6)

$$R_T=\left(\frac{\partial E_h}{\partial i}\right)_{i=i_l}\simeq\frac{RT}{\alpha_a F i_l} \quad [9]$$

in which the Tafel relation [$i = i_o \exp(\alpha_a\eta_a F/RT)$] is assumed to be applicable. If we assume that for the anodic transfer coefficient, α_a, in Eq. [9] we can use the value obtained for the active dissolution of copper [$\alpha_a = 1.44$ (7)], we obtain for $i_l = 0.018$ A/cm²[2] at 30°C

$$R_T\simeq 1\ \text{ohm}\cdot\text{cm}^2$$

This leads to $R_{x,o} < 1$ ohm · cm². As shown in Fig. 6, in the electropolishing region the observed $R_{x,o}$ is of

[2] The current density used in Ohashi *et al.*'s experiments (4).

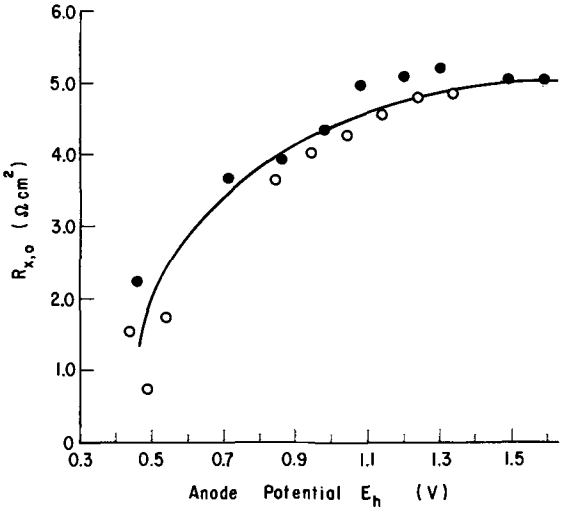

Fig. 6. Effect of anode potential on the parallel resistance $R_{x,o}$ at $f = 1$ kHz (this work). Data by Ohashi *et al.* (4). Best electropolishing region: $1.0 < E_h < 1.6V$. Active dissolution occurs when $E_h < 0.4V$ (7).

the order of 4.5-5.0 ohm · cm². $R_{x,o}$ in the active dissolution of copper is probably much smaller than that in the electropolishing region (Fig. 6). Considering R_T to be the slope of the anodic polarization curve at a given current density, it is evident under electropolishing conditions the observed $R_{x,o}$ does not represent the solution-side resistance.

We now turn our attention to the behavior of capacitance. From Ohashi's experimental data the parallel capacitance, $C_{x,o}$, in active dissolution of copper is of the order of 200-800 μF/cm². According to Bockris and Conway (8), Hoey (9), Noguet *et al.* (10), at $E_h > 0.3V$ [3] the double-layer capacitance of copper electrodes is of the order of 100 μF/cm² or higher. Even after a correction for surface roughness is made, the double-layer capacitance is still too large compared to the values of $C_{x,o}$ under electropolishing conditions.

It is concluded that the parallel resistance and capacitance obtained under the conditions of electropolishing do not represent the impedance at the anode/solution interface. This is in agreement with the results obtained with respect to the electrode reactions at the current plateau (1, 7). It should be mentioned that according to Hoey (9) the effect of the solution-side impedance on the over-all impedance of the $Cu/Cu_2O/$ aqueous solution system may be neglected when no direct current passes, and the frequency is larger than 10^3 Hz.

Solid Film Properties

We now examine the second extreme case, in which the impedance of the solid film is represented by parallel resistor and capacitor (R_x, C_x). The order of magnitude of the solid film thickness θ_f, then, may be estimated by

$$\theta_f \simeq \frac{\epsilon_0 \epsilon_f f}{C_{x,o}} = 8.854 \times 10^{-14} \frac{\epsilon_f}{C_{x,o}} f \qquad [10]$$

in which ϵ_f and f are the dielectric constant of the solid film and the roughness factor of the film, respectively. A study of the rest potential of copper anodes at the current plateau (7, 11), as well as electron diffraction studies (12-17) of electropolished copper, indicates that the anode during electropolishing is covered with copper oxides. According to Noguet *et al.* (10) and Heltemes (17) the dielectric constant of Cu_2O is 7.5-7.6, while that of CuO is 18 [Ref. (18)]. On the other hand, Hoey (9) has found that a film of the multilayer structure composed of Cu_2O, CuO, and an unidentified higher copper oxide has a dielectric constant of the order of 46-70, much higher than that of pure Cu_2O or CuO (7). Assuming that the possible range of the dielectric constant of the anode solid film is 7.5-70 and that for well-electropolished surfaces the roughness factor f is 1.3 (19), we obtain from Eq. [10]

$$\theta_f \simeq 13\text{-}124\text{Å}$$

If any portion of the solid film functions as a series resistor, the film thickness should be larger than 13-124Å.

According to Hoar (20) the film thickness estimated from impedance data is of the order of 6-60Å. Using an ellipsometric technique, Novak *et al.* (3) have found recently that the film thickness is of the order of 40-120Å at a limiting current density close to that in Ohashi's impedance experiments.

If the film thickness is really of the order of magnitude mentioned above, copper ions will transfer through the solid film under the electric field of 10^6-10^7 V/cm. Under this high field, the current density passing through an anode film is approximately given by the following form (21, 22)

$$i = A_2 \exp(BE) \qquad [11]$$

in which the apparent field strength, E, is given by $E = \Delta\eta_f/\theta_f$, where $\Delta\eta_f$ is the apparent overvoltage at the anode. The value of B may be estimated from the relation

$$R_{x,o} = \left(\frac{\partial E_h}{\partial i}\right)_{i_l} = \frac{\theta_f}{i_l B} \qquad [12]$$

Equation [12] yields $B = (1.5 - 14) \times 10^{-6}$ cm/V for $\theta_f = 13\text{-}124$Å and $i = 0.018$ A/cm². It is interesting to note that the value of B is 6.8×10^{-6} cm/V for a 60Å film, which is proposed to be the probable value of the film thickness by Novak *et al.* The fact that the value of B for a 60Å film is of the same order of magnitude as that for anodic oxide films formed on Ta, Al, Zr, Nb, InSb, etc. (22) under a high electric field strength gives strong support to the view that copper ions transfer through the anode film under the high electric field. For this reason, $R_{x,o}$ should be interpreted as the over-all reaction resistance of the solid film.

Finally, it is necessary to consider to what degree our interpretation of impedance measurements may be affected by nonisothermal conditions. When large current densities pass through the resistive film, the rate of heat generation by the Joule effect may be considerable. A temperature rise of the film may cause flow of electrolyte near the anode, causing a nonuniform current-density distribution. Assuming that in Ohashi's experiments the heat generated in the solid film was transferred to the electrolyte primarily by natural convection, we can estimate the order of magnitude of the average film temperature, T_e, at steady state

$$T_e - T_{soln} \approx \frac{0.24\, i_l^2}{h_m}\left(R_{x,o} \sim \frac{\Delta\eta_f}{i_l}\right) \qquad [13]$$

in which T_{soln}, i_l, and h_m are the temperature of the electrolyte in immediate contact with the anode, the limiting current density, and heat-transfer coefficient, respectively. The heat-transfer coefficient has been estimated (7) using the well-established correlation between Nu and Gr·Pr for heated vertical plates (23). Nu, Gr, and Pr are the Nusselt number, the Grashof number, and the Prandtl number, respectively. For the thermal conductivity and the thermal coefficient of volumetric expansion, the respective physical properties of water have been used. The calculated temperature difference, $(T_e - T_{soln})_{calc}$ is of the order of 1°C or smaller. Since in fact heat is also lost by thermal conduction through the back of the anode the temperature difference, $T_e - T_{soln}$, is probably smaller than 1°C.

Concluding Remarks

The impedance of the anode under electropolishing conditions may be approximately represented by the parallel connection of a resistor and a capacitor. The resistance of the parallel resistor starts to increase in the anode-potential region in which the passivation of copper by cuprous oxide takes place (7). The parallel resistance is nearly constant in the electropolishing potential region. Lowering of limiting current in the electropolishing region shows that the parallel resistance affects the over-all transport resistance of copper ions.

The generally accepted exponential form for ion transport under high field may be applicable for the transport of copper ions through the solid film.

Theory of Successive Electron Transfer Steps in Cyclic Voltammetry: Application to Oxygen Pseudocapacitance on Platinum

A. J. Appleby*

Laboratoire d'Electrolyse, C.N.R.S. Bellevue, 92-Bellevue, France

ABSTRACT

Previous work on the theory of the cyclic voltammetric (potential sweep) method is reviewed. In cases where a multielectron reaction occurs, it is shown that simple kinetic assumptions (that all electrons are transferred in a single step or that all steps save one are in pseudoequilibrium) are likely to lead to erroneous interpretations. The most fundamental parameter is (in the irreversible case) the variation of the peak maximum potential with log sweep rate. This will enable the rate-determining step to be located in the reaction sequence. The transfer coefficient and Temkin parameters determined from the peak shape are not necessarily those of the rate-determining step, but those of the potential-determining step. Results are applied to adsorbed oxygen film formation and reduction on platinum. It is shown that a two-stage reaction occurs, with the rate constant of the first anodic step (—OH formation) falling exponentially with coverage. This is associated with a rearrangement of the surface phase, accompanied by very rapid —O formation. In the cathodic direction, the position and shape of the peak is governed by the kinetic parameters of —O reduction, whereas —OH reduction is rate-determining. There is evidence that the heterogeneity factor and the free energy of the —O reduction step depend on coverage [cf. Ref. (6)]. The same mechanism may apply to palladium and rhodium and perhaps also to gold.

Since its inception by Will and Knorr (1) in 1960, the linear potential scan (triangular sweep) technique has received a great deal of attention from electrochemists who have desired an experimentally simple and rapid method of gathering information on processes involving adsorption and desorption at interfaces under nondiffusion-controlled conditions. Most instances of its application have involved studies of hydrogen and oxygen submonolayer films on the noble metals, generally from the qualitative point of view—*i.e.*, as demonstrations of irreversibility or of the existence of non-Langmuirian adsorption isotherms (2). In general, attempts to derive information of kinetic value from these studies have been few, although a number of attempts have been made to analyze peak parameters in kinetic terms (3-6). The reason for this paucity of analytical data is clear when it is realized that, in the potential sweep method, overpotential, current, reactant and product concentration, and ohmic potential drop change simultaneously, which results in mathematical analyses that are very much more difficult than, for example, in steady-state techniques. A further important point is that the universal assumption of the steady-state hypothesis, a normal situation for work involving reactions occurring in several stages in conventional kinetics, cannot be applied at all.

As a consequence of these problems, all kinetic analyses to date have involved a study of reactions that proceed in a single step under irreversible conditions (3-6). When the kinetics of all steps are considered to be sufficiently rapid for equilibrium to be maintained at the experimental scan rates under study, general equations may be derived in a straightforward way (3). In this paper, some of the assumptions and conclusions of earlier kinetic work are examined, and extensions of the equations to irreversible cases involving multiple stage reactions are described. The equations are applied to the formation and reduction of adsorbed oxygen films on platinum in acid solution, and the conclusions thus obtained are compared with earlier interpretations.

Previous Analyses of the Potential Sweep Method

Pseudoequilibrium case.—The pseudoequilibrium case was discussed by Srinivasan and Gileadi in 1966 (3) though the potential dependence of adsorption pseudocapacitance for various postulated isotherms had been previously calculated by Conway and Gileadi (7) and other authors (8, 9). In the pseudoequilibrium case, it is assumed that the adsorption-desorption steps are sufficiently rapid that equilibrium is maintained throughout the potential scan. In such a case, we can write a very generalized equilibrium

$$\frac{\theta}{(1-\theta)^m} = A_i \exp \frac{n\mathbf{F}}{RT}(E' - E_o + ct) \qquad [1]$$

where m is the reaction order for metal sites, A_i is the product of the activities of reactants in solutions, and n is the over-all number of electrons transfered in the over-all process

$$A_i + m\,S \rightleftharpoons X + ne^- \qquad [2]$$

where S represents the number of metal sites, and X the adsorbate, whose coverage is θ. E_o is the standard potential of the process, E' is the potential at the start of the linear sweep, whose scan rate is c. t is time in seconds. If S is the saturation coverage of X (in coulombs/cm^2), then it is clear that

$$S\frac{d\theta}{dt} = i \qquad [3]$$

where i is the current in amperes. Differentiation of Eq. [1] shows that

$$i = \frac{\theta(1-\theta)}{1 + (m-1)\theta}\left(\frac{Sn\mathbf{F}c}{RT}\right) \qquad [4]$$

where θ is the equilibrium coverage at the potential in question. The potential and current maximum is obtained from the second derivative of Eq. [1] in the usual way. We therefore find that

$$i_{max} = (1 + m^{1/2})^{-2}\left(\frac{Sn\mathbf{F}c}{RT}\right) \qquad [5]$$

$$\theta_{max} = (1 + m^{1/2})^{-1} \qquad [6]$$

When $m = 1$, the peaks are therefore symmetrical (*i.e.*, $\theta_{max} = \frac{1}{2}$), as shown by Srinivasan and Gileadi (3), whereas for large values of m (*e.g.*, adsorbates requiring several adjacent surface sites), the peaks are asymmetrical and flatter. If a coverage-dependent (*e.g.*, Temkin-type) isotherm is considered to operate, Eq. [1] must contain an exp $-r\theta/RT$ term, where r is the change in free energy of adsorption as θ moves from limitingly low to limitingly high values. The same procedure shows that i is then given by[1]

$$i = \frac{\theta(1-\theta)}{1 + (m-1)\theta + r\theta(1-\theta)/RT}\left(\frac{Sn\mathbf{F}c}{RT}\right) \qquad [7]$$

where θ_{max} is given by the same value as before. i_{max} is therefore given by

$$i_{max} = [(1 + m^{1/2})^2 + r/RT]^{-2}\left(\frac{Sn\mathbf{F}c}{RT}\right) \qquad [8]$$

Peaks under Temkin adsorption conditions are therefore lower and flatter than under Langmuir conditions. It is clear that if Eq. [6] is substituted in Eq. [1], then the potential of the peak maximum, $E' - E_o + ct_{max}$, where t_{max} is the elapsed time to the peak maximum, is constant, and is thus independent of c, the sweep rate. This is the practical criterion of reversibility. The above equations are all perfectly general and may be applied to a range of reversible systems provided that the over-all reaction is or can be written in the same form as Eq. [2]. The conclusions do not depend on any assumptions with regard to reaction mechanism.

Totally irreversible case.—For irreversible processes, it is necessary to consider the rate-determining step of the over-all reaction. If the back reaction is sufficiently slow to be ignored, we can in principle write (for a cathodic process), under Langmuir conditions

$$-S\frac{d\theta}{dt} = i = n\mathbf{F}k\,\theta^m \exp - \alpha n\mathbf{F}\,(E' - E_o + ct)/RT \qquad [9]$$

where k is the backward (cathodic) rate constant, α is the "transfer coefficient," and where the other symbols are as discussed previously. Such an equation was used by Ohashi *et al.* in 1966 (4) and Stonehart in 1968 (5). Srinivasan and Gileadi (3), on the other hand, considered the simple case of a one-electron process (H^+ discharge to give an adsorbed H atom), where both n and m are unity. A solution of Eq. [9] corresponding to the peak maximum is easily obtained by putting its time derivative equal to zero in the usual way. We thus obtain:

$$-i_{max} = \frac{S\alpha n\mathbf{F}c\theta_{max}}{mRT} \qquad [10]$$

If, on the other hand, the free energy of adsorption of the reactant is coverage-dependent and may be represented by a Temkin isotherm, then the expression for i (Eq. [9]) must be multiplied by exp $\alpha r\theta/RT$, where r is the change in free energy of adsorption as θ moves from limitingly low to limitingly high values. In such cases, a calculation shows that i_{max} is then given by an expression of the form

$$-i_{max} = \frac{S\alpha n\mathbf{F}c}{RT}\left(\frac{m}{\theta_{max}} + \frac{\alpha r}{RT}\right)^{-1} \qquad [11]$$

θ_{max} is found by integrating Eq. [9] (for the Langmuir case) with the boundary condition $\theta = \theta_o$ at $t = 0$, where θ_o is the starting coverage on the electrode. i_{max} (from Eq. [10]) is then substituted for i in the integrand, and the assumption is made that i is negligible when $\theta = \theta_o$ and $t = 0$. We then obtain for the general case, $m \neq 1$

$$\theta_{max} = \theta_o\left(\frac{m-1}{m}\right)^{\frac{1}{m-1}} \quad (m \neq 1) \qquad [12]$$

and for the special case, $m = 1$

$$\theta_{max} = \theta_o/e \quad (m = 1) \qquad [13]$$

The peak maximum therefore occurs at $\theta = 0.37\theta_o$ if $m = 1$, *i.e.*, the peaks are therefore asymmetrical, and the ratio of reversible to irreversible (with θ_o taken to be 1) peak heights is $e/4\alpha$. As θ_{max} is independent of c, then, from Eq. [9], we can write

$$-i_{max} = \text{const. exp} - \alpha n\mathbf{F}E_{max}/RT \qquad [14]$$

where E_{max} is the potential of the peak maximum. Thus, using Eq. [10]

$$dE_{max}/d\ln c = -RT/\alpha n\mathbf{F} \qquad [15]$$

Thus a Tafel-type shift of the peak potential with ln sweep rate should be observed. This may be taken as a criterion of the totally irreversible case.

For the Temkin case, integration of the rate equation to give a simple analytical solution for θ_{max} is not possible. However, we can write

$$-\int_{\theta_o}^{\theta_{max}} \theta^{-m} \exp - \alpha r\theta/RT\, d\theta = n\mathbf{F}k \exp - \alpha n\mathbf{F}(E' - E_o)/RT \int_0^t \exp - \alpha n\mathbf{F}ct/RT\, dt \qquad [16]$$

[1] Expressions similar to Eq. [4]-[8] were derived in Ref. (7) for the case $m = 1$.

where t is the elapsed time to the peak maximum. For $\exp - \alpha nFct/RT >> 1$ (*i.e.*, assuming the rate of reduction at $t = 0$ to be negligible), we obtain (using Eq. [11])

$$\left(\int_{\theta_o}^{\theta_{max}} \theta^{-m} \exp - \alpha r\theta/RT \, d\theta \right) (\theta_{max})^m \exp \alpha r\theta/RT = \left(\frac{RT}{\alpha nFc} \right) i_{max}/S = \left(\frac{m}{\theta_{max}} + \frac{\alpha r}{RT} \right)^{-1} \quad [17]$$

It is clear from Eq. [17] that θ_{max} is independent of sweep rate; thus the relationship between E_{max}, c, and αn (Eq. [15]) should also be valid in the Temkin case.

Intermediate cases.—Srinivasan and Gileadi (3) examined a first-order one-electron discharge process for different combinations of forward and backward rate constants and concluded that the general case (*i.e.*, where both forward and back reactions are important) applied only over a limited range of sweep rate (about two decades). A series of numerical analyses by Stonehart, Kozlowska, and Conway (6) for cases where a Temkin-type adsorption behavior occurs indicate a similar conclusion. The same workers point out that in totally irreversible cases peak symmetry is a function of the Temkin factor r [in addition to the effect of m (4)]. Thus, under Temkin conditions, with $m = 1$, increasing r produces broader but more symmetrical peaks; *i.e.*, it has in some degree a similar effect to increasing m (4, 6).

Stonehart and co-workers (6) write a rate equation of the form

$$i = nF \left(\vec{k}(1 - \theta) \exp (1 - \alpha)[nF(E' - E_o + ct)/RT] \exp - r\theta/RT - \overleftarrow{k} \theta^m \exp - \alpha[nF(E' - E_o + ct)/RT] \exp - r\theta/RT \right) = S \frac{d\theta}{dt} \quad [18]$$

where α is again the cathodic transfer coefficient, and $\vec{k}$ and $\overleftarrow{k}$ are the forward and backward rate constants. They apply numerical solutions of this equation to the reduction of noble metal oxide films. A discussion of the basic hypotheses underlying the use of this equation, together with a summary of their conclusions, is presented in the next section.

Adsorbed Oxygen Film Formation on Noble Metals

Cyclic voltammetric scans for the formation and reduction of the adsorbed oxygen layer on platinum are by now (1, 2) so familiar that they almost constitute the leitmotiv of recent electrochemistry. Scans on rhodium and palladium in acid solution are similar to those on platinum under the same conditions (1, 2, 6), whereas similar scans on iridium (1, 2), osmium (10), and ruthenium (11) show different characteristics. Only scans on platinum (and, by extension, those on rhodium and palladium) will be considered here.

Scans on platinum have been the subject of study by a large number of authors (1, 2, 4-6, 12, 13). In all cases, a considerable irreversibility between anodic and cathodic scans has been noted, except at low coverages [*i.e.*, when the anodic triangular sweep is terminated at low potentials (6, 12)]. It is of interest to enumerate some of the other characteristics of the anodic and cathodic pseudocapacitance peaks.

1) The anodic sweep is considerably broader and flatter than that in the cathodic direction. This suggests the operation of a Temkin-type isotherm, as discussed by Böld and Breiter (2) for the oxygen adsorption process.

2) The cathodic peaks show much hysteresis and are essentially symmetrical and quite narrow. They thus appear to be closer to the Langmuir case, though this is inconsistent with their symmetry, unless (*cf.*, Eq. [12]), the reduction reaction is second order ($m = 2$), when symmetrical peaks would be expected.

3) An important characteristic parameter, $dE_{max}/d \ln c$ (see Eq. [15]), has been examined by Will and Knorr (1) in both the anodic and cathodic directions in acid solution and in rather more detail by Gilroy and Conway (13), again in acid solution but in the cathodic direction only. In the anodic direction, Will and Knorr's conclusions, which refer to a sweep rate range greater than that required for Srinivasan and Gileadi's irreversibility-reversibility criterion (3), show that, although the fine structure of the peak is dependent on sweep rate, the position of the peak as a whole is virtually independent of ln sweep rate. Under irreversible conditions, the numerical analyses of Srinivasan and Gileadi and Stonehart *et al.* (6) show that the whole peak should be translated bodily without any change in shape; *i.e.*, for any current value on the peak (not only for i_{max}), the $dE/d \ln c$ relationship should be that given by Eq. [15]. This is not observed; the implication is, therefore, that at least the initial anodic process takes place under reversible conditions. Under cathodic conditions, the results of Will and Knorr indicate (with some scatter) $dE_{max}/d \ln c \simeq 50$ mV/decade. The results of Gilroy and Conway, conducted over a much wider sweep rate range (including some results from differentiated galvanostatic charging curves—*i.e.*, the equivalent of scans at extremely low sweep rates) show $dE_{max}/d \ln c$ in the region of 40 mV/decade. This fact indicates that the cathodic sweeps represent an irreversible process.

4) The i_{max}/peak width ratio (the "aspect ratio" of the peak) in the cathodic direction increases with increasing coverage (13).

It is generally accepted that the Pt-O adsorption reduction process occurs in at least two stages [*cf.* Böld and Breiter (2)]. The experimental results of Will and Knorr (1) and Gilroy and Conway (13) reinforce this idea. In both cases, for the cathodic sweep the value of $-RT/\mathbf{F}(d \ln c/dE_{max})$ was determined to be somewhat greater than unity. It should be noted that this term will always be equal to α for a totally irreversible reaction, even if r and α are θ-dependent, so long as the initial coverage on the electrode at the start of each cathodic scan is the same, and provided that the scanning rate has no effect on peak symmetry. This should be generally true and is supported by Gilroy and Conway's experimental results of peak form as a function of ln sweep rate. A general equation for the cathodic transfer coefficient, assuming that one step is rate-determining with all preceding steps in pseudoequilibrium, is given by the equation (14)

$$\alpha = x/\nu + \beta n' \quad [19]$$

where α in Eq. [19] is the equivalent of αn in Eq. [9] (*i.e.*, $-RT/\mathbf{F}(d \ln c/dE_{max})$ and where x is the number of electrons transferred per unit of the over-all reaction before the rate-determining step, whose stoichiometric number is ν. n' is the number of electrons transferred per unit rate-determining step, and β is the symmetry factor for electron transfer in the rate-determining step. There is compelling theoretical evidence to suggest that n' will not exceed unity, on the grounds that the total rearrangement energy of the system will be much greater in a simultaneous multielectron transfer than for a series of single electron transfers (15). Multielectron transfers can therefore be eliminated on activation energy grounds. In addition, the transition probability for a bi-(or other multi-)electron combination undergoing a Landau-Zener-type transition mechanism will be lower than for a single electron transfer—*i.e.*, such processes will be anadiabatic, and thus the pre-exponential term, as well as the activation energy, will be highly unfavorable to multielectron transfers. Consequently, we may confidently state that n' will be unity. The corresponding expression in the anodic direction is given by

$$(1 - \alpha) = x'/\nu + (1 - \beta) \quad [20]$$

where n' is taken to be unity and x' is the number of

electrons transferred before the rate-determining step in the anodic direction. Thus, in general, if n is the number of electrons involved in the over-all reaction, then

$$x + x' + \nu = n \qquad [21]$$

as ν is the number of times the one-electron rate-determining step occurs in the over-all process.

Kinetic data obtained from the use of Eq. [18], which implies a two-electron transfer with $x = x' = 0$, are thus likely to be illusionary. Although, formally, the value of the transfer coefficient αn may be used as a representative convention for the true physical meaning of the transfer coefficient (Eq. [19] for the cathodic process), conclusions drawn from its use are not likely to have any mechanistic meaning. It should be noted that the sum of the transfer coefficients in Eq. [19] and [20] is equal to n/ν, whereas the sum of the corresponding values as they appear in the formalism of Eq. [18] is simply n.

The sweep rate dependence results of Will and Knorr (1) and Gilroy and Conway (13) give us a possibility of determining the rate-determining step of the cathodic reduction process. The latter data are probably the more reliable, and indicate $dE_{max}/d \ln c$ values $\simeq$ 40 mV/decade, *i.e.*, at 25°C, $\alpha \sim 3/2$. Thus, from Eq. [19], with $\beta = \frac{1}{2}$ and $n' = 1$, $x/\nu = 1$. The most logical reaction sequence is an over-all two-electron transfer with $\nu = 1$ of the form (2)

$$Pt + H_2O \rightarrow PtOH + H^+ + e^- \qquad [A]$$

$$PtOH \rightarrow PtO + H^+ + e^- \qquad [B]$$

in which the second electron transfer step in the cathodic direction (*i.e.*, relation [A]) is rate-determining. The pH dependence of such a process would be $-RT/F$, which is consistent with that experimentally observed (2). In the anodic direction, the reaction is effectively at equilibrium, as discussed above. Again, in such a case a pH dependence of $-RT/F$ would be expected, as is observed (2). If, however, the anodic process were under kinetic control from the reaction that is rate-determining in the cathodic direction (reaction [A]), a pH dependence of zero would be expected. These observations reinforce the idea that a considerable change in reaction rate constant has occurred between the processes in the anodic and cathodic directions. A reaction taking place in more than two electron transfer steps to any great extent in the potential range of interest is not probable, as maximum coverages observed correspond to a monolayer whose coulombic area is twice that for adsorbed hydrogen. A two-electron over-all reaction taking place in two one-electron steps is therefore indicated.

Ohashi *et al.* (4), who used an equation of type [9] in their investigations of the cathodic reaction, attempted to determine the cathodic reaction order and the value of r (*cf.* Eq. [11]) by a series of plots of $1/i_{max}$ as a function of $1/\theta_{max}$ (to determine r from Eq. [11] and of $\ln i - m \ln \theta$ against potential (using Eq. [9]) to establish the value of m. Their plot of $1/i_{max}$ against $1/\theta_{max}$ indicates that r approaches zero as θ increases. They therefore assume (as would be expected in conventional kinetics) that r is constant and negligible. This conclusion leads them to obtain a value of $\alpha n \simeq 0.52$ and a value of m (from $\ln i - m \ln \theta$ against potential, assuming $r = 0$) equal to 2. However, it is quite clear that if r is a function of θ (say $\propto 1/\theta$) in Eq. [11], the results can be explained equally well in terms of $m = 1$. This however fails to account for the surprising symmetry of the adsorbed oxygen reduction peaks, which would be expected to be unsymmetrical (*cf.* Eq. [13]) when r is negligible (*i.e.*, at large θ_o). Their αn value, obtained in several different ways (4), is also quite inconsistent with that obtained from the sweep rate dependence of the peak potential (1, 13).

Stonehart *et al.* (6) determined some of the properties of the peaks that result from numerical integration of Eq. [18]. They examined the effect of the Temkin factor r on peak symmetry, and concluded that, for the irreversible case, a substantial increase in apparent symmetry takes place for comparatively small values of r. They therefore conclude that the changing "aspect ratio" of essentially symmetrical peaks with θ_o is due to the coverage (or time) dependence of r, but they find it necessary to propose at the same time a rising value of αn with increasing θ_o. Their αn values are in the range 0.52-0.96. The effect of an increase in αn is an increase in the slope of the peak leading edge—this numerical adjustment is necessary as r decreases so that symmetry is maintained. A numerical demonstration of this effect will be given below. Again, the major difficulty with the interpretation of Stonehart *et al.* is that αn values obtained by peak profile analysis are inconsistent with those resulting from sweep rate experiments (1, 13), which give αn values of about 1.5. The varying value of αn with coverage is also difficult to accommodate on any physical model. It will be shown that such inconsistencies result from a failure to take into account a two-stage reaction sequence.

Investigation of the Oxygen Adsorption-Reduction Process on Platinum as a Two-Stage Reaction

Formally, we can write the rate equations for steps A and B for adsorption and removal of adsorbed —O on Pt in the following forms (at constant pH, and ignoring diffuse double-layer effects)

Reaction [A]

$$S\frac{d\theta_1}{dt} = Sc\frac{d\theta_1}{dV} = k_1F\Big((1-\theta_1-\theta_2) [\exp(1-\beta)FV/RT \exp -(1-\beta)r_1(\theta_1+\theta_2-\tfrac{1}{2})/RT] - \theta_1 [\exp -\beta FV/RT \exp \beta r_1(\theta_1+\theta_2-\tfrac{1}{2})/RT] \Big) - Sc\frac{d\theta_2}{dV} \qquad [22]$$

Reaction [B]

$$S\frac{d\theta_2}{dt} = Sc\frac{d\theta_2}{dV} = k_2F\Big(\theta_1 [\exp(1-\beta')F(V-V_d)/RT \exp -(1-\beta')r_2(\theta_1+\theta_2-\tfrac{1}{2})/RT] - \theta_2 [\exp -\beta'F(V-V_d)/RT \exp \beta' r_2(\theta_1+\theta_2-\tfrac{1}{2})/RT] \Big) \qquad [23]$$

so that the total current flowing is given by the expression $Sc(d\theta_1/dV + 2d\theta_2/dV)$, where θ_1 is the coverage in —OH, θ_2 is that in —O r_1 and r_2 are the Temkin constants for each rate equation, and V is potential measured on a scale relative to the reversible potential under standard conditions (standard state taken to be $\theta = \frac{1}{2}$) for reaction [A]. V_d is then the (negative) potential difference between the standard potentials of reactions [A] and [B]. Fk_1 and Fk_2 are the appropriate exchange currents in each case.

A certain difficulty exists in defining the manner in which the free energy (Temkin) terms depend on total coverage. Generally speaking, this term is not necessarily linear with coverage—however, it will be seen that a linear dependence gives a sufficiently good account of the experimental data. From the "induced heterogeneity" model of Boudart (16), it is reasonable to suppose that these terms will depend on the total coverage of all similar species (*i.e.*, species with similar bonding characteristics and electronegativity) on the surface of the electrode (7). Because —O is essentially a double bonded species, whereas —OH is single bonded, it may well be that the former has a more substantial effect on the bonding characteristics of neighboring oxygen dipoles than the latter. There is indeed some evidence for this (17). Consequently, it may be more exact to write Temkin terms of the form $r(\theta_1 + p\theta_2 - \frac{1}{2})/RT$, where p is a weighting factor characteristic of the bonding difference between —OH and —O. In the numerical calculations this has been disregarded, for the simple reason that the predominant species on the electrode is always —O, with θ_1 playing

a minor role. Consequently, the r values as determined from numerical analysis refer to the change in —O coverage (θ_2). In order to cut down the number of variables in the two above simultaneous equations, a simplifying assumption that the two symmetry factors, β and β', were both equal to ½ was made.

Numerical Computations

Solutions of the simultaneous equations [22] and [23] were obtained for various postulated k_1, k_2, r_1, r_2, and V_d values as a function of sweep rate and starting potentials and coverages using the Runge-Kutta method and an IBM 1800 computer. Rate constant values used were dimensionless; *i.e.*, all numerical values were expressed as k/c, and thus in themselves contain the variation in the sweep rate parameter. The facts that had to be explained were as follows: (*i*) In the cathodic direction, reaction [A] is rate determining. At all potentials of interest, reaction [B] is therefore considerably faster than reaction [A]. (*ii*) In the anodic direction, at least at low coverage, the rate-determining step (*i.e.*, reaction [A]) is sufficiently rapid to be regarded as a quasi-equilibrium.

Anodic Process

A straightforward numerical integration of Eq. [22] for reaction [A] indicates that the classical flat-topped pseudocapacitance peak for oxygen adsorption on platinum can be approximated by the assumption that r_1/RT is about 40. The second oxidation step (reaction [B]) is assumed to be in pseudoequilibrium. A plot of the current-potential curve, with $k_1/c = 10$, and with current expressed on a nominal scale, is shown in Fig. 1. A k_1/c value of 10 is sufficient for reversibility (Fig. 2). The difficulty with this interpretation is that the calculated peak shape does not exactly reproduce that experimentally observed, which shows a dip following an initial peak and, more importantly, it provides no explanation for the change in dimensionless rate constant from the initial value of 10 to a much lower value (so that total irreversibility is exhibited) in the cathodic direction. This may be remedied by introducing the simple concept that the rate constant k_1 is coverage dependent. This will satisfactorily explain the change in rate constant in the cathodic direction, and it gives a more satisfactory account of the observed shape of the experimental peak. As $k_1\mathbf{F}$, the standard exchange current of reaction [A], is determined by exp $- f\lambda/RT$, where $f\lambda$ is a fraction of the reorganizational energy of the system [the energy required to change the ground state of reactants or products to a corresponding product or reactant state in the same nuclear configuration (18)], then it is reasonable to suppose that it will be exponentially affected by the bonding character of the adsorbate, if this should change with θ or time. If the surface rearranges to give a different adsorbed phase [for example, *via* a place exchange mechanism (6)], and if subsequent growth of the film takes place in the configuration prevailing at that particular time and θ value, then a simple model for the k_1 dependence on θ can be suggested. For example, initial adsorption of oxygenated species may be in a random manner, and this may be followed by the formation of a surface phase (not necessarily a phase oxide) as coverage rises. The maximum coverage that will not involve nearest neighbor sites on a close-packed plane is $\theta = 0.3$. After this coverage is exceeded, new oxygenated radicals will have to be accommodated in nearest-neighbor sites. A place exchange mechanism that reduces energy may then be favored, which at the same time reduces the net film growth rate. Further addition of oxygen radicals will then be to the edges of "islands" of surface phase, which will take on a uniform character. The degree of rearrangement, hence the reorganizational energy, can then be considered to be proportional to θ, and k_1 may be put equal to k_1° exp $- q(\theta_1 + \theta_2)$ at constant temperature, where q is a constant.

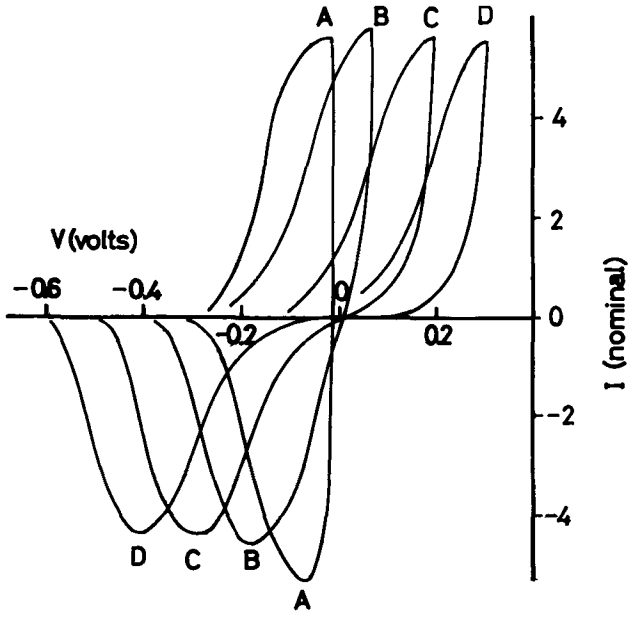

Fig. 2. Effect of changing k_1/c (invariant) for partial anodic coverages, second oxidation step (reaction [B]) ignored. $r_1/RT = 13$; A, $k_1/c = 10$; B, $k_1/c = 1.0$; C, $k_1/c = 0.1$; D, $k_1/c = 0.01$.

An examination of the effect of such a term is shown in Fig. 3 for $k_1^\circ/c = 10$ (to ensure initial reversibility, cf. Fig. 2). It has been postulated that k_1 changes by 3 orders of magnitude as $\theta_1 + \theta_2$ moves from low to high coverage to ensure sufficient irreversibility in the cathodic direction, so that q has been put equal to 6.9. r_1/RT has been taken to be 13, with reaction [B] as a quasiequilibrium (discussed in next section). It can be seen that the resulting anodic peaks show many of the features of experimental scans on platinum, for example, the initial rise followed by a dip. In practice, a further rise is noted after the dip, which may be attributed to the appearance of molecular oxygen on the surface.

Cathodic Process

Effect of V_d.—In the cathodic direction, it is postulated that the rate constant k_1 for reaction [A] corresponds to that for the highest value of θ reached in the anodic process and remains constant during the scan.

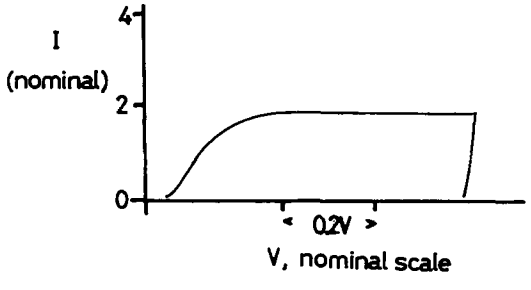

Fig. 1. Calculated anodic scan: $k_1/c = 10$ (invariant), $r_1/RT = 40$, reaction [B] in pseudoequilibrium.

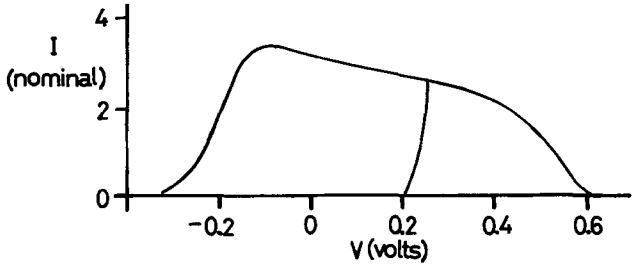

Fig. 3. Calculated anodic scans: $k_1^\circ/c = 10$, $q = 6.9$, $r_1/RT = 13$.

It is therefore the rate constant for an adsorbate with the degree of rearrangement corresponding to the initial value of θ. In order that reaction [A] should be rate-determining in the cathodic direction, it is necessary that $k_2 \exp \beta' \mathbf{F} V_d/RT$ should be much greater than k_1. To avoid the appearance of two cathode peaks, corresponding to two single-electron steps, it is clear therefore that the standard potential for the second oxidation step (reaction [B]) should be more cathodic than that for reaction [A]. For this reason, and because of the high k_2 value, reaction [B] must be a pseudoequilibrium in the anodic direction. The effect of changing V_d is shown for a hypothetical case in Fig. 4, where $r_1/RT = r_2/RT = 13$, and $\theta_2^o = 1$. V_d is taken to be 300, 400, and 500 mV. It can be seen that the effect of a 100 mV change in V_d is a translation of the peak by about 70-80 mV, with little change in the general form of the peak as a whole. In the case of platinum, the peak maximum in the anodic direction occurs at about 1000 mV *vs.* hydrogen in the same electrolyte, indicating a standard potential about 100 mV higher (see Fig. 3). The cathodic peak occurs in practice at about 800 mV *vs.* hydrogen. A rough estimate, therefore, for the value of V_d is about 300 mV.

Effect of r_2—The effect of changing r_2/RT is shown in Fig. 5. V_d is taken to be 300 mV, with $k_2/c = 80$ and $k_1/c = 0.02$. (k_2/k_1) $(\exp \beta' \mathbf{F} V_d/RT)$ is therefore about 30. r_1/RT is taken, as for the anodic direction, to be 13, and r_2/RT is given values of 13, 6, and 2. It can be seen that peaks with a good degree of visual symmetry result, whose shape (*i.e.*, "aspect ratio") is essentially controlled by the non-rate-determining reaction step (reaction [B]). They are quite different in form from the "totally irreversible" peaks, as reproduced in Ref. (3) and (6), because reaction [B] takes place under conditions of fast reduction close to its reversible potential. However, it is important to note that a simple assumption of reversibility for reaction [B], *i.e.*, if the relationship (from Eq. [23])

$$\theta_1 = \theta_2 \exp - \mathbf{F}(V - V_d)/RT \exp r_2(\theta_1 + \theta_2 - \tfrac{1}{2})/RT \quad [24]$$

is substituted directly for θ_1 in Eq. [22] (in the cathodic direction under totally irreversible conditions), is not a valid approximation for a calculation of the over-all peak shape. This is illustrated by the calculated shape for a pseudoequilibrium situation (potential on a nominal scale) for a totally irreversible reaction [A], using Eq. [24] with $r_1/RT = 13$ and $r_2/RT = 6$ illustrated in Fig. 6 (cf. curve B in Fig. 5). The shape of such a peak is much broader than that in Fig. 5, *i.e.*, it reflects a peak whose Temkin term is equal to $\beta r_1 + r_2$, rather than βr_2. The pseudoequilibrium assumption cannot be used because Eq. [24] is invalid in practice; on reduction of $-O$, the $-OH$ produced is immediately converted to H_2O under irreversible conditions and thus is removed from the reversible system. The steady-state assumption, implicit in Eq. [24], cannot therefore be applied, and the peak shape must be calculated directly from the appropriate rate equations (Eq. [22] and [23]).

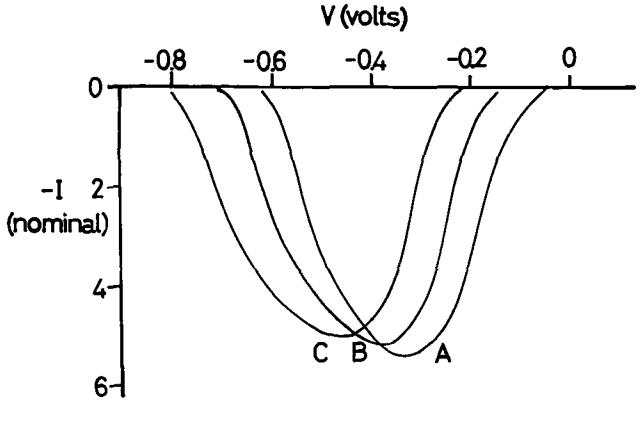

Fig. 4. Effect of changing V_d (cathodic scans): $k_1/c = 0.02$, $k_2/c = 8.0$, $r_1/RT = r_2/RT = 13$. Curves A, B, C: $V_d = 0.3$, 0.4, and 0.5V, respectively.

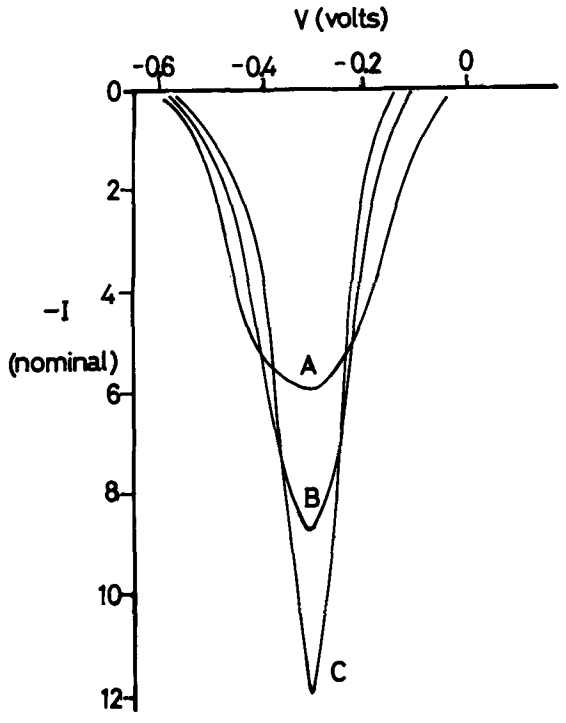

Fig. 5. Effect of changing r_2 (cathodic scans): $k_1/c = 0.02$, $k_2/c = 80$, $r_1/RT = 13$, $V_d = 0.3$. Curves A, B, C: $r_2/RT = 13$, 6, and 2, respectively.

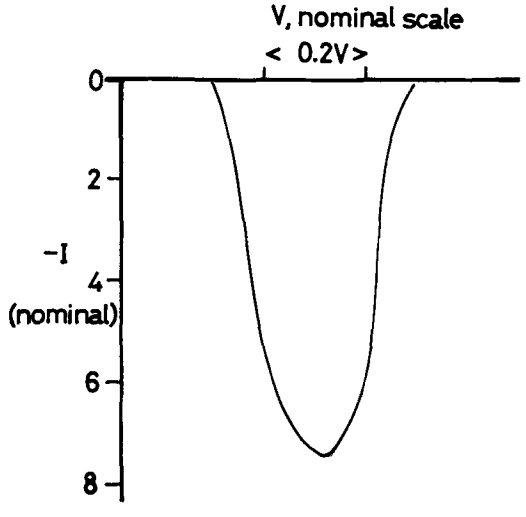

Fig. 6. Cathodic curve calculated using pseudoequilibrium assumption (Eq. [24]) for reaction [B]. $k_1/c = 0.02$, $r_1/RT = 13$, $r_2/RT = 6$.

Effect of k_1 *and* k_2*; effect of sweep rate.*—In Fig. 7 k_2/c is taken to be 80 and 8, representing a tenfold change in sweep rate. k_1/c is assumed to be 0.2, 2.0, and 20 for $k_2/c = 80$, and 10% of these values for $k_2/c = 8$, reflecting the sweep rate change. The ratio k_2/k_1 $(\exp \beta' \mathbf{F} V_d/RT)$ is therefore about 3.0, 0.3, and 0.03, respectively (for $V_d = 300$ mV). r_1/RT is assumed to be 13, and r_2/RT, 6. It can be seen that an increase in the $k_2/k_1 \exp \beta' \mathbf{F} V_d/RT$ ratio results in more symmetrical, less blunt peaks, and that $dV_{max}/d \log_{10} c$ decreases with increase in this ratio. The corresponding values are about 120, 90, and 60 mV, respectively (*i.e.*, from Eq. [15], $\alpha n = 0.5$, 0.75, and 1.0, respectively).

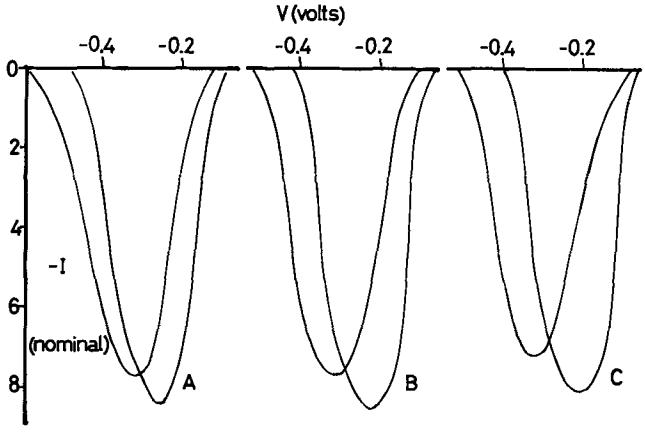

Fig. 7. Effect of one decade increase in sweep rate (cathodic scans). $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 0.3$. k_2/c for slower sweep equal to 80 in each case. Curves A, B, C: $k_1/c = 0.2$, 2.0, and 20, respectively, for slower sweep.

In Fig. 8, the ratio of $k_2/k_1 \exp \beta' \mathbf{F} V_d/RT$ is assumed to be one decade greater than the maximum in Fig. 7 (*i.e.*, 30, as in Fig. 5). A sweep rate change of 2 decades is considered here, taking $k_2/c = 800$, 80, and 8, with $k_1/c = 0.2$, 0.02, and 0.02, respectively. As in Fig. 7, $r_1/RT = 13$ and $r_2/RT = 6$. $dV_{max}/\log_{10}c$ is now 50 mV, close to the experimental value (1, 13). High sweep rates produce a broadened, though still sharp, peak, as is experimentally noted (13).

Figure 9 shows the effect of changing k_2/c at constant k_1/c and *vice versa*. Assuming $k_2/c = 80$, the peaks corresponding to k_1/c values of 20, 2.0, 0.2, and 0.02 in Fig. 7 and Fig. 8 are superposed to show the corresponding change in peak shape and potential of the maximum. Similarly, k_1/c is kept constant at 0.02 and k_2/c is varied through 3 decades from 80 to 0.08 using the same r_1/RT and r_2/RT values. The latter shown a change to the typical "totally irreversible" peak form [cf. Ref. (3) and (6)] at small k_2/c values, corresponding to $k_2/k_1 \exp \beta' \mathbf{F} V_d/RT$ values in the 0.3-0.03 range. The second peak appearing at the lowest k_2 value is a computer artifact and represents reduction of —OH (which would not be present in practice). In solving the simultaneous differential equations [22] and [23], a nonzero value (about 0.05) for θ_1 must be assumed in order to obtain meaningful solutions.

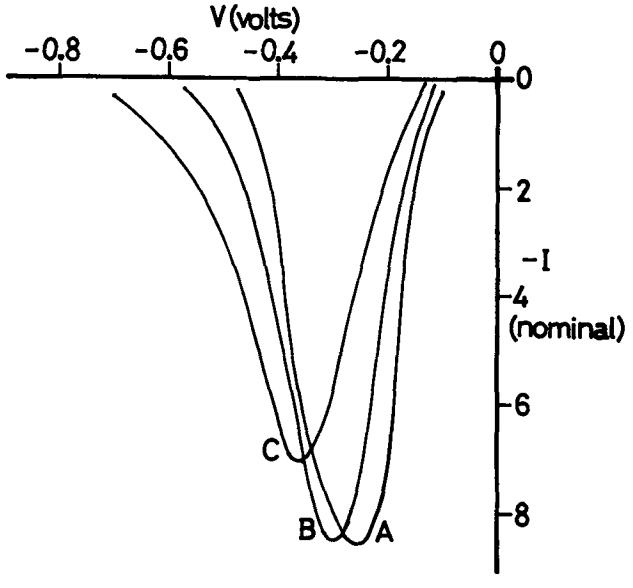

Fig. 8. Effect of sweep rate with reaction [A] rate-determining (cathodic scans). $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 0.3$. Curve A: $k_1/c = 0.2$, $k_2/c = 800$. Curves B and C represent a tenfold and hundredfold increase in c.

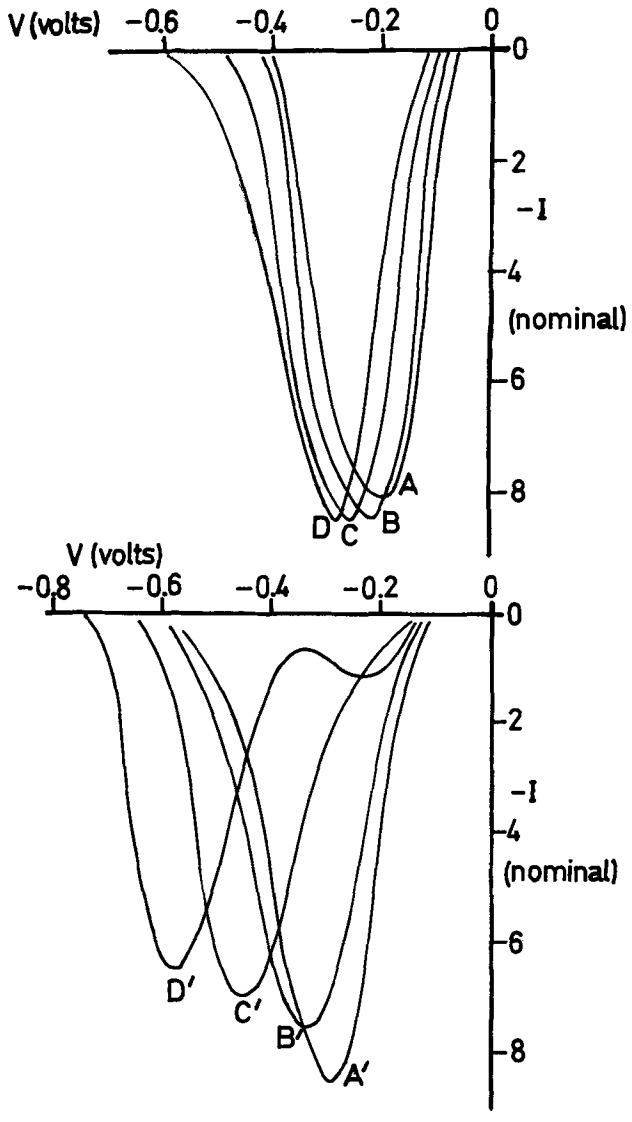

Fig. 9. Effect of relative changes in k_1 and k_2 (cathodic scans). $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 0.3$. Curves A-D: $k_2/c = 80$, $k_1/c = 20$, 2.0, 0.2, and 0.02, respectively. Curves A'-D': $k_1/c = 0.02$, $k_2/c = 80$, 8.0, 0.8, and 0.08, respectively.

General Conclusions

The above calculations demonstrate that symmetrical peaks closely resembling those for a single electron process with a low heterogeneity factor result from a two-stage two-electron reduction process in which the second stage is rate-determining. The criterion for this condition is that the rate of the first stage near the potential of the peak maximum should be at least 1½ orders of magnitude greater than that of the second stage under the same conditions. The peak maximum occurs close to the reversible potential for the first step (assumed to be more cathodic than that for the second step, otherwise two separate peaks result). The general shape of the peak is determined by the heterogeneity factor of the first step, with that for the second, rate-determining step, even though it may be greater, having little effect. Attempts to explain peak symmetry by the occurrence of reactions whose orders are higher than unity (4) are therefore unnecessary. The value of $dV_{max}/d \log_{10} c$, where V_{max} is the potential of the peak maximum, is in the region of 50 mV, in good agreement with the experimental value (1, 13). This corresponds to a value of the transfer coefficient of about 3/2, which is consistent with a rate-determining primary charge transfer (with $\beta = ½$) (13). The use of a simple pseudoequilibrium assumption (*i.e.*, the substitution of Eq. [24] in the cathodic reaction of Eq. [22]), which results in a transfer coefficient equal to $1 + \beta$

($\simeq$3/2) in a numerical evaluation leads to peaks that differ considerably in shape from those determined from a solution of the simultaneous rate equations. On this basis, it is suggested that transfer coefficient values obtained by fitting leading edge slopes or other peak parameters to those expected from simple models involving multielectron transfer steps may be completely erroneous. There is no question that the most useful parameter that can be obtained from a study of potentiodynamic scans under irreversible conditions is the dV_{max}/d ln c value. This should be measured over at least two decades to ensure that the irreversible condition applies. In all cases, it should be possible to derive a true kinetic transfer coefficient value from this parameter, and thus the number of pseudoequilibrium steps preceding the rate-determining charge transfer may be determined. Studies of multielectron steps by the potential sweep method must use a numerical computation based on the rate equations for the discrete single electron steps to find best fits for rate parameters. Parameter values will generally have to be supplemented by other studies, for example, rates at constant current or rates at constant potential as a function of time.

For the special case of the adsorption and reduction of the oxygen layer on platinum, examined here as a model, no attempt has been made to fit exact values of parameters in the rate equations. However, results may be summarized as follows:

1) Initial adsorption under anodic conditions is sufficiently fast as to be reversible and consists of the formation of —OH after a one-electron transfer, with a second very rapid step whose reversible potential is lower by about 300 mV[2] (standard state, $\theta = \frac{1}{2}$), which consists of —O formation.

2) The rate constant for the first anodic step (—OH formation) falls exponentially with coverage. This superficially gives the effect of a large Temkin term. The true value of the Temkin term in this step is 6-9 kcal/equivalent ($r/RT \simeq$ 10-15). Such an explanation gives a general peak shape in agreement with experiment. As the second anodic stage is in pseudoequilibrium, it is not possible to determine its Temkin parameter.

3) The exponential fall of the rate constant of the first reaction step with coverage results from surface rearrangement. This probably occurs as a consequence of, or alongside, the second oxidation step. A place-exchange mechanism is probably involved (6).[3] The net result is a uniform surface phase with a "fossilized" rate constant in the cathodic direction for the first anodic (second cathodic) reaction step. It is not possible to determine whether the rate of the second anodic step is coverage-dependent.

4) The rate-determining step in the cathodic direction is the second electron transfer (*i.e.*, —OH reduction). However, the shape and position of the cathodic peak are determined by the standard potential and r value of the primary (—O) reduction step.

This model gives rise to essentially symmetrical peaks with the correct dV_{max}/d log c dependence. A typical computed plot for a medium coverage case ($k_1^\circ/c = 10$, $q = 6.9$, $r_1/RT = 13$, $r_2/RT = 6$, $k_2 = 80$) is shown in Fig. 10. In practice, r_2/RT is probably lower than 6, and V_d rather more than 300 mV to agree with the correct shape and position of the cathodic peak. At high anodic potentials a further process starts to intervene: that of evolution of molecular oxygen. This is reflected in an extension of the leading edge of the cathodic peak close to the voltage axis, which represents reduction of adsorbed oxygen molecules. The over-all process, however, is undoubtedly not so simple as indicated above. This is illustrated by the plot in Fig. 11, which shows the variation in position of computed cathodic scans as a function of

[2] At least for coverages greater than about 0.2. See Appendix.

[3] It is not a rate-determining place exchange (19), which is inconsistent with the experimental dE_{max}/d log c value [see, however, Appendix and Ref. (23)].

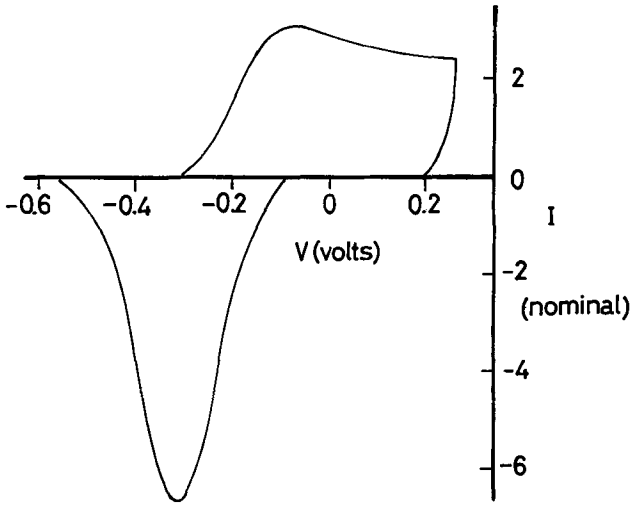

Fig. 10. Calculated anodic and cathodic scan for partial coverage case $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 0.3$. $k_1^\circ/c = 10$, $q = 6.9$, $k_2/c = 80$.

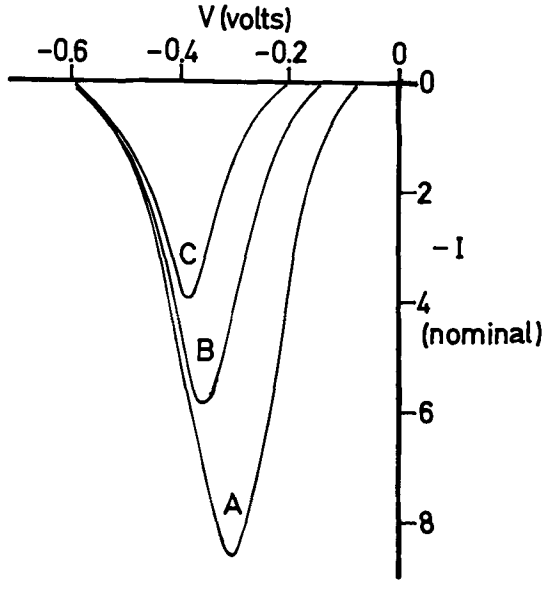

Fig. 11. Effect of partial initial coverage on cathodic scans. $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 0.3$. $k_1/c = 0.02$, $k_2/c = 80$. Curves A, B, C: θ_2 initial = 0.90, 0.50, 0.25, respectively.

coverage ($k_1/c = 0.02$, $k_2/c = 80$, $r_1/RT = 13$, $r_2/RT = 6$, $V_d = 300$ mV). Initial θ_2 values of 0.9, 0.5, and 0.25 are considered. It can be seen that the peaks stack with their trailing edges together, but narrow appreciably with decreasing coverage. In practice, this is not observed—on platinum, peaks at low coverage are as broad (or broader) than those at higher coverage, though their trailing edges do approximately stack together (6). On palladium, however, where the same process may apply, trailing edges are shifted cathodically as a function of increasing coverage (6). This argues that r_2/RT and V_d are coverage dependent (6), though this effect is of comparatively small order compared with the major change of k_1 with coverage. If standard potentials are expressed using $\theta = 0$ (rather than $\theta = \frac{1}{2}$) as a standard state, then trailing edges of peaks with differing r values (in the cathodic direction) stack together (*i.e.*, $E_0^{\theta=0} = E_0^{\theta=1/2} - r/2F$). This is illustrated (reading cathodically) by Fig. 2 in Ref. (6). Expressed on this convention V_d (representing the change in free energy of the —O deposit at low coverage) is therefore not strongly θ-dependent on Pt, but apparently is on Pd.

Recently, certain authors (20) have argued that the oxygen compound on the surface of platinum and other

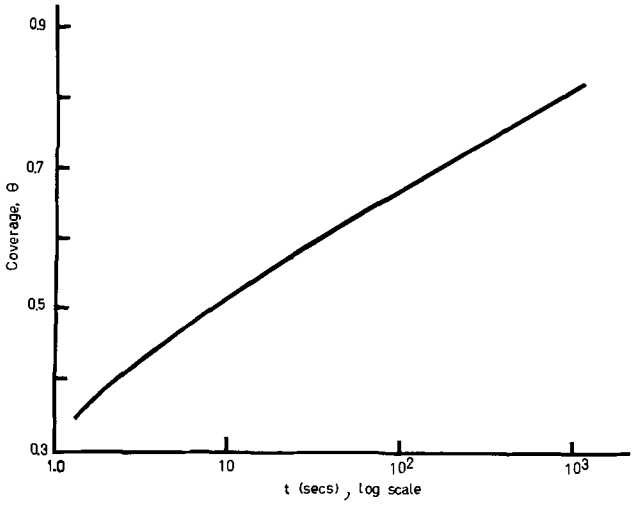

Fig. 12. Calculated potentiostatic film growth curve. $V = 0.1$ (1.2V vs. hydrogen), $k_1 = 10$, $r_1/RT = 13$, θ initial $= 0.3$. Reaction [B] in pseudoequilibrium.

Pt group metals and gold is entirely in a superficially adsorbed form until a coverage corresponding to 2 —O groups/Pt atom is reached. As a result of the present analysis, and of previous work (6), this would appear to be an oversimplification. This idea is also supported by recent ellipsometric work (21) under cyclic scanning conditions, which demonstrate that irreversible surface changes perhaps connected with place-exchange occur (6). It may well be that the equivalent of 2 adsorbed —O atoms/Pt atom represents only the first monolayer of unit cells of an epitaxial surface phase, whereas formation of a true phase oxide, involving rearrangement of deeper platinum layers, requires considerably more energy. Such conclusions, however, require further investigation for confirmation.

Several authors have shown that film growth on Pt in the submonolayer region is logarithmic with respect to time (22, 13). This concept is easily explained if film growth is considered to be totally irreversible under Temkin adsorption conditions, ignoring pre-exponential θ terms (*i.e.*, the $(1 - \theta)$ metal site term in Eq. [22]) (22). Gilroy and Conway (13), on the other hand, argue that an inverse logarithmic growth would be expected if pre-exponential θ terms are taken into account, based on the analytical solution of the integral of an equation of the same type as Eq. [22] under Langmuirian conditions ($r = 0$). Accordingly, a numerical integration of Eq. [22] under Temkin conditions at constant potential has been carried out, using $k_1^\circ = 10$, $q = 6.9$, and $r_1/RT = 13$, at $V = 0.1$V (*i.e.*, taking the reversible potential to be about 1.1V *vs.* hydrogen as previously discussed, at about 1.2V). As before, reaction [B] is assumed to be a pseudoequilibrium. The calculated curve (assuming $\theta_2 \simeq 0.3$ at $t \simeq 0$ as an initial boundary condition) is shown in Fig. 12. The initial rapid rise, followed by a slower logarithmic growth, is characteristic of experimental curves. This lends additional support to the ideas discussed above. However, it must be admitted that such experimental curves show no tendency to go to a limit at $\theta = 1$, indicating that bulk oxidation (place exchange) occurs at higher coverages—*i.e.* the concept of an active site $(1 - \theta)$ term is probably meaningless at high coverages.

Acknowledgment

This work was carried out as part of the basic research program of the Institute of Gas Technology, Chicago, Illinois. The author wishes to express his thanks to the Director and members of the computer staff for the valuable aid that made this study possible.

Manuscript submitted March 13, 1972; revised manuscript submitted Aug. 14, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

APPENDIX

Since this paper was prepared for publication, two important sets of experimental data on the platinum oxidation-reduction process have become available, namely those of Vetter and Schultze (23), and Koslowska, Conway, and Sharp (24). In many ways, they confirm the major suppositions used above, in particular, the initial reversibility of the anodic peak (in terms of low or negligible Tafel slopes) and the value of the Tafel slope for the cathodic process at medium to high coverages, in addition to the fall in the rate constant for oxidation by several orders of magnitude as a function of coverage (in terms of the intersection point of the anodic and cathodic Tafel lines (23).

Above, the anodic peak was considered to consist only of a single phase material, initially —OH, converted very rapidly to —O. Rearrangement of the surface caused the —OH rate constant to fall with coverage, so that an irreversible cathodic peak, kinetically controlled by —OH reduction occurs at the surface redox potential for the rapid —O → —OH process (about 0.8V *vs.* hydrogen in the same solution). The results reported in Ref. (24) show that the assumption of a single surface phase needs modification. Two initially reversible phases occur at low coverages ($\theta <$ ~0.2, based on —O coverage), and at least part of these surface compounds persists along with the rearranged surface phase [see also Ref. (12)], especially at low temperatures. These peaks occur between 0.8 and 1.0V and are normally partially masked by solution impurities [see for example the integrated cyclic scans of Böld and Breiter (2), compared with a steady-state θ-V curve obtained under high purity conditions, shown by Damjanovic and Brusic (25)]. The existence of a reversible phase at low coverage, followed by a progressively irreversible phase above 1.0V, is supported by capacitance measurements (23), and has been suggested as an explanation of oxygen reduction Tafel slopes (25, 17) and rest potentials of Pt oxygen electrodes (17). These initial phases represent adsorption not involving nearest neighbor sites (*i.e.*, where rearrangement is not possible, as discussed above).

In the analysis given in the text, it was proposed that the reversible potential of the —O → —OH reaction changes with coverage. This explains the cathodic translation of the reduction peak at increased coverage (6) and the broadened quasi-reversible peak at low coverage (12, 24), where the peak aspect ratio is controlled by r_1/RT (see Fig. 9), owing to the relative change in the rates of the two steps at the same potential. This change in reversible potential is confirmed by the translation of the cathodic Tafel lines as a function of coverage (23). Thus the initial reversible phase peaks may consist of —OH rather than —O [as suggested in Ref. (24)], if the surface redox potential for the process —O → —OH is sufficiently anodic at low coverage. The rearranged ($\theta > 0.2$) phase, due to its different free energy of formation, exhibits a lower (~0.8V) surface redox potential for this reaction.

It thus seems clear that the majority of the adsorbed oxygen on the surface at coverages greater than $\theta = 0.2$ behaves according to the mechanism described in the text, with the participation of small amounts of nonrearranged phases whose reduction peaks are hidden in the leading edge of the cathodic peak. The irreversible phase formed at high anodic potentials would be expected to have a limiting Tafel slope of $2RT/F$ at constant θ. This appears in the experimental results of Vetter and Schultze (23). The latter authors, however, give a very different mechanism of oxide formation and reduction from that given here, based on a place-exchange mechanism. It does not seem likely that place exchange can be involved in the reduction rate-determining step—an electron plus proton transfer must occur to explain the potential-pH dependence of the cathodic peak.

The author wishes to thank Professor Conway for his unpublished data (24) and for helpful discussions.

Technical Notes

Cathode Reactants in High Energy Density Aprotic Battery Systems

The Metallic Borosulfides

Frank M. Kimmerle* and Gaétan Giasson

Chemistry Department, Université de Sherbrooke, Quebec, P. Q., Canada

The choice of cathodic materials in aprotic battery systems represents a compromise between high cell type voltage, low equivalent weight, and compatibility with electrolyte solvent and anode material, *i.e.*, low self-discharge leading to a long shelf life. Among the several transition metal sulfides and halides evaluated (1), only one, the couple CuS/Li, seems to have been exploited commercially (2).

This exploratory work was undertaken in order to investigate the utility of other sulfur compounds. Boron trisulfide has a very high energy of formation and a low equivalent weight and thus an energy density in excess of 2000 Whr kg^{-1} for the reaction

$$B_2S_3 + 6Li \rightarrow 2B + 3Li_2S$$

Its very hygroscopic nature, its high solubility and chemical reactivity with various aprotic solvents, and its high degree of polarization render it, however, totally unsuitable as an electrode material. Although the synthesis and x-ray diffraction patterns of some transition metal borosulfides have been reported in the literature (3, 4) very little is known about their physical characteristics or chemical behavior. We suspected that these compounds, intermediate between the sulfides of the transition metals and boron, might combine the chemical inertness of the former with the high energy density of the latter.

Experimental

Synthesis of the transition metal borosulfides was most conveniently carried out by heating stoichiometric mixtures of elemental boron, sulfur, and metal in an evacuated sealed quartz or Vycor tube (2). Heating at temperatures from 600° to 1200°C was continued for 2-4 weeks depending on sample size to ensure equilibrium conditions. The synthesis using B_2S_3 and or metal sulfides yielded identical compounds but had the inconvenience that mixing of the reagents in an inert atmosphere was mandatory. Four compounds have definitely been identified from chemical analysis and comparison of their x-ray diffraction patterns with those reported in the literature. Their compositions are given as AgBS, CuBS, $Pb_2B_2S_5$, and MnB_2S_4. The latter two correspond to a 2:1 and 1:1 ratio of metal sulfide and boron trisulfide which may be regenerated by thermolysis decomposition. Further analysis of the structure was not attempted with these polycrystalline materials.

The borosulfides were found to be very stable in air, water, caustic solutions, and most mineral acids with the exception of MnB_2S_4 which decomposed slowly in water to yield MnS and boric acid. Analysis by gas chromatography (GC) after 30 days contact with three aprotic solvents, propylene carbonate (PC), dimethylformide (DMF), and dimethylsulfoxide (DMSO), at room temperature did not indicate significant solvent decomposition. The solubilities of the borosulfides (monitored by chemical analysis and atomic adsorption over a 60 day period) also indicated little variation (<5%), followed the order PC < DMF <DMSO, and were approximately equal to those of the corresponding sulfides.

Cathode disks of about 1 mm thickness and 1¼ in. diam were fabricated in the following manner. After

* Electrochemical Society Active Member.
Key words: aprotic batteries, borosulfides, lithium.

mortarizing the borosulfide, it was intimately mixed with 10-20% graphite (Fisher grade No. 38), powdered polypropylene (Du Pont), and compacted at 800 kg cm^{-2} for several minutes at 150°C onto a copper wire mesh. The porosity could be varied by including some electrolyte salt (*e.g.*, $LiClO_4$, LiBr) which was subsequently leached out. For evaluation purposes we preferred this type of electrodes: rugged, quite flexible, and uniformly smooth without cracks or imperfections. A lower polypropylene content caused a certain fragility, unevenness, and a tendency for the electrodes to flake off but it also resulted in material having higher current densities and might therefore be preferred for practical work. The prototype cells used in these studies consisted essentially of three disks: the depolarizer, a fiber glass separator saturated with electrolyte, and a thin lithium anode, pressed lightly together at the bottom of a small cylinder. Although assembled in an Argon filled glovebox, they were dipped in hot wax or covered with a layer of epoxy and kept for up to four months in the laboratory. A third electrode, consisting of a lithium ribbon plunged into the same electrolyte and connected to the cell by a Luggin capillary, was occasionally used as a reference electrode. Although its potential is without precise thermodynamic significance, it does facilitate a simple separation of the overpotentials into anodic and cathodic polarization effects.

The aprotic solvents were twice redistilled from material equilibrated for one week with activated 4A Linde Molecular Sieves. The water content (Karl Fisher Analysis) was less than 50 ppm (PC), 60 ppm (DMF), and 150 ppm (DMSO). The electrolyte solutes $LiClO_4$ and LiBr, although dried in a vacuum oven, at 150°C for 48 hr, contributed some additional moisture but further purification was not deemed necessary for evaluation purposes. All cell discharges were carried out at 3 mA with 1¼-in. disks or at current densities of 0.4 mA cm^{-2} of geometric area at 23°C. We confirmed Dey's observation (5) that PC itself constitutes a cathode reactant and will sustain 1V *vs.* the lithium electrode for several days, forming propylene (GC analysis) and Li_2CO_3 (x-ray diffraction analysis). Analogous behavior was observed with mixtures of acetonitrile (AN) and PC with LiBr electrolyte, while DMSO formed a thio ether (6). In DMF however a rapid decay of the discharge potential occurred and the initial current can be attributed to impurities from the solvent or graphite.

Thus, despite the fact that DMF displays a lower dielectric constant, lower specific conductance, and higher solubilities of the borosulfides, that it polymerizes to yield a gel in the presence of Li metal, and that lithium has not been successfully plated from Li solutions (*i.e.*, that the reaction is irreversible) (7), we chose to use a 1.4M $LiClO_4$ solution of DMF as an electrolyte since it allows us to follow the complete discharge of cathode reactant. Typical discharge curves are given in Fig. 1. For AgBS plateaus corresponding to two one electron changes can clearly be discerned and close to 100% current efficiency is observed, although not at useful potentials. The potential decreases gradually for CuBS and $Pb_2B_2S_5$ but two regions are again clearly distinguishable. MnB_2S_4 which has the highest solubility also gives the poorest performance yielding only about 15% useful discharge. The polarization of the lithium electrode remained below 0.5V during the first part of the discharge increasing slightly when the second plateau was reached.

Figure 2 indicates that the performance is significantly improved using PC or PC-AN electrolytes. For AgBS, as incidently for Ag_2S, Cu_2S, and CuS, the improvement is due almost entirely to a decrease of the polarization of the lithium anode. The CuBS now shows a distinctive plateau at 1.6V and about 50% utilization before the decomposition of the electrolyte becomes evident. Mixtures of PC and AN having a lower freezing point gave almost identical results and significant improvements in performance should be sought by changing the physical characteristics of the electrodes such as porosity, optimum thickness, etc.

An evaluation of these cathodic materials is made in Table I. Apparent current densities, electrode preparation, cell design, etc., were kept as identical as possible and thus, although arbitrarily, established a basis of comparison. Column 2 indicates that the open-circuit voltages of the transition metal borosulfides are lower than the respective sulfides and a modest 2V.

Table I. Cathodic reactant materials

Couples, Li/X	$E^{25°C}$, Volts	ΔG_f, kcal/mole	$C_{calc.}$, A-hr/g	$W_{calc.}$	$W_{pract.}$, Whr/kg DMF	PC
S	2.64		1.67	3080	—	—

CuS	2.33		0.561	1140	230	—
AgBS	2.07	−26	0.355	670	200	290
Ag_2S	2.71		0.216	560	100	—
$Pb_2B_2S_5$	2.18	−106	0.449	880	140	140
PbS	2.25		0.224	480	50	—
MnB_2S_4	2.09	−100	1.05	1720	90	90
MnS	1.92		0.616	1020	40	—

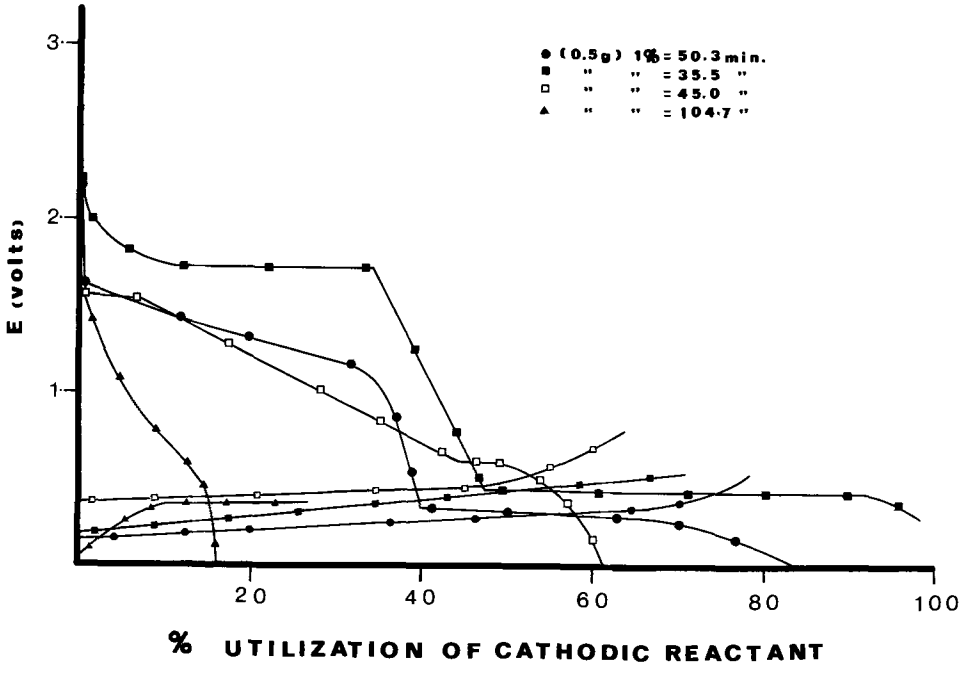

Fig. 1. Discharge characteristics of metallic borosulfide. Cathode and anode potentials vs. Li reference electrode in DMF (1.4M $LiClO_4$). ● ● CuBS; ■ ■ AgBS; □ □ $Pb_2B_2S_5$; ▲ ▲ MnB_2S_4.

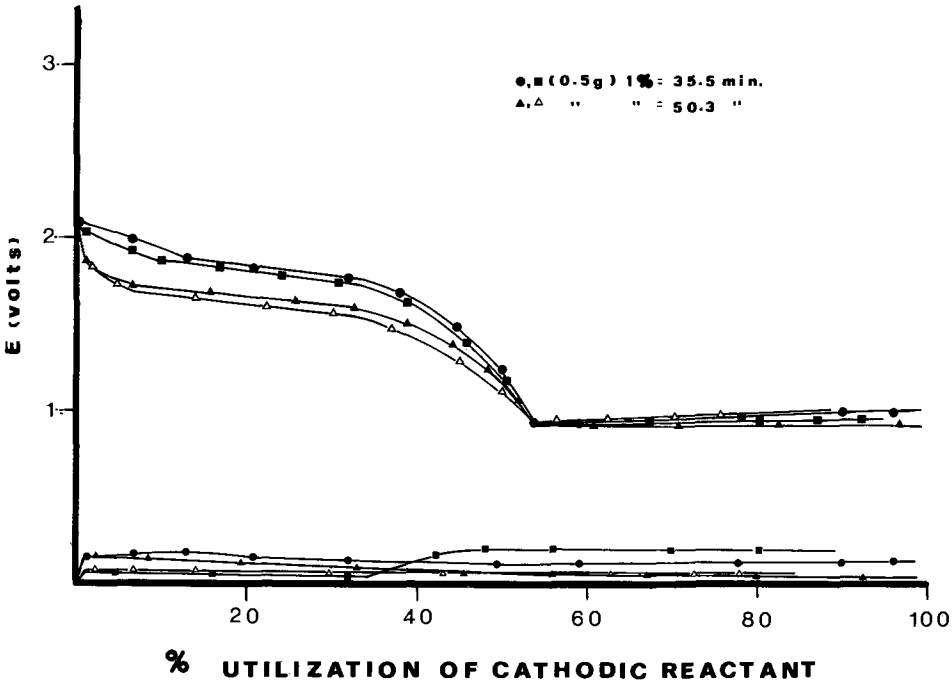

Fig. 2. Discharge characteristics. Cathode and anode potentials vs. Li reference electrode. PC + AN: volume ratio 3:1, ● ● AgBS in PC (1.0M $LiClO_4$); ■ ■ AgBS in PC + AN (LiBr saturated); ▲ ▲ CuBS in PC (1.0M $LiClO_4$); △ △ CuBS in PC + AN (LiBr saturated).

However, the lower equivalent weight and hence C (column 4) indicate the reason for the comparatively high theoretical energy density (column 5). The free energy of formation of the four new depolarizers (column 3) were calculated from the electrode potentials of the couples Li/S and Li/X and the ΔG_f for the metallic sulfides and may include an uncertainty of up to 10%. The practical energy density was established by integrating the area between anode and cathode potentials of graphs such as Fig. 1 and 2 up to the end of the first discharge plateau.

The highest energy density was obtained for CuBS exceeding that of the copper sulfides, and the other three borosulfides also show striking improvements with respect to their sulfide analogs.

Preliminary results indicate further that the CuBS and AgBS will support current densities of up to 5 mA cm^{-2} for short periods and that 50% discharged electrodes may be recharged several times although at low power efficiencies.

Conclusion

The discharge curves obtained at room temperature indicate clearly that with optimization of electrode porosity, electrolyte, and cell configuration, performance in excess of the insoluble metal sulfides can be realized. The synthesis of the metal borosulfides employed is far too expensive to warrant practical interest. Nevertheless the projected cell performance is sufficiently competitive to encourage us to establish discharge efficiencies at low temperatures and storage life at high temperatures using prototype batteries.

The Kinetics of $Fe^{2+}/FeCl_2^+/HCl(aq)$ on Pyrolytic Graphite Electrodes

B. G. Ateya* and L. G. Austin**

Department of Materials Science, Fuel Science Section, Pennsylvania State University, University Park, Pennsylvania 16802

Silverman and Dodson (1) have shown that the homogenous electron-exchange reaction of iron in strong hydrochloric acid solutions involves the ions $FeCl_2^+$ and Fe^{2+} and they give activation energies and entropies of 9.7 kcal/mole and −20 cal/deg mole for this exchange. The corresponding ferrous-ferric electrode reaction is

$$FeCl_2^+ + e^- \rightleftarrows Fe^{2+} + 2Cl^-; \quad E^\circ = 0.700V \text{ (1f HCl)}$$

* Electrochemical Society Student Associate.
** Electrochemical Society Active Member.
Key words: exchange current, activation energy.

where $FeCl_2^+$ is the predominant ferric species in concentrated hydrochloric acid solutions.

We have determined transfer coefficients, exchange currents, and the activation energy for this reaction on the edge atom and basal plane faces of pyrolytic graphite, using the rotating disk technique.

Experimental

The pyrolytic graphite electrode used was obtained from the General Electric Company and had a theoretical density of 2.223 g/cm³ and a measured density of 2.21 g/cm³, indicating negligible porosity. It was machined to a cylinder of 1/8 in. diam, with edge atom face at the ends. The electrode was fitted with shrinkable Teflon tubing over the immersed region. It was found necessary to spray a thin Teflon layer over the rod, fit and heat-shrink the shrinkable tubing, and then reinforce the tightness at the end by shrinking another short piece of tubing over the first. This technique prevented slow creep of electrolyte between the tubing and the electrode cylindrical surface. The electrode end was then machined, perpendicular to its axis, and polished, using 0.3 and 0.05μ alumina powder, to a mirror-like finish; the polished surface had a double layer capacity of about one-tenth of the machined surface. After rinsing, the surface was cleaned by briefly evolving first oxygen and then hydrogen. The same procedure was used to prepare electrodes of 0.6 cm diam, used in the transition time measurements.

No precautions were taken to ensure ultra-high purity conditions, since the rate of the redox reaction is sufficiently high to dominate over any impurity reaction. The electrode was used in a rotating disk assembly capable of a range of speeds up to 12,000 rpm, measured by a stroboscope; the electrode assembly weighed about 2g and the system gave no observable vibrations. All tests were run in 4*N* HCl which is strong enough (2) to make $FeCl_2^+$ the major oxidized species. Electrode potentials were measured using a Luggin capillary and a saturated calomel reference electrode. The junction potential was estimated to be 30 mV, giving a theoretical reversible potential for equal concentrations of ferrous and ferric iron of 0.425V *vs.* the reference electrode. The open-circuit potential observed for 0.093*N* ferrous and 0.096*N* ferric was 0.433V *vs.* the reference electrode. The counterelectrode was an inch-long platinum wire bent in a circle around the axis of the test electrode and positioned well below it: movement of the counterelectrode did not affect the results.

A blank test with no dissolved iron gave residual currents of less than 0.3 mA/cm² over the potential range −0.2 to +1.0V *vs.* the reference; the effect of residual current was negligible under all test conditions. The resistance between the test electrode and Luggin tip was estimated by the blanked-out portion on an oscilloscope trace on current interruption using a mercury-wetted relay interruptor circuit. Double-layer capacity was measured in 0.5M K_2SO_4 using a triangular voltage sweep method, so that the relative area of different electrodes could be compared. Potassium sulfate gave a wide voltage range in which double-layer capacity was constant, whereas pseudocapacity was present in 4*N* HCl as the electrode went toward the chlorine evolution potential.

Results

Using the formation constants of 30.0, 4.0, and 0.1 (3), the equilibrium ratios of ferric iron species at room temperature were calculated to be $FeCl^{2+} = 0.04$, $FeCl_2^+ = 0.68$, and $FeCl_3 = 0.27$. To test whether slow chemical steps were contributing to the rate expressions, galvanostatic transition times were measured for both anodic and cathodic currents. Over a range of transition times from 0.3 sec to nearly 30 sec, $i\tau^{1/2}$ was constant within ±3% for each current direction, giving values of diffusion coefficients of (5.7) (10^{-6}) and (5.5) (10^{-6}) cm²/sec, anodic and cathodic respectively, based on total iron concentrations. It was concluded that chemical steps did not affect the rate at the high current density used, almost 40 mA/cm². Calculations of the diffusion layer thickness showed edge effects to be negligible.

From the theory of the rotating disk electrode (4)

$$i_L = 0.62nFD^{2/3}\gamma^{-1/6}\omega^{1/2}R_b \text{ A/cm}^2 \qquad [1]$$

For the range of Reynold's numbers used, the Newman correction (5) to Eq. [1] is less than 0.1%. Figure 1 shows a typical set of data. It is seen that the equation is obeyed both for oxidation and reduction directions. Using a mean value of kinematic viscosity of 10^{-2} stokes, the measured values of D as a function of temperature are shown in Fig. 2. Thus, for the oxidized and reduced species

$$D = (5)(10^{-6})\exp\left[\frac{4500}{2}\left(\frac{T-298}{298T}\right)\right]$$

$$\pm 20\% \text{ cm}^2/\text{sec}$$

over the range $T = 273°$-$320°$K. It is evident that within the experimental error of the tests the difference between the diffusion coefficients of the oxidized and the reduced species is too small to be detected.

If the reaction is a simple, first-order, one-electron transfer reaction, the net anodic current is

$$i = i_o[(R_S/R_b) \exp(\alpha\eta/b) - (P_S/P_b) \exp(-\beta\eta/b)] \quad [2]$$

where subscripts S and b refer to surface and bulk concentrations. Since the rotating disk gives a uniform diffusion layer thickness

$$R_S/R_b = 1 - i/i_{La}$$
$$P_S/P_b = 1 + i/i_{Lc} \quad [3]$$

where i_{La} and i_{Lc} are limiting anodic and cathodic currents, which are readily measured at a given rpm. Then

$$\eta = 2.3(b/\alpha) \log q - 2.3(b/\alpha) \log i_o$$

where

$$q = \frac{1}{\left(\frac{1}{i} - \frac{1}{i_{La}}\right) - \left(\frac{1}{i} + \frac{1}{i_{Lc}}\right) \exp(-\eta/b)} \quad [4]$$

The measured polarization, η_m, was corrected for ir between the electrode and Luggin tip using the resistance r measured as described above, $\eta = \eta_m - ir$. The relative magnitude of the ir correction depended on conditions but was always less than 30%. Figure 3 shows some typical plots of η *vs.* log q.

It is concluded that the simple kinetic expression of Eq. [2] adequately describes the experimental results, at least up to currents of about 0.7 of the limiting current. The values of the transfer coefficients α and β determined from the slopes of the lines are $\alpha = 0.4 \pm 0.04$, anodic, and $\beta = 0.6 \pm 0.04$, cathodic, so that $\alpha + \beta = 1.0$. The concentrated electrolyte used makes diffuse double-layer effects fairly small (6), so that these values are significantly different from one half. From the slope and intercepts the values of exchange current density are obtained. Figure 4 shows i_o as a function of temperature; hence the apparent activation energy, $E^{\ddagger}$, is estimated to be 11.5 kcal/mole, with true values (7) of 18.0 kcal/mole anodic, 1.8 kcal/mole cathodic. The double-layer capacity was estimated to be 35 ± 3 μf/cm^2, in the potential region 0.1-0.5V (*vs.* standard calomel reference) where residual current and surface adsorption are a minimum.

The experiments were repeated using the basal plane of the pyrolytic graphite as the reacting face. A 0.3 cm thick disk containing a 0.15 by 0.15 cm hole was fitted to a corresponding stud on a cylinder of the graphite cut to give edge atom face contacting basal plane face, thus acting as a current collector. The double-layer capacity was 32 ± 3 μf/cm^2 both for unpolished and polished basal plane face. However,

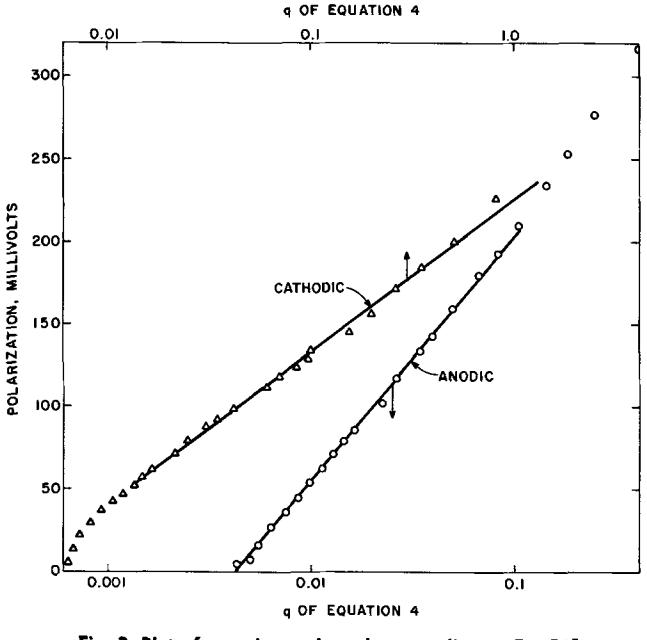

Fig. 3. Plot of experimental results according to Eq. [4]

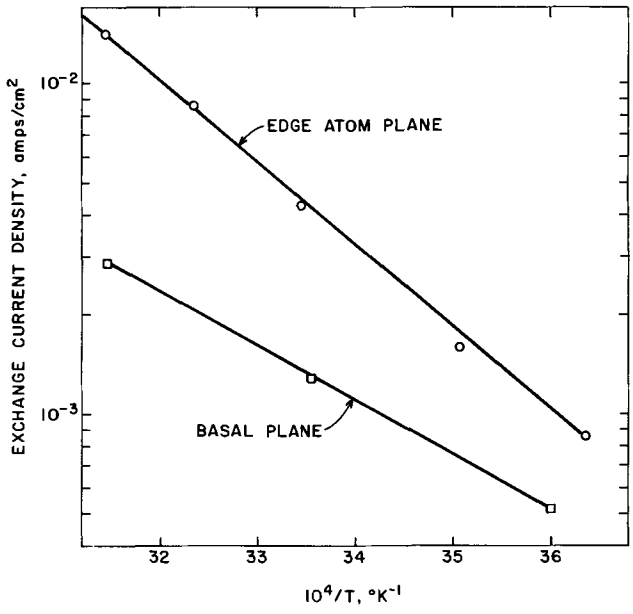

Fig. 4. Activation energy plot of exchange current

because the pyrolytic carbon is an approximation to a single crystal of graphite, the electronic conductivity normal to the basal plane is lower and somewhat higher ir effects were observed via the blanked-out portion on current interruption. The exchange current density for the basal plane face was three to four times smaller than that on the edge atom face, depending on the temperature, as it also appeared to have a slightly lower activation energy (see Fig. 4).

Conclusions

By rotating disk electrode measurements it is concluded that the diffusion coefficients of both iron species in 4N HCl are about (5) (10^{-6}) exp [4500/2 (T − 298/298T)] ± 20% cm^2/sec. The kinetics of the reaction

$$FeCl_2^+ + e^- \rightleftarrows Fe^{2+} + 2Cl^-$$

on the edge atom and basal plane surfaces of pyrolytic graphite, in the presence of excess H^+ and Cl^-, appear to be first order in iron species with one-electron transfer. The transfer coefficients are α(anodic) = 0.4 ± 0.04 and β(cathodic) = 0.6 ± 0.04. These values are in good agreement with transfer coefficient values on platinum in different media (8). Exchange current density at 25°C is (4) (10^{-3}) A/cm^2 for concentrations of 0.094N ferric, 0.06N ferrous, or k = (5.2) (10^{-4}) cm/sec, assuming unit activity coefficients. This agrees with the value of 2.29 × 10^{-4} cm/sec reported by Galus and Adams (9) for the same reaction at carbon paste electrode. The apparent activation energy over the temperature range 273°-320°K is 11.5 kcal/mole. This is slightly larger than the value of 9 kcal/mole on platinum in 1N $HClO_4$ reported by Randles (10). The rate parameters are based on unit polished surface area, with double-layer capacity in 0.5M K_2SO_4 of 35 ± 3μf/cm^2. The rate constant on basal plane of the same reactive area as the edge atom plane is (1.5) (10^{-4}) cm/sec at 25°C, and the activation energy is 9.5 kcal/mole. The Newman J factor (11) for these exchange currents is roughly 0.05, so that correction for the position of the Luggin capillary is negligible.

Brief Communication

Vapor-Deposited Gold Electrodes: Effects of Undercoatings

Radoslav Adzic,[1] Jean Horkans,† B. D. Cahan,* and Ernest Yeager*

Department of Chemistry, Case Western Reserve University, Cleveland, Ohio 44106

Vapor-deposited metal-film electrodes on smooth glass substrates are attractive for optical reflectance studies of electrochemical systems because of the high optical quality of the surface and a ratio of true to apparent area relatively close to unity. With gold, the double layer capacity of the vapor-deposited films has been found by the authors to be approximately one-half that observed on mechanically polished electrodes of the bulk metal at the same potentials. Metals such as gold, however, do not adhere well when deposited directly on a glass substrate, and some kind of undercoating generally has been used by various authors (1-4) in order to obtain adherence, *e.g.*, Paik *et al.* (3) used glass Ta-Pt-Au. A number of substances yield adherent vapor-deposited gold films. The purpose of this note is to call attention to the fact that these undercoats can seriously interfere with the optical and electrochemical measurements.

Four undercoats on glass have been examined for gold films: a sputtered tantalum underlayer, a platinum over tantalum layer, a sputtered titanium underlayer, and a sputtered niobium layer. Only the niobium was found to be a satisfactory undercoating.

The glass substrate (microscope slide) was cleaned by ultrasonic treatment first in Alconox solution and then in distilled water and finally vapor degreased in isopropanol. After the vacuum chamber was pumped down to a pressure of $\sim 10^{-6}$ Torr, the substrates were heated to ~200°C to drive off any residual volatile impurities and then maintained at ~100°C during the course of vapor deposition. The Nb is presputtered for ~1 hr before the shutter is opened and a film of approximately 10-50Å thickness is deposited on the substrate. A thick (2000-5000Å) film of Au is evaporated on this undercoating in the same vacuum system without exposing the Nb layer to air.

A much better vacuum than the 10^{-6} Torr available for the present work is required for the vapor deposition of most metals to avoid oxide formation. Fortunately, gold does not oxidize and hence high quality films could be deposited even with this poor vacuum.

The current-potential behavior in the double layer region of such an Au electrode in 1*N* $HClO_4$ is shown in Fig. 1. The squareness of the voltammogram indicates that the primary process occurring in this po-

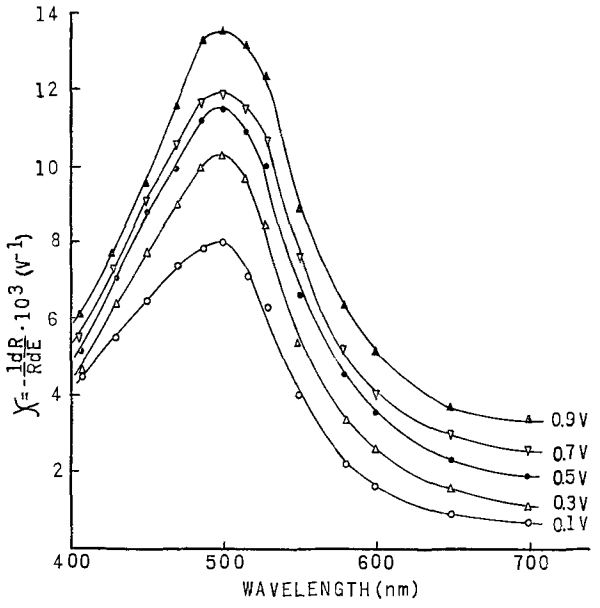

Fig. 2. Wavelength dependence of the electromodulation coefficient, $\chi = -\frac{1}{R}\frac{dR}{dE}$, at different potentials, α-Pd-H reference electrode, for evaporated gold electrode with a niobium undercoating in 1M $HClO_4$. Angle of incidence = 45°, parallel polarization.

tential region is double layer charging. No small peaks are observed which would indicate the presence of impurities or interference from the undercoat.

The electroreflectance was measured at various electrode potentials using an a-c potential modulation (35 mV rms) with a phase sensitive detection system and a single reflection. In Fig. 2 the in-phase portion of the electromodulation coefficient, $\chi = R^{-1}dR/dE$, measured at 45 Hz is shown; under these conditions, the out-of-phase portion of the signal is very small compared to the in-phase portion. The magnitude of χ increases with increasing electrode potential. The position of the peak at 500 nm is independent of potential. The electrochemical and optical behavior of the Au electrode with a Nb undercoat are in good agreement with results obtained using bulk Au either electropolished or mechanically polished.

Substantial complications have been encountered with other undercoatings. The use of Ta directly under Au has been found to be unsatisfactory because of apparent formation of a Ta-Au alloy or compound with considerably different spectral properties than pure Au. A Ta-Pt-Au sandwich was tried with the intermediate Pt layer to isolate the Ta from the Au. The Pt, however, interfered considerably with both the electrochemical and optical measurements. The voltammetry curves showed evidence of hydrogen peaks involving platinum and the wavelength and potential dependence of χ was changed as can be seen from a comparison of Fig. 2 with corresponding figures in earlier publications (1, 2). The changes in the electroreflectance are believed to have been caused by partial exposure of Pt or a Pt-Au alloy.

Titanium was also investigated as a possible undercoat. Effects due to Ti were evident in the voltammetry curves with the appearance of an additional peak at ~0.95V *vs.* α-PdH reference electrode. The addition of titanium sulfate to the solution was found to intensify this peak, thus indicating that titanium probably entered the solution from the substrate layer. During cyclic voltammetry studies with halide ions present in solution, the Ti undercoat was attacked sufficiently rapidly that the disappearance of the undercoat could be seen from the reverse side through the glass after a few hours. This raises questions concerning the use of Ti as an undercoat for gold [see, for example, Ref. (4)].

Niobium appears to be a satisfactory undercoat material, showing good agreement with bulk Au electrodes in both the voltammetry and optical measurements. The only difficulty so far encountered is in unbuffered aqueous NaF solutions, where some attack of the undercoat occurs. The authors advocate the use of an Nb undercoat in studies involving metal-film electrodes.

Nonstoichiometry and Thermodynamics of Chromium Sulfides

D. J. Young, W. W. Smeltzer,* and J. S. Kirkaldy

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The composition-equilibrium sulfur pressure isotherm at $T = 700°C$ for the system CrS_x with $1.000 < x < 1.500$ is reported. The phases CrS, Cr_7S_8, Cr_5S_6, Cr_3S_4, Cr_2S_3 (trigonal), and Cr_2S_3 (rhombohedral) were found and their existence ranges determined. Cr_3S_4 has a wide range of homogeneity and deviations from stoichiometry within this range can be described with the aid of a Wagner-Schottky model. The phase changes between adjacent sulfides are first order and the free energies of these reactions are reported.

The present-day use of Ni-Cr alloys at high temperatures in sulfur containing atmospheres points up the current paucity of knowledge of the system Ni-Cr-S. Its phase diagram is, of course, essential to the understanding of chemical reactions between the components. In a companion study (1) to the present work, isothermal sections of this diagram are reported. They indicate that the lowest free energies are reached in the region of the chromium sulfide phases, this factor controlling the behavior of the ternary system. The thermodynamics of the Cr-S binary system are therefore of considerable interest. To date, however, structural, thermodynamic, and kinetic studies have failed to yield a complete and self-consistent picture.

Jellinek (2) has determined the structures and existence ranges of the chromium sulfides which are reproduced in Table I. All sulfides were synthesized at 1000°C and x-ray powder patterns determined at room temperature. Cr_7S_8 and higher sulfides were found to be stable at room temperature. On the other hand, it appeared that the homogeneity range of CrS is narrower at room temperature than at the temperature of preparation. Thus, quenching led to disproportionation. The compositional ranges were estimated from the results of synthesizing sulfides from known amounts of the elements. Therefore, they are imprecise.

More recently, Igaki *et al.* (3) studied the Cr-S system by determining the sulfur partial pressure (P_{S_2}) in equilibrium with sulfides of known stoichiometry. In contrast to Jellinek, they conclude that CrS_x in the range $1.200 \leq x < 1.390$ is homogeneous. This observation is difficult to understand as symmetry arguments (4) predict that the phase change $Cr_5S_6 \rightarrow Cr_3S_4$ is first order. Trigonal Cr_2S_3 and rhombohedral Cr_2S_3 were found to have existence ranges of, respectively, $1.420 \lesssim x \lesssim 1.463$ and $1.463 \lesssim x \lesssim 1.480$. Thus, both phases are metal excess with respect to Cr_2S_3.

Igaki *et al.* also determined the standard free energy of the reaction

$$2Cr_3S_{4+(s)} + 1/2\, S_{2(g)} \rightleftarrows 3Cr_2S_{3-(s)}$$

as

$$\Delta G^\circ = -5.90 \times 10^4 + 38.6T \text{ cal}$$

for $1270°K < T < 1370°K$. Here Cr_3S_{4+} represents the sulfur rich limit of the phase and Cr_2S_{3-} represents the metal rich limit of the trigonal phase. The only other thermodynamic information available for the system is the determination by Hager and Elliot (5) of the free energy of formation of the lowest stable chromium sulfide in equilibrium with chromium metal. They found $\Delta G^\circ = -48{,}400\ (\pm 1100) + 13.4\ (\pm 0.8)T$ cal for $1375°K < T < 1570°K$ referred to 1 atm sulfur atoms. The identification of the sulfide phase was, however, equivocal.

Despite the discrepancies between the results of Jellinek and Igaki *et al.*, it is clear that some at least of the chromium sulfides are nonstoichiometric over considerable ranges. The nature of the lattice defects responsible for these deviations from stoichiometry is of interest but no investigations in this field have been reported. Indirect evidence may, however, be found from kinetic studies of the sulfidation of chromium metal and chromium alloys by invoking the Wagner-Hauffe theory (6, 7).

Table I. Properties of CrS_x

Phase	Symmetry	Existence range: Jellinek (2)	Existence range: Igaki *et al.* (3)	Existence range: Present work
CrS	Monoclinic	Narrow		
Cr_7S_8	Trigonal	$1.136 < x < 1.149$		$1.130 < x < 1.142$
Cr_5S_6	Trigonal	Narrow		$1.190 < x < 1.203$
			$1.200 < x < 1.390$	
Cr_3S_4	Monoclinic	$1.265 < x < 1.316$		$1.286 < x < 1.377$
Cr_2S_3(tr)	Trigonal	Narrow	$1.420 < x < 1.463$	$1.423 < x < 1.463$
Cr_2S_3(rh)	Rhombohedral	Narrow	$1.463 < x < 1.480$	$1.463 < x < 1.500$

Mrowec *et al.* (8) found that the rate of sulfidation of chromium with minority additions of nickel was lower than that of pure chromium. In both cases the sulfide product was Cr_2S_3. If the nickel is assumed to be incorporated as Ni^{2+}, then the kinetic effect may be explained if Cr_2S_3 is a metal-deficit material. Thus, the introduction of cations having a lower charge reduces the number of cation vacancies and hence the cation diffusivity. This conclusion is in conflict with the observation of Strafford and Hampton (9) that the addition of molybdenum lowers the sulfidation rate of chromium. If the alloying element is incorporated as Mo^{4+}, then a metal excess structure for Cr_2S_3 must be invoked to explain the kinetic effect.

In the present study the composition-equilibrium sulfur pressure isotherm at $T = 700°C$ was constructed. From it are deduced the nature of phase transitions (first order or otherwise), the free energies of these transitions, and the existence ranges of the various sulfides. The Wagner-Schottky model (10) of nonstoichiometry is employed in a discussion of the probable point defects responsible for deviations from stoichiometry.

Experimental

Chromium sulfide of initial composition $CrS_{1.500\pm0.003}$ was equilibrated at 700°C with controlled partial pressures of sulfur. Equilibrium was judged to be attained when the sample weight was constant to within one part in 10^4 over a period of 8 hr. The composition of the sulfide was calculated from the weight loss of the sample assuming chromium to be involatile. At selected compositions, the sample was analyzed for sulfur by combustion and subsequent iodometric determination of the product SO_2. Results obtained in this way were always in agreement [to within the analytical error of ±0.1 weight per cent (w/o)] with those calculations from weight losses.

As the equilibration process is slow, the same sample was brought to equilibrium at successively lower values of P_{S_2} until a composition of approximately CrS was obtained. Reproducibility of the resulting set of P_{S_2} *vs.* x values was checked by equilibrating the CrS at a few successively higher values of P_{S_2} until a composition of $CrS_{1.50}$ was regained. It was found in this way that the error in x was ±0.003.

Sulfur pressures were controlled by mixing known proportions of H_2S and H_2 and flowing the resultant mixture over the sample at 700°C. The flow rates of the individual gases were measured with flowmeters calibrated by the soap bubble method. Gas mixtures were analyzed for H_2S by the method of Dunicz and Rosenqvist (11) and P_{S_2} was calculated from the thermodynamic data of Lewis and Randall (12). A "once-through" gas flow system was chosen in preference to a circulating gas system for the reasons enumerated by Hager and Elliott (5). Tests with argon and nitrogen showed that gas adsorption on the sample gave rise to no detectable weight change.

The temperature of the chromium sulfide sample was measured to within ±2°C and controlled at 700° ± 4°C.

Phase identification was accomplished by comparing Debye-Scherrer powder patterns with those obtained by Jellinek (2).

Materials.—Matheson ultrahigh purity hydrogen (<10 ppm total impurities) and Matheson C. P. grade H_2S were employed. For very low sulfur pressures, Matheson premixed H_2-0.5% H_2S was further diluted with hydrogen. Chromium sulfide was supplied by Atomergic Chemetals as nominally 99.995% Cr_2S_3. Its analysis is given in Table II.

Table II. Analysis of Cr_2S_3 starting material

Element	Ni	Co	Cu	Fe	Ca	Mg	Mn	V
Concentration (ppm)	<10	<20	20	110	100	18	~3	—

Results

The P_{S_2}-composition isotherm at $T = 700°C$ is shown in Fig. 1. Also shown in this figure are the results of x-ray structure determinations. All phases found by Jellinek (2) were detected. Existence ranges for the sulfides are summarized in Table I. Owing to the large uncertainty in P_{S_2} in the region $1.0 < x < 1.1$ it is not possible to state the existence range of CrS. It would appear from the results of Jellinek (2) that CrS is in fact closely stoichiometric. According to our observations Cr_7S_8 and Cr_5S_6 have quite narrow existence ranges, the results for the former being in close agreement with those of Jellinek.

All phase changes are first order with the possible exception of trigonal $Cr_2S_3 \rightarrow$ rhombohedral Cr_2S_3. The data are not sufficiently precise to determine the nature of this transition. The transition $Cr_5S_6 \rightarrow Cr_3S_4$ is clearly first order whereas Igaki *et al.* find no discontinuity in their x *vs.* P_{S_2} plot in this region.

Free energies at $T = 700°C$ for the various phase equilibria may be calculated directly from the equilibrium P_{S_2} values. Referred to 1 atm $S_{2(g)}$ they are

$$2Cr + S_{2(g)} \rightleftarrows 2CrS \qquad \Delta G°_{973} \simeq -67 \pm 4 \text{ kcal}$$

$$14CrS_{1+} + S_{2(g)} \rightleftarrows 2Cr_7S_{8-} \qquad \Delta G°_{973} = -60.1 \pm 0.4 \text{ kcal}$$

$$5Cr_7S_{8+} + S_{2(g)} \rightleftarrows 7Cr_5S_{6-} \qquad \Delta G°_{973} = -57.4 \pm 0.4 \text{ kcal}$$

$$3Cr_5S_{6+} + S_{2(g)} \rightleftarrows 5Cr_3S_{4-} \qquad \Delta G°_{973} = -55.7 \pm 0.8 \text{ kcal}$$

$$4Cr_3S_{4+} + S_{2(g)} \rightleftarrows 6Cr_2S_{3-(trig)} \qquad \Delta G°_{973} = -37 \pm 1 \text{ kcal}$$

$$xCr_2S_{3+(trig)} + S_{2(g)} \rightleftarrows yCr_2S_{3-(rhom)} \qquad \Delta G°_{973} = -32.5 \pm 0.8 \text{ kcal}$$

If Hager and Elliott's free energy of formation for the lowest sulfide is extrapolated to $T = 700°C$ a value of -70 ± 2 kcal results. The agreement between this value and the one obtained in the current work for the first reaction above indicates that the sulfide formed by Hager and Elliott was indeed CrS. Extrapolation of free energy data (3) for the phase change $Cr_3S_{4+} \rightarrow Cr_2S_{3-}$ leads to $\Delta G°_{973} = -43$ kcal, in poor agreement with the present results.

Nonstoichiometry in the phase field of Cr_3S_4 may be defined in terms of a quantity, Δ, such that the composition of the material is given by $Cr_3S_{4+\Delta}$. The logarithm of $|\Delta|$ is plotted against $\log_{10} P_{S_2}$ in Fig. 2. The slopes

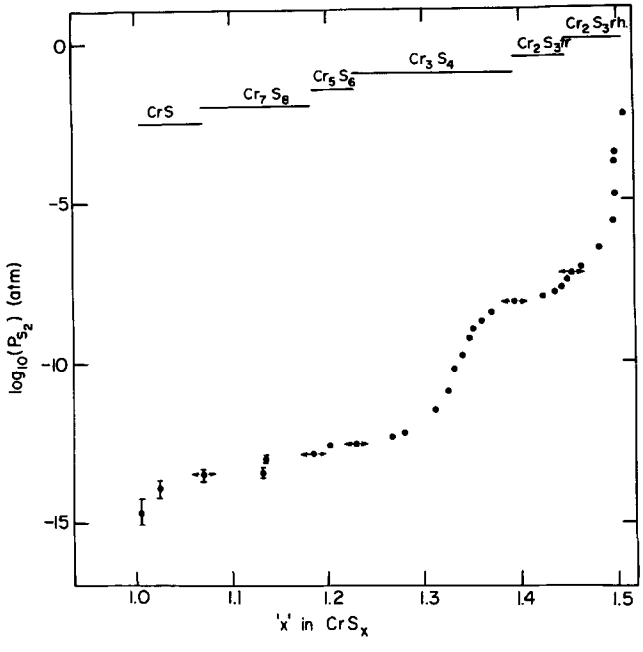

Fig. 1. P_{S_2}-composition isotherm at 700°C. Results of powder pattern phase identifications are shown in upper part of figure. Points with horizontal arrows are in two-phase fields.

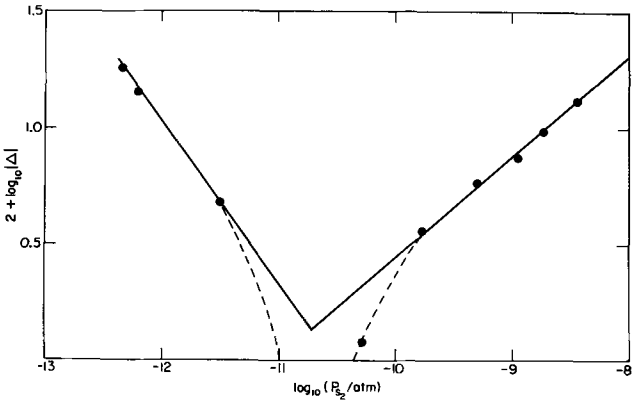

Fig. 2. Dependence of nonstoichiometry in $Cr_3S_{4+\Delta}$ on P_{S2}

of the linear portions of this plot are such that

$$\Delta \propto P_{S_2}^{1/2} \quad \Delta > 0$$

and

$$-\Delta \propto P_{S_2}^{-2/3} \quad \Delta < 0$$

This behavior is discussed in the following section.

The two forms of Cr_2S_3 both display metal excess type nonstoichiometry. The precision of our data is insufficient to deduce a pressure dependence. Strafford and Hampton (13) also find Cr_2S_3 to be metal excess.

Discussion

A defect reaction model for nonstoichiometry must not only explain the experimentally observed pressure dependence but must also be consistent with the known crystal structures of the compounds. The extraordinarily wide existence range of Cr_3S_4 and the frequent appearance of this material as a result of sulfidation of Cr and Ni-Cr alloys (1, 14) make the defect structure of Cr_3S_4 a subject of some interest. Pertinent considerations are the crystal structure of Cr_3S_4 and the adjacent phases $Cr_2S_{3(trig)}$ and Cr_5S_6.

The NiAs type structure in which all the sulfides crystallize may be visualized as consisting of approximately hexagonally close-packed sulfide ions in the octahedral interstices of which structure the metal ions reside. The sublattice of octahedral sites is, however, fully occupied only in the case of CrS. The cation sublattice in sulfides higher than Cr_7S_8 consists of alternately filled and partialy filled layers at right angles to the c axis. The partially filled layers have, in Cr_5S_6, every third site vacant, in Cr_3S_4, every second site vacant, and in trigonal Cr_2S_3, two in every three sites vacant. The rhombohedral modification of Cr_2S_3 is slightly less well ordered than the trigonal form.

It is to be emphasized that the vacancies mentioned above are characteristic of the pure stoichiometric compounds. They therefore bear no charge but are, of course, available for occupancy by other species.

According to Jellinek (2), the bonding in chromium sulfides is best regarded as consisting of ionic Cr-S bonds and metallic Cr-Cr bonds. In fact, Cr_3S_4 shows metallic conductivity (15). Whilst a purely ionic picture is undoubtedly an oversimplification it is useful in formulating defect reactions and will be employed in this discussion.

It has been suggested (15) that the half-filled metal layers in Cr_3S_4 are occupied by Cr^{2+} ions while the completely filled layers are occupied by Cr^{3+} ions. (The metallic conduction of Cr_3S_4 can be rationalized within the framework of this model.) If the sulfide ions form a truly close-packed hexagonal array, then taking the radius of S^{2-} as 1.84Å, the radius of an octahedral site is 0.76Å and that of a tetrahedral site is 0.41Å. It is therefore improbable that S^{2-} will occupy any site other than its normal hexagonal one. The radii of Cr^{2+} and Cr^{3+} are respectively 0.84Å and 0.69Å indicating a preference for octahedral sites. This tendency is reinforced by the greater crystal field stabilization energy afforded by such sites for d^4 and d^3 cations. Supernumerary (defect) cations are therefore expected to occupy octahedral rather than tetrahedral sites.

It will be convenient in the discussion which follows to distinguish three different types of octahedral sites: those normally occupied by trivalent cations; those normally occupied by divalent cations; and those sites which, in a perfect stoichiometric crystal, are vacant. A defect notation particularly well-suited to this purpose is that proposed by Rees (16) in which sites are represented by squares, □, and the real charge of the species normally occupying the site by a subscript. Thus, for example, a trivalent cation on its normal site is represented by $Cr^{3+} \mid \square_{3+}$, a vacancy where a divalent cation is expected by $\square_{2+}$, and a stoichiometric vacancy by $\square_0$. Note that the latter two species are quite different, the first having an effective charge and the last having none. Similarly $S^{2-} \mid \square_{2-}$ represents a divalent sulfur anion on its normal lattice site.

From the preceding discussions it is reasonable to suppose that the incorporation of excess sulfur into Cr_3S_4 results in disorder only in the already partially vacant metal layers. We therefore propose as the nonstoichiometric reaction

$$\begin{gathered} 1/2\ S_{2(g)} \rightleftarrows S^{2-} \mid \square_{2-} + \square_{2+} + 2h \\ 2h + 2Cr^{2+} \mid \square_{2+} \rightleftarrows 2Cr^{3+} \mid \square_{2+} \\ 2Cr^{3+} \mid \square_{2+} + \square_{2+} \rightleftarrows (2Cr^{3+} \mid \square_{2+}, \square_{2+}) \end{gathered} \qquad [1]$$

Here the expression in parentheses represents a defect complex. The incipient nucleation of the new Cr_2S_3 phase is readily apparent. Thus, equilibrium [1] is consistent with the phase change reaction

$$2Cr_3S_{4(s)} + 1/2\ S_{2(g)} \rightarrow 3Cr_2S_{3(s)} \qquad [2]$$

The equilibrium expression for [1] is readily obtained. Let n_v be the concentration of vacant sites, $\square_{+2}$, and N be the concentration of sites in the divalent cation sublattice. Then

$$n_v = N K_x P_{S_2}^{1/2} \exp(-w_v/kT \qquad [3]$$

where K_x is the partition function for $S^{2-} \mid \square_{2-}$, w_v is the internal energy change involved in the creation of a divalent cation vacancy, and $n_v << N$ has been assumed. The pressure effect noted for $\Delta > 0$ in Fig. 2 is explained. Assignment of positive holes to localized sites in equilibrium [1] is not really necessary as Cr_3S_4 is a metallic conductor (15) and the concentration of free carriers formed in the defect reaction is negligible compared to that of the intrinsically available carriers.

When deviation from stoichiometry in Cr_3S_4 occurs in the metal excess (sulfur deficit) direction, the structure is moving towards that of Cr_5S_6. Thus vacancies must be filled in the divalent cation sublattice. Since the metal atoms required to fill these sites can come only from the trivalent cation sublattice, the defect reaction must involve both metal sublattices. The following reaction is proposed

$$\begin{gathered} 20Cr^{3+} \mid \square_{3+} + 10Cr^{2+} \mid \square_{2+} + 10\ \square_0 + 40S^{2-} \mid \square_{2-} \\ \rightleftarrows 18Cr^{3+} \mid \square_{3+} + 9Cr^{2+} \mid \square_{2+} + 3Cr \mid \square_0 + 6\ \square_0 \\ + 36S^{2-} \mid \square_{2-} + 2S_{2(g)} + (2\ \square_{3+} \\ + \square_{2+} + \square_0 + 4\ \square_{2-}) \end{gathered} \qquad [4]$$

The left-hand side of Eq. [4] is equivalent to $10Cr_3S_4$ and the terms in parentheses sum to the absence of one Cr_3S_4 unit, *i.e.*, they are equivalent to zero. Again, the ionization state of Cr | $\square_0$ need not be specified as the material is metallic. However, the precipitation of the new Cr_5S_6 phase may be visualized in terms of an ionization of these species

$$\begin{gathered} 18Cr^{3+} \mid \square_{3+} + 9Cr^{2+} \mid \square_{2+} + 3Cr \mid \square_0 \\ + 6\ \square_0 + 36S^{2-} \mid \square_{2-} \rightleftarrows 12Cr^{3+} \mid \square_{3+} + 6Cr^{2+} \mid \square_{3+} \\ + 9Cr^{2+} \mid \square_{2+} + 3Cr^{2+} \mid \square_0 + 6\ \square_0 + 36S^{2-} \mid \square_{2-} \end{gathered}$$

The right-hand side of the equation is equivalent to $6Cr_5S_6$ and involves a vacancy at every third site in the divalent sublattice as required.

To obtain an equilibrium expression for [4], let n_i be the concentration of the Cr $|$ $\square_0$ species and w_i the internal energy change involved in their creation. Then, assuming $n_i << N$

$$n_i = N K_x^{-4/3} P_{S_2}^{-2/3} \exp(-w_i/kT) \quad [5]$$

The pressure dependence of deviations from stoichiometry in the metal excess range (Fig. 2) is explained.

It is of interest to relate Δ and P_{S_2} with the intrinsic, or stoichiometric, disorder and sulfur pressure, $P_{S_2(o)}$, at which $\Delta = 0$. From [1] and [4]

$$\Delta = (n_v - 4/3\, n_i)/4N \quad [6]$$

An intrinsic disorder reaction consistent with [1] and [4] is

$$2Cr^{3+} \mid \square_{3+} + 9Cr^{2+} \mid \square_{2+} \rightleftarrows 3Cr \mid \square_0 + 4(2Cr^{3+} \mid \square_{2+}, \square_{2+}) \quad [7]$$

whence

$$\frac{n_i}{N}\left(\frac{n_v}{N}\right)^{4/3} = \exp(-E_f/kT) \quad [8]$$

where E_f is the internal energy required to create a defect pair of the type (Cr $|$ $\square_0$ + 4/3 $\square_{2+}$) and therefore equals (w_i + 4/3 w_v). Putting $n_f = n_i = 3/4\, n_v$ leads to the definition of intrinsic disorder

$$\delta = n_f/N \quad [9]$$

Combination of Eq. [3], [5], [6], [8], and [9] leads, after some algebra, to the result

$$\Delta = \frac{\delta}{3}\left(\frac{P_{S_2}^{1/2}}{P_{S_{2(o)}}^{1/2}} - \frac{P_{S_2}^{-2/3}}{P_{S_{2(o)}}^{-2/3}}\right) \quad [10]$$

Curve fitting the data to [10] leads to estimates of $\delta = (3.27 \pm 0.04) \times 10^{-2}$ and $P_{S_{2(o)}} = (3.16 \pm 0.05) \times 10^{-11}$ atm. The success of the fit may be judged from the linearized plot in Fig. 3.

The high concentration of intrinsic defects in Cr_3S_4 and the consequently wide existence range of the material indicate that the cationic diffusion coefficient of this material should be large. Such a conclusion is supported by the observation of wide zones of Cr_3S_4 in various diffusion couple experiments (1). Studies of cation self-diffusion as a function of stoichiometry would be of interest in this context.

The metal excess type nonstoichiometry observed in Cr_2S_3(tr) and Cr_2S_3(rh) is in agreement with the findings of Igaki *et al.* (3) and Strafford and Hampton (9). Mrowec *et al.* (8), however, deduced a metal deficit structure for Cr_2S_3. The fact that these latter authors used a much higher sulfur pressure (P_{S_2} = 1 atm) may account for this apparent anomaly.

Properties of Anodic Oxide Films Formed in the Anodization of Silicon Nitride

C. J. Dell'Oca*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The anodization of silicon nitride films on silicon has been characterized using ellipsometry. Calculations made indicate that the sensitivity of ellipsometry to the anodization depends on the initial silicon nitride thickness. Ellipsometry data obtained during stepwise anodization are consistent with a model of two layers on silicon where the anodic oxide layer grows at the expense of the silicon nitride. The thickness ratio of oxide produced to silicon nitride used falls within ±0.25 of the theoretically expected value, 1.81, and depends to some extent on anodization conditions. The refractive index and growth ($\log_{10} J$ *vs.* E) properties of the oxide are similar to those of anodic oxides of silicon. Stepwise etchback studies on the oxide give results which are consistent with the anodization data and which indicate an abrupt silicon nitride-anodic oxide interface.

Anodization of silicon nitride is of practical importance because it converts silicon nitride to a more soluble form and thus can be used in the localized etching of silicon nitride films passivating semiconductor devices (1). Areas can be selectively anodized while the remaining area is protected from anodization usually by a greater dielectric thickness in the form of silicon dioxide. One direct application of silicon nitride anodization has been to silicon bipolar transistors where silicon nitride is added to the existing thermally grown silicon dioxide passivation to provide protection from ionic contaminants. Here, the anodization was used to open windows in the silicon nitride to facilitate electrical contact to the active device area (2).

Because of its insulating properties, the anodization must be studied with thin silicon nitride films deposited on more conducting substrates. This poses certain difficulties in determining the properties of the oxide produced. In the past, the conversion of silicon nitride to anodic oxide has been qualitatively followed by infrared interferometry (1), and the oxide thickness has been measured by destructive techniques (3). More recently, nuclear microanalysis has been used to determine the constituents of the oxide (4). In the present investigation, ellipsometry was employed to nondestructively study the anodization of silicon nitride.

Experimental

The specimen used in these studies is shown in Fig. 1. The substrate was a chemically mechanically polished silicon slice which was thermally oxidized to provide electrical insulation. An opening cut in the insulation by photolithography and etching exposed the underlying silicon surface and precisely defined the anodization area of the subsequently deposited silicon nitride. The anodization area was kept small, about 0.13 cm^2, primarily to keep the power dissipated during anodization small; but it also served to minimize effects resulting from small thickness gradients which may occur in the silicon nitride. A substrate was accepted for deposition of Si_3N_4 if the exposed silicon surface was covered by less than 20Å of oxide. Calculations indicate that the effect of this layer on optical measurements may be neglected. Silicon nitride films were grown by chemical vapor deposition employing the reaction of $SiCl_4$ and NH_3 in H_2. The indices of refraction of the silicon nitride films were within 1.98 ± 0.02.

The anodizations were carried out at constant current[1] in a closed glass vessel containing a solution of 0.04M KNO_3 in ethelene glycol which was stirred and maintained at 25°C. In some cases, 2% water was added to the solution. The water content of the solution was periodically determined by the Karl Fisher method.

Electrical contact to the silicon was made using mercury through a window cut in the backside oxide and was facilitated by an "O" ring vacuum chuck (2). The chuck was rigidly attached to a ground glass joint through which a glass tube facilitated both vacuum and electrical connection to the chuck. The entire assembly was fitted into the anodization vessel through a mating joint. A similar mating joint on the ellipsometer held the assembly for ellipsometric measurements.

During anodization the voltage between the mercury contact and a platinized platinum cathode was monitored by a Keithley 610C electrometer and its output recorded on one channel of a Hewlett Packard 7100 BM strip chart recorder. The other channel monitored the cell current through a small precision resistor. A Cimroon 7400A digital voltmeter was used to give precise voltage readings and to hold the final voltage value at the end of each anodization.

Anodizations were carried out in a stepwise fashion. After each anodization step the anodized surface was rinsed with a spray of isopropyl alcohol, blown dry with nitrogen gas, and measured with a Rudolph ellipsometer. Unless otherwise stated, all thickness and refractive index measurements were made by ellipsometry at an angle of incidence of 70° and employing an He-Ne laser light source of 6328Å wavelength.

Calculations

Based on prior evidence (1, 3), the expected optical model consists of two layers on silicon where the outer layer, presumably anodic silicon dioxide, grows at the expense of the silicon nitride layer during anodization (Fig. 1). Ellipsometry of such a model can best be understood by first considering the case of a single nonabsorbing homogeneous film on silicon. In ellipsometry the growth of such a film is characterized by an ellipsometry curve (a plot of Δ vs. ψ, which are quantities measured in ellipsometry) with film thickness as a parameter along the curve. Within rather wide limits, this curve is unique to the index of refraction,[2] n, of the film (5). Thus, in the anodization of Si_3N_4 it is expected that the ellipsometry measurements would begin at a point representing its thickness on the silicon nitride ellipsometry curve. As anodization proceeds, the ellipsometry curve obtained would eventually approach and end on the curve for oxide when anodization of the silicon nitride is complete. This general behavior can be seen in Fig. 2 which presents some representative calculated conversion curves. In this graph, the solid curve to the left represents a portion of the ellipsometry curve covering the range from 400 to 1500Å of only a silicon nitride layer on silicon. Similarly, the upper and lower solid curves are portions of the curve for only a silicon dioxide film on silicon. The dashed lines are the conversion curves for various initial thicknesses of Si_3N_4 calculated using indices of refraction of 1.46, 2.00, and $3.862-0.0335j$ respectively for the oxide, nitride, and silicon substrate, and a conversion ratio of 1.75. The conversion ratio (CR) is the thickness ratio of oxide produced to silicon nitride consumed in the anodization.

Several points can be made from these calculations. First, ellipsometry will have the highest sensitivity to conversion if the Si_3N_4 is about 900Å prior to anodization. Other thicknesses give rise to smaller Δ-ψ loops. Second, ellipsometry points must be obtained away from the parent curve if they are to be useful. This is because, *e.g.*, in the conversion of 1000Å of Si_3N_4,

[2] The index of refraction is written as $N = n - jk$.

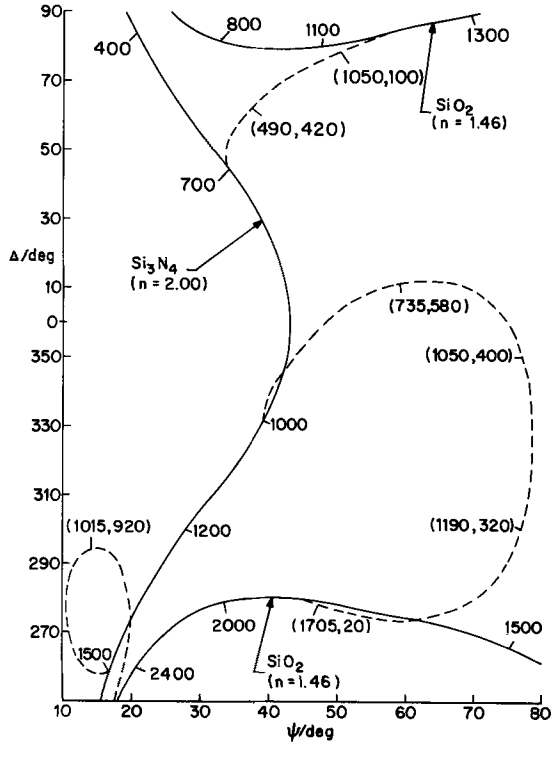

Fig. 2. Calculated conversion curves (broken curves) for Si_3N_4 films of 700, 1000, and 1500Å. Numbers in brackets respectively indicate thickness of oxide produced and Si_3N_4 remaining in angstroms.

initially during the anodization the composite film (the two layers treated as one) still looks much like a thinner silicon nitride film when in fact the oxide plus nitride is thicker than the original film. In fact, although it might be normal to expect that as conversion occurs the index of refraction of the composite film gradually changes from that of Si_3N_4 to that of the oxide, this is not always the case. For example, the far left point of the 1500Å conversion curve represents a composite film with an apparent index of refraction of about 3. On the other hand, in the conversion of 1000Å of Si_3N_4, there is a region immediately after conversion begins where the composite film has a higher index of refraction than Si_3N_4, while near the end of the conversion the composite film has a lower index of refraction than SiO_2. Therefore, the composite film may appear optically more or less dense than either of its constituents.

Results

Ellipsometry of anodization and etchback.—General agreement was found between calculated and experimental ellipsometry conversion curves for silicon nitride films ranging from 500 to 1500Å; but, because of greater sensitivity, the study was centered around films between 910 and 950Å. In order to illustrate the characteristics of the ellipsometry results and the analyses used to arrive at the properties of the oxide, two examples are discussed. One represents an anodization (Fig. 3) while the other represents a different anodization followed by an etchback (Fig. 4).

Figure 3 shows an ellipsometry curve typical of anodization. The experimental points were obtained at intervals in the stepwise anodization of 916Å Si_3N_4 film at a current density of 20 mA/cm^2. These results were curve fitted with the aid of a computer which, when given the initial thickness (916Å) and index of refraction (1.98) of the Si_3N_4 layer, varied the index of refraction of the oxide produced and the conversion ratio until the mean square deviation between the experimental points and the calculated curve was minimized. The layers were assumed to be nonabsorbing. The dashed line represents the best fit to the data and yielded a conversion ratio of 1.81 and an index of refraction, n, of 1.45 for the oxide. The thickness of

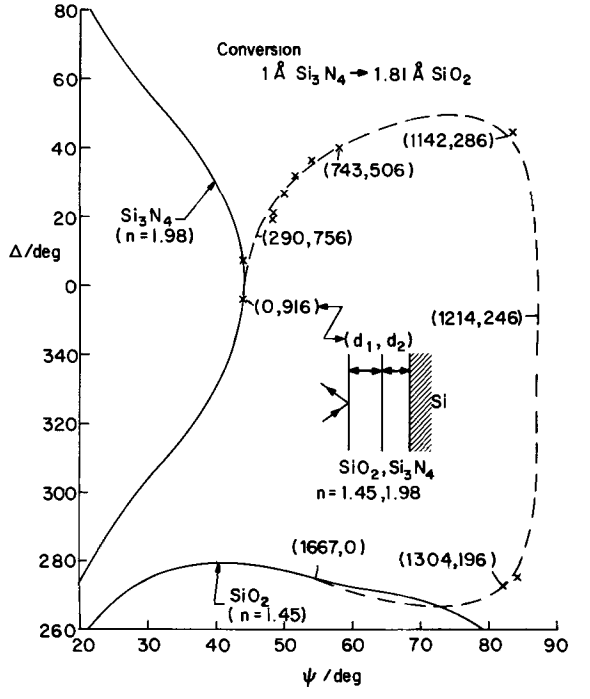

Fig. 3. Ellipsometry results from anodization of a 916Å Si_3N_4 film at 20 mA/cm^2. Dashed line is computed from the model and values given in the figure. Curves for Si_3N_4 and SiO_2 are also shown (solid lines).

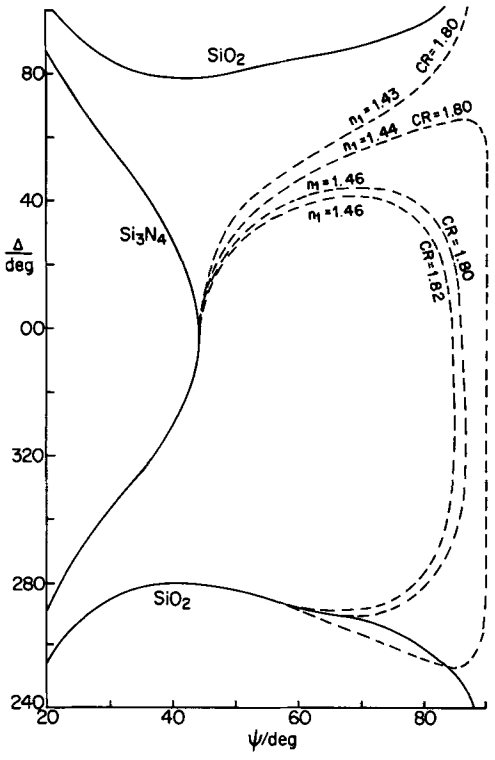

Fig. 4. Calculated conversion curves for small independent variations in *CR* and index of refractions of oxide (n_1).

each layer at each experimental point was also determined.

It is difficult to show how *CR* and n_1 enter into the curve fitting; however, an indication of the sensitivity of ellipsometry to separate variations in these quantities is given in Fig. 4. Quite distinct curves are calculated for small changes in these quantities. Therefore, determination of these quantities can be accurately made.

A typical etchback ellipsometry curve is shown in Fig. 5. Here, a 929Å silicon nitride film was first partially anodized and then etched back. The etchback points (open circles) trace out a curve which, as expected, eventually approaches the ellipsometry curve

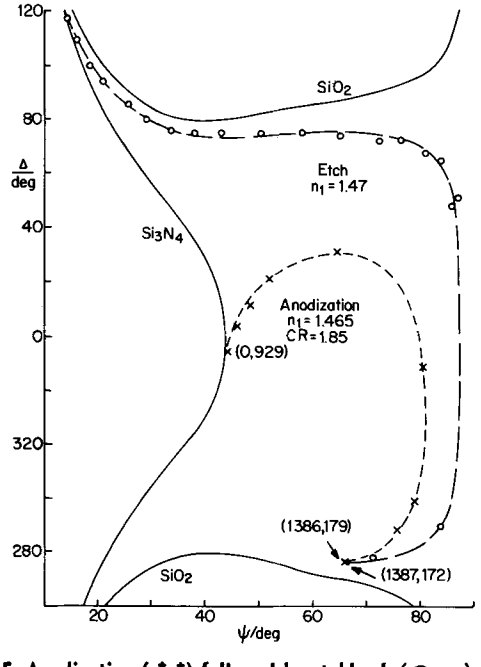

Fig. 5. Anodization (-*-*) followed by etchback (○ —) ellipsometry results. Broken lines computed from $n_2 = 1.98$ and n_1 and *CR* as shown.

for silicon nitride as the oxide is removed. These points were fitted using essentially the same computer program as in fitting the anodization results. In this case, however, the index of refraction of the oxide and thickness of the silicon nitride remaining after anodization were varied to obtain the best fit. The refractive index of the silicon nitride was known. The best fitting curve to the etchback results is given in the figure and indicates that the oxide has a refractive index of 1.47.

Since the approach to fitting the anodization and etchback results are independent of each other, the parameters determined may be directly compared for consistency. That is, the refractive index of the oxide and the thickness of each layer after anodization or prior to etchback may be compared. In Fig. 5, a refractive index, for the oxide, of 1.47 determined from etchback compares favorably with 1.465 from anodization. (More comparisons will be given later in the discussion of the oxide properties.) In Fig. 5 the final thicknesses of the oxide and silicon nitride as determined from anodization were 1386 and 179Å, respectively, which compares favorably with 1387 and 172Å prior to etchback as determined from the etchback results. The consistency of the thickness measurement observed in all the anodization and etchback experiments will now be discussed. The agreement was generally better for the oxide thickness, usually within about 10Å, while that of the remaining nitride was within about 25Å. The higher value for the latter occurs because in curve fitting the etchback results the ability to determine the remaining silicon nitride thickness decreases with its thickness and becomes very poor for very thin films (~100Å). At this point small changes in this thickness do not appreciably affect the etchback curve. However, the remaining silicon nitride can also be measured after all the oxide is removed and it turns out that, except for the very thin films, this value and that determined from anodization and etchback were all within 25Å. The consistency of these results indicates a precision of better than 2% in measuring total film thickness.

A summary of the anodization characteristics as determined by ellipsometry is given in Table I and these will be discussed in greater detail in the following sections.

Conversion ratio.—The conversion ratio expected theoretically on the basis of densities for converting Si_3N_4 (3.1 g/cm³) to SiO_2 (2.2 g/cm³) is 1.81. Experimentally, the observed values range from 1.55 to 2.1 and appear to depend on anodization conditions. In order to ascertain that such a range was real and not a result of the measurement technique, the conversion ratio was determined by an independent method. In this method part of the oxide was masked and retained during some of the etchback ellipsometry experiments. Because the silicon nitride has an etch rate about two orders of magnitude lower than that of the oxide, the oxide can be completely removed with insignificant reduction in silicon nitride thickness. The silicon nitride thickness was then determined precisely by ellipsometry and the oxide step was measured by the Tolanski interference technique. The *CR* measured in this way is considered accurate to the first decimal place. The *CR* determined from anodization, etchback, and the

independent method are consistent (Table II) and it must be concluded that the observed spread in conversion ratios is real.

The dependence of *CR* on anodiation conditions is not completely clear (first two lines of Table I). With 2% water intentionally added to the electrolyte the conversion ratio increases with current density of formation. However, this is based on a singe anodization curve at each formation. The values are somewhat higher and the dependence on current density opposite to that previously found for this particular solution (3). With water not intentionally added to the solution, the *CR* is higher and on the average closer to the theoretically expected value. However, the dependence on current density is less clear. The results appear to be tempered by the Si_3N_4 deposition conditions since samples from the same deposition gave more consistent *CR*'s, although the water content which varied between 0.1 and 0.3%, could also be a factor. The average *CR*'s given in Table I have a standard deviation less than 0.04.

Properties of the oxide.—The oxide is rapidly attacked by even dilute HF. In a 0.5% HF solution the ellipsometry results indicate that the first 100Å or so etch more rapidly than the rest of the oxide which etches at a constant rate. Some curves showing the removal of oxide with time are given in Fig. 6. The etch rate is about 5Å/sec with no apparent dependence on current density of oxide formation. The average etch rates from two etchback curves at each current density is shown in Table I. These etch rates are appreciably higher than that of thermal oxides of silicon. The etch solution was renewed for each etch step to reduce effects of depletion. On reaching the Si_3N_4 interface, the etch rate changes almost abruptly and an abrupt silicon nitride oxide interface is indicated in agreement with previous infrared transmission results (1). The break in the etch curves (Fig. 6) signifies the point where all the oxide is removed, and this is an indication of the ability of ellipsometry to determine the interface position from fitting etchback results. That is, the break in the curve should occur when the oxide thickness is zero. In most cases (5 out of 8) the interface was predicted within 10Å, one of these and the three worst cases 20, 30, and 50Å are shown in this figure.

	1.443	1.470

The index of refraction of the anodic oxide has a value falling within 1.45 ± 0.02 (last line Table I) and is within experimental error the same as that of thermal and anodic oxides on silicon (7). As shown in Table III, the index of refraction was generally somewhat larger when determined from curve fitting etchback results than from anodization results. At times a small change in ellipsometry measurements was found between the final anodization and the measurements prior to etchback indicating that perhaps small adjustments occur in the film with time. In general there was no noticeable dependence of refractive index on current density or water in the electrolyte. The latter has an effect on anodic oxides of silicon (7).

Kinetics of oxide growth.—Figure 7 shows a typical time development of the various layers as determined from ellipsometry during constant current formation. As expected, a linear time dependence is observed. From the rate of change of oxide thickness it is possible to calculate the efficiency of oxide formation if it is assumed that the oxide is SiO_2 with a density of 2.2 g/cm³. The efficiencies are low, in the order of 1%, and increase slightly with current density as has been found previously (3) (average values are given in Table I). Figure 8 shows a typical dependence of cell voltage on film thickness. Although there is some scatter in the data, the voltage dependence on film thickness can be described as linear within the precision of the present experiments. Of interest is the rate of change of voltage with total thickness, dV/dx, because with certain justifiable assumptions it leads to the electric field, E_1, in the oxide during growth. The cell voltage can be written as $V = E_1 x_1 + E_2 x_2 + V_o$, which is respectively the sum of the voltage in the outer and inner layers plus a constant voltage which, at a given current density, takes into account *IR* drops, contact voltage, etc. This constant is generally difficult to determine and drops out when dV/dx is taken. Two

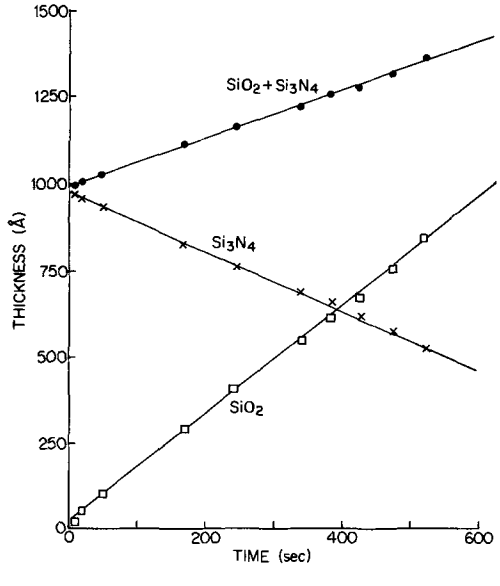

Fig. 7. Typical thickness development with time for anodization at 20 mA/cm².

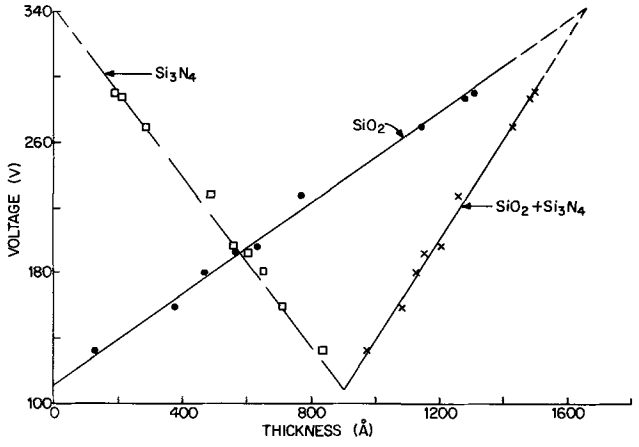

Fig. 8. Typical voltage dependence on thickness at 20 mA/cm²

assumptions are made. First, the electric field in each layer is independent of its thickness and there appears to be support for this (3, 8). Secondly, during anodization at a given current density the electric field in the silicon nitride is assumed to be the same as that determined from conductivity measurements on MNS (metal/silicon nitride/semiconductor) structures. The second assumption should be a direct consequence of the first, except that MNS measurements are usually made at constant voltage whereas the present experiments are at constant current. Spot checks indicated that in MNS structures the conductivities determined by the two methods are essentially the same as long as sufficient time for current stabilization is allowed in the constant voltage case.

Figure 9 gives the oxide growth rate on a logarithmic scale as a function of electric field. If the density of the oxide were known, this could then be transformed to the more familiar ionic current density ($\log_{10} J$) *vs.* electric field plot. The points to the right on this figure represent dV/dx determined from the voltage *vs.* total thickness data using the method of least squares. The applied current density, J_{total}, is given opposite each cluster of results. The curve to the left represents the electric field in the silicon nitride which was arrived at in the following manner. The electric field value for each J_{total} was obtained from previous

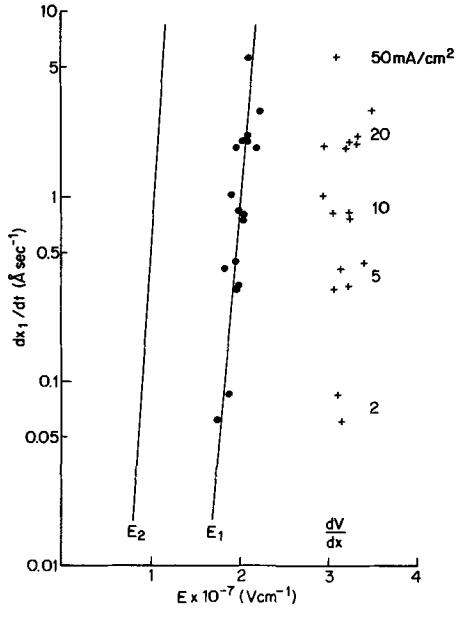

Fig. 9. Oxide growth rate as a function of electric field in the inner (far left curve) and the outer (center curve) layer and in the total film. The latter is denoted by +'s, and the formation current density is noted to the right of these points.

measurements made at this laboratory on MNS structures (9). These values were then plotted on this figure at points corresponding to the average dx_1/d_t for that J_{total}. The curve in the center is drawn through points representing the calculated electric field in the oxide. The horizontal scatter in these points is much less than that observed in dV/dx. This reduction in scatter occurs by the way CR enters into the expression for the electric field. Surprisingly, if an oxide density of 2.2 g/cm³ is assumed it turns out that the line drawn through these points is coincident with the line drawn by Young and Zobel through their results obtained from the anodization of silicon (10).

From comparisons wih previous anodizations of silicon nitride, Tripp (3) calculated, from the point where all the silicon nitride was anodized, an electric field of 1.93×10^7 V cm^{-1} for an oxide growth rate of 27.4 Å/min^{-1}. At this growth rate, our results are in agreement.

Having determined the electric field in the oxide, it is now possible to determine V_0 by extrapolation from results such as are given in Fig. 8. Here the extrapolated intersection of the oxide and oxide plus nitride curves gives the cell voltage and oxide thickness at the point when all the silicon nitride is anodized. Then the product of this oxide thickness and its electric field gives a voltage which differs by V_0 from the extrapolated voltage. Generally the values of V_0 found were not significant (1-6V) when compared to the experimental accuracy, uncertainty of extrapolation, and the magnitude of the voltage used in the anodizations. This result supports the idea that ionic conduction is controlled by the oxide bulk and not the interfaces.

Discussion

One of the questions raised in the anodization of silicon nitride concerns the nature of the silicon nitride oxide interface. In the original work, Schmidt and Wonsidler concluded that the interface was abrupt from infrared absorption evidence (1). Later Tripp corroborated this evidence but, claiming that the *IR* method was insensitive, opted for a graded oxy-nitride interface on the basis of oxide solubility data (3). That is, he found a significant difference in oxide thickness between the point where the entire film became easily soluble in HF and the point where the conversion of silicon nitride was complete, the latter being coincident with the point where the silicon began to anodize. This result was interpreted in terms of a graded interface. If this is the case then the interface extends over a significant distance, and it would be expected that the etch rate decreases across the interface. The present etch experiments employing very dilute HF did not detect such a dependence and indicate that if a graded interface exists it must be very thin (less than about 30Å). A similar conclusion has also recently been reached on the basis of micronuclear analysis (4). Re-examining Tripp's data it appears that a large portion of the difference in oxide thickness indicating a graded interface can be accounted for within the experimental uncertainties quoted. Although, as pointed out by one of the reviewers, it is possible, but not likely, that the transition region is as insoluble as Si_3N_4 in dilute HF.

The anodization of silicon nitride is similar to the anodization of silicon. The oxide produced has the same index of refraction, the efficiency of oxide growth is low, and the electric field causing oxide growth is very high. In fact it appears that the log J *vs.* E curve is the same as that found previously by Young and Zobel for the anodization of silicon (10); however, there is scatter in both sets of data. Although it was assumed in calculating this curve that the anodic oxide of silicon nitride had the same density as that of thermal oxides of silicon, this value is not critical. Some variation from this value would not significantly effect the curve because of the steep exponential dependence of ionic current on electric field in the

oxide. Similar log J *vs.* E curves may *a priori* be expected for silicon nitride and silicon anodization if the nitrogen atoms liberated in the anodization of silicon nitride do not electrically interact in the oxide, and if ionic conduction is principally controlled by the oxide and not the interfaces. Such behavior may be taken in support of the original postulate that gaseous nitrogen is liberated during the anodization (1). Recently it has been found that at low current densities about 0.1 nitrogen per oxygen atom remains in the oxide (4). Such a high concentration of impurities would be expected to affect the film properties as is the case with phosphates in anodic oxides of tantalum (6). However, the present experiments were at current densities where incorporation of nitrogen was not found (4).

In summary, the properties of silicon nitride anodization have been studied using ellipsometry. The anodic oxides produced in the anodization of silicon nitride have growth characteristics which are similar to those of anodic oxides of silicon. The refractive index is also the same except that, within the accuracy of these experiments, no dependence on water concentration was resolved for anodic oxides of silicon nitride. The present experiments indicate that the ionic conduction is largely controlled by the oxide and not by the interfaces.

Acknowledgment

The Electrical Conductivity of CaO-Doped Nonstoichiometric Cerium Dioxide from 700° to 1500°C

R. N. Blumenthal, F. S. Brugner, and J. E. Garnier

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The electrical conductivity of sintered specimens of CaO-doped CeO_2 [0.1-16.0 m/o (mole per cent)] was measured over the temperature range 700°-1500°C and from 1 to 10^{-22} atm of oxygen. All specimens of CaO-doped CeO_2 exhibited mixed conduction. Two limiting case regions were observed. At low temperatures and high oxygen pressures, the conductivity is predominantly ionic. In this region the conductivity is independent of P_{O_2} and between approximately 1 and 8 m/o CaO is proportional to mole per cent CaO. The following equation for ionic conductivity

$$\sigma_i \simeq 6.0[\text{m/o CaO}] \exp -0.62/kT$$

was obtained by fitting the conductivity data in this region to an expression derived on the basis of an oxygen vacancy model. An approximate expression for the diffusion coefficient for oxygen vacancies

$$D_{V_O^{\cdot\cdot}} \simeq 3.7 \times 10^{-3} \exp -0.62/kT$$

was calculated from the above expression and the Nernst-Einstein relation. At high temperatures and low oxygen partial pressures and for lower CaO contents the conductivity is predominantly electronic. In this region the magnitude and P_{O_2} dependence of σ is similar to "pure" CeO_2. A thermodynamic argument is also presented which favors oxygen vacancies as the nonstoichiometric defect in both pure and CaO-doped CeO_2.

Only a limited number of studies (1-4) have been reported on the electrical conductivity of CaO-doped nonstoichiometric cerium dioxide. Kevane *et al.* (2) measured the electrical conductivity as a function of temperature (250°-1500°C), oxygen pressure (1-10^{-4} atm), and CaO content (0.03-0.86% Ca). They reported mixed conduction, electronic and ionic. The electronic conductivity was predominately n-type at elevated temperatures; at lower temperatures p-type behavior was observed. A recent electrical conductivity study of solid electrolytes in air by Meyer and Marincek (4) indicates that a 15 m/o (mole per cent) CaO-doped CeO_2 specimen is predominantly an ionic conductor. Ionic transference measurements in air by Yushina and Pal'guev (5) confirm the ionic conductivity of CeO_2 doped with 5-15 m/o CaO in the temperature range 700°-1100°C.

The solubility of CaO in CeO_2 based on an x-ray study has been reported to be 15 m/o CaO at 1600°C (6). Although no thermodynamic study on CaO-doped CeO_2 has been reported, the range of oxygen pressure over which the fluorite structure is stable should be large because CeO_{2-x} is thermodynamically stable (7-9) over a wide range of P_{O_2} and temperature. For

Key words: oxygen vacancy, diffusion, electrical conductivity, calcia-doped cerium dioxide, activation energy.

example, the fluorite structure of CeO_{2-x} is stable to values of P_{O_2} as low as 10^{-20} atm at 1023°C.

The above conductivity studies on CaO-doped CeO_2 have been made over only a rather limited range of oxygen pressures and CaO content. The results of a recent electrical conductivity study (10) on cerium dioxide over a wide range of oxygen pressures (1-10^{-21} atm) and temperatures (800°-1500°C) have been interpreted in terms of a nonstoichiometric defect model involving triply and quadruply ionized cerium interstitials and localized electrons. This defect model was based on a comparison of the isothermal oxygen pressure dependence of the electrical conductivity and a theoretically derived expression for the conductivity using the law of mass action.

The purpose of this study was (*i*) to measure the electrical conductivity over a wide range of temperature, oxygen pressure, and CaO content and (*ii*) to characterize the electronic and ionic conductivity by a comparison of the data with proposed defect models for CaO-doping and oxygen nonstoichiometry.

Theory

Defect model for ionic conductivity.—It is generally assumed that doping CeO_2 with CaO produces oxygen vacancies (2). In order to test the oxygen vacancy model, a room temperature study (11) was made in this laboratory comparing the true density and calculated values of the density based on lattice parameter data. The true density was determined using a water pycnometric technique. The measurements were made on powder obtained by crushing and grinding the sintered CaO-doped CeO_2 specimens in an alumina mortar and pestle. With this procedure the problem associated with pores in the density measurements was eliminated. The results of this study, for specimens in the stoichiometric condition with CaO contents between 0.1 and 16 m/o, are shown in Fig. 1. Curves A and B corresponding to Eq. [1] and [2],[1] respectively

$$CaO \rightarrow Ca_i^{\cdot\cdot} + O_i'' \qquad [1]$$

$$CaO \rightarrow Ca_i^{\cdot\cdot} + 1/2\, V_{Ce}'''' + O_o^x \qquad [2]$$

were calculated assuming calcium ions occupy cerium interstitial sites and the formation of charge-compensating defects which can be oxygen interstitials or cerium vacancies. Curves B and C corresponding to Eq. [3] and [4], respectively

$$1/2Ce_{Ce}^x + CaO \rightarrow Ca_{Ce}'' + 1/2Ce_i^{\cdot\cdot\cdot\cdot} + O_o^x \qquad [3]$$

$$CaO \rightarrow Ca_{Ce}'' + V_o^{\cdot\cdot} + O_o^x \qquad [4]$$

were calculated assuming calcium ions occupy cerium sites and the formation of charge-compensating defects

[1] The notation used to identify defects in this paper is the same as used by Kröger (22).

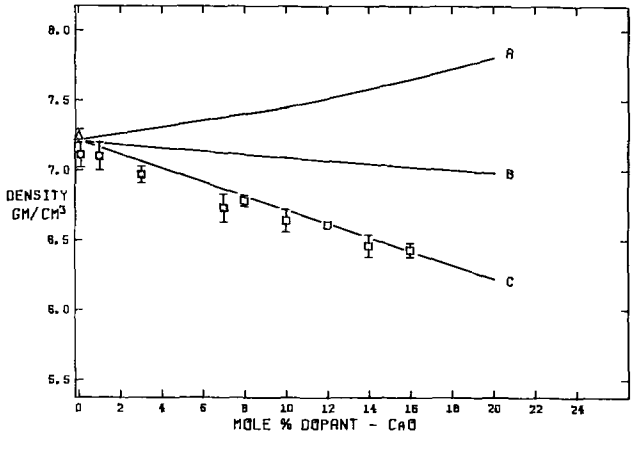

Fig. 1. Comparison of pycnometric density and calculated values of the density based on lattice parameter data for specimens of CeO_2 doped with CaO between 1 and 16 m/o.

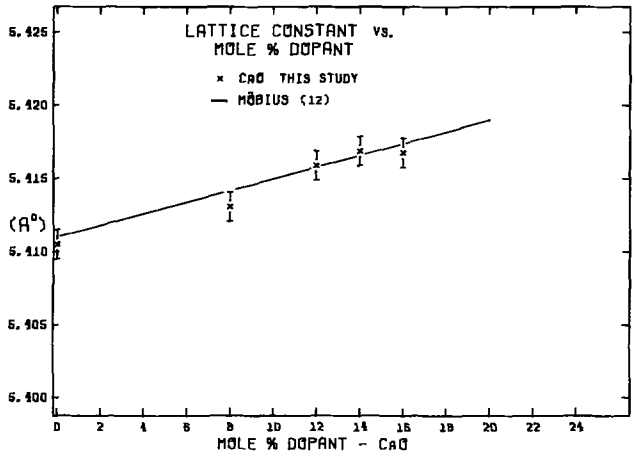

Fig. 2. Room temperature lattice parameter of CaO-doped CeO_2 vs. mole per cent CaO. The data points represented by the average values and the error bars were determined in this study (11). The solid line represents the reported results of Mobius (12).

which can be cerium interstitials or oxygen vacancies. The lattice parameter data used in these calculations is shown in Fig. 2. The data points shown in Fig. 1 correspond to the room temperature true density measurements made on the CaO-doped specimens used in this conductivity study. The agreement between the experimental data and curve C confirms the existence of oxygen vacancies in CaO-doped CeO_2.

The simplest model for ionic conduction in CaO-doped CeO_2 is to assume that the ionic conduction occurs by the migration of oxygen vacancies with only one state of ionization, $V_o^{\cdot\cdot}$. For this case the ionic conductivity, σ_i, may be represented by the expression

$$\sigma_i = 2B[V_o^{\cdot\cdot}]e\mu_{V_o^{\cdot\cdot}} \qquad [5]$$

where the bracketed term represents the number of a given species divided by the number of sites available for that species, B is a parameter which relates the concentration in site fraction to number/cubic centimeter, e is the charge on an electron, and $\mu_{V_o^{\cdot\cdot}}$ is the mobility of doubly ionized oxygen vacancies. If the oxygen vacancies are isolated point defects randomly distributed and the concentration of nonstoichiometric defects is small, then

$$[V_o^{\cdot\cdot}] = \frac{(\text{m/o CaO})}{200} \qquad [6]$$

In addition, if $\mu_{V_o^{\cdot\cdot}}$ is assumed to be a function of temperature only

$$\mu_{V_o^{\cdot\cdot}} = \mu'_{V_o^{\cdot\cdot}} \exp(-E_i/kT) \qquad [7]$$

Combining Eq. [5], [6], and [7] the relation for ionic conductivity is

$$\sigma_i = A(\text{m/o CaO}) \exp(-E_i/kT) \qquad [8]$$

where

$$A = B\,\mu'_{V_o^{\cdot\cdot}}\, e/100$$

Equation [8] may be tested in a region near stoichiometry where the ionic conduction predominates (*i.e.*, $\sigma \simeq \sigma_i$) by observing if σ is directly proportional to the CaO content in this region. In the region of this limiting case, σ should also be independent of P_{O_2}.

Defect models for electronic conductivity.—In a previous study on "pure" nonstoichiometric CeO_2 the isothermal dependence of σ on P_{O_2} was rationalized in terms of a defect model involving triply and quadruply ionized cerium interstitials and localized electrons (10). However, as discussed above the predominate defects produced by doping CeO_2 with CaO are oxygen vacancies. Based on thermodynamic considerations it can be shown that for both pure and CaO-doped CeO_2 the concentration of cerium interstitials is dependent on the concentration of oxygen vacancies.

For example applying the law of mass action to the defect reaction

$$1/2Ce_i^{\cdots\cdot} = 1/2Ce_{Ce}^{x} + V_o^{\cdot\cdot} \quad [9]$$

obtained by subtracting Eq. [3] from Eq. [4] yields

$$K \simeq \frac{[V_o^{\cdot\cdot}]}{[Ce_i^{\cdots\cdot}]^{1/2}} \quad [10]$$

Since the free energy change for Eq. [4] is more negative than Eq. [3], ΔG, for the defect reaction described by Eq. [9] is negative and $K > 1$.

Then according to Eq. [10]

$$[V_o^{\cdot\cdot}] > [Ce_i^{\cdots\cdot}]$$

because $[V_o^{\cdot\cdot}]$ and $[Ce_i^{\cdots\cdot}]$ are < 1. On the basis of the above thermodynamic argument it appears that if the addition of CaO to CeO_2 produces oxygen vacancies then the nonstoichiometric defects in pure CeO_2 are oxygen vacancies. Of course this argument would be invalidated if significant defect interaction occurs because of the addition of CaO to CeO_2 or as a result of large departures from stoichiometry.

Assuming the oxygen vacancies are doubly ionized, the nonstoichiometric defect reaction in CeO_2 may be characterized by the following reaction

$$O_o^x + 2Ce_{Ce}^x = 2Ce_{Ce}' + V_o^{\cdot\cdot} + 1/2\,O_2(g) \quad [11]$$

Electron transport is assumed to occur by a "hopping" type process (13, 14). Applying the law of mass action to Eq. [11] yields

$$K_1 = \frac{[Ce_{Ce}']^2\,[V_o^{\cdot\cdot}]\,P_{O_2}^{1/2}}{[O_o^x]\,[Ce_{Ce}^x]^2} \quad [12]$$

If the appropriate electroneutrality expression is

$$[Ce_{Ce}'] = 2[V_o^{\cdot\cdot}] \quad [13]$$

and $[O_o^x]$ and $[Ce_{Ce}^x] \simeq 1$ then

$$[Ce_{Ce}'] \propto P_{O_2}^{-1/6} \quad [14a]$$

or

$$\sigma_e \propto P_{O_2}^{-1/6} \quad [14b]$$

if μ_e is temperature dependent only.

It should be noted that under isothermal conditions and over a range of oxygen pressures the electrical conductivity of pure CeO_2 was observed (10) to be proportional to $P_{O_2}^{-1/5}$ (*e.g.*, between $P_{O_2} = 10^{-6}$ and 10^{-9} at 1100°C). However, at lower oxygen pressures (*i.e.*, large departure from stoichiometry) the dependence of σ_e on P_{O_2} involves a more complicated relationship (10). Thus the above analysis is inconsistent with the behavior of the oxygen pressure dependence of σ, which would seem to imply that either or both the mass action approach or the defect reaction given in Eq. [11] are incorrect.

Greener *et al.* (15) discussed a defect model proposed by Bevan involving a simple divacancy, $(V_o - V_o)^{\cdots\cdot}$, to explain the $P_{O_2}^{-1/5}$ dependence of σ in pure CeO_2. However, because of electrostatic repulsion between the negatively charged vacancies this model does not appear to be physically reasonable.

With the addition of CaO to CeO_2, the electroneutrality relation is

$$2[Ca_{Ce}''] + [Ce_{Ce}'] = 2[V_o^{\cdot\cdot}] \quad [15]$$

for the doubly ionized oxygen vacancy model.

Two interesting limiting cases may be readily deduced for this defect model. At low CaO contents and where the departures from stoichiometry are sufficiently large that

$$[Ce_{Ce}'] >> 2[Ca_{Ce}''] \quad [16]$$

the equation derived for CaO-doped CeO_2 would be the same as Eq. [14] which was derived for pure CeO_2.

However for near-stoichiometric conditions, where the CaO content is sufficiently large that

$$[Ce_{Ce}'] << 2[Ca_{Ce}''] \quad [17]$$

then the concentration of electron carriers, $[Ce_{Ce}']$, is given by Eq. [18] for the doubly ionized oxygen vacancy model

$$[Ce_{Ce}'] = \frac{K_1^{1/2}}{[Ca_{Ce}^{\cdot\cdot}]^{1/2}}\,P_{O_2}^{-1/4} \quad [18]$$

According to Eq. [18] for a given temperature and P_{O_2}, $[Ce_{Ce}']$ should decrease with increasing CaO content. On the basis of these simple limiting case models for CaO-doped CeO_2 the P_{O_2} dependence of σ_e, under isothermal conditions, might be expected to vary between $P_{O_2}^{-1/4}$ and $P_{O_2}^{-1/6}$ over a limited region of nonstoichiometry and CaO content. Since $\sigma \propto P_{O_2}^{-1/5}$ for pure CeO_2 over a range of oxygen pressures (10), it would be expected that both pure and CaO-doped CeO_2 should exhibit a similar isothermal dependence of σ_e on P_{O_2}, at least over a limited range of oxygen pressures.

Experimental

Conductivity specimens of CeO_2 doped with CaO (0.1-16.0 m/o CaO) were prepared by dry mixing the appropriate proportions of CeO_2 and $CaCO_3$ powder. The chemical analysis of CeO_2 and $CaCO_3$ powders are shown in Tables I and II, respectively. These mixtures were calcined for 12 hr at 1000°C in air. The calcined material was ground in an alumina mortar and pestle to an approximate particle size of 20μ or less. These powders were then pressed into bars 2 × 1/4 × 1/4 in. with a pressure of 20,000 psi. The bars were placed in an alumina boat and completely covered with CaO-doped CeO_2 powder of the same composition to avoid loss of CaO during sintering. A molybdenum-wound resistance furnace was used to sinter the bars at 1650°C for 3 1/2 hr in an argon atmosphere. Conductivity specimens were cut from the sintered bars to an average length of 2 cm. The bulk density measurements were determined from the mass of the specimen and the volume which was obtained from the external dimensions of the specimen. The nominal calcia content, the ratio of bulk density to true density, and the results of the chemical analysis on several of these specimens are shown in Table III. The nominal calcia content specimens, 0.3, 2.0, 5.0, and 7.0 m/o CaO, agree with

the results of the x-ray fluorescence and the atomic absorption analysis within the reported experimental error of these analyses ±10%. With the exception of the 1 m/o CaO specimen, the nominal values of mole per cent CaO of all specimens analyzed were within the reported experimental accuracy of the x-ray fluorescence and atomic absorption analysis. Thus, in this study the nominal mole per cent CaO values will be used to identify the calcia content of each specimen.

The electrical conductivity measurements on the above CaO-doped cerium dioxide specimens as a function of P_{O_2} in the temperature range 700°-1500°C were made in a molybdenum-wound resistance furnace. A standard four-probe d-c technique was employed for the electrical conductivity measurements. The experimental apparatus employed was essentially the same as that described in an earlier publication (16). Four-probe conductivity specimens were prepared from sintered bars of CaO-doped CeO_2 by wrapping with 0.01-in. diameter platinum wire. Two current leads were wrapped near the ends of the specimen and two potential leads were wrapped closer to the center with a spacing of approximately 1 cm. An Altair Model C2 constant current source with a continuously variable range from 1 to 50 μA was used to supply the current. The d-c conductivity measurements were found to be independent of the applied field and time in this study. In addition a-c measurements in the frequency range 10-1000 Hz were found to be in agreement with the d-c measurements. These results indicate that ohmic behavior was achieved and that polarization was not a problem in these measurements.

Oxygen partial pressures were achieved by means of two methods. For pressures from 1 to 10^{-4} atm, premixed and analyzed O_2-Ar mixtures at 1 atm total pressure were used in the study. Controlled oxygen partial pressures in the low-pressure region were obtained by introducing known mixtures of CO and CO_2 at 1 atm total pressure. The well-known free energy values for the CO/CO_2 reaction were used to calculate the oxygen partial pressure. A linear flow rate of 0.7 cm/sec was maintained for all gas mixtures used in this investigation to avoid errors arising from thermal diffusion (17). However, no flow dependence was noted when the flow rate was increased or decreased within 50% of this value. Electrical conductivity measurements were made at various temperatures between 700° and 1500°C for a fixed gas mixture for both increasing and decreasing temperature. Data were taken in 200°C increments, starting at 700°C and proceeding to 1500°C while heating. During cooling from 1400° to 800°C data was recorded at 200°C intervals. Since the composition of calcia-doped nonstoichiometric ceria has a unique value for each CaO content, oxygen partial pressure, and temperature, the above technique insured the measurement of equilibrium conductivity because the nonstoichiometric equilibrium state was approached from both higher and lower compositions of oxygen. In addition some isothermal conductivity measurements were made. The conductivity data obtained from both techniques were found to be in good agreement.

Results and Discussion

The electrical conductivity of sintered specimens of calcia-doped nonstoichiometric cerium dioxide (0.1-16.0 m/o CaO) was measured as a function of temperature (*i.e.*, 700°-1500°C) and oxygen pressure ($1-10^{-21}$ atm). Typical behavior of the conductivity as a function of the reciprocal absolute temperature in Ar-O_2 and CO-CO_2 mixtures is illustrated in Fig. 3 for a nonstoichiometric cerium dioxide specimen doped with 1.0 m/o CaO. The measured values of the conductivity, σ_{meas}, for the sintered specimen have been corrected for porosity using the relation (18)

$$\sigma = \sigma_{meas} \frac{\rho_{theor}}{\rho_{meas}} \qquad [19]$$

where ρ_{theor} is the theoretical density and ρ_{meas} is the bulk density of the sintered specimen. For all of the CaO-doped specimens two distinct types of behavior are observed as illustrated in Fig. 3. At lower temperatures and high oxygen pressures (*i.e.*, Ar-O_2 mixtures), the conductivity is independent of oxygen partial pressure and exponentially dependent on temperature. At higher temperatures and low oxygen pressures, the conductivity exhibits n-type behavior. Based on the simple limiting case defect models discussed in the theory section, the ionic conductivity should be proportional to mole per cent CaO and independent of P_{O_2}; whereas the electronic conductivity of Ca-doped CeO_2 should exhibit a dependence on P_{O_2} similar to pure CeO_2. Isothermal plots of log σ *vs.* log P_{O_2} were made for each of the CaO-doped specimens to test these simple models (13). Typical plots are shown in Fig. 4-6 for 1, 5, and 12 m/o CaO, respectively. For comparative purposes the conductivity (10) of a pure CeO_2 specimen is shown as a dashed line in these figures.

A qualitative explanation of the observed electrical conductivity data may be given in terms of three regions as follows:

Region 1: At high temperatures and particularly at low oxygen pressures, the σ of the CaO-doped specimens exhibits a similar P_{O_2} dependence as pure CeO_2.

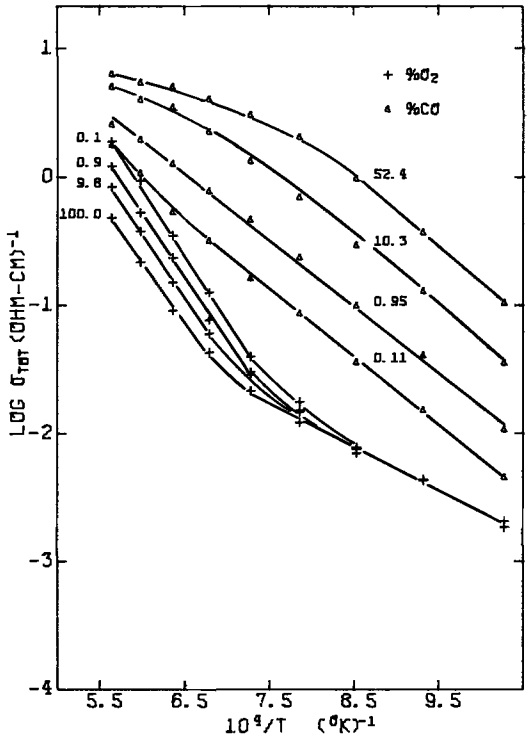

Fig. 3. Log σ vs. $1/T$ for 1 m/o CaO-doped CeO_2 in Ar-O_2 and CO-CO_2 mixtures.

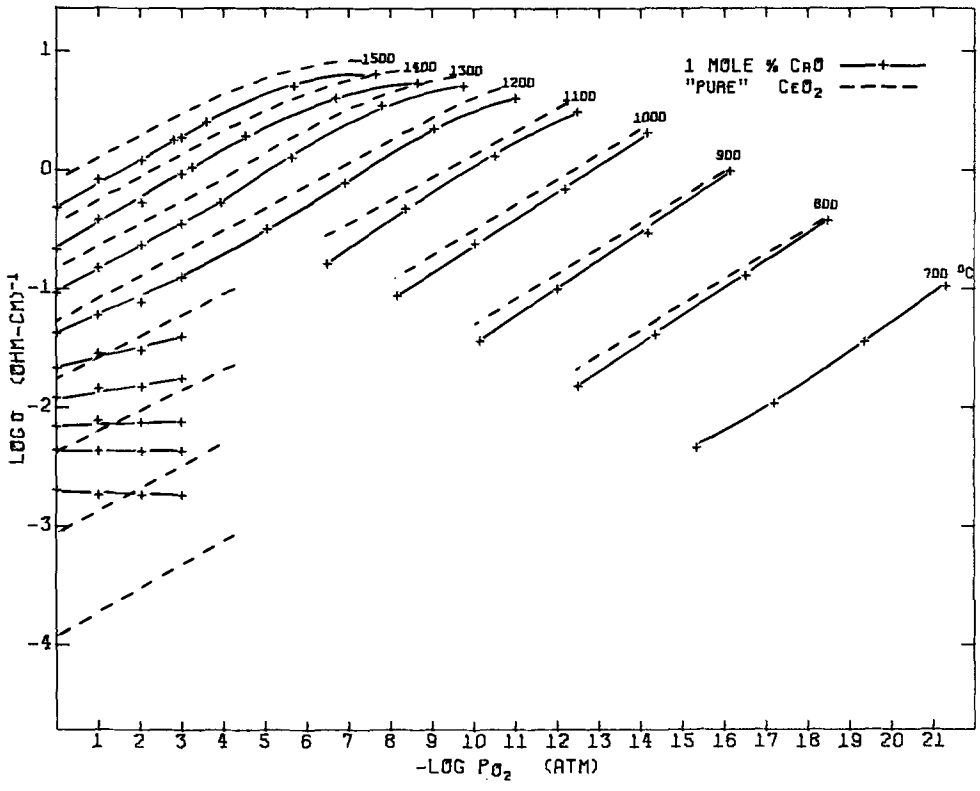

Fig. 4. Comparison of isothermal plot of log σ vs. log P_{O2} for pure nonstoichiometric cerium dioxide and 1.0 m/o CaO-doped CeO_2 sintered specimens.

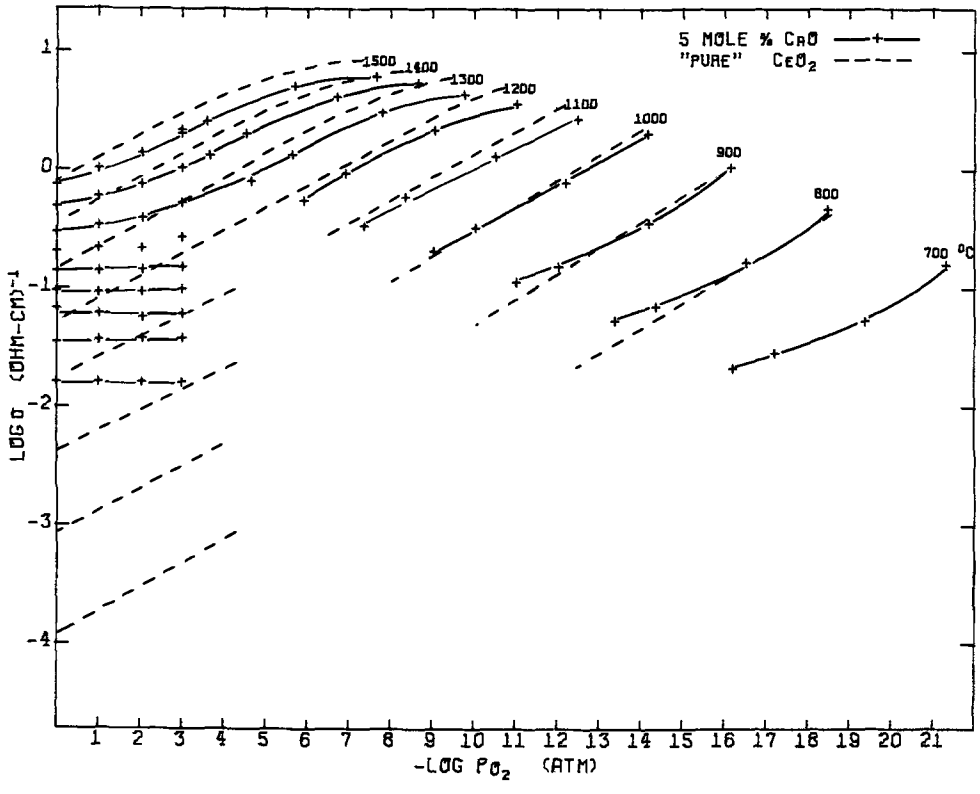

Fig. 5. Comparison of isothermal plot of log σ vs. log P_{O2} for pure nonstoichiometric cerium dioxide and 5.0 m/o CaO-doped CeO_2 sintered specimens.

The conductivity in this region appears to be predominantly electronic (*i.e.*, $\sigma \simeq \sigma_e > \sigma_i$) and is probably controlled by the same nonstoichiometric defects as in pure CeO_2. As the CaO content increases, lower oxygen pressures (*i.e.*, a higher concentration of nonstoichiometric defects) are required to "mask" out the effect of the CaO.

Region II: For low temperatures and high oxygen partial pressures (*i.e.*, near stoichiometric conditions), the conductivity of the CaO-doped specimen is independent of oxygen partial pressure. The σ is also much larger than that of pure CeO_2. Since σ_i is to a first-order approximation independent of the oxygen pressure, this observation is consistent with a conduction process which is primarily ionic (*i.e.*, $\sigma \simeq \sigma_i > \sigma_e$).

Region III: For all oxygen pressures and temperatures intermediate to regions I and II, the conductivity appears to be mixed, *i.e.*, where σ_e and σ_i are of the same order of magnitude.

As discussed in the Theory section, the simple limiting case defect models for electronic conduction predict that the concentration of electronic defects should decrease with increasing CaO content. However, based on the defect model for CaO doping, the ionic conductivity is directly proportional to the CaO content. As a test of these models, isothermal plots were made of

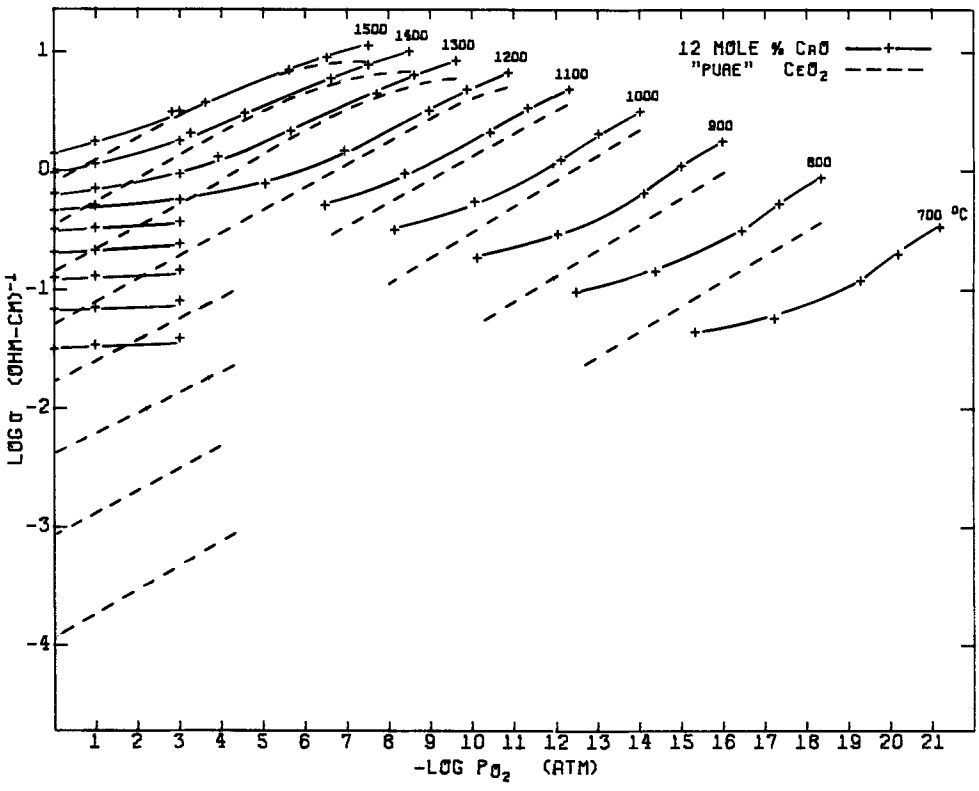

Fig. 6. Comparison of isothermal plot of log σ vs. log P_{O_2} for pure nonstoichiometric cerium dioxide and 12 m/o CaO-doped CeO_2 sintered specimens.

log σ *vs.* log mole per cent CaO for all of the gas mixtures used in this study (11, 13). Typical plots of log σ *vs.* log mole per cent CaO are shown in Fig. 7, 8, and 9 for atmospheres containing 100% O_2, 0.1% CO, and 48.1% CO, respectively. The same three regions of behavior discussed above may be observed. In region I (*i.e.*, $\sigma \simeq \sigma_e$) the magnitude of the conductivity of pure and CaO-doped CeO_2 are similar. This region extends to higher CaO compositions and lower temperatures in more reducing gas mixtures (*i.e.*, lower oxygen partial pressures). In region II (*i.e.*, $\sigma \simeq \sigma_i$) the slope of log σ *vs.* log per cent CaO is approximately one. This region is observed primarily at lower temperatures and higher oxygen pressures. For example, in an atmosphere of 100% O_2 (Fig. 7) this region extends from approximately 1 to 8 m/o CaO in the temperature range 700°-1100°C, whereas in a strongly reducing atmosphere (48.1% CO, Fig. 9) this region is barely detectable at 700°C. At high oxygen pressures, low temperatures, and low CaO contents (0.1 m/o CaO, Fig. 7) a curvature in the line is observed. This effect is probably due to impurities in CeO_2. For example,

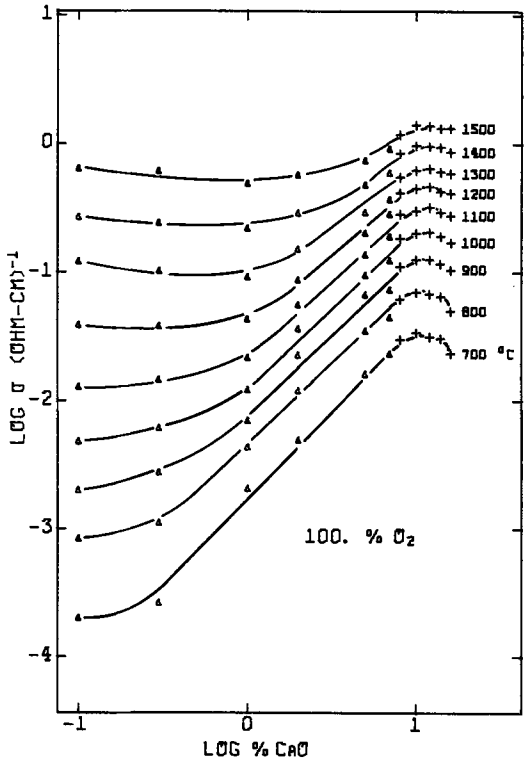

Fig. 7. Isothermal plot of log σ vs. log mole per cent CaO in CeO_2 in 100% O_2.

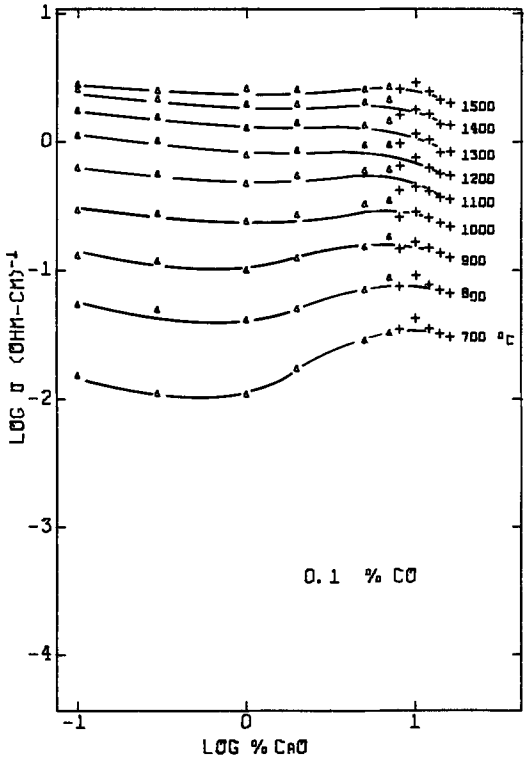

Fig. 8. Isothermal plot of log σ vs. log mole per cent CaO in CeO_2 in 0.1% CO.

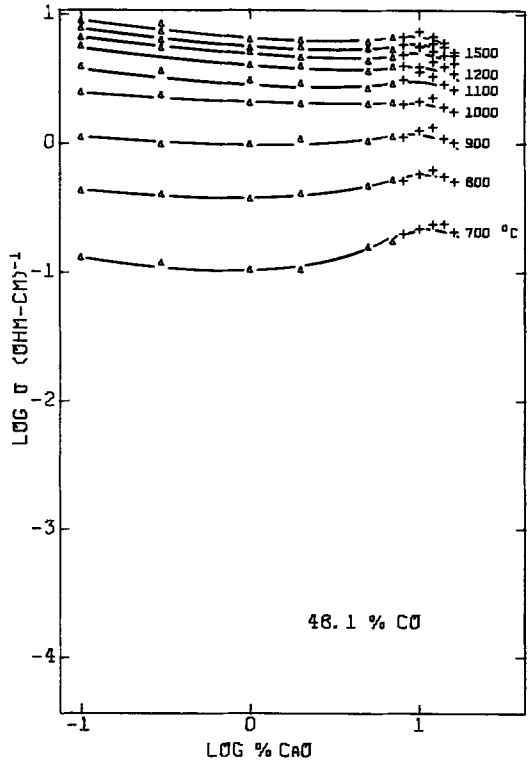

Fig. 9. Isothermal plot of log σ vs. log mole per cent CaO in CeO_2 in 48.1% CO.

the conductivity for pure CeO_2 has been reported (10) to be influenced by impurities in this temperature and oxygen pressure region (*i.e.*, in the near stoichiometric condition). Thus, it appears that a dopant concentration of $>$ 0.3 m/o CaO is required to produce a sufficient number of defects to completely swamp out the effect of impurities in near stoichiometric CeO_2. Region III is a region of mixed conduction. Another interesting observation from Fig. 7-9 is that at high CaO compositions the conductivity appears to exhibit a maximum with increasing CaO content. This behavior also appears to be relatively independent of temperature and oxygen partial pressure. Similar behavior has been reported for other fluorite oxide systems doped with lower valent cations. Two different models have been used to explain the maximum in σ observed in CaO-doped ZrO_2 (19). One model is based on a clustering of defects and the other on synthetic zones of composition. In both of these models the activation energy increases with increasing CaO content. In contrast to the predictions of these models, the activation energy for CaO-doped CeO_2 determined from a plot of log σ *vs.* $1/T$ at 1 atm of O_2 is independent of CaO content. Also in the vicinity of the σ maximum only a very small variation in the magnitude of the conductivity with CaO content is observed. Although the reported solubility (6) is 15 m/o CaO in air at 1600°C, the dependence of temperature and oxygen pressure on the solubility limits of CaO-doped CeO_2 is not known. Thus the question of whether the concentration of CaO in this region exceeds the solubility of CaO in CeO_2 cannot be easily ascertained. Because of these considerations no attempt has been made to analyze the maximum in the conductivity of CeO_2 doped with CaO.

The qualitative interpretation of the electrical behavior of CaO-doped CeO_2 observed in this study may be summarized as follows. CaO-doped CeO_2 exhibits both electronic and ionic conductivity. Two, limiting case regions were observed. At low temperatures and high oxygen pressures, and CaO contents of approximately 1-8 m/o CaO, the conductivity is proportional to mole per cent CaO and is predominately ionic. Whereas at high temperatures and low oxygen partial pressures and lower CaO contents the conductivity is predominately electronic.

The qualitative predictions of the limiting case defect models for electronic conduction (*i.e.*, similar magnitude and P_{O_2} dependence as pure CeO_2) in CaO-doped CeO_2 appear to be consistent with the observed behavior of the conductivity in this limiting case region. It should be noted that the limiting case models for oxygen vacancies would be expected to apply only in the oxygen pressure region where $\sigma \propto P_{O_2}^{-1/5}$ in pure CeO_2. However, for oxygen pressures below this region, the conductivity of pure and CaO-doped CeO_2 are actually in closer agreement. This implies that the same defects are responsible for the nonstoichiometric behavior in pure and CaO-doped CeO_2. In the Theory section the inconsistencies of the previously proposed cerium interstitial defect model for pure CeO_2 and CaO-doped CeO_2 have been discussed. The problem with the mass action interpretation of the doubly ionized oxygen vacancy model has also been discussed. In addition information on the transference number should be available in order to determine a more exact dependence of σ_e on temperature, oxygen pressure, and CaO content. Because of these considerations no attempt has been made in this paper to analyze quantitatively the conductivity data in terms of the above defect models.

In order to analyze quantitatively the proposed oxygen vacancy model for ionic conductivity, Eq. [8], the conductivity in the region where ionic conductivity predominated was plotted as a function of CaO. These results are shown in Fig. 10 at $P_{O_2} = 1$ atm for 700°-1000°C and for CaO contents between 1 and 16 m/o. A direct proportionality was observed for specimens with CaO contents between approximately 1 and 8 m/o CaO. The parameter E_i in Eq. [8] was obtained from the plot shown in Fig. 11 of log σ *vs.* $1/T$ at $P_{O_2} =$ 1 atm for several different CaO contents. The average value of E_i determined from a least square analysis was 0.62 $\pm$ 0.03 eV for compositions from 1.0 to 14.0 m/o CaO. A value of $A = 6.0 \pm 0.5$ was determined by curve fitting Eq. [8] to the data shown in Fig. 11. Thus if the proposed limiting case defect model for ionic conductivity is correct and ionic conductivity predominates in the composition region, 1-8 m/o CaO, (*i.e.*, $t_i \simeq 1$), σ_i may be approximated by the relation

$$\sigma_i \simeq [6.0 \pm 0.5]\ [\text{m/o CaO}] \exp -0.62/kT \qquad [20]$$

An approximate expression for the diffusion coefficient of oxygen vacancies, $D_{V_O^{\cdot\cdot}}$, in CaO-doped CeO_2

$$D_{V_O^{\cdot\cdot}} \simeq 3.7 \times 10^{-3} \exp -0.62/kT \qquad [21]$$

was determined in this study from the above data and the Nernst-Einstein relation. It is interesting to note that the diffusion coefficient for oxygen vacancies in

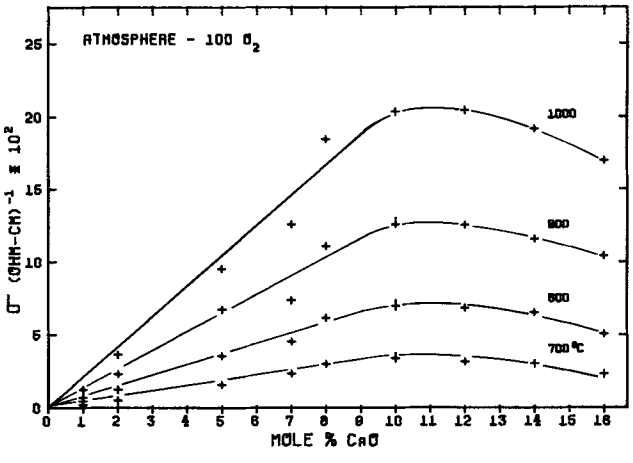

Fig. 10. Isothermal plot of σ vs. mole per cent CaO in CeO_2 at 1 atm O_2.

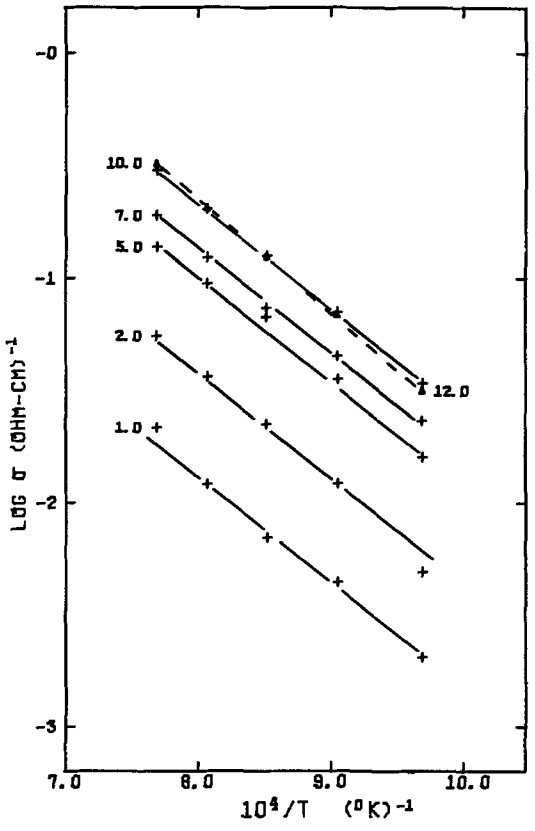

Fig. 11. Log σ vs. 1/T for 1, 2, 5, 7, 10, and 12 m/o CaO-doped CeO_2 at 1 atm O_2.

CaO-doped CeO_2 is larger than in CaO-doped ZrO_2 (20).

A recent study of oxygen self-diffusion (21) in ceria-yttria solution at $P_{O_2} = 1$ atm in the temperature range 850°-1150°C indicates that the activation energy, approximately 20 kcal/mole, is essentially independent of yttria composition (*i.e.*, for x between 0 and 0.2 in the formula $Ce_{1-2x}Y_{2x}O_{2-x}$). The activation energy obtained in this study (~14 kcal/mole) for diffusion of oxygen vacancies produced by CaO is in relatively good agreement with the self-diffusion of oxygen in $Ce_{1-2x}Y_{2x}O_{2-x}$). It is also interesting to note that the reported (21) activation energy for oxygen self-diffusion in pure ceria varied from about 24 kcal/mole in near stoichiometric ceria to about 4 kcal/mole for $CeO_{1.8}$. Thus it might be expected that the activation energy for oxygen diffusion in CaO-doped CeO_2 would decrease in the presence of a large concentration of nonstoichiometric defects (*i.e.*, at low oxygen pressures).

A study of transference measurements on CaO-doped CeO_2 has been initiated in this laboratory to determine t_i as a function of temperature, P_{O_2}, and CaO content. These data when combined with the above σ data should allow the determination of the T, P_{O_2}, and CaO dependence of the electronic and ionic conductivity. The combined results of these studies should permit a more quantitative test of the simple limiting case defect models for ionic and electronic conductivity.

D-C Conduction and Electroluminescence in Dielectric-Embedded ZnS:Mn,Cu,Cl

John M. Fikiet[1] and John L. Plumb[2]

Department of Electrical Engineering, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

The effect of binder on the d-c characteristics of electroluminescent ZnS:Mn,Cu,Cl phosphor powder dispersed in a plastic (polymethylmethacrylate) binder was investigated. A plot of the current-voltage characteristic showed that $I = I_0 \exp \sqrt{V/V_I}$, where I_0 and V_I are constants for a given sample, suggesting current limited by Schottky emission from Cu-rich lines in the phosphor. As the phosphor concentration in the binder is increased, V_I decreases to a nearly constant value much smaller than calculated for a uniform electric field in an insulator. This result indicates that Schottky emission occurs at points of field concentration, such as at the ends of Cu-rich lines.

Electroluminescence in Mn-activated ZnS is enhanced by the incorporation of Cu (1), and the resulting doubly activated phosphor is electroluminescent to both a-c and d-c excitation (2-4). High efficiency and brightness in ZnS:Mn,Cu,Cl powder dispersed in an insulating binder and excited with a d-c voltage have been reported by Vecht, *et al.* (5-6). Two different methods of phosphor activation were used, one being post activation by the conventional slurrying technique (7) which resulted in a quantum efficiency as high as 170% and the other being simultaneous activation followed by copper coating of the phosphor which resulted in a brightness as high as 1000 ft-L. Close control of the ZnS purity and the Mn and Cu additions was described, but little information regarding the current-voltage characteristic or the effect of binder on cell properties was reported.

In the case of a-c excitation of activated ZnS powder dispersed in an insulating binder, a purpose of the binder is to avoid discharges and breakdown (7), and the only apparent effect on electroluminescence is to modify the electric field distribution (8, 9). The brightness with a-c excitation has been reported not to depend on binder material or proportion of binder to phosphor (10). The brightness and efficiency with d-c excitation, however, should depend significantly on proportion of binder to phosphor.

Electroluminescence with d-c excitation has been observed and studied in ZnS phosphor crystals and films as well as embedded powder. Light emission from the cathode region has been observed in Cu-activated and Mn-activated crystals relatively free of internal barriers (11), and this electroluminescence is most readily ascribed to impact excitation by injected electrons accelerated in a high-field region adjacent to the cathode (12). This mechanism is also consistent with data obtained for Mn-activated ZnS films made d-c electroluminescent by converting a surface layer of ZnS to Cu_2S (13).

Electroluminescence in both crystals and embedded powders has been observed as originating at the tips of striations or lines within the crystal or powder particle (14, 15). These lines are believed to be a separate phase of Cu_2S existing at crystal imperfections (16). Electrons can be injected into the ZnS from this separate conducting phase at points of electric field concentration. Electroluminescence in ZnS:Mn,Cu,Cl films has been observed to originate at the anode (17). The current-voltage characteristics of the films indicate that electron injection occurs at the ends of Cu or Cu_2S lines that extend from the cathode to the vicinity of the anode (18).

Vecht *et al.* (6) have investigated the brightness-current and brightness-voltage characteristics of the electroluminescent ZnS:Mn,Cu,Cl powder-binder system and the effect of varying the concentration of Cu and Mn in the phosphor powder. The present paper describes the current-voltage characteristics and the effect of varying the concentration of phosphor powder in the insulating binder.

Electroluminescent Cell Preparation and Characteristics

Electroluminescent cells were made by dispersing ZnS:Mn,Cu,Cl phosphor powder in polymethylmethacrylate (PMMA) and sandwiching this mixture between Al and transparent, conducting, tin oxide electrodes. The phosphor was prepared by the post-activated slurry technique described by Vecht *et al.* (6). Aqueous solutions of Cu and Mn acetates and HCl solution were added to luminescent grade ZnS. The mixture was dried, pulverized, and fired at 900°C for 1 hr in a nitrogen atmosphere. The powder was sifted through a 320-mesh sieve and mixed with PMMA[2] in a solvent. This mixture was spread with a sharp edge (at constant height) onto a tin-oxide-coated glass substrate[3] and allowed to dry a few minutes at room temperature and finally at 65°C. To form a top electrode Al was deposited by evaporation.

The phosphor powder was analyzed for Cu and Mn content by atomic absorption film spectrometry and for Cl content by coulometric titration. The thickness and roughness of each phosphor film were measured with a Zeiss light section microscope and the cell fabrication was completed only if the film was flat and 30 to 35 μm thick.

The tin oxide layer was contacted with a Ag paint. The d-c voltage producing average electric fields ranging from 70 to 280 kV/cm in the phosphor/binder layer were applied between the Ag and Al. The cell current was measured with a Keithley 103 microvolt-ammeter and the luminance with an RCA 4473 photomultiplier.

In two cells, no phosphor was dispersed in the PMMA binder. Varying voltage was applied to the cell and the current at each voltage was measured after the charging component had decayed to a negligible value. There was no significant difference between ascending and descending data. The logarithm of the current is plotted *vs.* the square root of the voltage in Fig. 1. The current-voltage characteristic is seen to follow the relation

$$I = I_0 \exp \sqrt{V/V_I} \qquad [1]$$

where I_0 and V_I are constants for the cell. This current-voltage characteristic can be explained as the result

[1] Present address: American Embassy, Peace Corps, Caracas, Venezuela.
[2] Present address: Transitron Electronic Corporation, Wakefield, Massachusetts 01880.
Key words: carrier injection, insulator, polymethyl methacrylate, zinc sulfide.

[3] Corning IRR 7420.

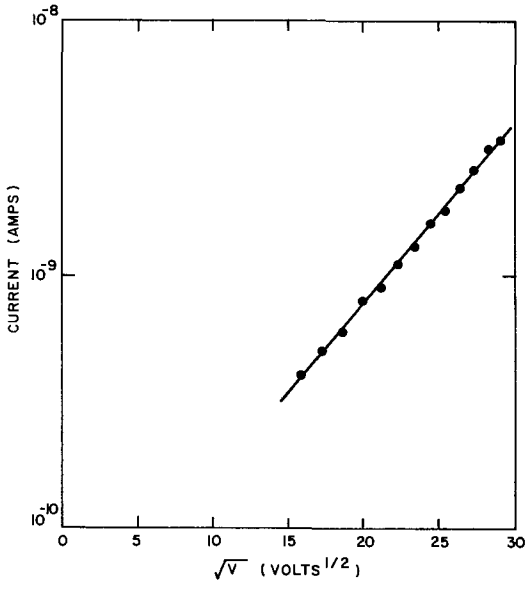

Fig. 1. Current-voltage characteristic for a 30-μm thick polymethylmethacrylate binder film without phosphor plotted as logarithm of current *vs.* square root of voltage.

of a thermal process such as Schottky emission, *i.e.*, field-enhanced thermal injection from a metal electrode caused by image-force lowering of the barrier (19).

The factor V_I in the exponent of Eq. [1] is related to the slope of the curve in Fig. 1. Theoretically, for Schottky emission

$$I = AT^2 \exp\left[-e(\phi_0 - \sqrt{eV/4\pi K\epsilon_0 d})/kT\right] \quad [2]$$

where A is Richardson's constant and ϕ_0 is the contact barrier height (20). The constant V_I of Eq. [1] is therefore

$$V_I = 4\pi K\epsilon_0 dk^2T^2/e^3 \quad [3]$$

where K is the high-frequency dielectric constant of the PMMA, ϵ_0 is the free-space permittivity, and d is the PMMA thickness. Here it is assumed that the electric field is uniform and equal to V/d.

Cells with phosphor dispersed in the PMMA binder were electroluminescent immediately on application of d-c voltage. The brightness for a given current was not as high as that reported by Vecht *et al.* (6), but the voltage required to produce a given brightness was less. The electroluminescent cells prepared by Vecht *et al.* (6), from phosphor simultaneously activated and copper-coated also exhibited lower luminance for a given current and higher luminance for given voltage than those prepared from post-activated powder, but these required a forming step after preparation. In cells prepared in the present work, the current decreases slowly with time, as also does the luminescence. The voltage was set at the maximum value for 5 min and then a voltage-current-luminescence characteristic was recorded.

In Fig. 2 are plotted log I *vs.* $\sqrt{V}$ for a cell with pure ZnS (cell A) and another with ZnS:Mn,Cu,Cl dispersed in the binder (cell B). The phosphor concentration is 0.5g of phosphor per cubic centimeter of binder. The Mn concentration is 0.40%, the Cu concentration is 0.09%, and the Cl concentration is 0.005% by weight, in the ZnS. The curves are linear and the slopes are greater than in Fig. 1. (Note the change in the vertical scale.) The slope is greater for cells with ZnS:Mn,Cu,Cl than those with pure ZnS dispersed in the PMMA binder.

A number of cells were fabricated with varying phosphor binder ratio. The relation of Eq. [1] was obeyed by the d-c current-voltage characteristic of each cell, and only the constants I_0 and V_I varied. I_0 and V_I are plotted *vs.* phosphor concentration in Fig. 3. Also plotted are I_0 and V_I for zero phosphor concentration, *i.e.*, with no phosphor dispersed in the binder. It is seen that I_0 falls on introduction of the phosphor and then increases rapidly as the phosphor concentration is increased. V_I decreases sharply and then becomes relatively independent of phosphor concentration.

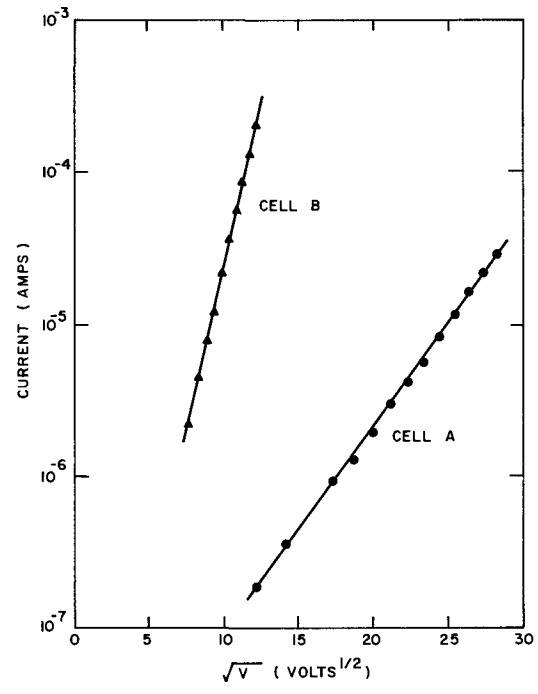

Fig. 2. Current-voltage characteristics for films with pure ZnS (cell A) and ZnS:Mn,Cu,Cl phosphor (cell B) mixed into binder.

The luminance-voltage characteristic for each cell obeyed reasonably the relation

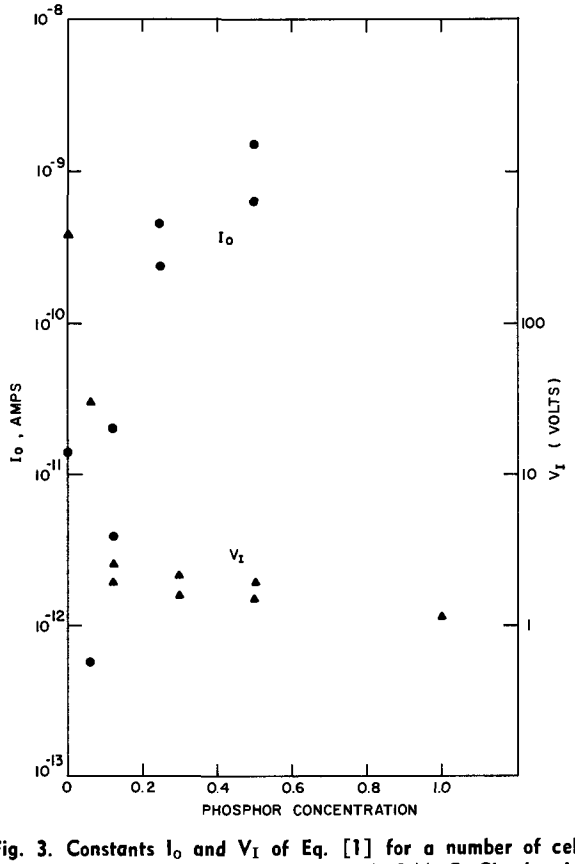

Fig. 3. Constants I_0 and V_I of Eq. [1] for a number of cells with electroluminescent films of various ZnS:Mn,Cu,Cl phosphor concentrations.

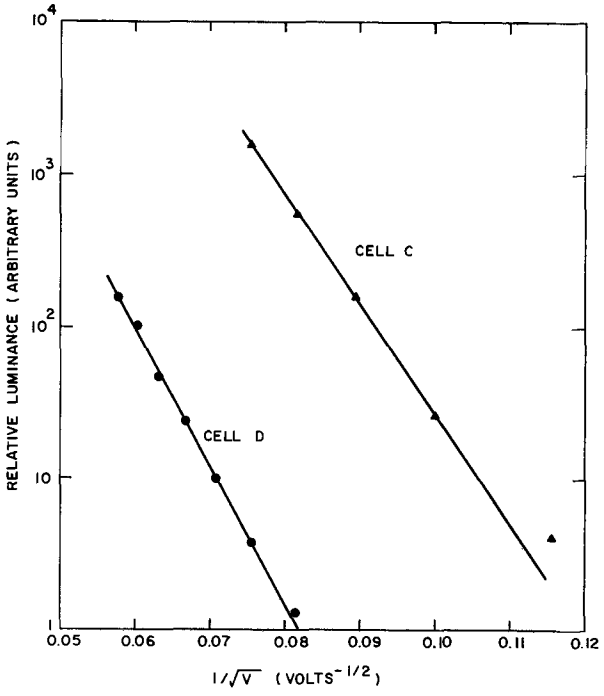

Fig. 4. Typical luminance-voltage characteristics plotted as logarithm of luminance *vs.* reciprocal square root of voltage. In cell C the phosphor concentration is 1.0 g/cm^3 of binder. In cell D the phosphor concentration is 0.25 g/cm^3 of binder.

$$L = L_0 \exp \sqrt{V_L/V}$$

for higher voltages. Log L is plotted *vs.* $1/\sqrt{V}$ for two cells of different phosphor binder ratios in Fig. 4. In cell C the phosphor concentration is 1g of phosphor per cubic centimeter of binder, and in cell D it is 0.25g of phosphor per cubic centimeter of binder. Log L is plotted *vs.* log I for the same cells in Fig. 5. In general, the luminance at constant voltage increased as the phosphor concentration was increased. The luminance at constant current seemed to increase with decreasing phosphor concentration to about 0.25g of phosphor per cubic centimeter of binder and then become relatively independent of phosphor concentration.

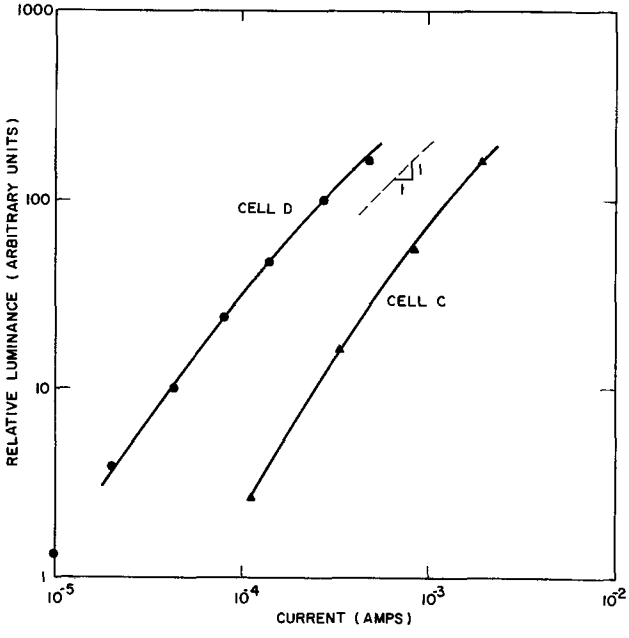

Fig. 5. Luminance-current characteristic for same cells as in Fig. 4. Unity slope is approached at higher luminances.

Discussion

Polymethylmethacrylate is an atactic polymer and amorphous (21). Optical transmittance is constant for wavelengths longer than 3500Å, which corresponds to an optical bandgap of 3.55 eV. The a-c conduction and loss in polymers is generally attributed to rotation of polar groups not directly attached to the main polymer chain. The d-c conduction in polymer films has also been assumed ionic (22, 23). The d-c conduction in other insulating films at high fields and room temperature has been found to be normally Schottky emission from electrodes, or field-enhanced release of electrons from traps in the insulator, the Poole-Frenkel effect (19). Schottky emission has been reported, however, for 1-mm thick PMMA (24) 1-mil thick Mylar (25), and 2-mil thick polyvinyl formal (25). Current-voltage characteristics appropriate for Poole-Frenkel conduction have been reported for 1-mil thick Mylar (26) and polymerized thin films of silicone oil (27) and styrene (28). The thickness of the PMMA films studied in the present work is 1.4-1.6 mils.

The dielectric constant of PMMA is given as 3.3-3.9 at 60 Hz and decreases as frequency is raised (29). It passes through a broad minimum of approximately 2.5 at 10^7 Hz and is approximately 2.6 at 10^9 Hz. A high-frequency value can be calculated from the slope of the curve in Fig. 1. Assuming Schottky emission to be dominant and using Eq. [3], the experimental value for K is 2.7 and compares well with published values.

The large increase in the slope of the log I *vs.* $\sqrt{V}$ curves on addition of ZnS or ZnS:Mn,Cu,Cl can be attributed to a nonuniform field, *i.e.*, a field much greater in value than V/d at ends of ZnS particles or at tips of conducting Cu-rich lines. If ZnS particles in the binder are assumed to provide conduction paths from one electrode to another, it is possible for conduction to be controlled by Schottky emission of electrons from conducting lines or from an electrode into ZnS. Assuming the high-frequency dielectric constant of ZnS to be 5.7 (30), insulator thicknesses d were calculated from Eq. [3]. These are effective insulator thicknesses since the field is in this case not uniform. For the two cells whose characteristics are plotted in Fig. 2 the effective ZnS thickness is 3.7 μm in cell A and the effective ZnS:Mn,Cu,Cl thickness is 0.7 μm in cell B as compared to binder-phosphor thicknesses of 30 and 35 μm, respectively, in the two cells. This indicates a greater concentration of field in the activated ZnS, likely at the tips of Cu-rich lines, than in unactivated ZnS.

The sharp decrease that is observed in the constant V_I of Eq. [1] as the phosphor is introduced into the binder can therefore be explained. As conduction in the phosphor becomes much greater than conduction in the binder, V_I approaches a constant value. The constant I_0 falls as the phosphor is introduced, and then rises as the phosphor concentration is increased.

A linear log I *vs.* $\sqrt{V}$ dependence of current on voltage has also been observed in evaporated electroluminescent films of ZnS:Mn,Cu,Cl contacted with Al and tin oxide electrodes (18). For these films an effective phosphor film thickness of 0.13 μm, for example, was calculated for a phosphor film with an actual thickness of 5.6 μm.

In Fig. 5, the slope of the curves of luminance *vs.* current appears to approach unity at high luminances. A linear dependence of luminance on current can be attributed to direct excitation of Mn luminescence centers without ionization, and Vecht and Werring (31) have proposed collision-excitation of Mn centers by conduction electrons to be the dominant process. In d-c electroluminescence current injection into the phosphor from electrodes or binder must occur. The results described above indicate that injection is essentially from electrodes. The mixing of electroluminescent phosphor with a plastic binder facilitates the spreading of the material into a layer of uniform thickness. The effect on the d-c characteristics of changing

the electroluminescent layer thickness and phosphor particle size were not investigated and may be important.

Manuscript submitted Dec. 4, 1972; revised manuscript received April 18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Silicon Surface Contamination: Polishing and Cleaning

R. L. Meek,* T. M. Buck, and C. F. Gibbon

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A Rutherford backscattering study using 2 MeV He^+ ions has shown that the principal contaminants heavier than Si remaining on silica-sol polished silicon surfaces are S (10^{14} cm^{-2}), Cl (10^{13} cm^{-2}), Ca (10^{14} cm^{-2}), Cu (10^{14} cm^{-2}), and a heavy metal in the range Pt-Au-Pb (10^{12} cm^{-2}). Preoxidation cleaning using HNO_3 and HF was found to be erratic in the ability to yield surfaces free of Ca and Cu and always left heavy metal contaminants. Cleaning with H_2O_2:HCl and H_2O_2:NH_4OH solutions always removed all elements heavier than chlorine to below the level of detectability. Both cleaning treatments left S and Cl at levels $\sim 10^{13}$ cm^{-2}. Breakdown voltage measurements indicated that junction quality was not predominantly controlled by surface impurities present after preoxidation cleaning, although the diode quality on cleaned wafers was much higher than on as-polished wafers.

Fabrication of silicon integrated microelectronic devices typically begins with sawing, etching, polishing, and cleaning of wafers before thermal oxidation. Impurities, particularly the fast diffusing heavy metals, left on the surface after these steps may be diffused into junction regions where they can degrade device properties. Determination of the identity and amount of these impurities on polished and cleaned surfaces is particularly amenable to the ion scattering technique (1-4).

Several workers (5-14) have investigated the absorption of metal cations onto silicon, germanium, and other semiconductor surfaces, usually using radiochemical techniques, and studied the consequent deleterious effects on junction properties. Kern (15) has recently reviewed the radioactive tracer work on semiconductor surface contamination. Typically, it is found that contact with solutions contaminated with ~1 ppm of heavy metal ions may leave on the order of monolayers of surface contamination (6, 12, 13). In this work we have determined the surface contamination levels actually introduced by typical processing operations.

Key words: contamination, soft junctions, silicon surfaces, polishing, cleaning, ion backscattering.

Experimental

Polishing.—Mendel (16) has recently reviewed the methods for polishing silicon. The conclusion is that the most satisfactory surfaces for device fabrication, that is those most nearly perfect (16-18), can be ob-

tained with the silica-sol polishing method (19). The silica-sol polishing medium is a colloidal suspension of silica gel in aqueous sodium hydroxide solution having a *p*H of 9.9. The suspension is about 30% silica having a particle size range of 100-400Å.

The results of a semiquantitative spectrographic analysis of the silica-sol solution are presented in Table I. The principal contaminants are Mg, Ca, Al, Ti, Fe, Cu, and Pb. The solution as it comes off the polishing pad has also been analyzed. In that solution the concentration of Mg, Ca, and Cu has increased and K appears. We have polished wafers with an iron ring deliberately placed on the pad in an attempt to increase iron contamination since earlier work (17) had indicated that iron might be a significant polishing-introduced contaminant. Of equal interest is the list of elements sought but not found in either the new or used solutions since these include Pt, Au, and Tl. We have quite often found a surface contaminant in the mass range Pt-Pb (*i.e.* Pt, Au, Hg, Tl, or Pb).

Cleaning.—In various polishing facilities a variety of ways of treating the silicon wafers in removing them from the polishing block have evolved. Those we have examined are given in Table II and range from the very simple method of simply rinsing off the wafers and block in flowing water, heating to remove, and rinsing off the mounting wax in acetone (WFF1) to much more involved procedures involving several organic solvents, HF and HNO_3 (ROM2).

Two basic final preoxidation cleanings have been considered and are summarized in Table III. The first of these uses HNO_3 and HF (NHF), while the second is based on use of solutions (20) of H_2O_2:NH_4OH and H_2O_2:HCl (PNH). We have also examined a slight modification of the NHF procedure (NHFA) which adds a final HCl dip in an attempt to remove Cu and the Pt-Pb mass range quite often found after the basic NHF cleaning.

Table I. Contaminants in silica-sol polishing solution as determined by qualitative spectrographic analysis* (parts per million by weight)

	Unused solution	Solution off pad	Solution off pad with Fe ring
Mg	1	10	10
Al	100	100	100
K	†	10	10
Ca	10	1000	1000
Ti	100	100	100
Fe	10	10	10
Cu	1	10	10
Pb	1	1	1

Elements sought but not found: Li, V, Cr, Mn, Co, Ni, Zn, Ga, Ge, As, Rb, Sr, Zr, Nb, Mo, Pd, Ag, Cd, In, Sn, Sb, Cs, Ba, Ta, W, Pt, Au, Tl, Bi.

Table II. Summary of slice demounting (preclean) procedures

RDCP
1. Rinse with DI water, blow dry.
2. Heat to remove from block.
3. Scrub with Triton-X 100.
4. Rinse with trichloroethylene.

ROM 1
1. Scrub under tap water, rinse DI water, blow dry.
2. Heat to remove from block.
3. Boil 5 min in trichloroethylene.
4. Acetone rinse, swab with methanol.

ROM 2
1. Flood with DI water, blow dry.
2. Heat to remove from block.
3. Boil in trichloroethylene, rinse acetone, methanol.
4. 1:1 HF:H_2O, DI rinse.
5. HNO_3, DI rinse, methanol rinse, blow dry.

WFF 1
1. Scrub with detergent under flowing tap water, blow dry.
2. Heat to remove from block.
3. Rinse in acetone.

WFF 2
Same as WFF 1 but no detergent.

Table III. Summary of preoxidation cleaning procedures

NHF
1. Rinse, trichlor, acetone, H_2O.
2. Superoxol boil, rinse H_2O, HF dip, rinse H_2O.
3. HNO_3, 80°C, 10 min, rinse H_2O.
4. HF dip, rinse H_2O, blow dry.

NHFA
1-4. Same as NHF.
5. Dip in HCl 2 min.

PNH
1. Scrub with Triton-X100, rinse H_2O, ethanol.
2. NH_4OH: $4H_2O$: H_2O_2, 80°C, 10 min, rinse H_2O.
3. HF dip, rinse H_2O.
4. 4HCl: H_2O_2: H_2O, 80°C, 10 min, rinse H_2O.
5. HF dip, rinse H_2O, spin dry.

Ion scattering.—The MeV Rutherford ion backscattering technique (1-4) has proven to be an excellent tool for identification and quantitative determination of silicon surface contaminants. A schematic of the basic experimental arrangement is shown as Fig. 1. A beam of 2 MeV He^+ ions is collimated through two Ta collimators 1 mm in diameter about 2m apart. The backscattered (177°) He ions were detected in a 50 mm^2 surface barrier detector having an energy resolution of 16 keV. Secondary electron suppression and pile up rejection electronics were used. The silicon samples were surrounded by a baffle cooled to liquid nitrogen temperature and were mounted in a two axis goniometer which allowed the sample to be aligned with a <110> axis parallel to the beam. This channeling combining with pile-up rejection allows maximum sensitivity since pile-up counts beyond the silicon edge, which would tend to obscure true surface impurity counts, can be virtually eliminated, while still maintaining a sufficient total beam current to give reasonable measurement times (typically 30 min). The scattering chamber was maintained at 10^{-6} Torr and the He ion fluence was typically 10^{16} cm^{-2}.

MeV He^+ ions are known to closely obey the Rutherford scattering law. The scattered ion yield per unit solid angle is given by

$$\frac{dn}{d\Omega} = \frac{n_o N b^2}{16} \sin^{-4}\left(\frac{\theta_c}{2}\right) \quad [1]$$

where

$$b = \frac{Z_1 Z_2 e^2}{\frac{1}{2}\left(\frac{M_1 M_2}{M_1 + M_2}\right) V^2} \quad [2]$$

and Z_1 and Z_2 are the atomic numbers of incident particle and target atom, M_1 and M_2 are the respective masses, and θ_c is the center of mass scattering angle; e is the electronic charge, V is the velocity of the incident ion, n_o is the number of incident ions, and N is the number of target atoms cm^{-2}. The center of mass and laboratory scattering angles are related by

$$\sin(\theta_c - \theta_L) = \frac{M_1}{M_2} \sin\theta_L \quad [3]$$

Since the scattering is elastic, ions scattered from a target atom of given mass at a given θ_L have a characteristic energy, E, given by

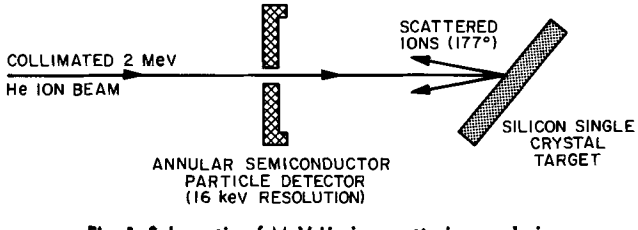

Fig. 1. Schematic of MeV He ion scattering analysis

$$\frac{E}{E_o} = \frac{M_1^2}{(M_1 + M_2)^2}\left\{\cos\theta_L + \left(\frac{M_2^2}{M_1^2} - \sin^2\theta_L\right)^{1/2}\right\}^2 \quad [4]$$

where E_o is the ion energy before the scattering event.

It is convenient to define a sensitivity factor α, which depends on the scattering cross section, such that

$$n = \alpha N_c/F \quad [5]$$

where n is the impurity concentration (atom cm^{-2}), N_c is the number of counts at an energy corresponding to that impurity, and F is the incident ion fluence in microcoulombs. This sensitivity factor is plotted, for our experimental conditions, in Fig. 2. For a few tens of microcoulombs and peaks of a few counts, the sensitivity is then $\sim 10^{12}$ cm^{-2} for masses near Cu and $\sim 10^{11}$ cm^{-2} for masses near Au.

The mass resolution decreases with increasing mass since the detector energy resolution is constant. Near Cu the mass separation is about 6 keV/atomic mass units and near Au is only 1 keV/atomic mass units so that we are not able to definitively identify the heaviest mass species, but rather only a mass range.

Diode formation.—After surface characterization as described above, a masking oxide was grown on the wafers at 1050°C in steam, a pattern of 1 × 2 mil openings cut, a 8 × $(10)^{14}$ cm^{-2} boron diffusion source implanted, and diodes formed by diffusing for 40 min at 1130°C in pure O_2. After a light etch, the breakdown voltages of 15 diodes on each wafer were determined.

Results

Typical experimental data.—In Fig. 3 is the spectrum obtained from a typical silica-sol polished, WFF1 precleaned, surface of <111> 10 ohm-cm, n-type silicon. The impurities detected on this sample are sulfur, chlorine (the two isotopes are clearly resolved, especially for somewhat larger total fluence), calcium, perhaps titanium, and copper. The absence of pulse pile-up is evident from the absence of background counts at high energy. Somewhat longer counting times reveal a slight contamination in the Pt-Pb mass range (about $3(10)^{11}$ cm^{-2}). Figure 4 is the spectrum

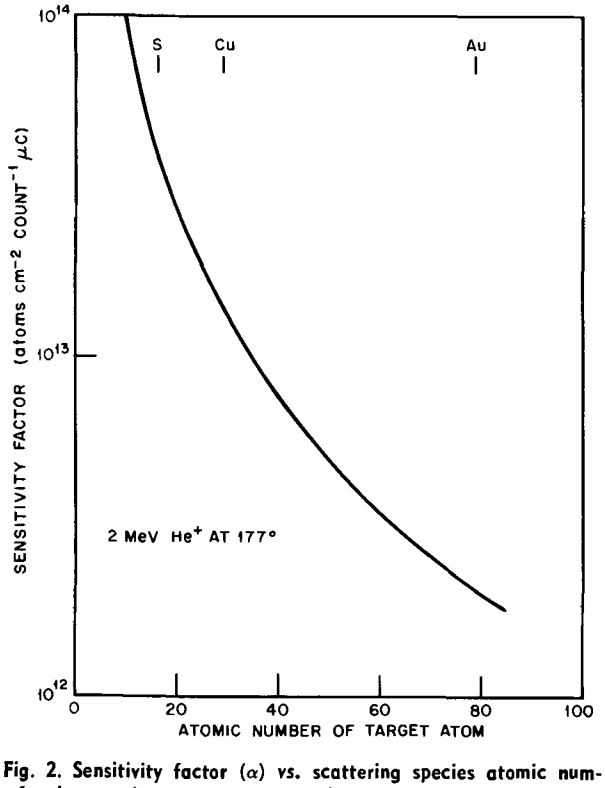

Fig. 2. Sensitivity factor (α) *vs.* scattering species atomic number for the experimental geometry used.

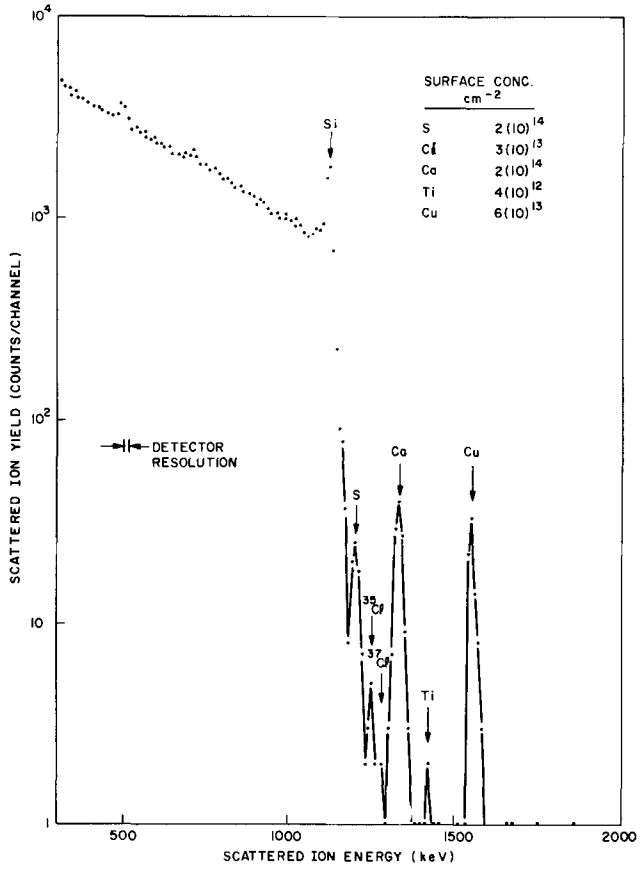

Fig. 3. Typical scattered ion spectrum from a silica-sol polished surface. The He ion dose is $(10)^{16}$ cm^{-2}.

for a sample which had been NHF cleaned after polishing. Here sulfur, chlorine, and a species in the mass range Pt-Pb remain on the surface.

Sawed and etched surfaces.—Wafers for polishing are produced by ID sawing from silicon ingots and etching to remove surface damage (17, 21). We have examined the surface contamination on the sawed and etched wafers; the results are tabulated in Table IV. Numerous contaminants are seen. Sulfur and chlorine are first detected after sawing, and, as will be seen, persist throughout the polishing and cleaning. A rather broad peak is found in the mass range Mo-Ba, the structure of which suggests it is mostly Ag, I, and Ba. Ba and S are thought to originate from the $BaSO_4$ used as a filler in the wax used to hold the ingot during sawing. K and Ca probably come from the water used during cutting and the metals from the steel ID blade and the Cu-Ni alloy used to bond the diamond grit to the blade. Results after etching are shown in the third column of Table IV. Of particular interest are the facts that S and Cl remain and that Cu and species in the Pt-Pb mass range are not detected.

Contamination of clean surfaces in contact with polishing solution.—As will be discussed subsequently, it is possible to prepare clean silicon surfaces free of contaminants heavier than chlorine. The contamination levels introduced on such clean silicon surfaces left in contact for 30 min with unused and used silica-sol polishing solutions are given in Table V. The S and Cl levels are typical of the cleaned surface, and K, Ca, Ti, Fe, Cu, and something in the Pt-Pb range are each found at $\sim 10^{12}$ cm^{-2}. The level of impurities is fairly independent of whether the solution was new or used except that Cu and Pt-Pb are found only after immersion in the used solution. It will be recalled from Table I that the Cu concentration is an order of magnitude greater in the used solution.

There are at least two reasons to suppose that the contamination found on as-polished surfaces will be different. The first is that as the surface is being polished its adsorption-desorption characteristics may be different than a clean silicon surface with its native oxide. The second is that the treatment (preclean) which the slice receives during removal from the polishing block may introduce or remove some surface impurities.

Polished surfaces.—Table VI summarizes the data for polished samples treated in various ways. S ($\sim 10^{14}$ cm^{-2}), Cl ($\sim 5(10)^{13}$ cm^{-2}), and K ($\sim 10^{13}$ cm^{-2}) are found on all as-polished samples. Ca is not present on RDCP precleaned surfaces but appears at $\sim 10^{13}$ cm^{-2} on ROM1 or ROM2 surfaces and at $\sim 10^{14}$ cm^{-2} on WFF1 or WFF2 surfaces. This seems reasonable since the latter involve scrubbing with tap water. Cu is present at roughly $\sim 10^{14}$ cm^{-2} on all as-polished samples except that which had the ROM2 treatment. This is explicable since the nitric acid involved in ROM2 should remove Cu.

Species in the Pt-Pb mass range are present at 10^{11}-10^{13} cm^{-2} except on samples which had the ROM1 or ROM2 preclean. Finally we note that placing

[b] Not discerned due to magnitude of neighboring peaks.
[c] Iron ring on polishing pad.

the Fe ring on the polishing pad had no effect and that Fe is only rarely found, and then at very low levels, $\sim 10^{12}$ cm^{-2}. Based on the cleanliness of the as-polished surface one would tend to prefer the most complicated demounting procedure (ROM2). However, as will be shown, equally clean surfaces can be prepared regardless of the preclean used, even when the sample is simply rinsed with tap water (WFF2) so that extensive effort at the preclean stage is probably not justified.

The results for cleaned surfaces are also given in Table VI and summarized in more tractable form in Table VII. The NHF cleaning leaves S and Cl at $2(10)^{13}$ and 10^{13} cm^{-2}, respectively. Ca is found at various levels from undetectable to 10^{12} cm^{-2} and Cu at levels from undetectable to 10^{14} cm^{-2}. The mass range Pt-Pb is found at levels from 10^{11} to 10^{13} cm^{-2}, increasing for increasing levels on the as-polished sample but in every case being greater on the cleaned sample than on the as-polished surface. This very likely indicates that some species in this mass range is actually introduced by the cleaning.

Adding a HCl dip to the NHF cleaning (NHFA) reduces all contamination levels. In particular it removes Ca and Cu and markedly reduces the Pt-Pb mass range. However, Fe is quite often found after this HCl dip, even when it was not detectable on the as-polished surface. Subsequent work has shown that Fe is in fact a contaminant in HCl.

The PNH cleaning on the other hand reduces S and Cl to $\sim 10^{13}$ cm^{-2} and no impurities heavier than Cl are ever found on PNH cleaned surfaces.

Diode quality.—Two sets of wafers from different parts of the same ingot were polished, WFF1 precleaned, and then preoxidization cleaned in various ways before diode formation as described previously. The results are summarized in Table VIII. One observes:

1. The as-polished wafers give the poorest results for both sets, as expected; comparison with Table VII suggests that this may be related to the retention of copper on the surface.

2. The two groups of wafers, although processed through diode formation simultaneously in one batch, show a very large difference in diode formation properties. The surface contamination was similar in both cases so this does not appear to be a surface contamination-related effect. The wafers in each group were from different parts of the same ingot and one might conjecture that some bulk contaminant was nonuniformly distributed through the ingot.

Table VII. Polished and cleaned surfaces (surface concentration, cm^{-2})

	Polished	NHF	NHFA	Peroxide ammonia
S	$(10)^{14}$	$2(10)^{13}$	$(10)^{13}$	$(10)^{13}$
Cl	$(10)^{13}$	$(10)^{13}$	$3(10)^{12}$	$(10)^{13}$
Ca	$(10)^{14}$	N.D. to $(10)^{12}$	N.D.	N.D.
Fe	N.D.*	N.D.	N.D. to $(10)^{12}$	N.D.
Cu	$(10)^{14}$	N.D. to $(10)^{14}$	N.D.	N.D.
Pt-Pb	$(10)^{11}$-$(10)^{13}$	$(10)^{11}$ to $(10)^{13}$	N.D. to $(10)^{12}$	N.D.

* N.D. = not detectable.

Table VIII. Diode formation results for polished and cleaned surfaces

	As polished	NHF	NHFA	PNH
Group I				
BV range	~0V	~1V	~1V	~1V
Diode quality (on 10 μA scale)	All very soft	All soft	All soft	All soft
Group II				
BV range	20-110	102-116	100-108	100-118
Diode quality (on 10 μA scale)	80% soft	All hard	All but one hard	All hard

Furthermore we have found when gettering processed material to produce hard diodes (22) that typically 10^{15} cm^{-2} of Cu and Fe and 10^{13} cm^{-2} of Au are gettered. On the other hand, gettering of control wafers (23) indicates that impurities of this concentration are not usually present in the starting material. We have also examined the back sides of the wafers of Table VIII to see if impurities had already been "self-gettered" to the back side of the wafers as has been found to be the case with other wafers which formed hard diodes as processed (22). No such effect was found for either group. Identification of the steps in processing responsible for impurity introduction is under investigation but it appears from the present work that impurities introduced by polishing and preoxidation cleaning are not significant contributors to soft diode formation. This is emphasized by the case of the PNH ($HCl:H_2O_2$ and $NH_4OH:H_2O_2$) cleaning procedure since these metal surface impurities are not detected, yet in one case all the diodes are hard and in the other they are all soft.

Conclusions

The conclusions of the present work may be summarized as follows:

1. The manner in which polished wafers are treated (precleaned) in removing them from the polishing block is not an important factor in the final observed surface contamination of cleaned wafers.
2. Fe is not an important surface contaminant after silica-sol polishing.
3. S and Cl are present at $\sim 10^{13}$ cm^{-2} after all cleaning procedures studied.
4. Other major contaminants are Ca, Cu, and some species in the Pt-Pb range.
5. The peroxide-ammonia, peroxide-hydrochloric acid cleaning eliminates Ca and Cu much more reliably than does the $HF:HNO_3$ cleaning.
6. $HF:HNO_3$ cleaning leaves a heavy mass impurity in the Pt-Pb range. An added HCl dip reduces it.
7. The peroxide-ammonia cleaning procedure removes all surface impurities heavier than Cl to below the level of detectability.
8. Impurities left after silica-sol polishing and preoxidation cleaning do not appear to control diode quality.

Acknowledgments

The authors would like to recognize the contribution of E. I. Povilonis in the processing and measurement of the diodes, and thank W. F. Flood and R. O. Miller for polishing samples.

$Ga_{1-x}Al_xAs$-GaAs P-P-N Heterojunction Solar Cells

H. J. Hovel* and J. M. Woodall*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Solar cells consisting of $pGa_{1-x}Al_xAs$-pGaAs-nGaAs have been fabricated by the liquid phase epitaxial growth of Zn-doped $Ga_{1-x}Al_xAs$ on n-type GaAs substrates. The spectral response of the cells has been used to calculate the absorption coefficient of the alloy layer; the coefficient varies as $(h\nu - Eg)^{1/2}$, and indirect bandgaps of 2.071 and 2.094 eV for compositions of $x = 0.73$ and $x = 0.86$, respectively, are indicated. The solar cell characteristics were measured in sunlight at Air Masses of 0.9 and 1.3 and in simulated sunlight at Air Mass 0; the open-circuit voltages ranged from 0.97 to 1.0V, the short-circuit currents from 20 to 22.5 mA/cm^2, and the efficiencies (corrected for contact area) from 11.7 to 12.8% at Air Mass 0 and a temperature of 80°F. The short-circuit current and open-circuit voltage increase and decrease, respectively, linearly with temperature. The efficiency has a maximum at around −75°C, and decreases at a rate ($\Delta\eta/\Delta T$) of 0.022% per °C up to 200°C and at over twice that rate above 200°C. Efficiencies of almost 6% at 300°C and over 3% at 350°C were measured using a quartz-halogen light source that simulates Air Mass 1.

It has long been recognized that GaAs solar cells would be preferable to Si solar cells if the costs were equal. Some advantages of GaAs over Si include a higher theoretical efficiency [24% for GaAs compared to 21% for Si (1)], the ability to operate at higher temperatures, and a superior resistance to degradation from particle radiation. In fact, however, the highest measured efficiency for GaAs (13%) (2) has not equaled the value for Si (15%) at Air Mass 1, and the cost of GaAs cells greatly exceeds that for Si cells (Air Mass is a term which quantifies optical absorption and scattering in the earth's atmosphere). Therefore the major interest in the past few years has been in Si cells rather than GaAs, and the situation seems likely to remain that way due to the high level of technology developed for Si, its abundance as an element, its relatively low cost, and its excellent solar cell behavior.

Recently, however, GaAs solar cells have been reported (3, 4) with higher efficiencies produced by the addition of a thin, epitaxial layer of p-type $Ga_{1-x}Al_xAs$ on the GaAs p-n junction surface. Efficiencies of over 16% at Air Mass 1 and 19-20% at Air Mass 2 have been measured. This enhances the outlook for GaAs cells in particular satellite applications where cost is not the limiting factor. The improvement in efficiencies can be attributed to five factors: (*i*) the close lattice match between $Ga_{1-x}Al_xAs$ and GaAs, which results in a low surface recombination velocity at the GaAs p-n junction surface (which is now the interface); (*ii*) a reduction in the series resistance, since the heavily doped, transparent, p-type $Ga_{1-x}Al_xAs$ alloy layer acts as the electrical contact to the p-type GaAs; (*iii*) longer diffusion lengths in the GaAs p-region due to the lower doping allowed there as a result of the highly doped alloy layer; (*iv*) the optical transparency of the alloy layer which allows light over much of the solar spectrum to reach the GaAs; and (*v*) the presence of a barrier at the interface which prevents minority carriers from the p-type GaAs region from entering the alloy layer, and which therefore improves the collection of these carriers.

This paper describes the fabrication of the heterojunction solar cells by liquid phase epitaxy and the technology of contacting, etching, and applying antireflective coatings. The absorption coefficient of the alloy layer as a function of wavelength has been calculated for various compositions by an analysis of the spectral response of the cells. Finally, the electrical and optical properties of the devices are discussed, as well as the effect of temperature on the device behavior.

Fabrication

The solar cell consists of an n-type GaAs substrate, a p-type GaAs surface region of the order of a micron wide, and a p-type $Ga_{1-x}Al_xAs$ alloy layer on the pGaAs surface, with compositions ranging from $x = 0.27$ to $x = 0.86$ and thicknesses from 2 to 20μ. In form, the solar cell is similar to the heterojunction lasers reported by a number of authors (5, 6), except that the compositions and doping levels are different, and is similar to the $pGa_{1-x}Al_xAs$-nGaAs cells reported by Alferov *et al.* (7) (the latter had no pGaAs region). The cells are fabricated by a vertical liquid phase epitaxy technique in a system described previously (8); the main features of this apparatus are shown in Fig. 1. For most of the experiments n-type (100) GaAs substrates (~1 cm^2 surface area) doped with either 1-2 × 10^{17} Si atoms/cm^3 or 1-2 × 10^{18} Sn atoms/cm^3 were used. Preparation of the substrate was accomplished by: (*i*) lapping with 2μ grit; (*ii*) etching with 2% bromine-methanol solution for 2 min; (*iii*) etching with 1:3:4, $HF:HNO_3:H_2O$ for 15 sec; (*iv*) etching with 1:1:2 $NH_4OH:H_2O_2:H_2O$; and (*v*) rinsing with deionized water and drying in air. The substrate is placed in the recess located in the carbon substrate

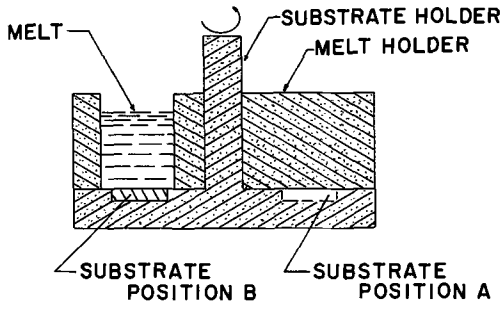

Fig. 1. Melt and substrate holder arrangement used in the liquid phase epitaxial growth of $Ga_{1-x}Al_xAs$-GaAs structures.

holder. A mixture of Ga, Al, GaAs chunks, and Zn is placed in the melt chamber located in the carbon melt holder; typical proportions consist of 5.0g of Ga, 0.03g of Al, >0.5g of bulk GaAs, and 0.03g of Zn, although both the Al proportions and Zn content can be changed in order to vary the alloy composition and junction depth, respectively. The apparatus of Fig. 1 is placed in a quartz growth tube which is evacuated and flushed with palladium-purified hydrogen. The system is then heated to 900°C and maintained at that temperature for a period of 1/2 hr to allow the melt to equilibrate. The substrate is initially enclosed by the high purity carbon (position A) to prevent any appreciable loss of As from the surface during the equilibration period; similarly, the melt chamber is capped to minimize loss of Zn due to the high Zn vapor pressure. At the end of the equilibration period the substrate holder is rotated with respect to the melt holder until the substrate is covered by the melt (position B), and the system is cooled from 900° to 890°C at a rate of 0.1°C/min, after which the sample is rotated away from the melt once more. Since the substrate thickness is nearly equal to the depth of the recess in the carbon holder, the melt is "wiped off" the substrate surface at this point, preventing spurious growth during cooling to room temperature.

During the growth of the Zn-doped $Ga_{1-x}Al_xAs$ layer, Zn diffuses into the n-type substrate to form the p-type GaAs region. For the high Al compositions ($x = 0.86$) and for the high substrate doping levels (2×10^{18} cm^{-3}) it was sometimes found that the Zn content in the melt was not sufficient to counterdope the substrate and no pGaAs region was produced, while the same Zn content with a $x = 0.7$ composition would produce the pGaAs region, indicating that the segregation coefficient in the alloy layer decreases somewhat with increasing Al content. For a given alloy layer composition and substrate doping level, the junction depth (width of the pGaAs region) is controlled by varying the Zn content in the melt as shown in Fig. 2. The junction depth appears to obey a 0.59 power law dependence on the Zn concentration as suggested by previous studies of Zn diffusion into GaAs (9, 10). For the device studies, the junction depth was varied between 0.2 and 7.0μ, but most of the units were made with depths of 0.6-1.0μ since analysis showed (4) that the highest efficiencies are expected in this range.

To reduce the sheet resistivity of the alloy layer and facilitate making ohmic contact to it, Zn was diffused into the layer at 700°-720°C for 10-20 min using a sealed quartz ampule and $ZnAs_2$ as the diffusion source, raising the Zn concentration at the surface to greater than 10^{19} cm^{-3}. The reverse side of the substrate is then lapped until the total sample thickness is around 0.2 mm. A contact pattern is applied to the $Ga_{1-x}Al_xAs$ surface either by electroless plating of Au-Zn followed by electroplated In, or by evaporating Au-Zn through a metal mask with the sample at about 300°C. Contact to the back side of the cell was made by electroless Au-Sn plating followed by In electroplating, or by evaporation of Au-Ge-Ni. In general, evaporation was

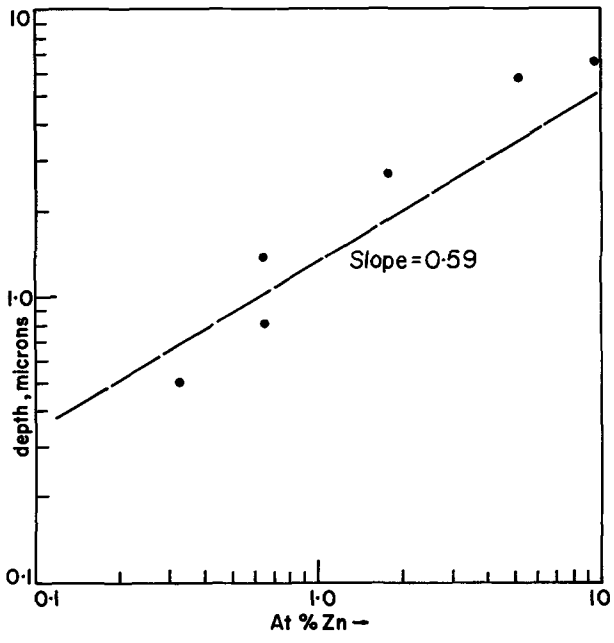

Fig. 2. Junction depth vs. zinc concentration in the melt for a substrate doping of 2 x 10^{17} cm^{-3} and an alloy composition of 0.7.

preferred because it left the sample surfaces in a cleaner state and seemed to produce lower contact resistances.

In order to perform a variety of experiments and to facilitate mounting, the wafers were diced into four to six cells of 0.18-0.10 cm^2 surface area, and the units were mounted onto TO-5 headers with gold wires thermocompression bonded between the contact stripes and the header posts. The surfaces were then masked with Apiezon wax and the devices were etched for about 5 min in $9H_3PO_4$-$1HNO_3$ to reduce the reverse leakage current to between 0.5 and 5 nanoA at −1V. After removal of the wax and careful cleaning of the surface, a layer of SiO was evaporated onto the devices as an antireflection coating. The SiO coating is about 750Å thick, designed for a reflection minimum at 5200-5500Å, and was evaporated with the sample at 150°C.

In general, when the wafer was uniform in appearance after the growth of the alloy layer, the four to six cells cut from the wafer were very similar in their behavior, *i.e.*, the voltage and current output and efficiencies were about the same for all the units. When nonuniformities (such as excess growth on the sample surface due to small amount of melt left on the sample after "wiping") were present several of the units would behave better than the others.

It was also occasionally noticed that the thermocompression bonding of Au wires to the contact stripes caused degradation in some of the cells, and it was concluded that thermocompression bonding is not a good way to contact these devices.

Spectral Response and Absorption

The energy band diagram of a $pGa_{1-x}Al_xAs$-pGaAs-nGaAs solar cell, both in equilibrium and with light incident, is shown in Fig. 3. Light with energy less than E_{g1} but more than E_{g2} passes through the alloy layer and is absorbed in the GaAs, generating hole-electron pairs which can be separated by the junction electric field and will then give rise to photocurrent and photovoltage. Since there is no appreciable barrier in the valence band at the alloy-GaAs interface, the upper layer acts as a transparent ohmic contact in this range of photon energies, while the energy barrier

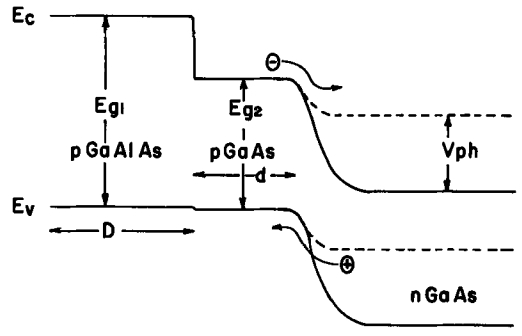

Fig. 3. Energy band diagram of a $Ga_{1-x}Al_xAs$-GaAs solar cell showing photocurrent and photovoltage generated by incident light.

in the conduction band[1] at this interface prevents photogenerated electrons in the pGaAs region from entering the $Ga_{1-x}Al_xAs$ and being lost. Incident light with photon energies greater than E_{g1} is attenuated by the alloy layer in accordance with its absorption coefficient. The generation rate of hole-electron pairs at a distance y into the GaAs from the alloy-GaAs interface is given by

$$g = F(\lambda) \exp(-\beta D)\, \alpha(\lambda) \exp(-\alpha y) \qquad [1]$$

where $F(\lambda)$ is the number of incident photons at wavelength λ, β and D are the absorption coefficient and thickness of the alloy layer, respectively, and α is the absorption coefficient of GaAs. Using this generation term, the minority carrier continuity equations can be solved to find the densities of electrons in the pGaAs region, holes in the nGaAs substrate, and hole-electron pairs in the depletion region, and the spectral response can be obtained by solving for the short-circuit current and dividing by the input flux, $F(\lambda)$. The result can be written as (4)

$$R(\lambda) = \exp(-\beta(\lambda)D) \cdot R'(\lambda) \qquad [2]$$

where $R(\lambda)$ is the spectral response of the device and $R'(\lambda)$ is the response of the underlying GaAs p-n junction alone. The assumptions involved in [2] are that the recombination velocity at the alloy-GaAs interface, the drift fields in the GaAs regions outside the depletion region, the collection of carriers generated in the alloy layer, and the reflection of light incident on the cell are all negligible.

Equation [2] was evaluated by computer for the same combinations of junction depths, diffusion lengths, and alloy layer thicknesses and compositions as expected in the experimental devices. When the $Ga_{1-x}Al_xAs$ thickness is taken as zero, the response $R(\lambda) = R'(\lambda)$ of the GaAs p-n junction rises sharply at 1.4 eV, increases slowly from 1.5 to 1.8 eV, and becomes constant for photon energies above 1.8 eV. The measured spectral response of the heterojunction cells (with the $Ga_{1-x}Al_xAs$ layer included) can therefore be used to compute the absorption coefficient β of the $Ga_{1-x}Al_xAs$ for any alloy composition having a bandgap energy above 1.5 eV [since the function $R'(\lambda)$ is known].

The spectral response (number of carriers collected/number of incident photons at a given wavelength) was measured by illuminating the device with monochromatic light from a Perkin-Elmer prism spectrometer. The light was "chopped" at 13 Hz, and the short-circuit current of the cell was fed into a lock-in amplifier which was used to drive an x-y recorder. The result was a plot of short-circuit current per unit incident power as a function of wavelength, which becomes short-circuit current per photon after dividing by the photon energy.

The normalized spectral responses of several $Ga_{1-x}Al_xAs$-GaAs solar cells of various compositions are shown in Fig. 4; these cells all have about the same junction depths and doping levels (and therefore about the same diffusion lengths). The response rises rapidly at the GaAs band edge, becomes flat above 1.7 eV, and remains fairly constant with increasing energy until the alloy layer begins to attenuate the light. The absorption coefficient of the alloy layer is found from [2] after including the effects of the reflection of light from the surface as a function of wavelength

$$\beta(\lambda_2) - \beta(\lambda_1) = \frac{1}{D} \ln \frac{R(\lambda_1)R'(\lambda_2)[1-\pi(\lambda_2)]}{R(\lambda_2)R'(\lambda_1)[1-\pi(\lambda_1)]} \qquad [3]$$

where $\beta(\lambda_2)$, $R(\lambda_2)$, $R'(\lambda_2)$, and $\pi(\lambda_2)$ are the absorption coefficient, total response, response of the GaAs p-n junction alone, and reflection from the device surface at wavelength λ_2, and $\beta(\lambda_1)$, etc., are the same quantities at λ_1. Since λ_1 can be chosen before cut-off begins [$\beta(\lambda_1) = 0$] and since the GaAs junction response can be taken as constant, [3] simplifies to

$$\beta(\lambda_2) = \frac{1}{D} \ln \frac{R(\lambda_1)[1-\pi(\lambda_2)]}{R(\lambda_2)[1-\pi(\lambda_1)]} \qquad [4]$$

The reflection $\pi(\lambda)$ from an SiO-coated GaAs sample as a function of energy is shown in Fig. 4, and the $Ga_{1-x}Al_xAs$ absorption coefficients (plotted as $\beta^{1/2}$ *vs.* energy) calculated from [4] are shown in Fig. 5.

From the steepness of the plots for the two lower compositions, it can be inferred that the direct band edges are being measured, with bandgap values of 1.69 and 1.99 eV, respectively. [The lowest bandgap for the $x = 0.23$ composition is, indeed, believed to be direct (12, 13), but it cannot be inferred from Fig. 5 that the lowest bandgap for the $x = 0.46$ compositions is direct, since this composition is very near the crossover point (12, 13) and an indirect edge at a slightly lower energy would be hidden in Fig. 5.] For the $x = 0.73$ and 0.86 compositions, the slow rise in absorption indicates that the bandgap is indirect, and the absorption coefficient behaves as

$$\beta \propto (h\nu - Eg)^{1/2} \qquad [5]$$

for $\beta^{1/2} \leq 18\ \text{cm}^{-1/2}$, with intercepts (bandgaps) of 2.071 and 2.094 eV, respectively. These values are in good agreement with those reported by Onton *et al.* (12) but slightly higher (by 0.1 eV) than those reported by Casey and Panish (13) for compositions

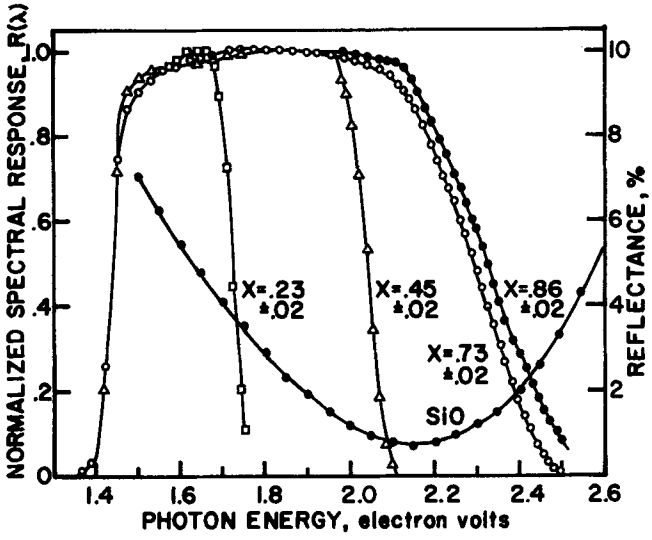

Fig. 4. Normalized spectral response for various alloy compositions. The $Ga_{1-x}Al_xAs$ thicknesses range from 11-16μ The reflection of incident light from a SiO-coated GaAs surface is also shown.

[1] It is probable that some grading in composition takes place between the $Ga_{1-x}Al_xAs$ and the GaAs due to the nature of the liquid phase epitaxial method of growth for these two materials. The distances over which this grading is expected to take place should be relatively small at these growth temperatures, and the diagram in Fig. 3 should be a reasonable approximation to the actual situation. [See Womac and Rediker (11).]

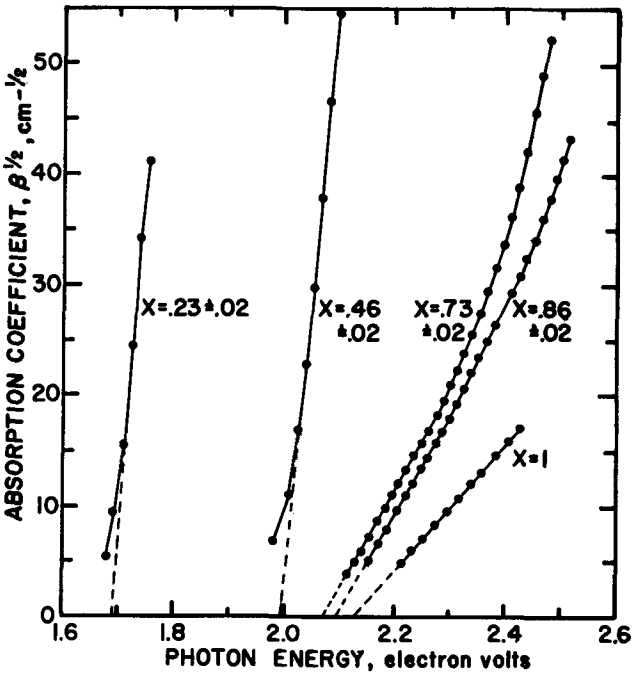

Fig. 5. Calculated absorption coefficients for $Ga_{1-x}Al_xAs$. The bandgaps indicated by the intercepts are 1.69, 1.99, 2.071, and 2.094 for the $x = 0.23$, 0.46, 0.73, and 0.86 compositions, respectively. The absorption coefficient in AlAs is also shown [after Lorenz *et al.* (14)].

with $x > 0.23$. The onset of direct band absorption is suggested by the steeper rise above 2.4-2.5 eV.

The absorption coefficient of AlAs ($x = 1$) as reported by Lorenz *et al.* (14) is shown in Fig. 5 for comparison. A bandgap of 2.125 eV is indicated for this material.

The method outlined above for computing the absorption of the $Ga_{1-x}Al_xAs$ layer from the spectral response slightly underestimates the absorption coefficient because it neglects any contribution to the measured response from the collection of carriers generated in the alloy layer. The error should be relatively small, however, as long as the thickness of the layer is three or more times larger than the electron diffusion length in the layer. (For the devices of Fig. 4 and 5, the thicknesses D ranged from 11 to 16μ, while the diffusion length in the alloy should be less than 2μ at the high doping levels present after the Zn diffusion step.) For photon energies where β is small, the total number of carriers generated in the alloy layer is small, and although the carriers are generated fairly uniformly throughout the layer, only those are collected which are about a diffusion length or less away from the $Ga_{1-x}Al_xAs$-GaAs interface. At higher photon energies where β is large, most of the carriers will be generated near the surface and not collected for large D. The largest error probably occurs when $\beta \approx 1/D$ ($25 < \beta^{1/2} < 30$ for these devices) and probably does not exceed 10%.

Solar Cell Characteristics

The current-voltage characteristics of a typical $Ga_{1-x}Al_xAs$-GaAs solar cell, both in the dark and during illumination, are shown in Fig. 6. As a first approximation, the current obeys the familiar relationship

$$J = J_o (\exp (qV/AKT) - 1) - J_{sc} \qquad [6]$$

where J_{sc} is the short-circuit photocurrent density and the modifying factor A varies from 1.4 to 2.1 from growth run to growth run with no discernable correlation with growth parameters. The short-circuit current density J_{sc} and the open-circuit voltage V_{oc} are determined from the intercepts of the characteristic with the current and voltage axes, respectively. In

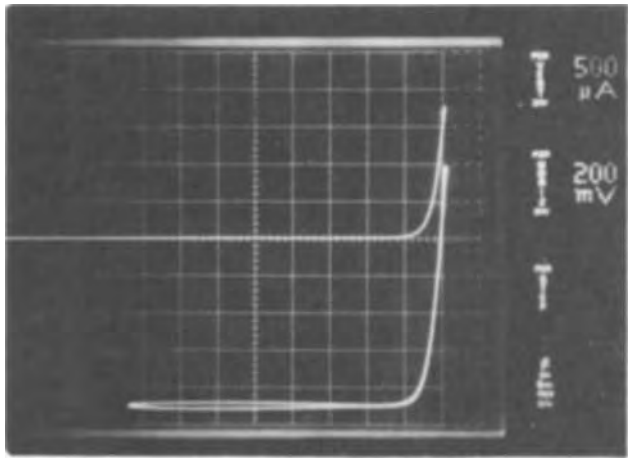

Fig. 6. Voltage-current characteristic with and without light for cell 298. The zero of the axes is at the center of the graph. The power output is equal to the maximum value of $V \times I$ in the fourth quadrant.

keeping with standard solar cell theory, the maximum power ($V_{mp}J_{mp}$) that can be obtained from the cell is equal to the greatest value of $V \times J$ in the fourth quadrant, and the ratio of the maximum power to the product of J_{sc} and V_{oc} is known as the "usage factor" (or "fill factor").

The open-circuit voltage, short-circuit current, and maximum power output were measured in sunlight on cloudless days at around noontime. The power input/square centimeter was measured with an Eppley thermopile. The device parameters for several cells of various junction depths, alloy thicknesses, and alloy compositions are shown in Table I, where the measurements were made at sea level, with an Air Mass of around 1.3 and a temperature of 65°F. (The Air Mass, which is the ratio of the optical path length of sunlight through the atmosphere to the path length when the sun is at the zenith, was determined by measuring the sun's angle and modifying the result by the altitude compared to sea level.) Table II lists the same solar cell parameters measured at an altitude of 12,800 ft, with an Air Mass of around 0.9 and a temperature of 45°F [values for several of these cells at Air Mass 1 and 2 were given earlier (3)]. The short-circuit current has been corrected for the contact area of 5-7% and both the uncorrected and corrected efficiencies are given. Around Air Mass 1, the short-circuit currents are of the order of 18-21 mA/cm² and the open-circuit voltages usually range from 0.97 to 1.0V (300°K). The usage factors vary from growth run to growth run, apparently due to differences in series

resistance when the doping in the alloy layer is too low and the significant sheet resistivities or contact resistances are present (it has been discovered recently that "firing-in" the Au-Zn contacts to the alloy layer and the Au-Ge-Ni contact to the substrate at temperatures in excess of 400°C for several minutes in a H_2 atmosphere is an important step in achieving negligible contact resistance). The usage factors are generally between 0.74 and 0.82 with 0.79-0.80 being typical, and the voltage output at the maximum power point, V_{mp}, is usually in the range of 0.79-0.84V. The output power and the over-all efficiency are functions of the Air Mass value, *i.e.*, functions of the atmospheric conditions (3, 4), since the spectral distribution of sunlight reaching the earth's surface is substantially modified by atmospheric absorption and scattering (15, 16); the higher the Air Mass value is, the greater is the degree to which ultraviolet and near-infrared radiation are lost in the atmosphere, and sunlight effectively becomes channeled into the visible range of wavelengths where the highest response of the cells is obtained. The efficiency therefore increases with increased Air Mass value.

Table III lists the solar cell parameters measured using an Air Mass 0 (outer space) simulator at the Jet Propulsion Laboratories in Pasadena, California. Since the major difference between AM0 and AM1 sunlight is the ultraviolet content, the efficiency drops sharply from AM1 to AM0 (the alloy layer for these thicknesses attenuates light of all energies greater than 2.5 eV). Nevertheless, these efficiencies are equal to most of the present-day silicon values, and higher efficiencies are expected (4) as the $Ga_{1-x}Al_xAs$ layer is made thinner.

Table IV lists the alloy thickness and composition and the junction depths for these cells. By comparing the short-circuit currents of the units in Tables I-III with their fabrication parameters in Table IV, it can be seen that higher currents are obtained for thinner alloy layers of a given composition, as expected from the reduced absorption in the $Ga_{1-x}Al_xAs$. Increasing the Al composition in the alloy has the same effect. The data also implies that higher currents are obtained for junction depths of around a micron, as predicted from computer evaluations of the spectral response integrated with the solar spectrum (4), than for junction depths greater than 1μ; that is due to a maximum in the sum of the photogenerated electrons collected from the surface p region and the photogenerated holes collected from the base (n region) at a junction depth of around 0.6-0.8μ. However, the collection is quite high for the devices of Tables I-IV even when the junction depth is 3μ, which indicates that the minority carrier diffusion length of electrons in the pGaAs region is 4μ or greater (4), in agreement with the results of Hayashi and Panish (5) for diffusion lengths in heterojunction lasers.

The effect on the device behavior of varying the input power and the temperature was observed with the use of collimated light from a quartz-iodine lamp operating at about 3200°K; the light was shown through a 2-mm thick wafer filter onto the sample. Although this system does not duplicate the solar spectrum by any means, it does result in efficiency values (uncorrected for contact area) that are nearly the same as those measured in sunlight at Air Mass 1 (after the contact area correction is made). For convenience, therefore, this system will be referred to as an Air Mass 1 simulator.

The short-circuit current is proportional to the intensity (input power) of the incident light over at least three orders of magnitude, provided that the spectral distribution of the incident light remains constant as the intensity varies. This can be seen in Fig. 7, where neutral density filters (which attenuate light of wavelengths from 0.4-0.9μ equally) have been used to vary the input power from the Air Mass 1 simulator. The open-circuit voltage is proportional to the log of the input power, while the usage factor drops at low intensities and saturates above 10 mW/cm².

Temperature

The solar cell behavior as a function of temperature in the range of −190° to +150°C was measured by placing the unit in a vacuum of 1×10^{-5} Torr and illuminating it through a sapphire window with the Air Mass 1 simulator. For temperatures above 150°C, the devices were measured in air. The power input to the devices was 100 mW/cm².

The short-circuit current increases linearly with increasing temperature as can be seen in Fig. 8. The increase in J_{sc} could be partly due to a shift in the absorption edge (17) of the GaAs to lower energies as temperature increases, and partly due to an increase in the diffusion lengths. The shift in the GaAs absorption edge is only large enough to account for about 5% of the 50% variation in J_{sc} that occurs from 100° to 420°K, and it is probably offset to some degree by a shift in the $Ga_{1-x}Al_xAs$ absorption edge to lower energies as the temperature increases. Therefore the increase in J_{sc} is most likely due to improved collection efficiency resulting from increased diffusion lengths at higher temperatures. Higher diffusion lengths in turn could result from either larger diffusion coefficients or

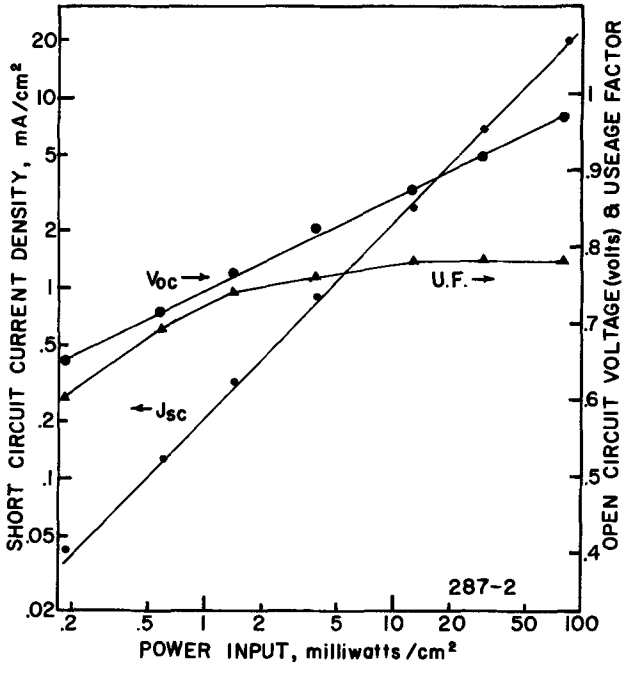

Fig. 7. Short-circuit current density (uncorrected for contact area), open-circuit voltage, and usage factor as functions of input power with the spectral distribution of the light held constant.

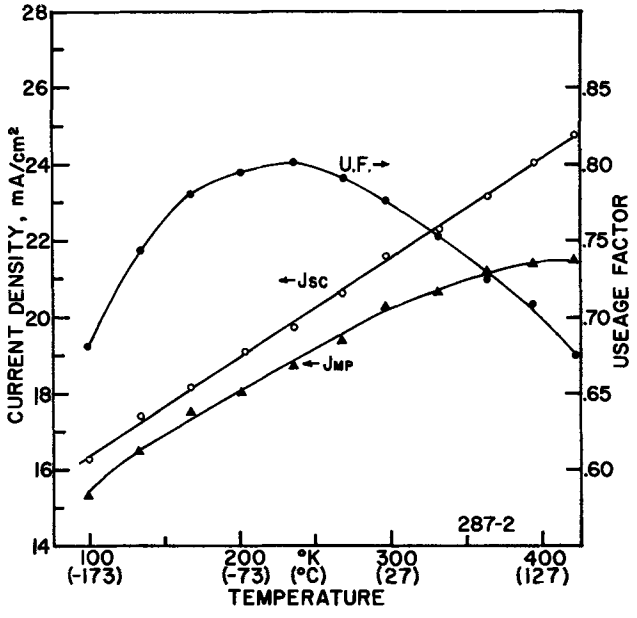

Fig. 8. Short-circuit and maximum power current densities (uncorrected for contact area) and the usage factor as functions of temperature. The unit was measured in vacuum with the Air Mass 1 simulator and a power input of 100 mW/cm².

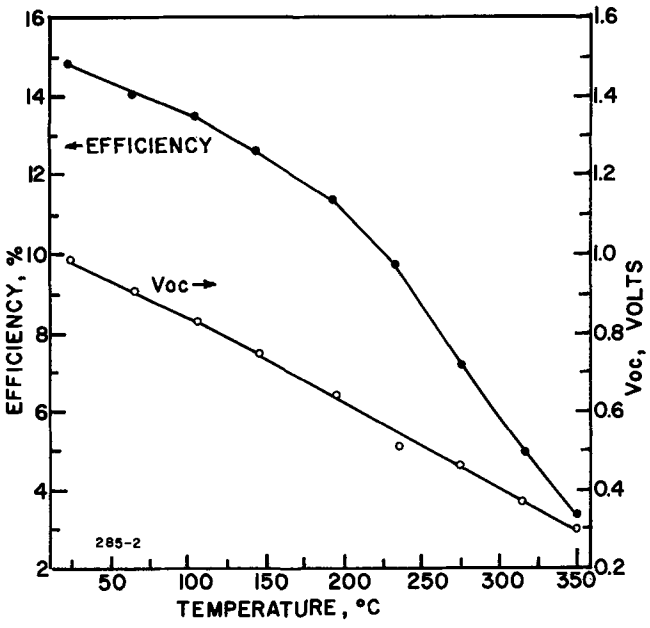

Fig. 10. Open-circuit voltage and efficiency (uncorrected for contact area) for a device measured in air with the Air Mass 1 simulator. The power input was 100 mW/cm².

higher lifetime. The current at maximum power, J_{mp}, follows the increase in short-circuit current up to about 0°C, then levels off and even decreases above 200°C. This behavior of J_{mp} can be attributed to the increasing "softness" of the "knee" in the I-V characteristic (Eq. [6]) as temperature increases. This "softness" is also the probable cause of the decreasing usage factor above −25°C as shown in Fig. 8.

The open-circuit voltage decreases linearly with increasing temperature, as seen in Fig. 9; the rate of decrease is around 2 mV/°C. The voltage at maximum power, V_{mp}, is proportional to V_{oc} above 0°C but saturates for temperatures below about −75°C. Both the efficiency and usage factor go through a maximum as a function of temperature at around −70° and −25°C, respectively, and decrease as the temperature is reduced below these values. The reasons for these variations are not clear at this time.

The open-circuit voltage and efficiency for a unit measured in air from 24° to 350°C with the Air Mass 1 simulator are shown in Fig. 10. The voltage decreases linearly as in Fig. 9, while the efficiency drops gradually at a rate (change in efficiency/change in temperature) of 0.022%/°C to about 11% at 200°C and more rapidly (0.059%/°C) for temperatures above 200°C. The efficiency is nearly 6% at 300°C and over 3% at 350°C. (This measurement, however, was a destructive one due to oxygen attack of the In contact at 350°C, although the device itself was not affected. There was no effect on the device or contact when the unit was cycled from −190° to +150°C in vacuum or up to 230°C in air.)

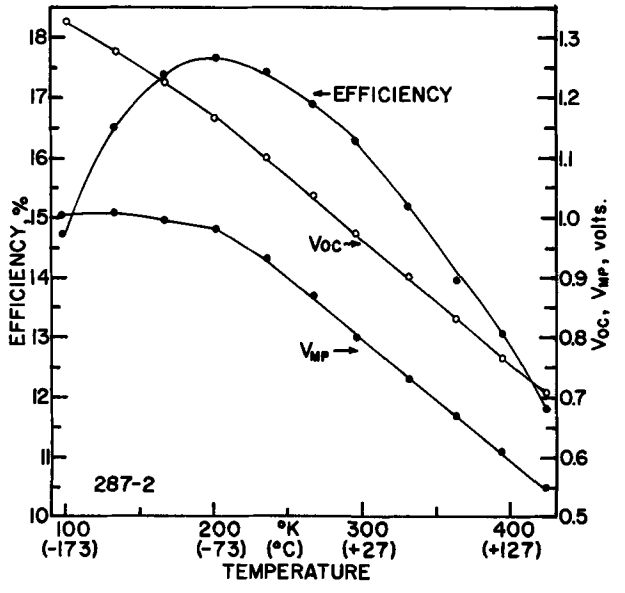

Fig. 9. Open-circuit and maximum power voltages and the efficiency (uncorrected for contact area) under the same conditions as in Fig. 8. The efficiency goes through a maximum at around −75°C.

Conclusions

Highly efficient solar cells can be fabricated using GaAs p-n junctions with a thin $Ga_{1-x}Al_xAs$ alloy layer on the GaAs surface. The alloy layer is grown by liquid phase epitaxy, and serves the purposes of reducing surface recombination and reducing series resistance. The $Ga_{1-x}Al_xAs$ is transparent to photons with energies up to about 2.1 eV and cuts off the light gradually in the range 2.1-2.6 eV due to the indirect bandgap. This high energy cut-off in the spectral response can be used to determine the absorption coefficient of the $Ga_{1-x}Al_xAs$ as a function of wavelength and composition, as long as the thickness of the layer exceeds about 6μ.

The behavior of the cells in sunlight at around Air Mass 1 was determined; typical devices have open-circuit voltages from 0.97 to 1.0V, short-circuit currents (corrected for contact area) of 18-21 mA/cm², and efficiencies (corrected for contact area) of 15 to 16%. At Air Mass 0, using a solar simulator, the currents were in the range of 20 to 22 mA/cm², and the efficiencies from 11.7 to 12.8%. The highest short-circuit currents are obtained with thin alloy layers of high Al composition and with junction depths of 0.8μ. Substantial short-circuit currents are obtained for junction depths of 3μ however, indicating electron diffusion lengths of 4μ or more in the p-type GaAs (doping level around 10^{18} cm^{-3}).

The short-circuit current and open-circuit voltage increase and decrease, respectively, linearly with increasing temperature. The efficiency has a maximum at around −75°C; it decreases gradually up to about 200°C, then decreases at twice the rate for higher temperatures. Efficiencies of nearly 6% at 300°C and over 3% at 350°C have been measured (using an Air Mass 1 simulator).

It is important to note, of course, that the efficiencies of these cells with 0.2 cm^2 area cannot be compared directly with the efficiencies of Si cells of 2 cm^2 area. However, it was the purpose of this work to demonstrate the soundness of the ideas involved and the feasibility of obtaining high efficiency GaAs cells, not to compete with Si on a 1:1 area basis. Presumably, the problems associated with scaling up these devices to larger areas should be no different than the problems associated with the scaling-up of other materials, and it is expected that $Ga_{1-x}Al_xAs$-GaAs cells with 1 or 2 cm^2 areas exhibiting similar or better efficiencies will be obtained in the near future.

Acknowledgments

The authors would like to express their appreciation to Dr. W. E. Howard for many helpful comments and suggestions. They would also like to thank Mr. R. M. Potemski, Mr. S. Renick, and Miss A. Benoric for their assistance during portions of the work. Finally, the services of the Jet Propulsion Laboratories in making the AM0 solar simulator measurements possible were greatly appreciated.

Phosphorus Isoconcentration Diffusion Studies in Silicon

J. S. Makris* and B. J. Masters

IBM System Products Division, East Fishkill Laboratory, Hopewell Junction, New York 12533

ABSTRACT

^{32}P-concentration profiles were obtained of diffusions conducted in intrinsic and extrinsic silicon, employing isoconcentration conditions for the latter. All diffusions were conducted in evacuated closed quartz capsules at diffusion temperatures ranging from 950° to 1200°C. The temperature dependence of phosphorus diffusivity in intrinsic and extrinsic silicon is described by the empirical equations $D_{int} = 5.3 \exp(-3.69\ eV/kT)$ cm^2/sec and $D_{ext} = 0.39 \exp(-3.12\ eV/kT)$ cm^2/sec, respectively.

The phosphorus diffusivity is seen to increase about a factor of 10 over the value obtained in intrinsic silicon for the highest phosphorus concentration employed. The results are explained by assuming the diffusion process of phosphorus into silicon is primarily controlled by monovacancies in the single negative charged state.

This is the fourth in a series of investigations (1-3) dealing with the diffusion of substitutional atoms in the silicon lattice. Throughout this series particular attention has been focused on the diffusion coefficient dependencies upon background doping level and upon diffusant concentration. In order to explain the observations, a general mechanism of diffusion has been proposed (3), in which the existence of negatively charged, neutral, and positively charged vacancies is assumed, and in which the diffusion of ionized substitutional impurities is considered to be controlled primarily by the concentration of vacancies of charge type opposite to that of the diffusing impurity.

The present investigation was undertaken in order to extend the measurements of diffusivity dependence upon concentration and upon background doping level to include phosphorus as the diffusant impurity, as well as to provide a further test of the proposed diffusion mechanism.

Experimental Procedure

For the entire investigation Czochralski grown silicon single crystals cut in the <100> direction with a boron background concentration of 1.6×10^{16} atoms B/cm^3 ($\rho = 1$ ohm-cm) were used. Crystal dimensions were 1.25 in. in diameter and 0.007 in. thick. Dislocation density was less than 4×10^3 lines/cm^2. The crystals were chemically mechanically polished to eliminate surface damage.

All diffusions were conducted employing the evacuated sealed quartz capsule technique and appropriate Si(P) source powders. To obtain the phosphorus diffusivities in intrinsic silicon as a function of temperature, a phosphorus-doped silicon powder source with a concentration of $\sim 4 \times 10^{18}$ atoms P/cm^3 was used. To obtain the diffusivities in extrinsic silicon as a function of temperature, a high phosphorus concentration silicon source powder, 4.5×10^{20} atoms P/cm^3, was used. For determining the diffusivities as a function of background doping at a constant diffusing temperature, 1000°C, the concentrations of Si(P) powder sources ranged from 4×10^{18} to 4.5×10^{20} atoms P/cm^3. Phosphorus contents in all Si(P) source powders were determined by neutron activation techniques.

For phosphorus diffusions into intrinsic silicon, the crystals were cleaned in hydrofluoric acid, rinsed in deionized water, and dried in hot nitrogen. The cleaned crystals were placed erect in a quartz boat containing

* Electrochemical Society Active Member.
Key words: phosphorus, isoconcentration, diffusion.

2.5 g of the Si(P) source powder, 4×10^{18} atoms P/cm^3, and the boat and crystals placed in a quartz capsule sealed at one end. (All quartzware was previously etched in $3HNO_3$-1HF, rinsed in deionized water, and baked out under vacuum at 1200°C.) Each capsule containing the silicon crystals and source powder was baked out at 450°C for 0.5 hr under vacuum of 6×10^{-6} Torr and then sealed. Diffusions were conducted in furnaces which were controlled to ± 1°C and had a constant temperature zone of at least 10 in. Diffusion temperatures and times employed were: 950°C for 24 hr, 1000°C for 4 hr, 1050°C for 3 hr, 1100°C for 1 hr, and 1200°C for 1/2 hr. After each diffusion the hot quartz capsules were quenched in running cold tap water.

^{32}P-concentration profiles in intrinsic silicon were obtained by neutron activating the phosphorus diffused wafers to produce a fraction of ^{32}P which has a half life of 14.3 days. The ^{31}Si also produced has a half life of 2.6 hr and this was allowed to decay at least 48 hr before the crystals were further processed. Mesas of known diameter were made on the neutron-activated diffused crystals by etching away several microns of silicon from the edge regions, and autoradiograms were made to ensure lateral homogeneity of the diffusion and to ensure that the silicon had decayed below detection levels. Sectioning of the crystals was done by successively oxidizing and removing layers of silicon of predetermined thickness using the anodic oxidation technique (4). Each dissolved layer removed was captured and placed into a vial. A "cocktail" was made containing the dissolved layer and appropriate scintillation solution.

Counting was done using a liquid scintillation counter. Each cocktail was counted and corrected for decay against a standard similarly prepared. Extreme precautions were taken to ensure a low statistical counting error of the cocktails having a very low ^{32}P-concentration by counting for a long time. Sectioning was carried out until near background counting rate was reached.

Diffusions into extrinsic silicon crystals were conducted employing the isoconcentration technique (2). In this technique, all electrical and elastic effects of concentration gradients are eliminated. First a long time prediffusion is done using Si(P) source powder and then a second diffusion is done using a neutron-activated portion of the same source powder. The prediffusion is designed to produce a relatively flat phosphorus concentration profile several microns deep into the crystal. Prediffusion and the second (sequential) diffusion are done at the same diffusion temperature in order to ensure equilibrium conditions of the diffusing species at the silicon crystal surface. The crystals and the quartz capsules were prepared as described above for the phosphorus diffusions in intrinsic silicon. Prediffusion times ranged from 2.3 hr at 1200°C to 250 hr at 950°C. Sequential diffusion times employed were the same as those used for the intrinsic silicon diffusions. In the sequential diffusion an intrinsic silicon crystal was included in the capsule for comparison. The ^{32}P-concentration profiles from the sequential diffusion were obtained using the same sectioning and counting techniques as described above. For all the sequential diffusions into extrinsic silicon the radiophosphorus profiles were much shallower than the prediffusion profiles.

Results

Radiophosphorus profiles for diffusions conducted at 1200°C are shown in Fig. 1. Profiles shown are typical of ones obtained for other diffusion temperatures. Concentration profile I is of the diffusion conducted into intrinsic silicon using the low source concentration. Profile II is of the prediffusion conducted into silicon using the highest source concentration. This profile was obtained by neutron activating the crystal after prediffusion. Only a portion of the profile was obtained to show the flatness of the concentration gradient. Actually the concentration profile of the prediffusion extends much deeper into the crystal than is shown. Concentration profiles III and IV are of the sequential diffusion conducted into extrinsic (isoconcentration condition) and intrinsic silicon, respectively. Only profiles I and III, obtained under intrinsic and isoconcentration diffusion conditions, conform to the complementary error function (5)

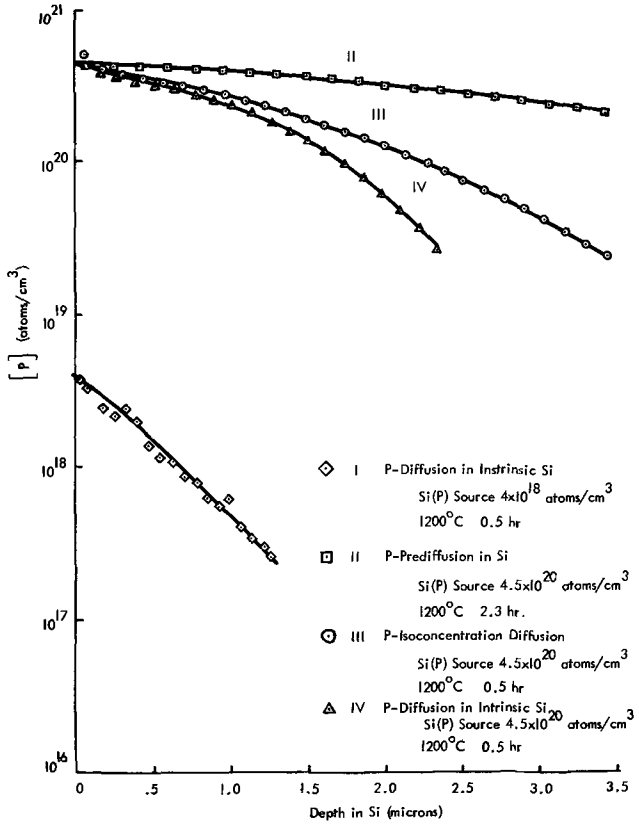

Fig. 1. Phosphorus concentration profiles in silicon for diffusions conducted at 1200°C.

$$C_x = C_o \operatorname{erfc} [x/2\ (Dt)^{1/2}] \qquad [1]$$

The diffusivities calculated for intrinsic and isoconcentration conditions, as well as diffusion temperatures and times employed, are listed in Table I. In Fig. 2, diffusivities *vs.* the reciprocal of absolute temperature for the present investigation, as well as the intrinsic or near intrinsic data of others (6-9) are plotted. A least squares fit of the combined data of Maekawa, Mackintosh, and our intrinsic diffusion data is well represented by the relationship

$$D_{\text{int}} = 5.30 \exp (-3.69\ \text{eV}/kT)\ \text{cm}^2/\text{sec} \qquad [2]$$

The diffusion coefficient as a function of temperature for the highest phosphorus concentration employing isoconcentration diffusion conditions is

$$D_{\text{ext}} = 0.39 \exp (-3.12\ \text{eV}/kT)\ \text{cm}^2/\text{sec} \qquad [3]$$

In Table II the results of phosphorus diffusivity measurements at 1000°C for various background doping levels, N_D, are summarized. The free electron concentration was determined using the equation

$$n = \tfrac{1}{2}[N_D + (N_D^2 + 4n_i^2)^{1/2}] \qquad [4]$$

in which n_i is the intrinsic electron concentration, which was calculated using Morin and Maita's empirical

Table I. Intrinsic and extrinsic (0.9 atom per cent P-doped) diffusion data

Temp. (°C)	Time (hr)	$D_{\text{intrinsic}}$ (cm^2/sec)	$D_{\text{extrinsic}}$ (cm^2/sec)
950	24	3.27×10^{-15}	4.83×10^{-14}
1000	4	1.45×10^{-14}	1.76×10^{-13}
1050	3	4.12×10^{-14}	5.5×10^{-13}
1100	1	1.49×10^{-13}	1.36×10^{-12}
1200	0.5	1.13×10^{-12}	8.55×10^{-12}

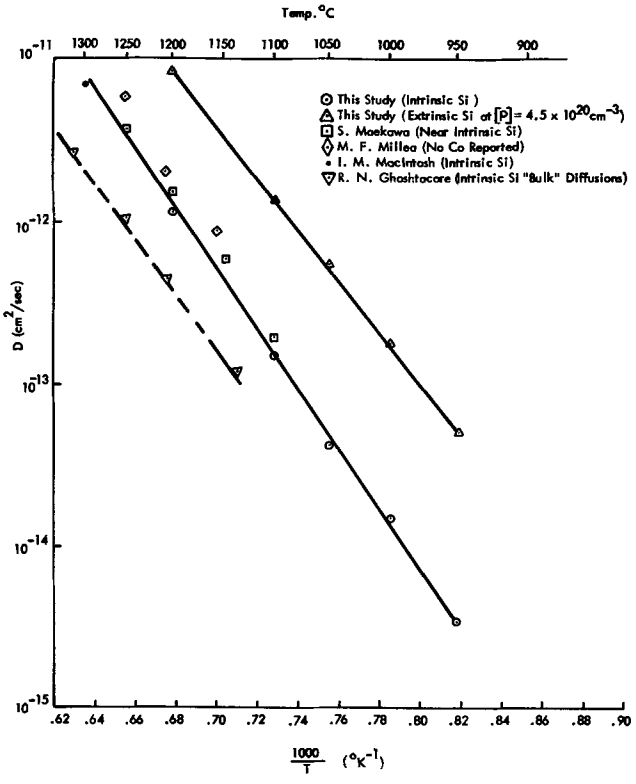

Fig. 2. Temperature dependence of phosphorus diffusivity in intrinsic silicon. Phosphorus diffusivity data for intrinsic and near intrinsic silicon of other investigations are also included.

relations (10)

$$n_i = 3.87 \times 10^{16} T^{3/2} \exp - (1.21 + \Delta Eg)/2kT \quad [5]$$

$$\Delta Eg = - 7.1 \times 10^{-10} (n_i)^{1/2} T^{-1/2} \quad [6]$$

The use of the equations above imply the common assumptions of nondegeneracy, charge neutrality in the crystal, and complete ionization of the background dopant at the diffusion temperature.

In Fig. 3, phosphorus diffusivities as a function of background electron concentration for diffusions conducted at 1000°C are plotted. The arsenic data (2) for diffusions conducted at 950°C are also shown for comparison. Phosphorus is observed to have the same behavior as arsenic. That is, phosphorus diffusion into silicon appears to increase almost linearly with increasing free electron concentration.

Discussion

From Fig. 2 it is apparent that the intrinsic diffusion measurements obtained in the present study are in good agreement with the data of Mackintosh (8), Maekawa (6), and Millea (7), but not with the "bulk diffusivity" values reported by Ghoshtagore (9, 11).[1] This discrepancy has been attributed by Ghoshtagore to a depth dependence of diffusivity arising from higher vacancy concentrations near the free surface than in the bulk. Neither in the present study nor in any other profiling experience of this laboratory has an intrinsic

[1] Note added in proof: Since the preparation of this paper, new data on the "surface limited" intrinsic diffusivity of phosphorus have been published by R. N. Ghoshtagore [*Solid State Electron.*, 15, 1113 (1972)], and these values are in good agreement with the intrinsic diffusivities reported in the present study.

Table II. Phosphorus diffusivity at 1000°C as a function of electron concentration

Background conc. (atoms/cm³)	n (electrons/cm³)	D (cm²/sec)
Intrinsic	9.27×10^{18}	1.45×10^{-14}
[P] 1.95×10^{19}	2.31×10^{19}	2.21×10^{-14}
[P] 4.4×10^{19}	4.58×10^{19}	2.71×10^{-14}
[P] 2.8×10^{20}	2.8×10^{20}	1.95×10^{-13}
[P] 4.5×10^{20}	4.5×10^{20}	1.76×10^{-13}

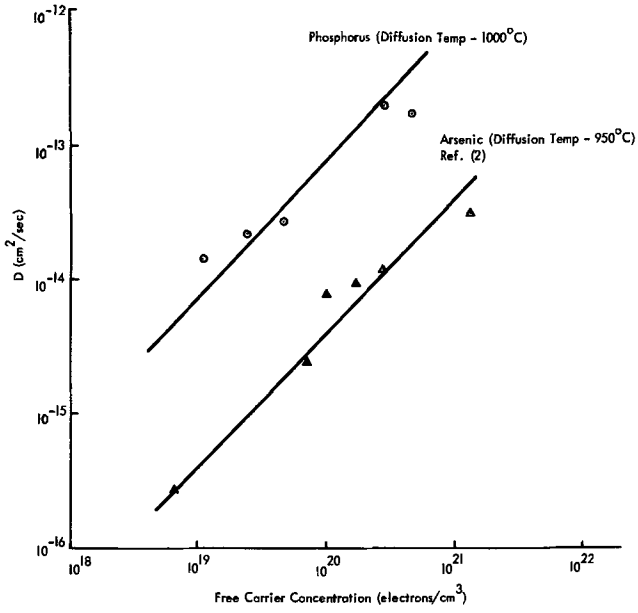

Fig. 3. Phosphorus diffusivity as a function of free carrier concentration for diffusions conducted at 1000°C. Arsenic diffusivity data of Masters and Fairfield (2) for diffusions conducted at 950°C.

diffusion coefficient decrease with increasing depth, in confirmation of Ghoshtagore's observations, been observed. However, it must be recognized that our experimental conditions have differed considerably from those employed by Ghoshtagore, and further investigations of this effect would be highly desirable.

The diffusivity measurements obtained under extrinsic isoconcentration diffusion conditions are in qualitative agreement with the concentration dependencies indicated in previous studies (6-8), and owing to the absence of steep concentration gradients, are capable of a much more quantitative interpretation. The very significant increase in phosphorus diffusivity with doping level, accompanied by decreased activation energy and entropy of diffusion under extrinsic conditions, is reminiscent of the results encountered for arsenic isoconcentration diffusion (2). This similarity is further evidenced in Fig. 3, in which the phosphorus diffusivity dependence upon free electron concentration obtained at 1000°C is compared with the previously reported 950°C arsenic data. In both instances, an approximately first-order dependence is observed, and it appears likely that similar mechanisms of diffusion are operating in the two cases.

In a previous study of gallium diffusion in boron-doped silicon (3), a general model for the migration of substitutional ionized impurities in silicon was developed. In this model, the diffusion of donor impurities is presumed to be controlled primarily by the local concentration of singly ionized acceptor monovacancies, with a negligibly small contribution from the un-ionized vacancy population. The model further assumes the existence of a vacancy acceptor level located near the middle of the forbidden gap, a matter which is discussed in more detail elsewhere (12).

For such an acceptor level, the negative vacancy concentration is approximated by (13)

$$[V^-] \simeq [V^\circ](n/n_i) \quad [7]$$

in which $[V^\circ]$, the neutral vacancy concentration, is estimated (1) to be

$$[V^\circ] \simeq 5 \times 10^{25} \exp(-3.4 \text{ eV}/kT)/\text{cm}^3 \quad [8]$$

This simplified model predicts that the ratio of phosphorus diffusivities for extrinsic to intrinsic silicon should be equal to the ratio of the corresponding charged vacancy concentrations

$$D_{ext}/D_{int} \simeq [V^-]_{ext}/[V^-]_{int} \quad [9]$$

From the above equations the ratio of phosphorus diffusivities should have the following dependence

$$D_{ext}/D_{int} \simeq n/n_i \quad [10]$$

The solid line in Fig. 3 shows the first-order dependence which is in reasonable agreement with observed results. It appears that the phosphorus concentration dependency observed in the present study is well accounted for in terms of this simplified model.

Summary

Phosphorus diffusivity in intrinsic silicon was found to be in good agreement with most investigators and in disagreement with Ghoshtagore's results. To a first approximation, a first-order phosphorus concentration dependency was observed at fixed diffusion temperature. The results are explained by assuming phosphorus diffusion in silicon to be primarily controlled by monovacancies in the negative charged state. The results are consistent with the previous investigations (1-3) and provide further support that the mechanism for substitutional atom diffusion in silicon is primarily controlled by monovacancies opposite in charge to the diffusing species.

Undercut Isolation—A Technique for Closely Spaced and Self-Aligned Metalization Patterns for MOS Integrated Circuits

C. N. Berglund, J. T. Clemens, and E. H. Nicollian*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A new technique for achieving electrically isolated, closely spaced, and self-aligned metalization patterns on thin insulating films for integrated circuit applications is described. This scheme takes advantage of the shadowing effect of an undercut area etched in a two-layer insulator sandwich. A pattern first etched in the upper insulator delineates and acts as an etch mask for undercutting and thinning down the second insulator on the semiconductor substrate. The major requirement is that the first insulator be weakly or not at all affected by the etch for the second insulator. Because of the masking effect of undercutting, a thin metal evaporation will be discontinuous at all undercut edges resulting in electrically isolated metalization patterns with virtually zero lateral spacing between them. The silicon dioxide-alumina double insulator system with titanium-palladium-gold metalization was used and the details of the technique, including methods of selectively connecting isolated metal patterns, are described. Experimental data are presented to show that undercut isolation can be achieved with high reliability, undercut edges several centimeters in length being typically observed between unintentional shorts. Advantages and utility of the technique are illustrated by describing the design of a charge-coupled device.

One of the well-known problems in integrated circuit fabrication is undercutting which occurs when one attempts to etch through multiple layers of different materials on a semiconductor wafer. If the upper layer either etches slower or not at all in the etchant required for the lower layer, there will be a ledge of the upper material formed when the lower layer is etched. When the two layers are insulators, for example, this leads to serious difficulty in making reliable electrical connections on an integrated circuit. Recently there have been several successful attempts to make use of undercutting effects like this to simplify device fabrication (1-3). Advantages cited include the fact that undercutting can be used to achieve a self-aligned metalization pattern with virtually no lateral spacing between adjacent metal lines. Most of the work has been directed towards fabrication of Schottky-barrier field-effect transistors (2), with the lower metal usually being deposited directly onto the semiconductor substrate. In this paper we shall show that the undercutting effect also can be used to isolate metal patterns on two different thicknesses of insulators and that reliable and selective contact can be made between the two patterns or between either pattern and semiconductor substrate (4). In this way, the attractive features of the technique, such as the fact that it is self-aligning and has virtually no lateral spacing between adjacent metal lines, are combined with the additional versatility arising from having both levels of metalization on top of insulating films. This makes the undercutting isola-

* Electrochemical Society Active Member.
Key words: charge-coupled devices, silicon devices, thin insulator films.

tion scheme of general interest for integrated circuit semiconductor device fabrication.

In describing the undercut isolation technique, we shall restrict ourselves to one specific material system, the silicon-silicon dioxide-alumina (Si-SiO_2-Al_2O_3) double insulator system (5) with titanium-palladium-gold (Ti-Pd-Au) metalization (6). It is evident that other materials systems will work equally well and in some cases may have important advantages.

We will first describe the essential structure of the undercut isolation scheme and report on experimental results with respect to its fabricational feasibility and associated defects that can potentially reduce integrated circuit yield. Secondly, we will describe the design of a charge coupled device (CCD) shift register employing undercut isolation to illustrate its utility.

Undercut Isolation Scheme

Fundamental structure.—The standard procedure used in Si planar technology to isolate, electrically, adjacent metalization lines is to etch away a metal region, thus forming an isolation gap. This technique, however, possesses a major drawback, namely that the gap width is limited in minimum size by photoresist and metal etching technology. A possible way to reduce (or eliminate) this lateral gap is to transfer it to the vertical position. Using a stepped insulator structure, it is possible to visualize the lateral gap approaching zero dimension. However, to fabricate experimentally such a structure one must rely upon a shadowing effect during vacuum deposition of metal to provide the necessary discontinuity of metal over the insulator step. In practice, one will rarely find complete electrical isolation at such a step because: (*i*) oxide steps are never completely vertical, and (*ii*) incident metal vapor during deposition, originating from a spatially extended source, never can be purely vertical to the spatially extended sample.

A possible method of overcoming these two deleterious effects is to form a ledge (or overhang) at the insulator step, so that a desired shadowing effect will occur and form an isolation gap. In the next section, we shall describe a specific two material insulator system that may be used to construct the desired physical geometry.

Al_2O_3-SiO_2 insulator system.—This double insulator system has a disjoint etching characteristic (*i.e.*, Al_2O_3 may be patterned or etched in phosphoric acid, H_3PO_4, but is inert in hydrofluoric acid, HF; conversely, SiO_2 may be patterned with HF, but is essentially inert in H_3PO_4). Using this fact, we will now describe a technique by which one may fabricate a double insulator MOS structure electrically isolated by means of the proposed overhang structure.

The important cross-sectional views of the MOS structure during fabrication are illustrated in Fig. 1. A silicon wafer is thermally oxidized and a thin layer of Al_2O_3 is deposited along with a layer of SiO_2 [Fig. 1(a)]. This deposited layer of SiO_2 will be used as an etch mask for the Al_2O_3, because standard photoresist materials are severely attacked by the 180°C boiling aqueous solution of phosphoric acid used to etch Al_2O_3. The SiO_2 is patterned by standard photolithography techniques and then the Al_2O_3 is patterned [Fig. 1(b)].

In the next step, the desired undercut ledge is formed. This is accomplished by etching the structure in an aqueous HF solution possessing a calibrated etch rate (nominal etch = 10 parts by volume H_2O and 1 part by volume conc HF). This process step thins the thermal oxide in the exposed area to a predetermined thickness and undercuts the Al_2O_3 film forming the desired overhang [Fig. 1(c)]. A second film of Al_2O_3 is now deposited over the entire structure, thereby passivating it [Fig. 1(d)]. This step is included to assure a completely passivated structure.

Finally, a titanium-palladium (Ti-Pd) metalization film of thickness less than the overhang gap in Fig. 1(d) is vacuum deposited over the wafer, yielding the undercut isolated double insulator MOS structure shown in Fig. 1(e).

Experimental Results and Discussion

Fabricational aspects.—To explore the feasibility of the previously described technique, we fabricated 20 mil² undercut isolated MOS capacitors on n-type <100> Si wafers. Figure 2 is a cross section of the test structure with critical dimensions indicated. Figure 3 is a scanning electron microscope (SEM) photomicrograph of the first Al_2O_3 overhang immediately after the thermal oxide thinning step where the oxide has been deliberately overetched to expose the Si substrate (for dimensional reference) and to illustrate the rigidity of overhang.

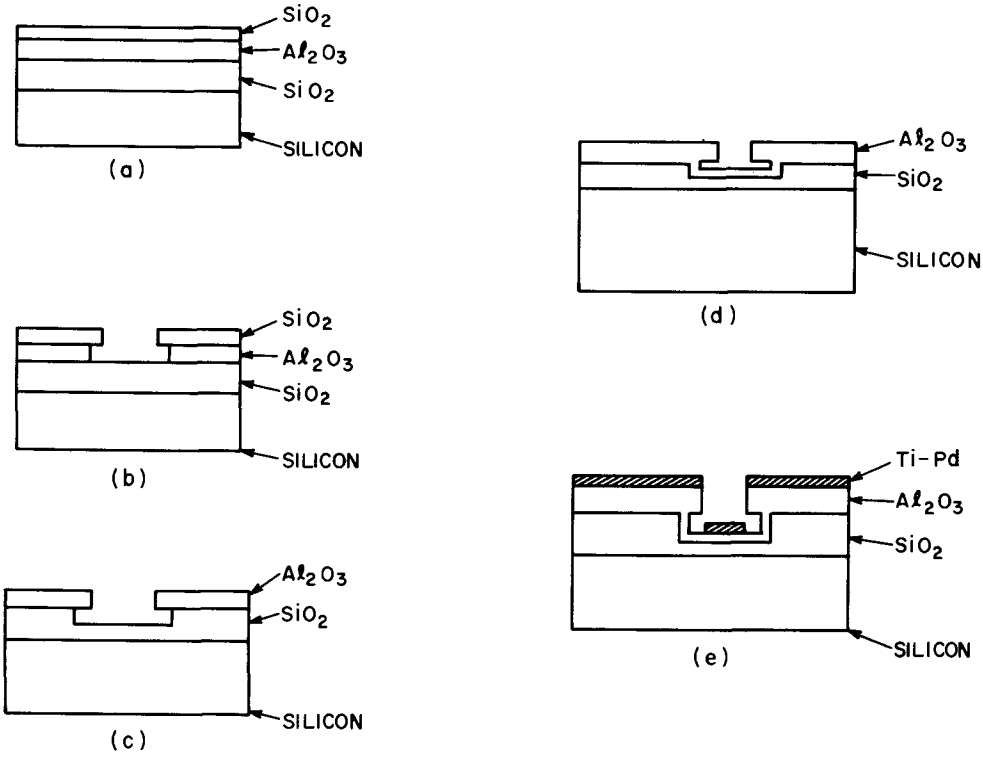

Fig. 1. Steps illustrating the basic undercut isolation scheme described in the text.

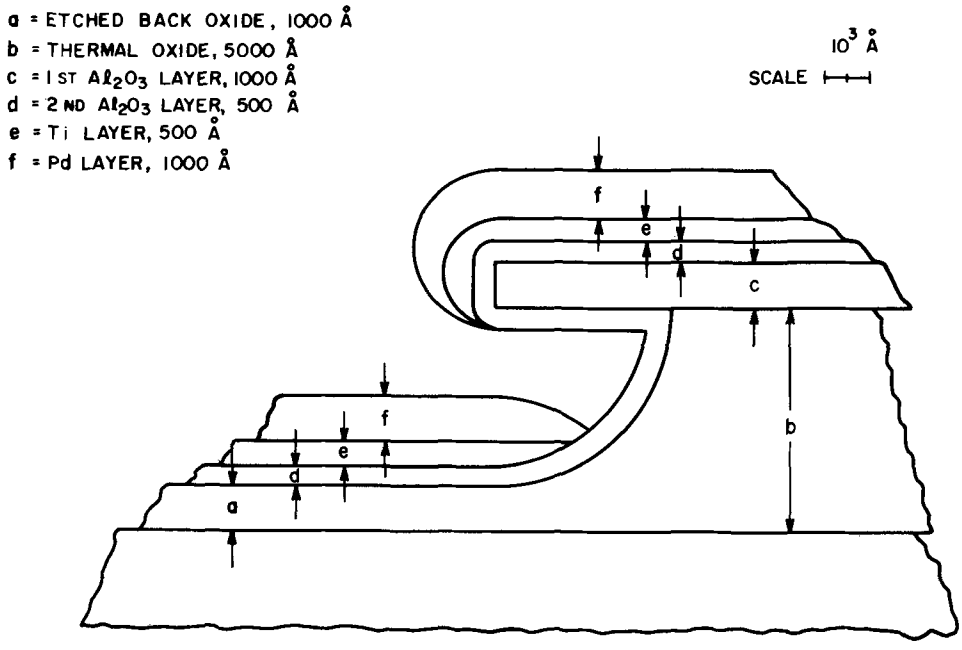

Fig. 2. Sectional drawing of undercut edge of an experimental structure.

To check the passivation character of the second Al_2O_3 deposition, samples were soaked in buffered HF to decorate pinholes at the overhang edge. No significant pinholes or voids were observed in the passivated layer. Figure 4 (a) and (b) is a photomicrograph of a finished experimental sample at the stage shown in Fig. 1(e) which shows the final desired isolation gap in the metalization layer.

Electrical characteristics.—All important electrical characteristics of the undercut isolation technique [namely: (*i*) isolation yield per unit length (or equivalent linear defect density); (*ii*) MOS characteristics; and (*iii*) insulator and isolation gap breakdown strength and stability] may be measured with the capacitor structure. Let us consider each separately.

(*i*) *Isolation yield per unit length.*—Several hundred MOS structures were checked for vertical shorts on each test wafer fabricated. Typically, less than 10% of the structures were shorted, one wafer in particular yielding only 2% shorts. Scratches, due to handling, were often observed on the shorted MOS pads, and a large fraction of shorted pads were located in the immediate vicinity of the edge of the wafer. To ascertain the failure mechanism in shorted unscratched MOS pads, SEM photomicrographs of those pads were obtained. Figure 4(c) illustrates the observed failure mode, particulate matter causing metallic bridging between metalization levels.

In order to obtain a quantitative figure for unintentional shorts useful for circuit/device design, assume that spatial location of a short occurring between lower metalization and upper metalization levels is a random variable. The probability of a short occurring per unit length of isolation edge then may be easily characterized. It is straightforward to show that probability, $P(l)$, of finding no shorts in a length l of isolation edge is given by

$$P(l) = \exp(-l/l_0) \qquad [1]$$

where l_0 is average distance between shorts. An estimate of l_0 may be obtained from previously described yield data. Recalling that each MOS pad is a 20 mil^2 (0.20 cm perimeter), a 10% probability of shorting corresponds to l_0 (10%) = 2 cm; while a 2% probability corresponds to l_0 (2%) = 10 cm.

(*ii*) *MOS characteristics.*—MOS characterization of both isolated (thin insulator) and field (thick insulator) capacitors indicated that their electrical characteristics are essentially identical to those found on standard double insulator (Al_2O_3-SiO_2) capacitors. The midgap interface state density was approximately 2.0×10^{10} cm$^{-2} \times$ eV^{-1}; and flatband voltage for the thin insulator pad was approximately 0.3V.

(*iii*) *Insulator breakdown strength and stability.*—Breakdown electric field strength in the etch-back insulator region was found to be approximately 5.2×10^6 V/cm. This means that the insulator breakdown strength is not seriously degraded by thinning of the thermal oxides. Additionally, breakdown electric field strength associated with the undercut isolated edge, measured by destructive breakdown between metal levels, was found to be approximately 6.5×10^6 V/cm.

Stability measurements under bias-temperature aging were also performed. The isolated thin insulator MOS pads, under a bias of -1.0×10^6 V/cm at 350° for 30 min, exhibited a shift in flatband voltage of 0.10V and an increase in interface state density at mid-bandgap from 2.0×10^{10} cm$^{-2} \times$ eV^{-1} to 5.5×10^{10} cm$^2 \times$ eV^{-1}. Similar results, except for a correspondingly larger shift in flatband voltage (a factor of 3-5 larger), were obtained on the field capacitors. Such results indicate that double insulator MOS characteristics and Si-SiO_2 interface properties obtained from the undercut isolation process are essentially equal to those obtained from the standard double insulator (Al_2O_3-SiO_2) process and that additional Al_2O_3 deposition does not degrade usually observed characteristics of the SiO_2-Al_2O_3 system.

Undercut Isolation Charge-Coupled Device

In the preceding sections, we have demonstrated feasibility of a metalization isolation scheme that possesses, in addition to a zero lateral isolation gap, excellent MOS characteristics. Such a scheme may have many applications in integrated circuit design. However, an immediate application lies in the area of CCD's.

Several studies have indicated that operational ability and charge transfer efficiency of this device depends critically upon absolute magnitude of interelectrode spacing (7, 8). In this section, we will describe how the overhang technique may be used to fabricate a two-phase p-channel CCD with zero interelectrode spacing. In addition to this primary device feature, the undercutting technique will also yield the structure for attaining charge propagation directionality, *i.e.*, a stepped electrode configuration formed by different insulator thicknesses (9). The processing procedure outlined here is only one of many possibilities considered. It was chosen because it is similar to one first used to fabricate a CCD using undercut isolation (4).

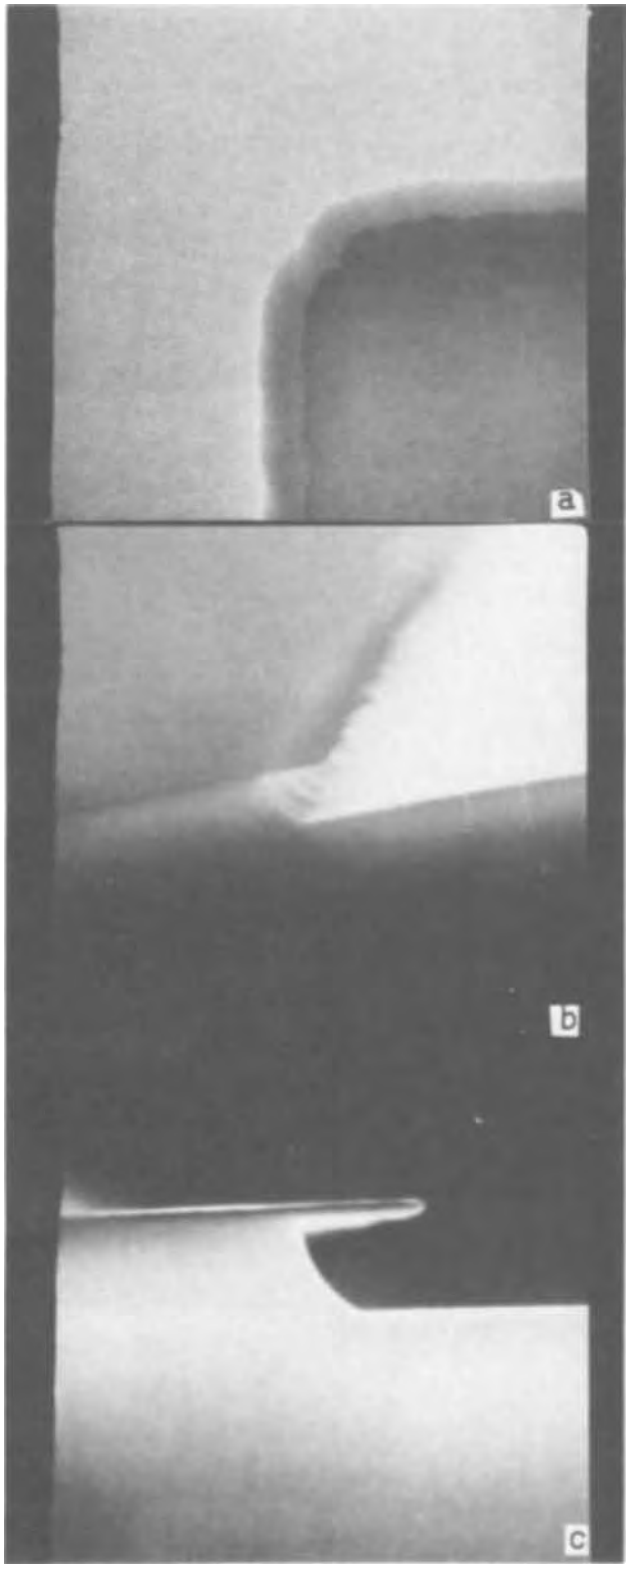

Fig. 3. Several electron microscope views of an undercut isolated edge before second Al_2O_3 deposition.

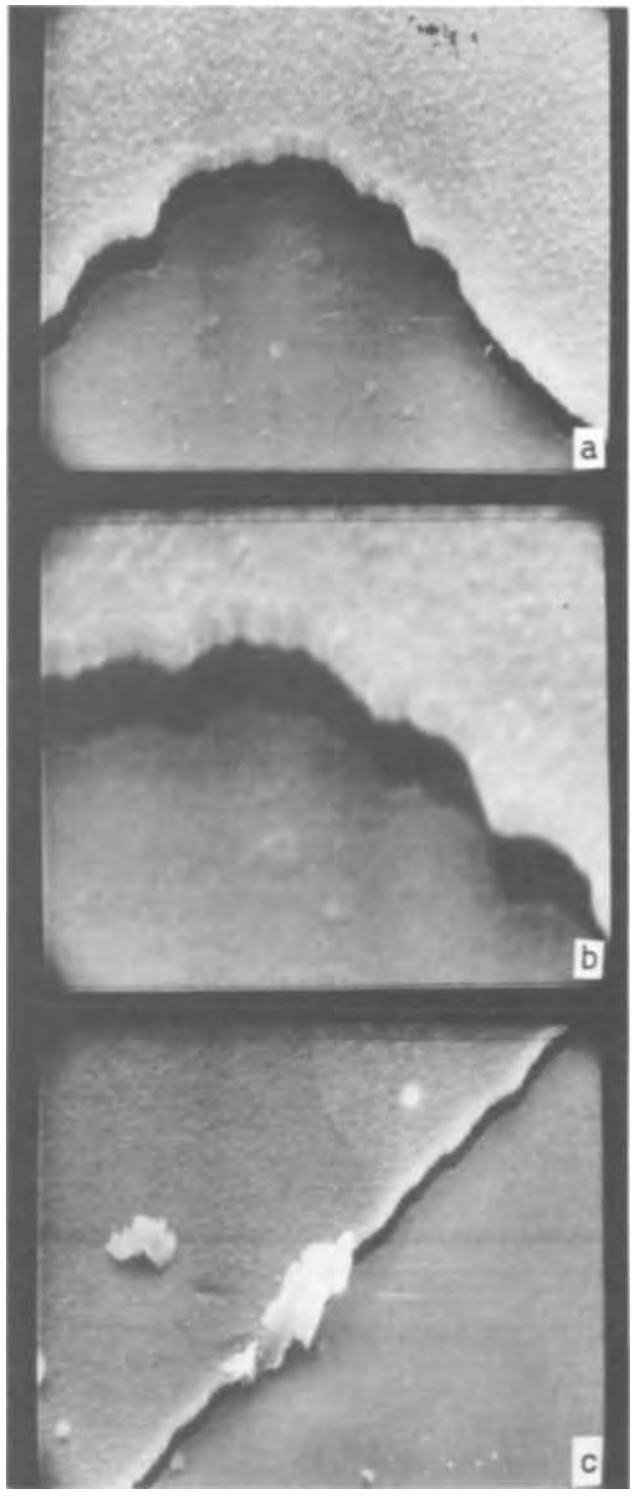

Fig. 4. An undercut isolated edge after titanium-palladium deposition.

Fabrication scheme.—Figures 5-8 illustrate the important steps and features in the CCD fabrication. Initially, appropriate p-type diffusions for input-output circuitry are performed and are followed by growth of a thick field oxide [Fig. 5(a)]. Charge transfer channels and contact regions are defined in the field oxide using a sloped oxide technique; and a thinner SiO_2 layer (~1000Å) is deposited and defined by the previously described technique. Patterned Al_2O_3 is left only in those regions where isolation overhangs are desired [Fig. 5(c)]. Exposed oxide is thinned (to 1000Å in transfer regions) and the overhang ledge is produced. The second layer of Al_2O_3 (~500Å) is deposited for passivation and contact windows defined. Figure 6 depicts final insulator structure immediately prior to metalization.

Metalization of the CCD can be achieved by one of several approaches previously described. Here we will describe only one possible scheme. First, a Pd silicide is formed in the contact windows and, then, a Ti (~500Å) and Pd (~1000Å) layer is evaporated over the wafer. Photoresist is now applied for selective gold plating (Fig. 7), and gold is plated to a thickness of approximately one micron. When the gold plate is as thick as the isolation gap, shorting (or bridging) will

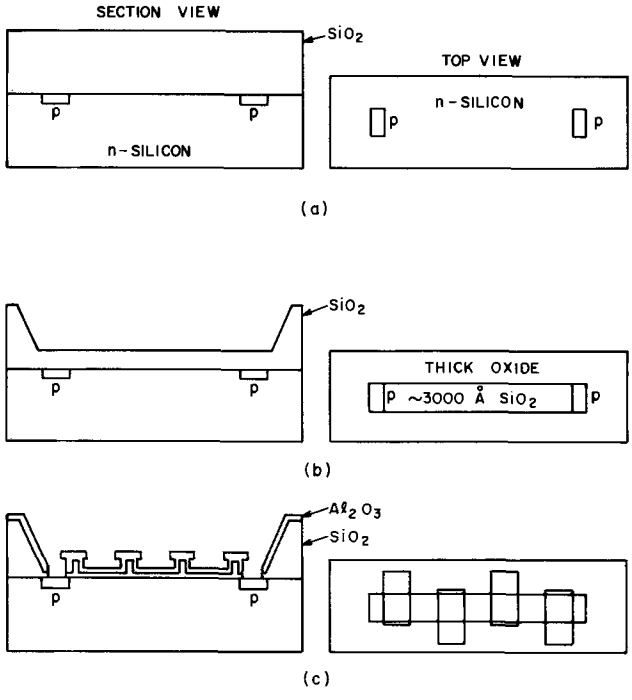

Fig. 5. Illustration of CCD fabrication steps prior to metalization.

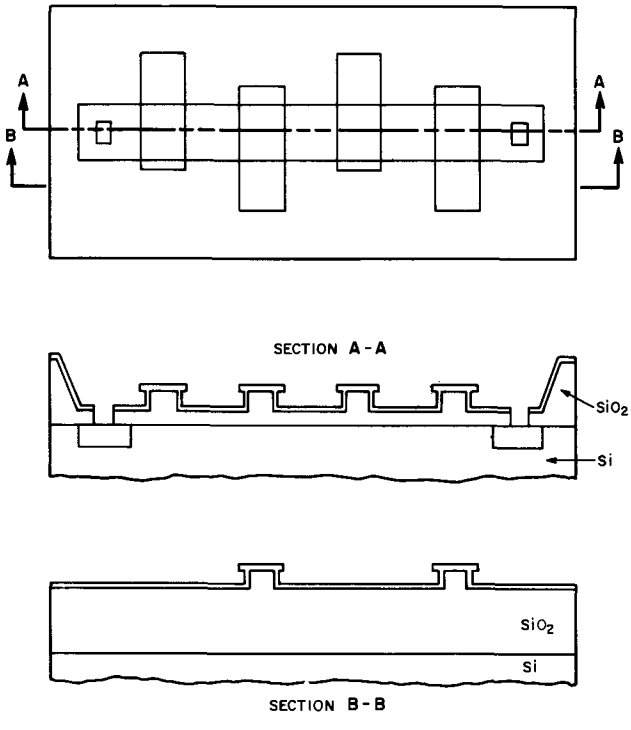

Fig. 6. Further details of CCD fabrication procedure prior to metalization.

occur between isolated and field regions, thereby yielding the selective interconnection desired. Necessary electrode structure for the two-phase CCD, an isolated overhang pad electrically connected to an adjacent metalization pad on the thinned insulator region is generated by selective etching of the Pd and Ti layer. Final device structure is illustrated in Fig. 8. A CCD has been fabricated along lines described here and is reported elsewhere (4).

Electrical characteristics.—Area per bit for the desired CCD structure is determined by minimum linewidths and spacings associated with photoresist technology. If a set of parallel CCD's is designed, then area per bit is given by

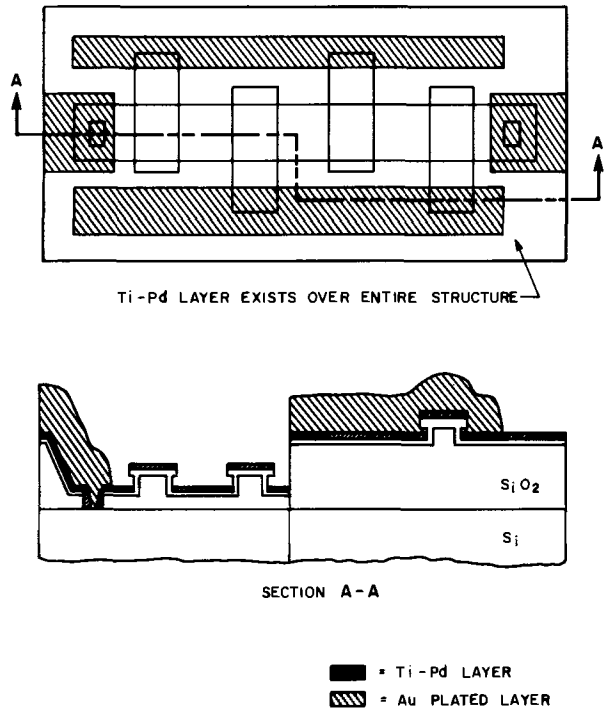

Fig. 7. Illustration of gold plating for selective electrical connection of isolated regions.

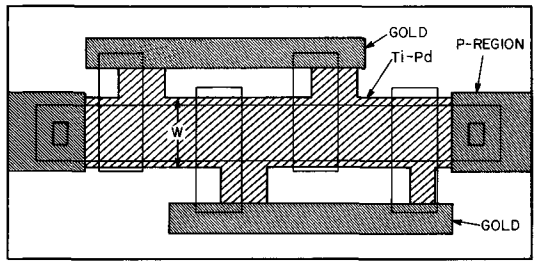

Fig. 8. Finished CCD

$$\text{Area/Bit} = (2/L)(W + F) \quad [2]$$

where L = minimum electrode width; W = minimum transfer channel width; and F = minimum field oxide width between adjacent channels. Assuming a standard 10.0μ (0.40 mil) photoresist technology, an 800μ^2 (1.28 mils^2) area/bit is realizable. This quantity compares favorably with various proposed CCD structures (10).

The most significant advantages of this device, however, are two fold. It is a completely self-aligned structure, which implies, with respect to its electrical characteristics: (*i*) the structure possesses maximum ratio of active signal storage area to total bit area obtainable; and (*ii*) performance of the basic CCD cell itself is not a function of, or sensitive to, photolithography realignment.

Device yield and manufacture considerations.—The contribution to process yield associated with the isolation overhang technique may be estimated for an n-bit CCD. Total isolated edge length per bit is given by $2(W + F)$. Consequently, probability of producing n good bits $P(n)$ is from Eq. [1] and [2] given by

$$P(n) = \exp[-2n(W + F)/l_o] = \exp(-n \cdot 10^{-3}) \quad [3]$$

where we have assumed a 10.0μ technology and l_o = 4.0 cm, (1024 bit CCD = >37% yield of CCD's with no metalization shorts at the undercut edge).

Conclusions

We have shown, using the (Al_2O_3-SiO_2) double insulator undercut system and titanium-palladium metalization, that reproducible electrical isolation between

adjacent metal patterns can be achieved. Using a simple MOS capacitor pattern, it has been possible to answer the important questions about the technique. It has been found that the excellent and reliable MOS properties of the (Al_2O_3-SiO_2) double insulator system have not been compromised by additional processing necessary for undercut isolation and that very high breakdown voltages exist between adjacent isolated metalization levels. One of the potential problems with the technique, unintentional shorts between adjacent metal lines, has been characterized and shown to be relatively unimportant.

The undercut isolation technique can and does possess many potential applications in integrated circuit design. As an immediate example, we have illustrated use of the technique for fabrication of a CCD. The described device has an area/bit smaller than, or equal to, any competing CCD and should possess superior electrical characteristics.

Manuscript submitted Nov. 30, 1972; revised manuscript received April 12, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Growth of High Purity CdTe Single Crystals by Vertical Zone Melting

R. Triboulet and Y. Marfaing

Laboratoire de Physique des Solides, C.N.R.S. (92) Meudon-Bellevue, France

ABSTRACT

The synthesis of CdTe in a Bridgman furnace, under determined vapor pressure of cadmium, and its purification by the vertical zone melting technique is described. The influence of the thermodynamic state of the crystals after synthesis on the conductivity type of the zone-melted purified material is shown. Purity, homogeneity, and compensation of the material, as determined by electrical measurements, photoluminescence, and spectrographic trace analysis, are presented and discussed.

The different applications of CdTe, as solar cells, electrooptic modulators, or γ-ray detectors, necessitate a carefully characterized pure material. On the other hand, the identification of native defects in CdTe, which is not a clearly solved problem, requires a material in which the foreign impurity concentration is lower than the native lattice defects concentration. Therefore, the preparation of a high purity material is of prime importance. For that purpose, different methods have been used: synthesis and crystallization from highly purified cadmium and tellurium (1); horizontal zone melting under vapor pressure of cadmium (2, 3); sublimation of the compound (4-6); crystal growth from Te solution, for instance by T.H.M. (7); and vertical zone melting by the Heumann method (8) applied to CdTe (9-11). It is this last method that we have used.

The preparation of the quartz tubes, the synthesis of the compound, and the zone-melting process will be successively described. The results concerning the purity, the time changes of the characteristics and the homogeneity will then be given. The segregation profiles will be finally studied by electrical measurements and photoluminescence.

Preparation and Purification of the Compound

Preparation of the tubes.—Metals generally react with silica to form silicates. With cadmium, at high temperature, there is formation of cadmium metasilicate $CdSiO_3$. This reaction is more intense when traces of cadmium oxide are present and, because the material sticks on the quartz walls, brings about, in addition to a contamination by the impurities included in silica, the breakage of the tubes. Consequently, it is of prime importance to avoid all direct contact of the silica with the material and to reduce any oxides. This is partly ensured by coating the inner surface of the quartz tubes with graphite.

For this purpose the tube is preliminarily cleaned for some minutes with a 25% aqueous solution of HF, rinsed in ultra pure water, and evacuated to 10^{-6} Torr for about twenty hours at 1150°C. It is then connected for some seconds with a container filled with ultra pure benzene, the vapors of which are drawn in and, by cracking, deposit graphite on the walls. The injection of benzene vapors is followed by fore-vacuum pumping. This process is repeated several times to deposit successive thin layers of graphite up to the desired thickness. The adhesive coating is then backed out under 10^{-6} Torr, at 1150°C, for several hours. After cooling, the rupture of vacuum is achieved by connecting the tube with a bag of very pure argon or hydrogen.

The elements, Cd and Te (99.9999% from Koch Light), are used in bars to limit their surface of contact with air during the manipulations. Cadmium is etched in a solution of 4% HNO_3 in ethanol, and tellurium is etched in diluted HCl. One hundred and sixty grams of Cd + Te are loaded into the 15 mm ID tube

Key words: Bridgman crystallization, electron mobility, photoluminescence, resistivity.

which includes a small container of cadmium in its upper part. The tube is sealed under 10^{-6} Torr. Its total length is then 30 cm. Two liquid nitrogen traps are inserted between the tube and the diffusion pump to avoid contamination by oil.

Synthesis of the compound.—The CdTe is synthesized, under a controlled vapor pressure of cadmium (3), in a Bridgman furnace, constituted by three superposed furnaces A, B, and C, as shown in Fig. 1. The temperature of the upper furnace A controls the vapor pressure of cadmium and allows one to use the solid-liquid vapor equilibrium to adjust the deviation from stoichiometry of the compound. A determined pressure of cadmium gives a determined composition of the compound. The temperature of this furnace is regulated by means of a thermocouple which is fastened to the top of the synthesis tube. Thus, this end remains always, for any position inside the furnace, at a constant temperature. The central furnace B is formed of six piled up refractory pancakes surrounding circular spiral resistances in Kanthal A1. These resistances are arranged so as to obtain, with a 20 cm high furnace, a temperature plateau of 12 cm at ±10°C. The temperature gradient at the solid-liquid interface is around 50°C/cm.

For the synthesis, the temperature of furnace B is progressively raised to about 800°C while the top of the tube is maintained at 500°C. Near 800°C the exothermic reaction of formation of the compound takes place. The temperature of furnace B can then be rapidly raised to 1120°C, while the temperature of furnace A is simultaneously adjusted to give the desired vapor pressure. The temperature of furnace C is set at 850° ± 20°C. The tube is subsequently slowly lowered into the furnace at a rate of 0.3 cm/hr. After this normal freezing, which gives an impurity segregation along the ingot, the lower furnace C is slowly cooled to room temperature, in 24 hr, by a controlled program, to limit the dislocation density in the material.

For temperatures of the upper furnace higher than 820°C, the obtained crystals are generally n-type, while for temperatures lower than 800°C, the crystals are generally p-type. The intermediate temperature range corresponds to high resistivity material. These data, in agreement with those of Ref. (1), are notably influenced by the nature and the concentration of impurities.

Zone melting.—After synthesis the thickness of the graphite layer has diminished as consequence of reaction with oxides. The ingot is taken out of the tube which, for this procedure, has been chosen slightly conic. The same tube is cleaned, backed out, and graphitized again as described above. This new layer prevents, as much as possible, the CdTe from being in contact with silica, although diffusion can probably exist between silica and CdTe across this stratified layer. The best results have been obtained with the Heraeus "Heralux" quality tubes. The tube is then loaded with the ingot, evacuated to 10^{-6} Torr, and sealed with a quartz plug positioned to rest on the ingot.

The tube is then placed in the zoning apparatus (Fig. 2). The temperature of the graphite susceptor ring is regulated with a precision of ±0.5°C and controlled by a thermocouple. The temperature is adjusted by substituting for the zone melting tube a thermal analysis tube of the same dimensions, with a thermocouple. We have chosen a temperature of about twenty degrees above the melting point of CdTe: the molten zone is then approximately one centimeter wide.

As a consequence of the reaction of oxides with graphite, the periphery of the ingot presents small gas pockets, hence a first pass is performed at 4 cm/hr for a better filling of the tube. The following passes (10-20 generally) are carried out at rates between 2.5 and 0.25 cm/hr and stopped at 2 cm from the top of the ingot. The vapors of Cd and Te produce a self-sealing of the end of the ingot which completely isolates it

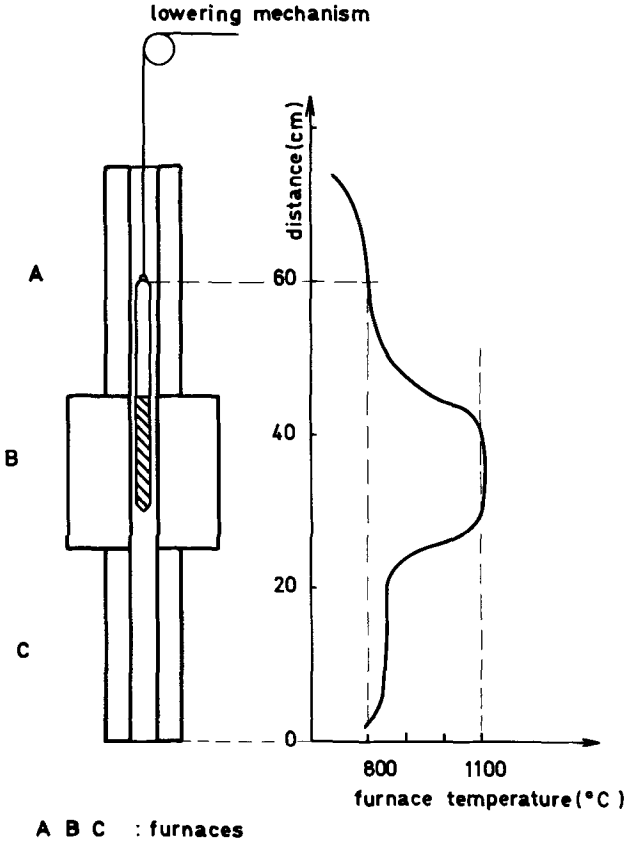

Fig. 1. Schematic diagram of the Bridgman furnace and of its temperature profile.

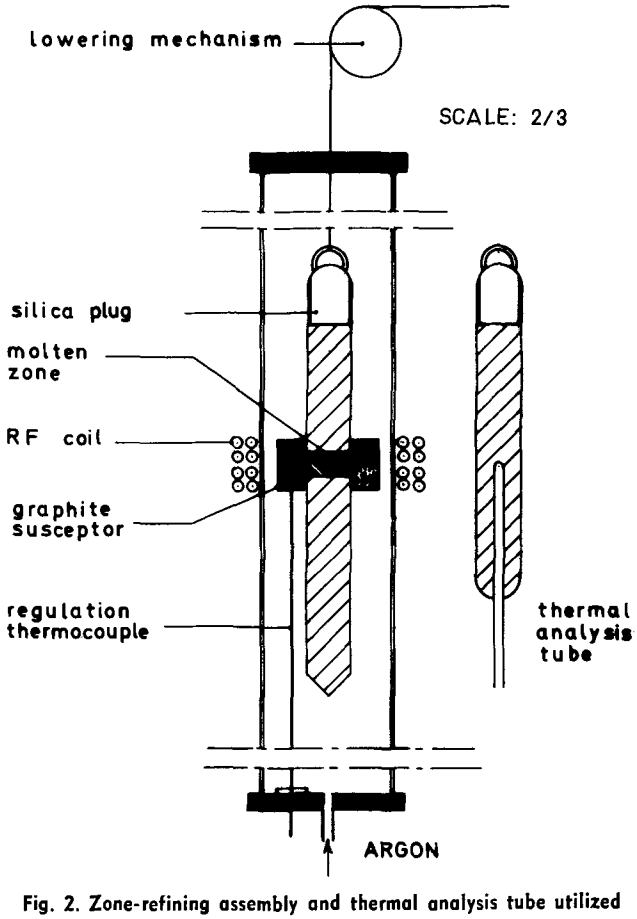

Fig. 2. Zone-refining assembly and thermal analysis tube utilized to adjust the molten zone temperature.

from the small void space at the upper part of the tube. The ingots so obtained contain large single crystals, about 2-3 cm^3 in size.

Results

Conductivity type of the crystals.—Woodbury and Lewandowski (11) have found a relation between the susceptor temperature and the conductivity type of the crystals: for temperatures higher than 1200°C, the crystals are p-type, and for temperatures lower than 1160°C, n-type. They do not find any obvious correlation between resistivity and susceptor temperature in the intermediate range.

Our zone melting has always been carried out at a liquid temperature of about 1115°C (susceptor temperature 1170°C). Under these conditions, the characteristics of the material, after zone melting, seem to depend on the initial state of the material, *i.e.*, the vapor pressure of cadmium during the Bridgman growth. Thus, for vapor pressures of cadmium lying between 2 and 2.8 atm (upper Bridgman furnace temperature 820°-850°C), the material is n-type with a resistivity between 10-500 ohm-cm, and an electron concentration between 1.5×10^{13} to 8×10^{14} cm^{-3} at room temperature. A vapor pressure of one atmosphere (upper furnace temperature 760°C) corresponds after zone melting to a high resistivity p-type material. So, although the equilibrium reached during zone melting tends to reduce the departure from stoichiometry, the history of the material, *i.e.*, the thermodynamic conditions of its synthesis, should be taken into consideration. As a matter of fact, according to our experimental process, it is possible to get a material of very reproducible characteristics.

Purity.—Emission spectrography was used to follow the segregation of impurities. The amounts of Si, Ca, and Mg do not vary along the ingots while Cu, Fe, and Ag segregate to the end of the ingots. These impurities were the only ones detected by this method.

Qualitative analysis by means of ionic probe reveals the presence of Al, Na, Cl, F, K, Co, Fe, and Si, depending on the samples.

Mass spectrometry analysis was conducted; for most of the elements the limit of detection was around 0.5 ppm. Numerous elements could not be measured because of associations and interferences. One found a large concentration of C (a few ten ppm) and small amounts (around one ppm) of S, Na, and K.

One of the most typical results of trace analysis is that distribution profiles of impurities along the ingots are not clearly seen if the analyzed samples are of a larger size. This suggests the presence of inhomogeneities and the coexistence of pure and impure regions at short distance. The main acceptor impurities seem to be copper and sodium and the residual donor impurities could be the halogens and aluminum.

Because of the sensitivity limitations of spectrographic methods and the difficulties of bringing them into play, electrical measurements were currently used to determine purity.

The electrical measurements data for some of the purest samples are summarized in Table I.

Mobilities of $\sim 10^5$ cm^2/V sec at 32°K—the maximum of the mobility curve, probably located at about 20°K, is not still reached at this temperature—are the highest mobilities measured until now in cadmium telluride.

Some curves of mobility *vs.* temperature are plotted on Fig. 3. Curve 1 corresponds to one of our purest

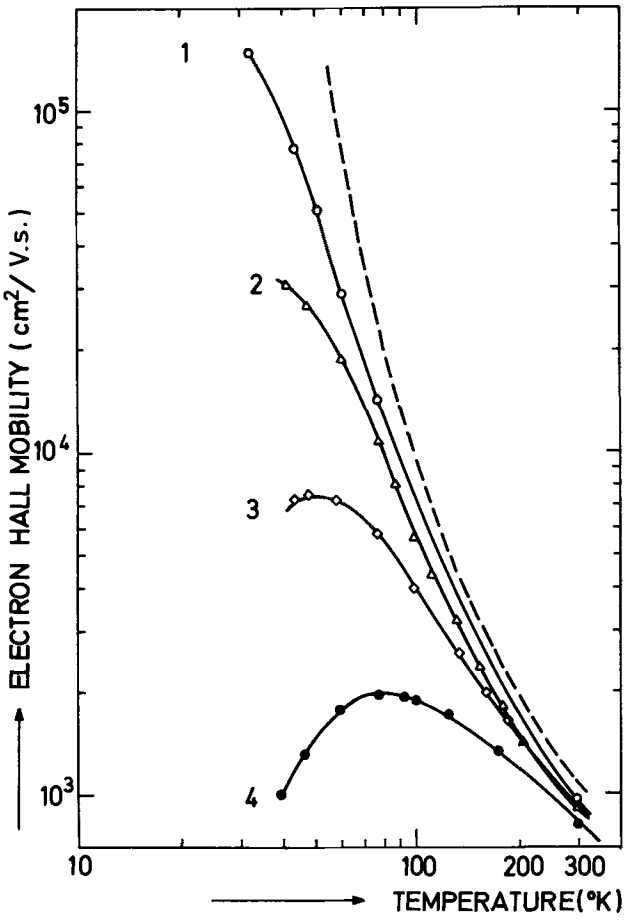

Fig. 3. Electron mobility *vs.* temperature for samples cut from the head (1) to the end (4) of vertical zone melted ingots.

samples (24A5) with $\mu_{32°K} = 1.46 \times 10^5$ cm^2/V sec.[1] The dashed curve represents the theoretical curve calculated for a scattering by LO phonons by Segall *et al.* (12). The following curves, 2, 3, and 4, are related to samples of decreasing purity, *i.e.*, samples taken in less pure parts of an ingot. The maximum of the mobility curve shifts towards higher temperatures when the purity decreases.

Figure 4 represents the photoluminescence spectrum of a pure sample (16A12). This spectrum is characteristic of a high purity and uncompensated sample.

The intensity of the free exciton line (1.596 eV), which is self-absorbed in the crystal, is remarkably high. The one and two LO phonon replicas are at 1.575 and 1.554 eV. The line at 1.594 eV is attributed to excitons trapped on neutral hydrogenic donors at $E_c - 0.011$ eV (13, 14). By comparison, the line at 1.591 eV, which is associated to a neutral acceptor-exciton complex, with $E_A = E_V + 0.05$ eV, is very weak. Only a weak line at 1.540 eV emerges in the 1.550 eV region, generally rich in impurity transitions (15).

This spectrum shows also a line at 1.605 eV which probably corresponds to the radiative band-to-band transition and its first phonon replica at 1.584 eV. These lines, never seen before, constitute another proof of

[1] On such samples, a total concentration of electrically active centers around 10^{14} cm^{-3} has been determined by M. Caillot (Private communication).

the high quality of the crystals and permit a direct measurement of the cadmium telluride bandgap at 4.2°K.

By comparison, the spectra of less pure samples present the following characteristics: the band-to-band transition is not seen; the free exciton line is weak or absent; the bound exciton line at 1.591 eV, which may be related to the presence of shallow acceptor impurities, is very strong; while in the 1.550 eV region, intense broad lines emerge corresponding to donor acceptor-pair transitions.

Instability of the sample characteristics.—We have observed a shift, with time, of the characteristics of the purest zone-melted samples of low electron concentration, corresponding to an increase in compensation (11): both the electron mobility and concentration decrease. These changes are very accelerated by heating even at moderate temperatures. As an example, the dependence of the resistivity at room temperature *vs.* time t for a sample first kept under static vacuum (10^{-2} Torr) after contact soldering has been plotted on Fig. 5. For the first 80 days the resistivity increases with time. During the subsequent period (80-110 days) the sample is exposed to air and its resistivity decreases. When the sample is put again under vacuum its resistivity tends to recover the high values measured at the end of the first stage. This experiment shows the strong influence of the ambient conditions on the electrical properties. The variation of electron concentration during the first period follows the law: $n = A - B \log t$, which could be interpreted in terms of a chemisorption phenomenon (16).

Homogeneity.—The statistical dispersion of the electrical characteristics of samples cut in the pure part (2 cm) of an ingot has been studied. In Fig. 6 is presented the statistical distribution of mobilities at 35°K and of carrier concentrations at room temperature for about fifteen samples.

The mobilities at 35°K, which are close to the maximum of the mobility curve, have more scattered values than the room temperature carrier concentrations. $n_{300°K}$ is equivalent to $N_D - N_A$ while the low temperature mobility is limited by the total concentration $N_D + N_A$. It appears that $N_D + N_A$ can largely fluctuate from one sample to another, while $N_D - N_A$ changes weakly. This can be explained by self-compensation between impurities and native defects.

Some samples present an abnormally low mobility at room temperature. These effects have been attributed by different authors (17, 18) to the existence of microinhomogeneities in the material. The electronic mobility at room temperature, *vs.* the ratio of the carrier concentrations at 300°-35°K, has been plotted in Fig. 7. The greater this ratio, the lower is the mobility. This is an indication that microhomogeneities are to be related to the presence of trapping levels in which electrons freeze out when temperature decreases.

Impurities Segregation, Results and Discussion

The distribution profiles of impurities in ingots obtained after 2, 10, and 20 passes, have been studied by means of electrical measurements and photoluminescence.

Figure 8 gives the electron mobility at 35°K *vs.* the distance along the ingot axis for ingots grown with 2,

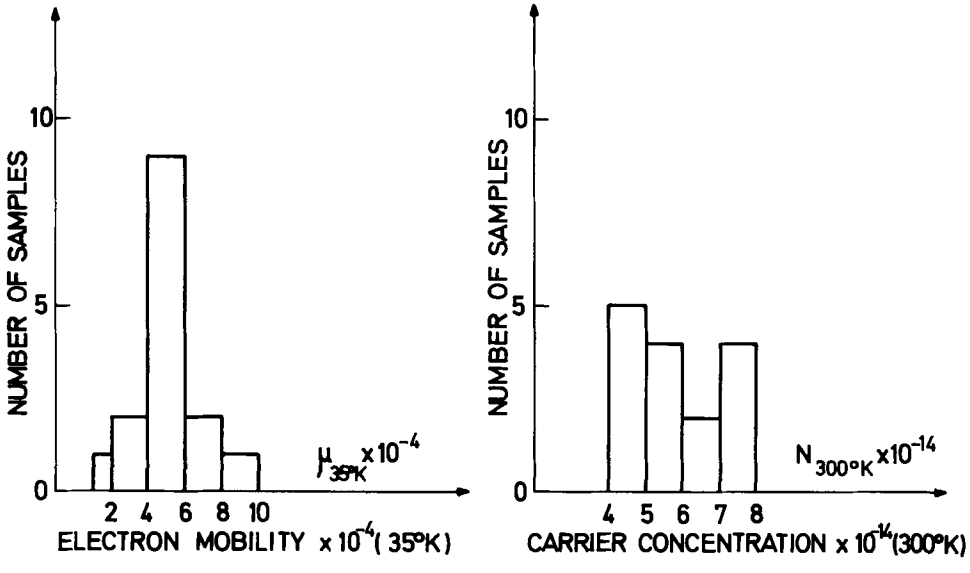

Fig. 6. Statistical distribution of the electron mobilities at 35°K and of the carrier concentrations at room temperature for 15 samples cut in the purest part of a vertical zone melted ingot.

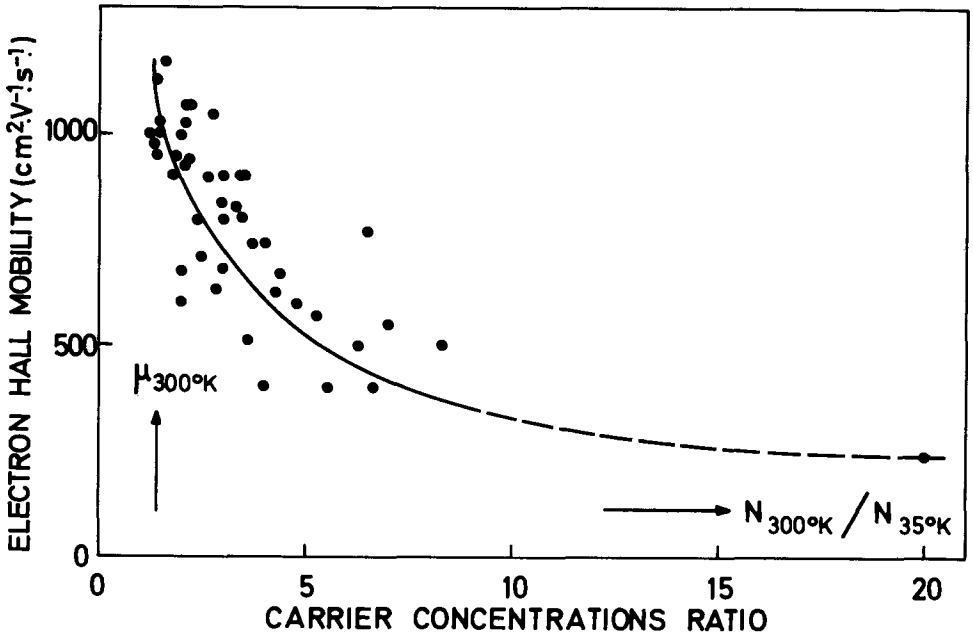

Fig. 7. The room temperature electron mobility vs. the carrier concentrations ratio at 300° and 35°K.

10, and 20 passes. These profiles cannot be directly compared to the classical impurities distributions obtained after zone melting. They are in fact the result of zone melting superposed upon normal freezing for the whole distribution of impurities. High mobilities are rapidly reached in the first part of the ingots. Some ingots, after 10 passes, already present mobilities up to 10^5 cm²/V sec. The increase in the number of passes has more the effect of increasing the length of the purest part of the ingot (2/3 of the ingot after 20 passes) rather than of improving the purity which seems to reach a limit value probably depending on a contamination-purification equilibrium.

Considering the impurities distribution coefficient values in CdTe (generally ranging between 0.2 and 0.5), zone-melting purification is not sufficient to explain the fairly high mobilities measured after only 2 passes, whereas our Bridgman-grown material does not present mobilities higher than 5×10^3 cm²/V sec at low temperatures. One can think that, in these samples, impurities assemble to form highly compensated microinhomogeneities, which explain the high mobilities found at low temperatures. On the other hand the additional scattering, brought about by these heterogeneities, causes small mobility values at room temperature (between 240 and 700 cm²/V sec). Thus the low temperature mobility would be significant of purity only if the theoretical mobility value is observed at room temperature ($\sim 10^3$ cm²/V sec).

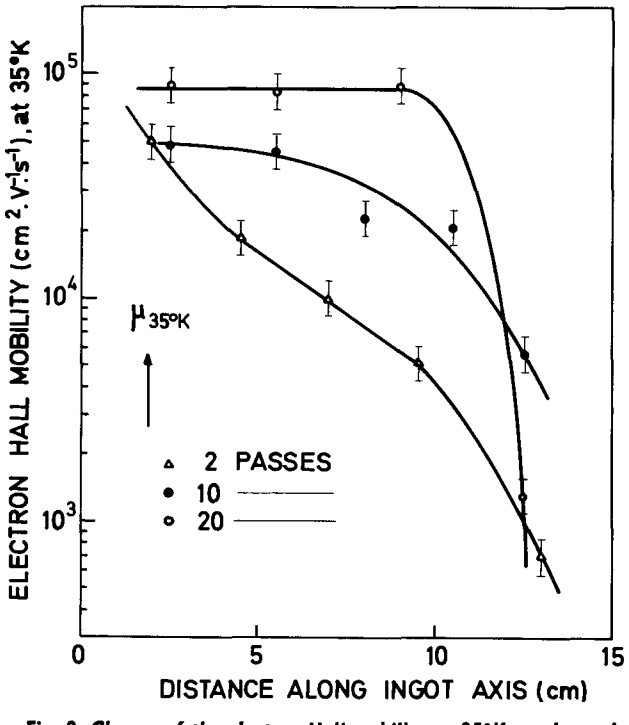

Fig. 8. Change of the electron Hall mobility at 35°K on the position of the samples along the ingot growth axis.

Another marked effect on low temperature mobilities is probably the departure from stoichiometry which can be high in CdTe: $\sim 10^{20}$ at cm^{-3} from each side of the stoichiometric composition (19, 20). In fact, some observations suggest that, due to the particular equilibrium reached during the process, the material approaches the stoichiometric composition: indeed, it is habitual to find some cadmium—or tellurium as the case may be—around the zone-melted ingots.

The carrier concentration *vs.* the position of the samples along the ingot is plotted in Fig. 9. The variation range is not very important. However a rather strong dispersion is observed, which reflects the fluctuations in compensation.

The ratio between the intensity of the two impurities-bound exciton lines at 1.594 and 1.591 eV, seen in photoluminescence, *vs.* the distance along the ingot axis is plotted in Fig. 10. This ratio is very sensitive to purity. The intensity of the line at 1.594 eV is related to the concentration of the donors which are neutralized under light excitation at helium temperature, *i.e.*, N_D, while the intensity of the 1.591 eV line is for the same reason related to the acceptor concentration, N_A. The variations of the 1.594 eV line follow roughly these of $n_{300°K}$ as it is observed: in the ingots grown with 10 and 20 passes its intensity varies little with sample position. On the contrary, the line at 1.591 eV is multiplied by a factor 25-250 from the tip to the top of the ingots, depending on the ingots. This line is associated to a compensating acceptor center probably involving impurities.

The ratio $I_{1.594}/I_{1.591}$ is thus close to the ratio N_D/N_A and characterizes the compensation state of the material.

Conclusion

Very pure crystals have been prepared by the vertical zone melting method, as confirmed by electrical and photoluminescence measurements; low temperature electron mobilities above 10^5 cm²/V sec were found, while in photoluminescence the band-to-band radiative transition is seen at low temperature.

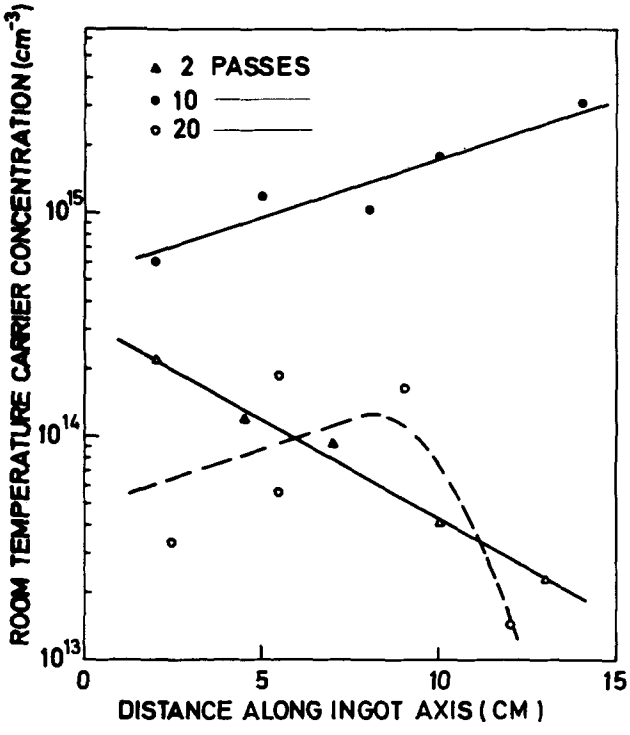

Fig. 9. The room temperature carrier concentration vs. the position of the samples along the ingot growth axis.

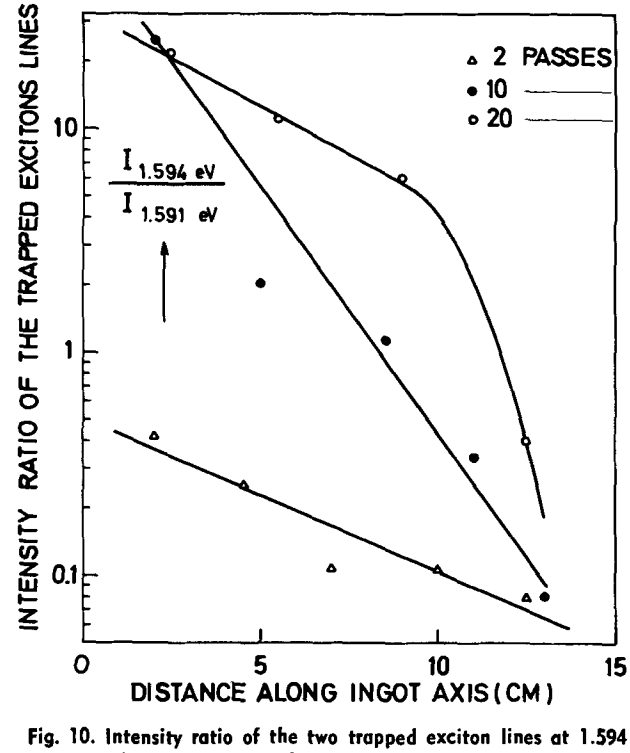

Fig. 10. Intensity ratio of the two trapped exciton lines at 1.594 and 1.591 eV vs. the position of the samples along the ingot axis.

The following points seem to be determinative in the results of our purification: the particular care taken in the preparation of the quartz tubes; the synthesis and Bridgman crystallization performed under determined thermodynamic conditions; all the operations, from synthesis to zone melting, achieved in the same quartz tube (the manipulations, always corresponding to pollution, are thus reduced to the minimum); and the temperature of the melted zone fixed and known with precision.

We suggest that the purity reaches a limiting value depending on a contamination-purification equilibrium and that microinhomogeneities can explain, in some materials, the simultaneous occurrence of low mobilities at room temperature and abnormally high mobilities at low temperature. Thus low temperature mobility is indicative of purity only when the theoretical room temperature mobility is observed.

The ratio of the intensity of two exciton lines at 1.594 and 1.591 eV is shown to characterize the compensation state of the material.

The conductivity type of the zone-melted samples depends on the thermodynamic state of the material after synthesis. This state is controlled by the vapor pressure of cadmium during the preliminary Bridgman growth.

Thus it appears possible, by the vertical zone melting method, to obtain a high resistivity material suitable for different applications, by a correct adjustment of this vapor pressure.

However, this material brings up problems of stability, compensation, and inhomogeneities which need further studies.

Acknowledgments

The authors wish to thank G. Didier for his skillful assistance in the preparation of the crystals. We also thank S. Godefroy of C.N.E.T. and J. Rioux for the spectrographic traces analysis.

Oxidized Boron Nitride Wafers as an *In-Situ* Boron Dopant for Silicon Diffusions

David Rupprecht*,[1] and Joseph Stach**

Solid State Device Laboratory, Electrical Engineering Department, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Hot-pressed 93% boron nitride wafers when properly oxidized and used as an *in situ* boron dopant in open-tube silicon diffusions are capable of providing sheet resistance tolerances of ±1-2% across a silicon wafer and ±4% within a run and from run to run. Although for the experimental conditions studied silicon sheet resistance variations were not expected to be a function of diffusion ambient, ambient flow rate, or source to silicon spacing the contrary was found to be true and the relationships opposite to that intuitively expected. By correlating sheet resistance, impurity profiles, and ellipsometric measurements the observed dependence of sheet resistance *vs.* ambient, ambient flow rate, and source to silicon spacing is explained in terms of Si-B phase formation.

The use of boron nitride (BN) wafers as a diffusion source for p-n junctions in silicon has been investigated by Goldsmith *et al.* (1) in view of efficient manufacturing techniques and employed by Nicholas (2) as a boron source for the study of anomalous diffusion in silicon. In review, Goldsmith *et al.* (1) have indicated that boron nitride wafers when oxidized and employed as in Fig. 1 provide (*a*) equal impurity mass transfer to all silicon wafers regardless of position within diffusion boat, (*b*) equal impurity mass transfer to all portions of a silicon wafer, (c) low temperature diffusion capabilities, and (*d*) the absence of carrier gas mixing or composition problems. Nicholas (2) was primarily concerned with the anomalous diffusion mechanism and considered his results not specific to the use of a BN source. It is the purpose of this report to contribute additional data and to further discuss the consequences of a boron nitride wafer source on diffusion.

Experimental

The material employed in this investigation was Carborundum Grade A boron nitride (ABN) wafers[2] and the important physical properties are as outlined in Table I. The material as received is chemically stable and requires an oxidation step prior to sourcing (1). Cleaning and oxidation procedures to prepare ABN wafers as a boron source were decided upon after several depositions were performed with wafers as received. Poor cosmetic appearance of the ABN after high-temperature deposition coupled with erratic silicon sheet resistance readings indicated a need for more precise control of the ABN's history prior to deposition.

The cleaning procedure chosen is outlined in Table II and was based on the following goals: (*a*) degreasing of an ABN wafer and (*b*) development of a virgin surface. Methanol treatments were avoided in cleaning because of loss of wafer physical strength due to the solvation of the boric oxide binder material used in hot pressing the ABN wafers (3).

Simultaneous development of the source during deposition was deemed imprudent after a review of potentially analogous BBr_3 reaction rate problems as discussed by Parekh and Goldstein (4), and a separate oxidation step preceding deposition was initiated in which precise control of a volatile boron source could

be obtained. The oxidation procedure was based on thermogravimetric data, TGA, (5) compiled at 950°C, Fig. 2. The TGA data is presented as a log-log plot of net weight increase (decrease) of the ABN wafer as a function of time and gaseous ambient.

The slope (m) of the oxidation curve equals 0.86. The two controlling extremes, reaction rate limitation of oxide growth, $m = 1$, and diffusion rate limitation, $m = 0.5$, are also plotted. Comparison of the experimental slope to these extremes suggests a reaction rate limited oxide growth for BN in dry O_2[3] for the time and temperature studied. Evaluation of the data yields the following mathematical representation of oxidation of BN and volatilization of oxidized BN in dry N_2 at 950°C

$$W_I = 0.35t^{+0.86} \quad [1]$$

$$W_D = 0.25t^{-0.40} \quad [2]$$

where W_I = per cent weight increase of BN in dry O_2, W_D = per cent weight decrease of oxidized BN in dry N_2, and t = time in hours.

Extrapolating from the volatilization in dry N_2 data, reoxidation of source should not be required until after 2000 hr of continuous usage (approximately 80 days). No attempt was made to verify this sourcing life-time.

Assuming ideal gas behavior and applying a straight line approximation to the weight loss data, the dynamic vapor pressure of the volatilizing species, assumed to be B_2O_3, can be obtained from the following equation

$$P_{BN} = \frac{N_{BN}}{N_G} P_T \quad [3]$$

where P_{BN} = dynamic vapor pressure of oxidized BN, N_{BN} = moles of oxidized BN vaporized per unit time, N_G = moles of gas passing sample per unit time, and P_T = total pressure. For values obtained from weight loss data, $N_{BN} = 4.73 \times 10^{-6}$ moles/hr, $N_G = 9.6 \times 10^{-2}$ moles/hr

$$P_{BN} = 4.93 \times 10^{-5} \text{ atm}$$

Comparison of this value to extrapolated values of B_2O_3 vapor pressure obtained from Speiser *et al.* (7) and Soulen *et al.* (8) suggests that the volatile species is not totally composed of B_2O_3 vapor pressure at 950°C of 3×10^{-7} atm.

Work by Randall and Margrave (6) on vapor equilibrium in the B_2O_3-H_2O system indicates significant increases in vapor pressure of B_2O_3 for ambients containing 1% H_2O. Extrapolation from their work at 1000°C indicates that for approximately 300 ppm H_2O the observed vapor pressure of hydrated B_2O_3 in the form of HBO_2 is approximately 5×10^{-5} atm. Spectrographic analysis of the volatilized vapor confirms that the significant vapor species is HBO_2. The expected oxidation and deposition reactions from this information are proposed as follows:

$$\text{Oxidation: } 2BN + 3O_2 \rightarrow 2B_2O_3 + 2N_2 \quad [4a]$$

$$B_2O_3 + H_2O \rightarrow 2HBO_2 \quad [4b]$$

$$\text{Deposition: } 2HBO_2 + 2Si \rightarrow 2SiO_2 + 2B + H_2 \quad [5]$$

Elevated temperature storage of the ABN wafers after oxidation is necessary because of boric oxide's great affinity for water vapor (9). No reasonable degree of tolerance with respect to sheet resistance could be obtained with ABN wafers stored at room temperature and room humidity. As such the ABN wafers when not in use were stored in the mouth of the diffusion tube with dry N_2 flushing the diffusion tube at all times. Figure 3 schematically represents ABN wafers after oxidation and their relationship to silicon wafers.

Table II summarizes preparation of ABN as a diffusion source. While the extrapolated time between reoxidation of source is long, the authors chose to reoxidize daily for 15 min. Recent work by Assour (10) suggests that potential purity problems associated with ABN can be minimized with frequent reoxidations.

Experimental conditions pertaining to deposition work are as follows. All depositions were performed with 1.5 in. BN and silicon wafers in a 60 mm ID quartz tube, three-zone furnace capable of ±1.0°C, and 15 in. flat zone. The silicon consisted of a 3-7 ohm-cm arsenic-doped, 8-10μ thick epitaxial layer on (111) 0.013 ohm-cm maximum arsenic-doped substrate. Deposition performance was ascertained with sheet resistance measurements, ρ_s, and profiles. The four-point probe employed consisted of a linear array tungsten carbide probe of 0.04 mm ±10% tip radius, 1.00 mm spacing, 200g ± 2% loading, and a resistivity tester consisting of a 0.001-10 mA ±0.1% of full scale current source, and 0-20 mV ±0.5% of full scale digital voltmeter. Sheet resistance data, ρ_s, was generated by probing the diffused silicon in five areas, (top, bottom, left, right, and center) and then averaging these values. Where the symbol $\bar{\rho}_s$ appears, several ρ_s's have been averaged. To adequately characterize the BN deposition system in terms of process variables the following tests

[3] Air Products brand of bottled O_2, consisting of less than 0.5 ppm total hydrocarbon content; other constituents such as water vapor not provided.

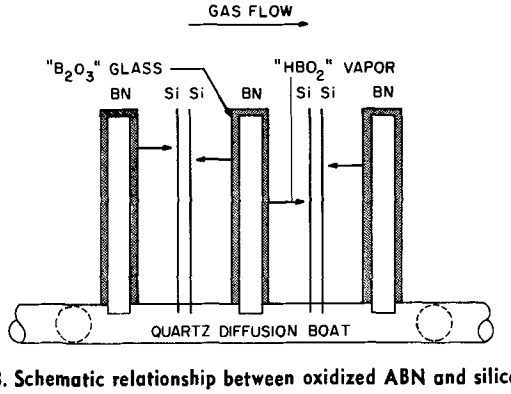

Fig. 3. Schematic relationship between oxidized ABN and silicon

were performed: (*a*) ρ_s *vs.* flow rate, (*b*) ρ_s *vs.* spacing, (*c*) ρ_s *vs.* ambient, (*d*) doping concentration *vs.* penetration, (*e*) ρ_s *vs.* run number, and (*f*) ρ_s *vs.* time, temperature; except where noted all diffusions were performed with the stacking arrangement depicted in Fig. 1, temperature = 950°C, diffusion time = 30 min, dry N_2 ambient at 0.45 standard liters/min, and silicon to BN spacing nominally 125 mils center to center.

Results and Discussion

To better understand the mechanism of mass transport of HBO_2 from BN to silicon the following process variables were investigated: (*a*) $\bar{\rho}_s$ *vs.* flow rate, Fig. 4; (*b*) $\bar{\rho}_s$ *vs.* BN to silicon spacing, Fig 5; and (*c*) $\bar{\rho}_s$ *vs.* ambient, Fig. 6. The data contained in these figures are

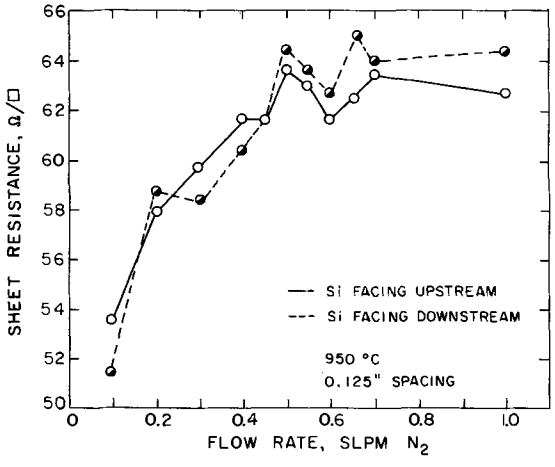

Fig. 4. Sheet resistance vs. flow rate

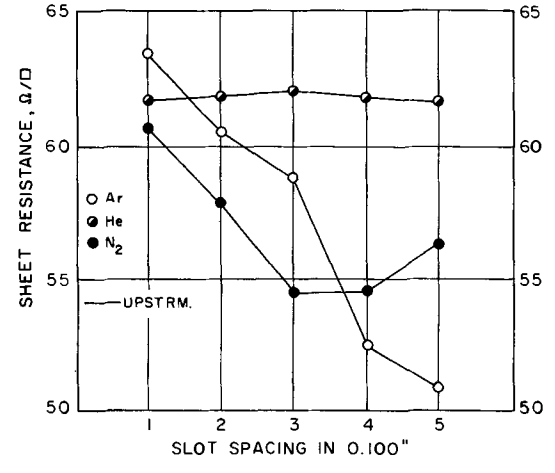

Fig. 5. Sheet resistance vs. ABN to silicon spacing

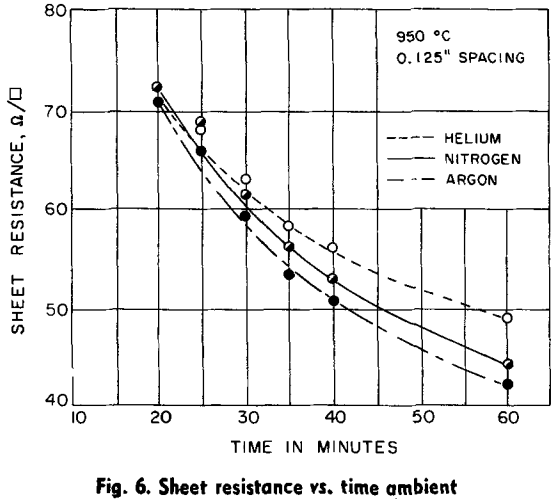

Fig. 6. Sheet resistance vs. time ambient

the average values of at least three distinct data. Briefly, the contents of the figures are as follows. Figure 4 indicates that $\bar{\rho}_s$ increases as flow rate increases between 0.1-0.6 standard liters/min and is relatively constant for flow rates between 0.6-1.0 standard liters/min. Figure 5 indicates that for increasing silicon to boron spacing $\bar{\rho}_s$ decreases for argon and nitrogen ambients and remains constant for helium ambients. Figure 6 indicates that for longer diffusion times differences in $\bar{\rho}_s$ as a function of ambient increase.

For the data collected a paradox intuitively exists. For the particular stacking arrangement and flow rates considered, the calculated Reynolds number, Re, for flow through an angular ring is approximately 1. Characteristically, turbulence does not onset until Re $\geq$ 2000 (11), and as such it is to be expected that mass transport of HBO_2 to be governed by Fick's law of concentration gradient diffusion rather than turbulent transport. For the temperatures considered diffusivities of HBO_2 are on the order of 1-5 cm^2/sec and it would be expected that an equilibrium concentration of HBO_2 be established in the volume between BN and silicon wafer in a fraction of a second. For these conditions, one would expect $\bar{\rho}_s$ to be constant with flow rate, spacing, and ambient.

A review of the literature indicates that for other liquid and gaseous diffusion systems high doping levels have produced films not easily etched in HF (12). Busen and co-workers, (13-15) have considered such films as a Si-B phase necessary to uniform processing control. The appearance of HF unetchable films on Si wafers processed in He ambient suggest the presence of a Si-B phase and the possibility of this phase dictating the data observed. Following the example of Busen *et al.* (13), ellipsometry as described by Vedam *et al.* (16) was employed to identify the presence and relative thickness of a Si-B phase.

Argon and helium ambient samples for $\bar{\rho}_s$ *vs.* spacing data were scribed in halves and one set of halves subjected to ellipsometry while the other set of halves was profiled using anodic oxidation (17) and four-point probe measurements (18). To insure that a minimum of oxide was present when ellipsometric measurements were performed, the silicon wafers and an undiffused control wafer were stripped of any oxide by immersion in concentrated HF for 1 min. Measurements obtained with the ellipsometer were compared to measurements made on the undiffused silicon wafer and data obtained by Vedam and So (19). Ellipsometric measurements are extremely accurate in determining thin films on the order of a monoatomic layer (20) and even small deviations in Ψ, amplitude ratio, and Δ, relative phase change, from the true values are indicative of a thin oxide layer or phase. Ψ and Δ measurements differing from that obtained for the control silicon were interpreted as indicative of various thicknesses of a Si-B phase.

Before discussing the implications of these measurements it is instructive to compare typical diffusion profiles obtained for argon and helium ambients to the ideal complementary error function profile, Fig. 7. Reference to Fig. 7 indicates the differences in calculated and experimental junction depths and the deviation of experimental profiles from erfc. Following the work of Joshi and Dash (21) the deviation in profiles from theoretical can be explained in terms of dislocations if the associated areas under the respective curves are equal. The basic premise for this test is that dislocations do not change the flux entering the surface but cause only a redistribution of the solute in the bulk. Calculation of the number of solute atoms per square centimeter, Q, for the profiles of Fig. 7 reveal that Q(erfc) = 1.75×10^{15} atoms/cm^2, Q(argon) = 2.27×10^{15} atoms/cm^2, and Q(helium) = 1.83×10^{15} atoms/cm^2. While Q(helium) is within 4% of Q(erfc), Q(helium) is less than the minimum Q and 3×10^{15} atoms/cm^2 required to generate dislocations as calculated by Schokley (22).

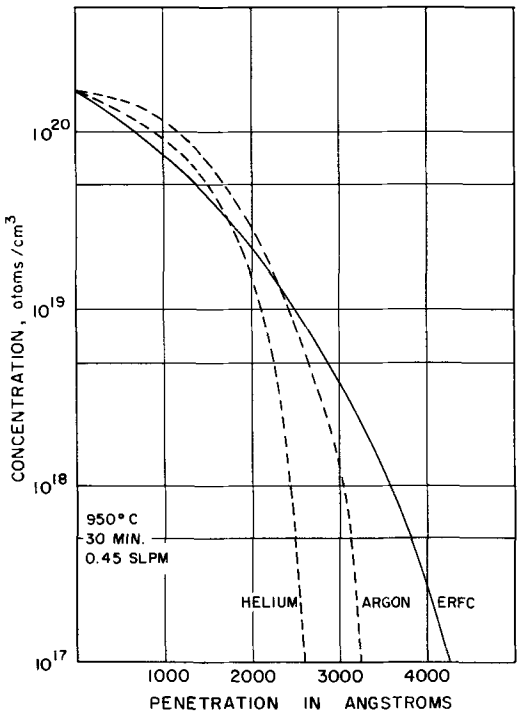

Fig. 7. Argon and helium ambient profiles compared to complementary error function profile.

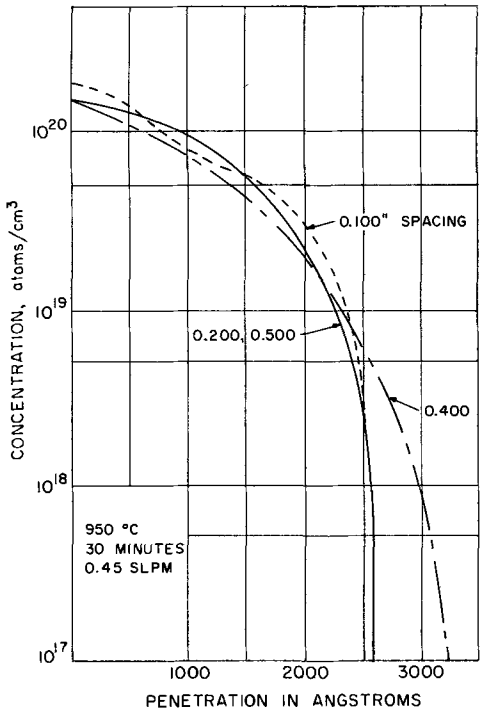

Fig. 8. Helium ambient profiles as a function of ABN to silicon spacing.

From this data it is unlikely that the observed ABN diffusion phenomena are primarily the result of dislocations but rather as previously suggested the result of phase formation.

As described by Boltaks (23) the formation of a new phase during diffusion, assumed in this case to be the Si-B phase described by Busen and co-workers (13-15), invariably leads to diffusion retardation.

Inspection of Table III, $\bar{\rho}_s$, x_j — Ψ, and Δ data, reveals two trends: (*i*) for the nitrogen ambient deposition, as spacing between BN and silicon decreases $\delta\Psi$ and $\delta\Delta$ increase (indicating an increase in Si-B phase thickness) along with an increase in $\bar{\rho}_s$ and a decrease in x_j; (*ii*) for the helium ambient, all $\delta\Psi$ and $\delta\Delta$ are larger than those for N_2 ambient and as spacing decreases $\delta\Psi$ and $\delta\Delta$ increase while $\bar{\rho}_s$ and x_j remain constant. The junction depth measurements of Table III were obtained from impurity profiles of Fig. 8 and 9. A few additional comments concerning these profiles are in order.

For the helium ambient profiles, Fig. 8, 100-, 200-, and 500-mil spacings, the profiles are approximately the same while the ellipsometric data varies significantly. It is felt that in all cases the thickness of a Si-B phase is above a critical thickness necessary to reach a saturated diffusion coefficient. The profile for 300-mil spacing is deleted from Fig. 8 because the silicon wafer was damaged during profiling; the 400-mil spacing profile is felt to be experimentally incorrect because of the discrepancy between calculated sheet resistance $\bar{\rho}_s$ cal = 55 ohms/□, and measured sheet resistance, $\bar{\rho}_s$ = 61 ohms/□.

For the argon ambient profiles, Fig. 9, the spacing increases, junction depth increases, and Ψ and Δ measurements correspondingly approach that of the undiffused silicon indicating a decrease in Si-B phase formation; the 500-mil spacing was deleted because of damage during profiling. It can be hypothesized from the data of Table III and Fig. 8 and 9 that (*a*) as the Si-B phase increases above a specific thickness its effect becomes diminished and the average diffusion coefficient of boron in silicon becomes independent of any increase in thickness (in reality it may become slowly varying function) and (*b*) below this thickness the diffusion coefficient of boron in silicon becomes dependent on the thickness of the Si-B phase, and in such a manner that increasing Si-B phase thickness retards diffusion and increases sheet resistance.

Although additional ellipsometric data must be gathered and correlated, it will be assumed that the phenomena of Fig. 4-6 can be interpreted in terms of a Si-B phase with it implied that increasing Si-B thickness is due to increasing mass transport and reaction of HBO_2 at the silicon surface. As such for Fig. 4, increasing $\bar{\rho}_s$ with flow rate indicates the presence of an Si-B phase and the enhanced transport of HBO_2. At present it is unresolved whether this enhanced mass transport occurs as the result of (*i*) an increase in the drift component of the volatilizing species due to an increase in gas flow rate or (*ii*) an increase in the

vapor pressure of the volatilizing species due to an increase in flow rate of a hydrated ambient gas and the corresponding increase in dynamic conversion of B_2O_3 to HBO_2. While it is unlikely that mechanism (*i*) is reasonable for the flow rate considered the occurrence and degree of B_2O_3 hydrated during (*a*) the BN oxidation step, (*b*) loading and unloading of silicon for diffusion, and (c) during diffusion must be determined before supporting experiment results can be attributed entirely to mechanism (*ii*).

Reference to Fig. 5 suggests that differences in diffusion coefficients for HBO_2 in Ar, He, and N_2 are significant and except for the He ambient an equilibrium concentration of HBO_2 in the volume separating BN and Si is not established during diffusion. As indicated by $\bar{\rho}_s$ and ellipsometric data for the nitrogen and argon ambients, as the source to silicon distance decreases $\bar{\rho}_s$ and Si-B phase thickness increases. Only for the helium ambient was the diffusivity of HBO_2 large enough to establish an HBO_2 concentration at all source to silicon spacings sufficient for critical Si-B phase thickness. The data of Fig. 6 is interpreted as follows. Differences in $\bar{\rho}_s$ *vs.* time for various ambients reflect differences in time to reach a critical Si-B phase thickness above which the diffusion coefficient is relatively constant. Considering stagnant ambient diffusion coefficients and assuming that for the flow conditions considered the relationship for the time-averaged diffusion coefficients are the same, the time-averaged diffusion coefficient of HBO_2, $\bar{D}$, in helium, argon, and nitrogen has the following relationship: $\bar{D}_{He} > \bar{D}_{N_2} > \bar{D}_{Ar}$. In turn, it is expected that the time to establish the critical Si-B thickness, $\bar{t}$, follows the inverse relationship, $\bar{t}_{Ar} > \bar{t}_{N_2} > \bar{t}_{He}$. Therefore, it is expected as depicted in Fig. 6 that $\bar{\rho}_{sHe} > \bar{\rho}_{sN_2} > \bar{\rho}_{sAr}$.

To determine the reliability and general performance of the BN deposition system the following tests were performed: (*a*) ρ_s *vs.* run number for argon, nitrogen ambient, 0.45, 0.60 standard liters/min, Fig. 10; (*b*) ρ_s per cent deviation *vs.* x, y position on silicon wafer, Fig. 11; and (*c*) ρ_s *vs.* slot number in deposition boat, Fig. 12. Examination of Fig. 10 suggests improved sheet resistance tolerance for 0.45 standard liters/min flow rate and Ar ambient while Fig. 10 shows no appreciable across wafer ρ_s variation (1-2%) for any of the wafers mapped. The mappings were performed on Si randomly chosen from wafers processed at 0.45 standard liters/min and obtained by scribing the Si wafers into 250 mil squares and four-point probing. Data presented in Fig. 12 are of one of three large scale depositions performed. No significant pattern as a function of position was observed. The results of all three depositions are plotted in Fig. 13 in terms of frequency of occurrence *vs.* sheet resistance. As indicated by $\pm 2s$ limits (s = standard deviation) 95% of all measurements fell within ±4% of the 64 ohms/□ norm. In Fig. 14, sheet resistance data for 0.125-in. spacing runs 3-11% higher for temperatures less than 1000°C than that reported by Goldsmith *et al.* (1) for a furnace with fast recovery time. While the data of Fig. 14, 0.125-in. spacing, agrees well with data by Goldsmith *et al.* (1) for a furnace with slow recovery time, the furnaces used in obtaining the above presented data are of the tight tolerance, fast recovery type, and it is assumed that the differences and similarities observed are due to other experimental differences.

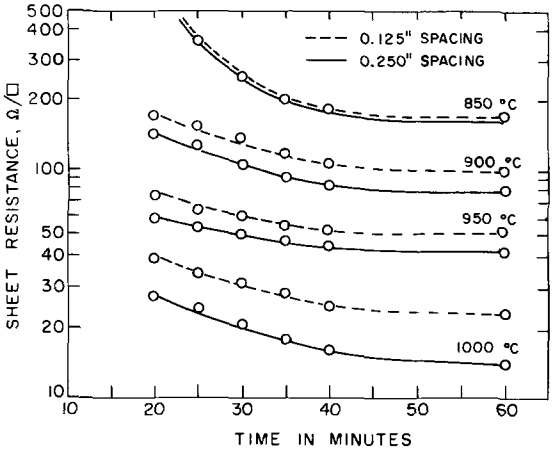

Fig. 14. Sheet resistance vs. time, temperature, and spacing; nitrogen ambient.

Summary and Conclusions

The presented work supports claims by Goldsmith *et al.* (1) but with the additional qualifications: (*i*) the oxidized material is hygroscopic and the vapor pressure of the species changes with water vapor absorption such that if the care in storage is not exercised reproducibility of ρ_s is difficult; and (*ii*) ρ_s values are affected by gas ambient, flow rate, and source to silicon spacing and ρ_s reproducibility may also be a function of these parameters. However, for the studied experimental conditions, the BN deposition system is capable of $\pm$1-2% ρ_s variation across a silicon wafer, $\pm$4% ρ_s variation from run to run.

The mechanism to explain the observed experimental profiles is suspected to be due to reactive diffusion and it has been tentatively demonstrated that the observed phenomena can be explained in terms of Si-B phase thickness: below a specific thickness, increasing Si-B phase thickness decreases junction depth while above a specific thickness, increasing Si-B phase thickness has negligible effect on junction depth. Additional work is needed before the complete consequences of a Si-B phase on device processing and electrical performance can be obtained.

Acknowledgments

The authors would like to thank Mr. D. Ott of the Carborundum Company for providing ample ABN samples and technical support and Dr. K. Vedam and M. Mallin for their assistance with ellipsometric data. Part of the research presented was supported by contract DAAB07-71-Q0299 sponsored by United States Army Electronics Command Post, Fort Monmouth, New Jersey.

ABSTRACT

Single crystals of $Gd_3Ga_5O_{12}$ with dislocation and inclusion levels below 5/cm^2 were grown in a nitrogen atmosphere with an infrared television system of computer controlled Czochralski crystal growth. Coring was prevented by a high crystal rotation rate and a slow pull rate during growth, although striations occurred in the crystal at high rotation rates. Dislocations were avoided by good crystal diameter control during growth and low thermal gradients in the crystal puller. Etching and polishing techniques were developed to reveal defects.

$Gd_3Ga_5O_{12}$ (GGG) has attracted interest as a substrate material for the epitaxial growth of rare earth iron garnet films (1, 2). The crystal growth of GGG by the Czochralski method has been reported (3-5). Some questions still remain on the growth conditions necessary to eliminate inclusions of iridium, which come from the crucible, and other defects. This paper describes the growth conditions necessary to produce crystals with less than five dislocation and iridium inclusion type defects per cm^2. Also, the sources of defects and methods for revealing them are described.

Experimental

The starting materials, Ga_2O_3 and Gd_2O_3, were either 99.9 or 99.99% purity and were prereacted by sintering at 1400°C to give $Gd_3Ga_5O_{12}$. The sintered powder was melted in nitrogen atmosphere in a 77 cm^3 tapered iridium crucible which held about 400g of GGG. The crucible had a 57 mm ID at the top and a height of 60 mm; the outside was flame sprayed with zirconia. Zirconia crucibles and powder were used to insulate the iridium crucible in the crystal puller. An iridium tube with one end sealed and openings at the side was inserted in the lower half of the iridium crucible to dampen the convective temperature fluctuations (6). The gas atmosphere in the crystal puller was either pure nitrogen or 1% O_2-99% N_2. All crystals were grown along the [111] axis with an oriented seed crystal.

An infrared television system for computer controlled Czochralski crystal growth (7) was adapted to the growth of GGG (8) as shown in Fig. 1. The silicon diode array type TV camera supplied information which enabled the computer to calculate the crystal diameter throughout the crystal growth process and to regulate the power to the puller to control the diameter. Figure 1 shows the TV camera focused on the growing crystal and the image displayed on the TV monitor. The marker pulse was positioned manually on the TV monitor to indicate to the computer the location of the center of the crystal and the melt interface. The logic control circuit (9) was used to sample the TV voltage at the points necessary to determine the crystal diameter. Every 15 sec, the computer calculated the crystal diameter and the rate of change of diameter per unit length of pulled crystal. The Tektronix storage scope provided a display of the variables, such as crystal diameter, rate of change of crystal diameter, rf power to the puller, and length of pulled crystal, as cal-

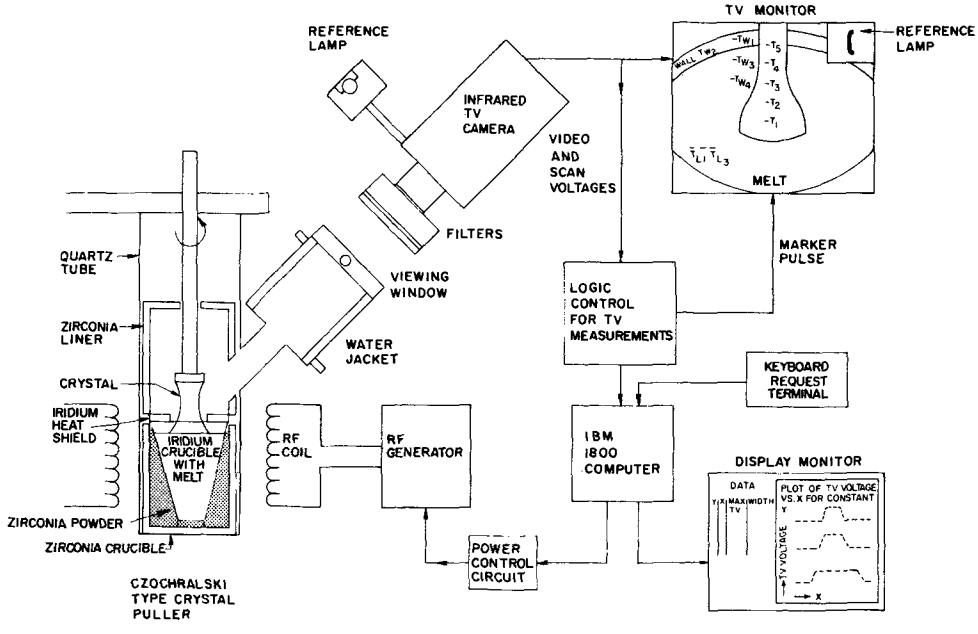

Fig. 1. Infrared television system for the computer controlled crystal growth of $Gd_3Ga_5O_{12}$.

culated by the remotely located IBM 1800 computer. The keyboard was used to enter new commands to the computer. The computer adjusted the power output of the rf generator to keep the crystal diameter or the rate of change of diameter within specified limits. The computer program for crystal growth was divided into four sequential sections: (*i*) crystal diameter reduction after dipping the seed crystal in the melt; (*ii*) growth at a small diameter (3 mm); (*iii*) increase of crystal diameter to the final size; and (*iv*) growth of the main body of the crystal at a constant diameter. In adapting the computer process to the growth of GGG, the most significant changes were made in the computer program which provided better control of the crystal diameter and the rate of change of diameter per unit length of pulled crystal. Also, the GGG required an iridium crucible.

The crystals were grown at rates of 3-6 mm/hr with rotation rates of 60-80 rpm. The higher pull rate was used before growth of the main body of the crystal. The most usual crystal diameter was 15 mm; however, crystals up to 22 mm diam were grown. A 15 mm diameter was a convenient size for GGG wafers to be used in liquid phase epitaxy experiments. The length of the main body of a crystal was usually 6 cm and the weight of a 15 mm diam crystal was about 100g. A typical crystal required 26 hr to grow and 6 hr to cool.

Some crystals pulled along the [111] axis were examined for striations normal to the direction of growth by taking 1 mm thick longitudinal slices midway between the centers and edges of the crystals, polishing them with 3μ diamond paste, and then inspecting them on a polarizing microscope. The appearance of the striations was not influenced by the radial position used for the longitudinal slice. The remainder of the crystals were oriented and sliced normal to the growth direction. A multiple blade cutter with 30μ SiC abrasive slurry was used to produce 28 mil wafers which were lapped with a 30μ resin-bonded diamond disk to remove saw damage and produce a flat surface. Two mils of material were removed from each side during this operation. This was followed by 9, 6, 3, and 1μ diamond paste polishing and then chemical polishing (500Å silicon dioxide in alkaline medium). Final wafer thickness was 20 mils. In many cases, the wafers were suitable for defect examination after a 6μ polish. Dislocation etch pits were revealed by a 10 min etch in a 1:1 mixture of H_2SO_4 and H_3PO_4 at 140°C. Wafers used as substrates for the deposition of magnetic films were cleaned in organic solvents after chemical polishing and dried in warm nitrogen. Over 20 crystals pulled from stoichiometric melts were cut entirely into wafers. Each wafer was examined on a polarizing microscope for coring, strain, dislocations, and iridium inclusions.

Crystals of GGG were grown from melts containing excesses of Ga_2O_3 or Gd_2O_3 to determine the affect of nonstoichiometry on the lattice parameter. Also, high purity (99.999%) GGG powders with excesses of Ga_2O_3 and Gd_2O_3 were heat-treated and used for lattice parameter measurements. One set of samples was annealed in air at 1650°C for 9 hr and another set was annealed at 1400°C for four periods of 16 hr each with grinding between each annealing period. X-ray measurements were made on a Guinier focusing camera with monochromatic CuK_α radiation and a silicon internal standard. Lattice constants were determined from a least squares reduction of film data for Bragg reflections in the range $25 < 2\theta < 75°$ and are accurate to a standard deviation of $< \pm 0.01\%$.

Results

Figure 2 shows two crystals of GGG. The first crystal, G-36, was grown under computer control during the diameter reduction, diameter increase, and the initial 10 mm growth of the main body of the crystal. The remainder of the crystal was grown with constant power to the crystal puller. The diameter reduction was used to remove dislocations (10) which were present in the seed crystal. The diameter of crystal G-36 was increased slowly from 3 to 14 mm by the computer to avoid introducing strain in the crystal. The second crystal, G-57, was grown under manual rather than computer control. It shows a rapid diameter increase, which can occur with manual control, producing strain in the main body of the crystal. The principle advantage of the computer controlled growth process was the improved crystal diameter control, which resulted in better crystal quality. Under computer control, the crystal diameter was more easily reduced to 3 mm to remove dislocations and could be increased gradually without introducing new strain and dislocations. Under manual control, there was a tendency for the crystal diameter to increase too rapidly when the diameter was being increased from about 3 to 14 mm. This was found to cause strain and dislocations.

Initially, the crystals were grown in a 99% N_2-1% O_2 atmosphere to avoid the gallium oxide vaporization problem described (3) for inert atmospheres. This resulted in attack on the iridium crucible walls (oxidation and vaporization of the iridium), a build-up of iridium on the melt surface, and condensation of iridium particles on the pulled crystal. The presence of oxygen in the puller atmosphere resulted in a rougher crystal surface. This latter point is illustrated by the difference in surface appearance of crystal G-36 (Fig. 2) grown in 99% N_2-1% O_2 and crystal G-57 which was grown in pure nitrogen. Repeated use of the seed crystals caused a build-up of iridium deposits on their surfaces. This accounts for the dark regions near the top of each crystal in Fig. 2.

Generally crystals grown under computer control with a nitrogen atmosphere in the puller had less than 5 defects (dislocations and iridium inclusions) per cm^2 and some crystals had a high percentage of wafers free of these and all other defects. The nitrogen atmosphere did not cause gallium suboxide inclusions from the decomposition of Ga_2O_3. Also, no significant loss of Ga_2O_3 was observed with either atmosphere. Crystals could be pulled overnight (16 hr) at constant power with only the expected small decrease in crystal diameter as the liquid level was lowered and the additional radiant heat came from the crucible wall. A sizable loss of Ga_2O_3 would have caused a lowering of the melting point and a large decrease in crystal diameter.

The principal defects in GGG were due to iridium inclusions and coring. Gallium suboxide inclusions were rarely observed. The triangular and hexagonal shapes of the iridium inclusions are shown in Fig. 3. These inclusions were identified as iridium by electron microprobe analysis. The 1:1 H_2SO_4:H_3PO_4 etch was used to reveal the dislocation pattern around the iridium inclusion in Fig. 3b. This source of dislocation has been described (11). Dislocation density and iridium inclusions could not be related to the position of the wafer along the length of the crystal from the data available on more than 20 crystals.

Dislocations were also observed from strain produced by rapid crystal diameter increases during growth and in a few crystals by severe temperature gradients above the melt which were produced by directing an inert gas flow near the crystal-melt interface.

Striations present in GGG are illustrated in Fig. 4. These striations occur normal to the direction of pulling and were usually spaced between 10 and 45 μm. The spacings corresponded to time periods of 9-40 sec without any direct correlation with rotation rate. They disappeared when the rotation was reduced from 70-60 rpm. The striations are believed to result from temperature fluctuations which produce growth rate changes. We have observed melt temperature fluctuations caused by high rotation rates during the growth of other high melting materials. An attempt was made to relate the striations to a variation in Ga_2O_3 or Gd_2O_3 concentrations. However, electron microprobe analysis across a 200 μm region of striated GGG in steps of

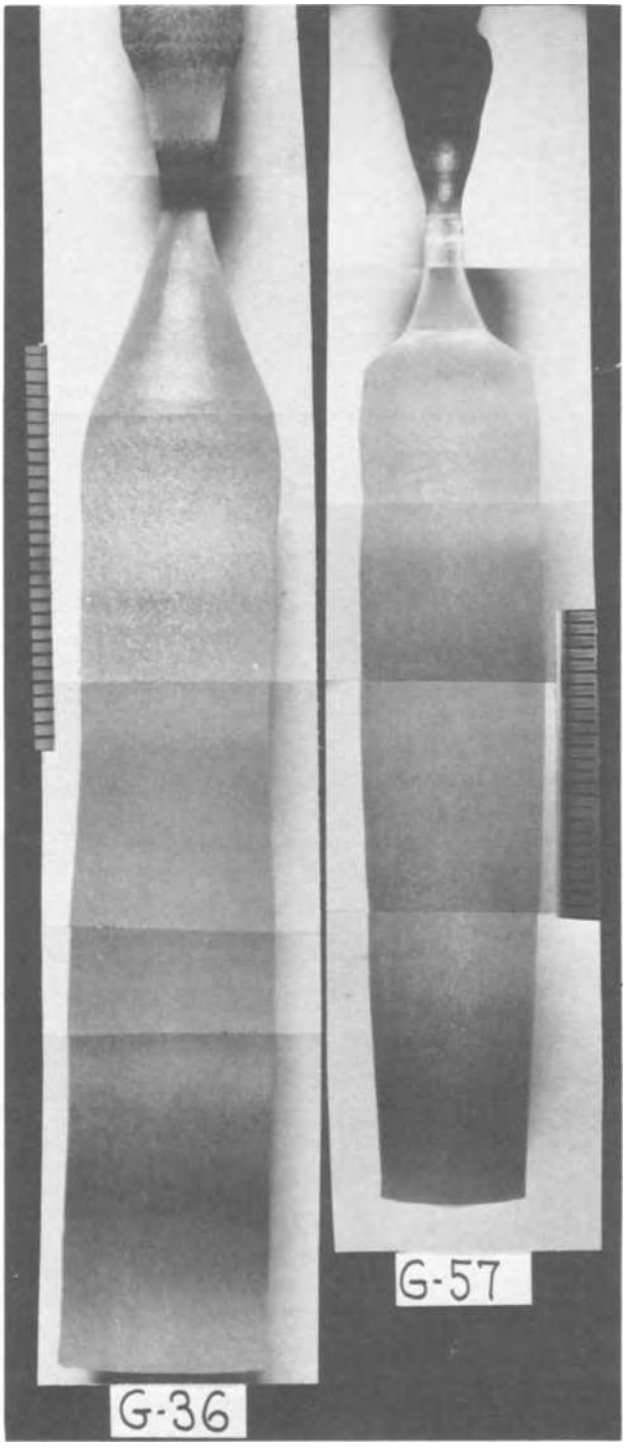

Fig. 2. Two single crystals of $Gd_3Ga_5O_{12}$. Crystal G-36 was grown under computer control and crystal G-57 was grown with manual control of the power. Scale shows 1 mm divisions.

2 μm failed to detect any changes in gallium or gadolinium concentrations. The limit of detection for these elements was about 1 weight per cent (w/o). The only impurity detected was silicon below 200 ppm and its concentration had no relation to the striations.

The striations were not caused by thermal asymmetry in the melt or by departure of the rotation axis from the thermal center of the melt. This type of striation is dependent on the amount of crystal grown per revolution. In the case of GGG, the vertical travel per revolution was about 1 μm, whereas the actual striations were 10 μm or larger.

Strain associated with (211) facets on the growth interface has been reported (4) for GGG. This strain can impede the motion of magnetic bubbles in films

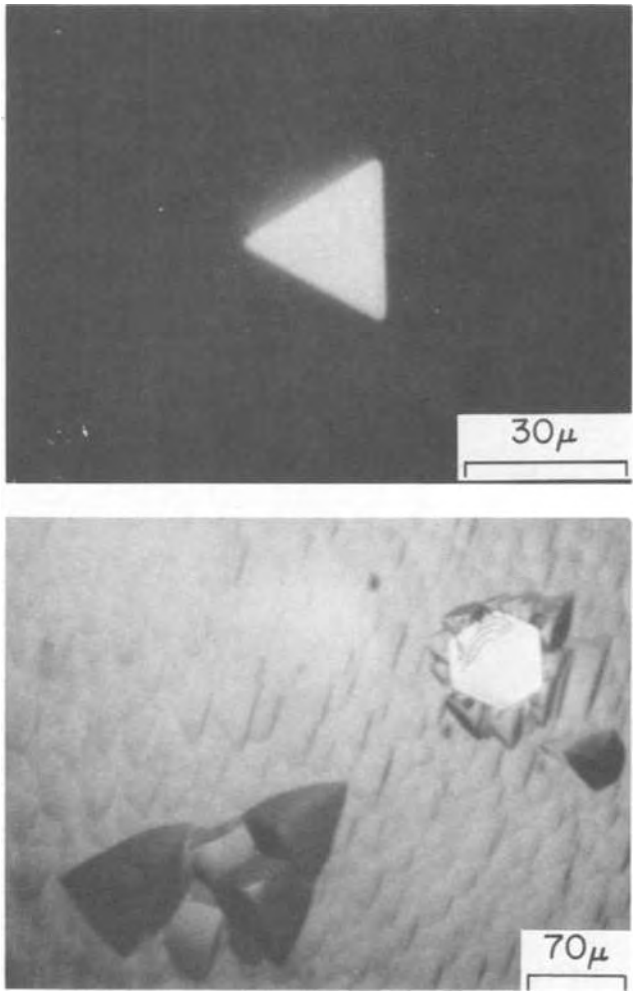

Fig. 3. Top photograph shows triangular shaped iridium inclusion. Lower photograph shows hexagonal iridium inclusion on etched surface of $Gd_3Ga_5O_{12}$.

grown on GGG substrates. In other garnets (12), high rotation rates have prevented this coring effect by producing a flat growth interface. In our crystal puller, high rotation rates (80 rpm) and slow growth rates (3 mm/hr) prevented coring. These conditions were used to grow the low defect (less than 5/cm^2) crystals. The 80 rpm rotation rate did cause striations; however, the motion of the magnetic bubbles in the epitaxial film was not influenced by the striations in the substrate wafer.

Table I shows the lattice parameter data on a flux grown GGG single crystal, Czochralski pulled GGG crystals grown from melts containing either excess Ga_2O_3 or excess Gd_2O_3, and powder samples sintered at 1400° and 1650°C. The compositions indicated in the

Table I. Influence of composition and temperature on the lattice parameter of $Gd_3Ga_5O_{12}$

Composition	Lattice parameter a_o, Å

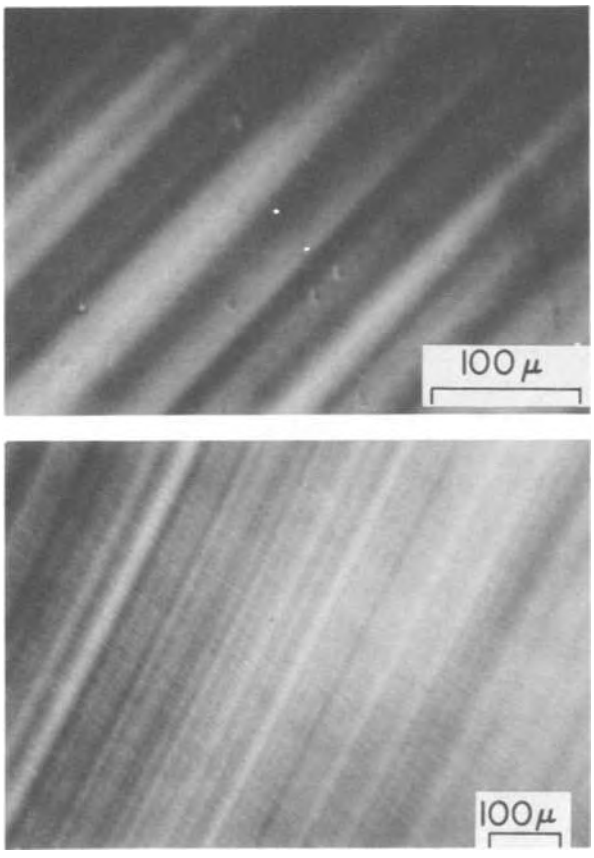

Fig. 4. Striations normal to the growth axis of $Gd_3Ga_5O_{12}$

table are the melt compositions from which the crystals were grown and the initial composition of the powder samples which did not show a significant weight change after annealing. The flux grown crystal was obtained from a melt containing PbO and excess Ga_2O_3 by cooling below 1250°C. The flux crystal and the 1400°C sintered samples had the smallest lattice parameters. The largest lattice parameters were obtained from the 1650°C sintered samples of GGG with excess Gd_2O_3 and the crystal pulled from a melt of 2 w/o excess Gd_2O_3. The lattice parameter of the pulled crystals was more strongly influenced by excess Gd_2O_3 than excess Ga_2O_3.

No significant difference in lattice parameter was observed between the initial and final section of a pulled crystal that was grown from a stoichiometric melt in a 24 hr period. A sizable loss of Ga_2O_3 by evaporation would have resulted in an increase in lattice parameter during growth. The wider range of lattice parameters obtained with the sintered compositions at 1650°C was not observed in the pulled crystals and the 1400°C annealed compositions. This suggests that the range of solid solubility is smaller near the melting point (1750°C) and at 1400°C; therefore retrograde solubility may occur. Also, an order-disorder effect may influence the lattice parameter since the pycnometric densities of the two stoichiometric Czochralski pulled crystals that were measured (7.100 and 7.068 g/cm^3) were lower than the density calculated (7.113 g/cm^3) from x-data for a stoichiometric crystal with a lattice constant of $a_o = 12.385$Å. Geller (13) has reported other cases of rare earth oxide solubility in gallium and aluminum garnets.

Summary

Single crystals of GGG with less than 5 defects/cm^2 from iridium inclusions and dislocations were obtained with a TV system of computer controlled Czochralski crystal growth. A pure nitrogen atmosphere in the crystal puller was successful in reducing iridium inclusions in the pulled crystals. Coring was prevented by a high crystal rotation rate and a slow pull rate during growth; striations in the crystal were observed at such high rotation rates. Dislocations were avoided by good crystal diameter control during growth. An etching procedure was developed to reveal dislocations. The lattice parameter of GGG did not vary during the 26 hr period required for growth. Excess Ga_2O_3 in the melt caused only a slight decrease in lattice parameter while excess Gd_2O_3 raised the lattice parameter significantly.

Composition of Phosphosilicate Glass by Infrared Absorption

A. S. Tenney*,[1] and M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The ratio of the intensity of the P=O absorbance band at ~1325 cm^{-1} to that of the Si-O band at ~1050 cm^{-1} has been correlated with the composition of vapor-deposited phosphosilicate glasses over the range 0-20 mol per cent P_2O_5. While the ratio of the linear absorbances of these bands depends somewhat on deposition temperature as well as on film composition, the ratio of the areas of these bands is uniquely related to film composition over the range of deposition temperature studied. The deposition rates and compositions of these films (for a constant flow of reactant gases) were found to be relatively weakly dependent on deposition temperature. These results for phosphosilicate glass combined with previously published calibration curves for borosilicate and arsenosilicate glasses allow the rapid, nondestructive determination of the compositions of all three doped glasses commonly used as sources for impurity diffusion into silicon.

Properties of phosphosilicate glass (PSG) make it useful in a variety of applications in semiconductor technology. It serves as a source for the diffusion of phosphorus into silicon (1), as a general "getter" of sodium and other metal ions (2, 3), and, more specifically, as a diffusion mask allowing the selective diffusion of zinc into III-V compounds (4-7).

Since the properties of PSG which make it useful in a given application may depend on the PSG composition, it is important to be able to control and determine this composition. Composition control is frequently achieved by controlling temperature and reactant gas composition during the chemical vapor deposition of the PSG film (8). In many applications, the chemical composition need not be known as long as the dependence of the property of interest on the deposition conditions (reactant flows, temperature, etc.) is known. However, it has been shown that films of dissimilar composition may be deposited in different deposition systems under nominally identical deposition conditions (9). Thus, results determined for one deposition system are not unequivocally transferable to other systems. It is usually more convenient, therefore, to know the film composition and in quality control applications a rapid, nondestructive determination is often desirable. Finally, a detailed understanding of the processes involving these films requires knowledge of the film composition.

Composition determinations based on the IR spectra of vapor-deposited borosilicate (9-11) and arsenosilicate (12) glasses have proven useful. The IR reflectance spectra of silicate glasses have been employed as a qualitative test for the presence of phosphorus oxide (13).

The P=O absorbance value at 1330 cm^{-1} has been employed to determine the composition of layers of PSG formed by passing P_2O_5 vapors over thermally oxidized silicon wafers (25). This method requires an accurate knowledge of the PSG thickness and also that the integrated absorptivity (absorption per atom of phosphorus) be independent of PSG composition.

The etch rates of phosphosilicate glasses in selective etchants have proved to be a useful means of determining PSG compositions particularly in light of the fact that little instrumentation is required (3, 21-24, 28). However, this method is destructive and is complicated by the fact that the etch rate of a glass generally depends on its "history" as well as on its composition.

In the present work, the ratio of the absorbance of the P=O band at 1325 cm^{-1} to that of the Si-O band at 1050 cm^{-1} was determined for vapor-deposited phosphosilicate glasses as a function of composition over the range 0-20 m/o (mole per cent) P_2O_5. This method is nondestructive. The employment of absorbance ratios obviate the need to know the film thickness. Since the relationship between absorbance ratio and composition is empirical, the integrated absorptivity need not be independent of PSG composition.

Experimental

Glasses were deposited by passing Ar-diluted mixtures of SiH_4, PH_3, and O_2 over 10 ohm-cm p-type chemically polished <100> silicon wafers heated to 300°-700°C in a previously described vertical deposition system (14). For instance, with flow rates of 3800 cm^3 min^{-1} Ar, 40 cm^3 min^{-1} O_2 ,150 cm^3 min^{-1} SiH_4 (1% in Ar), and 13 cm^3 min^{-1} PH_3 (1% in Ar), a 1.0μ thick film 4.9 m/o in P_2O_5 was deposited in 35 min at 400°C. Although similar films may be deposited by the oxidation of SiH_4 and $POCl_3$, these become damaged on heating to the temperatures usually employed to achieve phosphorus diffusion in silicon and, therefore, were not included in this work (15).

The vibrational spectra of these films were determined over the range 4000 to 250 cm^{-1} employing a Perkin-Elmer Model 457 double-beam recording spectrophotometer with scan rates of 1000 and 500 cm^{-1} per min over the ranges 4000-2000 and 2000-250 cm^{-1}, respectively. A silicon wafer of the same resistivity and type as those of the substrate was placed in the reference beam.

Film thicknesses were determined within an uncertainty of ±100-200Å from the interface colors employing the color chart of Pliskin and Conrad (16) after determining ellipsometrically that the refractive index of these films was 1.45 ± 0.03. Deposition rates were determined by recording film color *vs.* time during the deposition. A graphical arrangement of Pliskin and Conrad's color chart facilitates the recording of these data and the calculation of the deposition rate (17).

The compositions of these films were determined by microprobe analyses for silicon and phosphorus using high-purity, undoped samples of silicon and gallium phosphide, respectively, for reference. The PSG films were generally about 1μ thick and the electron beam was kept low enough in energy (~6 keV) to assume no penetration to the Si substrate (26, 27). From the phosphorus to silicon atomic ratio, the phosphosilicate glass composition was calculated assuming that phosphorus is present in these films as P_2O_5 and silicon as

SiO_2. The uncertainty in the values of mol per cent P_2O_5 thus determined is estimated to be less than 1 m/o.

Results and Discussion

The phosphosilicate glass composition may be related to the ratio of the absorbance of the P-O band at about 1325 cm^{-1} to that of the Si-O band at about 1050 cm^{-1}. However, these bands are not so well resolved as those of the borosilicate (8, 9) and arsenosilicate (12) binary mixtures. The absorbance of the Si-O band is significant at 1325 cm^{-1}. A calibration curve based on the ratio of the total absorbance at 1325 cm^{-1} to that at 1050-1100 cm^{-1} [2] would indicate a value of about 0.045 for this ratio for pure SiO_2. Much more important is the fact that the uncertainty in absorbance introduced in drawing the base line (see Fig. 1), while negligible in the calculation of Si-O absorbance, is significant in the P=O absorbance calculation for glasses low in phosphorus concentration.

It has been found more reproducible to calculate the linear absorbance ratios as follows. The base line for the Si-O band is drawn as shown in Fig. 1. The Si-O absorbance in the 1325 cm^{-1} region is largely corrected for by drawing the P=O base line as the straight line tangent to the absorbance curve at points on either side of the P=O absorbance at 1325 cm^{-1}. The absorbances of the two bands are taken to be the maximum differences in absorbance units between their respective base lines and the absorbance curve (A-B and A'-B' for the P=O and Si-O bands, respectively, in Fig. 1). For the P=O band this is not necessarily at the frequency of maximum total absorbance. The linear absorbance ratio for the glass whose spectrum is shown in Fig. 1 is thus

$$R = (\text{A-B})/\text{A'-B'})$$

This ratio is shown in Fig. 2 as a function of glass composition for several deposition temperatures. The curve is drawn to represent results for glasses deposited at 400°C only. There appears to be a small but systematic dependence of the linear absorbance ratio on temperature. Glasses of similar compositions exhibit increasing linear absorbance ratios with increases in deposition temperature. A similar (although opposite) temperature dependence was observed for borosilicate glasses; but it was further established that the ratio of band areas (approximated by the product of the linear absorbance times the half-width) was uniquely related to the glass composition (9).

A similar approximation for the P=O band area is complicated by the fact that the base line for this band

[2] The frequency of maximum absorbance of the Si-O band varies somewhat with composition (20).

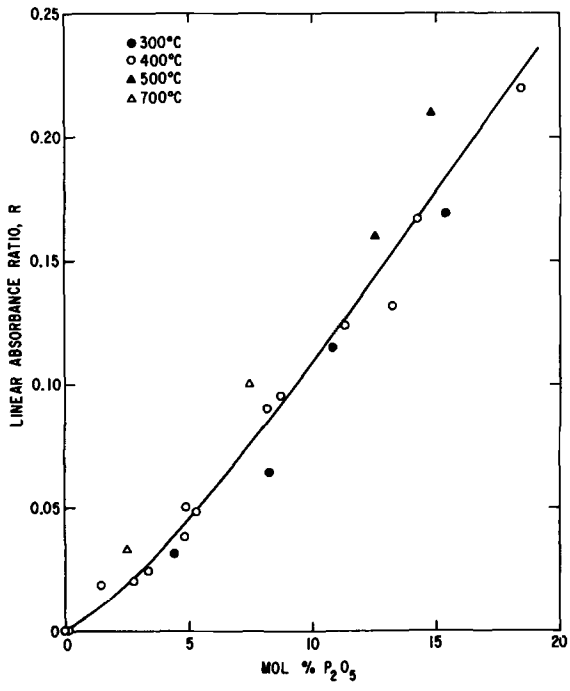

Fig. 2. Linear absorbance ratio vs. mole per cent P_2O_5 for phosphosilicate glasses vapor-deposited at temperatures ranging from 300° to 700°C.

is generally far from horizontal. However, the half-width of this band may be constructed by drawing the line parallel to the base line through the point half way (in absorbance units) between the base line and the point on the absorbance curve farthest from the base line. The line C-D in Fig. 1 represents this construction. The projection of C-D on the horizontal axis, (C-D)p, is taken to be the half-width of the P=O band in cm^{-1}. The half-width of the Si-O band is taken to be the width of the band (in cm^{-1}) at half the maximum absorbance (C'-D' in Fig. 1).

Thus the band area ratio for the glass whose spectrum is shown in Fig. 1 is[3]

$$R^* = \frac{(\text{A-B}) \times (\text{C-D})\text{p cm}^{-1}}{(\text{A'-B'}) \times (\text{C'-D'}) \text{ cm}^{-1}}$$

The composition dependence of the band area ratio is shown in Fig. 3. Employing this calibration curve, the compositions of phosphosilicate glasses 0-20 m/o in P_2O_5 vapor deposited at temperatures ranging from 300° to 700°C may be determined from the IR spectra of these glasses. The scatter of 1-2 m/o observed in these results is too large to be attributed to the uncertainty of the microprobe analysis. It is due primarily to the fact that, for all concentrations studied, the P=O band is relatively weak and its area is difficult to calculate with less than about 10% uncertainty.

Employing the band area ratio in lieu of the linear absorbance ratio may appear to reduce the temperature dependence in the resulting calibration curves much less dramatically than in the borosilicate glass case (9). [Thus, PSG compositions may be determined from the more simply calculated linear absorbance ratio (Fig. 2) with little loss of precision.] It must be pointed out, however, that the highest P_2O_5 compositions included are about 20 m/o. The dependence of the linear

[3] It would be more nearly correct to construct C'-D' parallel to the base line as C-D is constructed. The Si-O base line is so nearly horizontal, however, that the correction introduced is negligible. Even more nearly correct would it be to draw C-D and C'-D' parallel to their respective base lines not geometrically but logarithmically. Finally, for a true representation of the integrated intensity, of these bands, the spectra should be recorded in linear absorbance units and the area ratios determined with a planimeter. However, all of these refinements have an effect on the relationship between the area ratio as calculated above and the chemical composition which is insignificant when compared to the uncertainties introduced in determining the absorbance and half-width of the P=O band.

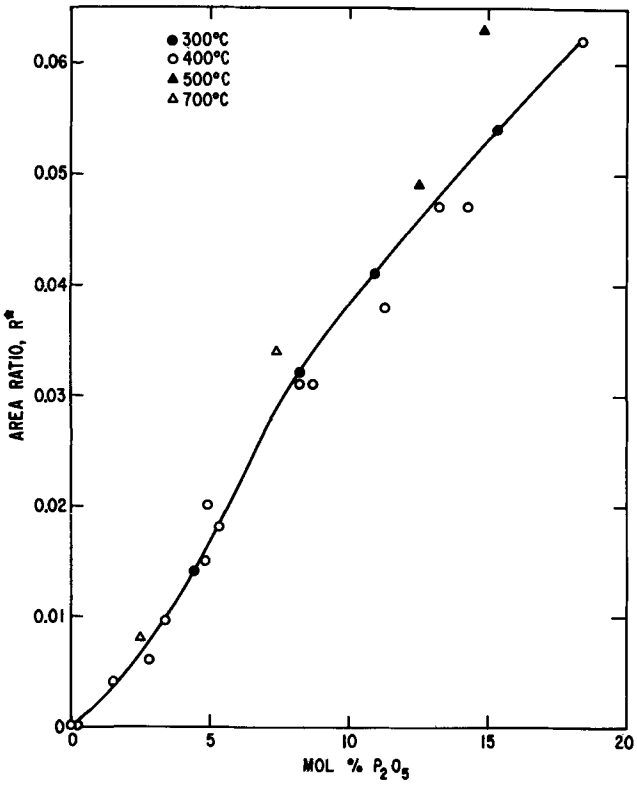

Fig. 3. Band area ratio vs. mole per cent P_2O_5 for phosphosilicate glasses vapor-deposited at temperature ranging from 300° to 700°C.

absorption ratio on temperature was not detected in borosilicate glasses less than about 25 m/o in B_2O_3.

Extension of the calibration curves shown in Fig. 2 and 3 to glasses of more than 20 m/o P_2O_5 is made difficult by the fact that at about this composition the 1325 cm^{-1} band begins to broaden and decrease in intensity with increases in P_2O_5 concentration while new bands begin to appear at frequencies closer to that of the 1050 cm^{-1} Si-O band. These trends are seen in Fig. 4 where the spectra of four glasses of different composition are shown. Except for the absence of significant absorption at ~3000 cm^{-1} (18), the spectrum of the glass 15 m/o in P_2O_5 is in good agreement with previously published results for similarly deposited glasses (18, 20, 22).

The dependence of deposition rate and of glass composition on deposition temperature is shown in Fig. 5 and 6, respectively, for three different reactant gas compositions. N_{PH_3} is defined to be the PH_3 flow rate divided by the total hydride flow rate. Except for the results at 300°C for the hydride mixture where $N_{PH_3} = 0.31$, neither the deposition rate nor the composition of the film appears to be a strong function of deposition temperature. Similar results were found by Kern and Heim who concluded that the deposition rate and composition of phosphosilicate films are less dependent on deposition conditions than are those of borosilicate films (19).

The rate of deposition from hydride mixtures dilute in PH_3 ($N_{PH_3} < 0.15$) increases monotonically with increases in temperature while increasingly prominent maxima are observed in the temperature dependence of the deposition rate with increases in PH_3 concentration over the range $0.2 < N_{PH_3} < 0.3$ (see Fig. 5). (The absolute values of the deposition rates for the different gas mixtures shown in Fig. 5 are not directly comparable because different total hydride flow rates were employed for each gas mixture. The apparent equality of these values at 500°C is coincidental.)

The P_2O_5 concentration in glasses deposited from a given reactant composition decreases monotonically with increases in deposition temperature as shown in Fig. 6.

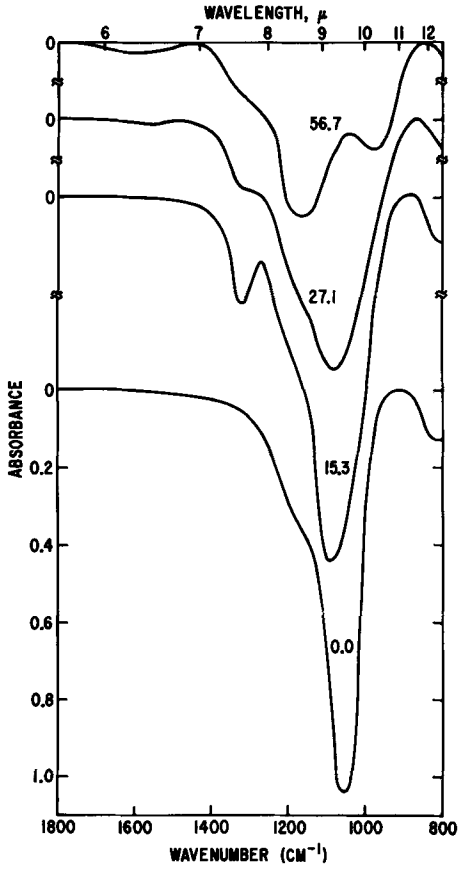

Fig. 4. Vibrational spectra of vapor-deposited phosphosilicate glasses 0, 15.3, 27.1, and 56.7 m/o in P_2O_5.

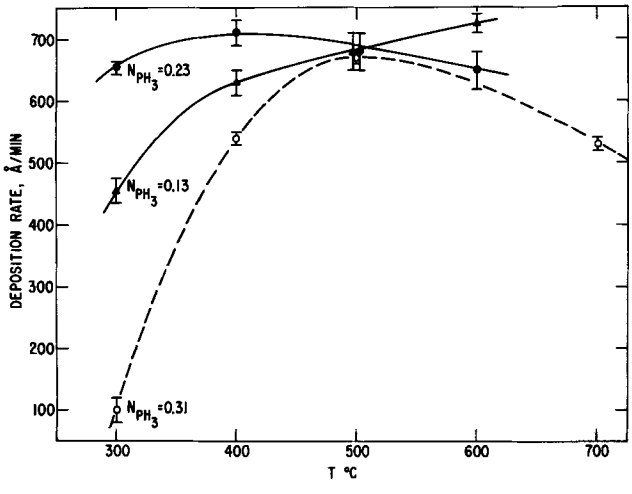

Fig. 5. Temperature dependence of the rate of deposition of phosphosilicate glasses from the indicated hydride mixtures.

If it is assumed that these films are the stoichiometric products of the reaction of SiH_4 and PH_3 with excess O_2, the composition of the film may be calculated from that of the hydride mixture by the relation

Table I. Mole per cent P_2O_5 observed at high deposition temperatures and calculated by Eq. [1]

N_{PH_3}	Mole per cent P_2O_5	
	Calculated	Observed (Fig. 6) (600°-700°C)
0.13	7.0	7 ± 1
0.23	11.5	11 ± 1
0.31	18.4	14 ± 1

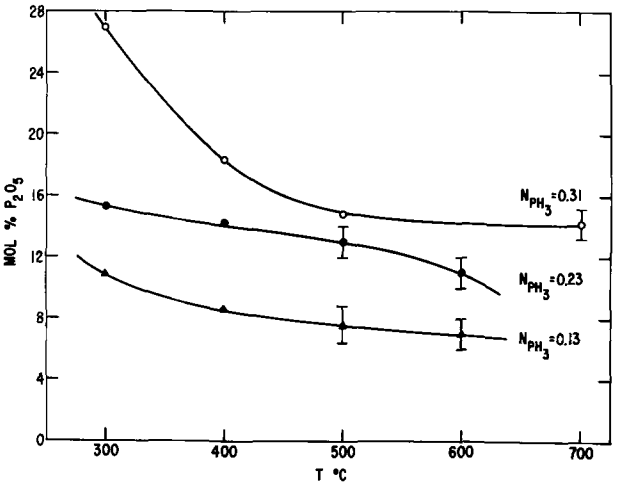

Fig. 6. Temperature dependence of the composition of phosphosilicate glasses deposited from the indicated hydride mixtures.

$$\text{mol per cent } P_2O_5 = 100N_{PH_3}/(2 - N_{PH_3}) \quad [1]$$

A comparison of the PSG compositions thus calculated with those observed at high deposition temperatures is made in Table I.

While the P_2O_5 concentration calculated assuming stoichiometry is about 4 m/o higher than that observed for glasses deposited at high temperatures from a hydride mixture of $N_{PH_3} = 0.31$, the calculated and observed compositions are in good agreement for glasses deposited (at high temperatures) from glass mixtures lower in PH_3 concentration. It has been reported that glasses up to 5 m/o in P_2O_5 ($N_{PH_3} \sim 0.095$) are the stoichiometric products of the oxidation of SiH_4 and PH_3 at 400°C while further increases in N_{PH_3} are not accompanied by proportionate increases in P_2O_5 concentration (19). The present results suggest that increases in deposition temperature cause increases in the values of N_{PH_3}, for which the reaction proceeds stoichiometrically to about 0.23 at 600°-700°C. For higher values of N_{PH_3} the reaction product is still less than stoichiometric in P_2O_5.

Acknowledgments

We thank M. F. Ciccarelli for performing the microprobe analyses of the phosphosilicate glasses and R. B. Bolon and E. Lifshin, as well as Mr. Ciccarelli, for many useful discussions concerning the analytical aspects of this work.

The Composition of Oxides Formed on Electroless Ni-P Deposits

S. T. Pai and J. P. Marton

Welwyn Canada Limited, London, Ontario, Canada

The initial state of electroless Ni-P deposits varies with the composition of the chemical solution employed and with the deposition conditions (1, 2). The initial state of Ni-P deposits prepared from nickel sulfate solution and deposited at 25°C is known to be a single phase, fine polycrystalline material of Ni and P, in which the P atoms are dissolved in the Ni lattice, forming a solid solution (3). Upon heating the deposit in an oxygen environment up to 400°C, an oxide layer will form. Some previous work (4-6) has been done on the electrical, optical, and other properties of the Ni-P oxide layer. However, little is known about the exact composition. Knowledge of the composition is important for a better understanding of the optical and electrical properties. The present investigation is an attempt to find the nature of the oxides formed on Ni-P deposits by reflection electron diffraction.

In this work we used two types of Ni-P deposits. One type was made at the over-all composition of 16 atomic per cent (a/o) of P and the other at 30 a/o. They were prepared from acid solution of nickel sulfate and hypophosphate at pH = 5.3 and 3.3, respectively. The substrates used were activated borosilicate glass. The details of deposition process were reported elsewhere (7). Heat-treatment of these samples was carried out in vacuum, inert gases (Ar and He), oxygen, and open air environments. Reflection electron diffraction results revealed that all samples heated in vacuum or inert gases have either Ni or Ni + Ni_3P structures only (8), whereas samples heated in oxygen or open air showed NiO structure with a few additional weak rings appearing in the diffraction pattern. The results were obtained by employing an AEI EM6G electron microscope and are shown in Fig. 1. The diffraction patterns were taken at 100 kV.

In Figure 2 are microdensitometer traces of the diffraction patterns. Curve (a) is the diffraction pattern obtained from a sample containing about 30 a/o P,

Key words: oxides, electroless Ni-P deposits.

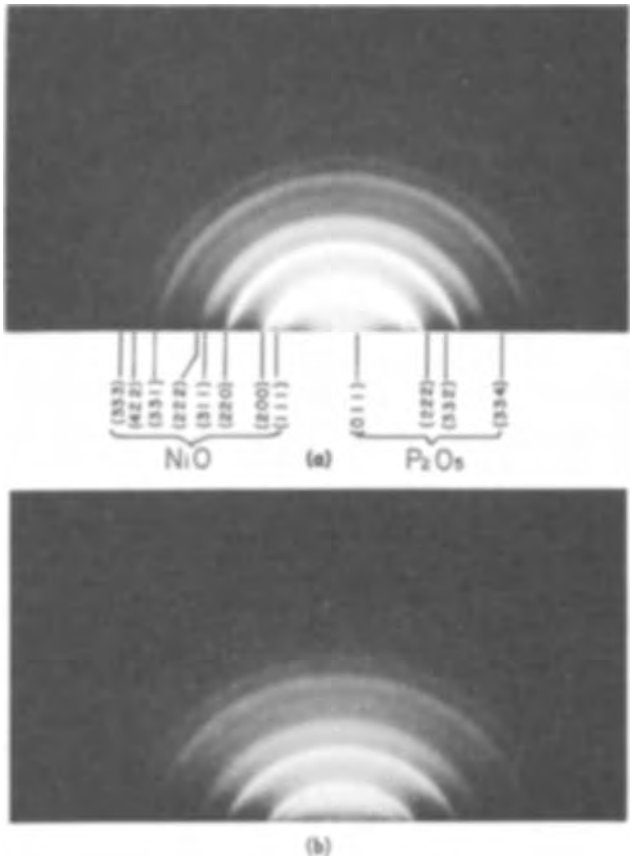

Fig. 1. Reflection electron diffraction patterns of Ni-P oxides taken at 100 kV for two phosphorous concentrations. (a) P content, 30 a/o (b) P content, 16 a/o.

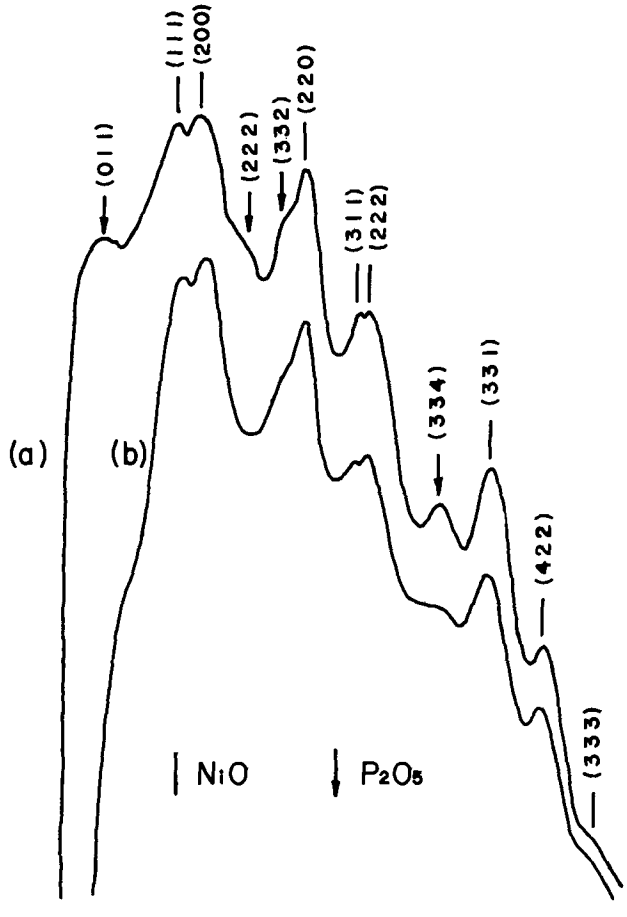

Fig. 2. Microdensitometer traces of plates in Fig. 1(a) and (b). The structure corresponds to NiO and to P_2O_5. The peaks for P_2O_5 at higher P concentration in (a) are easily discernible. At lower P concentration in (b) the peaks are weaker.

and curve (b) is that from a sample containing about 16 a/o P. From the figure, we can see that as the P content increases, so do the intensities of the additional rings. Their positions are marked by vertical arrows. The pattern indicates that the additional rings have a direct connection with the P content in the deposits. Upon close examination of the diffraction patterns, the rings were identified to be due to orthorhombic P_2O_5 crystallites within a 1% experimental error using lattice constants (9) $a = 9.23$Å $b = 7.18$Å, and $c = 4.94$Å.

The present finding suggests that the surface oxides of Ni-P deposits contain both NiO and P_2O_5 and that the P_2O_5 crystallites are dispersed in the NiO matrix, forming a crystalline mixture. As pointed out before, the optical constants and the electrical properties are related to the composition of the material under study, so the present findings may furnish some useful information for investigations of the optical and other properties of oxidized Ni-P surfaces.

Localized Plastic Deformation of GaP and GaAs Generated by Thermocompression Bonding

W. A. Brantley and D. A. Harrison[1]

Bell Laboratories, Murray Hill, New Jersey 07974

Thermocompression (TC) bonding is employed in the assembly of a variety of devices fabricated from the compound semiconductors GaAs, GaAlAs, and GaP, such as IMPATT's, lasers, and LED's. In this technique the semiconductor chip is heated to temperatures around 300°-400°C, and pressure is applied for bonding to heat sinks or contact wires. Recent evidence (1) indicates that dislocations may be generated in <111> oriented GaAs at 380°C by TC bonding at loads exceeding ~7.5 kg/mm².[2] Although the detailed experimental investigations have not been performed to date on compound semiconductor devices, dislocations may affect device characteristics and long-term reliability directly or, perhaps more likely, indirectly by serving as rapid "pipe" diffusion regions for impurities or as sites for enhanced dopant diffusion and precipitation (2). Accordingly, it is important in general to determine the conditions of stress and temperature for which dislocations may be generated in compound semiconductors during device processing.

This paper presents the results of low temperature stressing experiments performed on GaP and GaAs specimens having typical device dimensions of the order of 10 mils. The TC bonding station was employed solely as a mechanical loading apparatus to achieve combined stresses and temperatures which might be encountered during device processing. Subsequently, the stressed specimens and unstressed controls were immersed in various etchants which have previously been demonstrated to reveal dislocations. The results for both GaAs and GaP demonstrate that nonuniform loading conditions often prevail during TC bonding and that localized plastic deformation, *i.e.*, the introduction of dislocations, is possible at temperatures as low as 200°C. Moreover, the extent of deformation is strongly dependent on the hardness of the medium in contact with the semiconductor.

A variety of compound semiconductor device materials was employed for the stressing experiments: (*i*) GaP p-n junction material for green light-emitting diodes (LED's) consisting of n- and p-type liquid-phase epitaxial (LPE) layers, each approximately 1 mil thick, grown on an n-type liquid encapsulated Czochralski (LEC) GaP substrate (3); (*ii*) a GaP slice consisting of only the n-type LPE layer on an n-type LEC substrate; (*iii*) S-doped bulk GaAs grown by the LEC technique (4); and (*iv*) a GaAs slice with an n-type layer about 8 μm thick grown by vapor-phase epitaxy (VPE) on an n^+ substrate (5), similar to slices presently being fabricated into IMPATT's. Slice (*iv*) was grown in the <100> orientation whereas the remaining material was <111> oriented.

The GaP specimens were in the form of dice approximately 15 mils square and 10 mils in height, prepared by lapping and chemically polishing the starting slice followed by slurry cutting. The GaAs specimens were in the form of mesas having approximately 8 mils top diameter and 6 mils height, prepared by lapping and chemically polishing one side of the starting slice followed by Au ball masking and sandblasting for the other side. Individual specimens were placed on a Au-plated Cu stud and stressed by the TC bonding station at 300° or 400°C using a sapphire ram and loads of 30, 100, or 300g with several specimens per condition. The stressing temperatures were measured with a thermocouple placed in contact with the top of the stud, and these temperatures were in good agreement (temperature difference <20°C) with values obtained with the aid of temperature-indicating markers painted on top of the studs.

Gershenzon and Mikulyak have reported that bulk plastic deformation of GaP does not occur below 900°C (6) although experimental evidence for dislocation generation in GaP at 600°C has been obtained (7). Therefore, a 5 mil (hexagonal cross section) loading ram was initially utilized in order to increase the applied stress on the 15 mil square dice; the 5 mils correspond to the distance between opposite hexagonal faces. Etched p($\sim 1 \times 10^{18}$ Zn/cm³, $\sim 1 \times 10^{19}$ N/cm³) layers of the p/n/n GaP specimens are illustrated in Fig. 1 for (a) the unstressed condition and after stressing at 300°C by the TC bonding station with (b) 30, and (c) 300g

[2] 1 kg/mm² = 9.8 × 10^7 dyn/cm² = 1.42 × 10^3 psi.

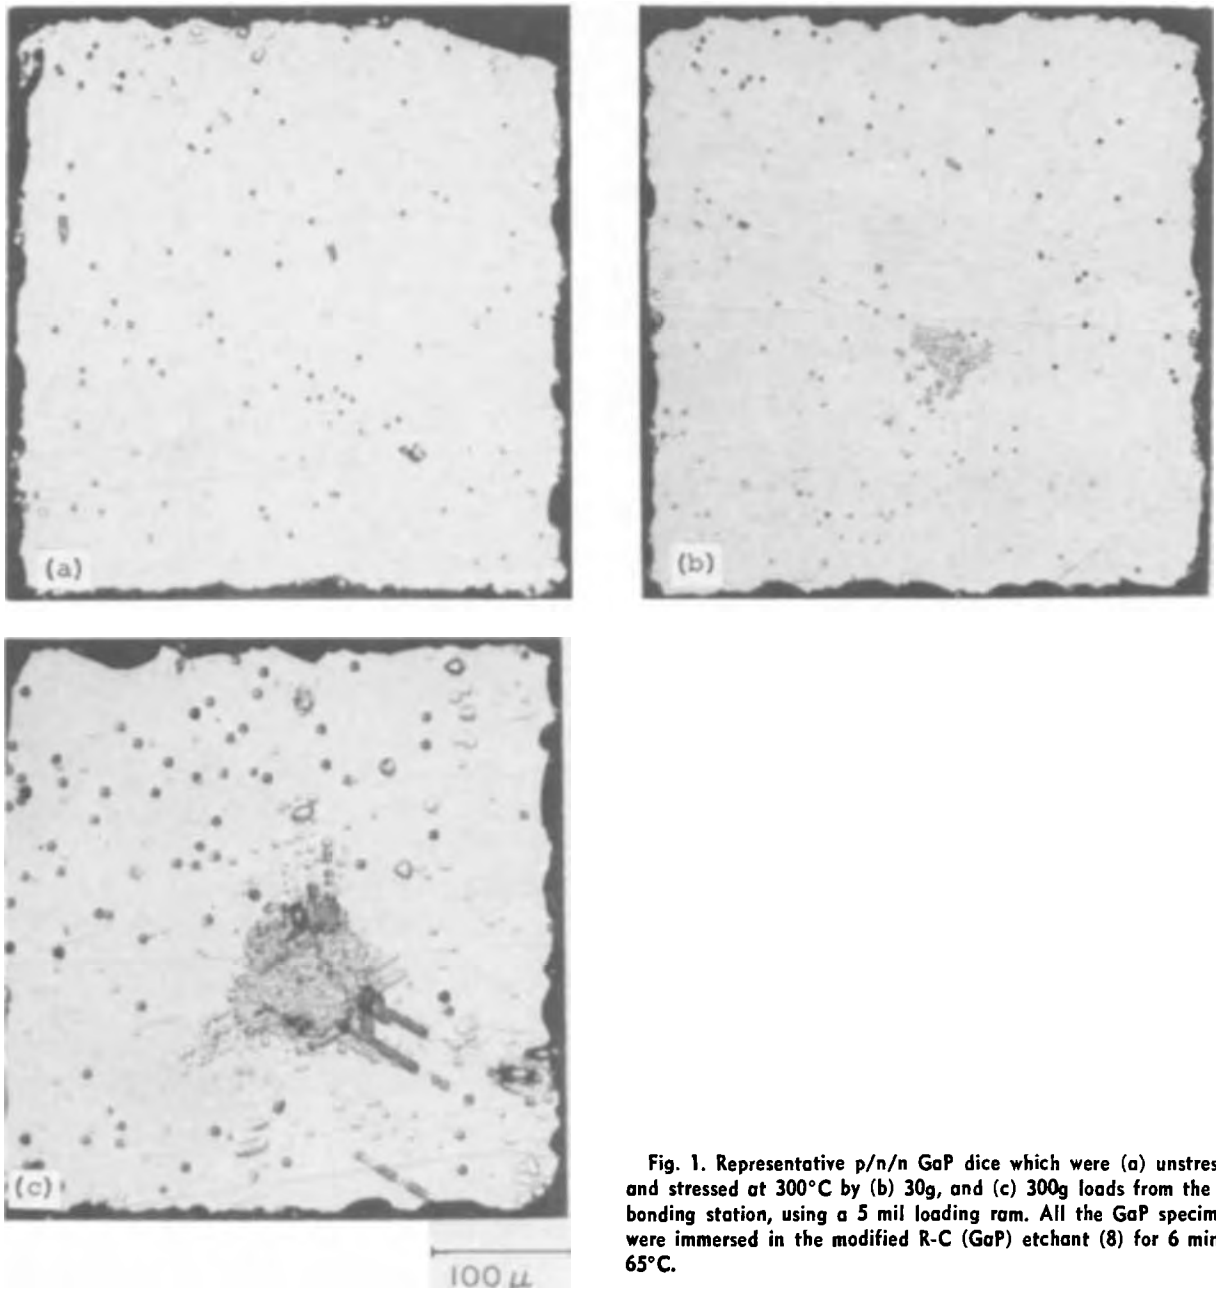

Fig. 1. Representative p/n/n GaP dice which were (a) unstressed and stressed at 300°C by (b) 30g, and (c) 300g loads from the TC bonding station, using a 5 mil loading ram. All the GaP specimens were immersed in the modified R-C (GaP) etchant (8) for 6 min at 65°C.

loads. All GaP specimens were immersed in the modified R-C etchant (8) for approximately 6 min at 65°C to reveal emergent dislocations.

The clusters of small etch pits in the center of Fig. 1 (b and c) are due to fresh dislocations generated by the mechanical stressing. This interpretation follows immediately from the increasing dislocation density with applied load, the similar appearances for the small pits and the larger sharp-bottomed pits corresponding to old, grown-in dislocations, and the existence of numerous small etch pits in rows lying along one of the three <110> directions corresponding to traces of oblique {111} slip planes. (The sides of the dislocation etch pits produced by the R-C etch lie along <110> directions.) The prominent etch grooves in Fig. 1(c) are not observed for unstressed specimens and may be traces of stacking faults (8) or twinned regions generated by the applied stress. However, diffraction contrast experiments would be required for precise identification of these defects. The dislocation density increases from 1 to 2 $\times$ 10^5 cm^{-2} for unstressed specimens to values exceeding 10^7 cm^{-2} in the regions of localized deformation. Thus, localized plastic deformation of GaP can occur at temperatures as low as 300°C. In all cases, the mechanical deformation behavior for the n-type LPE layers of the n LPE/n LEC GaP dice was similar to that for the p-type LPE layers of the p/n/n specimens subjected to the same stressing conditions.

The effect of stressing temperature on deformation behavior is evident from comparison of Fig. 1(c) and 2(a). These two p/n/n GaP specimens were stressed with 5 mil rams, the latter by a 100g load at 400°C and the former by a 300g load at 300°C. The extent of localized deformation is conspicuously greater at 400°C compared to 300°C, even though a smaller load was utilized at 400°C. Dislocations also were generated in the 15 mil square GaP dice at 400°C when a 20 mil ram was employed, for loads exceeding ~30g. An etched p/n/n specimen subsequent to stressing at 400°C with the larger ram and a 100g load is illustrated in Fig. 2(b). It is apparent that nonuniform loading near the specimen periphery occurred with the 20 mil ram. Dislocation generation in GaP was even observed at 200°C for a 600g load. A different stressing apparatus was utilized, having a weighted stainless steel piston larger than the die surface confined within a nearly tight-fitting sleeve (2). However, the similar appearance of the deformed area to Fig. 2(b) indicated that nonuniform loading occurred, with the local stress consider-

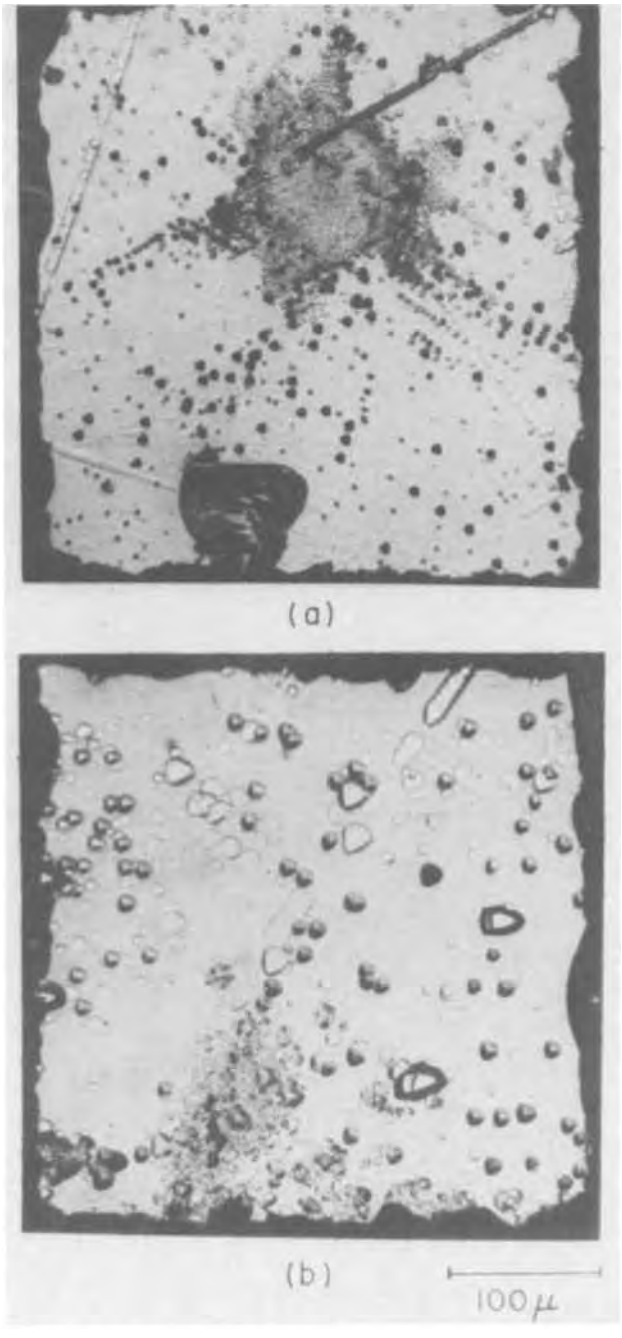

Fig. 2. Additional p/n/n GaP specimens which were stressed at 400°C by a 100g load: (a) 5 mil ram and (b) 20 mil ram. The prominent fracture in the lower portion of (a) occurred during the course of the chemical etching and the microscopic observation.

ably exceeding the nominal value of ~4 kg/mm² corresponding to the 600g load.

Additional experiments established that under appropriate conditions dislocation generation in the GaP specimen dice could be prevented for stressing in the 300°-400°C temperature range with the thermocompression bonding station. Localized plastic deformation was not observed in specimens gripped and loaded peripherally by a specially designed collet or in specimens centrally stressed with a Au loading tip. The absence of dislocation generation in these two cases is evidently due, respectively, to the applied stress being well distributed and to deformation of the softer Au loading tip in contact with the GaP specimens in comparison to the sapphire loading ram.

For GaAs mesas from the <111> oriented, bulk-grown ($n \sim 4 \times 10^{17}$ cm^{-3}) material the onset of macroscopic dislocation generation occurred for loads between 30 and 100g at 300°C and below 30g at 400°C. The loading ram utilized was larger than the top surface of the GaAs mesas, and the 30g load corresponds to a nominal compressive stress of ~1 kg/mm². Complementary results were obtained with the Schell (9, 10), modified (11) R-C (12), and A-B (13) etchants. For mesas fabricated from the {100} GaAs and having the VPE layer ($n \gtrsim 1 \times 10^{16}$ cm^{-3}) for the top surface, similar deformation behavior was found at 400°C, the only temperature investigated. Experiments with the weighted piston apparatus demonstrated that localized deformation in GaAs also is possible at 200°C, for ~300g loads on 14 mil square dice prepared by sawing (2). No evidence of dislocation generation was observed at room temperature for loads up to ~1000g on the 8 mil mesas, above which fracture generally occurred.

No mechanical deformation data are available for GaP to permit comparison with the present stressing experiments. The present investigations have demonstrated that under the proper loading conditions dislocation generation is possible in GaP at temperatures as low as 200°C, considerably below the values previously reported. The likelihood of localized deformation is greatly enhanced by utilization of a stressing medium (such as the sapphire ram) harder than GaP and by loading over an area smaller than the specimen which is expected to produce stress concentration effects (particularly at corners of the hexagonal ram). In addition, the greater lateral extent of the deformation bands in Fig. 1(c) and 2(a), compared to the 5 mil ram size, demonstrates that not only dislocation generation but also some dislocation mobility is possible for GaP in the 300°-400°C temperature range.

For GaAs, limited information concerning bulk deformation behavior is available. Previous studies (14-16) have indicated that the initial generation of large numbers of fresh dislocations in n-type, <111> oriented GaAs requires a compressive yield stress exceeding 20 kg/mm² at 400°C. Extrapolation of curves for the temperature dependence of the yield stress suggests that stresses over an order of magnitude greater (possibly ~400 kg/mm²) may be required at 300°C. (For GaP, dislocation generation and mobility are more difficult.) Moreover, dislocations in GaAs evidently possess considerable mobility in this temperature range since dislocation motion is possible at 300°C for stresses of the order of 1 kg/mm² (17).

However, nonuniform loading conditions can exist for TC stressing of specimens with dimensions of the order of 10 mils; *cf.*, Fig. 2(b). Under these circumstances, high local stresses which greatly exceed nominal computed values can arise and induce dislocation generation at temperatures considerably less than predicted from bulk deformation behavior. The very limited amount of plastic flow at room temperature previously reported (18) for GaAs deformed by indentation, where an extremely high stress is expected, appears to be an extreme example of this behavior.

Acknowledgment

The authors gratefully acknowledge the assistance of W. L. Boughton, C. Waters, and N. J. Engelmann with the TC bonding experiments. Helpful comments and encouragement from R. H. Saul and J. R. Patel are appreciated. The GaAs material for these experiments was grown by M. E. Weiner and L. C. Luther, and the GaP material was grown by O. G. Lorimor. The assistance of R. A. Furnanage in having the slurry cutting of the GaP specimens performed is also appreciated.

Manuscript submitted March 6, 1973; revised manuscript received April 26, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Colorimetric Determination of Boron in Aqueous Solutions and in Borosilicate Glass by Solvent Extraction

A. S. Tenney*,[1]

General Electric Corporate Research and Development, Schenectady, New York 12301

Boron has been determined in steel (1), in soils (2), and in natural waters (3) colorimetrically by extracting methylene blue fluoroborate with 1, 2 dichloroethane. Recently (4) a modification of this method was employed to determine boron in thin films of pyrolytically deposited borosilicate glass. The details and short discussion of the procedure are presented here.

Sample Preparation

(*i*) If necessary, the boron-containing sample is dissolved in a measured amount of H_2O and diluted to the range 1-4 μg B/ml.

(*ii*) To a 30 ml polyethylene dropping bottle (A. H. Thomas, No. 2247-S) 2.0 ml of the solution made in step (*i*), 2.0 ml dilute HF (DHF: 50 ml 50% HF/1 H_2O), and 3.0 ml 0.001M methylene blue solution (MBS: approximately 374 mg/liter) are added. The bottle is then shaken and allowed to stand at least 1 hr.

Standards are stored as aqueous solutions of H_3BO_3. Standard samples are prepared by mixing 2.0 ml standard solution, 2.0 ml DHF, and 3.0 ml MBS as in step (*ii*). Blanks consist of 2.0 ml DHF, 2.0 ml H_2O, and 3.0 ml MBS.

(*iii*) To samples, standard samples, and blanks, 10.0 ml 1,2 dichloroethane are added. The mixture is shaken and allowed to stand overnight (about 16 hr).

Absorbance Measurement

The bottles are inverted so that the organic phase may be squeezed into 1 cm cells. Absorbance is determined in the range 4000-7000Å with a double beam recording spectrophotometer (Perkin-Elmer Model 202) using a blank as reference and drawing a base line with a blank in both beams.

The spectra of the boron-containing samples appear to have three absorbance peaks relative to the base line: a minor one at about 4900Å and major ones at 6050-6300Å and at 6750Å as shown in Fig. 1 (the exact positions of the latter two peaks being more or less dependent on the boron concentration). Actually, the two major peaks result from the fact that the blank exhibits a relatively sharp band while the boron-containing samples display broader bands with maxima at about 6600Å.

Calibration curves of absorbance of these three peaks *vs.* boron concentration in micrograms per milliliters (in the original sample, not in the organic phase) are shown in Fig. 2. The standard deviation for determinations on standard samples was 0.01 absorbance indirating that boron may be determined in the range 0-5 μg/ml with an uncertainty of $\pm$0.05 to 0.1 μg/ml using results from the two major peaks. Since 2.0 ml of solution are used, the limit of detectability is about $\pm$0.1 μg boron.

The calibration curve of the minor peak absorbance at 4900Å may be extended to boron concentrations of at least 20 μg/ml. However, it was found easier and more precise to dilute the boron-containing samples to less than 5 μg B/ml and employ the major peak absorbances. Nevertheless, the minor peak may be employed to estimate the boron present should a sample contain enough boron that the major peak absorbances are too large to be determined.

The absorbance is quite sensitive to the HF concentration (1) so at least three standard samples were always analyzed with a batch of samples.

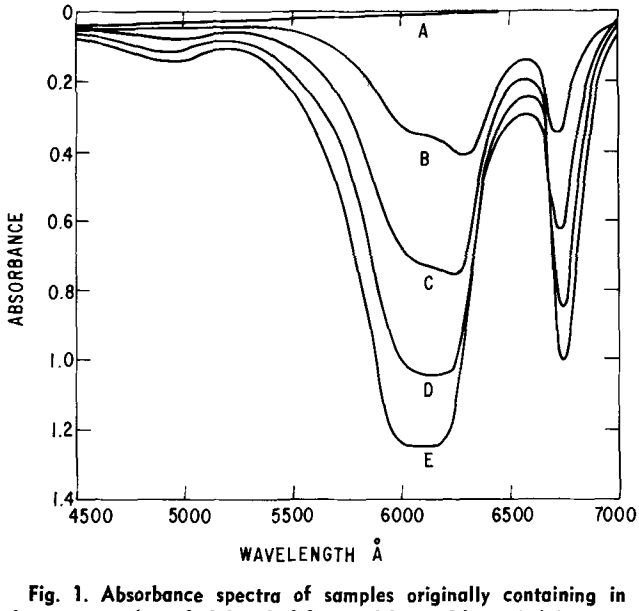

Fig. 1. Absorbance spectra of samples originally containing in the aqueous phase 0, 1.0, 2.0, 3.0, and 4.0 μg of boron/ml (spectra A through E, respectively) *vs.* wavelength.

Key words: boron analysis, methylene blue, doped oxides.

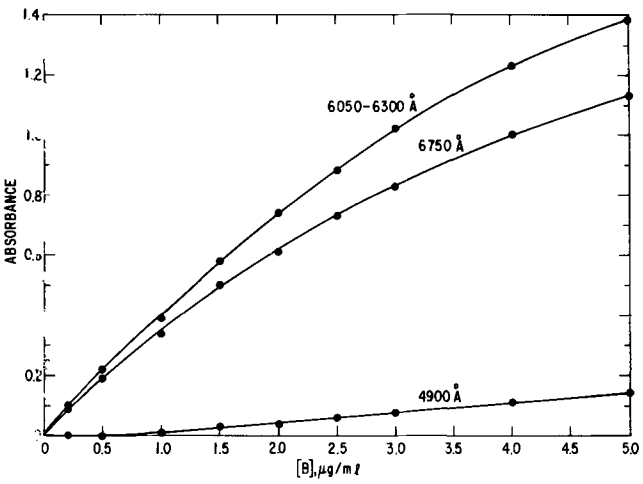

Fig. 2. Absorbance at 4900, 6050-6300, and 6750Å vs. concentration of boron in μg/ml of aqueous solution.

The procedure described here is simpler than those employed previously (1-3), firstly because of the use of a double beam recording spectrophotometer which automatically subtracts the significant absorbance of the bl nk, and secondly because no procedure is employed to eliminate interfering ions such as NO_3^-, As-V, and Cr-VI (2). Nevertheless, this procedure should be generally useful in the determination of microquantities of boron in aqueous solutions in the absence of these ions.

To determine boron in glass, only a slight modification of the above procedure is required. The sample is dissolved in a measured amount of DHF and diluted in DHF to 1-4 μg B/ml. Two milliliters of this dilution are mixed with 2.0 ml H_2O and 3.0 ml MBS and treated as described above. Because of the interference of arsenic (2), this procedure may not be used to determine boron in arsenic-containing glasses.

This procedure was combined with an atomic absorbance analysis for silicon to determine the composition of thin films of borosilicate glass pyrolytically deposited on silicon wafers (4).

Distribution of Sodium in Sputtered SiO_2 as Determined by Neutron Activation and U.V. Spectrographic Analyses

Satish Kumar*,[1] and L. V. Gregor*

IBM System Products Division, East Fishkill, Hopewell Junction, New York 12533

Neutron activation techniques have been applied to epitaxial silicon (1) to measure the impurity concentration in the outer layer of epitaxial films. Kern (2) investigated semiconductor surface contamination by radioactive tracer techniques. Lunde (3) applied nondestructive neutron activation analysis on single-crystal silicon for different impurities. Yon *et al.* (4) studied the sodium distribution in thermal SiO_2 on silicon by radiochemical and MOS analysis.

Contamination in sputtered SiO_2 films can cause an increase in MOS surface leakage current due to surface inversion. Sodium ion is one of the major contaminants that cause this problem. Neutron activation and u.v. spectrographic techniques have been rarely applied to sputtered SiO_2 films. The purpose of this work was to investigate the presence and distribution of sodium in sputtered SiO_2 and to determine the source of the sodium.

Experimental Methods

Wafer Preparation

Silicon wafers (2-ohm cm, p-type 2.25 in. diam) were thermally oxidized to a SiO_2 thickness of 500 ± 30Å. Oxidation was done in dry oxygen in an all-quartz system at 1000° ± 2°C for 50 min. The wafers were annealed to 1050°C for 15 min in N_2.

Key words: sodium, sputtering, SiO_2, MOS.

Sputtering Technique

Sputtered SiO_2 was deposited by rf sputtering of a commercial fused silica target at a frequency of 13.56 MHz. Gallium-indium alloy (75:25) was applied to the back of the wafers, taking care that no alloy touched the front side. SiO_2 deposition was accomplished by placing wafers in a parallel plate sputtering system so that they were electrically and thermally connected to the anode plate by Ga-In.

A turbomolecular pump was used to eliminate pump oil back-streaming. After 2 μm of SiO_2 was deposited, excess Ga-In was removed by Freon, and the remaining Ga-In was removed by dipping the wafers in hot H_2SO_4 + HNO_3 (1:1) for 5 min at 100°C. The wafers were then rinsed in deionized water and dried with N_2.

After 2.0 μm of sputtered SiO_2 was deposited over the wafers, they were annealed to decrease the oxide charge level created during sputtering.

Aluminum dots 0.060 in. diam were deposited by use of a metal mask, at ambient temperature, to a thickness of 1.0 ± 0.1 μm. The wafers were annealed again to decrease the surface state density.

CV Measurement

MOS capacitance/voltage characteristics were measured (2) with a Boontoon 1 MHz capacitance bridge after oxide was removed from the back of the wafer.

Neutron Activation Analysis

Dissolution technique.—The wafers to be analyzed by neutron activation analysis were cut into strips ¾ × 2

in. and packed along with the standard in an evacuated quartz capsule for activation. The neutron irradiation was carried out for 24 hr at a thermal flux of 3×10^{13} neutron/cm^2/sec.

After activation, the wafer samples were scrubbed in deionized water, dried, and stripped in 48% HF. The solution containing the dissolved oxide was then assayed for radioactive Na^{24}. The results of this analysis are shown in Runs 1 and 2 of Table I.

The high activity of Si^{31} was allowed to decay about one day (nine half lives) to avoid interference.

Nondestructive analysis.—Six wafers with 2 μm of sputtered SiO_2 were also analyzed by neutron activation analysis. They were accompanied by a set of untreated wafers to establish a sodium blank for the silicon.

Samples ½ × 1 in. were cut from each wafer containing sputtered SiO_2. The "flat" of each wafer served as reference, and samples were cut parallel to the flat. The control wafer samples were cut to slightly larger dimensions to serve as spacers in packaging the samples for neutron bombardment. Zirconium foil was used to encapsulate the samples.

The neutron flux for the irradiation was 1×10^{13} neutron/cm^2/sec. Exposure time was approximately 40 hr. Irradiated samples were initially surveyed for impurities by gamma ray spectroscopy, which permitted resolution of the 1.38 meV photopeak of Na^{24}. The integrated counts comprising this photopeak were compared for samples and comparator standards. The sodium in parts per million by weight is shown in Run 3, Table I.

Analysis of quartz target by neutron activation.—An 8.3g piece of sputtering target was subjected to analysis by using the instrumental neutron activation analysis (INAA) technique. The sample and Br, P, and Na standards were irradiated for 24 hr in a thermal neutron flux of 3×10^{13} neutron/cm^2/sec.

After irradiation, the sample was etched for 30 min in 48% HF, rinsed, and mounted for counting on the multichannel pulse height analysis system.

Gamma spectral analysis showed the presence of 16 peaks, which could be assigned to Br^{82} and Na^{24}, and β^- particles produced bremsstrahlung which was assigned to P^{32} by half-life measurement. The results of the analysis are shown in Table II. No other elements were observed, but some may have been present in the range masked by the sodium.

U.V. Spectrographic and Flame Photometric Analysis

Gallium-indium alloy.—A sample of the alloy was dissolved in concentrated nitric acid. After evaporation to dryness, the resulting nitrate was converted to oxide over a Meker burner. The sample was run in duplicate against a Ga_2O_3 standard, by using a 20A d-c arc in an oxygen-argon atmosphere (1:3).

For flame photometric analysis, a sample was weighed in a plastic beaker and dissolved with high-purity nitric acid. The sample was diluted and analyzed relative to solution standards for alkali elements, by using a flame photometric technique.

Stainless steel shield.—A sample of stainless steel used as the sputtering shield was dissolved in aqua regia and heated to dryness over a Meker burner to convert the sample into oxide. This oxide was run against Fe_2O_3 standards. A d-c arc in an oxygen-argon atmosphere (1:3) was used for excitation.

For flame photometry, the sample was etched, rinsed in deionized water, dried, and weighed on a microbalance. The sample was dissolved with aqua regia and diluted and then analyzed relative to solution standards by using a flame photometric technique for sodium and potassium.

Sulfuric and nitric acid.—A 50-ml amount of each acid was placed in platinum dishes and dried over a hot plate. Ten milligrams of graphite were added to each residue and compared against graphite standards. A d-c arc in a 1:3 oxygen-argon atmosphere was used for excitation.

Discussion

Neutron activation analysis was used to determine the amount of sodium present in sputtered SiO_2 films. Neutron activation analysis by the dissolution technique was used on the wafers of Runs 1 and 2, and neutron activation analysis by the nondestructive technique was used on Run 3.

The three sputtering runs were made under the same conditions. All the wafers, including controls, had gone through precleaning steps to remove any surface contamination. Generally, control wafers showed a sodium content of less than 1 ppm, except for Run 3 in which it was 6.8 ppm because of contamination. The sodium content on blank wafers is comparable to that obtained by Lunde (3) by neutron activation on single-crystal silicon slices. Run 1 had the highest amount of sodium in the wafers (32 ppm), and Run 2 had the lowest, probably because the sputtering system had been cleaned just before the run.

In Run 1, two wafers went through all the processing steps except for sputtering. The average amount of sodium was only 0.4 ppm, which indicates that sodium is picked up only during the sputtering process.

The nondestructive neutron activation technique was applied to Run 3. Three wafers of this run with the highest sodium content were selected and etched with dilute hydrofluoric acid (HF). Neutron activation analysis then showed that the average amount of Na in the three wafers was 5.5 ppm, as compared with 21 ppm originally. This significant reduction in Na can take place only if the Na is concentrated near the surface of the sputtered quartz film.

In order to find the source of sodium in the sputtered quartz films, the materials shown in Table III were analyzed by neutron activation and u.v. spectrographic analyses. The highest amount of sodium present (8 ppm) came from the stainless steel shield. This comparatively high amount of sodium could be resputtered into the SiO_2 thin film. The amount of sodium coming from other sources was relatively small.

Table I. Analysis of sputtered SiO_2 films by neutron activation technique

Run 1 Wafer number	Run 1 Na in weight (ppm)	Run 2 Wafer number	Run 2 Na in weight (ppm)	Run 3 Wafer number	Run 3 Na in weight (ppm)	After etch

Ga-In (75:25)	<1	U.V. spectrographic
Stainless steel shield	8	U.V. spectrographic
Sulfuric acid	0.01	U.V. spectrographic
Nitric acid	0.1	U.V. spectrographic

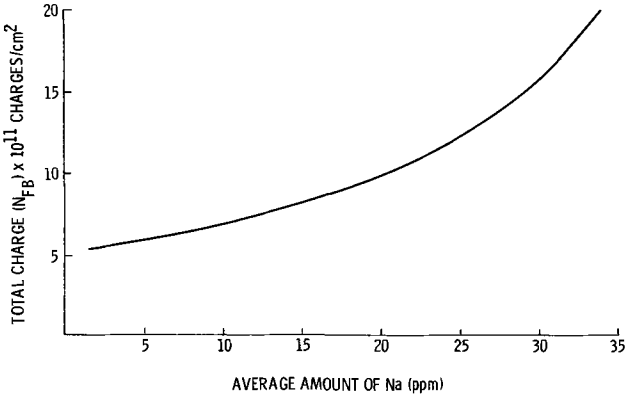

Fig. 1. Average amount of sodium *vs.* total charge

Figure 1 shows the correlation between Na in films *vs.* N_{FB} for 2.0 μm thick sputtered SiO_2 on oxidized monitor wafers. Table II shows the average amount of Na for each of the three sputtering runs and the corresponding N_{FB} charge.

Conclusions

1. Most of the sodium appears concentrated on the top surface of the sputtered SiO_2, because the amount of sodium decreases to a relatively small level upon etching. This finding was checked by neutron activation analysis.

2. The materials that commonly come in contact with sputtered SiO_2 were analyzed by uv spectrographic, flame photometry, and neutron activation techniques. The stainless steel shield contained the largest amount of sodium (8 ppm) of all the materials examined. This sodium could be incorporated into films as a result of resputtering.

Conduction Characteristics of the Lithium Iodide-Aluminum Oxide Solid Electrolytes

C. C. Liang*

P. R. Mallory and Company, Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

The conduction characteristics of the polycrystalline lithium iodide containing aluminum oxide were studied. It was found that the incorporation of aluminum oxide substantially increased the conductivity of lithium iodide. Lithium iodide containing 33-45 mole per cent (m/o) aluminum oxide exhibited conductivities in the order of 10^{-5} ohm^{-1} cm^{-1} at 25° ± 2°C. Inasmuch as no substantial amount of aluminum oxide was found soluble in the lithium iodide under the experimental conditions, the increase in conductivity could not be explained by the classical doping mechanism. The electronic conductivity of the lithium iodide-aluminum oxide solid was negligible compared to the ionic conductivity. Therefore, it is suitable as a solid electrolyte in solid-state battery systems.

The use of lithium iodide as a solid electrolyte material in the solid-state battery systems was reported previously (1-4). Lithium iodide is chemically compatible with such an active anode material as lithium and has extremely low electronic conductivity. Therefore, it is suitable as a solid electrolyte for high voltage cells. However, the relatively low ionic conductivity of lithium iodide (10^{-7} ohm^{-1} cm^{-1} at 25°C) limits the rate capability of the solid electrolyte cells. In an attempt to increase the ionic conductivity of lithium iodide Schlaikjer and Liang (5, 6) studied the conduction characteristics of lithium iodide doped with various calcium compounds. They found that the freshly quenched lithium iodide containing 1 mole per cent (m/o) of calcium iodide showed a conductivity of 10^{-5} ohm^{-1} cm^{-1} at room temperature. However, the conductivity would decrease with time and reach 10^{-6} ohm^{-1} cm^{-1} after about 500 hr. Further investigations on the polycrystalline lithium iodide revealed that the conductivity of the lithium iodide based solid electrolyte can be stabilized at 10^{-5} ohm^{-1} cm^{-1} at room temperature by the incorporation of aluminum oxide. The results of these investigations are discussed in this report.

Experimental

Material pretreatment.—Anhydrous lithium iodide was prepared from dehydrating Foote Mineral LiI · $3H_2O$ under vacuum. The dehydration process was similar to that reported previously (5). The hydrated lithium iodide was heated at about 120°C in a vacuum oven for about 48 hr. After the dehydration, the solid lithium iodide could be fused in a helium-filled Vacuum Atmosphere dry box (less than 15 ppm H_2O and O_2) without decomposition or discoloration. Analyses of the lithium iodide showed that the iodide content was as expected and no excess of alkali was found in the sample.

Fisher adsorption grade aluminum oxide and Alcoa F-1 activated aluminum oxide were dried in an oven at 600° ± 50°C for at least 24 hr. They were transferred to the helium-filled dry box and heated at 600° ± 50°C again for 4 hr. Both types of aluminum oxide were used in the preparation of the solid electrolytes.

Solid electrolyte preparation.—Powder mixtures of the anhydrous lithium iodide and the 600°C dried aluminum oxide in various mole ratios were blended, heated at 550°C for about 17 hr, quenched to ambient temperature, and pulverized. All processes were carried out in the helium-filled dry box. The H_2O and O_2 content in the dry box was maintained at less than 15 ppm.

Conductivity measurement.—The conductivity cell was made by the procedures described as follows. A weighed amount of lithium iodide-aluminum oxide powder was pressed into a pellet in a 0.6 in. diameter steel die under a pressure of 100,000 psi. The geometric area of the pellet was calculated from the diameter and the thickness of the pellet was measured with a micrometer while the pellet was still in the die. Lithium electrodes with steel current collectors were pressed on both sides of the pellet under 50,000 psi. The resistance of the conductivity cell was measured by means of a General Radio conductance bridge at 1000 Hz. It was also determined from the potential drop between the two lithium electrodes upon passing a direct current. The conductivity of the pellet was calculated from the measured resistance and the physical dimensions of the pellet.

Debye-Scherrer powder pattern.—Debye-Scherrer powder patterns of the anhydrous lithium iodide, the 600°C dried aluminum oxide, and the lithium iodide-aluminum oxide electrolyte were obtained at room temperature using the conventional techniques with CuKα radiation.

Cell fabrication and evaluation.—Li/LiI(Al_2O_3)/PbI_2, Pb; Li/LiI(Al_2O_3)/CuI,Cu; and Li/LiI(Al_2O_3)/AgI,Ag

* Electrochemical Society Active Member.

Key words: solid electrolyte, lithium iodide, ionic conductivity, solid electrolyte cells, solid-state batteries.

solid electrolyte cells were fabricated. The cathodes were well blended mixtures of the metal iodide [40 weight per cent (w/o)], the parent metal powder (30 w/o), and the electrolyte (30 w/o). The anodes were thin lithium metal disks and the current collectors were steel disks for the anodes, and lead, copper, or silver disks for the cathodes. The metal iodides and the metal powders were dried in a vacuum oven at about 100°C for about 16 hr. The solid electrolyte cells were fabricated by pressing the cathode, the electrolyte, and the anode in a 0.6 in. diameter steel die under a pressure of 100,000 psi.

The open-circuit voltages of the solid electrolyte cells were measured by means of a Tacussel Aries 10,000 digital voltmeter (internal impedance $> 10^{12}$ ohms). The voltages under constant current were measured by means of a Keithley 610B electrometer and recorded by a Varian 14A strip chart recorder.

Results

During the 550°C treatment of the lithium iodide and aluminum oxide mixture, a slurry was obtained. Presumably lithium iodide was melted whereas aluminum oxide remained solid.

The inclusion of aluminum oxide caused a substantial increase in the conductivity of the polycrystalline lithium iodide. Figure 1 shows the conductivity of the lithium iodide-aluminum oxide electrolyte as a function of the aluminum oxide content at 25° ± 2°C. It was noted that the maximum conductivity, about 10^{-5} ohm^{-1} cm^{-1}, occurred at 35-45 m/o aluminum oxide. Furthermore, the conductivity did not change with time. The lithium iodide-aluminum oxide powder which had been stored in a covered brown glass bottle in the dry box for 6 months exhibited the same pellet conductivity as the freshly prepared powder.

The apparent activation energy of the conduction process for the lithium iodide-aluminum oxide electrolytes in the temperature range of −40°-100°C was found to be 10 kcal/mole (Fig. 2). This is in good agreement with the value obtained for both single crystal (7) and polycrystalline (5) lithium iodide.

In order to determine the suitability of the lithium iodide containing aluminum oxide as a solid electrolyte material, the open-circuit voltages of the Li/LiI(Al_2O_3)/PbI_2,Pb; Li/LiI(Al_2O_3)/CuI,Cu; and Li/LiI(Al_2O_3)/AgI,Ag cells were measured at 25° ± 2°C by means of a high internal impedance (greater than 10^{12} ohms) digital voltmeter. The results of these measurements agreed extremely well with those calculated from the Gibbs free energies of formation (8, 9) as shown in Table I. Furthermore, not only no change in the open-circuit voltage was observed after 2 years storage on the Li/LiI(40 m/o Al_2O_3)/PbI_2,Pb cells, but the discharge characteristics of these cells were also found to be similar to those of the freshly fabricated cells (Fig. 3). It was noted further that a 100% discharge efficiency was obtained on the 5 mA-hr/cm^2 Li/Li(40 m/o Al_2O_3)/PbI_2,Pb cells under a current of 75 $\mu A/cm^2$ or less at room temperature (Fig. 4).

The x-ray diffraction patterns of the LiI(Al_2O_3) electrolytes and the anhydrous LiI and Al_2O_3 used for the preparation of the LiI(Al_2O_3) electrolytes are shown in Table II. Both LiI and Al_2O_3 lines were found in the LiI(Al_2O_3) patterns.

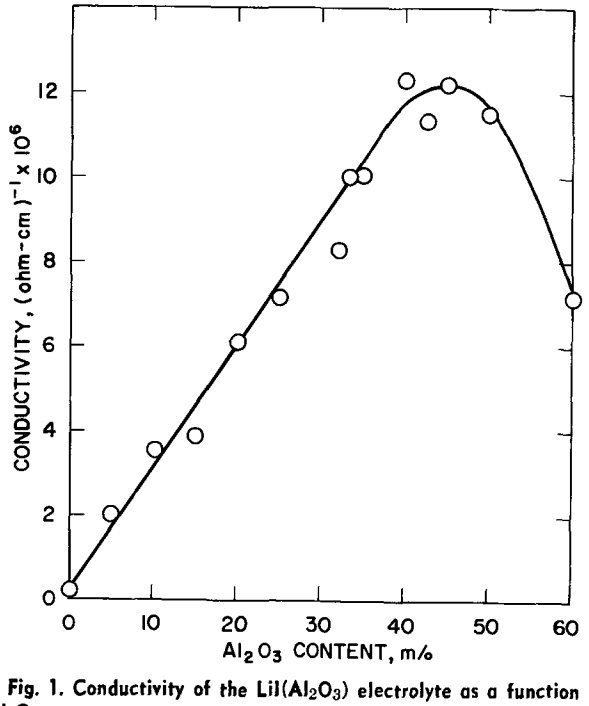

Fig. 1. Conductivity of the LiI(Al_2O_3) electrolyte as a function of Al_2O_3 content

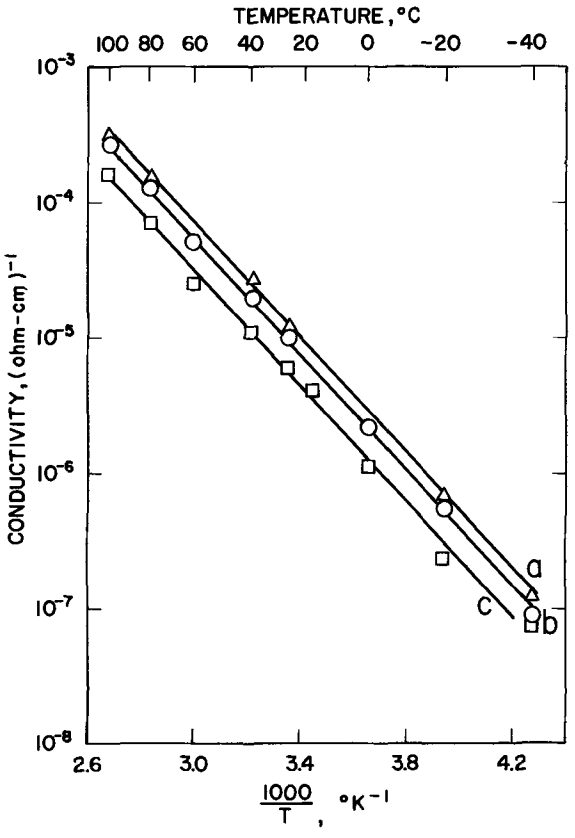

Fig. 2. The effect of temperature on the conductivity of the LiI(Al_2O_3) electrolyte (a) LiI(40 m/o Al_2O_3); (b) LiI(33 m/o Al_2O_3); and (c) LiI(20 m/o Al_2O_3).

Discussion

It is noted that the conductivity of the lithium iodide-aluminum oxide electrolyte can reach 10^{-5} ohm^{-1} cm^{-1} at room temperature at an aluminum oxide content ranging between 35 and 45 m/o. Furthermore, the conductivity remains constant even after a long storage period. In addition to these findings, the following conclusions can be reached from the experimental results.

1. The electronic conductivity of the lithium iodide-aluminum oxide is insignificant compared to its ionic conductivity.

The Li/LiI(Al_2O_3)/PbI_2,Pb; Li/LiI(Al_2O_3)/CuI,Cu; and Li/LiI(Al_2O_3)/AgI,Ag solid electrolyte cells ex-

hibit open-circuit voltages as expected according to thermodynamics. This clearly indicates that the LiI(Al_2O_3) electrolytes have low electronic conductivity (5). Furthermore, after a 2 year storage period, the Li/LiI(Al_2O_3)/PbI_2,Pb cells exhibit not only the same open-circuit voltage, but also the same discharge characteristics as the freshly made cells. Therefore, one concludes that the electronic conductivity is indeed insignificant and the lithium iodide-aluminum oxide solid is suitable as a solid electrolyte material.

2. The conduction mechanism of the lithium iodide-aluminum oxide electrolytes is identical with that of lithium iodide. The cation vacancies are the principal mobile species.

*** The diffraction patterns of the LiI (20 m/o Al_2O_3) and LiI (60 m/o Al_2O_3) electrolytes are similar to that of Table II, part (c).

Inasmuch as the lithium iodide-aluminum oxide electrolytes are practically pure ionic conductors, the fact that only ohmic behavior was observed during the d-c measurements on the Li/LiI(Al_2O_3)/Li conductivity cells indicates the reversibility of the lithium electrodes with respect to the LiI(Al_2O_3) electrolyte. Furthermore, the activation energy for the conduction process in the studied temperature range was found to be identical with that of lithium iodide in the extrinsic region (5, 7). Therefore, we conclude that the conduction mechanism of the lithium iodide-aluminum oxide is identical with that of lithium iodide and that the lithium ion vacancies are the principal mobile species (5, 7).

3. No chemical reaction was observed between the lithium iodide-aluminum oxide electrolyte and the electrodes. The electrolyte is suitable for high-energy solid-state battery systems using lithium anodes.

The Li/LiI(Al_2O_3)/PbI_2,Pb cells which were stored for 2 years exhibited identical open-circuit voltage and

similar discharge characteristics as the freshly made cells (Fig. 3). If the aluminum oxide in the electrolyte were reduced by the metallic lithium, both the open-circuit voltage and the discharge characteristics would have changed significantly due to the formation of Li_2O and Al. Figure 4 shows the discharge curves of the Li/LiI (40 m/o Al_2O_3)/PbI_2,Pb cells under various constant currents. It is noted that a 100% discharge efficiency may be realized at 75 $\mu A/cm^2$ or less indicating that the LiI(Al_2O_3) solid electrolytes can be used in practical solid-state battery systems.

4. The increase in the ionic conductivity by the incorporation of aluminum oxide in lithium iodide cannot be explained by the classical doping mechanism.

The x-ray diffraction patterns of the LiI(Al_2O_3) electrolytes showed both the lithium iodide and the aluminum oxide lines indicating insignificant solubility of aluminum oxide in the lithium iodide lattice and *vice versa*. Furthermore, no new lines were present in the diffraction pattern to show the formation of a solid complex between the two starting compounds.

It is conceivable that Li^+ vacancies are created by the dissolution of Al_2O_3 molecules in the lithium iodide lattice (2 Al^{3+} replaces 2 Li^+ and 3 O^{2-} replace 3 I^- creating 1 Li^+ vacancy to balance the charge). However, if this were the mechanism for the increased conductivity, one would expect that a few mole per cent of Al_2O_3 would be sufficient to reach the equilibrium concentration of the vacancies. Indeed, it was observed during the electrolyte formation at 550°C that at least a substantial amount of the aluminum oxide remained solid even at 2 m/o indicating a less than 2 m/o solubility of aluminum oxide in lithium iodide. Since it was known (5) that 1 m/o of vacancies would result in an ionic conductivity of about 10^{-5} ohm^{-1} cm^{-1} at room temperature, the fact that about 40 m/o undissolved Al_2O_3 is required to attain the 10^{-5} ohm^{-1} cm^{-1} conductivity suggests that the classical doping mechanism is not valid in the present case.

The mechanism of the conduction enhancement will be discussed in a subsequent publication.

Some Aspects of Sodium-Sulfur Cell Operation

Jacques Fally, Claude Lasne, Yvon Lazennec, and Pierre Margotin

Compagnie Générale d'Electricité, Marcoussis, Essonne, France

ABSTRACT

An experimental sodium-sulfur cell using a beta-alumina electrolyte is described. The cell uses carbon felt as a cathode current collector with molybdenum wires as terminals and with a beta-alumina tube. At temperatures between 300° and 350°C and at a current density of 0.2 A/cm^2 lifetime is about 200 cycles with a 30-35% depth of discharge and a power density of 0.3 W/cm^2 at the working potential. Experiments at greater depth of discharge are described.

The great interest in the sodium-sulfur storage battery using beta-alumina as the electrolyte is due to the fact that the characteristics of the anodic and cathodic reactants allow one to expect batteries with an energy density higher than 150 W-hr/kg, under satisfactory economic conditions (1-5). This fact makes the sodium-sulfur battery one of the most promising power sources for urban electric vehicles when comparison is made with other conventional electrochemical systems.

As for any electrochemical cell, correct optimization of each component (anode, cathode, separator) is of great importance in determining over-all performance.

In the sodium-sulfur case, the beta-alumina ceramic separator represents a major performance-determining component. It will be discussed in a separate article.

The present paper is only concerned with the aspects connected with cell operation: experimental cell technology, cathode study, long-term cycling behavior, influence of electrolyte composition, and certain operating conditions on lifetime.

Key words: sodium-sulfur cells, beta-alumina, high-temperature cells.

Technology and Results

A schematic and a photographic representation of an experimental glass cell are shown in Fig. 1. The glass-ceramic technology was chosen because it presented no difficulty of construction and permitted the study of fundamental problems related to battery operation in the laboratory.

The two-block beta-alumina electrolyte is a closed-end tube of 8 mm OD and approaching a wall thickness of 600μ. The active surface is about 10 cm^2. The anodic compartment consists of a glass tube sealed off under vacuum and sealed to the beta-alumina tube. A molybdenum wire (2 mm diameter) is used as the terminal. The anode compartment filling is achieved by molten sodium nitrate bath electrolysis; this procedure avoids all the difficulties of handling metallic sodium and provides a high-purity reactant. Initial contact between

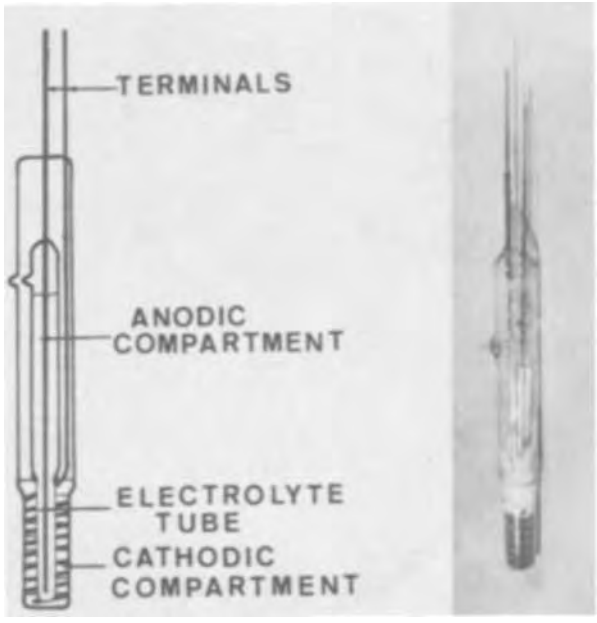

Fig. 1. Sodium-sulfur experimental glass cell using beta-alumina closed-end tube as electrolyte

the beta-alumina and the molybdenum current collector is made by a small molybdenum spring.

The cathode compartment consists of a sealed outer glass vessel surrounding the anode reservoir and electrolyte, containing graphite felt rings and a molybdenum spiral as the terminal. The sulfur thickness is 5 mm. Because of the larger volume of sodium polysulfide reaction product it is necessary to put into the cell about 30% less sulfur than the theoretical absorption capacity of graphite felt. Before sealing the compartment, a low pressure of inert gas is admitted to prevent boiling off of sulfur at the testing temperature.

The theoretical capacity of such a cell, limited by the sulfur electrode, is about 6 A-hr.

Cycling runs were carried out on these cells under the following conditions at 330°C: *(i)* 1 hr discharge at 200 mA/cm² (power produced 300-350 mW/cm² depending on the cell resistance); *(ii)* 3 hr charge at 67 mA/cm²; and *(iii)* depth of discharge being 35%.

The initial cell specific resistance, in the range 1.6-2.0 ohm-cm² yielded a maximum power of 600-700 mW/cm². In order to increase the specific power, a few runs were carried out under the same cycling conditions as above with thinner electrolytes (200-300μ in thickness). These were unsuccessful, probably because of a higher mechanical fragility when the tube thickness decreases.

Cathode Study

Because of the very low conductivity of sulfur, it is necessary to use an electronically conductive material in the cathode reactant. Graphite felt is very suitable for this application, but its cost is still too high for a practical power source. Accordingly, other cathodic collectors were tried, in particular graphite powder with a grain size smaller than 300μ. The optimum composition for sulfur-graphite powder mixtures is in the range 70-80 weight per cent (w/o) sulfur and 20-30 w/o graphite. Figure 2 shows that the resistance of mixtures containing more sulfur are too high and vary rapidly with sulfur content, while mixtures containing more graphite are insufficiently fluid. It is also apparent that cathode thickness has an important influence on cell resistance. These data indicate that construction of high capacity sodium-sulfur cells with graphite powder cathodes is not practical. For instance, with the same cell geometry, and at a temperature of 330°C, the part of the cell resistance due to the cathode is 4.6 ohm-cm² of active electrolyte surface for a 20 w/o suspension of graphite powder in molten sulfur, while a felt cathode only represents 0.5 ohm-cm² and contains 5 w/o graphite. Runs have also been carried out with graphite cloth, the absorption capacity of which was too low, and with stainless steel felts, which presented the same disadvantage. In addition, with stainless steel considerable corrosion problems occurred.

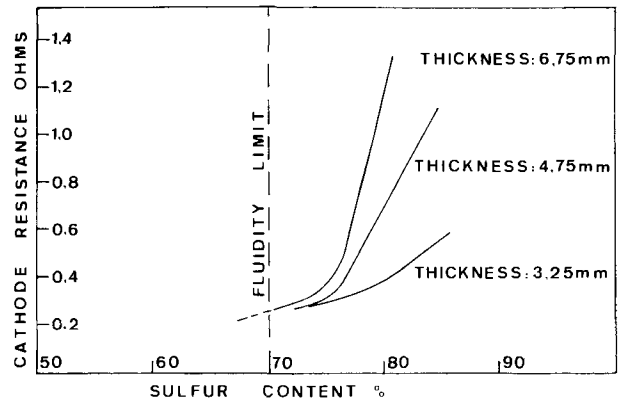

Fig. 2. Relation between graphite powder-sulfur cathode resistance and sulfur content for various cathode thicknesses

In view of these observations, graphite felt was finally chosen as the cathode current collector.

With the glass cells described above, the depth of discharge was limited to 40%, corresponding to the polysulfide composition range Na_2S_5 to Na_2S_3. During charge, when the catholyte composition reaches the sulfur-pentasulfide two-phase region of the sodium-sulfur phase diagram (6), the cell resistance increases considerably and the applied voltage often rose to values higher than 3V, above which electrolytic decomposition of beta-alumina may occur. This rise is probably forming an insulating layer due to free sulfur formation at the cathode-electrolyte interface. However, it was found that if a thin (1 mm) layer of insulating mineral felt (Kaowol) was interposed between the electrolyte and the graphite felt cathode, more than 70% depth discharge can be attained. An improvement in depth of discharge was also noted when the glass wall and molybdenum spiral were replaced by a metallic-walled cathode.

Time Behavior of Experimental Cells

Cells exhibited two kinds of phenomenology during cycling.

Firstly, a progressive increase in internal resistance occurred, which results in a decrease in power. In Fig. 3 a series of current-voltage characteristics is plotted at various stages of a cell's lifetime. After a life of 82 A-hr/cm², power at the working point decreased by 10%. Figure 4 shows the same degradation in a different plot; it can also be seen that the behavior was

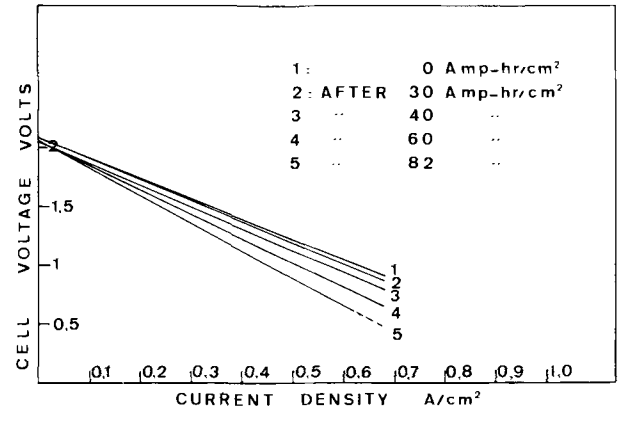

Fig. 3. Performance of a cell in continuous operation at 200 mA/cm² during discharge and 67 mA/cm² during charge

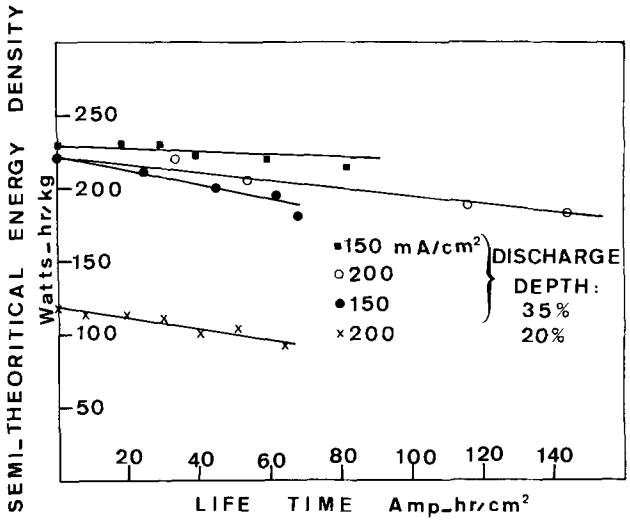

Fig. 4. Cell energy density under various conditions of current density and discharge depth

slightly different at 150 and at 200 mA/cm². The lower "semitheoretical" energy density in one of the runs is caused by a low discharge depth voluntarily limited to 20%. (For the "semitheoretical" energy density only the weight of the reactants, but not of the container and other components, is taken into account.) Secondly, between 1000 and 1500 hr of cycling, the electrolyte rather suddenly develops electronic conductivity, which quickly renders the cell useless.

Influence of Electrolyte Composition

The appearance of electronic conductivity in the electrolyte is connected either with metallic sodium precipitation in beta-alumina or with crack formation. Metallic sodium precipitation is probably a result of the presence of foreign ions in the electrolyte lattice, such as Mg^{++}, since beta-alumina behavior during filling of the anodic compartments by molten sodium nitrate electrolysis is strongly influenced by magnesia additions as indicated below.

No difficulties have been encountered in filling beta-alumina tubes with a 0.8 w/o magnesia content of total beta-alumina using the electrolytic process. However, no cell with a magnesia content of 3 or 6 w/o could be filled by electrolysis. In such cases, metallic sodium appears in the electrolyte in the form of black dendritic accumulations as seen in Fig. 5. This phenomenon, which is thought to be caused by internal discharge of sodium ions, is first initiated at the sodium-beta-alumina interface, then progresses through the whole ceramic producing a short circuit. The impossibility of filling beta-alumina tubes with a high magnesia content by the electrolytic method is probably due to the same phenomenon. Indeed, filling has been shown in the present work to be possible if electrolytes containing only 0.8% magnesia are used. From the data in Table I it may be seen that the lifetime of experimental cells greatly depends on beta-alumina composition. Thus, from a practical point of view, the lifetime improvement obtained by using additive-free electrolytes compensates the small decrease in specific power due to an increase in resistivity. In addition, it may be concluded that high impurity levels are the

Table I. Correlation between chemical composition and lifetime

Electrolyte composition	Lifetime (A-hr/cm²)	Remarks
Commercial β-alumina	17	High impurities level (3000 ppm)
8.5 Al_2O_3, Na_2O + 0.8 w/o MgO	31.5	
8.5 Al_2O_3, Na_2O + 3 w/o MgO	—	Damaged during filling
8.5 Al_2O_3, Na_2O + 6 w/o MgO	—	Damaged during filling
8.5 Al_2O_3, Na_2O	90	Low impurities level (70 ppm)

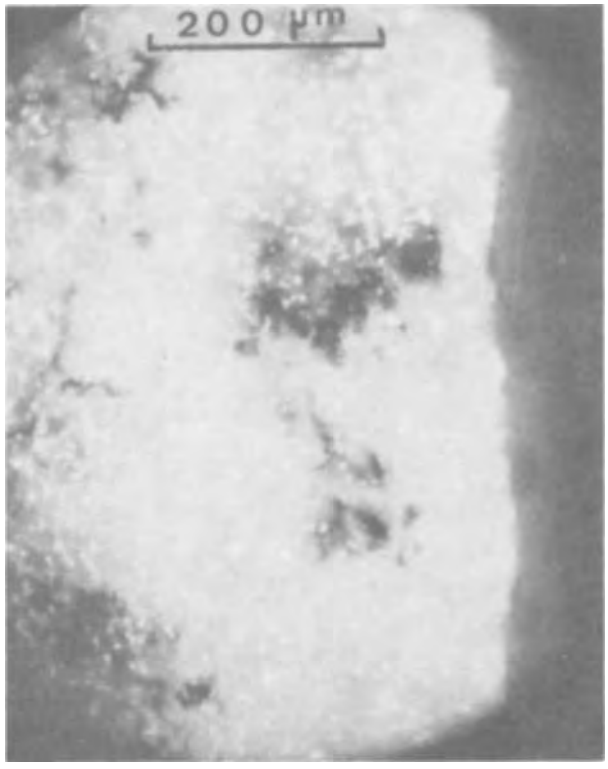

Fig. 5. Metallic sodium precipitation in beta-alumina containing 3 w/o magnesia during filling of electrolyte tubes by molten sodium nitrate electrolysis

cause of the poor results obtained with commercial beta-alumina.

Other evidence of the importance of impurities is shown by the fact that potassium and silicon (etched from the glass by molten sodium) penetrate into beta-alumina during cycling to give levels higher than 1%. Figure 6 is an electron microprobe photograph show-

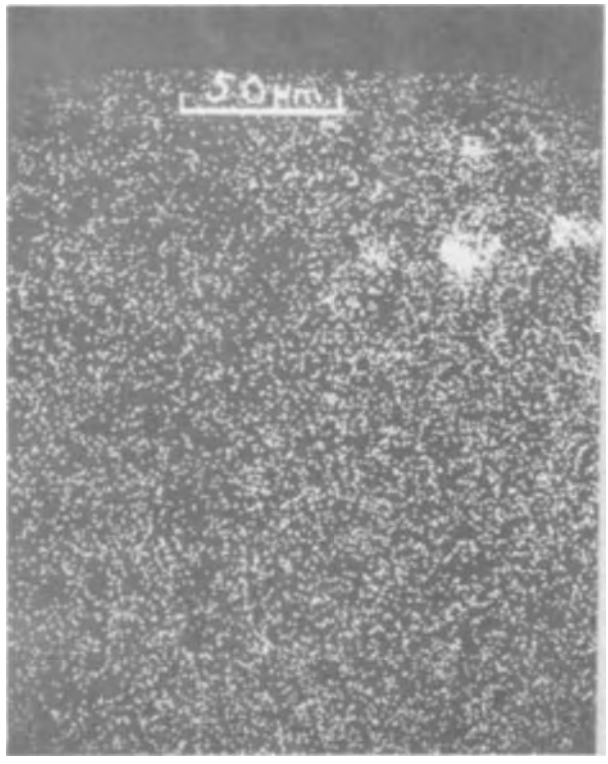

Fig. 6. Beta-alumina contamination by potassium from glass corrosion as seen by electron microprobe examination

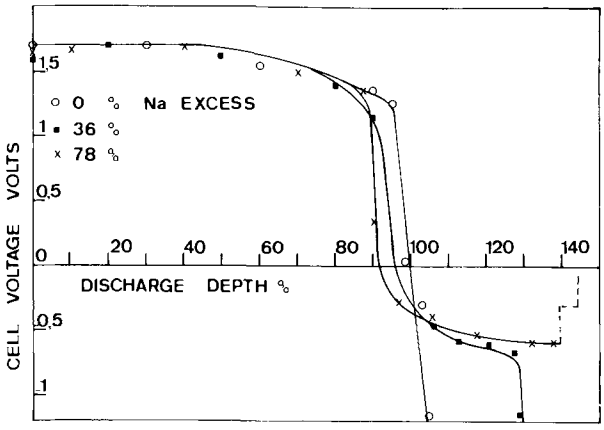

Fig. 7. Discharge curves of three cells with different amounts of excess sodium (compared with Na_2S_3 stoichiometry)

ing the potassium distribution in the electrolyte. It is possible that these impurities also have effect on lifetime.

Effect of Operating Conditions

As already indicated no significant influence of current density in the 150-200 mA/cm^2 range on cell lifetime is observed.

Nevertheless, polarity reversal experiments on some cells (by prolonging discharge beyond Na_2S_3) seem to show another possible cause of cell degradation. Cell life may also be limited by mechanical strains due to solid reaction products. Prolonged discharge curves of three sodium-sulfur cells are shown on Fig. 7. These cells differ by the sodium amount available in their anodic compartment compared with that required for Na_2S_3 stoichiometry.

Those data indicate that: (*i*) inversion of cell polarity occurs as soon as the catholyte composition reaches Na_2S_3; (*ii*) a voltage plateau occurs at an overpotential of about −0.6V; (*iii*) a second voltage drop occurs corresponding to sodium depletion in cases where it is not in great excess (*cf.* curve for 36% excess in Fig. 7); and (*iv*) the electrolyte ruptures at a composition of about Na_2S_2 if there is a sufficient excess of sodium. This rupture seems to be induced by the presence of solid sodium polysulfides. During normal operation this occurs despite control of the total faradaic balance, indicating the total cathode composition. It is possible that such solid reaction products locally occur at the cathode-electrolyte interface, and break the ceramic. Such a point of view is supported by Fig. 8 which is a scanning electron microscope photograph of beta-alumina which has received normal cycling. Superficial grains show conchoidal fractures. Polysulfide solidification during cooling of discharged cells can probably cause the same effect.

Conclusion

The detrimental influence of magnesia additions on cycle life (and probably of a number of other impurities introduced during electrolyte preparation or cycling) resulted in the use of only beta-alumina electrolytes, without additives, and of rigidly controlled purity (<70 ppm) in the sodium sulfur cell. Contamination of beta-alumina by potassium and silicate (or silicide) ions from glass seals can, however, only be

Fig. 8. View of beta-alumina surface after operation in sodium-sulfur cell (scanning electron microscope)

avoided by a new experimental cell technology. Control of catholyte composition (*i.e.*, the working range on the discharge curve) also seems to be an important factor in cell longevity.

The average lifetime obtained to date is 90 A-hr/cm^2, with an upper limit of 150 A-hr/cm^2. It seems necessary to us to double this figure before a battery in the range of few hundred watts can be constructed.

Study of a Beta-Alumina Electrolyte for Sodium-Sulfur Battery

Jacques Fally, Claude Lasne, Yvon Lazennec, Yves Le Cars, and Pierre Margotin

Compagnie Générale d'Electricité, Marcoussis, Essonne, France

ABSTRACT

The structural properties of sodium aluminates (beta-aluminas) as ionic conductors have been studied. The Al_2O_3-Na_2O diagram for Al_2O_3 above 84 mole per cent between 1100° and 1600°C is described. The fabrication of closed-end tubes (for use as battery electrolyte) by electrophoretic deposition is shown to give a useful and reproducible product. Finally, the physical and electrical properties of sodium-conducting ceramics prepared in this way are evaluated.

As shown in a preceding paper, studies of sodium-sulfur batteries have indicated the strong influence of the β-alumina electrolyte on cell operation. It has accordingly been necessary to study the structural properties of sodium aluminates as electrolytes for optimization of cell performance.

Pure β-alumina electrolyte closed-end tubes, with and without additives, have been prepared. The chemical, physical, and electrical properties of these tubes have been determined in relation to optimum cell operation.

Phase Diagram and Structural Properties Study

Al_2O_3-Na_2O phase diagram.—Recent work in this laboratory has examined the Al_2O_3-Na_2O system (1) for alumina concentrations higher than 84 mole per cent (m/o). The method used a sodium oxide vapor loss. Phases were identified by x-ray diffraction. It has been shown that depending on temperature the phases present have β-alumina structure (generally accepted $Na_2O \cdot 11Al_2O_3$) (2) and β″-alumina structure (with the theoretical formula $Na_2O \cdot 5.33Al_2O_3$) (3-5). Beta″-alumina prepared by solid-state reaction between α-alumina and sodium carbonate above 1050°C is always present with β-alumina. Above 1400°C, the proportion of β-alumina in the mixture increases and at 1550°C the transformation $\beta'' \rightarrow \beta$ is complete.

This transformation is not reversible. It would appear that only the β-phase is stable.

As shown in Fig. 1, the domain of the β-phase extends up to 1400°C from $Na_2O \cdot 5.33Al_2O_3$ to $Na_2O \cdot 8.5Al_2O_3$. The zone represents the coexistence domain of β and β″. By extrapolation of the obtained domain boundaries to melting, we get a peritectic point, the composition of which is about $Na_2O \cdot 8.5Al_2O_3$. It is remarkable that $Na_2O \cdot 11Al_2O_3$ β-alumina is outside the domain. The results obtained confirm those of other workers for the temperature range above 1700°C (6, 7), and extend the Na_2O-Al_2O_3 diagram to lower temperatures.

Structure.—As β and β″ phases always coexist, crystallographic aspects of their juxtaposition were studied.

Crystals of composition corresponding to the zone described above were grown using a lead oxide (PbO) evaporation flux method, (6). Weissenberg and oscillating crystal patterns were obtained and compared with those corresponding to pure β-alumina. Figure 2 represents patterns obtained around $\vec{c}$ axis on β and on β + β″. Both photographs show that all β-alumina reflections satisfy the $P6_3/mmc$ space group whose parameters for a hexagonal lattice are $a = 5.50$Å and $c = 22.52$Å.

For the β + β″ pattern a second reflecting system appears, located at about the third from pair planes of β-alumina. The systematic extinctions and the different symmetry elements identify without ambiguity β″-alumina (whose space group is $R\bar{3}m$) in a hexagonal multiple cell description, yielding the parameters $a'' = 5.58$Å and $c'' = 33.95$Å where the $\vec{a}''$ and $\vec{c}''$ directions are in perfect coincidence with the $\vec{a}$ and $\vec{c}$ directions of β-alumina.

Hence we may assume that hexagonal β-alumina (stable phase) and rhombohedral β″-alumina (metastable phase) coexist in epitaxy.

Electrolyte Preparation

Taking into account the above results, only hexagonal β-alumina was used for electrolyte preparation. This is a two-step process, *viz.*, synthesis of β-alumina by fusion and fabrication of closed-end tubes.

Synthesis of β-alumina by fusion.—Beta-alumina has been obtained by induction melting of a mixture of α-alumina and sodium carbonate in a water-cooled copper crucible. The initial mixture compositions used varied between $Na_2O \cdot 5.33Al_2O_3$ and $Na_2O \cdot 11Al_2O_3$. In some cases additions of magnesia and zirconia were incorporated in the mixtures before melting.

The fused mass was in each case first crushed, then milled in a stainless-steel ball mill. Metallic impurities introduced during milling were leached out by hydrochloric acid, which also eliminates the sodium aluminate sometimes present. This method gives powders

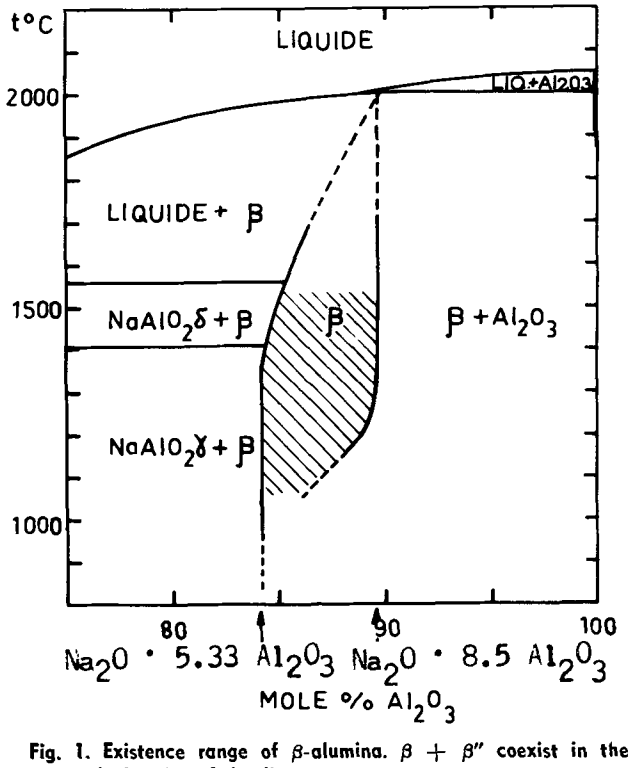

Fig. 1. Existence range of β-alumina. β + β″ coexist in the cross hatched region of the diagram.

Key words: beta-alumina, solid electrolyte, sodium sulfur battery.

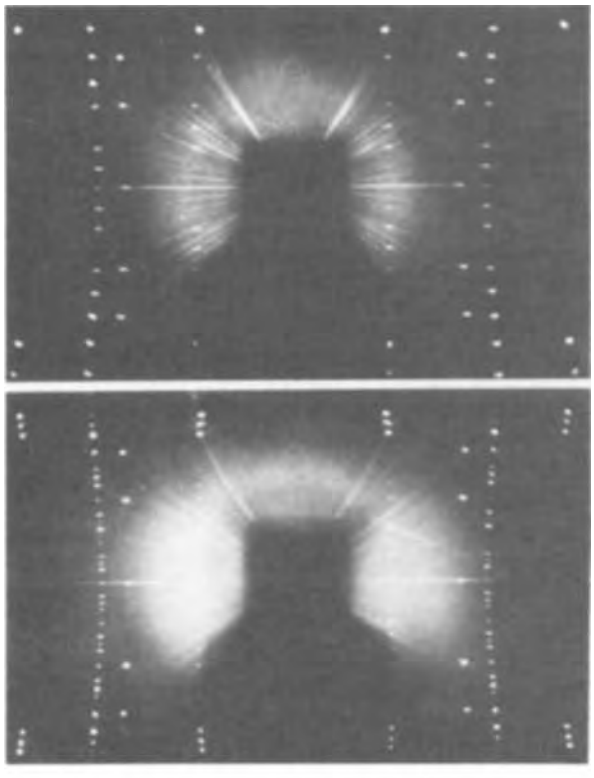

Fig. 2. Oscillating crystal patterns around c axis of hexagonal lattice (β- and β + β″-aluminas).

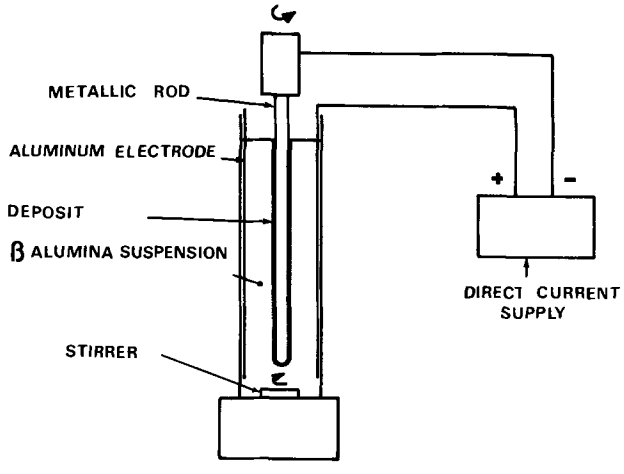

Fig. 3. Schematic view of electrophoretic deposition apparatus

with a low level of metallic impurities as shown in Table I. Their specific surface area is about 2 m^2/g.

Fabrication of closed-end tubes.—Tubes were formed by electrophoretic deposition of β-alumina on a metallic rod. (Figure 3 is a schematic view of the electrophoretic deposition apparatus.) The powder was suspended in an organic solvent and electrically charged by adsorption of positive charges from dissociation of a dissolved organic acid. Using this method, homogeneous tubes of wall thickness between 200 and 2000 μm may be obtained. In general, tubes used in experimental cells had a wall thickness of about 600 μm.

Table I. Spark mass spectrometry analysis of β-alumina samples

Elements	Mg	Si	K	Cr	Fe	Cu	Ga
Powder	10	8	13	5	15	2	3
Tube before working	1.5	20	20	—	16	1	7
Tube after working	10	>150	>760	5	17	2	7

Sintering was carried out at about 1850°C in air with a propane-oxygen furnace. Beta-alumina crucibles are used to prevent sodium loss from the tubes, which becomes important at 1500°C. Their sodium oxide content automatically determines the final content of the tubes. We have established that the firing temperature may be lowered to 1700°C by using a 1 w/o zirconia addition. Magnesia, however has no effect on sintering.

Analysis and Characterization of Electrolytes

Analysis and physical characterization were performed to obtain reproducible electrolytes and to obtain correlations between their properties and their electrochemical behavior.

Chemical analysis.—The sodium content of the β-alumina was determined by atomic absorption after dissolution of β-alumina in lithium borate. The error of this method is $\leq \pm 5\%$. The sodium content of the majority of electrolytes was about 6.2 ± 0.2 w/o.

The impurity content of the tubes and the powder were measured by spark-source mass spectrometry. Table 1 shows that the β-alumina powders obtained are of high purity and that the manufacturing process does not substantially contaminate the electrolytes.

Ion and electron microprobe examinations were used for impurity distribution determinations. This method showed that zirconium is localized at grain boundaries, while magnesium is found in the β-alumina lattice.

Figure 4 is a scanning electron microscope photograph of a fractured β-alumina tube showing cleavage.

Physical characterization.—Crystalline structures were determined by x-ray diffraction. The density of the tubes measured by the hydrostatic method in tetrabromoethane was between 3.15 and 3.20 cm^3/g.

Micrographic examinations were carried out on polished samples etched with pure boiling orthophosphoric acid. They showed the distribution of porosity near

Fig. 4. Fracture scanning electron microscope examination of a β-alumina tube showing cleavage.

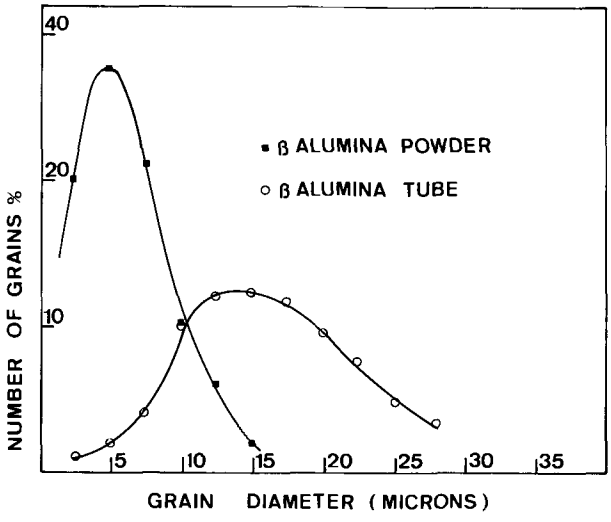

Fig. 5. Grain size distribution of powder and of β-alumina tube

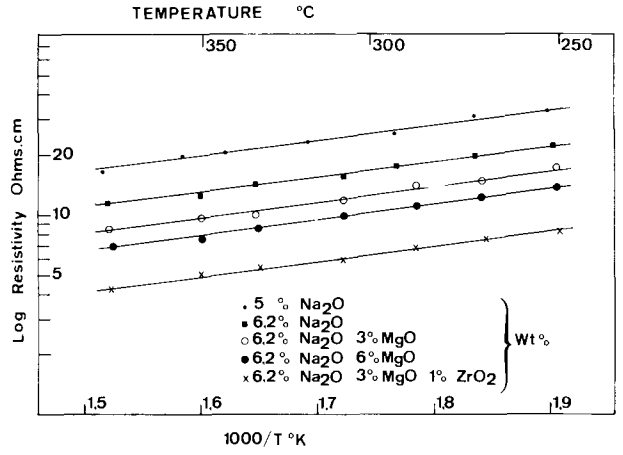

Fig. 6. Variation of log resistivity of β-alumina tubes vs. reciprocal temperature

grain boundaries, the possible presence of a second phase (perhaps α-alumina), and the grain size distribution. Figure 5 shows that the average grain size is about 15 μm. Comparison with the grain size distribution of the powder shows that the grain growth during sintering is low.

The sintering process used represents a compromise between the conditions for small grain size and low residual porosity.

Electrical characterization.—A four-probe a-c technique at 1000 Hz enabled electrolyte resistivity to be measured directly on tubes. Accuracy of the method is ±1 ohm-cm at 350°C and is independent of the frequency (in the range 200-100,000 Hz). Electrical contacts were made with platinum wire and platinum or silver paste.

Resistivity of low soda content samples containing α-alumina reaches 20 ohm-cm. On the other hand, magnesia additions decrease the resistivity to 8 ohm-cm. Values of 5 ohm-cm are obtained by use of zirconia additives.

These values are the lowest for β-alumina compared to the literature (8-10).

Discussion

The above characterizations of the different electrolytes studied lead to evident correlations between their electrochemical behavior and their properties. In particular, magnesia additions which decrease the resistivity are undesirable with regard to experimental cell lifetime (11). A resistivity of 13 ohm-cm at 350°C of the pure β-alumina electrolyte seems sufficiently low for its use in a high-power battery.

A considerable incorporation of impurities in the electrolyte, especially of potassium and silicon, took place during cycling in our glass cells. This may be explained by the corrosion of the glass by molten sodium, and can perhaps account for a substantial part of battery aging. In addition, sodium analysis of electrolytes after cycling indicates a sodium oxide content of about 6.2 w/o. This corresponds to the original composition, which is therefore not modified by electrochemical cycling.

Lifetime is also a function of tube wall thickness, thicker tubes giving a longer lifetime (11).

Conclusions

A study of the structural properties of β-aluminas, and the correlations discussed above, demonstrates that the electrolyte developed in this work is β-alumina, without additions and with a low impurity level.

In addition, the manufacturing process produces electrolyte tubes with reproducible chemical, physical, and electrical properties.

The average lifetime of experimental cells using these tubes (600 μm wall) is about 90 A-hr/cm² (current density 200 mA/cm² during discharge) as discussed previously (11).

It would appear that a very long lifetime may be obtained with such electrolytes. For this it is necessary to avoid any contamination of the electrolyte during operation. A thorough knowledge of the degradation mechanism is also necessary. This is the subject of current work.

Transient Response of the System Ta/Ta_2O_5/Electrolyte

I. Ion Current Transients

D. F. Taylor *,[1] **and M. J. Dignam***

Department of Chemistry, University of Toronto, Toronto 181, Ontario, Canada

ABSTRACT

The dielectric relaxation model for ion current transients is tested against both new data obtained under potentiostatic conditions and data obtained by Dewald under galvanostatic conditions. A single set of system constants reproduces both sets of data. As has been already shown for the system Al/Al_2O_3/electrolyte, some of the system constants appear to vary slightly with film formation conditions, a possible consequence of minor structural or compositional changes. The results of a-c impedance measurements made during steady-state film growth were also reproduced by the same set of system constants for frequencies below 1 kHz. Above 1 kHz, an anomalous increase in a-c conductance with increasing frequency was observed.

The purpose of this paper (Parts I and II[2]) is to test the dielectric relaxation model for ion current transients (1-8) against a variety of forms of data for the valve metal-oxide system Ta/Ta_2O_5/electrolyte ($0.2N$ H_2SO_4). In Part I, the model is first presented in greater mechanistic detail than heretofore, incorporating the substantial modifications which have been made (2-8) since its inception (1). Equations relevant to ion current transients are then derived and compared against new and published data.

Other models which have been proposed to account for ion current (faradaic current) transients in connection with the anodic oxidation of the valve metals (principally Ta, Nb, Al, and Bi) are the high field Frenkel defect model (9, 10) due to Bean *et al.* and the ionic avalanche model (11-13) due to Young. It was Young who first showed that the form of potentiostatic ion current transients for the tantalum system could not be accounted for, even qualitatively, by the high field Frenkel defect model (11). Subsequently, Dignam and Ryan showed the same was true for the aluminum system (14).

Young proposed the ionic avalanche model specifically to account for potentiostatic transients, which it does do qualitatively. The fit achieved, however, is not very good and the fitting parameter varies with field strength. Since the mechanism underlying the equations has not been set out in any detail, it is neither possible to make an independent estimate of the fitting parameter nor even to predict the form of its dependence on field strength. Furthermore, the model has not been developed to the point where it can be tested against data for any other form of transient.

Finally, Adams, van Rysselberghe, and Willis [ref. (15), sec. 20.5] have proposed a mechanism in which the rate-controlling step is injection of interstitial metal ions at the metal/oxide interface, with the number of sites at which injection can take place being controlled by the concentration of step sites at the interface, which in turn is assumed to depend on the rate of oxide formation through, for example, the properties of screw dislocations. The model has not been set forth in mathematical terms and hence cannot be tested against the results of kinetic measurements.

For the reasons outlined, only the dielectric relaxation model is tested in this paper.

Theory

The principal postulates on which the dielectric relaxation model is based are:

1. Defect injection at one of the interfaces constitutes the rate-controlling step for ion conduction through the oxide film.
2. Dielectric relaxation processes occur within the oxide phase and are responsible for ion current transients.

In order to derive analytic expressions relating the current density, field strength in the oxide film, and time, these postulates require considerable amplification. A difficulty arises, however, since within the framework provided by postulates 1 and 2, a number of models can be proposed which ultimately predict the same form for the transient response of the system. We have chosen to handle this problem by developing a very specific model, indicating in the process, however, the alternatives which exist.

Before a model for the interfacial process can be presented we require a mechanism for ion transport within the oxide film. In the remainder of this section, a description of mobile ionic defects is presented following which postulates 1 and 2 are amplified in turn.

Nature of mobile defects.—The dielectric relaxation model of ion current transients can be developed from almost any model for the mobile defects. Only the transport mechanism due to Dignam (16, 2, 4, 8) however appears to be consistent with the unusual transport number values found for the valve metal-oxide systems (8). We proceed, therefore, on the basis of this mechanism, which is summarized briefly below. [For further details see ref. (8).]

The model is directly applicable to odd valent (M_2O_3 and M_2O_5) vitreous metal oxides only, although it can be extended to cover some mixed vitreous oxides. Using the random network model of the vitreous state due to Zachariasen, a "network" defect pair can be imagined to be formed by the rupture of one of the metal-oxygen bonds in an ionic fashion, followed by separation of these "ionized dangling bonds" through a series of partner exchanges. Alternatively, one may imagine forming such a defect pair by transferring the molecular ionic group TaO_2^+ from one region of the vitreous oxide to another, then allowing the structure to relax in the two perturbed regions. In either case the defect pair may be described as one region with a stoichiometric excess of one-half an oxygen ion, and another with a stoichiometric excess of one-fifth of a tantalum ion. The properties of these defects of importance in the present study are that they bear a charge of $-e$ and $+e$, respectively, where e is the charge on the proton, and that defect migration occurs via a cooperative motion of both the metal atoms and the oxygen atoms in the neighborhood of the moving defect, such motion constituting irreversible displacement of the atoms, no single atom, however, being displaced as far as one interatomic distance.

[2] See pp. 1306-1310 of this issue.

In addition to accounting for transport number data, this transport mechanism predicts the correct value for the activation energy for ionic conduction in bulk vitreous B_2O_3 (8).

Model for interfacial control.—The postulate that defect injection at one of the interfaces constitutes the rate-controlling step for ion transport through valve metal oxide films was first proposed by Mott and Cabrera (17). The justification for this postulate in the case of the valve metal-oxide systems follows.

In general, a space charge region must exist near the interface (or interfaces) at which the ionic defects enter the film (15, 8). Space charge effects have been investigated for the tantalum system by both Young (18, 19) and Vermilyea (20-22), the results limiting the thickness of the characteristic space charge length for the system either to the order of 10Å or less, or to very much larger than the film thickness, *i.e.* $\gtrsim 10^5$Å. If the former is the case (which corresponds to bulk control) the concentration of mobile ionic defects must be of the order of the lattice ion concentration, which is improbable. If the latter is the case, then the rate will be controlled at one or both of the interfaces.

There is no very convincing evidence upon which a decision between control at one or the other interface can be made. Thus lack of dependence of the kinetics of film growth on the crystallographic orientation of the metal surface (18, 23) does not preclude rate control at the metal-oxide interface, as noted in ref. (8), p. 217. As electrolyte composition does appear to have a small effect on the interfacial kinetics [see ref. (8), p. 229] we have chosen to develop the model on the basis of control at the oxide/electrolyte interface. It is fair to say, however, that at present no generally accepted model of the oxide-solution double layer exists. The details of the following development are accordingly in considerable doubt. Fortunately, the forms of the resulting equations, Eq. [5] and [7], are preserved on altering many of the details of the interfacial processes, including the interface at which the rate is assumed to be controlled. The following should therefore be considered only as one example of a model for the interfacial processes which leads to [5] and [7].

Equilibrium is assumed to be maintained with respect to reactions of the following type

$$\left(\begin{array}{c} M \\ \diagdown \\ \quad O \\ \diagup \\ M \end{array}\right)_{\text{surface}} + H_2O \rightleftharpoons \left(\begin{array}{c} M\text{—}OH \\ \\ M\text{—}OH \end{array}\right)_{\text{surface}} \qquad [1]$$

with the interfacial electrochemical reaction being represented by

$$(M\text{—}OH)_{\text{surface}} \rightarrow (M\text{—}O^-)_{\text{surface}} + H^+_{aq} \qquad [2]$$

[For further details see ref. (8).] Vermilyea (24) has demonstrated that rapid proton exchange takes place between the surface region of anodically formed Ta_2O_5 and the electrolyte. We assume, therefore, that [2] and its reverse are in equilibrium, giving

$$m = (M_p - m)\frac{1}{X(H^+)}\exp -\left[\frac{\Delta G^\circ_{pa} - edE_d}{kT}\right] \qquad [3]$$

where M_p is the total number of surface hydroxyl groups and O^- groups per unit area at the film/double-layer interface, m the number of excess negative charges per unit area at this interface arising from proton abstraction, $X(H^+)$ the mole fraction (or Raoult law activity) of hydrogen ions at the outer Helmholtz plane, ΔG°_{pa} the standard free energy change for proton abstraction, and edE_d the electrical energy term for proton abstraction with E_d the field strength in the double layer of effective thickness d, and e the charge on the proton. We have used the convention of choosing the sign of E_d to be positive for anodic film growth, which differs from that used in ref. (8).

Assuming now that each site of excess negative charge acts as a site for injection of an anion network defect bearing a charge $-e$ into the oxide film, we have for high field strengths (17)

$$i = em\nu_o \exp\left[-(Q_o - ebE_d)/kT\right] \qquad [4]$$

where ν_o, Q_o, and b are the kinetic frequency term, activation energy, and activation distance, respectively, for defect injection, and i the ion current density or faradaic current density. In writing [4], it has been assumed that the field assisting defect injection is that in the double layer, E_d, rather than that in the bulk of the film, say.

For $M_p >> m$, elimination of m between [3] and [4] and setting $\Delta G^\circ_{pa} = \Delta H^\circ_{pa} - T\Delta S^\circ_{pa}$ yields

$$i = i_o \exp\left[-W(E_d)/kT\right] \qquad [5]$$

where

$$i_o = e\nu_o\left[\exp\left(\Delta S^\circ_{pa}/k\right)\right]/X(H^+)$$

and

$$W(E_d) = (\Delta H^\circ_{pa} + Q_o) - e(d + b)E_d \qquad [6]$$

If a quadratic field term is included in Eq. [3] and/or Eq. [4] (5, 8), Eq. [6] takes the form

$$W(E_d) = Q_e - u^*E_d(1 - u^*E_d/CQ_e) \qquad [7]$$

where the effective activation energy at zero field strength, $Q_e = \Delta H^\circ_{pa} + Q_o$, and the effective activation dipole at zero field strength, $u^* = e(d + b)E_d$, while C is a dimensionless constant, the value for which is determined by the mechanism or mechanisms leading to the quadratic field term (5, 8).

Assuming that space charge within the oxide film is negligible, a condition which must apply if ion transport is controlled entirely at an interface, the field strength in the film, E, is related to that in the double layer, E_d through the equation

$$\epsilon_o K_d E_d + me = \epsilon_o E + P \qquad [8]$$

where ϵ_o is the permittivity of free space, K_d the effective dielectric constant of the double-layer region, and P the polarization of the oxide film. Equation [8] is simply the continuity condition on the normal component of the electric displacement (allowing for surface charge) applied to the oxide/double-layer interface.

It can be shown [ref. (8) p. 174] that $\epsilon_o K_d E_d$ will be very much larger than the surface charge density, me, for the Ta/Ta_2O_5/electrolyte system provided that $\Delta G^\circ_{pa} \gtrsim 0.8$ eV, whereas it would appear that ΔG°_{pa} has a value of about 1.3 eV [ref. (8), p. 235]. Accordingly, me will be neglected in comparison with $\epsilon_o K_d E_d$.

P may be written in terms of a fast component, P_1, which follows the field in the normal manner, *i.e.*, $P_1 = \epsilon_o \chi_1 E$, and one or more slow components P_k, $k = 2,3\ldots$, viz.

$$P = \epsilon_o \chi_1 E + \sum_{k=2,3\ldots} P_k \qquad [9]$$

so that [8] becomes, on neglecting me

$$\epsilon_o K_d E_d = \epsilon_o K_1 E + \sum_{k=2,3\ldots} P_k \qquad [10]$$

where $K_1 = 1 + \chi_1$ and is the dynamic dielectric constant of the film.

Under steady-state conditions of constant E and i, the polarization components P_k, $k = 2,3\ldots$ will ultimately take up their equilibrium (or steady-state) values, *i.e.*, $P_k = \epsilon_o \chi_k E$, $k = 2,3\ldots$, in which case [10] reduces to

$$K_d E_d = K_s E_{ss} \qquad [11]$$

where the subscript ss denotes steady-state conditions, and $K_s = 1 + \chi_1 + \chi_2 + \chi_3\ldots$ is the static dielectric constant of the oxide. Equation [11], with [5] to [7] gives

$$i_{ss} = i_o \exp [-W_{ss}(E)/kT] \quad [12]$$

$$W_{ss}(E) = Q_e - u^*_{ss}E(1 - u^*_{ss}E/CQ_e)$$

where $u^*_{ss} = u^*K_s/K_d$ and is the effective steady-state activation dipole. Young (25, 26) has shown that the inclusion of a quadratic field term in $W_{ss}(E)$ can account for the kinetics of steady-state film growth on Ta and Nb, while Dignam *et al.* (27, 28) have shown the same to be the case for Al.

Equation [12] may be written

$$i_{ss} = \alpha \exp \beta_{ss}E \quad [13]$$

where $\beta_{ss} = u^*_{ss}$ (1-2 $u^*_{ss}E/CQ_e)/kT$ and is the differential steady-state field coefficient, while

$$\alpha = i_o \exp [-(Q_e - (u^*_{ss}E)^2/CQ_e)/kT]$$

For a series of measurements made at a fixed temperature, since E varies by only a few per cent for several decades change in i_{ss}, β_{ss} and α may be treated as essentially independent of E. Similarly [5] may be written

$$i = \alpha \exp \beta E_d \quad [14]$$

where

$$\beta/K_d = \beta_{ss}/K_s \quad [15]$$

For conditions in which the applied field strength is changing very rapidly, [10] gives $K_d dE_d/dt = K_1 dE/dt$, which with [14] gives

$$\lim_{dE/dt \text{ large}} \frac{d \ln i}{dE} = \beta_t E \quad [16]$$

where the transient differential field coefficient, β_t, is given by

$$\beta/K_d = \beta_t/K_1 = \beta_{ss}/K_s \quad [17]$$

The ratio of the steady-state to the transient field coefficient is thus equal to the ratio of the static to the dynamic dielectric constant for the film. [For further and more detailed discussion relating to the field coefficients, see ref. (8).] Vermilyea (29) was the first to note that two field coefficients are required to characterize the behavior of many of the valve metal-oxide systems.

Kinetics of polarization.—To complete the development of the model we require expressions describing the time dependence of the "slow" polarization components. The form chosen for these kinetics dictates the form of the transient kinetics predicted. The rate of change of a thermally activated polarization process is often expressed as (15)

$$(dP_j'/dt) = (1/\tau_j)(\epsilon_o\chi_j'E - P_j'), \; j = 2,3 \ldots \quad [18]$$

Equation [18] predicts ion current transients for a constant field, and field transients for a constant ion current, that decay with a characteristic time or times which are simply related to the τ_j and hence independent of i. Experimentally, however, the characteristic time for decay of the transients is found to be proportional to $1/i$ (3, 7, 10, 14). To obtain this result, the polarization kinetics for sufficiently high ion current, i, must take the form

$$\lim_{i \text{ large}} \frac{dP_k}{dt} = B_k i(\epsilon_o\chi_k E - P_k), \; k = 2,3 \ldots \quad [19]$$

If network defects are responsible for ion transport through vitreous oxide films their passage through the film will be accompanied by local irreversible structure changes, such changes constituting in general polarization changes. For large enough ion current, this could constitute the principal mechanism whereby the "slow" polarization components decay to their equilibrium (or steady-state) values, and would lead to Eq. [19] with eB_k being a measure of the interaction cross-sectional area for the moving network defects in relation to the kth polarization component; *i.e.*, if the passage of a network defect through the film is assumed to bring about equilibrium polarization for the polarization component P_k within a distance r_k of the defect, then $B_k = \pi r_k^2/e$.

The total rate of change of P, including thermally activated processes, is now obtained on combining [9], [18], and [19], viz.

$$\frac{dP}{dt} = \epsilon_o\chi_1 \frac{dE}{dt} + \sum_{k=2,3\ldots} B_k i(\epsilon_o\chi_k E - P_k) + \sum_{j=2,3\ldots} (1/\tau_j)(\epsilon_o\chi_j'E - P_j') \quad [20]$$

Note that we are not entitled to set $P_2 = P_2'$, $\chi_2 = \chi_2'$ etc., since P is divided into components P_2', $P_3' \ldots$ on the basis of the activation energies for the polarization processes, whereas it is divided into the components P_2, $P_3 \ldots$ on the basis of structural features and their association with the mechanism of network defect migration. It must be true, however, that $\Sigma P_k = \Sigma P_j'$, and $\Sigma\chi_k = \Sigma\chi_j'$.

In summary, the set of kinetic equations for this model are given by [10], [14], and [20].

Experimental

Potentiostatic ion current transients.—The apparatus used for forming the tantala films and for the measurement of the transients has been described (6). In a typical run, anodic oxidation of a Ta electrode was carried out galvanostatically in 0.2*N* aqueous H_2SO_4 at 2.39×10^{-4} A · cm^{-2} and 22.6°C, up to a potential of 45.18V *vs.* $Hg/Hg_2SO_4/H_2SO_4$ (0.2*N*). Following careful rinsing in distilled water, they were then stored at room temperature in air for a period of at least one month before being used for potentiostatic ion current transient measurements. This long waiting period was to ensure that the "slow" polarization components had decayed substantially prior to initiating the potentiostatic transient measurements. The transient measurement was effected by returning the electrode to the cell and applying potentiostatically a potential in the neighborhood of 41V *vs.* $Hg/Hg_2SO_4/H_2SO_4$ (0.2*N*), the precise potential being varied somewhat from specimen to specimen to test the influence of the field strength used for the experiment on the kinetic parameters.

Data points from a typical run are shown in Fig. 1. They fall on a curve of the same form as those reported earlier by Young for the Ta/Ta_2O_5/electrolyte system (11) and by Dignam and Ryan for the Al/Al_2O_3/electrolyte system (14).

A-C impedance measurements under conditions of steady-state film formation.—The procedure employed for these measurements is essentially that used by Goad and Dignam (30). The apparatus used for the

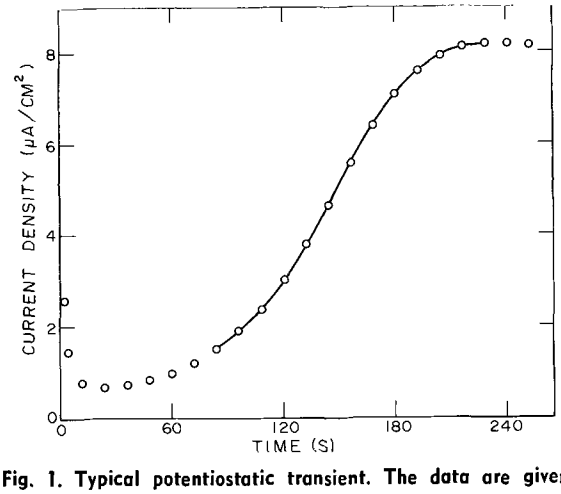

Fig. 1. Typical potentiostatic transient. The data are given by the open circles.

present studies, however, was a considerable refinement on the original in that the process of data aquisition was automated and recorded in digital form for subsequent analysis. This led to a substantial improvement in measurement accuracy.

The technique involves superimposing a small, constant amplitude a-c current onto the constant d-c formation current. The d-c electrode potential, and the components of the a-c electrode potential which are respectively in and out of phase with the a-c current are then recorded as a function of time. The data so obtained can then be processed to give the parallel-circuit-equivalent effective a-c conductivity, $\sigma_{a\text{-}c}$, and effective dielectric constant, K_{eff} (30).

Oxide films were grown galvanostatically to a final cell potential of approximately 95V with a small a-c current superimposed on the d-c current. The amplitude of this a-c component was constant and equal in magnitude to approximately 1% of the d-c current. Before and after each run, both the d-c and a-c voltages appearing across a standard shunt resistance were measured and recorded.

Frequencies in the range 3-7771 Hz were combined with current densities of 233 ± 2 μA/cm^2 (768-7771 Hz) and 1.16 ± 0.01 mA/cm^2 (3-768 Hz) to provide a wide range of (ω/i_{ss}) values. The variations in the current densities arose only from variations in electrode area; the actual current flowing during any given run was constant to within 0.02%.

The d-c cell potential was measured between anode and reference electrode, but the in- and out-of-phase a-c voltage components were measured at the anode with respect to ground, as a much cleaner and more stable a-c signal was then obtained. Since both components of the a-c voltage (measured against ground) appearing at the reference electrode were found to be independent of time, no measurable error was introduced in this way.

The a-c voltage components were measured using a phase sensitive detector combined with automatic alternate switching between reference signals which were respectively in and out of phase with the a-c cell current. At the end of each interval, the d-c voltage, and the magnitude, polarity, and identification (in or out of phase) of one a-c voltage component, were recorded automatically on paper tape.

Both the d-c electrode potential, V_o, and the two a-c components, V_{in} and V_{out}, were observed to increase linearly with time, so that the data could be presented in the form of the parallel equivalent a-c conductivity, $\sigma_{a\text{-}c}$, and effective dielectric constant, K_{eff} as was done in a recent publication from this laboratory (30). These are related to the observables through the equations (30)

$$\sigma_{a\text{-}c} = I_\omega \dot{V}_{in}\dot{V}_o/E_o(\dot{V}_{in}^2 + \dot{V}_{out}^2) \quad [21]$$

$$\omega\epsilon_o K_{eff} = -I_\omega \dot{V}_{out}\dot{V}_o/E_o(\dot{V}_{in}^2 + \dot{V}_{out}^2) \quad [22]$$

where $\dot{V}_{in}$ is the time derivative of the amplitude of the component of the a-c electrode potential which is in phase with the impressed a-c current density of amplitude, I_ω, etc., while V_o and E_o are the d-c components of the electrode potential and field strength, respectively. The d-c current density, I_o, and field strength, E_o, as well as the electrode area (and hence I_ω) were calculated from V_o and the d-c cell current using the steady-state data of Young (25). In reduced form, the results therefore take the form $\sigma_{a\text{-}c}$ and K_{eff} as functions of I_o and angular frequency, ω. In Fig. 2 and 3, $\sigma_{a\text{-}c}/I_o$ and K_{eff} are plotted against log (ω/I_o), the points in each case falling on a smooth curve despite the fact that different values for I_o have been used. This same behavior has been noted previously (30) for the system Al/Al_2O_3/electrolyte, and as noted there is a natural consequence of the fact that ionic transients for these systems appear to involve the charge passed per unit area, (*i.e.*, $\int_0^t Idt$) as the variable characterizing the decay of the transient rather than time ($\sigma_{a\text{-}c}/I_o$, K_{eff}, and ω/I_o are all dimensionally independent of time). The large negative values of K_{eff} occurring for small ω/I_o are noteworthy since they reflect the large contribution of the ion current transients to the current component which is out of phase with the field (30).

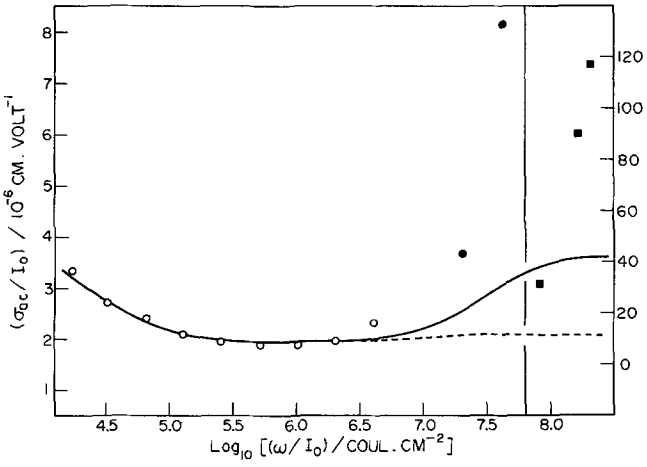

Fig. 2. Dependence of ($\sigma_{a\text{-}c}/I_o$) on (ω/I_o). The open circles represent data obtained for I_o = 0.233 mA/cm^2, the filled symbols data for I_o = 1.16 mA/cm^2. The change in symbols emphasizes the change in scale past the vertical line. This scale change does not apply to the computed curves.

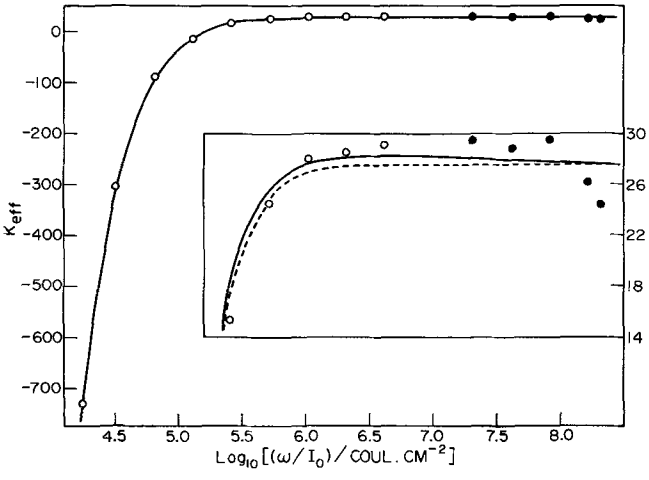

Fig. 3. Dependence of K_{eff} on (ω/I_o). Data point identification as in Fig. 2.

Analysis and Discussion

Galvanostatic transients.—It is convenient to begin with an analysis of the galvanostatic transient measurements of Dewald (10) on the system Ta/Ta_2O_5/0.1*N* H_2SO_4, as these provide, without difficulty, values for the constants χ_k and B_k. The experiments were performed by forming tantala films under steady-state conditions ($I_{ss} \sim 10^{-4}$ A/cm^2, room temperature) then increasing abruptly the current density by a factor of 2. The field strength was observed to increase rapidly initially, go through a maximum, then decay more slowly to the steady-state field strength corresponding to the new impressed current. Goad and Dignam (7) have shown that the data beyond the maximum can be fitted within experimental error by an equation of the form

$$\frac{E - E_2}{E_2 - E_1} = M_1 \exp(m_1 q) + M_2 \exp(m_2 q) \quad [23]$$

where E_1 and E_2 are the steady-state field strengths corresponding to the formation and final current densities, respectively, and M_1, M_2, m_1, m_2 are constants.

Goad and Dignam (7) derive an equation of the same form as [23] from the equations for the dielectric relaxation model and the following approximations

$$\sum_k B_k i(\epsilon_0\chi_k E - P_k) >> \sum_j (1/\tau_j)(\epsilon_0\chi_j' E - P_j') \quad [24]$$

$$I >> i_c \quad [25]$$

where $I = i + i_c$ is the total current density, and $i_c = \epsilon_0 dE/dt + dP/dt$ is the charging current density. The second approximation is shown to be valid beyond the maximum in $(E - E_2)/(E_2 - E_1)$ while the first is simply assumed to be valid, since i is substantial ($\sim 10^{-4}$ A/cm^2) throughout the transient. The analysis leading to [23] requires only two ion current driven polarization terms and has been published (7). Following an identical procedure, Taylor (31) has extended the analysis to include three terms, the result being given in the Appendix. Including only two terms, χ_2, B_2, χ_3, B_3 are related to M_1, m_1, M_2, m_2 through the following equations: B_2 and B_3 are the roots of the equation

$$x^2 + c_1 x + c_2 = 0 \quad [27]$$

where

$$c_1 = \frac{m_1(1 + M_2) + m_2(1 + M_1)}{1 + M_1 + M_2}$$

and

$$c_2 = \frac{m_1 m_2}{1 + M_1 + M_2}$$

while

$$\chi_j = (c_3 + c_4 B_k)/(B_k - B_j) \quad [27]$$

where

$$c_3 = K_1 \frac{(m_1 M_1 + m_2 M_2)}{(1 + M_1 + M_2)}$$

and

$$c_4 = K_1(M_1 + M_2)$$

These equations, with Dewald's results and $K_1 = 27.6$ (15) give (7)

$$\chi_2 = 36.0,\ B_2 = 0.657 \times 10^{-4}\ \text{cm}^2/\text{coulomb}$$

$$\chi_3 = 16.4,\ B_3 = 4.34 \times 10^{-4}\ \text{cm}^2/\text{coulomb} \quad [28]$$

These values for B_2 and B_3 correspond to interaction-cross-sectional radii for the network defects of 1.82 and 4.69, respectively, values which appear to be of the correct magnitude. One may also calculate $K_s = K_1 + \chi_2 + \chi_3 = 80.0$ and hence the ratio of the steady-state to transient field coefficient, $\beta_{ss}/\beta_t = K_s/K_1 = 2.9$ (see [17]) which is in good agreement with independent estimates (8). The dielectric relaxation model provides, therefore, an entirely satisfactory account of galvanostatic transients. To be acceptable, however, the model, with the same values for the constants, must account for other forms of transient.

Potentiostatic ion current transients.—An exact analysis of the data of Fig. 1 on the basis of the equations for the dielectric relaxation model and over the entire range of the data is beyond our present capabilities, as the equations are in fact incomplete. One would require a knowledge of the relaxation times, τ_j, and of the equations relating the set of polarization components $\{P_j'\}$ to the set $\{P_k\}$. Dignam and Ryan (14) have attempted such a complete analysis of potentiostatic transients for the system Al/Al_2O_3/electrolyte by making a number of simplifying approximations. The result was qualitative agreement over the entire curve. On the basis of this partial success, the initial current decay is interpreted as a decrease in charging current density, i_c associated with the approach of the slow polarization components, P_j', toward their equilibrium values via thermal activation, *i.e.*, in this region i is very small so that

$$\sum_j (1/\tau_j)(\epsilon_0\chi_j' E - P_j') >> \sum_k B_k i(\epsilon_0\chi_k E - P_k) \quad [29]$$

(see Eq. [20]). As P increases, however, so does E_d (see Eq. [10]) and hence i (see Eq. [14]) so that ultimately the total current density, I, begins to increase. Furthermore, as i increases, a point is reached at which the inequality [29] is no longer valid. In fact for i large enough, based on the results for the galvanostatic transients, the inverse of [29], namely [24], must apply. Under conditions in which [24] is satisfied, the kinetics of the transients are effectively independent of polarization mechanisms involving thermal activation, making the analysis relatively easy.

Accordingly, for [24] and [25] valid approximations (which will only be true for times greater than some value lying beyond the minimum in I) and making the further approximation that E is constant during the potentiostatic transient, [20] integrates to give

$$P = \epsilon_0(K_s - 1)E + \sum_k (P_k^0 - \epsilon_0\chi_k E)\exp(-B_k q) \quad [30]$$

where $q = \int_0^t I dt$ and is the charge passed per unit electrode area, while P_k^0, is the value of P_k for $q = 0 = t$. Eliminating P from [30] using [10], and E and E_d from the resulting equation using [13] and [14] and the approximation $(\partial\beta/\partial E)_T \simeq 0 \simeq (\partial\alpha/\partial E)_T$, gives

$$\ln(I/I_{ss}) = \sum_{k=2,3} A_k \exp(-B_k q) \quad [31]$$

where $A_k = (P_k^0 - \epsilon_0\chi_k E)B_k/\epsilon_0 K_d$ and is independent of time (and q) for E constant.

Extrapolation of the data in Fig. 1 from the region beyond the minimum in I to time zero (in an attempt to estimate the ion current density in the region up to the minimum) and integrating, gives on the basis of the values for the constants obtained in the previous section, $B_3 q >> 1$ and hence $A_3 \exp(-B_3 q) << A_2 \exp(-B_2 q)$ for values of q lying beyond the minimum. Under these conditions (which are the only ones in which [31] is a valid approximation) [31] reduces to

$$\ln(I/I_{ss}) = \ln[I(t = 0)/I_{ss}] \exp(-B_2 q) \quad [32]$$

where the time $t = 0$ is chosen to lie sufficiently beyond the minimum in I so that [23] and [24] are valid.

The solid line in Fig. 1 is calculated from [32] with $B_2 = 6.14 \times 10^3$ cm^2/coulomb and is typical of the fit achieved in a total of five determinations. The value of B_2 was chosen in each case to minimize the variance in I, the mean of the five determinations being given by $B_2 = (6.6_3 \pm 0.3_6) \times 10^3$ cm^2/coulomb in excellent agreement with the value obtained from Dewald's galvanostatic transient data, 6.57×10^3 cm^2/coulomb. No variation of B_2 with the final steady-state current, I_{ss}, was observed.

Using Young's data (11), obtained for a tantala film formed at 100V (constant potential) for 3.5 hr then annealed by immersion in boiling water for 5 min, Dignam and Ryan (14) calculate a value for B_2 of 8.0×10^3 cm^2/coulomb. Furthermore, good agreement with the data was achieved. That this value differs somewhat from those reported above is undoubtedly due to the fact that the films in this instance were formed in an entirely different manner than were those giving rise to the values near 6.6×10^3 cm^2/coulomb. A similar slight dependence of B_2 on film formation conditions (but not on measuring conditions) has already been noted for the system Al/Al_2O_3/electrolyte (14, 8). Since the constants B_2 and B_3 must be dependent on the detailed structure and composition of the oxide film, then if this structure and/or composition varies somewhat with formation current density, say, then B_2 and B_3 will vary with formation current density. For both the aluminum and tantalum systems, B_2 decreases slightly with increasing formation current density, the rate being about 10% per decade of current density for the aluminum system (14).

In a recent paper (12) Young attempted to fit [32] to his potentiostatic data and while he achieved a reasonably good fit, it was not the excellent fit achieved here and previously in this laboratory (14). The reason for this appears to lie in Young's failure to ap-

preciate the approximations inherent in [32] (*i.e.*, conditions [24] and [25]) which restrict its application to the region of the curve lying well beyond the minimum in I.

A-C impedance measurements.—Expressions for $\sigma_{a\text{-}c}/I_0$ and K_{eff} as functions of (ω/I_0) and the system constants (β_t, β_{ss}, K_1 and χ_k, B_k for $k = 2,3$) have been derived by Goad and Dignam (30) from the equations for the dielectric relaxation model on the assumption that inequality [24] is valid. This will be the case for the measurements presented herein since the smallest value of I_0 was 2.33×10^{-4} A/cm^2. The analysis has been extended to include an additional ion-current-driven polarization term by Taylor (31), the result being given in the Appendix. The dashed lines in Fig. 2 and 3 have been calculated from these equations using the values for the parameters obtained from Dewald's data and the values for β_{ss} calculated from Young's steady-state data (25). For frequencies below about 1 kHz, the agreement between the experimental and calculated curves is excellent. At the high frequency end, however, while K_{eff} shows no significant discrepancy, the calculated value for $\sigma_{a\text{-}c}/I_0$ is too low by a factor of about 50. The solid line was calculated from essentially the same set of constants but including an additional set of polarization parameters with the following values: $\chi_4 = 0.52_6$, $B_4 = 3.33 \times 10^7$ cm^2/coulomb. The significance of this particular choice for χ_4, B_4 is covered in Part II of this paper. At this point we simply note that the inclusion of an additional set of polarization parameters with these values does not reduce the high frequency discrepancy in $\sigma_{a\text{-}c}/I_0$ significantly. It appears likely that some new process is responsible for the rapid rise in $\sigma_{a\text{-}c}$ with increasing frequency. We are, however, unable to offer by way of explanation any mechanism which would lead to such a dramatic increase in $\sigma_{a\text{-}c}$ with increasing frequency. If the phenomenon occurs as well during the galvanostatic and potentiostatic transients, then from the value of (I_0/ω) or of ω at which it appears, we calculate that it will make a negligible contribution over the regions of the transient curves which we have analyzed. Thus while the anomalously high values for $\sigma_{a\text{-}c}$ are not accounted for by this model, neither are they in conflict with it.

Other forms of ion current transient.—Young (32) has published data on the tantalum system obtained in the following way. A film was grown galvanostatically until a certain voltage, V', was reached, at which time the voltage was reduced suddenly to zero. The voltage was held at zero for time t' (differing from experiment to experiment) then the voltage V' was re-applied. The so called "instantaneously" observed ionic current, obtained by an extrapolation procedure, was found to be less than the formation current density and to decrease with increasing t'.

In a recent paper (12) Young claims to have analyzed the results of the above measurements on the basis of the dielectric relaxation model obtaining qualitative agreement only. The analysis, however, was based implicitly on the assumption that inequality [24] is valid for the conditions of zero applied potential, whereas it is easily shown from the parameters reported herein and the form of the observed potentiostatic transients that [29] is the correct inequality. The data may be fitted exactly if this correction is made and the τ_j and χ_j' treated as disposable parameters (since one has in effect an infinite number of disposable parameters and the general behavior predicted by the model is correct). Such an exercise is, however, without merit. A test of the model against this or similar data must await independent information on the kinetics of polarization via mechanisms involving thermal activation. Under the high field conditions frequently encountered when dealing with the valve metal oxide systems, these kinetics may not even be in accord with [18]. Measurements relating to charging current made at low field strength will not necessarily give useful information about high field polarization kinetics.

Dell'Oca and Young (33) report a-c impedance measurements on the Ta/Ta_2O_5/electrolyte system made during the course of a potentiostatic transient experiment of the same kind reported herein. They claimed their results to be opposed to the predictions based on the dielectric relaxation model for ion current transients. This claim has already been shown to be incorrect by Dignam and Taylor (34). However, it appears necessary to state our position once again, since the same claim has been repeated in a recent review by Dell'Oca, Palfrey, and Young (13). In this review, no mention is made of our rebuttal.

The argument presented originally by Dell'Oca and Young, and repeated in the review mentioned above, is based on an improper analysis of the data. They fail to consider the contribution to the out of phase a-c current component arising from ion current relaxation phenomena (34). This contribution can be very large (see, *e.g.*, Fig. 3). Most important, however, the model that they discredit is in fact one of their own making, although they claim it to be an extension of the dielectric relaxation model, expected "... on the logic of Dignam's theory..." [ref. (13), p. 17]. In effect they assume that $P_j' = P_j$, $\chi_j' = \chi_j$, and $(1/\tau_j) \propto B_j$ for all j (see [20] and following). We are unable to conceive of any mechanism, reasonable or otherwise, which would lead to such relations. The model presented herein certainly does not, as noted already, nor does the original outdated model (1) which leads to equations substantially of the same form as those for the present model. Furthermore, the experimental results are contrary to these relations, since apparently only two B_k values are required to account for ion current transients, while a large range of τ values appears to be necessary to account for dielectric behavior in the absence of ion current (15).

Summary and Conclusions

The dielectric relaxation model has been shown to give an accurate and self-consistent account of several kinds of ion current transient, the parameters being in every case of the expected magnitude (8). Certain kinds of transients cannot at present be used to provide a quantitative test for the model since information on the kinetics of polarization at high field strengths via mechanisms involving thermal activation is not available.

We are aware of no data which are in conflict with the dielectric polarization model, though a large number of phenomena are not encompassed by it (*e.g.*, the high value observed for $\sigma_{a\text{-}c}$ at high frequencies, see Fig. 2). The crucial test of the theory, however, is to look for direct evidence of polarization changes which are in accord with [19], and test whether or not the kinetics which describe these changes are consistent with those deduced indirectly through the study of ion current transients. The first part of this test has already been reported (6), the results being consistent with the dielectric relaxation model. In Part II of this paper, a quantitative investigation of the ion current driven polarization processes is undertaken.

APPENDIX

Galvanostatic transients.—Using the identical procedure given in ref. (7), Eq. [9] to [11], [13] to [15], [17], and [20], with the inequalities [24] and [25], lead to the following equations for galvanostatic transients when a total of three polarization components

which are driven by the passage of ion current are included. [For details see ref. (31).]

$$\frac{E - E_2}{E_2 - E_1} = M_1 e^{m_1 q} + M_2 e^{m_2 q} + M_3 e^{m_3 q} \qquad [A\text{-}1]$$

where the constants M_j, m_j are related to the system parameters, χ_k, B_k, through the following equations. The parameters B_2, B_3, B_4 are the roots of the equation

$$x^3 + c_1'x^2 + c_2'x + c_3' = 0 \qquad [A\text{-}2]$$

where

$$c_1' = \frac{m_1(1 + M_2 + M_3) + m_2(1 + M_1 + M_3) + m_3(1 + M_1 + M_2)}{(1 + M_1 + M_2 + M_3)}$$

$$c_2' = \frac{m_1m_2(1 + M_3) + m_2m_3(1 + M_1) + m_3m_1(1 + M_2)}{(1 + M_1 + M_2 + M_3)}$$

$$c_3' = m_1m_2m_3/(1 + M_1 + M_2 + M_3)$$

while the parameters χ_k are given by

$$\chi_j = \frac{c_4' + B_kB_lc_5' + c_6'(B_k + B_l)}{(B_k - B_j)(B_l - B_j)} \qquad [A\text{-}3]$$

where $j = 2,3,4$; $k = 3,4,2$; $l = 4,2,3$, and the constants c_4', c_5', and c_6' are given by

$$c_4' = K_1\left[\frac{m_1^2M_1 + m_2^2M_2 + m_3^2M_3}{1 + M_1 + M_2 + M_3} - \left(\frac{m_1M_1 + m_2M_2 + m_3M_3}{1 + M_1 + M_2 + M_3}\right)^2\right]$$

$$c_5' = K_1(M_1 + M_2 + M_3)$$

$$c_6' = K_1\frac{(m_1M_1 + m_2M_2 + m_3M_3)}{(1 + M_1 + M_2 + M_3)}$$

For $\chi_3 = 0$, one obtains by the same process [26] and [27], which in turn are equivalent to those presented in ref. (7).

A-C impedance under conditions of steady-state film formation.—The parallel-equivalent, effective a-c conductivity, $\sigma_{a\text{-}c}$, and effective dielectric constant, K_{eff}, are defined by the equations

$$\sigma_{a\text{-}c} = I_{in}/E_\omega \qquad [A\text{-}4]$$

$$K_{eff} = I_{out}/E_\omega\epsilon_0\omega \qquad [A\text{-}5]$$

where I_{in} and I_{out} are the amplitudes of the a-c current components which are respectively in and out of phase with the a-c field of amplitude E_ω. Equations [A-4] and [A-5] are equivalent to [21] and [22] [see ref. (30)].

Using Eq. [9] to [11], [13] to [15], [17], and [20] with the inequality [24] and the identical procedure given in ref. (30), the following expressions for $\sigma_{a\text{-}c}$ and K_{eff} can be obtained (31)

$$K_{eff} = \frac{\left[\left(K_sT_1 - \frac{\beta_{ss}}{\epsilon_0K_s}T_2\right)I_o^6 + \left(T_3 - \frac{\beta_{ss}}{\epsilon_0K_s}T_4\right)I_o^4\omega^2 + \left(T_5 - \frac{\beta_{ss}}{\epsilon_0K_s}T_6\right)I_o^2\omega^4 + K_1\omega^6\right]}{(T_1I_o^6 + T_7I_o^4\omega^2 + T_8I_o^2\omega^4 + \omega^6)} \qquad [A\text{-}6]$$

$$\frac{\sigma_{a\text{-}c}}{I_o} = \frac{\left[\beta_{ss}T_1I_o^6 + \left(\frac{\beta_{ss}}{K_s}T_3 + \epsilon_0T_2\right)I_o^4\omega^2 + \left(\frac{\beta_{ss}}{K_s}T_5 + \epsilon_0T_4\right)I_o^2\omega^4 + \left(\frac{\beta_{ss}K_1}{K_s} + \epsilon_0T_6\right)\omega^6\right]}{(T_1I_o^6 + T_7I_o^4\omega^2 + T_8I_o^2\omega^4 + \omega^6)} \qquad [A\text{-}7]$$

$$T_1 = B_2^2B_3^2B_4^2$$

$$T_2 = B_2B_3B_4(\chi_4B_2B_3 + \chi_3B_2B_4 + \chi_2B_3B_4)$$

$$T_3 = B_2^2B_3^2(K_1 + \chi_2 + \chi_3) + B_2^2B_4^2(K_1 + \chi_2 + \chi_4) + B_3^2B_4^2(K_1 + \chi_3 + \chi_4)$$

$$T_4 = B_2B_3(\chi_2B_3 + \chi_3B_2) + B_2B_4(\chi_2B_4 + \chi_4B_2) + B_3B_4(\chi_4B_3 + \chi_3B_4)$$

$$T_5 = B_2^2(K_1 + \chi_2) + B_3^2(K_1 + \chi_3) + B_4^2(K_1 + \chi_4)$$

$$T_6 = \chi_2B_2 + \chi_3B_3 + \chi_4B_4$$

$$T_7 = B_2^2B_3^2 + B_2^2B_4^2 + B_3^2B_4^2$$

$$T_8 = B_2^2 + B_3^2 + B_4^2$$

Equations [A-6] and [A-7] reduce to Eq. [10] and [11] of ref. (30) on setting $\chi_4 = 0$.

Transient Response of the System $Ta/Ta_2O_5/Electrolyte$

II: Investigation of Faradaic-Current-Driven Polarization Processes

D. F. Taylor*,[1] and M. J. Dignam*

Department of Chemistry, University of Toronto, Toronto 181, Ontario, Canada

ABSTRACT

Voltage pulse experiments were carried out on the system $Ta/Ta_2O_5/0.2N$ H_2SO_4 to test for the presence of polarization processes which are driven toward their equilibrium (or steady-state) values by the passage of faradaic current. Such processes were observed, their behavior being in quantitative accord with that predicted by the dielectric relaxation model using the system constants determined from measuremens of ion current transients (see Part I). In addition, an "anomalous" effect was observed which appears to be related to the anomalous a-c conductance effect reported in Part I, but is otherwise unexplained. It is believed that these experiments constitute a crucial test of this model, and one that it has passed successfully.

In Part I of this paper (1), the dielectric relaxation model for ion current transients has been outlined and tested successfully against galvanostatic and potentiostatic transient data as well as a-c impedance data obtained during steady-state film formation. However, none of these experiments show directly the presence of a polarization process whose rate is proportional to the ion-current density, such processes being required by the theory.

The problem may be stated as follows. From the values for the constants determined in Part I, the extraordinary polarization current is predicted to be at most a few per cent of the ion current producing it. Even the calculated contribution to the effective dielectric constant made by the ion-current-driven polarization processes during ion-current transients is negligible (2). All attempts to detect the extraordinary polarization current in the presence of ion current are consequently bound to be unsuccessful. It is therefore necessary to observe the effect in the absence of ion current. Equation [20] of Part I, reproduced below for convenience, holds the key to this apparent paradox.

$$dP/dt = \epsilon_0 K_1 dE/dt + \sum_k B_k i(\epsilon_0 \chi_k E - P_k) + \sum_j (1/\tau_j)(\epsilon_0 \chi_j' E - P_j') \quad [1]$$

When ion current is flowing, both types of polarization mechanism operate to produce a change in the polarization of the film on making a sudden change in the field. For a sufficiently small ion current density, all changes in the polarization will be thermally activated. Thus when a square-wave voltage pulse of sufficient amplitude to induce a significant flow of ion current is applied potentiostatically across a preformed film, the polarization of the oxide will be driven upward during the pulse by both the ion-current and thermal mechanisms. After the pulse, however, the polarization must return to its original equilibrium value by thermal relaxation alone, since the ion current is then negligibly small.

The time integral of the capacitive discharge current is a measure of the total polarization induced during the pulse. An increase in the ion current which flows during the pulse should polarize the oxide layer to a greater extent, and this in turn should manifest itself as a larger discharge current. In this paper, the total charge passed during the discharge period, q_-, is measured as a function of the faradaic charge passed during the voltage pulse, q_f, and the results compared with those predicted from the dielectric relaxation model.

Experimental Procedures

A description of the apparatus and materials has been published (3). In a typical run, anodic oxidation of the electrode blade was carried out galvanostatically at 22.6°C with a current density of 2.39×10^{-4} A-cm^{-2}, and film growth was halted at 45.18V (Hg/Hg_2SO_4 reference electrode). A number of pulse measurements were made on each fresh electrode by switching the cell potential sequentially from V_1 to V_2 to V_1. $(V_2 - V_1)$ was held constant at 25.01V for all the experiments, while V_1 ranged between 0 and 25.01V. These values were chosen so that significant ion current would flow only during the charging pulse.

In our earlier investigation (3), the voltage drop across a current-measuring resistor in the potentiostat circuit was monitored by an oscilloscope and camera, and four pictures with different time scales and baseline positions were required for each selected value of V_1. In the present series of experiments, electronic integration of the current-time curves improved the accuracy considerably. The current-measuring resistor was fixed at a value of 20 ohms, and the oscilloscope and camera recorded net charge passed as a function of time. A suitable constant bias voltage was applied to the second input terminal of the oscilloscope just after switching to V_2, and was removed immediately following the return of the cell voltage to V_1. This signal in effect subtracted out the contribution to the total charge made by the fast polarization processes, and allowed the use of a very sensitive scale on the oscilloscope. Electronic integration prohibited a change in measuring resistor midway through the period of interest, but the increase in sensitivity achieved with the biasing voltage more than compensated for this loss.

The polarizing pulse width was varied between 10.6 and approximately 26 msec, but remained constant for the entire set of measurements carried out on a given electrode. Only one voltage pulse and resulting oscilloscope trace were required for each value of V_1. For the first set of experiments, a minimum of 1 hr was allowed between successive pulses and V_1 was changed by no more than 2V between such successive measurements.

In a second series of voltage-pulse experiments, a different approach was used. Rather than waiting for "equilibrium polarization" at each value of V_1, the pulse switching circuit was triggered at 1-min intervals for 10 or 15 min, with only the last charge-time curve being recorded. In all other respects, the experimental procedure for the two series was the same.

Two experimental difficulties were encountered with these measurements, which were not eliminated completely. The first was the appearance of a false charge

Key words: dielectric properties of anodic tantala, polarization processes in anodic tantala, anodic films, thin films, anodic oxides, tantala films.

component at the output of the integrator, arising presumably from circuit transients during the rapid voltage changes from V_1 to V_2 and from V_2 to V_1. Studying the effect in the absence of a cell (*i.e.*, with only the 20-ohm measuring resistance present) it was found that slowing down the switching speed substantially reduced this effect, but did not eliminate it entirely. The residual effect appeared as small, false, charge components, introduced during the two switching intervals, but remaining constant at other times. The false charge components were found to be dependent on load conditions and on $V_2 - V_1$, but not on V_1.

The second experimental difficulty appeared as a short duration anodic voltage pulse superimposed on V_2 and introduced on switching from V_1 to V_2. This meant that significant ion current flowed even for values of V_2 which would otherwise have led to negligible ion current. The amount was small, however, corresponding to the order of 10 nanocoulombs/cm², so that it introduced no difficulties in data analysis.

Results

Figure 1 shows a typical charge-time curve obtained directly from an oscilloscope trace. The position of the curve lying within the field pulse has been reduced by 7.70 μcoulombs/cm² by the application of the bias voltage to the oscilloscope terminals, as described earlier. Thus if it were not for the problem of false charges discussed earlier, the total charge passed per unit electrode area associated with the charging process, q_+, would be given by $Q_+ + 7.70$ μcoulombs/cm². Similarly, that associated with the complete discharge, q_-, would be given by $Q_- - 7.70$ μcoulomb/cm² provided that the discharge is complete within 0.2 sec. Again, assuming that the discharge process is complete within 0.2 sec, then the total faradaic charge passed during the field pulse

$$q_f = q_+ + q_- \qquad [2]$$

would be given by $Q_f = Q_+ + Q_-$.

For a series of measurements performed on a given electrode system and for a fixed value of $V_2 - V_1$, the effect of the false charges is simply to displace the origin of the graph of Q_- *vs.* Q_f a small amount from its correct position. Thus provided that the discharge process is complete within 0.2 sec, the graph of Q_- *vs.* Q_f for a given series of measurements will differ from that of q_- *vs.* q_f only by a shift in origin.

Figure 2 is a superposition of the results of the measurements obtained by the first procedure in which the electrode was held at V_1 for at least 1 hr before applying the voltage pulse. The individual origins have been shifted to obtain maximum coincidence of the data for the different runs. The choice of origin in Fig. 2 can be considered as essentially arbitrary, but corresponds to setting $Q_- = 0$ at $Q_f = 0$.

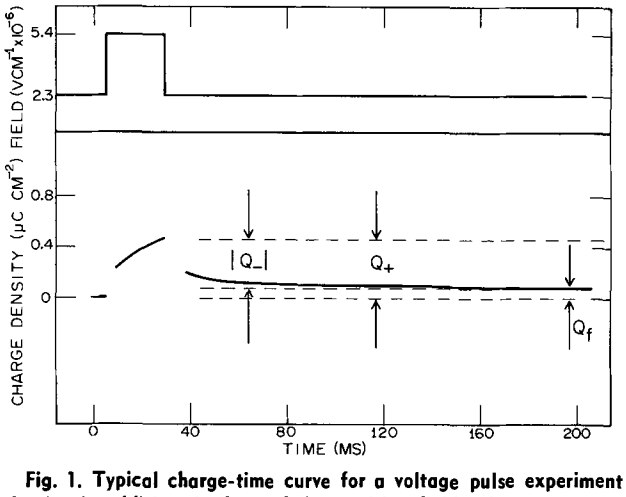

Fig. 1. Typical charge-time curve for a voltage pulse experiment showing in addition the form of the resulting field pulse.

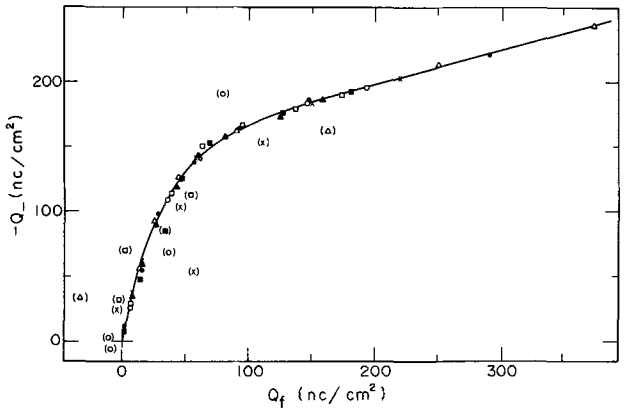

Fig. 2. Dependence of the observed charge passed for the discharge process, Q_-, on the observed faradaic charge passed during the voltage pulse, Q_f, on allowing ~1 hr between pulses. The origin is chosen so that $Q_- = 0$ when $Q_f = 0$. For all runs, $E_2 - E_1 = \Delta E = 3.20 \times 10^6$ V/cm; for runs designated by ▲, ○, and □, pulse width, $t' = 10.6$ msec, E_1 changing from 0.19 to 2.30×10^6 V/cm in steps of $0.26_4 \times 10^6$ V/cm; X, ■, and ●, $t' = 25.9$ msec, $E_1 = 0.19$-2.30 for X, to 1.77×10^6 V/cm for ■ and ●; for △, $t' = 25.9$ msec, $E_1 = 0.72$-2.04×10^6 V/cm plus 2.56 and 2.82×10^6 V/cm. Bracketed points are considered spurious.

Not all of the data obtained have been included in Fig. 2. For values of Q_f larger than about 0.4 μcoulomb/cm², the discharge current decayed over a period substantially greater than 0.2 sec, making the measurement of the total charge for the discharge process effectively impossible due to integrator drift. Data for such runs fall below the extrapolated curve in Fig. 2 as expected.

The results for the second set of experiments, in which voltage pulses were applied at the rate of one per minute for 10 to 15 min before recording the charge are shown in Fig. 3. Again the origins for the individual runs have been shifted to produce maximum coincidence between the runs, and the origin again selected so that $Q_- = 0$ for $Q_f = 0$.

For values of V_1 corresponding to $Q_f > 0.4$ μcoulomb/cm², Q_f and Q_+ were found to decrease initially with successive pulses, reaching ultimately steady-state values. Analysis of these data led to points falling below the extrapolated curve of Fig. 3, as was observed for the first set of measurements, presumably for the same reason.

Analysis and Discussion

Qualitatively, the results of Fig. 2 and 3 confirm our earlier findings (3) that $-Q_-$ is an increasing function of Q_f, as expected on the basis of the dielectric relaxation model for ion current transients. A more detailed analysis of the data follows, the symbols and equations of Part I being used without redefinition.

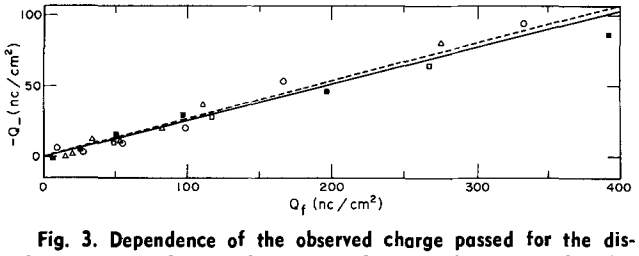

Fig. 3. Dependence of the observed charge passed for the discharge process, Q_-, on the observed faradaic charge passed during the voltage pulse, Q_f, when the repetitive pulsing technique is used. The origin is chosen so that $Q_- = 0$ when $Q_f = 0$. Pulse height and pulse widths as per Fig. 2; ■, E_1 from 3.09 to 1.77×10^6 V/cm in steps of $-0.26_4 \times 10^6$ V/cm; ○, $E_1 = 3.09$-2.04×10^6 V/cm plus 1.51×10^6 V/cm; □, $E_1 = 3.09$-2.56×10^6 V/cm; △, $E_1 = 3.09, 2.82$-2.16×10^6 V/cm in steps of $-0.13_2 \times 10^6$ V/cm.

For a voltage (or field) pulse of sufficiently short duration such that the polarization components P_j' and P_k change very little, the different polarization mechanisms may be treated as operating independently. Thus for such a pulse, the equation describing the time dependence of the component P_k, (Eq. [19], Part I) may be integrated over the duration of the pulse to give

$$q_k = \epsilon_0 \chi_k \Delta E[1 - \exp(-B_k q_f)] \quad [3]$$

where $\Delta E = E_2 - E_1$ is the height of the field pulse, q_f is the time-integral over the pulse duration of the ion current density, q_k is the time integral of the charging current density component, dP_k/dt, over the pulse duration, and the boundary condition $P_k(t = 0) = \epsilon_0 \chi_k E_1$ has been used. Since [3] will in general only be a valid approximation for ΔP_k small, *i.e.*, for $B_k q_f << 1$, we introduce this approximation in [3] to obtain

$$q_k = \epsilon_0 \Delta E \chi_k B_k q_f \quad [4]$$

Using the values of B_k, χ_k, $k = 2,3$ given in Part I, the condition $B_k q_f << 1$, $k = 2,3$ is satisfied for all the voltage pulsing experiments.

In the same way, the equation describing the time dependence of the component P_j' (Eq. [18], Part I) may be integrated over the duration of the pulse to give

$$q_j' = \epsilon_0 \chi_j' \Delta E[1 - \exp(-t'/\tau_j)] \quad [5]$$

where t' is the duration of the pulse, q_j' the time integral of the charging current component, dP_j'/dt, over the pulse duration, and the boundary condition $P_j'(t = 0) = \epsilon_0 \chi_j' E_1$ has been used. Note that for fixed ΔE and t', q_j' is constant; in particular it is independent of E_1 and q_f. This will be the case for any assumed form for the kinetics of a thermally activated polarization process so long as dP_j'/dt is a function of the displacement of the polarization component from its equilibrium value, but not of the polarization state itself. Thus kinetics in accord with $dP_j'/dt \propto \sinh[(\epsilon_0 \chi_j' E - P_j')/c_j'']$ satisfy this condition, whereas those in accord with $dP_j'/dt \propto [(\epsilon_0 \chi_j' E)^2 - (P_j')^2]$ do not. In the following development, we assume that this condition is satisfied and hence that q_j' is a function of ΔE and t' only.

Using this result and Eq. [4], the following expression for the total charge passed per unit area during the charging pulse is obtained

$$q_+ = q_0 + \epsilon_0 \Delta E q_f \sum_k \chi_k B_k + q_f \quad [6]$$

where $q_0 = \epsilon_0 K_1 \Delta E + \sum_j q_j'$ and is a function of ΔE and t' only. Equations [6] and [2] then give

$$-q_- = q_0 + \epsilon_0 \Delta E q_f (\chi_2 B_2 + \chi_3 B_3) \quad [7]$$

Since for all the experiments ΔE had the same value, namely 3.20×10^6 V/cm, while for any given set of measurements, t' was held constant, Eq. [7] predicts that for each set of measurements, $-q_-$ will be a linear function of q_f, with slope $\epsilon_0 \Delta E(\chi_2 B_2 + \chi_3 B_3)$. Thus for data obtained from runs in which the discharge process is complete within 0.2 sec, $-Q_-$ should be a linear function of Q_f with slope $\epsilon_0 \Delta E(\chi_2 B_2 + \chi_3 B_3)$. Furthermore, there should be no difference between the results obtained for the runs involving repetitive pulsing and those for the other runs, since the repetition period is greater than 0.2 sec. From Fig. 2 and 3, this clearly is not the case.

Setting aside this difficulty for the moment, the slope divided by $\epsilon_0 \Delta E$ for the four runs comprising the data of Fig. 3 is given by

$$[\text{Slope of Fig. 3}]/\epsilon_0 \Delta E = (9.3_0 \pm 0.4) \times 10^5 \text{ cm}^2/\text{coulomb} \quad [8]$$

On the basis of Eq. [7] and following, however, we have

$$[\text{Slope (Eq. [7])}]/\epsilon_0 \Delta E = (\chi_2 B_2 + \chi_3 B_3)$$
$$= (2.37 + 7.12) \times 10^5 \text{ cm}^2/\text{coulomb}$$
$$= 9.4_9 \times 10^5 \text{ cm}^2/\text{coulomb} \quad [9]$$

where the values for χ_k, B_k calculated from Dewald's data have been used in [9] (see Part I). The agreement between the observed and calculated slope is excellent. The solid line in Fig. 3 represents the least squares regression line, while the dashed line is drawn in accord with [9].

A similar analysis of that portion of the data in Fig. 2 which appears to fall on a straight line gives

$$[\text{Slope of linear part of Fig. 2}]/\epsilon_0 \Delta E = (9.6_5 \pm 0.6) \times 10^5 \text{ cm}^2/\text{coulomb} \quad [10]$$

again in excellent agreement with the theoretical value.

An explanation for the initial curved portion of Fig. 2 which occurred to us originally was that yet a further polarization component which changes via ion current flow must be present which has a "charge constant," $1/B_k$, of the order of 50 nanocoulombs/cm^2 (see Fig. 2). Including such a term in the analysis, adds to [7] a term of the form of [3], *i.e.*

$$-q_- = q_0 + \epsilon_0 \Delta E q_f (\chi_2 B_2 + \chi_3 B_3) + \epsilon_0 \Delta E \chi_4 [1 - \exp(-B_4 q_f)] \quad [11]$$

The solid line in Fig. 2 is the result of a nonlinear least squares analysis of the data according to [11], with $(\chi_2 B_2 + \chi_3 B_3) = 9.65 \times 10^5$ cm^2/coulomb (see [10]) and B_4, χ_4 chosen to minimize the variance in $-Q_-$. This gave $\chi_4 = 0.53$ and $B_4 = 3.3_3 \times 10^7$ cm^2/coulomb ($1/B_4 = 30$ nanocoulombs/cm^2). Despite the good fit achieved in this way, the explanation must be rejected for a number of reasons. First, the value of B_4 required for the fit corresponds to an interaction radius for the mobile ionic defect of 130Å, which is too large to be physically meaningful. Second, this explanation would not account for the absence of the "anomalous effect" when the experiments are performed by repetitive pulsing. Finally, on noting that the "charge constant" for this anomalous effect (30 nanocoulombs/cm^2) corresponds very closely to that for the anomalous a-c conductance effect noted in Part I (*i.e.*, the rapid rise of $\sigma_{a\text{-}c}/I_0$, Fig. 2, Part I, occurs in the region $I_0/\omega \sim 30$ nanocoulombs/cm^2) it is reasonable to assume that the same process or processes give rise to both anomalous effects. However, the anomalous a-c conductance effect cannot be accounted for simply by introducing the additional parameters χ_4, B_4, with the values given above, as noted in Part I.

As with the anomalous a-c conductance effect, we are unable to account for the anomalous charging process other than to suggest that the two are probably related. Again, however, and for the same reason, the present effect is not contrary to the dielectric relaxation model, but simply not encompassed by it.

Finally, we comment briefly on the observations that for $Q_f \lesssim 0.4$ μcoulomb/cm^2, the polarization induced by the ion current during the voltage pulse can apparently decay via thermally activated mechanisms in a time $\lesssim 0.2$ sec, while for $Q_f > 0.4$ μcoulomb/cm^2, a time greater than 0.2 sec is required for the decay. It would seem that small amounts of ion-current-induced polarization can dissipate via thermally activated mechanisms having small relaxation times, but that with progressively increasing ion-current-induced polarization, thermally activated relaxation mechanisms involving progressively larger relaxation times are involved. This illustrates the complex relationships which apparently exist between the polarization components divided on the basis of their relaxation times under thermal activation, and those divided on the basis of their interaction with the mobile ionic defects. In particular, the relationship $B_j \propto 1/\tau_j$ is clearly invalid. (See Part I for further discussion of this point.)

Criticism of the Dielectric Relaxation Model for Ion Current Transients

As noted in Part I, the authors are aware of no data which are contrary to the dielectric relaxation model for ion current transients. Some criticisms of the model of a more general nature have, however, been offered and we now direct our attention to these.

In a recent review (4) Dell'Oca, Pulfrey, and Young outline a model due to one of us (M.J.D.) and offer criticism of it. As the version of the model they present (5) is out of date, some of the criticism they offer is no longer relevant. The argument which they offer as being "Perhaps the main objection to Dignam's theory . . . . " [p. 17, ref. (4)] is, however, equally applicable to the current version of the model as it is to the original. Their point is that the value of K_s required to account for ion current transients is unreasonably large in relation to K_1. For both the tantalum and aluminum systems, one must set the ratio of the static to dynamic dielectric constant, K_s/K_1, to about 3 to account for the ratio of β_{ss}/β_t. (Note that K_1 is not defined as the dielectric constant at optical frequencies but rather that at a frequency ω' such that $1/\omega'$ is small compared with the times involved for ion current transients to decay.) Their criticism in this regard is based on an extrapolation of the value for the dielectric constant from 1 kHz to 0.01 Hz, from which they conclude that K_s is not expected to be more than 3.5% larger than K_1 (*i.e.*, K at 1 kHz).

A lower bound on K_s may be obtained in the following way which involves neither extrapolation nor assumptions concerning polarization mechanisms, kinetics, or the structural changes corresponding to the polarization changes. It involves simply the integration of the total charge passed following the application of a potential to a preformed specimen, the potential being large, but not so large as to lead to significant ion current. To illustrate the method, the data obtained by Dignam and Ryan (6) on the system Al/Al_2O_3/(glycol-borate electrolyte) will be used, as data for the tantalum system are not available in quite such a convenient form.

The experiments were performed as follows. Aluminum electrodes were formed at a constant current density of about 0.2 mA/cm² up to an anodic overpotential of 41.8V. The anode potential was then dropped to zero and the electrode removed from the cell and immersed in mineral oil at 60°C for 2 hr (to reduce the oxide polarization to zero). Following washing, they were returned to the cell and a linear ramp voltage was applied to the Al electrode in an anodic direction until about 80% of the formation voltage was reached, following which the potential was held constant. The results from one such measurement are reproduced in Fig. 4.

Following the application of the ramp voltage, the "fast polarization processes" will contribute a constant charging current component, $\epsilon_0 K_1(dE/dt)$, which will go to zero once the voltage rise ceases. The total charge corresponding to the area element A_1 in Fig. 4 is therefore the charge associated with the fast polarization processes on charging the electrode system from 0 to 33.8V. Since the steady-state ion current calculated for a field corresponding to 33.8V is negligible compared to the measured current, as is apparently the leakage current (the current is still falling after 400 msec) it is reasonable to assume that essentially all of the measured current is charging current, in which case

$$K_s/K_1 \gtrsim (A_1 + A_2 + A_3)/A_1 \simeq 2 \qquad [12]$$

where A_1, A_2, and A_3 refer to area elements in Fig. 4. This lower bound value for K_s is already impossibly large according to the argument advanced by Dell'Oca *et al.*, but is entirely consistent with a value for $K_s/K_1 \sim 3$. Although experiments of this form have not been performed on tantalum, estimates of K_s/K_1 from the charging currents observed initially in potentiostatic ion current transient measurement (see Fig. 1, Part I) give a value for the ratio approximately the same as that for aluminum.

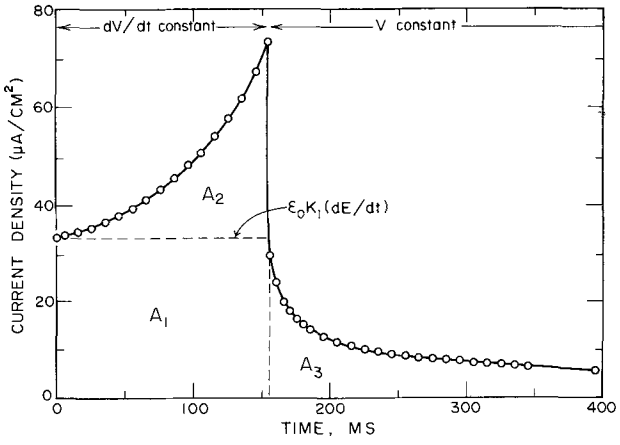

Fig. 4. Charging current transient for the system Al/Al_2O_3/(glycol-borate electrolyte) on reapplication of anodic overpotential at the rate of 209.4 V/sec to 33.8V, to an electrode formed at 0.2 mA/cm² to 41.8V. The data are according to Dignam and Ryan [Fig. 3, ref. (6)].

If most of the thermally activated polarization processes obey kinetics, say, of the following form

$$dP_j'/dt = (C_j''/\tau_j) \sinh [(\epsilon_0 \chi_j' E - P_j')/C_j''] \qquad [13]$$

then they would be active only at high field strengths. This in turn would account for the discrepancy between the estimate of K_s given by Dell'Oca *et al.* and that obtained here.

Reservations concerning certain features of the dielectric relaxation model have been expressed by one of us [M. J. D., ref. (7)]. One concerns the reasonableness of postulating two ". . . polarization mechanism(s) involving ion-current induction" [ref. (7), p. 272]. We now feel that this is not in fact an accurate statement of the postulate which is required to fit the data. Only a single mechanism need be postulated. However, the "slow" polarization components must be assumed to be divided into two classes, each class being characterized by an electric susceptibility parameter, χ_k, and a "relaxation charge density," $1/B_k$. This division could be based on local structure variations, variations in the detailed processes involved in the partner exchange steps required for network defect migration (see Part I), variations in the paths followed by the network defects, etc.

The other reservation expressed in (7) concerns the details of the proposed interfacial reactions. In particular, Siejka, Nadai, and Amsel (8), using nuclear methods of analysis for oxygen 16 and 18 appear to have shown that the contribution of the oxide-solution double-layer to the overpotential during film formation is zero within experimental error for both tantalum and aluminum anodized in an aqueous solution of 5 weight per cent ammonium citrate of pH 6. The implication of this result is that the outer Helmholtz plane and the "oxide surface" essentially coincide. If this is correct, the details of the interfacial model presented in Part I are not. Even if it is not correct, the details of the interfacial model are almost certainly incorrect, at least in part, as already noted (Part I). In any event, rate control by defect injection at one of the interfaces is not precluded, and this assumption is essentially all that is required to develop the model.

Summary and Conclusions

In this investigation, two sets of experiments have been carried out in an attempt to obtain confirmation for the existence of polarization processes which follow equations of the form of Eq. [19], Part I, *i.e.*

$$dP_k/dt = B_{ki}(\epsilon_0 \chi_k E - P_k) \qquad [14]$$

Equation [14] predicts that the presence of ion current during the application of a voltage pulse to an electrode system will lead to a greater polarization increase than would occur in its absence. Such an effect has definitely been observed. Furthermore, one of the sets of measurements (those involving repetitive pulsing) are in quantitative agreement with the behavior predicted on the basis of [14] and the values for χ_2, B_2, χ_3, B_3 determined from ion current transient measurements using the dielectric relaxation model. The other set of measurements also shows the effect predicted by [14], the agreement again being quantitative, but in addition another effect is observed which can be accounted for neither by [14] nor by any other process known to the authors. It appears likely, however, that the same process gives rise to both the anomalous charging effect and the anomalous increase in the a-c conductivity (Part I). While these effects are not encompassed by the dielectric relaxation model for ion current transients, neither are they in conflict with it.

We believe that these experiments constitute a crucial test of the model, and one which it has passed successfully. No other model proposed to date approaches the success achieved here by this model, yet much remains unexplained.

Pitting of Titanium

I. Titanium-Foil Experiments

T. R. Beck*

Flow Research, Inc., Kent, Washington 98031

ABSTRACT

Experiments were conducted in which pitting occurred at the edges and on the circumference of holes in titanium foil in chloride, bromide, and iodide solutions under potentiostatic conditions. Valence of dissolution was approximately 4. The effect of potential, temperature, concentration, pH, and solution flow on current density and pitting potential was determined. Very complex behavior not fitting a single kinetic, mass transport, or ohmic limitation was observed. A model combining a salt film on the metal surface with events in the electrolyte diffusion layer qualitatively fits the data.

Pitting attack of titanium alloys was recently reviewed (1), and thus the literature is not discussed to any extent here. Relatively little experimental work has been reported on pitting corrosion of titanium as compared to aluminum and iron alloys. The present series of papers presents a detailed experimental study of pitting of titanium and a proposed model.

Much of the pitting literature describes work at open circuit in which cathodic reactions on the same specimen provide the corrosion current. While valuable for relating to conditions in the field, such experiments are of limited value in formulating quantitative mechanisms.

Experimental conditions in this work were therefore idealized in order to make measurements that were directly applicable to the pitting surfaces. Specimens were potentiostated so that anodic dissolution currents could be directly measured as a function of potential. Specimen configurations were such that the active corrosion area could be measured and current densities could be determined. Pitting corrosion at the edges of a thin foil is described in this paper. In the following paper the system was further idealized by using artificial pits propagated at the ends of thin rods embedded in insulating material.

Key words: titanium, corrosion, pitting, pitting potential, pitting model.

Experimental

Pitting experiments were conducted with strips of titanium foil in beakers of chloride, bromide, or iodide solutions. The 0.0038 cm thick by approximately 1 cm wide × 5 cm long titanium foil anodes were suspended in the solutions. The analysis of the commercially pure foil is given in Table I. Bakers reagent-grade chemicals and distilled water were used to make up electrolyte solutions. A platinum counterelectrode and a saturated calomel reference electrode were used together with a Wenking potentiostat. All potentials are referred to the saturated calomel electrode (SCE) in this paper. Current measurements were displayed on an x-y plotter or strip-chart recorder. Open-circuit potentials of the foil specimens were measured with a Keithley electrometer. Fast potential transients were displayed on a Tektronix oscilloscope and photographed with a Polaroid camera.

Results

Most of the experiments were conducted in bromide solutions because pitting occurs rather readily and could easily be observed. A high potential is required to initiate and sustain pitting in chloride solutions and the current densities are extremely high. Pitting is somewhat more difficult to maintain in iodide solutions than in bromide and the simultaneously formed iodine obscured visibility.

Current vs. time.—Corrosion occurred at the edge of a foil specimen when it was potentiostated between the steady-state pitting potential of about 0.9V (SCE) and a potential of about 1.4V in neutral bromide solution. At potentials above about 1.4V, oxygen bubbles initially formed on the surface and a pit nucleated under each bubble. The pits were initially hemispherical but soon penetrated the foil and the corrosion then occurred at the circumferences of radially growing holes. A continuous transition from hemispherical pits to corrosion on the edges of the foil in the holes indicates that the same basic phenomenon is occurring. Corrosion at the foil edges, at the circumferences of the holes, and at the outer edges of specimens are considered to be a form of pitting in this paper. Examples of such pitting are illustrated in Fig. 1. In general the edge corrosion surface was more or less planar and at right angles to the foil faces.

Relations of corrosion current to time under potentiostatic conditions are shown in Fig. 2. At 1.2V applied potential the current increased rapidly, passed through a maximum, and then slowly declined. The initial rapid increase can be attributed to growth of cusps along the edge from the points of nucleation. The decline is due in part to uniting of individual cusps to form a smooth front and to decrease in area as the perimeter of the specimen decreases. Current density can be calculated from

$$i = \frac{I}{t\Sigma l} \qquad [1]$$

where I = current, t = foil thickness, and Σl = corroding length. The corroding length can be measured on the edges of the specimen or calculated from the number and the average circumference of the holes.

At a potential of 1.9V, which gives holes, the current increased linearly with time until oscillations set in. Initial penetration of the hemispherical pits through the foil occurs rapidly before the linear increase. Once a group of holes is initiated, they tend to grow in preference to nucleation of new pits. Thus there is a limited range in hole sizes. For the case of n holes growing at a constant current density on their circumferences it can be shown that

$$i = \left[\frac{zF\rho}{2\pi ntM}\,(dI/d\tau)\right]^{1/2} \qquad [2]$$

where ρ = density, M = molecular weight of Ti, and τ = time. The observed linear increase in total current indicates a constant current density at the circumferences of the holes. A reasonable agreement is observed for current densities calculated from Eq. [1] and [2] in Table II for 0.6M KBr solutions.

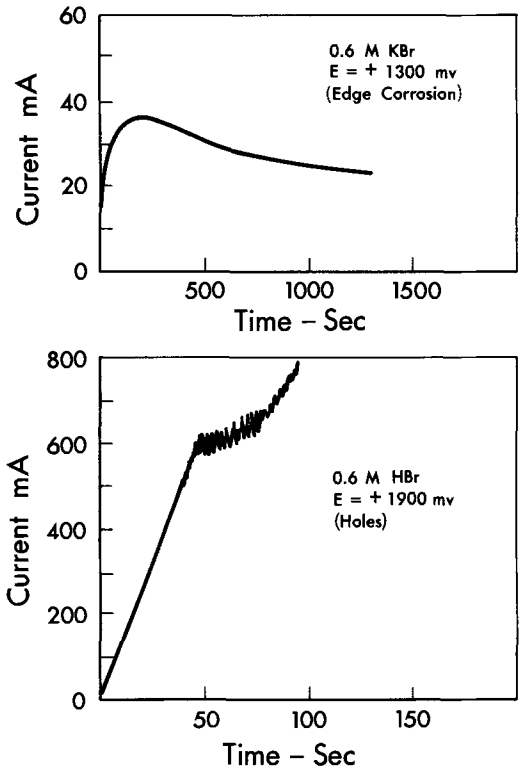

Fig. 2. Current vs. time plots in which corrosion was predominantly at the foil edge or on the circumference of holes.

Valence.—The valence for dissolution of the titanium foil was determined from weight loss of the specimens and an integration of current over the course of the experiments. Data shown in Table III in chloride and bromide solutions indicate a valence of about 4, consistent with results of other workers (2, 3). Iodide solutions were not used because of the observed oxidation to iodine on the foil faces. The experiments were not precise for a number of reasons: halide ion discharge, metal particles, and current oscillations.

Essentially, no valence 3 titanium was produced as there was no trace of the violet Ti^{3+} color produced in solution. Ti^{3+} salts can be readily detected from uniform dissolution in the active region in strong acid solutions well below the pitting potential. During pitting in acid halide solutions a colorless solution can be seen streaming down from the corroding areas. Observed in a 35× microscope, this stream contains small white particles. In neutral or basic solutions a floccu-

lent white precipitate can be seen streaming down from the corroding areas. These observations are consistent with formation of TiO^{++} or TiO_2 to be expected from Ti(IV) under acid and neutral to basic conditions respectively (4) at high anodic potentials.

Current density.—Current density in 0.6M KBr and 0.6M HBr varied with applied potential as shown in Fig. 3. The steady-state pitting potential is about 0.9V in these solutions. All of the pitting potentials given in this paper were determined by starting with specimens corroding at steady state and decreasing potential slowly until corrosion stopped. There is considerable scatter in the data so that it is not clear what relationship of current density to potential gives the best fit. Arrows are drawn from the experimental points indicating the direction of corrections that should be made. An arrow pointing down indicates roughness of the corroding surface and therefore a lower actual current density. An arrow pointing up indicates either that oscillations or a maximum in current occurred as illustrated in Fig. 2. Oscillations may indicate that not all of the corroding surface is active simultaneously.

Effect of concentration.—The relationship of current density to concentration is shown in Fig. 4 for an applied potential of 1.4V. Below a concentration of 0.02M no pitting occurred. At 0.02M the current was very unstable. The best straight line drawn by eye through the log-log plot from 0.06 to 4M has a slope of about 0.27.

Figure 5 shows steady-state pitting potential as a function of concentration for foil in HBr and KBr solutions. The data are rather scattered but show a decreasing trend in pitting potential with increased concentration. The average slope appears to be about −110 mV per decade of concentration on the semilog plot and independent of bulk *p*H in neutral to acid solutions.

Effect of temperature.—The effect of temperature on the pitting corrosion current density is shown in Fig. 6 for 0.6M KBr at potentials of 1.2 and 1.6V. From the slopes of the straight line segments of the log *i* *vs.* 1/T plots, activation energies at 1.2 and 1.6V are 12.2 and 10.0 kcal, respectively. Current density fell off from the straight line relationship at 15°C and pitting corrosion ceased altogether below about 15°C.

Steady-state pitting potential in 0.6M bromide solutions as a function of temperature is given in Fig. 7.

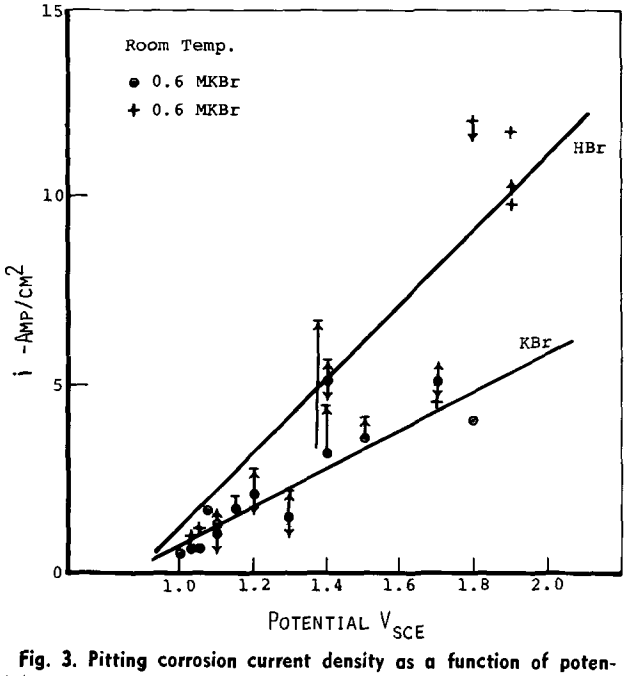

Fig. 3. Pitting corrosion current density as a function of potential.

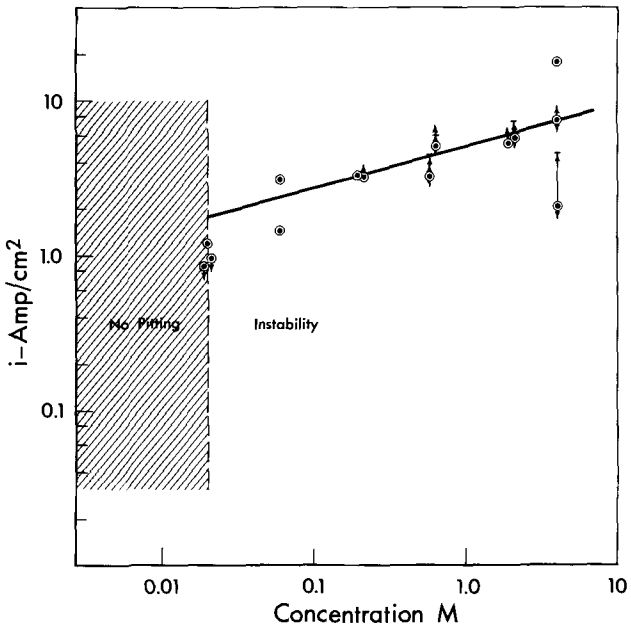

Fig. 4. Relationship of pitting corrosion current density to concentration of KBr at a potential of +1.4V.

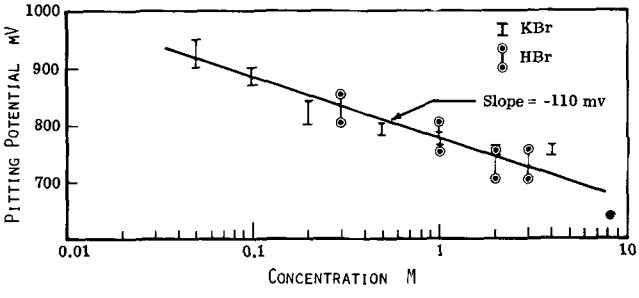

Fig. 5. Effect of concentration on steady-state pitting potential

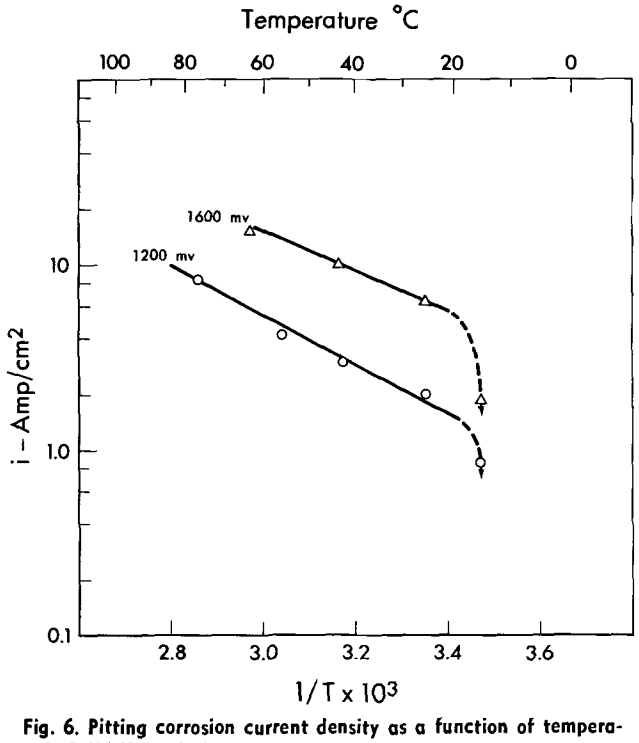

Fig. 6. Pitting corrosion current density as a function of temperature in 0.6M KBr solution.

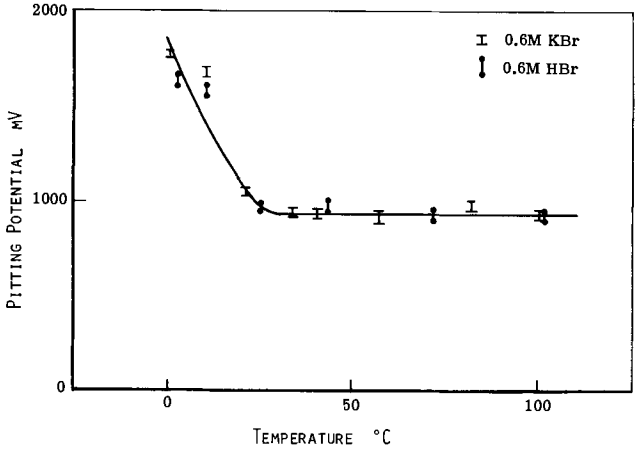

Fig. 7. Effect of temperature on steady-state pitting potential in KBr and HBr solutions.

At room temperature and above, the pitting potential appears to be constant at about 0.9V. Below room temperature the pitting potential rises sharply. This rise in the pitting potential is consistent with pitting corrosion not observed in bromide solution below 15°C in Fig. 6. Experiments conducted in a beaker inside a closed stainless steel pressure vessel gave a constant steady-state pitting potential of about 0.9V up to temperatures above 150°C.

Steady-state pitting potential in 0.6M iodide solutions, given in Fig. 8, increased with temperature and it appeared to be slightly higher in KI as compared to HI solutions. Pitting was very difficult to initiate above room temperature, *e.g.*, it would not initiate at a potential of greater than 10V at 50°C. The points above room temperature were obtained by initiating at room temperature at a high potential (2-5V), increasing the temperature, and then decreasing the potential slowly until pitting stopped. Pitting in iodide was accompanied by iodine formation on the faces of the foil.

An interesting phenomenon sometimes observed above room temperature is the occurrence of "red headed worms." Instead of forming a flocculent precipitate of titanium oxide in solution as is obtained below room temperature in iodide solution or in chloride and bromide solutions, the oxide sometimes forms a more compact wormlike body that is extruded from the pits. The oxide is reddish brown near the pit from tetraiodide or simultaneously formed iodine but the color is removed from the "body" by the solution. The result is a white-bodied "red headed worm" which appears to be gnawing into the edge of the foil.

Heating iodide solutions to near boiling gives readily initiated pitting and a lower steady-state pitting potential of 0.45V. Flocculent precipitated titanium oxide is also formed. As the temperature is lowered the oxide again clings to the surface and below 50°C pitting becomes difficult to sustain. The steady-state pitting potential appears constant between 50° and 100°C in iodide solution.

The effect of temperature on the steady-state pitting potential in bromide and iodide solutions is summarized in Fig. 9. Data of Posey and Bohlmann (5) for 1M sodium chloride solution over a wide range of temperature are also shown. Data obtained in 0.6M chloride solution in this work from room temperature to 100°C are in agreement with that of Posey and Bohlmann. The threshold current density to sustain pitting in chloride solution is greater than 20 A/cm^2 at room temperature.

Transient behavior.—Potential sweep measurements were made to test if a diffusion-limited process is involved in pitting. A diffusion-limited process initially at steady state should have no increase in current density with a rapid potential increase. This was found to be true for high sweep speeds (31,200 mV/min) for potentials below about 1.5V as shown in Fig. 10. Above this potential the current increased even with high sweep speed, indicating initiation of a new process.

Oscillations at a frequency of 1-4 Hz occurred on the downsweep above 1.4V. Below 1.4V the current decreased approximately linearly with potential, characteristic of a process controlled by an ohmic resistance. The extrapolated zero-current intercept potential decreased with higher sweep speed.

When a specimen of titanium undergoing pitting corrosion is suddenly open circuited its potential rapidly decays over the first 10^{-2} sec, goes through a minimum between 10^{-2} and 10^{-1} sec, and then increases to the normal passive potential of about zero volt. The open-circuit potentials were measured with the electrometer and oscilloscope. The minimum potential could be attributed to that of the corroding surface or a mixed potential established thereafter. Minimum potentials for specimens initially corroding at 1.2V in 0.6M chloride, bromide, and iodide solutions are shown in Fig. 11. The minimum potential appears to be relatively insensitive to the potential applied during pitting. In the case of chloride the minimum potential is close to the calculated (6) reversible potential for

$$Ti + 4X^- \rightarrow TiX_4 + 4e$$

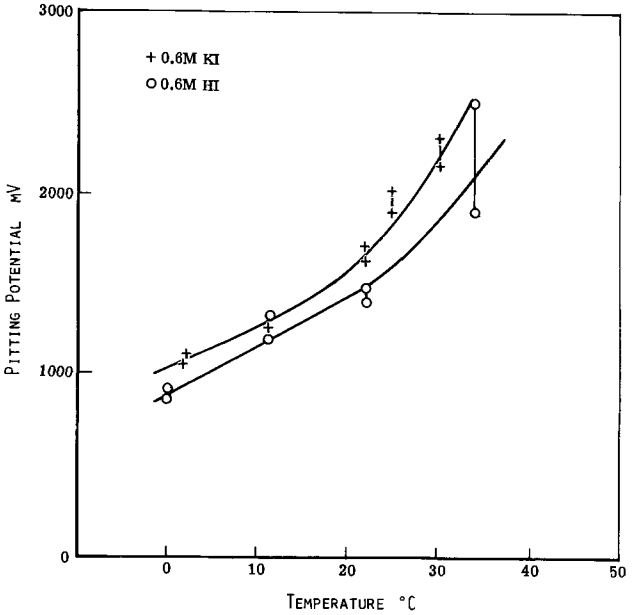

Fig. 8. Effect of temperature on steady-state pitting potential in 0.6M KI and HI solutions.

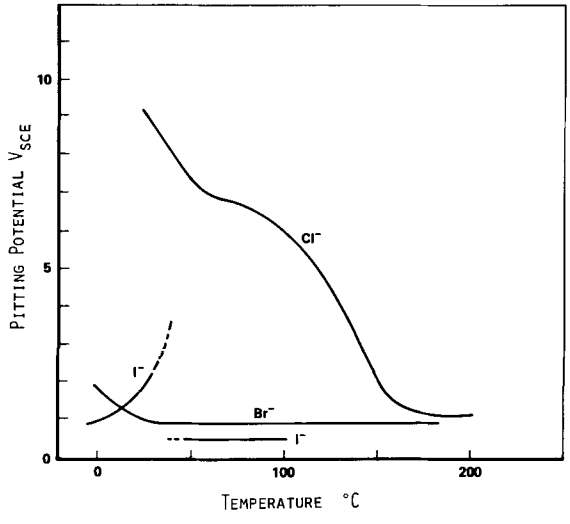

Fig. 9. Effect of temperature on steady-state pitting potential of C.P. titanium in 0.6-1M halide solutions [chloride from Posey and Bohlmann (5)].

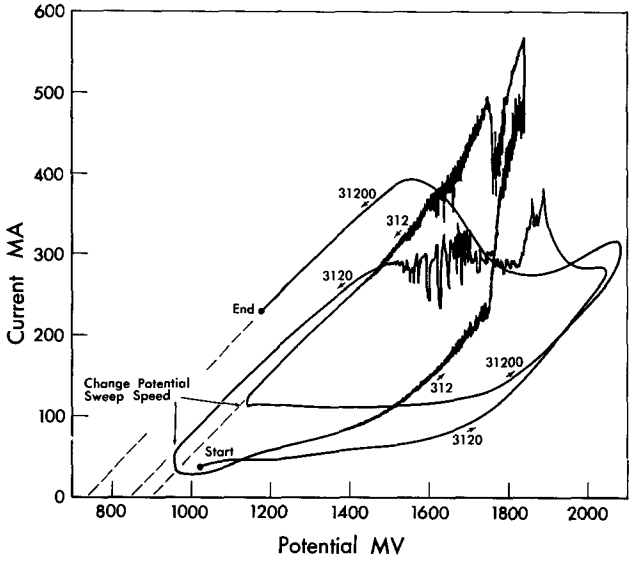

Fig. 10. Potential sweep experiments in 0.6M KBr (parameter in millivolts per minute).

but it is higher for bromide and iodide. Within the experimental error the minimum in bromide solutions was constant with concentration from 0.1 to 6M and with temperature from 0° to 100°C.

The intercepts from Fig. 10 and the minimum potential from Fig. 11 are plotted *vs.* time to reach that potential in Fig. 12. It appears that repassivation of a pitting titanium surface is very rapid below the pitting potential.

Effect of solution flow.—A hydrodynamic flow experiment was designed to verify if a diffusion-limited process is present. The experiment is illustrated in Fig. 13. A pit was initiated in the titanium foil diaphragm by piercing it with the sharpened titanium probe that was connected electrically through a current-limiting resistor to the cell cathode. Once initiated, pitting was controlled potentiostatically. The saturated calomel reference electrode was connected through a salt bridge having a porous Vicor end that has a high flow resistance without an excessive electrical resistance. Solution could be made to flow through the orifice-shaped pit by raising the level of a reservoir of solution connected by rubber tubing. Solution was collected in a graduated cylinder for determining the flow rate. Thus pitting current could be determined as a function of flow rate past the corroding surface under potentiostatic conditions.

Results in bromide and iodide solutions are shown in Fig. 14. The ratio of the current with solution flow to

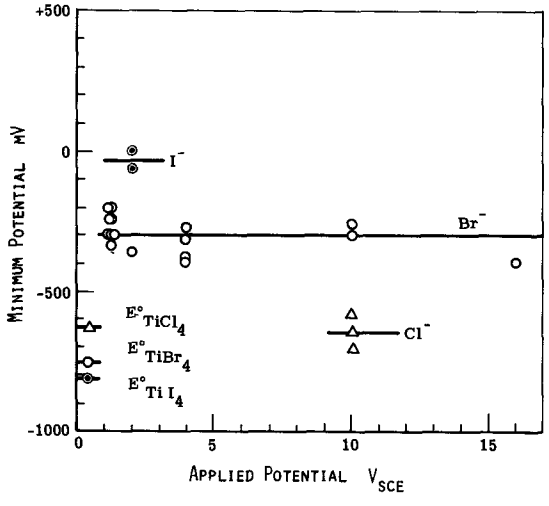

Fig. 11. Initial open-circuit potential during pitting of titanium in 0.6M halide solutions.

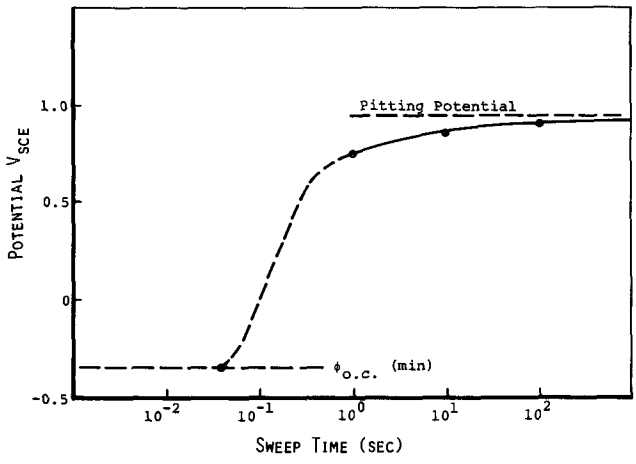

Fig. 12. Potential intercept as a function of sweep time

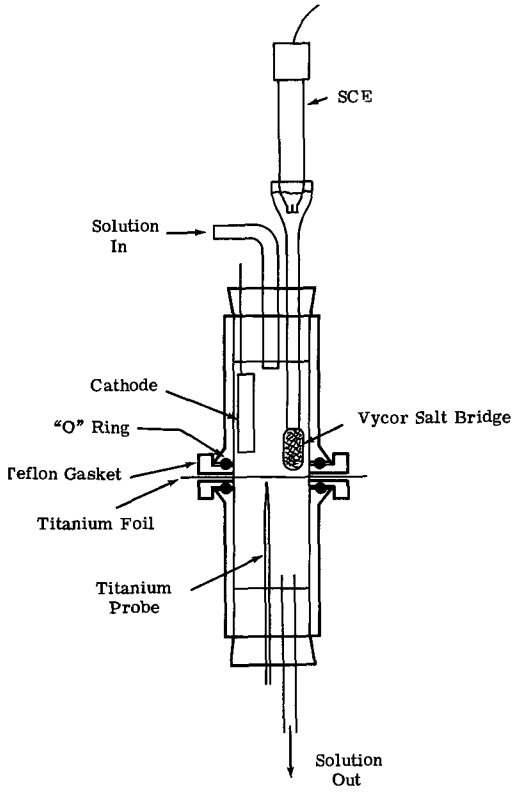

Fig. 13. Apparatus for flow experiment

the current at no flow is plotted against the flow rate. The current increased with flow rate in iodide and decreased with flow in bromide. The effect of flow was greater with the more dilute bromide solution. Pitting corrosion was completely stopped by flow in chloride solutions. Only a qualitative treatment has been made on the effect of flow because quantitative treatment is difficult with the technique used.

Great care was required to initiate pits in chloride solution. The potential was slowly increased to 10V prior to piercing the foil. When a potential of 10V was suddenly applied to a fresh foil in chloride solution, pits initiated at the periphery at the edge of the Teflon gasket.

Discussion

The experimental data make it evident that some rather complex events occur during pitting of titanium. The reaction is not under simple kinetic, mass-transport, or ohmic control. There is apparently a diffusion-limited current density on the upsweep in Fig. 10 but the current density either increases or decreases with fluid velocity in Fig. 14 depending on the

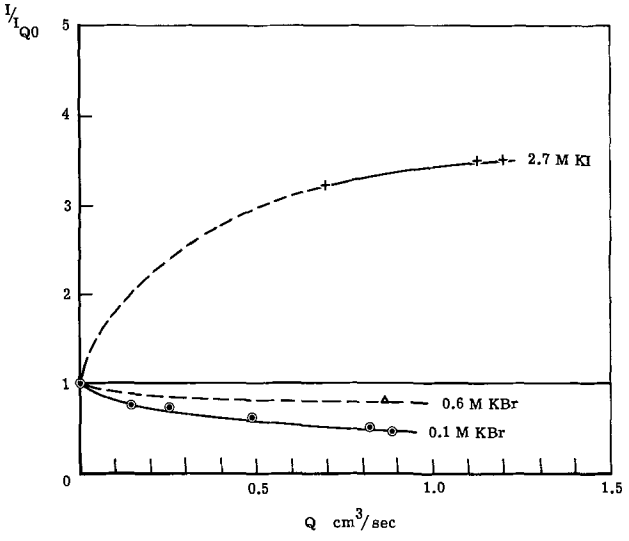

Fig. 14. Results of flow experiments for bromide and iodide solutions.

halide ion. The corrosion current density has a small dependence on halide ion concentration in Fig. 4, but increases appreciably with temperature in Fig. 6. On the other hand, the current density appears to be ohmically controlled on the downsweep in Fig. 10.

Pitting potential for titanium in solutions of the three halide ions exhibits some peculiar increases and decreases in Fig. 9. The zero-current potential intercept decreases with increasing negative sweep speed in Fig. 12 to a value that is to a first approximation independent of initial applied potential, halide concentration, or temperature.

How can these apparently diverse experimental observations be rationalized? A model will be put forth in qualitative form without proof here. Different aspects of it will be mathematically modeled and quantitatively tested in subsequent papers.

Model.—The essence of the model is presented in Fig. 15. It is assumed that a titanium tetrahalide (or oxyhalide) film is formed at the metal surface. On the solution side is a diffusion layer in which the halide dissolves and is transported away. Simultaneously, hydrolysis of the covalent tetrahalide occurs to give TiO^{++} or TiO_2 (depending on the bulk pH) and H^+ and halide ions. Current density at steady state is controlled by diffusion of either water to the salt film surface to dissolve it at a limiting rate or of halide ion to form the tetrahalide. The former is the charge acceptor concept considered by Wagner (7) in electropolishing. The latter would require that the dissolved tetrahalide is completely covalent, giving essentially no halide ions by dissociation.

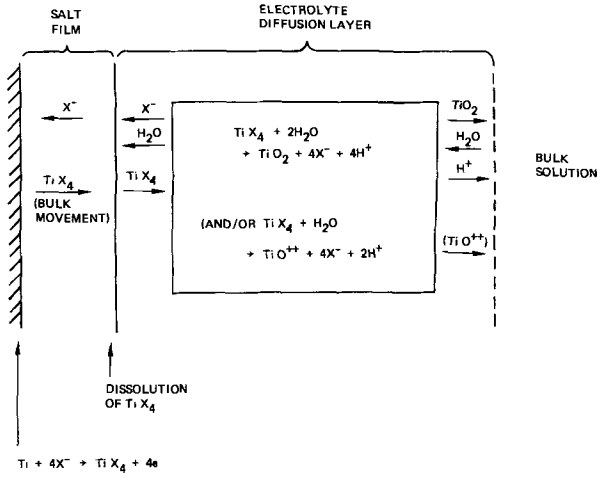

Fig. 15. Model for reactions in pit

The salt film grows to a thickness required to develop a potential drop across it corresponding to the potential applied and the current density. The metal to salt interface is assumed to be approximately the minimum open-circuit potential which is near the calculated reversible potential for the reaction

$$Ti + 4X^- \rightarrow TiX_4 + 4e$$

as indicated in Fig. 11.

The ohmic drop in solution appears to be only a small part of the total difference between the applied potential and the metal-to-salt interface potential in moderately concentrated solutions. Ohmic resistance of the solution can be approximated by

$$R(\text{soln}) = \frac{t \ln (\pi r_2/t)}{\pi\kappa} \text{ ohm-cm}^2 \qquad [3]$$

for hemicylindrical condition in electrolyte with conductivity, κ, between the position of the reference electrode, r_2, and an equivalent half cylinder with half circumference equal to the foil thickness, t. Calculated solution iR drop is 0.22 and 0.57V, respectively, for 0.6M HBr ($\kappa = 0.18$ ohm^{-1}-cm^{-1}) and 0.6M KBr ($\kappa = 0.07$ ohm^{-1}-cm^{-1}) for a current density of 5 A/cm^2. Total potential drops for these two solutions at 5 A/cm^2 *from* Fig. 3 are 1.4 − (−0.6) = 2.0V and 1.9 − (−0.6) = 2.5V, respectively. The differences between the total and solution potential drops can be attributed to the resistance of the salt film.

A rapid decrease in potential from a steady-state condition (Fig. 10) therefore gives a decreasing current density. The active pitting surface apparently passivates rapidly because the minimum open-circuit potential lasts for only a few tenths of a second before a rise to the normal steady-state open-circuit potential for passive titanium. The faster the potenial sweep in the negative direction, the less passivation occurs and thus the more negative the intercept as shown in Fig. 12.

The small dependence of pitting current density on concentration (Fig. 4) is consistent with diffusion of water through the electrolyte being the limiting rate. Regeneration of halide ion within the diffusion layer could also make the limiting diffusion rate of halide ion to the salt surface relatively independent of bulk halide concentration.

It appears from the experiments that a minimum current density of about 1 A/cm^2 is required to sustain pitting at the edge of the foil in bromide solution. The threshold concentration for pitting observed in Fig. 4 could be attributed to too high a solution resistance by Eq. [3] to maintain the required minimum current density.

Hydrolysis within the diffusion layer requires a limited range of the hydrolysis rate constant. If the hydrolysis is too slow it will occur outside of the diffusion layer resulting in no halide ion, oxyhalide, or oxide build-up in it. A large rate constant would give oxide close to the salt film surface which could cause blockage of dissolution.

Some aspects of pitting behavior in iodide solution could be attributed to oxide blockage. Increased current density with electrolyte flow in iodide solution shown in Fig. 14 could be attributed to decrease in diffusion layer thickness and faster removal of the blocking oxide. The lower pitting potential in HI as compared to KI in Fig. 8 could be attributed to a shift to soluble TiO^{++} in more acid solution. Decrease in pitting potential below room temperature in iodide solution could be attributed to slower hydrolysis and less blockage. The lower pitting potential above 50°C in iodide is consistent with increased rate of nucleation and growth of TiO_2 particles in solution as observed in TiO_2 pigment technology (8).

Pitting behavior in bromide and chloride solutions is consistent with a slower hydrolysis rate expected for the respective tetrahalides based on larger tita-

nium-halogen bond energies (6). Decreased current density with flow for bromide solutions as observed in Fig. 14 could be attributed to decrease in concentration of hydrolysis products which may be necessary to maintain the salt film and prevent passivation. The relative decrease in current with flow is greater in the more dilute solution which would have the smaller build-up of hydrolysis products at a lower current density. Complete cessation of pitting with flow in chloride solution could be attributed to cooling as well as decreasing concentration in the diffusion layer. Heat flux at a pitting surface in chloride is high enough to cause boiling, *i.e.*, a 9V drop at the surface and 20 A/cm^2 gives 180 W/cm^2 which is considerably greater than the heat flux required for boiling (9). Pitting in chloride solution is accompanied by an intense local agitation at the surface which may be attributed to local boiling.

Pitting potential.—Presence of a salt layer and very rapid passivation below the pitting potential suggests a new mechanism for the steady-state pitting potential. It is the potential at which the salt film thickness is such that a passivating species can be transported through it and cover the surface faster than the salt-forming reaction occurs. Two passivating compounds could be considered for titanium; oxide or hydride. Oxide is considered to be the more likely based on observations to be presented in subsequent papers.

This mechanism for pitting potential is related to one proposed by Vetter (10) except that he based the replacement of salt by oxide on thermodynamics rather than mass transport. Quantitative treatment of the present model will be presented in a subsequent paper.

Conclusions

The following conclusions are based on experiments conducted with edge pitting of titanium foil in chloride, bromide, and iodide solutions.

1. The valence for dissolution appears to be approximately 4.
2. At constant potential, current density in the corroding area appears to be approximately constant as edge pitting propagates in bromide solutions.
3. Current density in the corroding area increases with potential above the steady-state pitting potential in bromide solutions.
4. Current density at constant potential varies only as about the ¼ power of bulk concentration of bromide above a threshold level.
5. Current density at constant potential increases with temperature above a threshold level in bromide solution.
6. Steady-state pitting potential decreases logarithmically with bromide concentration, independent of pH.
7. Steady-state pitting potential bears a complex relation to temperature: it decreases in chloride solution from about 10V at room temperature to about 1V at 200°C, it decreases from about 1.7V at 0°C to 0.9V at room temperature and remains constant to above 100°C in bromide, and increases from about 1V at 0°C to over 10V at 50°C in iodide then drops to 0.45V from 50°C to at least 100°C.
8. With rapid potential transients between 1.0 and 1.5V in bromide solution the current density appeared to be constant on the upsweep as for a diffusion-controlled reaction but decreased linearly on the downsweep as with an ohmic controlled reaction.
9. Repassivation is very rapid below the pitting potential, *e.g.*, about 10^{-1} sec.
10. Hydrodynamic flow past corroding surfaces caused increased current in iodide, decreased current in bromide, and stopped pitting in chloride.
11. A model for the reactions in a pit consisting of a salt film plus electrolyte diffusion layer qualitatively fits the data presented.

Pitting of Titanium

II. One-Dimensional Pit Experiments

T. R. Beck*

Flow Research, Inc., Kent, Washington 98031

ABSTRACT

Experiments were conducted with pitting corrosion of the ends of titanium rods insulated on the sides with epoxy resin. The rods were potentiostated in the anode-facing-up position in chloride, bromide, and iodide solutions. After a small depth of corrosion a uniform current density was obtained characteristic of one-dimensional mass transport and conduction. Current density is mass-transport limited in the electrolyte and it appears that a salt film forms on the metal surface to absorb most of the potential applied.

In prior studies on pitting of titanium (1) it was observed that pits grown on foil were initially approximately hemispherical as observed for other metals (2-4). After the pits penetrated the foil, corrosion continued at the circumference of the holes with no apparent change in mechanism. The new corroding areas were nearly cylindrical and at right angles to the foil faces. A further simplification from a cylindrical to a planar surface would allow a one-dimensional analysis of the mass-transport phenomena.

In the present work, planar corrosion was obtained on the ends of small diameter rods or rectangular prisms of titanium which were cast in epoxy resin like the lead in a pencil. This technique of insulated cylinder has been reported by Edwards (5) with larger diameter specimens of copper in studies of electropolishing. A related technique was used by Pickering and Frankenthal (6) in which they did single-pit experiments through a hole drilled in a Lucite plate bonded to a steel surface.

Experimental

General.—Commercially pure, A-75, titanium from Titanium Metals Corporation was used for the experiments. Cross sections of three different size specimens were 0.163 cm diameter, 0.1 × 0.1, and 0.16 × 0.32 cm with lengths of 3-6 cm. The specimens were cast in epoxy resin with an outside diameter of 0.6 cm. The working end of each titanium "pencil" was ground flat with silicon carbide paper on a belt sander before each experiment. The initial surface was not critical as the corrosion reaction shortly established its own configuration of the surface.

All experiments were conducted with the titanium in the anode-facing-up position. Most of the experiments were done in an inverted cut-off polyethylene bottle with the titanium pencil mounted in a rubber stopper similar to the arrangement in Ref. (5). Electrolyte filled the cell to a level about 1 cm above the end of the pencil. Events in the "pit" formed at the working end of the pencil were observed through a B&L binocular zoom microscope at 7 to 35X. The cell was potentiostated using a Wenking Model 66TSI with platinum counterelectrode and saturated calomel electrode (SCE) reference. All potentials cited in this paper are in respect to the SCE. Most of the potential drop in the cell was within the pit, so the location of the counter and reference electrodes was not important electrically and they could be located at the side of the cell out of the way of the microscope. All experiments were conducted at room temperature (~21°C) unless otherwise specified. All chemicals used were Bakers reagent grade without further purification. Solutions were made with commercially supplied distilled water.

Cell current and electrode potential were displayed on a Hewlett-Packard strip chart recorder and X-Y plotter. Fast transients were displayed on a Tektronix oscilloscope and photographed with a Polaroid camera.

* Electrochemical Society Active Member.
Key words: titanium, corrosion, pitting, pitting potential, pitting model.

Potential vs. pit depth.—A cell illustrated in Fig. 1 was designed to measure the potential drop in the pit electrolyte. The cell was made of Plexiglas pieces cemented together. The titanium pencil was fitted in the bottom of the cell with a threaded Teflon sleeve. An annular platinum disk counterelectrode was axial to the titanium pencil. The titanium pencil was potentiostated in respect to a calomel reference electrode mounted in the cell.

A scale drawing of the Luggin capillary in the artificial pit showing the important dimensions is given in Fig. 2. The cross-sectional area of the tip was 2.4% of the area of the pit. Measurements of potential *vs.* position were made over a range of pit depths from 0.07 to 0.12 cm. At a distance above the pit the capillary flared out to a shaft diameter of 0.1 cm that fitted into a Plexiglas bushing mounted on split titanium leaf springs. A sliding fit sealed with stopcock grease was used in order to avoid breaking the capillary tip when it hit the electrode at the bottom of the pit.

The Plexiglas bushing mounted on split leaf springs of titanium maintained axial alignment of the Luggin capillary. The bushing and capillary were forced down against the spring by a micrometer head mounted on top of the cell. A Teflon tube filled with electrolyte connected the Luggin capillary-bushing assembly to a second calomel electrode in a reservoir outside of the cell. The signal from this calomel electrode was fed into Keithley Model 610B electrometer.

A Helipot connected as a voltage divider across a mercury cell provided an electrical analog signal of the Luggin capillary position. The Helipot was attached to the cell through a leaf spring which allowed axial movement but prevented rotation, and the shaft was connected to the micrometer. The signals from the Helipot and from the electrometer connected to the

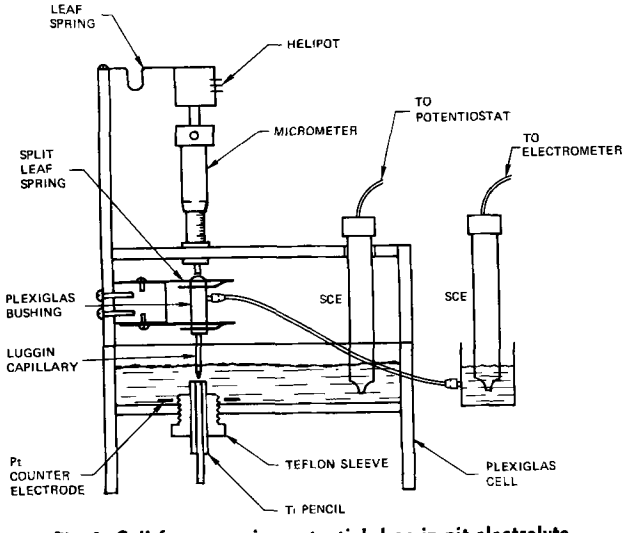

Fig. 1. Cell for measuring potential drop in pit electrolyte

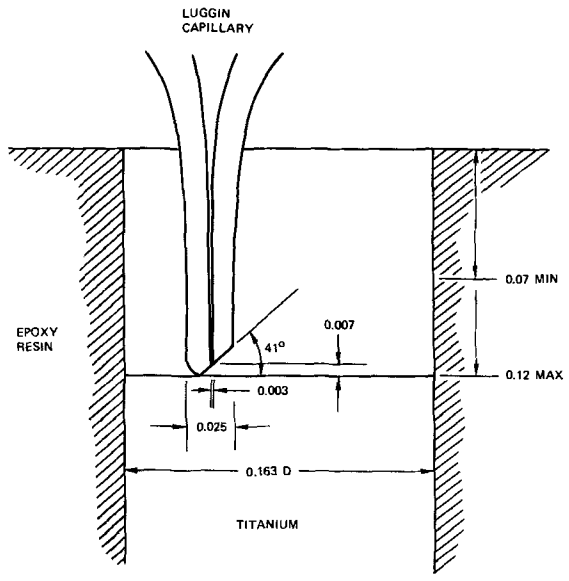

Fig. 2. Scale drawing of Luggin capillary in artificial pit. Dimensions in centimeters.

SCE from the Luggin capillary were displayed on the X-Y plotter. The Helipot signal, which was linear with Luggin capillary position, was calibrated with the micrometer. During the experiments periodic checks of Luggin capillary position and pit depth (seen through the epoxy resin) were made with a cathetometer.

Open-circuit potential transients.—The pattern of decay of potential of a working electrode with time after open circuiting is diagnostic in determining the type of potential drop, *e.g.*, electrolyte ohmic drops should disappear immediately while activation overvoltage should decay with log time (7).

A titanium pencil was potentiostated in a polyethylene cell. The circuit was opened by a Stevens Arnold, Inc. millisecond relay on the counterelectrode side. The signal from a separate calomel electrode in the cell was fed into a Tektronix Model 510 oscilloscope for short-time transients and through the electrometer to the strip chart to record longer period transients.

For each applied potential to the specimen a series of open-circuit transients was photographed on the oscilloscope screen at sweep speeds a decade apart from 10 μsec/cm to 100 msec/cm. The strip chart was used to obtain data out of 10 sec or more. This procedure gave some overlap for each scale when the data were replotted on a semilog graph.

Identification of gas from pits.—A small amount of gas was observed to emanate continually from the pits. An experiment was devised to determine if the gas was hydrogen or oxygen. The gas was collected in a section of 1 ml burette with a flared end filled with water and inverted over an artificial pit. After a few tenths of a milliliter of gas were collected, either hydrogen or oxygen were introduced. The gas mixture was sparked with platinum electrodes at the top of the burette and change in volume was determined.

Photographs.—Photographs of the corroded surfaces were taken with an Ultrascan Model SM-2 scanning electron microscope (SEM). All of the surfaces were prepared by corroding at constant potential. The total charge passed was 1000-2400 coulombs/cm^2 at 2.0-6.0V, 750 at 1.5V, 490 at 0.98V, and 120 at 0.94V.

Results

Current-potential curves.—A typical series of current-potential curves is shown in Fig. 3 for pitting of the 0.1 × 0.1 cm titanium pencil in 1M KBr. These curves obtained with a sweep rate of about −20 V/min, were taken at various times during propagation of a pit at a potential of 6.0V. Amount of charge passed up to the time of the measurement is the parameter.

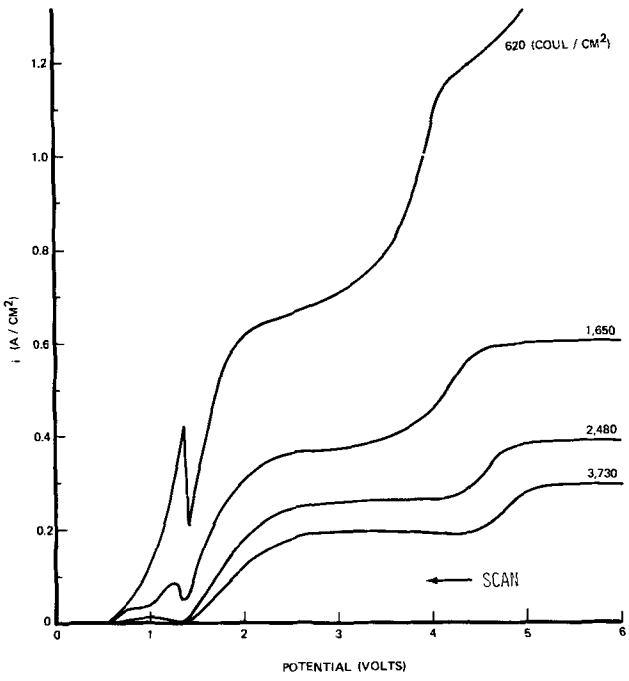

Fig. 3. Transient current density-potential curves for 10^{-2} cm^2 titanium electrode in 1M KBr. Parameter is amount of charge passed.

Three regions are observed: a hump between the pitting potential and 1.4V, a plateau between about 2.0V and 3.5-4.5V, and a second plateau about 4.0-5.0V, at least out to 17V. These will be referred to as the hump, the lower plateau, and the upper plateau, respectively. At slower sweep speeds the maximum of the hump occurs at a potential of about 0.98V and the steady-state pitting potential is 0.9V. With elapsed time or charge passed the current density in all three regions decreases and the half-wave potential between the lower and upper plateaus increases. The minimum between the hump and the lower plateau tends to remain constant at 1.4V. A positive sweep rate gives similar shape curves except that a second hump in current density occurs on the lower plateau at 1.8V.

Current-potential curves for more nearly steady-state conditions for 0.16 × 0.32 cm titanium pencils in 4.4M HBr are shown in Fig. 4. These curves were constructed from the constant-potential experiments from which the SEM photographs were taken. Interpolations were made for three charge densities. The current density decreased in these runs in a range of 0 to −1.7 power of the cumulative charge density depending on potential and charge density. The large nega-

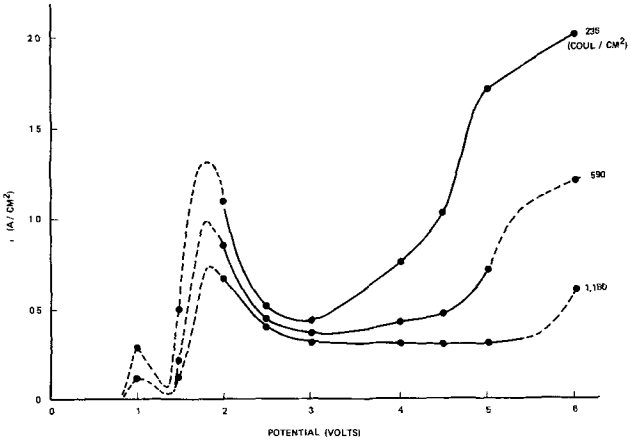

Fig. 4. Steady-state current density-potential curves for 0.05 cm^2 titanium electrode in 4.4M HBr. Parameter is amount of charge passed.

tive slope was related to the change from the upper to the lower plateau.

Above room temperature (50°-77°C) strong oscillations occurred between 0.9 and 1.5V in 4.4M HBr solution. The frequency was about 10 cycles/min.

The character of the corroding surface was different in the three regions. At the hump and up to a potential somewhere between 1.5 and 2.0V the pit was covered with what looked like a layer of compact gray mud. The metal surface after cleaning ultrasonically or by cathodic hydrogen evolution was very porous as can be seen for 0.94, 0.98, and 1.5V in the SEM photograph at 1000X in Fig. 5a, 5b, 5c.

On the lower plateau an orange-to-white precipitate was formed and extruded from the pit. The outer surface was chunky and white and the chunks slowly dissolved in the HBr solution. Deeper in the pit the material was orange and appeared to be somewhat gelatinous. Most of the material was easily removed with a jet of water after the experiments except for a thin film that adhered to the surface. After washing this film with acetone and drying it usually cracked and pealed off. The underlying metal surface appeared bright and crystallographically etched under the 35X binocular microscope. The SEM photograph in Fig. 5f shows the faceting and what looks like terraces. The transition to the terraced condition at 2.0 and 2.5V is shown in Fig. 5d and 5e.

On the upper plateau, a viscous orange solution covered the bottom of the pit and the shiny metal surface could be seen through it. With time the solution became translucent and the metal surface could no longer be seen. In washing out the pit material as above a salt film adhering to the metal was also observed. The underlying metal was polished as can be seen in the SEM photograph in Fig. 5g and 5h. In spite of being polished, it can be seen that there remained some differential metal removal between different grain faces. Some round bumps also covered the surface. Frankenthal and Pickering (8) also observed porous crystallographic and polished surfaces during the pitting of iron.

Good leveling of the titanium surface, as opposed to the above microtexture, occurred in bromide solution at all potentials as the pits deepened. Initially, when a potential above 2.5V is applied to a sanded pencil end the corrosion starts at the circumference of the titanium. The gelatinous corrosion product then spreads inwardly until the whole surface is active. Corrosion is initially greater at the circumference of the titanium as would be expected for primary current distribution. As the pit deepens, the surface becomes very level and at right angles to the epoxy resin walls. The surfaces were usually rougher in chloride and iodide solutions.

Stirring the precipitate in the pits with a glass microstirring rod always caused the current to increase in all three regions. Sometime the small gas bubbles (0.001-0.01 cm diameter) agglomerated into a larger bubble that filled the pit and forced out the precipitate. Current decreased during the growth of these bubbles and increased on their release. In switching from the upper plateau to 1.5V such a conglomerate bubble always formed. As it pushed up the precipitate a layered structure could be observed. Typically there was a compact layer about 10^{-3} cm thick that was next to the metal surface with a columnar layer about 10^{-2} cm thick above it.

In the prior paper (1) it was found that flow of electrolyte past the corroding surface in chloride solution stopped pitting. This was attributed to decreasing the diffusion layer thickness and removing hydrolysis products essential to the pitting process as well as decreasing temperature which appears to be at boiling in chloride solutions. Increasing the diffusion layer thickness in chloride solution should therefore promote pitting. An experiment was conducted with a titanium pencil in the anode-facing-up position in 6M HCl to test this idea. As corrosion propagated and depth increased, the potential to sustain pitting increased as shown in Table I, and the threshold current density, shown in Fig. 6, decreased as expected. The depth was calculated from the charge passed for valence (IV) titanium produced and checked with measured depth at the end of the experiment. Apparent electrolyte conductivity in the pit, calculated from the threshold current density, potential, and pit depth in Table I is seen to decrease exponentially with depth.

Generation of gas.—Volumetric measurements with the gas burette during pitting of titanium pencils in chloride solutions are given in Table II. Chloride solutions were used because the higher current density therein gave sufficient gas generation rate for measurement, whereas the gas generation rate was very low in bromide solutions. Only three possible gases, hydrogen, oxygen, or chlorine, could be generated in the pit under these conditions and the experiments were designed to determine which one.

Column 1 of Table II gives data for the gas collected from pitting in 1M HCl. The gas was sparked after collection, giving a decrease in volume indicating a combination of part of the gases. Hydrogen was then added from a platinum wire cathode in the same solution. No change in volume occurred on sparking, indicating that there was no residual oxygen (or chlorine) in the gas after the first sparking. The gas burette was then transferred without spilling to a cell with 1*N* H_2SO_4 electrolyte and oxygen was collected from a platinum wire anode. After sparking, the volume decreased as noted in column 1a. These results show that the gas from the pit was predominantly hydrogen but some oxygen (or chlorine) was also present.

Column 2 gives data for gas collected from an alkaline chloride solution in order to eliminate the possibility of chlorine being present. The solution was boiled in a flask to remove dissolved air and then cooled and poured into the cell with a minimum of agitation to minimize further air dissolution. A decrease in volume of the collected gas occurred on sparking showing that again a mixture of combustible gases were present. The burette was then transferred without spilling to a preboiled and cooled 0.3M NaOH solution in which oxygen was collected from a platinum wire anode. The gas was sparked during collection of oxy-

gen and the volume decreased linearly with time then increased linearly at the same rate. An amperometric equivalence point was thereby obtained at a residual volume of 0.095 cm^3. The residual gas is assumed to be nitrogen from air that redissolved in the solutions.

Column 3, Table II, shows the results of an experiment in which hydrogen was collected from a platinum wire cathode in preboiled 0.3M NaOH solution. Sparking again caused a slight decrease in volume. Addition of oxygen from a platinum wire electrode in the same solution with simultaneous sparking gave a linear decrease in volume followed by a linear increase with an equivalence point at a residual volume as above. In this case, there can be no doubt that the residual gas was nitrogen from dissolved air. A calculation of mass transfer rates of gases from bubbles to solutions (9) confirms that the experimental observations are reasonable. A more sophisticated gas analysis method might have been used but it would have been subject to the same problems of mass transfer in solution.

It appears that hydrogen is the dominant gas, and probably the only gas issuing from these pits. A rough estimate of the amount from the above experiments and counts of bubbles gave an estimated coulombic equivalent between 0.01 and 0.07 that of the anodic current in chloride and in bromide solutions. In general, there appeared to be a greater gas evolution rate at lower potentials and higher temperature.

Potential traverse in pit.—A typical potential traverse for the Luggin capillary is shown in Fig. 7. Calibrations for potential and position are shown. The potential varied smoothly until the tip of the capillary hit the bottom of the pit as noted by the discontinuity followed by a smaller slope. The length of this region of smaller slope is assumed to be the displacement of the Luggin capillary into the Plexiglas bushing (Fig. 1) because the summation of these displacements from each run agreed with measurements made with the cathetometer. The potential on the outward traverse was slightly lower for a given tip position presumably due to disturbing the precipitate with the capillary. The pit current usually also increased during the outward traverse indicating a slight decrease in resistance.

Eleven usable traverses were obtained for the lower and upper plateau between 2.0 and 8.5V applied. Five other runs were rejected because they were taken below 2.0V, had an inadequate sensitivity, or the curve was erratic. Slopes were determined for each usable curve and the electrolyte conductivity was calculated as a function of position by Ohm's law

$$\kappa = -\frac{i}{d\phi/dl} \qquad [1]$$

using the current density i at the time of measurement. Values of κ were averaged as a function of position from the pit bottom and plotted in Fig. 8 with their standard deviations. Values for capillary-opening positions outside of the pit mouth were rejected

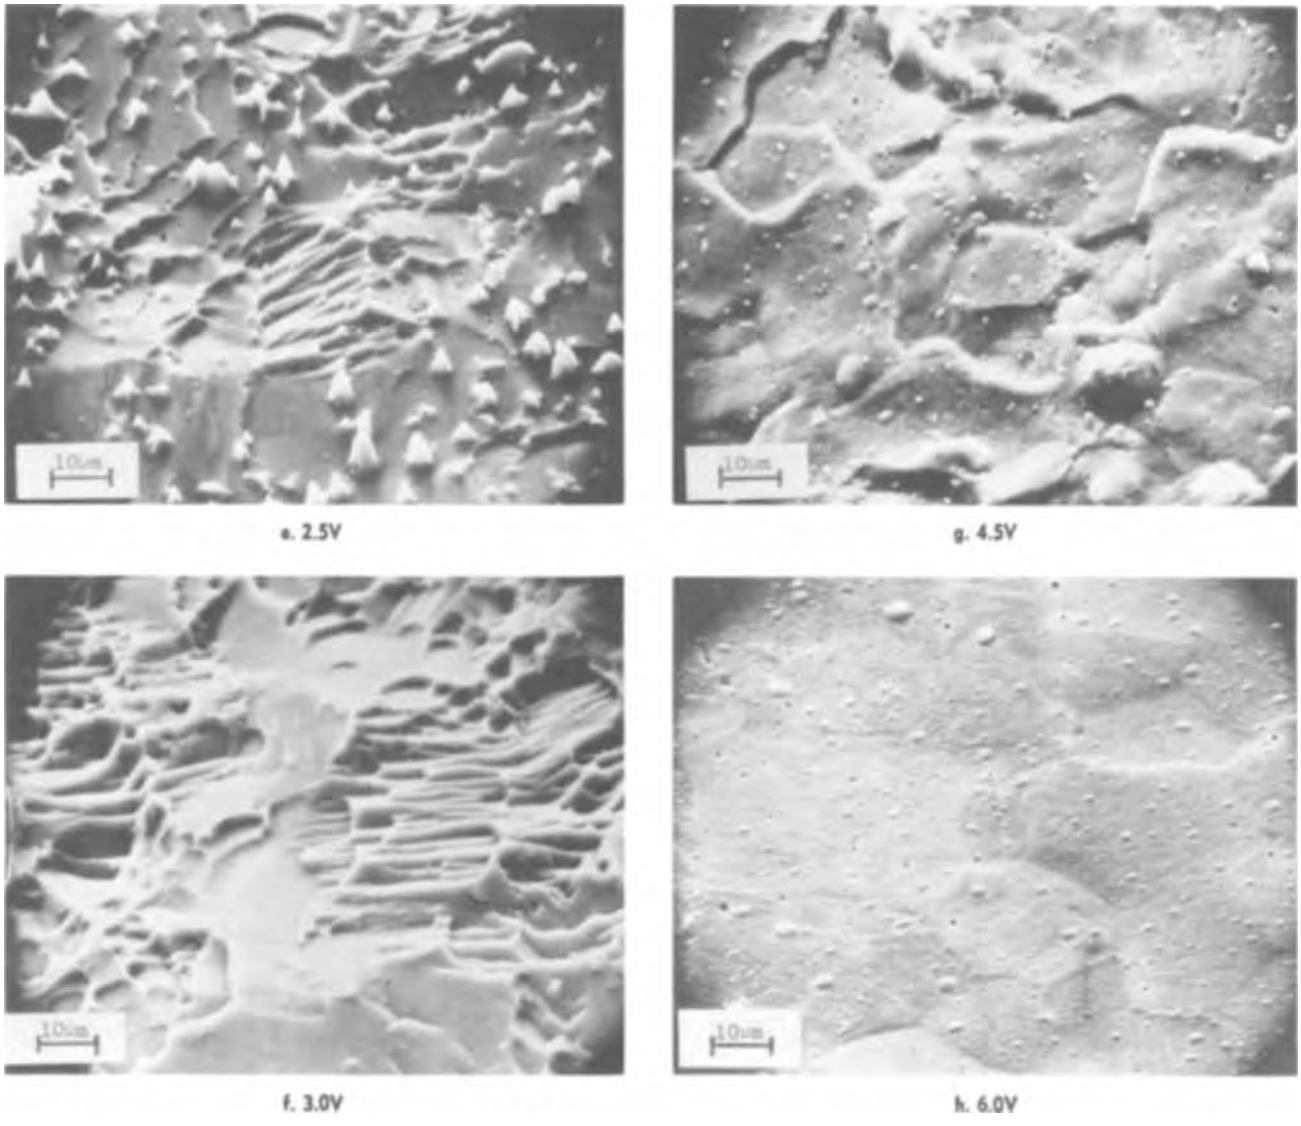

Fig. 5e-h. SEM photographs of titanium surfaces corroded at various constant potentials

from the averages. It is seen that conductivity decreases considerably within the pit and appears to become linear with distance from the bottom for small distances. The straight-line portion extrapolates to zero conductivity at a position equal to the distance of the capillary opening above the tip (Fig. 2) and has the equation

$$\kappa = 2.6l \qquad [2]$$

No significant correlation was found between calcu-

lated conductivities and current density or pit depth within the ranges used.

Open-circuit potential transients.—Potential transient data replotted from oscilloscope photographs and strip chart records are shown in Fig. 9. For applied potentials at 2.0 through 5.0V a linear relationship was obtained between open-circuit potential and logarithm of time from 10^{-6} to 10^{-2} sec. At 7.0V applied the linear region extended only about two decades of time. Below 2.0V there did not appear to be any linear region.

A minimum occurred at about 10^{-1} sec from open circuit for all applied potentials. Values of this minimum are shown in Fig. 10 for pits in 4.4M HBr and 5M HI. These were determined by visually observing the oscillosope screen for repeated open-circuit transients. The minimum could be interpreted as either the potential of the corroding surface or a mixed potential established at open circuit.

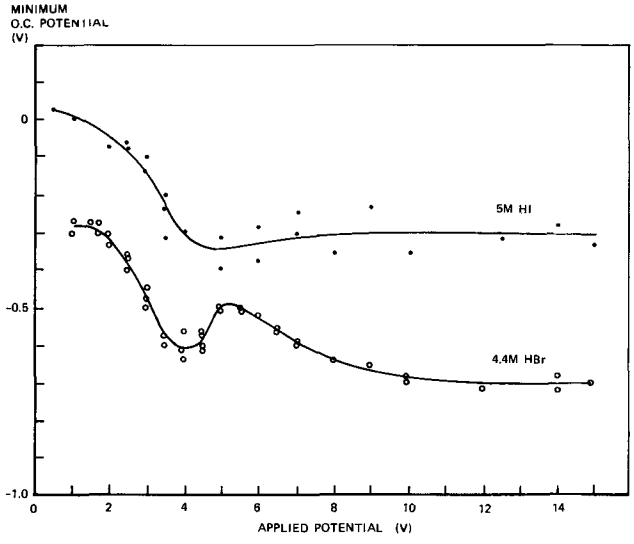

Fig. 10. Minimum open-circuit potentials for titanium pits in HBr and HI.

Discussion

Potential distribution.—The first task is to account for the potential distribution in and around a pit. The ohmic potential drop outside of the pit approximated by hemispherical conduction from an infinite distance to the pit mouth

$$\Delta\phi_{oo} = \frac{ir}{\kappa} \qquad [3]$$

is on the order of tens of millivolts for the current densities, pit radii, r, and conductivity, κ, for the concentration (4.4M HBr) used in the experiments. Measurements with the probe cell (Fig. 1) were in agreement with the low values predicted by this calculation. The metal surface is at a potential negative to the hydrogen electrode as demonstrated by hydrogen gas issuing from the pits in agreement with the minimum open-circuit potentials of −0.3 to −0.7V in HBr (Fig. 10). Therefore, nearly all of the difference between the applied potential and this negative potential must be accounted for within the boundaries of the pit.

An approximation for the ohmic potential drop inside the electrolyte of the pit is made by integrating Eq. [1], using the linear conductivity relationship of Eq. [2]

$$\Delta\phi_{ol} = \frac{i}{2.6} \ln (l/l_o) \qquad [4]$$

For a pit depth, $l = 0.1$ cm and a lower bound distance of molecular dimensions, $l_o = 10^{-7}$ cm, $\Delta\phi_{ol} = 5.3i$. This is, of course, a gross extrapolation down to molecular dimensions but it will serve as a first approximation. Values of Eq. [4] are shown in Table III, together with applied potentials and current densities from the potential-traverse experiments. It is seen

Table III. Calculation of potential drops in pit

ϕ_p (V)	i (A/cm^2)	ϕ_{oc} (V)	$\Delta\phi_{oo}$ (V)	$\Delta\phi_{ol}$ (V)	Unaccounted $\Delta\phi_u = \phi - \phi_{oc} - \Delta\phi_{oo} - \Delta\phi_{ol}$ (V)
1	0.005	−0.28	—	0.03	1.25
1.5	0.06	−0.28	—	0.32	1.46
2	0.11	−0.40	0.01	0.58	1.81
3	0.12	−0.48	0.01	0.64	2.47
4	0.11	−0.62	0.01	0.58	4.03
5	0.18	−0.50	0.02	0.95	4.53
8.5	0.25	−0.65	0.03	1.33	7.79

that the largest component of potential by difference $\Delta\phi_u = \phi - \phi_{oc} - \Delta\phi_{oo} - \Delta\phi_{oi}$, is unaccounted.

The unaccounted potential could either be due to error in the conductivity extrapolation or to potential drop in a thin salt film. A high surface activation overpotential can be excluded because hydrogen gas is produced.

Potential decay.—The potential decay experiments are diagnostic in that a linear relationship of potential with log time is characteristic of discharge of the electrical double layer by a reaction following Tafel kinetics (7, 10) or to discharge of capacitance across a film by high-field conduction (11). The former gives a constant Tafel slope independent of the initial potential, whereas the latter gives a variable slope which is a function of the film thickness.

A plot of the decay slopes as a function of applied potential from 2 to 5V is shown in Fig. 11. The data appear to be linear and the least squares line has a slope of −0.20 and an intercept of −0.55V. The potential-decay data are therefore consistent with high-field conduction through a salt film, the intercept being the potential for zero salt film thickness.

Presence of a salt film is in accord with the observations of Frank (12) and Vetter and Strehblow (13) for pitting of iron.

Paradox.—An apparent paradox exists in that the steady-state polarization data (Fig. 3 and 4) indicate a diffusion-limited process whereas the potential decay experiments indicate high-field conduction controlling. It will be assumed that both operate simultaneously and that they are series processes, *e.g.*, a salt film that maintains a thickness to use up, by high-field conduction, the potential applied and the rate of dissolution of this film is controlled by diffusion of water to the electrolyte-salt interface.

Model.—A qualitative model to describe the events in a pit has already been presented (1). A salt film is assumed to form on the metal surface. The simplest composition, TiX_4, is chosen although it could also be $TiOX_2$ or some other oxy-halide salt of Ti(IV). The halide ion is transported by high-field conduction through the salt to metal surface. The X^- ion occurs at a high concentration in the electrolyte next to the salt film because it is regenerated within the diffusion layer by hydrolysis of TiX_4. The salt is transported away from the metal-salt interface by bulk flow. (The alternative of high-field conduction of Ti^{4+} outward does not change the arguments presented here.)

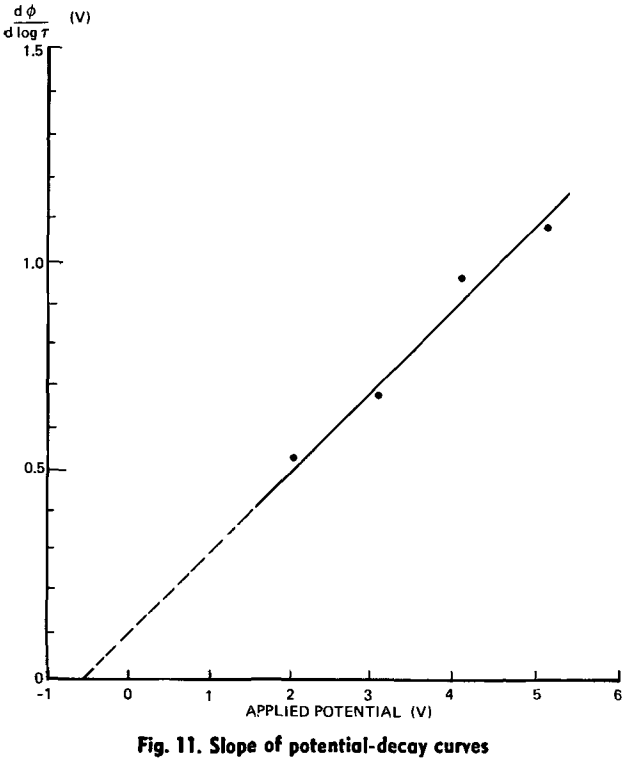

Fig. 11. Slope of potential-decay curves

At the salt-electrolyte interface the TiX_4 dissolves covalently in the water which has diffused to the interface. Within the diffusion layer, hydrolysis of TiX_4 to TiO_2 and/or TiO^{++} occurs, generating halide and hydrogen ions which make the solution acidic regardless of the *p*H of the bulk solution outside of the pit. If the hydrolysis goes to completion within the pit, the overall pit reactions are

$$Ti + 2H_2O \rightarrow TiO_2 + 4H^+ + 4e$$

or

$$Ti + H_2O \rightarrow TiO^{++} + 2H^+ + 4e$$

and only TiO_2, TiO^{++}, and H^+ are transported out. Water is then the only species transported into the pit from the environment at steady state.

Areas of agreement of the experimental data and the model can now be discussed, starting with the diffusion layer.

The orange viscous material deep in the pits in bromide solutions is consistent with the color of $TiBr_4$ or $TiOBr_2$ which would be an expected intermediate in the hydrolysis. White precipitate, at the outer part of the pits, and dense colorless liquid streaming out of the pits, are consistent with TiO_2 and TiO^{++} ion, respectively, expected from valence IV titanium.

Decrease in conductivity with distance into a pit may be attributed to an increase in viscosity due to high concentration of TiO_2 and TiO^{++}. Valence IV titanium has a known tendency to polymerize (14). The linear form of the decrease in conductivity with distance is yet to be understood quantitatively, however. Decrease in conductivity could not be attributed to concentration of conducting species in the model because both H^+ and X^- are generated in the diffusion layer and therefore should be at high concentration.

According to the model, the only species entering a pit at steady state is water. If this is the diffusion-limited species the current density would decrease with depth or thicker viscous layer. That the current density decreased in a variable way from 0 to −1.7 power of depth indicates a complex nature of the viscous layer. Increase in current density with stirring of the viscous layer is in accord with a diffusion-limited species in it.

The rapidly increasing current density with temperatures above 50°C for the lower plateau in iodide solution (1) can only be speculated upon at this time. It is known from TiO_2 pigment technology that nucleation and growth of TiO_2 particles from chloride or sulfate solutions occur above a temperature of 50°-60°C (15) and are arrested below this temperature. Growth of TiO_2 particles in a pit could decrease the concentration of TiO^{++} and thus avoid the viscous polymeric gel.

The requirement for a salt film has already been discussed but the points will be summarized here. The fact that hydrogen gas issues from the pits is the strongest argument that the metal surface is at a negative potential. Hydrogen generation can be attributed to diffusion of hydrogen ions through the salt film. Electric migration tends to carry them out. The observation of increased hydrogen gas rate when the potential was decreased is consistent with a greater diffusion flux of hydrogen ions through a thinner salt film.

Faceting and terraces observed on the metal surface at the lower plateau and the residual differences between grains indicates that the metal is reacting at close (tens of millivolts) to the reversible potential. The reversible potential for the reaction

$$Ti + 4Br^- \rightarrow TiBr_4 + 4e$$

is −0.76V (SCE) according to thermodynamic data in Latimer (16). The minimum in the open-circuit potential (Fig. 10) and the extrapolated intercept of the slopes of the potential decay curves (Fig. 11) are in approximate agreement with a mixed potential from this reaction and hydrogen ion reduction.

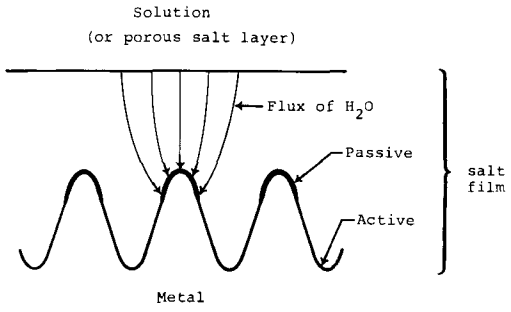

Fig. 12. Mechanism for initiating porous metal surface

Most of the potential drop in a pit cannot be accounted for in any other way than by resistance of a salt film. The potential decay (Fig. 9) and the constant double derivative of open-circuit potential to log time and applied potential (Fig. 11) are in accord with a salt film concept.

Although the model qualitatively is in accord with the experimental observations, several questions remain. The composition of the salt film is not known; whether it is TiX_4, $TiOX_2$, or other. The explanation of two plateaus in current density is unknown. The ratio of current densities of the upper to the lower plateau in eight experiments was 1.53 with standard deviation of ± 0.04. More work would have to be done to resolve which term in the diffusion equation changes by this amount.

Pitting potential.—The same value of pitting potential was obtained for the titanium pencils as was earlier determined for pitting on titanium foil (1), using the same technique of decreasing the potential of a propagating pit until the current decayed to zero. Pitting potential in an artificial pit at the end of a titanium pencil cannot be attributed to an equilibrium between a salt layer and a pre-existing oxide at the boundary of a pit (17) as there is no pre-existing oxide layer present after corrosion has progressed for a period of time.

The porous surface, Fig. 5a, 5b, and 5c, bearing no relation to the metal grains at potentials between the pitting potential and 1.5 to 2.0V needs explanation. Dissolution of a metal under mass-transport limiting conditions should produce electropolishing (18) as was observed on the upper plateau. In order to have preferential dissolution in holes or pores, the peaks must be passivated. A way to accomplish this would be to have diffusion of a passivating agent through the salt layer to reach the peaks at a sufficient rate for passivation but to reach the bottom of the pores at an insufficient rate as illustrated in Fig. 12. This is related to the concept of smoothing agents in electroplating (19) where the agents diffuse to peaks at a sufficient rate to block deposition but do not reach and block deposition in the valleys.

Two possible passivating agents are TiO_2 and TiH_2 layers. A number of considerations point to the oxide as being more likely. Mansfeld (20), for example, found that addition of water to methanol-1*N* HCl (anhydrous) caused the pitting potential to change approximately as

$$\phi_p = -0.4 + 0.15X \qquad \text{V (SCE)}$$

where X is weight per cent of water. Methanol-HCl would have hydrogen ions that could react and form hydride at -0.4V (SCE). Titanium does not passivate in this anhydrous solution (20, 21). Oxide is the only new passivating species expected with the addition of water. A quantitative treatment will be made in a later paper.

Conclusions

The following conclusions are based on experiments conducted with one-dimensional pits at the ends of insulated titanium pencils in the anode-facing-up position in chloride, bromide, and iodide solutions.

1. Current density is uniformly distributed and is mass-transport limited in a viscous solution in the pits.
2. Steady-state pitting potential for the titanium pencil in bromide solution is about 0.9V (SCE) as for earlier experiments with edge pitting of titanium foil.
3. Detailed microstructure of the corroding metal surface is related to the potential applied and varies from a sponge structure through a terraced crystallographic etch to electropolished surface between the pitting potential and about 6V applied.
4. The corroding metal surface is at a potential negative to hydrogen evolution. Hydrogen evolved is equivalent to about 1-10% of the anodic current.
5. Only a small part of the difference between the applied potential and that of the metal surface can be attributed to potential drop in the electrolyte, although the electrolyte conductivity decreases toward the metal surface.
6. It appears that a salt film on the metal surface absorbs the potential applied by high-field conduction.
7. Results observed with the titanium pencils are qualitatively and semiquantitatively in agreement with the dual layer salt-film-diffusion-layer model previously presented.

Electrochemical Deposition of Sodium Tungsten Bronzes

Jean-Paul Randin*

Hydro-Quebec Institute of Research, Varennes, Province of Quebec, Canada

ABSTRACT

The electrochemical deposition of sodium tungsten bronzes (Na_xWO_3) from Na_2WO_4/WO_3 melts has been studied between 700° and 900°C. The relation between the x-value in Na_xWO_3 and the concentration of WO_3 in the melt is linear between 2 and 10 mole/liter WO_3. Extrapolation of the linear section gives $x = 1.0$ at zero concentration of WO_3. The current efficiency of the bronze deposition depends on both the applied current and the melt temperature. This dependence is attributed to the occurrence of simultaneous chemical dissolution of the bronze. A transition temperature has been found below which Na_xWO_3 is deposited, and above which W (or W + Na_xWO_3) is obtained. The nature of the deposit is a function of the melt composition and temperature. The slope of the $(i)_{\eta=\text{const.}}$ *vs.* T^{-1} plot shows no break at, or near, the transition temperature, indicating that the rate-determining step for the deposition of Na_xWO_3 is the same as that for the deposition of W. The tungsten formation occurs most likely by decomposition of the previously deposited bronze. The content of platinum in a platinum-containing bronze is favored by a high temperature. The amount of platinum codeposited in the bronze is small compared to the amount of platinum dissolved from the anode. A relatively high concentration of platinum in the melt inhibits the bronze deposition. A nonelectrochemical reaction is believed to be responsible for the codeposition of platinum.

The sodium tungsten bronzes are nonstoichiometric compounds of the general formula Na_xWO_3, where $0 < x \leq 1$. They are chemically inert and have semimetallic properties, in particular, metallic luster and good electrical conductivity. Their properties have been reviewed recently (1-3).

Two methods have been extensively used for the preparation of these bronzes. The first method involves a solid-state reaction between a mixture of fine powders of sodium tungstate, tungsten trioxide, and metallic tungsten, the latter acting as a reducing agent, at a temperature between 500° and 1000°C in a nonoxidizing atmosphere. This reaction may be written as

$$3xNa_2WO_4 + (6 - 4x)\ WO_3 + xW \rightleftharpoons 6Na_xWO_3 \quad [1]$$

The bronzes produced by this technique are in the form of fine powders (4, 5).

The second method involves the electrolysis of a molten mixture of sodium tungstate and tungsten trioxide; it is essential when large single crystals are required. Crystal growth occurs at the cathode and oxygen evolution takes place at the anode, according to the over-all reaction

$$\frac{x}{2}Na_2WO_4 + \left(1 - \frac{x}{2}\right)WO_3 \rightarrow Na_xWO_3 + \frac{x}{4}O_2 \quad [2]$$

The growth of tungsten bronzes by fused salt electrolysis has been used by a number of investigators [see, for example (6-11)], but virtually no details about the actual growth method were reported until very recently. Banks, Fleischmann, and Meites (12) performed polarographic experiments which revealed a polymeric character of the WO_3 species reduced at the cathode for a melt concentration between 10 and 60 m/o (mole per cent) WO_3 and a temperature of 750°C. This work confirmed an earlier Raman spectroscopic investigation in which the formation of polyions in a Na_2WO_4/WO_3 melt at 710°C was suggested (13). Meites *et al.* (14) studied the voltammetric behavior of polytungstate melts. Potentiostatic investigation of reaction kinetics at the growing and dissolving sodium tungsten bronze electrode allowed Fredlein and Damjanovic (15) to propose two probable mechanisms of the process. Finally, Shanks (6) reported on the parameters for the growth of Na_xWO_3 crystals with predictable compositions and established the phases obtained as a function of melt composition and temperature.

Sodium tungsten bronzes containing platinum[1] have recently been claimed to exhibit a high electrocatalytic activity for the oxygen reduction reaction (16-18) and have attracted attention as possible electrocatalysts in fuel cells and energy storage devices.

The present work deals with the effect of the melt composition and temperature on the bronze composition and the nature of the phases obtained. The effect of current density and temperature on the current efficiency has also been studied, as well as the incorporation of platinum into the bronze crystal. The effect of platinum on the current efficiency and the process of platinum codeposition are discussed.

Experimental

The depositions were carried out in a recrystallized alumina crucible (Coors AD 99) placed in a top-fed furnace purged with purified helium. The helium was purified by passing it through a train, wihch included a BTS catalyst (BASF, Ludwigshafen-am-Rhein, Germany) maintained at 180°C to remove oxygen and CO, and Linde Type 3A and 13X molecular sieves to remove other impurities.

Molten mixtures were prepared by fusing reagent-grade Na_2WO_4 (A and C, American Chemical) and H_2WO_4 (Baker Analyzed Reagent). Both reagents were previously dried at 200°C. A typical charge was about 600g of the mixture $Na_2WO_4 + WO_3$. A new crucible was used for each new melt composition.

WO_3 concentrations were calculated as mole per cent or mole per liter of the melt (molarity) and were based on the weights of the reagents and corrected for the consumed quantities, according to reaction [2], if necessary. The molarities of the melts were calculated using density data reported by Morris and Robinson (19).

The temperature was monitored with a Chromel-Alumel thermocouple placed on the side of the crucible. This value was corrected by means of a calibration curve relating the temperature in the melt to that on the side of the crucible and determined at the end of a set of experiments in order to prevent contamination of the melt by the thermocouple sheath. The melt temperature, held constant by means of a proportional

control system (Thermolyne, Sybron Corporation), did not fluctuate more than 3°C.

The bronzes were grown at the end of a gold wire. The anode consisted of a gold wire or sheet (99.99% purity). In some experiments the gold wire used as the anode was placed within a porcelain crucible whose bottom had a 1 mm slit to provide ionic conduction between the compartments. The porcelain tube inside the cell acted as a chimney for the evolved oxygen and, therefore, prevented oxygen from going to the catholyte. However, no noticeable difference in the current efficiency was found with or without this device. A platinum sheet (99.99% purity, 1.5 × 1.0 × 0.01 cm) was used as the anode in electrolyses in which platinum incorporation was sought. The concentration of platinum in the melt was therefore maintained by anodic dissolution of the metal.

A bronze crystal grown in the same melt as the working bath was used as the reference electrode (15) in the activation energy measurements. A constant current d-c power supply (Hewlett-Packard, Model 6177B), an electronic coulometer (Koslow Scientific Company, Model 541), and a potentiostat (Wenking, Model 68TS3) were used.

X-ray diffraction angles and relative intensities of diffracted beams were determined on powdered samples (Philips Diffractometer, Ni-filtered CuK_α radiation). The sodium concentration of cubic bronzes was determined from the x-ray measurements of the lattice parameter using Brown and Banks (7) relation between lattice parameter and sodium content. High ($x > 0.85$) and low ($x < 0.5$) x-values were determined by wet chemical analysis.[2]

Spark-source mass spectrographic analysis[3] was used to determine the concentrations of trace elements, including platinum and gold. Concentrations of platinum higher than about 50 ppm were determined by optical emission spectroscopy.[3] Standard platinum samples were prepared for calibration of both the above methods.

Results

Growth of Na_xWO_3

Crystal characterization.—Crystal characterization and yield for different conditions of growth are summarized in Table I. Cubic phase material was obtained for all melt compositions with less than 50 m/o WO_3. The sodium tungsten bronzes grown in a melt containing 40 m/o WO_3 or less were of a cubic habit ({100} faces), while those grown in a 50 m/o WO_3 melt were dodecahedral ({110} faces). The bronzes grown in a 60 m/o WO_3 melt were tetragonal. These results are in agreement with the recent studies by Fredlein and Damjanovic (15) and Shanks (6).

The temperature of deposition has no significant effect on the crystal habit of the bronze except in a 50 m/o WO_3 melt from which needle-shape crystals are deposited above 850°C. The side faces of the needles are the {100} planes and the end faces the {110} planes.

The x-values vs. melt composition.—The relation between the x-values of the bronzes and the melt composition is given in Fig. 1. The results of the present study fit well with those previously reported (6, 8, 11, 15, 20). In Fig. 1, the melt composition is given in mole of WO_3 per liter, rather than in mole per cent WO_3 as in previous studies (6, 15), since the molarity of the melt is a more significant quantitative measure of the proportionality of the amount of reactant than the mole fraction.

The relation between the x-value in Na_xWO_3 and the concentration of WO_3 in the melt is linear between 2 and 10 mole/liter WO_3. Extrapolation of the linear section gives $x = 1.0$ at zero concentration of WO_3. The deviation from linearity at low concentrations of WO_3 is believed to be due to an activity effect of WO_3. A possible reason for the deviation from linearity at high WO_3 concentrations may be the change in the crystal structure of the bronzes (from cubic to tetragonal).

Platinum contamination.—Since the bronze crystals were prepared for subsequent electrocatalysis studies, platinum contamination was an important matter. In the preparation of pure bronzes, *i.e.*, without purposely added platinum, the aim was to keep the platinum contamination at a minimum level. It was thought that the first crystal grown in a freshly prepared melt would act as a scavenger in which most of the impurities would accumulate. The subsequently grown crystals were expected to have a much lower impurity concentration. Surprisingly, the platinum concentration found in crystal No. 77, deposited out of a freshly prepared melt, and that found in crystal No. 81 (Table I), deposited out of the same melt but after four bronze crystals had already been grown, are almost within the experimental error of the spark-source mass spectrograph (±50% at a few ppm level). In crystals No. 93-97, all deposited from the same freshly prepared melt, the platinum content did not vary from the first crystal to the sixth.

The platinum content of the reagents, also determined mass spectrographically, was found to be 2 ppm in Na_2WO_4 (A and C, American Chemical), and <0.2 ppm in H_2WO_4 (Baker Analyzed Reagent). Any other source of the platinum contamination of the melt is unlikely since gold used as the anode is a 99.99% purity material and does not dissolve significantly during the electrolysis.

Pre-electrolyses with large gold electrodes were carried out in an attempt to decrease the residual platinum concentration in the melt. These experiments were performed at high temperatures and high current densities since these experimental conditions will be shown later to favor platinum incorporation from an intentionally contaminated melt. Pre-electrolysis was first carried out in Na_2WO_4 at 930°C with a cathodic current density of 100 mA-cm^{-2} for 72 hr. Tungsten trioxide was then added and a second pre-electrolysis was performed. The crystals deposited in such a pre-electrolyzed melt exhibited a platinum concentration similar to that found in crystals deposited in a melt that had not previously been pre-electrolyzed.

Gold contamination.—Contamination of the bronze crystals by gold is also relevant to this study since gold was used as an anode in the deposition of pure crystals. Gold is more noble in the melt than platinum but nevertheless dissolves slowly during prolonged use as the anode. The typical gold concentration determined by spark-source mass spectrography is between 30 and 80 ppm. Crystals deposited from a melt pre-electrolyzed for a long time with gold electrodes contain up to 700 ppm gold. In the crystals deposited with a platinum anode the gold content is at the ppm level.

Other impurities present in the bronze samples at the ppm level are: Al, Si, Ti, S, Mo, Cl, Ca, P, Fe, Co, Ni, Cr, Y, V, Mg, and K.

Effect of current and temperature on efficiency.—The yields (coulombic efficiency) were determined by weighing and analyzing the bronze formed after the passage of an accurately measured amount of electricity and were found to depend on both current density and melt temperature (Table I). High current densities and low temperatures tend to favor high yields. In the depositions summarized in Table I, the applied current was increased during growth in order to take into account the increase in surface area. At the beginning of the deposition the gold wire area was about 0.2 cm^2 and cubic crystals as large as 1 cm in linear dimensions were easily grown. Typical currents used were from 3 to 30 mA.

In another set of measurements reported in Fig. 2 and 3 the current was held constant during the entire deposition. Since the surface area of the crystal increases with deposition time by about one order of magnitude, the following results are useful only from the point of view of crystal growth; no mechanistic conclusion can be drawn from them.

The yield of bronze as a function of applied current at different temperatures in a 50 m/o WO_3 melt are reported in Fig. 2. The first series of depositions was carried out at 840°C in a freshly prepared melt. The temperature of the melt was then decreased to 746°C and the second series of depositions was performed at this temperature at different constant currents. The next experiments were carried out at regularly increasing temperatures. The coulombic efficiency depends on both the melt temperature and the applied constant current. In addition, the deposition yield in a freshly prepared melt also depends on the first melt temperature. The efficiency of depositions carried out at 840°C in a freshly prepared melt containing 50 m/o WO_3 were only in the 20% range, whereas 80% efficiency was reached in the same but used (at lower temperatures) melt, at the same temperature.

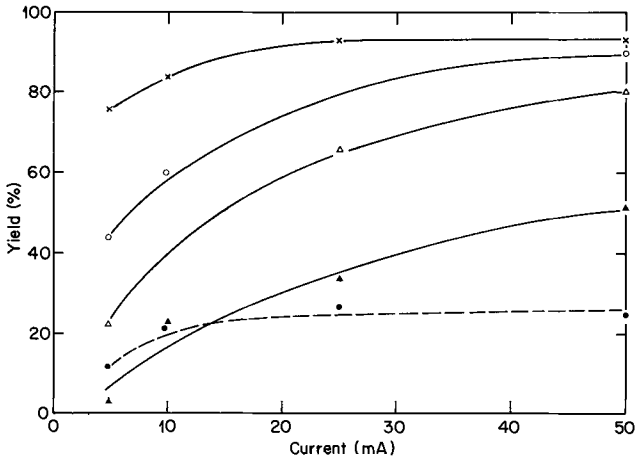

Fig. 2. Effect of current on the yield of deposition of Na_xWO_3 in a 50 m/o WO_3 melt. Total charge consumed 13.4 meq. First series of depositions in a fresh melt at 840°C (●), followed by depositions at 746°C (X), 792°C (○), 840°C (△), and 884°C (▲).

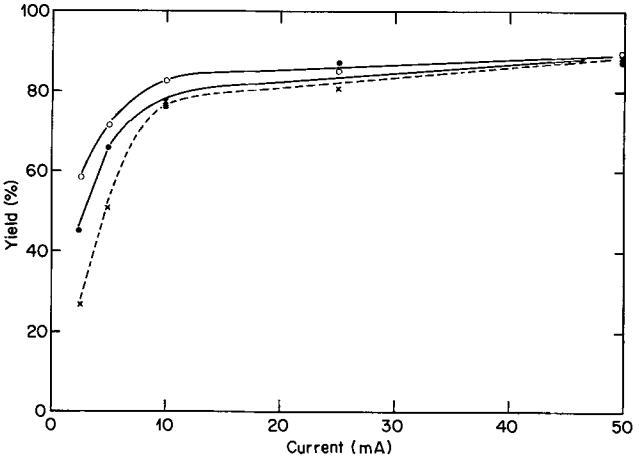

Fig. 3. Effect of current on the yield of deposition of Na_xWO_3 in a 20 m/o WO_3 melt. Total charge consumed 7.5 meq. First series of depositions in a fresh melt at 786°C (X), followed by depositions at 735°C (○), and 786°C (●).

In a 20 m/o WO_3 melt, the deposition efficiency depends on both the applied current and the melt temperature (Fig. 3) in a manner similar to that described for a 50 m/o WO_3 melt.

Effect of temperature on composition of deposit.—The deposition efficiency decreases with increasing temperature from the melting point to some higher temperature where the amount of bronze deposited suddenly decreases to zero and tungsten metal is recovered instead. The transition temperature between the deposition of Na_xWO_3 and metallic tungsten (or a mixture of W and Na_xWO_3) depends on the melt composition as shown in Fig. 4. Two phase domains can be distinguished: one at high temperatures where tungsten is the major constituent of the deposit, and the other at low temperatures where sodium tungsten

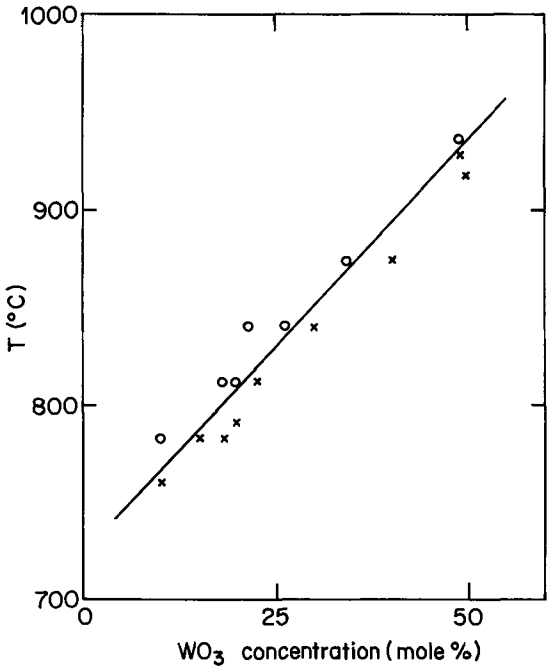

Fig. 4. Composition of the cathodic deposit as a function of the melt temperature and composition. X Na_xWO_3 deposit, ○ W (or mixture W + Na_xWO_3) deposit.

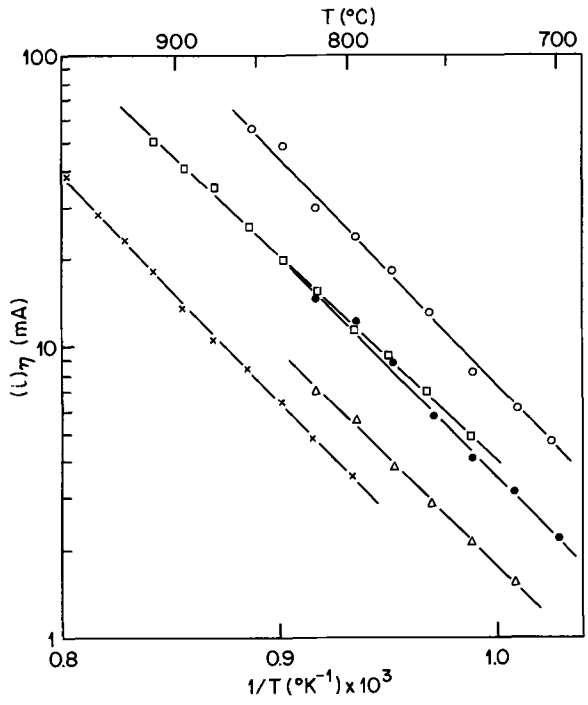

Fig. 5. Current at a constant potential vs. temperature relationship in a 20 m/o WO_3 melt at $\eta = -8.4$ mV (△), $\eta = -14.4$ mV (●), $\eta = -31.2$ mV (○), in a 40 m/o WO_3 melt at $\eta = -20.0$ mV (□), and in a 50 m/o WO_3 melt at $\eta = -10.0$ mV (X).

bronze is deposited. The transition temperature is well defined, *i.e.*, it ranges over only about 10°C. The results in Fig. 4 confirm those recently given in a more qualitative way by Shanks (6).

Within the bronze deposition domain the x-value does not depend significantly on the deposition temperature.

Heat of activation.—The bronze deposition reaction proceeds very fast and, consequently, the exchange current density, i_o, is difficult to measure since the Tafel region is inaccessible. For this reason, the deposition current at a constant over-potential has been taken as a measure of the deposition rate. These experiments were performed on a bronze crystal grown in the same melt for 15 hr at 10 mA. No significant growth of the bronze electrode occurred during these experiments. The maximum temperature at which the measurements can be performed is limited by the dissolution rate of the bronze reference electrode. In Table IV, it is shown that in a 20 m/o WO_3 melt a 65% weight loss is measured after 20 min at 863°C. This duration is roughly the stabilization period of the furnace to reach a constant temperature when changed from one temperature to another. The results reported in Fig. 5 for 20, 40, and 50 m/o WO_3 melts show no change of the slope $\partial \log (i)_{\eta=\text{const.}} \partial/(1/T)$ at, or near, the transition temperature. The activation energy varies between 32 and 35 kcal/mole between 700° and 900°C.

Growth of Na_xWO_3 Containing Platinum

Table II summarizes the platinum concentration, x-value, crystal faces formed, and yields obtained for different conditions of growth. The platinum content of Na_xWO_3 increases with increasing melt temperature, although there are some exceptions (crystals No. 55 and 104). High current densities also favor high platinum concentrations in the bronze.

The amount of platinum dissolved was determined from the weight loss of the anode during the deposition and compared to the amount of platinum incorporated in Na_xWO_3 during the same experiment. The ratio of deposited platinum to dissolved platinum is very low, *i.e.*, about 0.02 (Table III). It follows that the amount of platinum in the melt increases with the number of crystals prepared. After about 10 depositions, the melt contains about 1.5g of platinum [0.2 w/o (weight per cent)]. The observation and analysis of the solidified melt after such a series of depositions show the presence of metallic platinum segregated at the bottom of the crucible.

The coulombic efficiency of the deposition decreases with increasing temperature (Table II), as would be

60	1450	496.7	12.5	0.025

expected from the results obtained without platinum incorporation. In the presence of platinum, however, there is an additional effect presumably associated with the platinum. Under similar experimental conditions the yield decreases sharply from one sample to the next (crystals No. 57-60 in Table II). It is believed that the increasing amount of platinum in the melt inhibits the deposition of the bronze.

The presence of platinum in the range from 1 to 1450 ppm has no significant effect on either the x-value in Na_xWO_3 (Tables I and II) or the crystal habit of the bronzes.

Discussion

Efficiency of deposition.—The current efficiency of the bronze deposition depends both on the applied current and the melt temperature. The shape of the yield *vs.* current curves can be explained by the occurrence of a side reaction, the most likely being the occurrence of simultaneous chemical dissolution of the bronze. Because of the high yield in the low temperature range and the continuous increase in efficiency with increased current, the bronze deposition reaction is the predominant one. The secondary process, *i.e.*, the reaction that lowers the yield, increases with both temperature and time of contact of the crystal with the melt (lower applied current).

The open-circuit dissolution of a bronze crystal in the melt in which it has been grown occurs at a rate which depends on the temperature (Table IV). In the range of temperatures between 750° and 790°C, a 10% weight loss is recorded after 19 hr (Table IV). Under similar experimental conditions the deposition efficiency is about 90 or 80% for a 50 or 20 m/o WO_3 melt, respectively (Fig. 2-3). The agreement between the efficiency decrease and the weight loss is reasonable. Thus simultaneous chemical dissolution explains satisfactorily the dependence of the deposition efficiency on temperature and current.

It is difficult to explain why a bronze deposited at high temperature in a freshly prepared melt is deposited with a much lower yield than a bronze at the same temperature in a melt previously used at a lower temperature (Fig. 2). One possibility is that the tetramer of WO_3, which has been shown to be the reducible species (12, 13), forms at the lower temperature.

Effect of temperature on composition of deposit.—At temperatures lower than the transition temperature defined in Fig. 4, the dissolution reaction is most likely the reverse of the deposition reaction. At temperatures higher than the transition temperature the reaction product is metallic tungsten (or a mixture of W and Na_xWO_3). Van Liempt (21) has proposed that the tungsten originates from the decomposition of sodium tungsten bronze according to the reaction

Table IV. Open-circuit dissolution of bronzes

Melt composition (m/o WO_3)	Temp (°C)	Dissolution time (hr)	Initial bronze weight (g)	Weight loss (%)
20	766	19.00	2.669	10.7
20	816	7.00	4.455	11.1
20	863	0.33	4.367	64.8

50	927	16.00	≈2.5	100

$$6Na_xWO_3 \rightleftarrows xW + 3xNa_2WO_4 + (6 - 4x)WO_3 \quad [3]$$

The first product of electrolysis is the sodium tungsten bronze, irrespective of the melt temperature. When the temperature is higher than the transition temperature the bronze decomposition, (reaction [3]) gives rise to a metallic tungsten deposit.

The activation energy measurements reported in Fig. 5 support the above reaction for the tungsten deposition. The slope of the $(i)_{\eta=const.}$ *vs.* T^{-1} plot shows no break at, or near, the transition temperature, indicating that the rate determining step for the deposition of Na_xWO_3 is the same as that for the deposition of W. Therefore, the deposition of Na_xWO_3 is a prerequisite for the W deposition.

The reversibility of reaction [3] was tested by putting a bronze crystal, grown at a temperature lower than the transition temperature in the melt at a temperature higher than that of the transition. The bronze crystal dissolved completely after a short time (Table IV) leaving a gray powder at the bottom of the alumina crucible. The analysis of the remaining powder after washing the frozen melt shows that it contained metallic tungsten (along with Na_xWO_3). The gray powder left at the bottom of the crucible after dissolution of the bronze at high temperature becomes gold colored on decreasing the melt temperature.

Codeposition of platinum.—The following observations tend to indicate a nonelectrochemical process for the platinum codeposition but do not constitute final evidence: (*i*) platinum is always present in a pure bronze at the ppm level, even in a carefully pre-electrolyzed melt; (*ii*) the amount of platinum incorporated in the bronze is small compared to the amount of platinum dissolved (or eroded) from the anode and does not depend significantly on the temperature (Table III).

McHardy (18) has recently proposed an electrophoretic mechanism on the basis that most of the platinum occurs in the alumina inclusion particles. He suggests that a colloidal alumina particle eroded by the melt from the crucible acquires a negative charge by the equilibrium

$$Al_2O_3 + WO_4^{-2} \rightleftharpoons Al_2O_4^{-2} + WO_3 \quad [4]$$

and, hence, attracts cations to its surface. Collisions among colloid particles will bring about coagulation and, eventually, the particles will be large enough to settle out. Particles that settle out onto the growing crystal will be discharged, and the platinum ions will be reduced to the metal. If this hypothesis is correct, the final concentration of platinum in the crystal will depend on the concentration both of platinum ions and of colloid particles in the melt.

Following this argument, a crystal deposited in a melt which has never been in contact with alumina should not contain any significant amount of platinum. On the contrary, crystal No. 8 (Table II) grown in a freshly prepared melt contained in a platinum crucible using two gold wires as cathode and anode exhibits 255 ppm Pt. Moreover, the amount of alumina removed from the crucible by etching would be expected to increase with the aging of the crucible. Hence, if alumina takes part in the platinum incorporation, as suggested by McHardy, a bronze deposited in an alumina crucible used for a long time should be richer in platinum than a sample prepared in a new alumina crucible, provided that the platinum concentration in the melt is the same in both experiments. Contrary to this expectation, crystals No. 98 and 108 (Table II) deposited at roughly the same temperature and in the same melt contained in an alumina crucible incorporate the same amount of platinum. It is therefore unlikely that the colloidal reaction advanced by McHardy is the only operative process for the platinum codeposition.

The electrophoresis explanation may be a valid one when both the alumina and the platinum contents are high. When one of these concentrations is low, or zero, another mechanism is obviously involved. At high platinum concentrations a purely electrolytic

deposition process cannot be ruled out. However, the measurements reported in the present study (Table III) suggest another explanation. The amount of platinum deposited is low compared to the amount dissolved or eroded (Table III). At room temperature, the platinum contained in the melt has been shown to be present as a metallic deposit. One may assume that platinum (and not platinum ion) is also present in the melt at its high operating temperature. Metallic platinum may come from the reduction of the ionic platinum (arising from oxidation of the anode) at the cathode. The reduction may occur at a high current density which tends to deposit a powder that does not adhere to the cathode but drops down through the melt as colloidal particles. Another possibility is the mechanical erosion of the anode during the oxygen evolution reaction.

If colloidal platinum particles are present in the melt, their codeposition may occur through: (*i*) electrophoretic transport arising from the high potential gradient in the diffusion layer, (*ii*) transportation of the particle as a complex ion to the cathode layer, and (*iii*) mechanical trapping.

Codeposition of gold was also shown to arise during the growth of bronze, especially when a gold anode was used A mechanism similar to that occurring for the platinum incorporation is likely to be operative in the case of the gold codeposition.

In a platinum-containing melt, the current efficiency decreases sharply with the amount of platinum dissolved from the anode. One possible explanation for the decrease in the yield in the presence of platinum is the occurrence of reduction of platinum ions at the cathode giving rise to colloidal platinum along with the platinum incorporation in the bronze. This would not, however, account for the entire current consumed in the side-reaction (87% of the total current for crystal No. 60). Another likely explanation is the formation of a polymer between platinum and tungsten oxide, which would undergo preferential charge transfer. If this polymeric species does not deposit, little or no bronze is formed, but the species can presumably undergo further charge transfer, and very much more charge would then be required to reduce it to metal. A similar explanation has been proposed by Fredlein and Damjanovic (15) to account for the complete inhibition of bronze formation by the addition of 0.1% of a rhenium oxide to the Na_2WO_4/WO_3 melt.

Acknowledgments

Grateful acknowledgment is made to Dr. A. K. Vijh for numerous critical discussions and suggestions throughout the course of this work. The author is indebted to Drs. G. Bégin, G. Dionne, E. Dancy, G. Bélanger, and P. Lenfant for helpful discussions. The author thanks Mr. R. Bellemare for his assistance in the experimental work and Mr. R. Dubuc for the x-ray analysis. Special acknowledgments are due to Dr. D. S. Russell, Chemistry Division, National Research Council, Ottawa, for the careful determination of platinum and the authorization to publish the results.

Manuscript submitted Dec. 20, 1972; revised manuscript received May 7, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

The Drum-activated Graphite Ribbon Electrode

John T. Stock* and Joseph P. Sapio

Department of Chemistry, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

Film formation by products in oxidative electrosyntheses, with consequent cessation of current, can sometimes be alleviated by mechanical reactivation of the anode. A composite anode that consists of a graphite ribbon in contact with a rapidly rotating perforated graphite drum is described. This provides both high flow rate and continuous reactivation.

Anodic organic electrosyntheses often require quite long periods of electrolyses. Possible causes are low current efficiency, deactivation of the anode by products or by-products, or inefficient design or operation of the cell. The utility of graphite cloth electrodes in coulometry and in preparative-scale electrolyses has recently been pointed out (1). Bobbitt *et al.* (2-4) have made extensive use of graphite cloth or graphite felt anodes in their studies of the preparative-scale oxidative coupling of certain heterocyclic phenols. As in voltammetric studies (5-7), the attempted anodic electrolysis of aqueous alkaline solutions of these compounds sometimes results in a rapid fall in current due to deactivation of the anode. On the microscale associated with voltammetry, this effect can often be prevented or minimized by intermittent electrolysis (8) or by continuous reactivation of the electrode by a rotating drum (6, 7). Attempts were therefore made to extend the drum method to the preparative scale.

The essentials of the apparatus are shown in Fig. 1, (a) and (b). Ribbon A (see Fig. 1), which is of graphite cloth,[1] is 2.5 cm wide and approximately 10 cm long. One end carries polyethylene stretcher B (see Fig. 1), which is cut from the spine of a transparent report cover.[2] This stretcher is sprung over one end of the ribbon and heat-sealed to it. The tension thread, C, of nylon radio dial cord, is attached to the middle of the stretcher, passes up the glass guide tube, D, and is gripped in a binding post at the end of the brass strip spring, E. After passing around the graphite drum, F, the ribbon terminates at the post, G. This is a 12 mm diameter hardwood rod which has received several coats of waterproof varnish after having been grooved longitudinally. The free end of the ribbon is gripped by the glass rod, H, which lies in the groove and is secured by two collars of rubber tubing, as shown enlarged in Fig. 1 (c). Electrical connection to the ribbon is made by a length of 26 gauge platinum wire, one end of which runs along the bottom of the groove beneath the ribbon.

A sewing machine motor provided with a controller drives the plastic-coated steel shaft, I, at an essentially constant speed. This shaft carries the drum, F, but is insulated from it. Four rows of twelve 1.5 mm diameter holes, are drilled in the periphery of the drum, as shown in the horizontal cross section in Fig. 1 (d). These holes terminate in the 10 mm diameter central hole that is drilled from the underside of the drum. Rotation of the drum causes the cell solution to be drawn into this central hole, thrown out through the radial holes, and thus forced through the interstices of the ribbon.

The electrolyses with this drum-activated graphite ribbon electrode (DAGRE) were carried out with 250 ml portions of solution. For runs with $K_4Fe(CN)_6$, the platinum foil counterelectrode was isolated in a tube, J, the lower end of which carried a fritted-glass septum. In other runs, the counterelectrode was simply immersed in the cell solution. Power was supplied by a Beckman Electroscan 30 that was operated in the potentiostat mode. An asbestos-thread type junction, K, located close to the ribbon as shown in Fig. 1 and leading to a saturated calomel electrode (SCE), enabled the potential of the ribbon to be controlled.

Preliminary experiments with $K_4Fe(CN)_6$ in 0.01*M* $HClO_4$ showed that the current, which increased with drum speed, was both large and not very sensitive to drum speed when this reached approximately 1400 rpm. All of the subsequent runs were made at this rate of rotation. Figure 2 compares the rate of oxidation of $K_4Fe(CN)_6$ under these conditions with the considerably lower rate observed in a similar run in which the drum was stationary but the solution was vigorously agitated by a magnetic stirrer.

The high rotation rate results in slight abrasion of drum and ribbon, so that the solution may become gray during the run. However, the useful running life of a ribbon is in excess of 50 hr. This small but definite wear provides a degree of surface renewal, and hence

of electrode reactivation. The current-time curves, shown in Fig. 3 and obtained with the strongly deactivating system tyramine in alkaline solution (7), illustrate this effect. These curves were obtained under deliberately restricted conditions where only the rubbing portions of the ribbon and drum were exposed to the solution. The outer surface of the ribbon was heat-sealed to a polyethylene sheet and the top and bottom of the drum were varnished.

A series of preparative oxidative couplings of 0.5g portions of corypalline (1,2,3,4-tetrahydro-7-hydroxy-6-methoxy-isoquinoline) in 0.1*M* borax gave results similar to those reported by Kirkbright *et al.* (5), who used a platinum gauze anode. Although the anode-deactivating properties of corypalline are quite mild, those of isocorypalline (1,2,3,4-tetrahydro-6-hydroxy-7-methoxy-isoquinoline) are pronounced (7). In fact, when the oxidation of an aqueous alkaline solution of isocorypalline was attempted at a platinum gauze anode, the current fell rapidly to zero and no products could be detected (2). Electrolysis at a DAGRE potential of +0.35V of 0.5g of isocorypalline in 0.1*M* borax gave a 6% (actual) yield of the pure oxygen-linked coupling product [compound 18, see Ref. (2)]. The current fell from approximately 20 to 5 mA during the 5 hr run, after which approximately 30% of the starting material was recovered. A DAGRE with a 7 cm diameter drum is now being constructed, so that larger quantities can be subjected to electrolysis.

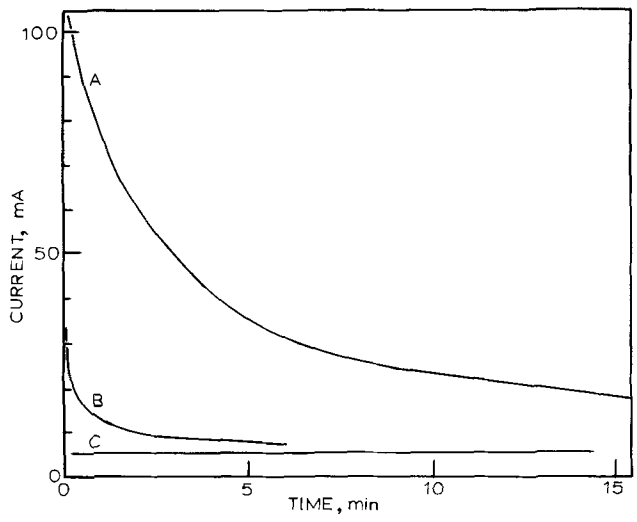

Fig. 3. Current-time relationships of 5.0 mM tyramine in 0.1M $NaHCO_3$ at 0.35V vs. SCE. Curve A, ribbon under tension; curve B, ribbon slack; curve C, residual current only.

Preliminary experiments with solutions of $K_4Fe(CN)_6$ and of corypalline have shown that the quite large electrolysis currents can be further augmented by mounting the cell in the bath of an 80-kHz ultrasonic generator. In view of a report that the anodic oxidation of certain inorganic ions such as iron(II) is more rapid at a frequency of 25 kHz than at higher or lower frequencies (9), the generator is now being rebuilt in variable frequency form.

Acknowledgments

We thank Professor J. M. Bobbitt of this Department both for supplies of corypalline and isocorypalline and for many helpful suggestions. This work was carried out with the partial support of the National Science Foundation (Grant No. GP-30574X).

Manuscript received Feb. 16, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Reduction of Crotonic Acid with Hydrogen on a Slurry Electrode

D. N. Baria[1] and Hugh M. Hulburt*

Department of Chemical Engineering, Northwestern University, Evanston, Illinois 60201

ABSTRACT

A slurry electrode system consisting of a suspension of metal or a supported metal powder in an electrolyte in contact with a gold foil electrode was studied as a hydrogen electrode for the reduction of crotonic acid in a supporting electrolyte of sodium p-toluene sulfonate. Current-voltage curves and current efficiency were studied. Effects of suspension concentration, crotonic acid concentration, butyric acid concentration, pH, and temperature were studied for platinum black and palladium-on carbon slurries. The results are consistent with the view that the potential-determining reaction is the discharge of hydrogen atoms adsorbed on the catalyst. Olefin competes for adsorbed hydrogen and this modifies the observed potential. Very low anodic limiting currents were observed in the presence of olefin, suggesting that it is strongly adsorbed on the anodic hydrogen electrode. The following electrokinetic expressions were established for cathodic currents: (*i*) for 5% Pd on C

$$\log i = \log k + 0.42 \log C_{H+} - 0.013 \log C_R - 0.49 \log C_{RH_2} + 0.23 \log W_{cat} - 0.22\, EF/RT$$

and (*ii*) for Pt black

$$\log i = \log k + 0.52 \log C_{H+} + 0.077 \log C_R + 0.028 \log C_{RH_2} + 0.45 \log W_{cat} - 0.30\, EF/RT$$

where i is the current, k is a constant, C_{H+} is hydrogen ion concentration, C_R is crotonic acid concentration, C_{RH_2} is butyric acid concentration, W_{cat} is catalyst concentration, E is the electrode potential, F is Faraday's constant, R is universal gas constant, and T is the absolute temperature.

A slurry electrode system consists of a suspension of a metal or a supported metal powder catalyst in an electrolyte in contact with an inert collector electrode. It has a larger surface area on which the electrode reaction can take place than plain plate-type electrodes or porous electrodes made of the same material.

Muller and Schwabe (1, 2) first measured the potential of suspended metallic powders in an electrolyte. Later Sokol'skii and Druz (3, 4) showed that it was possible to transfer the potential of a powdered metal catalyst suspended in an electrolyte onto a stationary electrode. Boutry, Bloch, and Balaceau (5) showed that a catalyst powder, suspended in an electrolyte in the presence of a conducting collector electrode, had all the properties and uses of a classical compact electrode.

Gerischer and Held (6, 7) showed that it was possible to draw considerably higher currents from a suspension of catalyst when hydrogen was oxidized or oxygen reduced. They followed the transport of current by individual catalyst particles by means of an oscillograph. Schwabe and Satsko (8) found that the current drawn by a suspension of platinized carbon was independent of catalyst concentration, whereas the currents obtained with Raney nickel and platinum black were appreciably greater and proportional to the catalyst concentration.

Fasman, Sokol'skii, and Shurov (9) studied polarization curves of moving powder electrodes by circulating the catalyst suspension through a polarized nickel screen. They determined the quantitative relations between catalyst potential and the collector electrode potential using the concepts of equivalent circuits. Lazorenko and Ushakov (10) derived relationships between the current drawn and the applied potential for slurry electrodes and showed that they behaved as normal compact electrodes with increased exchange current. Eyring (11) studied the effect of different catalysts, catalyst concentrations, and the effect of agitation on the polarization curves for the oxidation of hydrogen on slurry electrodes. He attempted the reduction of benzaldehyde and ethylene on slurry electrodes. Beck (12) studied the hydrogenation of substances with a triple bond on slurry electrodes.

The aim of the present work was to study the behavior of the slurry electrode for the electrochemical reduction of crotonic acid and to analyze the data obtained from it by the conventional steady-state methods known for compact electrodes. An over-all empirical equation was obtained for the current in terms of concentrations, pH, and temperature and potential for platinum black and 5% palladium on carbon catalyst powders using steady-state methods. The reaction mixture was analyzed to determine the products of the reaction and to obtain the coulombic efficiency.

Crotonic acid was chosen because it has an olefinic double bond which can easily be reduced. Also it is soluble in water and so presents no problems in preparing aqueous solutions of crotonic acid using sodium p-toluene sulfonate as supporting electrolyte.

Experimental

The electrolytic cell, shown in Fig. 1, consisted of a 300 ml glass round bottom flask, called the measuring or working electrode compartment, A, into which the catalyst and the electrolyte were charged. The measuring or the working electrode, C, was a smooth 24 carat gold strip, 8.9 by 1.3 cm, with a thickness of 0.025 cm. It was formed into a circle 2.5 cm in diameter such that the ends of the strip were 0.5 cm apart. The glass stirrer, E, was concentric with the circular measuring electrode. The stirrer rod, D, and the glass bearing, F, were ground to a precision fit. The counter or the opposing electrode, I, was a perforated bright platinum strip, 1.3 cm square and 0.013 cm thick, placed in the counterelectrode compartment, G, and separated from the measuring electrode compartment by a sintered glass disk, H. Gas could be bubbled from the bottom of the cell through a sintered glass sparger, B. The reference electrode was a Hg/HgO electrode. The capillary tip of the reference electrode, J, was kept at a distance of about 0.5 cm from the measuring electrode. The cell was kept at a constant temperature, within ±0.1°C, in a water bath.

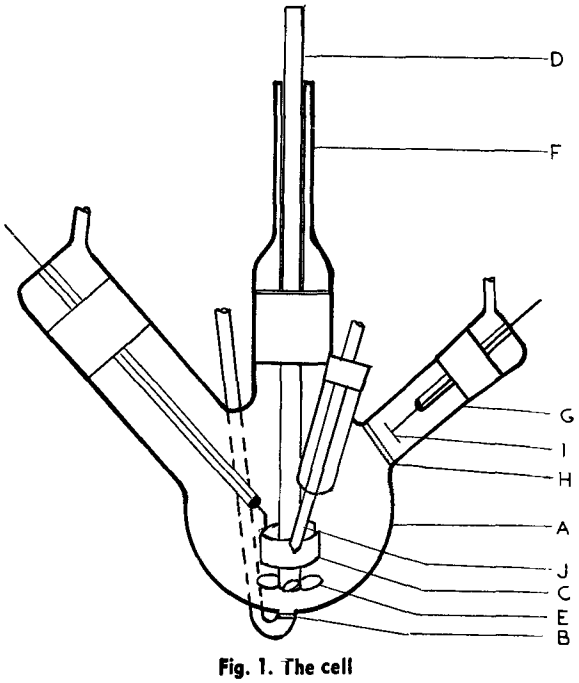

Fig. 1. The cell

Sodium p-toluene sulfonate and crotonic acid were purified by recrystallization before use. Three hundred milliliters of the electrolyte solution were prepared by dissolving 40g sodium p-toluene sulfonate, the required amounts of crotonic acid, butyric acid, and previously standardized sulfuric acid in deionized water. Sulfuric acid was used to control the pH of the solution. The cell was filled with the electrolyte and the required amount of the catalyst powder. The electrodes and the stirrer were put in place. The stirrer speed was always kept at a constant 1400 rpm, since earlier experiments had shown that higher speeds had no effect on the current drawn by the cell (13). The system was purged with nitrogen gas for 20 min to get rid of oxygen in the system. Then hydrogen gas was bubbled through the sparger at a flow rate of 2.5 ml/sec. It took about 15-20 min for the open-circuit potential to reach a steady value.

A Wenking Potentiostat 61TRS was used to measure and control the potential between the reference and measuring electrodes and to measure the current flowing between the counter and measuring electrodes. The current flowing in the cell attained a constant value in about 5 min for each potential setting.

The pH effect was studied by varying the pH of the electrolyte from 1.42 to 2.32; the crotonic acid effect was studied by varying crotonic acid concentration from 66.7 g/liter (0.7748M) to 6.667 g/liter (0.0775M); the butyric acid effect was studied by varying its concentration from 9.58 g/liter (0.1087M) to 23.95 g/liter (0.2718M); the catalyst concentration effect was studied by varying its concentration from 5.0 to 0.313 g/liter; and the temperature effect was studied by varying temperature from 20° to 40°C.

An Aerograph Hy-Fi Model A-600C gas chromatograph with an isothermal temperature controller and a hydrogen flame ionization detector was used to identify and determine the butyric acid formed.

Theory

Mechanism.—The probable course of the electrochemical reduction of crotonic acid is proposed as following the adsorption mechanism

$$S + H^+ + e \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} H \qquad \text{[step 1]}$$

$$H_{ads} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \tfrac{1}{2}H_2 + S \qquad \text{[step 2]}$$

$$S + R \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} R_{ads} \qquad \text{[step 3]}$$

$$R_{ads} + H_{ads} \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} RH_{ads} \qquad \text{[step 4]}$$

$$RH_{ads} + H_{ads} \underset{k_{-5}}{\overset{k_5}{\rightleftarrows}} RH_{2ads} \qquad \text{[step 5]}$$

$$RH_{2ads} \underset{k_{-6}}{\overset{k_6}{\rightleftarrows}} RH_2 + S \qquad \text{[step 6]}$$

where R stands for $CH_3CH = CHCOOH$, RH stands for $CH_3CH - CH_2COOH$, RH_2 stands for $CH_3CH_2CH_2COOH$, and S stands for surface of the catalyst.

Although the exact mode of action in the slurry electrode is not fully understood, it is probable that the hydrogen ions, dissolved hydrogen gas, and crotonic acid in the electrolyte solution are adsorbed on the catalyst surface. As the slurry is agitated, the catalyst particles come in contact with the collector electrode. At cathodic polarization, the collector electrode is more negative than the particles and when the particles touch the electrode, electrons are transferred from the electrode to the particles, which reduce the adsorbed hydrogen ions to hydrogen atoms. They can either desorb to form hydrogen gas or react with the adsorbed crotonic acid to form butyric acid. The catalyst particle moves away from the collector electrode. The butyric acid formed then desorbs from the catalyst surface into the solution. As room is made, more reactants are adsorbed on the particle and the cycle is repeated.

In preliminary work (13) it was established that butyric acid is formed both for cathodic and anodic polarization of the working electrode. It would seem unlikely that a direct electrochemical reduction of the double bond would occur under cathodic polarization. This possible alternative to step 1 has therefore been omitted. Moreover, addition of crotonic acid to a hydrogen saturated solution enhances the cathodic current but inhibits the anodic current, suggesting that adsorption of crotonic acid and the competitive reaction with adsorbed hydrogen dominate the direct electron transfer to the double bond.

If it is assumed that steps 4, 5, and 6 go in the forward direction only, making use of the steady-state approximation for the surface concentrations of the adsorbed species, one finds

$$\theta_{RH} = \frac{k_4}{k_5}\theta_R \qquad [1]$$

$$\theta_R = \frac{k_3 C_R(1 - \theta_H - \theta_{RH} - \theta_{RH_2})}{k_{-3} + k_3 C_R + k_4\theta_H} \qquad [2]$$

$$\theta_H = \frac{k_1 C_{H^+}(1 - \theta_R - \theta_{RH} - \theta_{RH_2})\, e^{-\beta\eta F/RT} + k_{-2}p_{H_2}^{1/2}(1 - \theta_R - \theta_{RH} - \theta_{RH_2})}{k_1 C_{H^+} e^{-\beta\eta F/RT} + k_{-1}e^{(1-\beta)\eta F/RT} + k_2 + k_{-2}p_{H_2}^{1/2} + k_4\theta_R + k_5\theta} \qquad [3]$$

where C_{H^+} = concentration of hydrogen ion; p_{H_2} = partial pressure of hydrogen gas; C_R = concentration of crotonic acid; θ_m = fractional coverage of the surface of the catalyst by species, m; and β = symmetry factor.

The current passing through the cell is proportional to the rate of step 1

$$i = k_{-1}\theta_H e^{(1-\beta)\eta F/RT} - k_1 C_{H^+}(1 - \theta_T)e^{-\beta\eta F/RT} \qquad [4]$$

where

$$\theta_T = \theta_H + \theta_R + \theta_{RH} + \theta_{RH_2}$$

At high cathodic overvoltage ($\eta \to -\infty$), Eq. [4] reduces to

$$i = -k_1 C_{H^+}(1 - \theta_T)e^{-\beta\eta F/RT} \qquad [5]$$

The fraction of bare surface, $(1 - \theta_T)$, is very small (nearly zero) at higher overvoltages. It should not vary much relative to the other fractional coverages and can be assumed to be constant. Under these conditions

$$\frac{\partial \ln i}{\partial \eta} = -\frac{\beta \mathbf{F}}{RT} \quad [6]$$

At high anodic overvoltages, the second term in Eq. [4] tends to zero. Using Eq. [3] and [4], one finds

$$i = k^2{}_{-1} \quad [7]$$

Equation [7] indicates that the current should reach a limiting value for high anodic overvoltages.

Over-all empirical equation.—The over-all cathodic reduction of crotonic acid can be represented by the following reaction

$$CH_3CH{=}CHCOOH + 2H^+ + 2e \rightarrow CH_3CH_2CH_2COOH$$

Using the concept of electrochemical reaction orders, the observed cathodic current can be expressed as

$$i_c = K_c C_R{}^{a_1} C_{H^+}{}^{b_1} C_{RH_2}{}^{d_1} \exp(-\beta \mathbf{F}E/RT) \quad [8]$$

Similarly for anodic polarization

$$i_a = K_a C_R{}^{a_2} C_{H^+}{}^{b_2} C_{RH_2}{}^{d_2} \exp((1 - \beta)\mathbf{F}E/RT) \quad [9]$$

At high cathodic overvoltages, the anodic partial current density may be neglected and the reaction orders can be obtained from the cathodic current-voltage curves.

$$\left.\frac{\partial \log |i|}{\partial \log C_R}\right|_{C_{H^+}, C_{RH_2}, E} = a_1 \quad [10]$$

$$\left.\frac{\partial \log |i|}{\partial \log C_{H^+}}\right|_{C_R, C_{RH_2}, E} = b_1 \quad [11]$$

$$\left.\frac{\partial \log |i|}{\partial \log C_{RH_2}}\right|_{C_{H^+}, C_R, E} = d_1 \quad [12]$$

The reaction orders for the anodic region can be obtained similarly from the anodic partial current density.

Effect of temperature and activation energy.—The effect of temperature on the current density is very similar to its effect on the rate of a heterogeneous chemical reaction. Hence the energy of activation can be studied by studying the effect of temperature on the current at constant potential.

The charge-transfer reaction associated with the cathodic current takes place in the direction

$$H^+ + e \rightarrow H_{ads} \quad [13]$$

The cathodic current density corresponding to this reaction is

$$i_c = n\mathbf{F}r_c \quad [14]$$

where n = number of electrons taking part and r_c = reaction rate for the cathodic process in the charge-transfer reaction.

According to Eq. [5], at constant potential, the rate constant k_1 must be proportional to the Boltzmann factor, $\exp(-E_c/RT)$, which expresses the apparent cathodic activation energy. Therefore

$$i_c = k_c C_{H^+}(1 - \theta_T) \exp(-E_c/RT) \quad [15]$$

where k_c = constant and E_c = apparent cathodic activation energy. Similarly, the anodic current density is given by

$$i_a = k_a \theta_H \exp(-E_a/RT) \quad [16]$$

where k_a = constant and E_a = apparent anodic activation energy. Therefore from Eq. [15] and [16] at constant potential and concentrations

$$\left.\frac{\partial \log i_c}{\partial (1/T)}\right|_{E,pH} = -\frac{E_c}{2.303R} \quad [17]$$

$$\left.\frac{\partial \log i_a}{\partial (1/T)}\right|_{E,pH} = -\frac{E_a}{2.303R} \quad [18]$$

The apparent activation energies E_c and E_a depend on the electrode potential E. These relationships have been derived by Vetter (14) and Delahay (15) for large excess of supporting electrolyte as

$$E_c = E^\circ{}_c + \beta \mathbf{F}E \quad [19]$$

$$E_a = E^\circ{}_a - (1 - \beta)\mathbf{F}E \quad [20]$$

Results

The current *vs.* potential plots for Pt black and Pd on C catalysts for varying pH, crotonic acid, butyric acid, and catalyst concentrations and temperature revealed a straight line relationship at high cathodic overvoltages, whereas they reached a rather low limiting current of about 3.5 mA for Pt black catalyst and 0.25-0.45 mA for Pd on C catalyst for low anodic overvoltages. Figures 2, 3, and 4 are typical current *vs.* potential graphs for Pt black slurry electrodes for varying pH, crotonic acid, and butyric acid concentrations, respectively. Figures 5 and 6 are typical current *vs.* potential graphs for Pd on C slurry electrodes for varying catalyst concentrations and temperature, respectively. All the data, except the ones at varying temperature, were taken at 20°C. The reaction orders with respect to pH, crotonic acid, and butyric acid were obtained using a linear least square fit of Eq. [8] and are tabulated in Table I for Pt black and for Pd on C catalysts. The activation energies calculated are shown in Table II. The coulombic efficiency based on butyric acid was calculated as 84.8 and 78.8% for two separate runs for Pd on C catalyst systems using gas chromatograph techniques for determining butyric acid.

Discussion

It was shown in preliminary experiments that the blank current, *i.e.*, the current when no catalyst is present, was less than 5% of the current obtained when

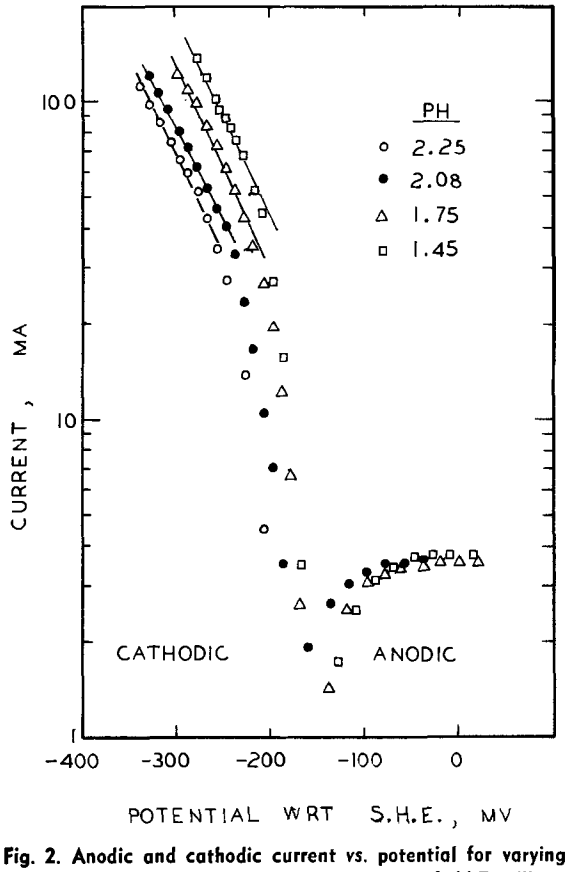

Fig. 2. Anodic and cathodic current *vs.* potential for varying pH values at constant crotonic acid concentration of 66.7 g/liter and Pt black catalyst concentration of 1.25 g/liter.

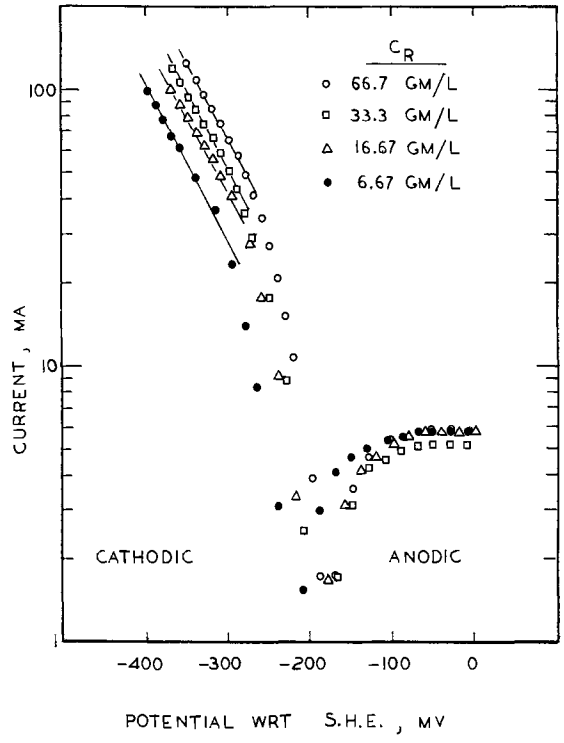

Fig. 3. Anodic and cathodic current vs. potential for varying crotonic acid concentrations at constant Pt black catalyst concentration of 1.25 g/liter.

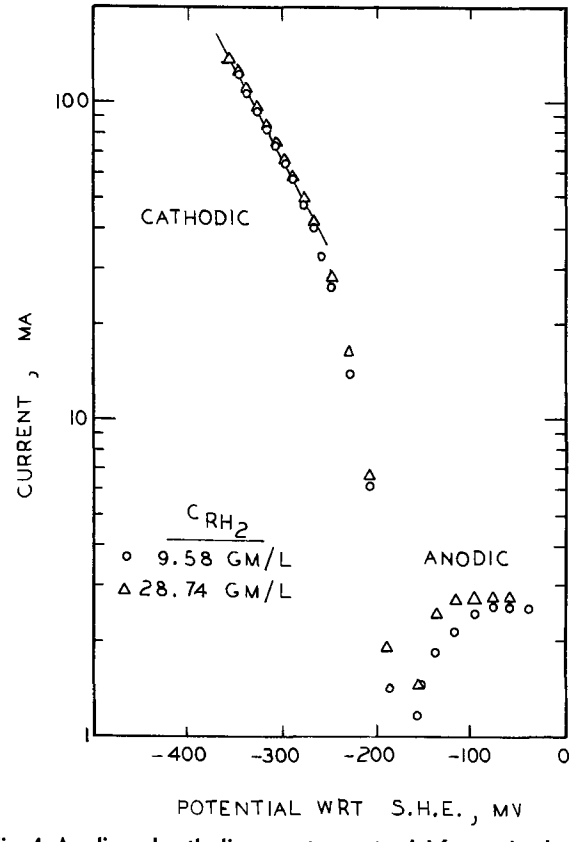

Fig. 4. Anodic and cathodic current vs. potential for varying butyric acid concentrations at constant crotonic acid concentration of 66.7 g/liter and Pt black catalyst concentration of 1.25 g/liter.

the catalyst was present. Hence this blank current was neglected and the observed current was taken as due to the slurry electrode alone. It was also shown that the pH effect was the same at two different crotonic acid concentration levels and it was hence assumed that each effect was independent of the other.

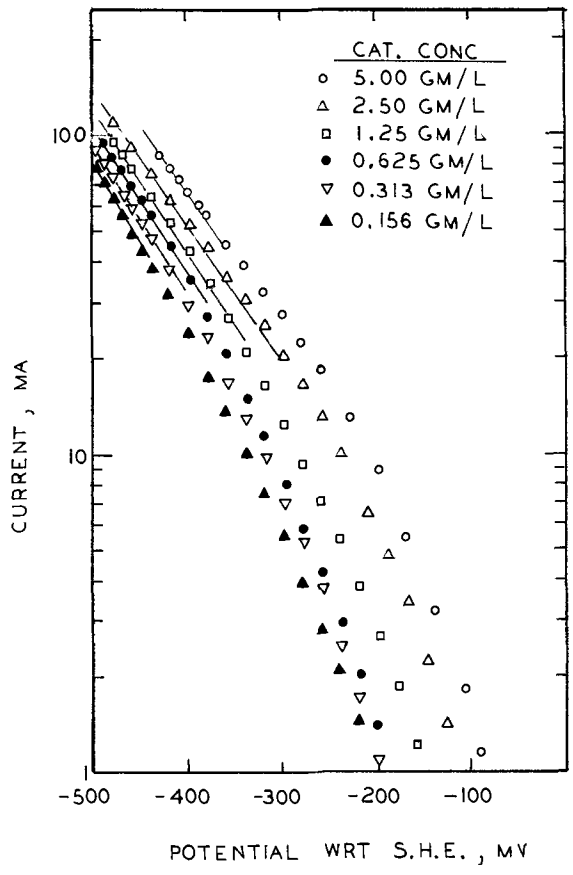

Fig. 5. Cathodic current vs. potential for varying concentrations of 5% Pd on C catalyst at constant crotonic acid concentration of 66.7 g/liter.

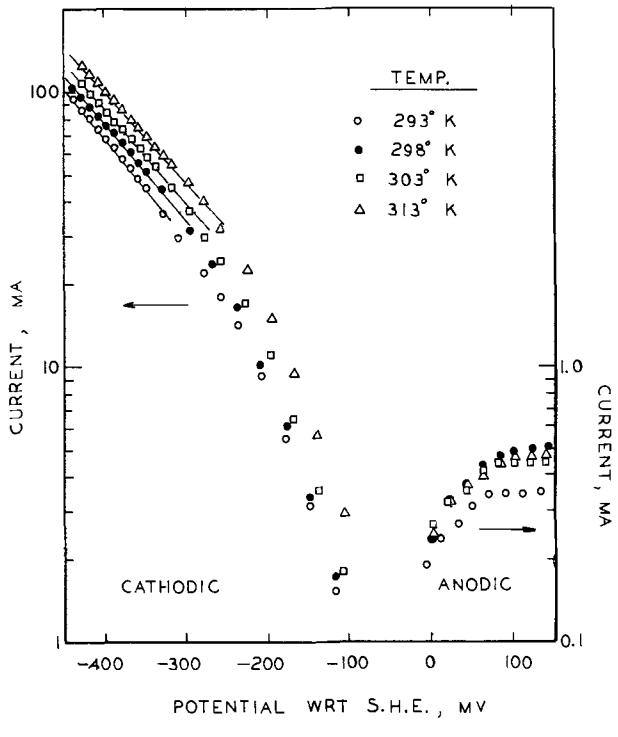

Fig. 6. Cathodic and anodic current vs. potential for varying temperatures at constant crotonic acid concentration of 66.7 g/liter and 5% Pd on C catalyst concentration of 5 g/liter.

Effect of pH.—The reaction order with respect to pH for both 5% Pd on C and Pt black catalysts was found to be around 0.5. This seems qualitatively correct, in that the higher the hydrogen ion concentration the

Pt black	−3.82 kcal/mole	−850	0.0045

larger will be the rate of the charge-transfer step and hence the current, independent of the catalyst used.

Equation [5] can be rewritten in terms of the potential, E, by substituting in it $\eta = E - E^o$

$$i = -kC_{H^+}(1 - \theta_T)e^{-\beta FE/RT} \qquad [21]$$

where

$$k = k_1 e^{-\beta FE^o/RT} = \text{constant} \qquad [22]$$

Equation [21] predicts a reaction order of unity with respect to hydrogen ion concentration, whereas the observed order is around 0.5. A similar situation in the oxidation of hydrocarbons was explained by Bockris *et al.* (16, 17), who proposed that there is a penetration of hydrogen atoms into the platinum lattice of the electrode and that a charged double layer exists within that electrode due to dipoles generated. The observed potential difference is the potential difference between the bulk of the solution and the interior of the electrode and does not take into account the potential drop through the double layer due to the dioples within the electrode. Hence, to make use of Eq. [21], the potential difference, E, has to be replaced by the observed potential difference, E_S, plus the potential of zero charge, E_{PZC}

$$E = E_S + E_{PZC} \qquad [23]$$

Experimental observations by Bockris *et al.* (16, 17) have shown that PZC changes with pH on a clean Pt foil by RT/F per unit pH unit as expressed by the following equation

$$E_{PZC} = E^o_{PZC} + (RT/F) \ln a_{H^+} \qquad [24]$$

where E^o_{PZC} = constant and a_{H^+} = activity of hydrogen ion.

This equation was obtained experimentally for a highly purified Pt electrode and has no theoretical basis. Hence it is reasonable to multiply the pH effect by a factor α to take into consideration that the system being considered in this study had a different electrode and different electrolyte from that studied by Bockris *et al.*

Therefore we write

$$E_{PZC} = E^o_{PZC} + (\alpha RT/F) \ln a_{H^+} \qquad [25]$$

and Eq. [21] can be written as

$$i = -ka_{H^+}{}^{(1-\alpha\beta)}(1 - \theta_T) \exp(-\beta F(E_S + E^o_{PZC})/RT) \qquad [26]$$

Therefore

$$\left.\frac{\partial \ln i}{\partial \ln a_{H^+}}\right|_{E_S} = 1 - \alpha\beta \qquad [27]$$

The fractional order $(\partial \ln i/\partial \ln a_{H^+})_{E_S}$ observed was 0.42 for Pd on C catalyst and 0.52 for Pt black catalyst (Table I). Since the experimental value of β was found to be 0.2 for Pd on C and 0.3 for Pt black, the value of α is calculated to be 2.9 for Pd on C and 1.6 for Pt black. The value of α different from unity is to be expected, since the present system is quite different from the one for which Eq. [24] was obtained.

Effect of crotonic acid concentration.—The reaction order with respect to crotonic acid concentration was found to be −0.05 for Pd on C and 0.07 for Pt black, and hence can be assumed to be zero for both the catalysts. A similar observation has been made in the electrochemical reduction of maleic acid (19). This zero order with respect to crotonic acid may be explained by reference to Eq. [21]. If it is assumed that the catalyst surface is saturated with adsorbed crotonic acid so that the fraction of crotonic acid adsorbed on the catalyst θ_R is constant for varying concentrations of crotonic acid, one finds for the apparent order

$$\left.\frac{\partial \ln i}{\partial \ln C_R}\right|_{E,pH} = 0 \qquad [28]$$

Effect of butyric acid concentration.—The observed effect of butyric acid concentration was different for the two catalysts studied. The reaction order is −0.48 for Pd on C and nearly zero for Pt black.

This would seem to imply that the adsorption of butyric acid is markedly weaker on Pd on C than on Pt black. However, more detailed data on the competitive adsorption of crotonic acid and butyric acid and their effects on the rate-limiting step would be necessary for fuller understanding of the apparent orders for crotonic and butyric acids. In the absence of data, speculation on this point seems highly inconclusive.

Anodic effects.—The anodic reaction orders with respect to pH, crotonic acid concentration, and butyric acid concentration were found to be negligible or zero, within limits of reproducibility.

The anodic limiting current that was observed in all cases is probably due to mass-transfer limitations. The reaction steps for the anodic current can be written as follows

$$H_2 \rightarrow 2H_{ads} \qquad [\text{step 1}]$$

$$H_{ads} \rightarrow H^+ + e \qquad [\text{step 2}]$$

$$CH_3CH{=}CHCOOH + 2H_{ads} \rightarrow CH_3CH_2CH_2COOH \qquad [\text{step 3}]$$

Mass-transfer limitation occurs when the hydrogen transfer from the solution to the catalyst surface becomes limited in the step prior to the charge-transfer reaction. Therefore increasing the potential does not increase the rate of step 2 and a limiting current is observed. A low limiting current would be observed if the crotonic acid were adsorbed tightly on most of the catalyst sites, leaving only a few sites available for hydrogen adsorption.

This was checked by obtaining the anodic current-potential curves with a Pd on C catalyst, but no crotonic acid, as shown in Fig. 7. A limiting current of 16 mA was reached as compared to 0.5 mA when crotonic acid was present. To check the effect of butyric acid, the anodic current-potential curve was obtained for a solution containing 9.5 g/liter butyric acid and Pd on C catalyst as shown in Fig. 7. This had a limiting current of 16.5 mA. The two curves, with and without butyric acid, were very similar except that the curve for the one without butyric acid rose at first more slowly with increasing potential than the curve with butyric acid. At higher potentials they were very alike. There was also a potential shift observed at open circuit. Since the pH of the solution with butyric acid (pH = 2.8) was much lower than the pH of the solution without it, the anodic current-potential curve was obtained for a solution without butyric acid containing Pd on C catalyst at pH = 2.8 made by adding sulfuric acid. As shown in Fig. 7, this curve can be superimposed exactly on the curve taken when butyric acid was present at the same pH. Hence the shift was due to pH effect and not to butyric acid *per se*.

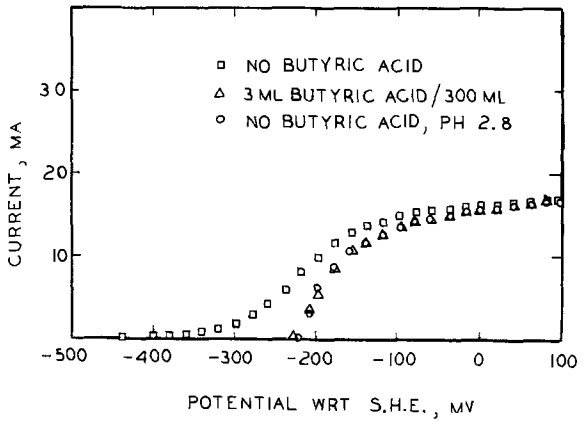

Fig. 7. Anodic current vs. potential, with and without butyric acid and no crotonic acid, and 5 g/liter 5% Pd on C catalyst.

The above experiments confirmed that addition of butyric acid did not inhibit the current when crotonic acid was absent. The current was inhibited when crotonic acid was present. Hence crotonic acid must be strongly adsorbed on the catalyst sites.

Effect of catalyst concentration.—The current was proportional to a fractional power of the catalyst concentration at constant potential for both Pd on C and Pt black catalysts at high overvoltages. It was presumed initially that since the charge is transferred during the collisions of the catalyst particles with the collector electrode, increasing the number of catalyst particles should increase the current proportionately at constant overvoltage and not constant potential. This was observed for oxidation of hydrogen on Pd on C and Pt black (11, 13). But it was not true for the present system studied, where the current was found to be independent of catalyst concentration for both the catalysts at constant overvoltage. This can be seen in Fig. 8 which is the graph of current-overvoltage for Pd on C catalyst. The catalyst concentration appeared to affect only the open-circuit potential.

Since the catalyst particles are around 0.5μ in diameter, they are at an average distance of 20 diameters or more apart in the solution for the range of concentrations used. Hence the assumption that the particles interfered with one another is hard to maintain.

Calculations to check the diffusion rate of hydrogen through the pores formed by a cluster of the catalyst particles revealed there was no limitation to the diffusion.

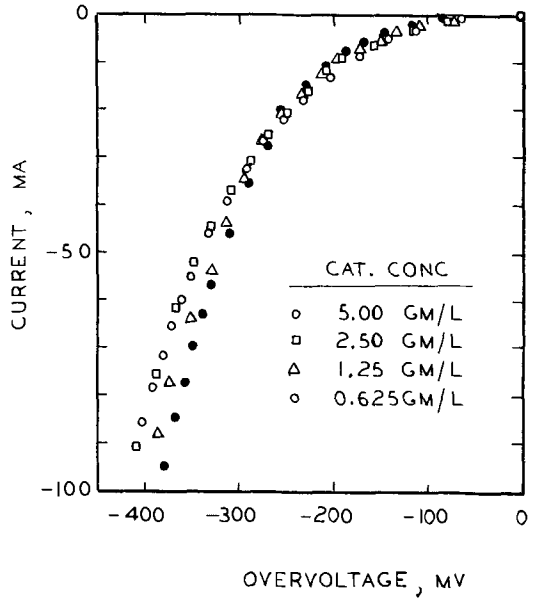

Fig. 8. Cathodic current vs. overvoltage for varying 5% Pd on C catalyst concentrations at constant crotonic acid concentration of 66.7 g/liter.

The decrease of the open-circuit potential with increased catalyst concentration could not be explained by the hypothesis that the pH of the solution increased due to adsorption of hydrogen ions from the solution on the catalyst particles since the pH of the solution with varying amounts of the catalysts was found to be constant at 2.45 in separate measurements.

A possible explanation is that since the clusters of the particles are loosely held together by a film of electrolyte, the electrical resistance is not the same throughout the cluster. When the cluster comes in contact with the collector electrode, only the hydrogen ions near the surface pick up the discharged electrons, whereas the ones further away cannot because of relatively higher resistance. As the catalyst concentration increases, the size of the clusters may increase, but only the same number of particles near the surface can discharge, and hence increased catalyst concentration has no effect on the total current.

In the absence of a fully satisfactory explanation, the cathodic current was expressed empirically as

$$i_c = kw^f e^{-\beta FE/RT} \qquad [29]$$

The values of f and β are 0.23 and 0.24, respectively, for Pd on C and 0.45 and 0.31 for Pt black.

Effect of temperature.—The cathodic activation energy values (Table II) represent activation energy not for the over-all reduction of crotonic acid, but only for the charge-transfer step. They are in agreement with those between —3 and —7 kcal/mole observed by Conway and MacKinnon (20) for the hydrogen ion reduction on metals. These low values of the activation energies are expected of atomic reactions like the hydrogen ion reduction where there is no breaking of chemical bonds.

The Tafel slope was found not to be a function of temperature in the range studied, but was constant (Table II). Conway *et al.* (20, 21) have noted that the Tafel slope given by $\beta F/RT$ is rarely found experimentally to be of that form, but is far less temperature dependent than is implied by that relation and is usually independent of temperature.

For the anodic polarization, no temperature effect was noticed, possibly because it was smothered by mass-transfer limitations evident from the low limiting anodic current.

Current efficiency.—Since the hydrogen formed could either desorb to form hydrogen gas or react with crotonic acid to give butyric acid, the reaction efficiency of around 80% meant that 80% of the hydrogen reacted with crotonic acid to give butyric acid, and that only 20% was desorbed to form hydrogen gas. Hence Pd on C catalyst was rather selective for the hydrogenation path and the current could be used as a measure of the reaction rate. This would be equally true of Pt black catalyst.

Manuscript submitted Sept. 29, 1972; revised manuscript received May 10, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

The Transient Response of a Disk Electrode

Kemal Nişancioğlu* and John Newman**

Inorganic Materials Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A mathematical model is proposed to treat the transient response of a disk electrode to a change in the applied current. The analysis reduces to a well-defined boundary value problem, which yields solutions in terms of newly defined eigenfunctions. The results allow the determination of time constants characteristic of decay due to an electrode reaction and due to a redistribution of charge within the double layer during the transient process.

The transient behavior of electrochemical cells has been of interest since the development of the commutator method for the assessment of electrode overpotentials (1). The subsequent invention of the more accurate interrupter technique (2) and its perfection in the last couple of decades (3, 4) have provided a reliable tool for the measurement of the uncompensated ohmic drop in the solution. The presence of a nonuniform current distribution at the electrode surface [such as in the case of a disk electrode below the limiting current (5-7)], however, appears to complicate the interpretation of interrupter data, as this subject has already received ample thought and experimentation (4, 8-12).

Newman (8) has shown that the step change in potential at interruption corresponds to the primary current distribution (5) and discussed the time constants for decay of the double-layer capacity due to a faradaic reaction and redistribution of charge within the double layer. A more complete mathematical study will be presented here in order to determine the transient response of a disk electrode to step changes in the cell current.

The problem was originally conceived for an ideally polarizable electrode with the purpose of calculating the transients one would observe during the charging and decay of the double-layer capacity. However, the effect of a faradaic reaction can be incorporated into the formulation without any added difficulty in the analysis. The more general case will therefore be analyzed with due notice of the mathematical subtleties relevant to an ideally polarizable electrode. [According to Grahame (18), an ideally polarizable electrode is one for which no steady current flows at any potential in the range of potentials of interest.]

The following assumptions are made in the treatment of the problem:

(*i*) The disk electrode is embedded in an infinite, insulating plane, and the counterelectrode is placed at infinity.

(*ii*) The diffusion layer is neglected. This is a fairly good assumption when the rate of stirring is high (high rotation speeds), and the current density at the electrode surface is considerably below the limiting current (13).

(*iii*) Linear kinetic relationships govern the electrode reaction. This situation is encountered for high reaction rate constants and sufficiently small current densities such that $|i| << i_o$, where i_o is the exchange current density (6).

(*iv*) The double-layer capacity is regarded to be independent of the potential. This is a reasonable approximation for small changes in the electrode potential, especially for cathodic polarizations with respect to the electrocapillary maximum.

The last three assumptions are stated for the sake of simplicity so that the phenomena which directly influence the transient behavior of an electrode can be singled out for investigation with a minimum number of complicating factors. The effect of steady-state mass transfer on the current distribution below the limiting current has been discussed elsewhere for various geometries with the consideration of nonlinear electrode kinetics (6, 7, 14, 15). Newman has treated the mass transfer problem in rapid double-layer charging at an ideally polarizable electrode (16). Some attention has been directed to the proper treatment of the capacitive effect of the diffuse double layer in transient problems in the presence of concentration and sizable potential variations, and the reader is directed to the pertinent literature (19-21). More discussion is also in order in a later section concerning the validity of the above assumptions in practical application.

Mathematical Model

The potential in the solution satisfies Laplace's equation

$$\nabla^2 \Phi = 0 \qquad [1]$$

The boundary conditions are

$$\frac{\partial \Phi}{\partial z} = 0 \qquad \text{at } z = 0, r > r_o \qquad [2]$$

** Electrochemical Society Student Member.
* Electrochemical Society Active Member.
Key words: interrupter, double-layer capacity, time constant, ideally polarizable electrode.

$$\Phi \to 0 \qquad \text{as } r^2 + z^2 \to \infty \qquad [3]$$

and the potential is well behaved on the axis of the disk. Furthermore, the normal component of the current density at the electrode surface is given by (13)

$$i_z = C\frac{\partial \eta_s}{\partial t} + (\alpha_a + \alpha_c)\frac{i_o F}{RT}\eta_s = -\kappa\frac{\partial \Phi}{\partial z}$$

$$\text{at } z = 0, r \leq r_o \qquad [4]$$

where

$$\eta_s = V - \Phi_o \qquad [5]$$

is the surface overpotential associated with the faradaic reaction, V is the electrode potential, Φ_o is the potential in the solution adjacent to the electrode, κ is the conductivity of the solution, C is the double-layer capacity, and $(\alpha_a + \alpha_c)\ i_o\ \mathbf{F}/RT$ is the kinetic coefficient for the faradaic reaction.

We would like to have our model simulate the transient response of a disk electrode for the charging or decay of the double-layer capacity immediately after the current is turned on or off, respectively. The potential in solution for the charging period can then be represented as the difference of a steady-state and a transient contribution

$$\Phi = \Phi^{ss} - \Phi^t \qquad [6]$$

such that each part satisfies Laplace's equation by itself. The electrode potential V can similarly be expressed as the difference of a steady-state and a transient part. The steady-state part of the potential includes the contribution of the total cell current, while the transient part contains no net current. Once the current is turned off, therefore, the steady-state part vanishes, and the decay period is represented by only the transient part: $\Phi = \Phi^t$.

Steady-State Part of the Potential

The solution of Laplace's equation for the potential distribution in a disk electrode system is well known for various steady-state boundary conditions at the electrode surface (5, 6, 9). A solution for the steady-state part of the potential will be presented here to meet the purposes of this analysis.

In rotational elliptic coordinates (5) η and ξ, the solution for the steady-state part of the potential satisfying the conditions [2] and [3] can be expressed as (6)

$$\frac{\Phi^{ss}}{\Phi_o^p} = \sum_{n=0}^{\infty} B_n^{ss} P_{2n}(\eta)\, M_{2n}(\xi) \qquad [7]$$

where $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$, $M_{2n}(\xi)$ is a Legendre function with known properties (7), and Φ_o^p is the uniform potential in the solution just outside the double layer corresponding to the primary current distribution (5). This quantity, in fact, is the ohmic drop which is normally measured by interrupter methods (8) and is identical to $I/4\kappa r_o$ in this work. The choice of Φ_o^p as the scaling factor in Eq. [7] is mathematically convenient since this normalizes the numerical value of B_o^{ss} to unity regardless of the electrode conditions. Substitution into the boundary condition [4] yields

$$-\frac{1}{\eta}\frac{\partial \Phi^{ss}}{\partial \xi}\bigg|_{\xi=0} = J\,(V^{ss} - \Phi_o^{ss}) \qquad [8]$$

where J is the dimensionless exchange current density given by

$$J = \frac{i_o r_o F}{RT\kappa}(\alpha_a + \alpha_c) \qquad [9]$$

Combining Eq. [7] and [8] and employing the orthogonality property of the Legendre polynomials (6) gives

$$\frac{V^{ss}}{\Phi_o^p} = 1 + \frac{4}{\pi J} + 2\sum_{n=1}^{n_{max}} a_{o,n} B_n^{ss} \qquad [10]$$

and

$$\sum_{n=1}^{n_{max}}\left[a_{m,n} - 2a_{o,m}a_{o,n} - \delta_{m,n}\frac{M'_{2m}(0)}{(4m+1)J}\right]B_n^{ss} = \frac{4}{\pi J}a_{o,m} \quad (m = 1, 2, \ldots, n_{max}) \qquad [11]$$

where

$$a_{m,n} = \int_0^1 \eta\, P_{2m}(\eta)\, P_{2n}(\eta)\, d\eta \qquad [12]$$

$$a_{o,m} = \int_0^1 \eta\, P_{2m}(\eta)\, d\eta = -\frac{P_{2m}(0)}{2(2m-1)(m+1)} \qquad [13]$$

$$\delta_{m,n} = \begin{cases} 0 \text{ if } m \neq n \\ 1 \text{ if } m = n \end{cases} \qquad [14]$$

The series in Eq. [10] and [11] are truncated at n_{max} for the purposes of numerical calculation. The accuracy of calculation hence depends on the number of terms taken into consideration. The coefficients B_n^{ss} for the first 10 terms in the series are listed in Table I for various J values. The quantity V^{ss}/Φ_o^p, which can directly be calculated from Eq. [10] once B_n^{ss} are obtained from Eq. [11], is identified as the dimensionless effective d-c resistance (17) $4r_o\kappa R_{eff}$ for the disk system with the reference electrode at infinity.

For an ideally polarizable electrode it is possible to express the coefficients B_n^{ss} explicitly. Since for large charging times the ideally polarizable electrode surface attains a uniform current distribution, we can replace the condition [8] with

$$-\frac{1}{\eta}\frac{\partial \Phi^{ss}}{\partial \xi}\bigg|_{\xi=0} = \frac{I}{\pi r_o \kappa} \qquad [15]$$

which yields

$$B_n^{ss} = -4a_{o,n}(4n+1)/\pi M'_{2n}(0) = -\frac{(4n+1)\,[P_{2n}(0)]^3}{(2n-1)(n+1)} \qquad [16]$$

An Eigenvalue Problem

The transient part of the potential can be expressed by a series expansion of the form

$$\frac{\Phi^t}{\Phi_o^p} = \sum_{i=1}^{\infty} C_i e^{-t/\tau_i} U_i(r, z) \qquad [17]$$

where U_i is a characteristic dimensionless potential defined here to be independent of time, and τ_i is a time constant for decay corresponding to the potential U_i. The analysis can be pursued conveniently in terms of two additional dimensionless quantities, *viz.* the

dimensionless eigenvalue

$$\Lambda_l = \frac{r_o C}{\kappa \tau_l} - J \qquad [18]$$

and the dimensionless time

$$\theta = \frac{\kappa t}{r_o C} \qquad [19]$$

Equation [17] then transforms to the form

$$\frac{\Phi^t}{\Phi_o^p} = \sum_{i=1}^{\infty} C_l e^{-\theta(\Lambda_l + J)} U_l(\eta, \xi) \qquad [20]$$

The transient part of the electrode potential can analogously be expressed as

$$\frac{V^t}{\Phi_o^p} = C_o e^{-\theta J} + \sum_{i=1}^{\infty} C_l e^{-\theta(\Lambda_l + J)} v_l \qquad [21]$$

where v_l is a constant which will henceforth be taken to be unity, thus providing a normalization for the eigenfunctions U_l.

The functions U_l satisfy Laplace's equation

$$\nabla^2 U_l = 0 \qquad [22]$$

and the conditions

$$\left.\begin{aligned} &\frac{\partial U_l}{\partial \eta} = 0 \quad \text{at } \eta = 0 \\ &U_l = 0 \quad \text{as } \xi \to \infty \\ &U_l \text{ well behaved at } \eta = 1 \end{aligned}\right\} \qquad [23]$$

The solution can therefore be given by

$$U_l = \sum_{n=1}^{\infty} B_{n,l} P_{2n}(\eta) M_{2n}(\xi) \qquad [24]$$

The zeroeth term is excluded from the summation since U_i includes no contribution to the net current. The boundary condition [4] now reduces to

$$\left.\frac{\partial U_i}{\partial \xi}\right|_{\xi=0} = \Lambda_i \eta (1 - U_{i,o}) \qquad [25]$$

Combining Eq. [24] and [25] and invoking the orthogonality property of the Legendre polynomials yield

$$\sum_{n=1}^{n_{max}} a_{o,n} B_{n,l} = \frac{1}{2} \qquad [26]$$

$$\sum_{n=1}^{n_{max}} \left[a_{m,n} + \frac{\delta_{m,n}}{\Lambda_l} \frac{M'_{2m}(0)}{4m+1} \right] B_{n,l} = a_{o,m}$$

$$(m = 1, 2, \ldots, n_{max}) \qquad [27]$$

The above set of equations can be solved simultaneously for Λ_l and $B_{n,l}$. Some results are given in Table II, and the first three eigenfunctions are plotted in Fig. 1.

Each term in Eq. [17], and the corresponding term in Eq. [21], describes a potential distribution and a state of charge in the electric double layer which can decay with a single time constant and involves no net current flow to the counterelectrode at infinity. The state of charge is proportional to $V - \Phi_o$ or to $1 - U_{i,o}$ for a particular eigenfunction. If this state of charge is nonuniform, it will have associated with it a flow of current through the solution in a direction which tends to make even the charge distribution across the electrode. At the same time, the double-layer charge may be decaying through the faradaic reaction (if $J > 0$).

If each eigenfunction is to represent a single time constant, the amount of current flowing through the solution (related to $\partial U_i/\partial \xi$ at $\xi = 0$) must be proportional, over the surface of the electrode, to the rate of change of the double-layer charge. Equation [25] represents this state of affairs. Only for certain characteristic decay constants Λ_l is it possible to find consonant current and charge distributions which decay with a single time constant, and these eigenvalues are not known in advance. The lowest eigenvalue, either $\Lambda_o = 0$ or $\Lambda_1 = 4.12130$, is the most important because its effect can most readily be observed experimentally after the other eigenfunctions have decayed to negligible values.

It is a further consequence of boundary condition [25] (current in solution is proportional to surface charge for each eigenfunction) that the eigenfunctions U_i satisfy the unusual orthogonality relationship

$$\int_0^1 U_{i,o}(1 - U_{j,o})\, \eta d\eta = \begin{cases} \dfrac{1}{\Lambda_l} \displaystyle\sum_{n=1}^{\infty} \frac{M'_{2n}(0)}{4n+1} B^2_{n,l} & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases} \qquad [28]$$

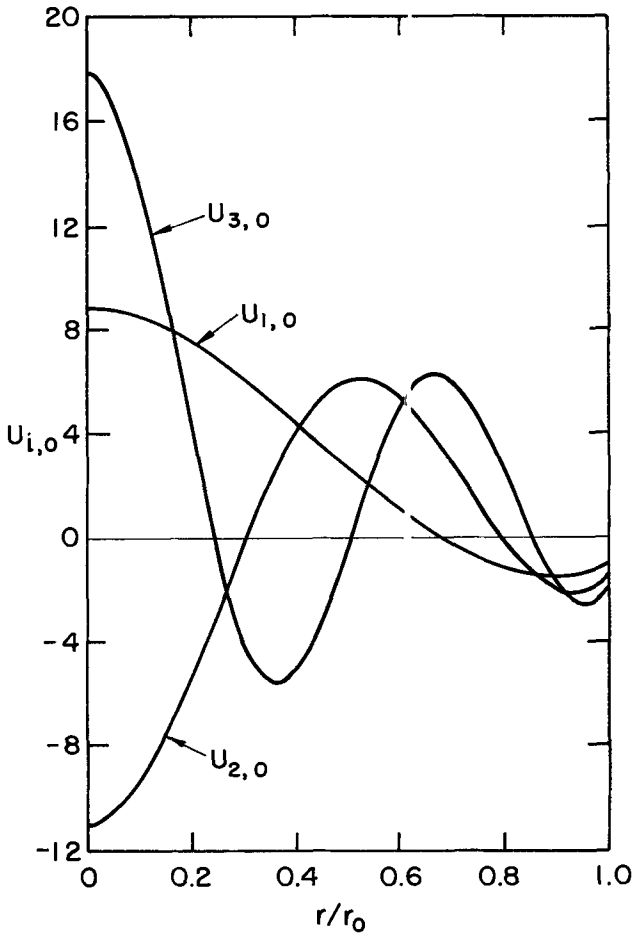

Fig. 1. The first three eigenfunctions for the transient solution

This has much the same meaning; the potential at the surface for one eigenfunction is in a sense orthogonal to the current density for another eigenfunction.

One can study the eigenfunctions in Fig. 1 to visualize how the current flows through the solution. The potential is nonuniform for a given eigenfunction because the state of charge is nonuniform. The current density in the solution is proportional to $1 - U_{i,o}$ and flows from a region of high charge to a region of low charge. The higher order eigenfunctions have more minima and maxima in the curves. The current need, therefore, flow a shorter distance in order to even up the charge, and the time constants are correspondingly shorter.

Transient Potential Distribution

In order to be able to calculate the values of C_i and thereby complete the analysis, we need to specify suitable initial conditions for the problem. Let us assume that the current is switched on as a step at $\theta = 0+$ and kept constant until $\theta = \theta_{ch}$, at which instant it is turned off. The time scale for the decay period can be defined as

$$\theta' = \theta - \theta_{ch} \qquad [29]$$

Therefore, for the charging period

$$V = \Phi_o = \Phi_o^p \quad \text{at} \quad \theta = 0+, \quad \xi = 0 \qquad [30]$$

and for the decay period

$$\left.\begin{aligned} V &= V(\theta_{ch}) - \Phi_o^p \\ \Phi_o &= \Phi_o(\theta_{ch}) - \Phi_o^p \end{aligned}\right\} \text{at} \quad \theta' = 0+, \quad \xi = 0 \qquad [31]$$

Application of the initial condition [30] for the charging period to Eq. [6] gives

$$\frac{\Phi_o^{ss}}{\Phi_o^p} - 1 = \sum_{i=1}^{\infty} C_i U_{i,o} \qquad [32]$$

Multiplication by $(1 - U_{j,o})\eta$ and integration with respect to η yields

$$C_j = \frac{\int_0^1 \frac{\Phi_o^{ss}}{\Phi_o^p}(1 - U_{j,o})\,\eta d\eta}{\int_0^1 U_{j,o}(1 - U_{j,o})\,\eta d\eta} = \frac{\sum_{n=1}^{\infty} \frac{M'_{2n}(0)}{4n+1} B_n^{ss} B_{n,j}}{\sum_{n=1}^{\infty} \frac{M'_{2n}(0)}{4n+1} B^2_{n,j}} \qquad [33]$$

Application of the corresponding initial condition for the electrode potential gives

$$C_o = \frac{V^{ss}}{\Phi_o^p} - 1 - \sum_{i=1}^{\infty} C_i = \frac{4}{\pi J} \qquad [34]$$

For the decay period where $\Phi = \Phi^t$ (the negative of the transient part for charging), the same results, summarized by Eq. [32]-[34], also apply as long as θ_{ch} is large enough so that the steady state has been reached right before interruption. If this is not the case, the equations for decay become

$$\frac{\Phi}{\Phi_o^p} = \sum_{i=1}^{\infty} C_i \left[1 - e^{-\theta_{ch}(\Lambda_i + J)}\right] e^{-\theta'(\Lambda_i + J)} U_i \qquad [35]$$

for the potential in the solution, and

$$\frac{V}{\Phi_o^p} = C_o(1 - e^{-\theta_{ch} J})\, e^{-\theta' J} + \sum_{i=1}^{\infty} C_i \left[1 - e^{-\theta_{ch}(\Lambda_i + J)}\right] e^{-\theta'(\Lambda_i + J)} \qquad [36]$$

for the electrode potential. The coefficients C_i are the same as for the charging period, given by Eq. [33] and [34].

For an ideally polarizable electrode ($J = 0$) the same relationships hold to express the potential in the solution, both for charging and for decay. The electrode potential, however, increases indefinitely once the current is turned on and decays to a nonzero value after the interruption of current. This is because of the fact that the net double-layer charge has no means for decay in the absence of an electrode reaction; it can only redistribute by flow of current through the solution in order to attain a final uniform state. Hence, for the charging period we have

$$\frac{V}{\Phi_o^p} = \frac{4}{\pi}\theta + D - \sum_{i=1}^{\infty} C_i e^{-\Lambda_i \theta} \qquad [37]$$

The constant term can be obtained by integrating condition [4] over the electrode surface for the total period of charging to obtain the net charge added to the double layer

$$2\pi C \int_0^{r_o}\int_0^{t_{ch}} \frac{\partial(V - \Phi_o)}{\partial t}\, dtrdr = 2\pi \int_0^{r_o}\int_0^{t_{ch}} i_z\, dtrdr = It_{ch} \qquad [38]$$

Substitution of Eq. [6] and [37] into the left side and integration lead to the result

$$D = 2\sum_{n=0}^{\infty} B_n^{ss} a_{o,n} = 1.08076 = 32/3\pi^2 \qquad [39]$$

Finally, the electrode potential for the decay period is

$$\frac{V}{\Phi_o^p} = \frac{4}{\pi}\theta_{ch} + \sum_{i=1}^{\infty} C_i e^{-\Lambda_i \theta'}(1 - e^{-\Lambda_i \theta_{ch}}) \qquad [40]$$

The analysis at this point can readily be extended to account for arbitrary changes in the cell current by a straightforward application of the superposition integral. If the time dependent cell current is given by $I(\theta)$, the electrode potential can be expressed as

$$4r_o\kappa V = I(\theta) + C_o J e^{-\theta J}\int_0^{\theta} I(\theta) e^{\theta J} d\theta + \sum_{i=1}^{\infty} C_i(\Lambda_i + J) e^{-\theta(\Lambda_i + J)} \int_0^{\theta} I(\theta) e^{\theta(\Lambda_i + J)} d\theta \qquad [41]$$

in the presence of an electrode reaction, and

$$4r_o\kappa V = I(\theta) + \frac{4}{\pi}\int_0^{\theta} I(\theta)\, d\theta + \sum_{i=1}^{\infty} C_i \Lambda_i e^{-\Lambda_i \theta} \int_0^{\theta} I(\theta) e^{\Lambda_i \theta} d\theta \qquad [42]$$

for an ideally polarizable electrode. One application of these equations would be for an a-c situation, where the frequency dispersion of the measured impedance is of interest. A more rigorous and accurate calculation has been performed by Newman (17) for this particular case. The present equations were used to compute the frequency dispersion in capacity measurements at a disk electrode and compared to Newman's results (17). The agreement is good for small frequencies, but a large number of terms is required in the series to attain any reasonable accuracy at high frequencies. The same numerical problem is encountered in calculating the short-time response of the potential to a step change in the current since the series do not converge very fast. An asymptotic

solution, applicable to small charging and decay periods, may therefore be desirable.

Results and Discussion

Figure 2 depicts a typical potential trace for double-layer charging and decay in the presence of a faradaic reaction, and Fig. 3 shows potential decay curves after the interruption of current for various values of the kinetic parameter J. For both representations, the current is interrupted after the double layer is charged to steady-state conditions. For large decay periods, the slope of each curve approaches the corresponding J value on a semilogarithmic scale as can be inferred from Eq. [36]. Curves similar to Fig. 2 could be constructed for different J values by making use of the information contained in Fig. 3 and by remembering that the ohmic drop is given by the primary distribution Φ_0^p and that the charging and decay portions of each curve are symmetric.

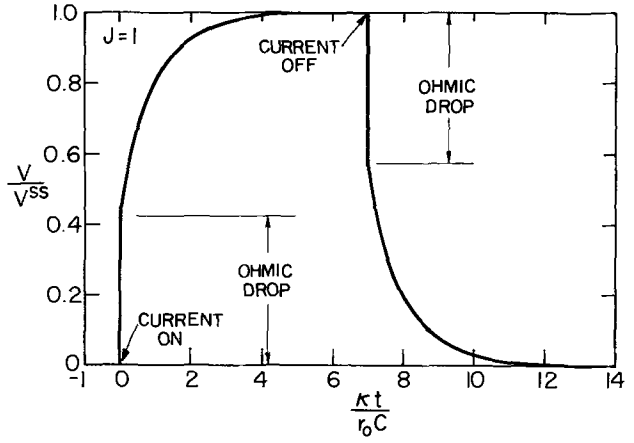

Fig. 2. Double-layer charging and decay in the presence of a faradaic reaction.

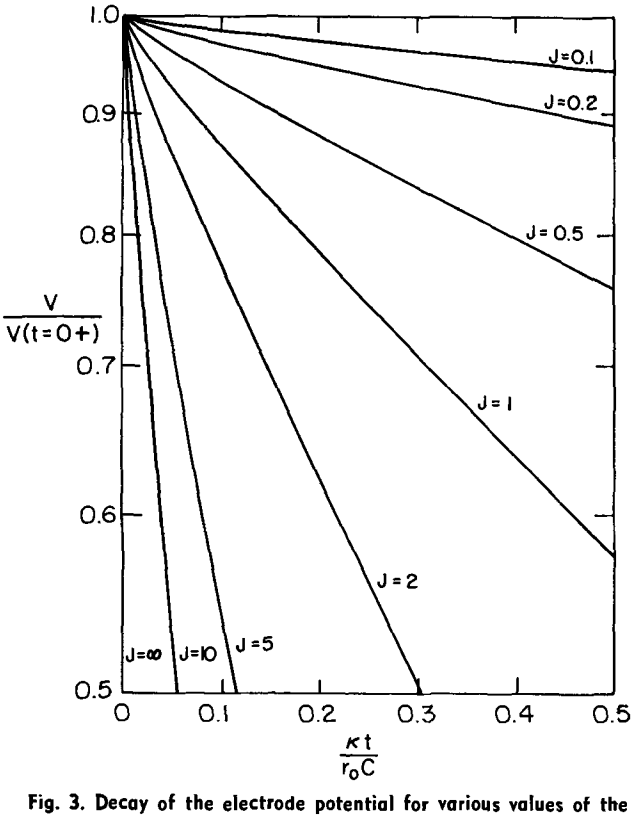

Fig. 3. Decay of the electrode potential for various values of the kinetic parameter J. A steady condition was attained before interruption of the current.

The fact that the instantaneous potential step immediately preceding both the charging and decay portions of Fig. 2 corresponds to the primary current distribution (8) is implicit in the present analysis by virtue of the particular initial conditions (Eq. [30] and [31] employed. Nanis and Kesselman (9) have expressed the contrary view in this regard. We would like to stress that the same criterion would hold for the ohmic drop even if the diffusion layer were taken into consideration. An experimental verification along these lines has been provided by Miller and Bellavance (12).

The transient response of an ideally polarizable electrode to step changes in the current is depicted in Fig. 4. The step portions again correspond to the primary distribution. The differences in comparison to Fig. 2 are obvious. The potential-time relationship becomes linear for sufficiently large charging periods as the surface current density attains a uniform distribution. After the interruption of current, the electrode potential decays to a nonzero value, given by $4\theta_{ch}/\pi$. Decay curves for various charging periods are sketched in Fig. 5 to show the effect of short charging times on the potential decay. The same effect is also discernable when J is greater than zero, but the dependence on the charging period was not of prime interest in constructing Fig. 3 and was suppressed by allowing a steady state to develop before current interruption.

An important result of the present analysis is the assessment of an accurate time constant for the decay of the double-layer capacity in the absence of concentration gradients at the electrode surface. From Eq. [18], we obtain

$$\tau_1 = \frac{1}{\Lambda_1 + J} \frac{r_0 C}{\kappa} \qquad [43]$$

When an electrochemical reaction is possible, the dominant time constant at long times is

$$\tau = \frac{r_0 C}{\kappa J} \qquad [44]$$

as identified by Newman (8). When an electrochemical reaction is not possible (the ideally polarizable electrode), this time constant becomes infinite, and the potential decays to a nonzero constant. The dominant time constant then is

$$\tau = \frac{r_0 C}{\Lambda_1 \kappa} = \frac{1}{4.12} \frac{r_0 C}{\kappa} \qquad [45]$$

also suggested in the same context (8) but without the determination of the numerical factor. The present analysis amplifies the roles and interrelationship of these two quantities and the processes they describe.

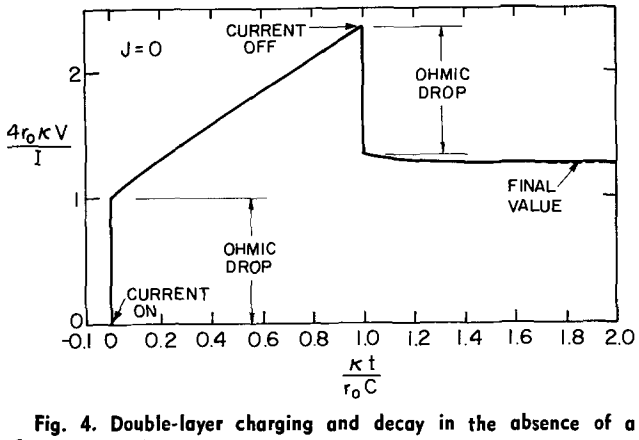

Fig. 4. Double-layer charging and decay in the absence of a faradaic reaction.

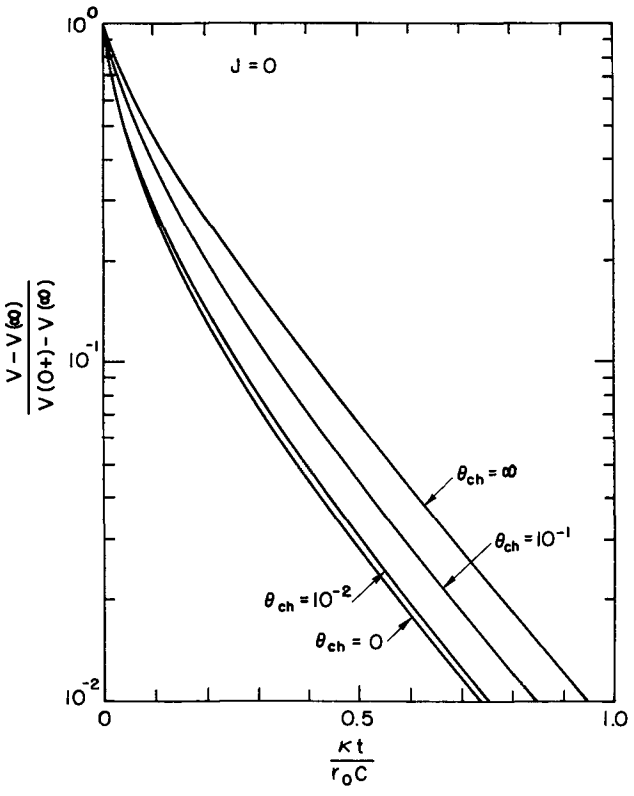

Fig. 5. Decay of the electrode potential for various charging periods in the absence of a reaction. The slope here is related at long times to the first eigenvalue Λ_1.

A direct experimental test of these time constants may be performed with the utility of an original reference electrode system designed by Miller and Bellavance (12). This consists of two probes positioned coaxially with the disk in the solution, so that the potential drop between two distinct locations in the solution could be measured. If linear electrode kinetics and finite exchange current densities are ensured, and concentration gradients near the surface of the disk are avoided, the time constant so measured should correspond to Eq. [43] for $i = 1$.

Validity and Significance of Theoretical Results in Practical Application

The reference electrode was assumed to be positioned at infinity relative to the working electrode in obtaining all our results. In practical situations, the reference electrode has to be placed at a finite distance from the disk, and if this is not accounted for in the evaluation of experimental data, serious errors may result (11). The necessary correction is rather simple to accomplish; since one can assume without significant error that the primary distribution (5) prevails in the bulk of the solution, the reading on the reference electrode can be extrapolated to infinite distance from the disk (12).

A possible application of the present results might be in the study of the double-layer structure at solid surfaces. Difficulties are encountered in the measurement of differential capacities at solid electrodes due to the frequency dispersion effect (17), except when it is feasible to construct and employ spherical electrodes (22, 23). Such difficulties may be overcome by attempting to measure relaxation times in interrupter experiments; in the absence of mass transfer, these relaxation times are related to the differential capacity of the disk electrode as shown in previous sections.

In practice, one first investigates the structure of the double layer in the presence of supporting electrolyte alone. If currents due to gas evolution and reduction of impurities are avoided, the working electrode is an ideally polarizable electrode. In this way, one finds out about the relationship between the electrode potential and the surface charge density (18). One may then add a small amount of reactant and assume that the same charge-potential dependence prevails. Investigations along these lines appear to be successful in depicting qualitatively the influence of the double-layer structure on faradaic reactions, as reviewed by Parsons (24).

Let us consider an ideally polarizable disk system where $r_0 = 0.635$ cm, $C = 30\ \mu f/cm^2$, $\kappa = 0.036$ $ohm^{-1}\text{-}cm^{-1}$, and the ohmic drop is 11 ohms. The current is interrupted after charging the electrode for 1 msec at $I = 5$ mA. The characteristic time constant for decay can be calculated from Eq. [45] as $\tau = 128\ \mu sec$. We can further compute

$$\Phi_0^p = 55\ \text{mV}$$

$$\Delta V \equiv V(\theta = 0+) - V(\theta = \infty) = 0.08076\,\Phi_0^p = 4.44\ \text{mV}$$

If the reference electrode is placed along the axis of the disk, we have

$$\Delta\Phi_0\,(r = 0) \equiv \Phi_0\,(r = 0,\ \theta = 0+) - \Phi_0\,(r = 0,\ \theta = \infty)$$

$$= \Phi_0\,(r = 0,\ \theta = 0+) = \Phi_0^{ss}\,(r = 0) - \Phi_0^p$$

$$= \Phi_0^p \left[\sum_{n=0}^{\infty} B_n^{ss} - 1 \right] = \Phi_0^p \left(\frac{4}{\pi} - 1 \right)$$

$$= 15\ \text{mV}$$

$$\Delta(V - \Phi_0) = \Delta V - \Delta\Phi_0\,(r = 0) = -10.6\ \text{mV}$$

$$V - \Phi_0\,(\theta = \infty) = V\,(\theta = \infty) = \frac{It_{ch}}{\pi r_0^2 C} = 132\ \text{mV}$$

It is interesting to note that $\Delta\Phi_0\,(r = 0)$ is larger than ΔV and can be detected with relative ease with a double-probe reference electrode (12). The negative value of $\Delta(V - \Phi_0)$ indicates that this quantity (which we would have called the electrode overpotential if a faradaic reaction were present) actually increases at the center of the disk as the charge redistributes itself in the double layer to effect a final uniform and nonzero charge distribution. The change in $V - \Phi_0$ during the transient process is also moderately small compared to its absolute value, so that the double-layer capacity C can be assumed to be independent of the potential in this range without much error.

In reality, it is impossible to have a perfect ideally polarizable electrode. One can approximate it by maintaining its potential by an external source (18). The transient response of a disk electrode under potentiostatic control has been treated elsewhere (25). If the current is interrupted, the potential of a real electrode will decay more or less slowly to its open-circuit potential due to the reduction of impurities present in the solution (18). Thus if an electrode reaction is possible either owing to the presence of impurities or a reactant in the solution, the characteristic times for decay are

$$\tau_e = \frac{r_0 C}{\kappa J} \qquad [46]$$

for the electrode potential, and

$$\tau_s = \frac{1}{4.12 + J} \frac{r_0 C}{\kappa} \qquad [47]$$

for the potential in the solution. Even if Tafel kinetics

might govern the electrode reaction soon after interruption, linear kinetics will take over at large times as the overpotential decays, and the above time constants will become prevalent. Thus, if J is small, let us say 0.005, then the electrode potential will decay with a time constant $\tau_e = 106$ msec whereas the potential in the solution will decay much more rapidly, with the time constant $\tau_s = 0.13$ msec.

If however, J is of order unity or larger, this effect is rather appreciable and has to be accounted for. One possibility is to measure τ_s and τ_e simultaneously by a disk electrode-double probe reference electrode setup appropriately hooked up to a dual-beam oscilloscope. By subtracting the reciprocals of the two time constants, we obtain

$$\frac{1}{\tau_s} - \frac{1}{\tau_e} = \frac{4.12\kappa}{r_o C} \qquad [48]$$

which is independent of the exchange current density.

If the electrode reaction is mass-transfer controlled, the characteristic times depend on additional parameters such as the diffusion coefficient of active species and the diffusion-layer thickness. For the situation where one is concerned about the reduction of impurities at the disk after the interruption of current, a reasonable estimate of the faradaic current can be obtained from

$$i_f = nFD\frac{c_\infty - c_o}{\delta} \qquad [49]$$

where δ is the Nernst diffusion layer thickness. Assuming a highly reversible reaction controlled by diffusion and the capacitive effect of the double layer, the capacitive current is

$$i_c = C\frac{\partial \eta_c}{\partial t} \qquad [50]$$

where η_c is the concentration overpotential (13), given by

$$\eta_c = \frac{RT}{n\mathbf{F}}\ln\frac{c_\infty}{c_o} \qquad [51]$$

Since the net current is zero

$$i = i_f + i_c = 0 \qquad [52]$$

When we combine these four equations and integrate, we obtain a characteristic time constant for this case

$$\tau_D = \frac{CRT\delta}{n^2\mathbf{F}^2 D c_\infty} \qquad [53]$$

τ_D thus depends inversely on the concentration of impurities, which has to be kept as small as possible. Consider the reduction of a bivalent ion ($n = 2$) with $D = 10^{-5}$ cm^2/sec, $\delta = 10^{-3}$ cm, and $c_\infty = 10^{-9}$ mole/cm^3. Then, $\tau_D = 0.2$ msec.

In case the capacitive effect can be ignored, and a purely mass-transfer-controlled electrode process is considered, the appropriate time constant is proportional to δ^2/D, or more exactly

$$\tau_D = \frac{3.26\,Sc^{1/3}}{\Lambda_D\,\Omega} \qquad [54]$$

where Ω is the angular frequency of rotation of the disk and Λ_D is a constant characteristic of the diffusion process. Determination of this constant requires a detailed analysis of the transient mass transfer problem at a disk electrode. With the simplifying assumption of a radially independent concentration distribution, Selman (26) obtained $\Lambda_D = 7.216$ for a step change of concentration. Using this value for Λ_D, $Sc = 1000$, and $\Omega = 250$ radians/sec, we obtain $\tau_D = 18$ msec. The characteristic decay time for a current step is always larger than that for a concentration step for the same system, according to the review by Selman (26). Nanis and Klein (27) report experimental relaxation times (defined as the time required for the overpotential to decay to 99 per cent of its initial value) of 50-0.5 sec for rotational Reynolds numbers between 130 and 8500, respectively, in 0.005M ferrocyanide-ferricyanide redox system in 2M KOH solution.

The above discussion suggests that the effects of the double layer and mass transfer can be controlled according to the needs of the experimenter by proper design of the electrochemical system and the experimental method. It is possible to reduce mass transfer effects by choosing a system where the relaxation times due to mass transfer are of a much larger scale than the relaxation times associated with the diffuse double layer. The magnitude of the effect is also important as well as its duration. Note that while the time constant in Eq. [54] becomes smaller as Ω increases, the amplitude of the corresponding concentration disturbance would decrease. In other words, the other extreme where the concentration effects would become negligible is the well-stirred solution case, one of our assumptions in treating the theoretical problem.

Conclusions

The transient behavior of a disk electrode for a step change in the applied current has been worked out theoretically in the absence of mass transfer effects. The analysis leads to a boundary value problem, which yields analytic solutions in terms of a new set of eigenfunctions U_i. These equations can be extended to account for arbitrary variations in the applied current by employing the superposition integral.

The results demonstrate (*i*) the effects of a faradaic reaction, (*ii*) the nonuniform primary current distribution on the double-layer charging and decay at a disk electrode, and (*iii*) the interaction of these phenomena to determine the resultant electrode behavior. The over-all treatment of the problem allows the determination of accurate time constants for each of these effects.

ABSTRACT

Molybdenum(VI) oxide reacts with molten LiCl-KCl eutectic at 450° to form MoO_2Cl_2, which probably is present as an anion $MoO_2Cl_4^=$, and pyromolybdate, $Mo_2O_7^=$. Both of these species are electrochemically reduced to MoO_2, which can be reoxidized to MoO_2Cl_2 by current reversal. A second reduction step, observed whether MoO_3 or $Mo_2O_7^{2-}$ is added to the melt, can be attributed to the reduction of $MoO_4^=$, formed as a secondary reaction product in the first step. The reduction of molybdate proceeds in two steps, the first at −0.85V and the second at −1.75V *vs.* the 1M Pt(II)/Pt reference electrode. The first step shows an abnormally short transition time, attributable to a slow equilibrium. The second step corresponds to a diffusion-controlled reduction with $n = 0.5$, yielding a product of the empirical formula $Li_5Mo_2O_8$.

The literature contains very little fundamental information on the behavior of molybdenum compounds in molten systems. Stavenhagen and Engels (1) described a sodium molybdenum bronze in the form of a dark bluish-grayish powder formed by electrolytic reduction of fused sodium molybdate. Cannery (2) reported the preparation of lithium, sodium, and potassium molybdenum bronzes using the same method. However, the next year Burgers and van Liempt (3) showed that the bronzes mentioned by Cannery were mixtures consisting of molybdenum(IV) oxide and molybdenum blue. According to Magneli, only molybdenum oxides were obtained by Hagg in similar experiments (4, 5). Wold, Kunmann, Arnot, and Ferretti (6) prepared pure MoO_2 crystals by electrolytic reduction of MoO_3-Na_2MoO_4 mixtures at 675°C. In addition, both sodium molybdenum bronze and potassium molybdenum bronze crystals were grown from molybdenum(IV) oxide-alkali molybdate melts under carefully controlled conditions. Senderoff and Brenner (7, 8) have investigated the reduction of molybdate dissolved in molten alkali halides. They found that the bulk of the reaction product was dispersed throughout

the melt as a black, water insoluble powder containing about 77% molydenum, corresponding to MoO_2 (75% Mo).

The present investigation was undertaken in order to study the reduction of molybdenum(VI) compounds and to characterize any reduction products observed. It was also considered possible that some aspects of molybdenum chemistry and interactions between molybdenum(VI) compounds and chloride melt could be deduced.

Experimental

Apparatus.—The instrumentation and equipment used in this study have been previously described (9-11).

Electrodes.—Platinum microelectrodes for voltammetry were prepared from 26B and S gauge platinum wire as described earlier (10). Indicator electrodes for chronopotentiometric measurements were made by sealing 26 gauge platinum wire into Pyrex glass and then spot welding a piece of 0.5 cm^2 platinum foil to the end of the wire extending from the platinum glass seal. The cathodes used for the preparation of the electrode deposits were constructed from 52-mesh platinum gauze. The counterelectrode was a ⅛-in. diameter graphite rod. All potentials are referred to the 1M Pt(II)/Pt reference electrode. Details on the generation and use of this reference electrode in LiCl-KCl have been described previously (11, 12).

Chemicals.—All chemicals used in this study were reagent grade. Those chemicals containing water of hydration were vacuum dried at 110°C before being added to the melt.

The LiCl-KCl eutectic was obtained from Anderson Physics Laboratories, Inc., Urbana, Illinois. The method of purification has been described (11). All experiments in the melt were carried out at 450°C unless otherwise noted.

Solid chemicals were added to the melt by means of a small glass spoon. A blanket of argon was kept over the melt at all times to exclude oxygen and water vapor. The purification train used in purifying the argon has been described (13).

Techniques for preparation and analysis of electrode deposits.—Before their insertion in the melt solution, the gauze electrodes were cleaned in boiling, concentrated HNO_3, rinsed with distilled water, and dried at 130°C for 20 hr. After the material had been deposited on the electrode, the electrode was allowed to cool, washed with deionized water, and dried at 120°C. The deposits were then dissolved in 5 ml of concentrated nitric acid by heating on a hot plate. The molybdenum content of the deposit was determined by addition of an excess of Pb^{2+} which was back-titrated with EDTA using xylenol orange as the indicator. The total molybdenum was also obtained by amperometric titration with lead, a procedure developed by Aylward (14). The amount of reduced molybdenum in the sample was determined by the method developed by Bourret (15). Lithium was quantitatively determined by flame photometry. Chloride was determined by the Volhard method.

Results and Discussion

MoO_3-LiCl-KCl system.—Preliminary steady-state voltammetric experiments (Fig. 1) showed that MoO_3 exhibits two reduction waves in LiCl-KCl at 450°. The half-wave potentials are approximately −0.3 and −1.75V. The voltammetric curves were not highly reproducible because of the formation of an insoluble product which rapidly increases the surface area of the electrode. Upon prolonged electrolysis at the limiting plateau, a brown-violet film formed on the electrode, and the current increased with time. Chronopotentiometric experiments with proper choice of concentration and current density circumvented the difficulty due to film formation. Two transitions, at −0.35 and −1.75V, respectively, were observed, in agreement with the voltammetric observations. The Sand equation was checked for the first reduction step

using four to six current densities at three different MoO_3 concentrations (Table I). Constancy of the quantity $I\tau^{1/2}/C$ indicated diffusion-controlled reaction. However, it was observed during the measurements that a volatile product was slowly evaporating from the melt. Therefore, owing to the uncertain concentration it was not possible to calculate a valid diffusion coefficient from the data.

To establish the nature of the volatile product, the apparatus shown in Fig. 2 was used. Previously dried MoO_3 was added to the melt, air was excluded, and the volatile product was displaced by inert gas into a weighed trap cooled with acetone and dry ice. The product was yellow in color, very volatile, and soluble in water. Analysis for Mo and Cl^- by the methods described above showed that the sample weight could be completely accounted for in terms of the compound MoO_2Cl_2. To determine the product formed from the

reaction of the oxide ion, the melt was extracted from the product with ethanol and acetone to yield $Li_2MO_2O_7$, which accounted completely for the sample weight. Accordingly the reaction between MoO_3 and the melt can be written

$$3MoO_3 + 2Cl^- \rightarrow MoO_2Cl_2 + Mo_2O_7^=$$

A phase diagram study of MoO_3 and Li_2MoO_4 was carried out to verify further the existence of $Li_2Mo_2O_7$. Phase transition temperatures were determined for eight samples ranging in composition from 42 to 55 m/o (mole per cent) MoO_3. The experiments were done by the visual polythermal method in which the temperature of the first crystals was measured by a Pt-Rh thermocouple. From Table II it is evident that a local maximum exists for the molar ratio $MoO_3/Li_2MoO_4 = 1$, implying the formation of a solid compound $Li_2Mo_2O_7$. An x-ray powder pattern of the 1:1 sample is described in Table III. No lines for MoO_3 or Li_2MoO_4 were found in the diffraction pattern, thus precluding the possibility that the material is a mixture of MoO_3 and Li_2MoO_4.

To determine whether the acid-base reaction occurs completely before the electrolysis experiments, the data of Table I were examined for a chemical reaction preceding charge transfer by plotting $I_o\tau^{1/2}/C$ *vs.* I_o and I_o/C. The plots showed no discernible downward slope, but only a scatter that could be attributed to uncertainties in concentration owing to volatility of the oxychloride, and perhaps to variation in electrode area with the formation of solid deposit.

Plots of E *vs.* log $(\tau^{1/2} - t^{1/2})$ were linear as shown in Fig. 3. This function would be expected to yield linear plots either for a totally irreversible charge transfer process or for a reversible process with the formation of a solid product of constant activity. Current reversal chronopotentiometry showed an anodic transition upon reversal of the current at the inflection point (Fig. 4): ratios of the coulombs of charge in the forward to backward electrolysis varied between 0.985 and 1.025, indicating the quantitative formation of a solid product that can be reoxidized. If the slope of the log plot is equated to $2.3\ RT/\alpha n_a F$, we calculate

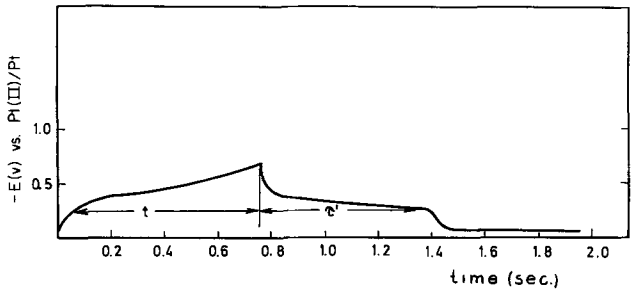

Fig. 4. Typical reverse current chronopotentiogram for the first reduction step of MoO_3. $I_f = I_r = 2.0$ mA/cm^2.

$\alpha n_a = 0.56$ rather than 2 for a reversible process. Neglecting the back-reaction, the value of $k_{f,h}$ at -0.208V, the starting potential, is calculated to be 3.18×10^{-3} cm-sec^{-1}.

Analysis of the reduction products of MoO_3.—Samples of the first reduction product, prepared coulometrically from 0.35M MoO_3 solution using a platinum gauze cathode, in the form of a homogeneous, brown-violet solid, were boiled in distilled water to remove chlorides and soluble molybdates and dried at 130°. Analysis revealed only MoO_2, and the x-ray powder pattern agreed in d-spacings and approximate relative densities with the ASTM files for MoO_2.

Attempts were also made to prepare the second reduction product, by holding the potential of the working electrode at -1.75V. A product showing x-ray lines of MoO_2, plus several weak lines, and containing Li but not K was formed, corresponding to a mixture of the first and second reduction products. The composition could not be completely accounted for in terms of MoO_2 and Li_2O or Mo_2O_5 and Li_2O. It is possible that the second reduction product is partially soluble in the melt.

MoO_2Cl_2-LiCl-KCl-system.—The solubility of MoO_2Cl_2 in the melt was determined at three temperatures, 400°, 450°, and 500°, by saturating an argon gas stream with the vapor and bubbling the dilute stream (heated to 120° to avoid crystallization from the vapor) through the melt for at least 2 hr, and analyzing the melt for molybdenum. The solubility was found to be 2.60 ± 0.12, 2.75 ± 0.14, and $2.78 \pm 0.09 \times 10^{-5}$ moles MoO_2Cl_2/cm^3 at the three temperatures. The relatively high solubility and low vapor pressure over the melt indicates a strong interaction between MoO_2Cl_2, probably to form an anion $MoO_2Cl_4^=$ with the chloride ion of the melt.

Chronopotentiometry indicated a single wave, occurring at a potential of -0.35V, in agreement with the postulated interaction between MoO_3 and melt. From the value of $I_o\tau^{1/2}/C = 560 \pm 10$ A-sec$^{1/2}$ cm mol^{-1}, $n = 2$, the diffraction coefficient was calculated to be 1.08×10^{-5} cm^2/sec.

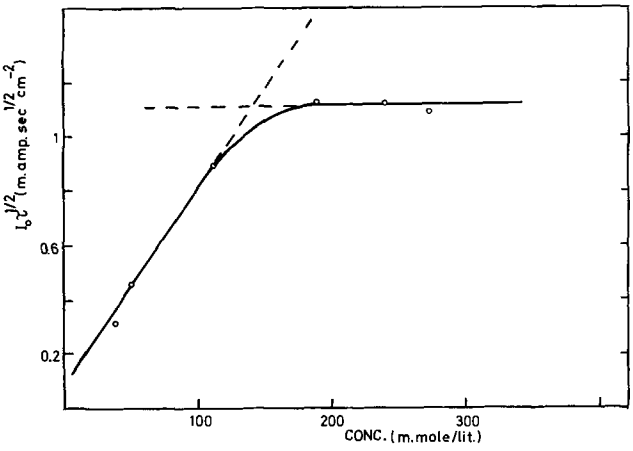

Fig. 5. Variation of $I_o\tau^{1/2}$ with Li_2MoO_4 concentration for the first reduction step.

Constant current electrolysis carried out at potentials never more negative than −0.35V, of a solution of MoO_2Cl_2 prepared by bubbling the vapor through the melt for 2 hr produced a brown-violet deposit. Comparison of the micromoles of molybdenum with the microfaradays of current consumed indicated a consumption of two electrons per molybdenum atom. The x-ray powder pattern agreed with that of the first reduction product of MoO_3 and with the ASTM pattern of MoO_2. The electrode reaction at −0.35V can thus be described as

$$MoO_2Cl_2 + 2e^- \rightleftarrows MoO_2 + 2Cl^-$$

or

$$MoO_2Cl_4^= + 2e^- \rightleftarrows MoO_2 + 4Cl^-$$

$Li_2Mo_2O_7$-LiCl-KCl system.—The chronopotentiometric behavior of $Li_2Mo_2O_7$ was found to be quite similar to that of MoO_3. Two waves were observed, one at −0.44V and the other at approximately −1.75V. The transition time data for the first reduction process (Table IV) were somewhat scattered, showing a trend to decrease with concentration and with increasing current density. When both MoO_3 (3.55 mM) and $Li_2Mo_2O_7$ (2.15 mM) were present, two waves were once again observed, one at −0.37V and the other at −1.75V. It is concluded that the first wave of MoO_3 is actually the sum of the first waves of MoO_2Cl_2 and $Mo_2O_7^=$.

The first reduction product of $Li_2Mo_2O_7$ was characterized as before, and identified as MoO_2. Accordingly, the first reduction process can be written

$$Mo_2O_7^= + 4e^- \rightarrow 2MoO_2 + 3\,O^=$$

with a following acid-base reaction, no doubt

$$3Mo_2O_7^= + 3\,O^= \rightarrow 6MoO_4^=$$

The complexity of this process presumably accounts for the lack of diffusion control in the over-all process.

$MoO_4^=$-LiCl-KCl system.—Chronopotentiograms were recorded over a concentration range of 8.03×10^{-3}M to 0.2725M Li_2MoO_4. At current densities below 2 mA/cm^2, two waves were discerned, one at −0.85V and the other at −1.75V. The first wave increased with concentration until the concentration reached 1.12×10^{-2}M, and leveled off at higher concentrations (Fig. 5). The slope of the plot at low concentrations yielded $I_o\tau^{1/2}/C = 9.87 \pm 0.6$ A-sec$^{1/2}$ cm mol^{-1}, corresponding to $nD^{1/2} = 1.45 \times 10^{-4}$ cm-sec$^{-1/2}$. Such an abnormally low transition time constant suggests an equilibrium such as

$$MoO_4^= + 2Cl^- \rightleftarrows MoO_3Cl_2^= + O^=$$

in which $MoO_3Cl_2^=$ exists as a minority component responsible for the first reduction step. If such an equilibrium exists, it must be relatively slow, because $I_o\tau^{1/2}$ was not found to decrease with increasing current density as would be expected for a prior chemical step with appreciable interconversion during the time of electrolysis.

With a molybdate concentration of 5.35×10^{-2}M and with a current density of 16 mA/cm^2 only the second transition was observed. The Sand equation was tested for four to five current densities at five different molybdate concentrations (Table V). The average value of $I_o\tau^{1/2}/C$ calculated from these data is 174 ± 6 A-sec$^{1/2}$ cm mol^{-1}, corresponding to $D = 1.64 \times 10^{-5}$ cm-sec^{-1} at 450°, taking $n = 0.5$ from the analytical data given below.

Attempts to prepare the first reduction product by constant current electrolysis were unsuccessful. Using 0.85M Li_2MoO_4, even with current densities lower than 100 μA/cm^2, the electrode potential rapidly rose beyond that corresponding to the first reduction step. Using current densities of 100 μA, 5 mA, and 10 mA/cm^2, deposits were prepared by electrolyzing at −1.18 to −1.2V, at −1.5V, and at −1.75V, respectively. Examination of the cathodes showed only one type of solid product, an adherent dark brown-black solid with a metallic luster. The samples were washed with distilled water, dried at 130°, and analyzed for Li and Mo with the results given in Table VI. The deposit was found to contain an average of 54.0% Mo and 9.85% Li but no K or Cl. The ratio Li/Mo is 2.52. No appreciable trend of composition with current density was observed. If it is assumed that the deposit contains only Li, Mo, and O, the empirical formula $Li_{2.49}MoO_{3.96}$ is obtained indicating an average oxidation state of 5.5 for molybdenum.

Additional preparations produced at −1.75V were analyzed for oxidation state, with the results listed in Table VII. The sum of Li_2O, Mo_2O_5, and MoO_3 is very close to 100%, confirming the absence of K and Cl, and indicating once more that the product is $Li_{2.5}MoO_4$ or $Li_5Mo_2O_8$. To ascertain whether the product is a single compound or a mixture, an x-ray powder pattern was obtained for the products prepared at −1.2, −1.5, and −1.75V. The d spacing along with relative intensities are given in Table VIII. No lines for LiCl or Li_2MoO_4 were found in the diffraction pattern. The diffraction data do not correspond with any known molybdenum compound listed in the ASTM files or with other deposits obtained by reduction of Mo(VI) compounds.

To study the stability of the product, one sample was heated at 300° under vacuum. No change in diffraction pattern was observed. The deposit was further boiled in distilled water 3 hr and dried at 200°. The boiled product exhibited a different x-ray pattern as shown in Table IX. The analytical data indicated Li/Mo to be 4.43/2 and the sum of the weight percentages of Li_2O + MoO_3 to be 97.66, indicating the presence of water in the sample or partial oxidation of Mo_2O_5.

The electrode reaction of molybdate can be written

$$2MoO_4^{=} + e^- \rightarrow Mo_2O_8^{-5}$$

The mechanism of this reaction is unclear. There is no evidence for dimerization of molybdate prior to reduction, and the diffusion coefficient is consistent with our expectation for a monomer. The simplest mechanism would be the formation of the anion MoO_4^{3-}, with the incorporation of equimolar amounts of MoO_4^{2-} with lithium ions to form the crystalline compound $Li_5Mo_2O_8$.

The Electrochemical Response of a Disk Electrode to Angular Velocity Steps

Stanley Bruckenstein[*,1], **Maria I. Bellavance, and Barry Miller**[*]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

An experimental study has verified the prediction that the establishment of a boundary layer at the surface of an impulsively started disk is complete in less than three tenths of a rotation. A similar result was found for a rotating disk electrode whose speed was stepped between two values. The current transient produced by a step change of the rotation speed of a disk electrode held in the convective-diffusion limiting current region of some electroactive species has been derived. Studies of the reduction of Ag^+, Fe^{3+}, and Hg_2^{2+} are in good agreement with theory and show that the relaxation process is limited by the convective-diffusion of the electroactive species rather than the hydrodynamic relaxation phenomenon.

Heretofore, nonsteady-state studies using the rotating disk electrode have been carried out at constant angular velocity by perturbing the potential and measuring the time-dependent current response, or vice versa. Recently, angular velocity programming of rotating (ring) disk electrodes has become feasible (1, 2) and is being used to advantage in electrochemical studies (2, 3). However, it became apparent that electrochemical transients could be produced by rapidly scanning or applying a step change to the angular velocity of a disk electrode.

In most disk electrode angular velocity studies, experimental problems such as adsorption of impurities from solution, growth of dendrites during metal deposition, or surface roughening by electrode dissolution can be minimized if rapid angular velocity programming is used. However, in such situations, appreciable deviation from steady-state flow conditions is unacceptable since the ultimate data treatment assumes a hydrodynamic steady-state. Hence, a quantitative treatment of the electrochemical transient resulting from an angular velocity perturbation would be of considerable utility.

In this paper, we consider one of the many possible situations, namely, the time-dependent current response obtained under potentiostatic conditions on application of an angular velocity step. To avoid electrochemical kinetic complications, the potential chosen in all the examples was sufficient to produce complete concentration polarization of the diffusing species. It will be shown that little change in current occurs during the time required for the new hydrodynamic "steady-state" to be attained, and the current-time transient results primarily from the relaxation of the (convective-) diffusion layer thickness.

Theoretical

Benton (4) investigated the time-dependence of fluid flow near an impulsively started disk ($\omega = 0$ at $t = 0$, $\omega = \omega_2$ at $t > 0$) using a series expansion technique. He found that the time dependence of the normal fluid velocity, w, could be represented, to a good approximation, by

$$w(\eta, \Phi) = -4(\nu\omega_2)^{1/2}\Phi^{3/2}\,[h_1(\eta) + h_2(\eta)\Phi^2 + h_3(\eta)\Phi^4 + \ldots] \quad [1]$$

where values of the functions $h_1(\eta)$, $h_2(\eta)$, and $h_3(\eta)$ were given in tabular form, and

$$\Phi = \omega_2 t \quad [2]$$

$$\eta = z/2(\nu t)^{1/2} \quad [3]$$

ν is the kinematic viscosity of the solution and z the normal distance coordinate, where $z = 0$ on the electrode.

A complete description of the electrochemical response of an impulsively started disk electrode would require that Eq. [1] be applicable for $0 \leq \Phi \leq \infty$. However, as Benton has pointed out, the third term in the series has outlived its usefulness by $\Phi = 2$ radians and Eq. [1] is a reliable description only in the range $0 \leq \Phi \sim 2$. This result was satisfactory for Benton's purposes, since the asymptotic steady-state is approached. Since no other work on this problem appears to have been done, and lacking an analytical description of the behavior of $w(\eta,\Phi)$ for $2 \sim \Phi < \infty$, the combined electrochemical/hydrodynamic problem was examined in the range $0 \leq \Phi \sim 2$. The details are given in the Appendix, and it was found that only a negligible fraction of the total electrochemical response took place by $\Phi = 2$. Thus it appeared justifiable to simplify the problem by assuming that the hydrodynamic relaxation was instantaneous compared to the electrochemical response. We have performed experiments, described below, that confirm this assumption.

No studies, describing the nonsteady-state fluid flow when the angular velocity of a disk is stepped from one value to another, ω_1 to ω_2, appear to have been made. However, our experiments indicate that the relaxation times of the electrochemical transient in this case were quite similar to those for the impulsively started disk. Thus, it seemed reasonable to assume again that the hydrodynamic relaxation would be instantaneous on the time scale of the electrochemical transient. Again, experiments reported below support this assumption.

Potentiostatic condition.—Consider the electrochemically reversible reaction

$$Ox + ne \rightleftarrows Red$$

where Ox exists at a bulk concentration C^b, and the electrode potential of the disk is held constant. At a certain instant in time, the velocity of a disk electrode is changed instantaneously. We distinguish between the impulsively started stationary disk problem and the situation in which the velocity step is applied to a rotating disk only in the way in which we describe the concentration profile at $t = 0$. For obvious reasons, the first problem is referred to as a Cottrell-Levich experiment and the second as a Levich-Levich experiment. In either experiment, the instantaneous diffusion layer thickness existing at $t = 0$, as determined by the Cottrell equation in one case, and by the Levich equation in the other, begins to change on applying the angular velocity step in a way governed by the nonsteady-state fluid flow and the convective-diffusion equation. Ultimately the diffusion layer thickness reaches a value governed by the new angular velocity.

Key words: rotating electrode, hydrodynamic relaxation, boundary layer, convective-diffusion, potentiostatic control.

The time-dependent convective-diffusion equation for the rotating disk electrode may be written

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial z^2} - w(z,t)\frac{\partial C}{\partial z} \quad [4]$$

Applying the Method of Moments as was done previously (5), Eq. [4] may be integrated with respect to z from 0 to ∞, thereby obtaining a gross mass balance

$$\int_0^\infty \frac{\partial C}{\partial t}dz = -D\frac{\partial C}{\partial z}\bigg|_{z=0} - \int_0^\infty w(z,t)\frac{\partial C}{\partial z}dz \quad [5]$$

Assuming that a simple time-dependent Nernst diffusion layer provides an adequate description of the problem, the upper limit of the integrals in Eq. [5] may be replaced by δ. Also, under potentiostatic conditions for the reversible electrochemical case, the concentration distribution of the electroactive species may be approximated by

$$C(z,t) = \begin{cases} C^s + (C^b - C^s)z/\delta & 0 \leq z \leq \delta \\ C^b & \delta < z < \infty \end{cases} \quad [6]$$

Hence

$$\frac{\partial C}{\partial t} = \begin{cases} \dfrac{-(C^b - C^s)z\dot{\delta}}{\delta^2} & 0 \leq z \leq \delta \\ 0 & \delta < z < \infty \end{cases} \quad [7]$$

and

$$\frac{\partial C}{\partial z} = \begin{cases} \dfrac{C^b - C^s}{\delta} & 0 \leq z \leq \delta \\ 0 & \delta < z < \infty \end{cases} \quad [8]$$

Thus, Eq. [3] becomes

$$\frac{\dot{\delta}}{2} = \frac{D}{\delta} + \int_0^\delta \frac{w(z,t)}{\delta}dz \quad [9]$$

Finally

$$w(z,t) = \begin{cases} w_1(z) & \text{at } t = 0 \\ w_2(z) & t \to \infty \end{cases} \quad [10]$$

and

$$\delta(t) \to \delta_L \qquad \text{as } t \to \infty \quad [11]$$

By assuming that $w(z,t) = w_2(z)$ at $t > 0$ for the reasons discussed earlier and remembering that $w(z) = 0.51\ (\omega^3/\nu)^{1/2}\ z^2$ (6), we can then substitute Eq. [12]

$$w(z,t) = w_2(z) = -0.51\left(\frac{\omega_2^3}{\nu}\right)^{1/2} z^2 = Kz^2 \quad [12]$$

into Eq. [9] and integrate to obtain

$$\Phi = \frac{A}{Q}\int_L^Y \frac{\theta d\theta}{(1-\theta^3)} \quad [13]$$

where

$$A = 1.3125 \quad [14]$$

$$Q = 0.8058\left(\frac{D}{\nu}\right)^{1/3} \quad [15]$$

$$Y = \delta/\delta_L = (i)_{t=\infty}/(i)_t \quad [16]$$

$$\delta_L = 1.6116\left(\frac{D}{\nu}\right)^{1/3}\left(\frac{\nu}{\omega_2}\right)^{1/2} \quad [17]$$

$$L = (i)_{t=\infty}/(i)_{t=0} \quad [18]$$

The lower limit of the integral in Eq. [13] is the ratio of the steady-state current reached after the angular velocity step to the current existing just prior to the velocity step. The upper limit corresponds to the ratio of the final steady current to the instantaneous current. δ_L is the steady-state convective-diffusion layer thickness attained at angular velocity ω_2.

Since Eq. [13] can be integrated in closed form, we obtain

$$\Phi = F(Y) - F(L) \quad [19]$$

where

$$F(\theta) = \frac{A}{3Q}\left\{ \tfrac{1}{2}\ln\frac{1-\theta^3}{(1-\theta)^3} - \sqrt{3}\tan^{-1}\left(\frac{2\theta+1}{\sqrt{3}}\right)\right\} \quad [20]$$

Equation [19] predicts that, for a given redox couple, a plot of Y (or Y^{-1}) *vs.* Φ for data obtained in experiments with the same L-values will yield a single curve. Also, from Eq. [19], we see that for data obtained in experiments involving different L-values, *e.g.*, L_1 and L_2, the plots of Y^{-1} *vs.* Φ will have the same shape and be displaced from each other on the Φ-axis by $F(L_1) - F(L_2)$.

Intercomparisons between different redox couples are best made by plotting Y^{-1} *vs.* $Q\cdot\Phi$. The new variable, $Q\cdot\Phi$, is independent of all species and solution parameters, as can be seen from Eq. [13], [19], and [20]. Hence, data obtained for any species at the same L-value should fall on the same curve when Y^{-1} is plotted *vs* $Q\cdot\Phi$.

Experimental

Chemicals.—The materials and general techniques used have been described elsewhere (2, 7). A 2.17 mM Fe^{3+}-1.0M H_2SO_4 solution was used in the Cottrell-Levich experiments and in one of the Levich-Levich experiments. The other Levich-Levich experiments used a 2.0 mM Ag^+-1.0M $HClO_4$ solution and a 4.0 mM Hg_2^{2+}-1.0M $HClO_4$ solution. Solutions were purged with nitrogen to remove oxygen and blanketed with nitrogen during all experiments.

Electrodes.—A platinum disk electrode, $r = 0.239$ cm, was used for the reduction of Fe^{3+} and Ag^+. An amalgamated gold disk electrode, $r = 0.238$ cm, was used for the reduction of Hg_2^{2+}.

Speed control.—A description of the motor speed apparatus and associated electronics has been given earlier (7).

Impulsively started disk experiment.—Three function generators were required to perform this experiment. The first function generator (Wavetek Model 114) changed the motor speed, and the second (General Radio Model 1340) was triggered by the first to produce a square wave pulse of variable duration. At the end of the square wave pulse, an oscilloscope (Tektronix Model 564 storage oscilloscope) was triggered simultaneously with the third function generator (Tacussel GSTP2), which provided the control signal to the potentiostat for the potential jump. The time between the motor speed step and the potential step was varied between 2 μsec and 2 sec in the experiments reported below. Effectively, 2 μsec was treated as zero time delay.

Cottrell-Levich experiment.—In these experiments, a potential step was applied to a stationary disk electrode. The initial potential was chosen so that no faradaic process was occurring, while the final potential was selected to lie on the limiting (convective-) diffusion current region for the reduction of Fe^{3+}. After a predetermined time, the angular velocity was stepped to the desired value. The Wavetek function generator provided the control signal for the angular velocity step, and the Tacussel function generator provided the potential step control signal to the disk electrode potentiostat (8). Current-time curves were recorded oscilloscopically. Triggering was accomplished by appropriate use of the two function generators.

Levich-Levich experiment.—The disk electrode potential was set to give the convective-diffusion limiting current for the reduction being studied and the

angular velocity set at the desired initial value. Using the Wavetek function generator as the control signal for the angular velocity step and oscilloscope trigger, the rotation speed was stepped to the desired final value and the current-time curve recorded.

Results and Discussion

Time of hydrodynamic relaxation.—Impulsively started disk.—Benton (4) concluded that boundary layer displacement thickness for an impulsively started disk would be close to the steady-state value two radians after the angular velocity step. In principle, the potential step method is capable of estimating the evolution time for the flow and thus testing Benton's conclusion. Consider the following experiment. At time $t = 0$, the disk is stepped from $\omega = 0$ to some constant value. The electrode potential is held so that the current at the disk electrode is zero. At $t = \tau$, the electrode potential is jumped to a value in the convective-diffusion limiting region, and the current transient recorded. If $\tau = 0$, both the rotation speed and potential change at the same time. If $\tau >> 0$, the potential step occurs after the new boundary layer has become established. Hence, by varying τ, it should be possible to detect, by comparison of i-t curves, whether the hydrodynamic steady state has been reached by a particular value of τ. An experiment of this sort is shown in Fig. 1.

Curve A of Fig. 1 represents the motor speed as determined from the motor tachometer voltage. The subscripts refer to the τ values in seconds for the experiments that were performed. Curve B is the current transient produced in a potential step at a stationary platinum disk electrode in a 2.17 mM Fe^{3+}-1M H_2SO_4 solution, and has all the characteristics of a situation very nearly approximating semi-infinite linear diffusion. Curve C is the superposition of current transients for $\tau = 0$ and $\tau = 2$ sec. In this, and in other experiments in which the i-t curves were magnified as they are for curves B′ and C′, all values of $\tau \geq 0$ produced current transients that superimposed on curves C and C′.

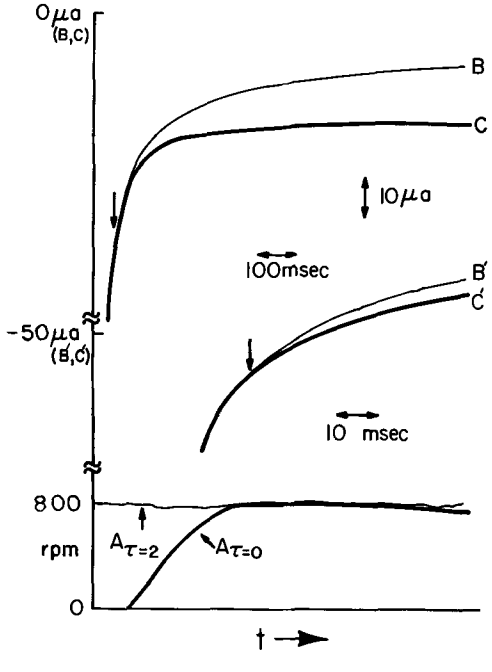

Fig. 1. Effect of time delay between a rotation speed step and a potential step on an i-t curve. 2.17 mM Fe^{+3}-1M H_2SO_4 solution. Speed step. 0→800 rpm (curve A: delay time indicated for subscript τ in seconds). Curve B: potential step at stationary disk electrode, 0.60 to 0.00V. Curves C and C′: potential step at rotating disk electrode, 0.60 to 0.00V, $\tau = 0$ sec. A delay time of two seconds produces curves that exactly superimpose on curves C and C′.

It is clear that the evolution time for the flow is less than the rise time of the motor speed, 0.027 sec. At the speed used, 800 rpm, this corresponds to 2.3 radians of rotation. The response characteristic of the motor system precludes making measurements at shorter times.

Despite the failure of this experiment to produce evidence for a hydrodynamic relaxation, it is possible to conclude that Benton's predicted value of two radians is not too large. In addition, the results in Fig. 1 indicate that a problem exists with the simplified boundary condition given by Eq. [12], where it was assumed that $\omega = \omega_2$ at $t > 0$. Because the motor speed rise time is greater than the evolution time of the flow, the early stages of the i-t response will not agree with theory.

ω-Stepped rotating disk.—Experiments analogous to those in the previous section were performed by stepping the rotation speed of the disk electrode from 100 to 400 rpm in the same solution used for Fig. 1. No evidence for a hydrodynamic relaxation was found for $\tau \geq 0$ for times as short as 0.065 sec, *i.e.*, 2.7 radians. Benton did not treat this case, but as assumed in the theoretical section, the evolution time for the flow is not longer than for an impulsively started disk.

The rise time for the motor speed was 0.020 sec, *i.e.*, 1.3 radians. Thus it was possible to compare i-t curves for varying τ values at times corresponding to an angular rotation larger than 1.3 radians, and it was found that all τ-values yielded identical i-t curves. However, data in the region 0.8 to 2.7 radians (0.020 to 0.065 sec) are without significance in this experiment because no difference can be detected between the i-t curves for a stationary electrode and one rotating at 400 rpm in this time interval. Hence, the relaxation of the boundary layer could not produce any detectable electrochemical effect.

Generally, in these sorts of experiments, the response of the motor speed, in terms of angular rotation, varied over a considerable range. The actual value depended on the initial and final rotation speed, and such data are given below where they are relevant.

Cottrell-Levich experiment.—Figure 2 shows a typical result obtained for the reduction of a 2.17 mM Fe^{3+}-1.0M H_2SO_4 solution. Curve A represents the oscilloscopically recorded i-t curve for the reduction of Fe^{3+} while curve B shows the time dependence of the motor speed. As can be seen, the change in motor speed occurs in a time that appears short compared to the current-time relaxation. Values of Y^{-1} (Eq. [16]) and Φ were calculated from curve A, assuming that

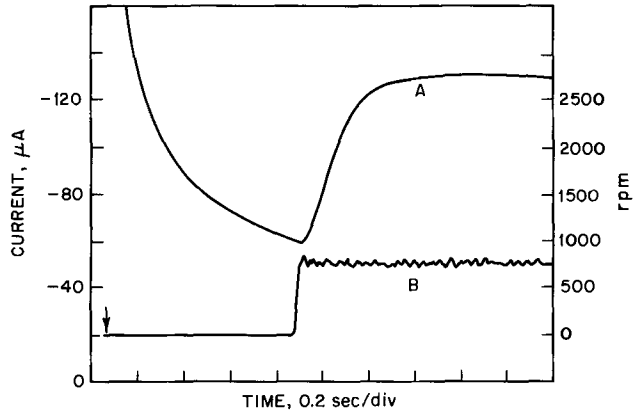

Fig. 2. Oscilloscope traces of a Cottrell-Levich experiment. Trace A: disk current, microamperes. Trace B: disk speed, rotations per minute. Horizontal sensitivity 0.2 sec/division, with vertical arrow on trace B indicating triggering time for both sweep and for disk potential step from +0.60 to 0.00V vs. SCE. Speed step 0-800 rpm. Minimum in trace A is $i_{Cottrell}$; plateau at upper right is i_{Levich}. Solution 2.17 mM Fe^{3+} in 1M H_2SO_4, Pt disk.

the minimum in the current-time curve corresponded to the instant the electrode speed changed.

Figure 3 presents the results of four such experiments corresponding to L-values between 1.546 and 2.870. The dashed line has been drawn through the experimental values obtained for $L = 2.870$. The initial flat region that exists cannot result either from the hydrodynamic relaxation process or the motor response time, since both processes are completed in much less than this time. We ascribe this delay to the change over from semi-infinite linear diffusion to convective-diffusion. At the time of the angular velocity step, the current at the disk is proportional to $t^{-1/2}$ (δ is proportional to $t^{1/2}$). During the 2 radians required to establish the boundary layer and for some time thereafter, i tends to decrease because of the existing diffusion process and to increase as a result of convective processes, thus producing a flat region until the convective-diffusion process predominates. These processes produce the equivalent of a time lag in the start of the experiment after the motor has reached the new rotation speed.

The solid lines in Fig. 3 represent the theoretical curves calculated from Eq. [19] for the experimental L-values. The points on these curves are the experimental Y^{-1}-values, shifted by the number of radians specified in the legend to Fig. 3. Excellent agreement exists between the Φ-shifted experimental points and the theoretical curves.

Levich-Levich experiments.—Reduction of Fe^{3+}.— Curve A of Fig. 4 represents the current transient produced in a 2.17 mM Fe^{3+}-1.0M H_2SO_4 solution on changing the rotation speed of a rotating platinum disk electrode from 144 to 1211 rpm. Curve B represents the time dependence of the motor speed. In these and in some of the other experiments that are described below, the angular rotation equivalent to the motor speed transient varied from 2 to 7 radians, and was not insignificant as compared to the current transient. Thus, an uncertainty arose in the time to be taken as the start of the current-time curve. We have arbitrarily used the intersection of the two linear segments of the motor speed-time curve to define the start of the experiment.

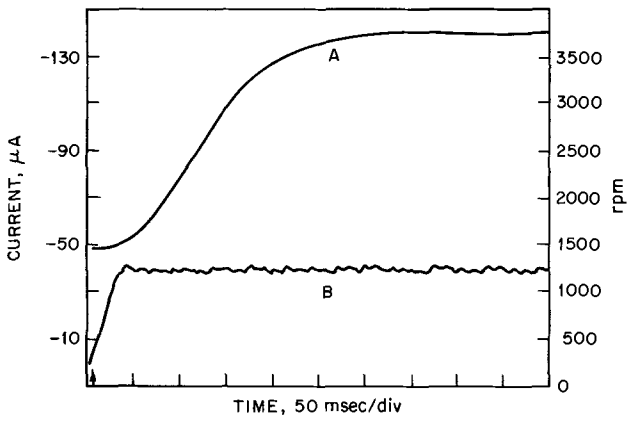

Fig. 4. Oscilloscope traces of a Levich-Levich experiment. Trace A: disk current, microamperes. Trace B: disk speed, revolutions per minute. Horizontal sensitivity 50 msec/division with vertical arrow indicating triggering time for programmed speed step from 144 to 1211 rpm. Disk potential 0.0V vs. SCE throughout. Solution and electrode of Fig. 2.

The results of five experiments for L-values between 1.512 and 3.848 are shown in Fig. 5. The dashed line is drawn through the current-time data obtained in jumping from 100 to 1600 rpm. In this data set, as in some of the others, a time delay occurs before the current begins to change. This delay is considerably less than that found in the Cottrell-Levich experiments.

All data sets can be made to coincide with the theoretical curves calculated from Eq. [19] (solid lines) by Φ-shifts in the range of -1.2 to -3.8 radians. Since the uncertainty in the time to be taken as the start of the experiment must be an appreciable fraction of the rotation required for the motor to reach speed (Φ_M in legend of Fig. 5), no significance can be attributed to the differences between these radian shifts and their absolute magnitudes. Hence, the agreement between theory and experiment is satisfactory.

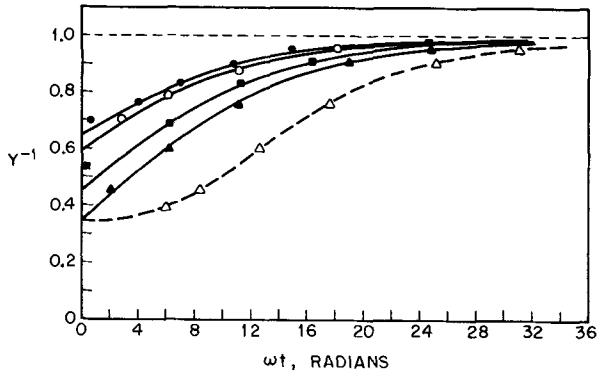

Fig. 3. Comparison of theoretical and experimental Cottrell-Levich curves for ferric reduction. Solid curves are calculated (see text). Experimental points are $Y^{-1} = i(t)/i_{\text{Levich}}$ vs. ωt, radians, where $t = 0$ is the point at which the tachometer reaches rated output in Fig. 2 data (same solution and electrode). Values of L, i_{Cottrell}, ω_2, and $\Delta\Phi$ shifts in the horizontal direction (see text) are as follows:

	L*	i_{Cottrell} (μA)	ω_2 (rad/sec)	$\Delta\Phi$ (rad)
●	1.546	58.2	41.89	—5.3
○	1.676	40.8	20.94	—5.6
■	2.200	60.0	83.78	—6.4
▲	2.870	46.0	83.78	—6.3
△	2.870	46.0	83.78	0.0

* Calculated from $i_{t=\infty}/i_{t=0}$.

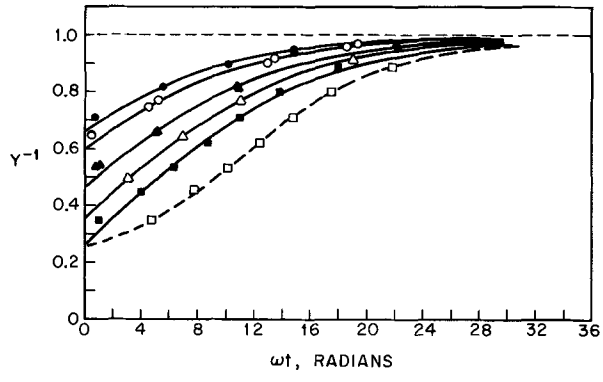

Fig. 5. Compression of theoretical and experimental Levich-Levich curves for ferric reduction. Solid curves are calculated (see text). Experimental points are $Y^{-1} = i(t)/i_{\text{Levich}}$ vs. ωt, radians, where $t = 0$ is the point at which tachometer reaches rated output in Fig. 4 data. Solution and electrode of Fig. 2. Values of L, final speed ω_2, $\Delta\Phi$ shifts, and Φ_M are as follows:

	L*	ω_2 (rad/sec)	$\Delta\Phi$ (rad)	Φ_M (rad)
●	1.512	94.25	—1.2	1.8
○	1.678	94.25	—2.4	2.0
▲	2.155	114.04	—3.0	3.4
△	2.820	126.81	—3.6	4.4
■	3.848	167.55	—3.8	6.9
□	3.848	167.55	0.0	6.9

* Calculated from $i_{t=\infty}/i_{t=0}$.

Reduction of Ag^+.—Figure 6 gives the results obtained for the reduction of a 2.0 mM Ag^+-1.0M $HClO_4$ solution at a rotating platinum disk. L-values between 1.514 to 3.966 were used. The radian shifts required to match the experimental Y^{-1}-Φ data to the theoretical curves are given in the legend to Fig. 6 and do not differ significantly from zero. Within the experimental error in determining the start of the experiment, all curves have been shifted the same amount and the shifts hardly differ from zero.

Intercomparison of current-time transients for different couples.—As was pointed out at the end of the theoretical section, a plot of Y^{-1} *vs.* $Q\cdot\Phi$ should be independent of redox couple, provided the same L-value is used. Figure 7 shows the results of such a plot using some of the data previously described. Also, a set of data for the reduction of 4.0 mM Hg_2^{2+} in a 1.0M $HClO_4$ solution at an amalgamated gold disk electrode is included. The slight differences in the L-values, 2.118 (Hg_2^{2+}), 2.148 (Ag^+), and 2.151 (Fe^{3+}), may be ignored.

The dashed curve in Fig. 7 passes through the data for Fe^{3+} reduction before any radian shift has been used. The three sets of Y^{-1}-t data required different radian shifts in order to have the experimental points fall on the theoretical Y^{-1} *vs.* $Q\cdot\Phi$ plot (solid curve, Fig. 7). All these shifts are within the experimental error and comparable to the radian shifts in the preceding experiments.

Conclusion

The relaxation time for the hydrodynamic boundary layer is short compared to the diffusion layer relaxation time at a rotating disk electrode. At a constant potential, the current transient produced by a step change in rotation speed is a function of only the initial and final rotation speeds and the Schmidt number. The Levich equation should accurately predict the time-dependent limiting convective-diffusion current at a rotating disk electrode if the square root of the angular velocity is modulated sinusoidally (7), provided the frequency of modulation (a few Hertz) and the amplitude of modulation do not exceed the limits implied by these relaxation studies.

Manuscript received April 19, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

APPENDIX

As was pointed out in the text, the potentiostatic problem in the region $\Phi < 2$ can be treated using Benton's results (4). His tabulated values of $h_1(\eta)$, $h_2(\eta)$, and $h_3(\eta)$ of Eq. [1] were fitted by a third order Newton-Gregory interpolation formula (9) in the range $0 \leq \eta \leq 0.3$. The results are of the form of Eq. [A-1]

$$h_i(\eta) = A_{i1}(\eta) + A_{i2}(\eta)^2 + A_{i3}(\eta)^3 \qquad [A\text{-}1]$$

where the values of A_{i1}, A_{i2}, and A_{i3} are given for $i = 1$, 2, and 3 in Table I.

Substituting Eq. [A-1] into Eq. [1] yields

$$w(\eta, \Phi) = -4(\nu\omega_2)^{1/2}\Phi^{3/2}\{\beta_1\eta + \beta_2\eta^2 + \beta_3\eta^3\} \qquad [A\text{-}2]$$

where

$$\beta_j = A_{1j} + A_{2j}\Phi^2 + A_{3j}\Phi^3 \qquad [A\text{-}3]$$

The potentiostatic problem is described, as before, by Eq. [4] through [11], but Eq. [12] is now replaced by Eq. [A-2]. It is necessary that Eq. [9] be expressed in terms of the variables Q, Y, Φ, and η by substitution of Eq. [2], [3], [15], and [16], respectively, into it. This yields

$$\frac{dY}{d\Phi} = \frac{0.95563}{Y} + \frac{2\Phi^{1/2}}{w_2\delta_L QY}\int_0^{QY/\Phi^{1/2}} w(\eta, \Phi)\,d\eta \qquad [A\text{-}4]$$

If Eq. [A-2] is substituted in Eq. [A-4], and the integration performed, the result is

$$\frac{dY}{d\Phi} = \frac{0.95563}{Y} - \frac{4}{Q}\left[\frac{\beta_1}{2}QY\Phi + \frac{\beta_2}{3}Q^2Y^2\Phi^{1/2} + \frac{\beta_3}{4}Q^3Y^3\right] \qquad [A\text{-}5]$$

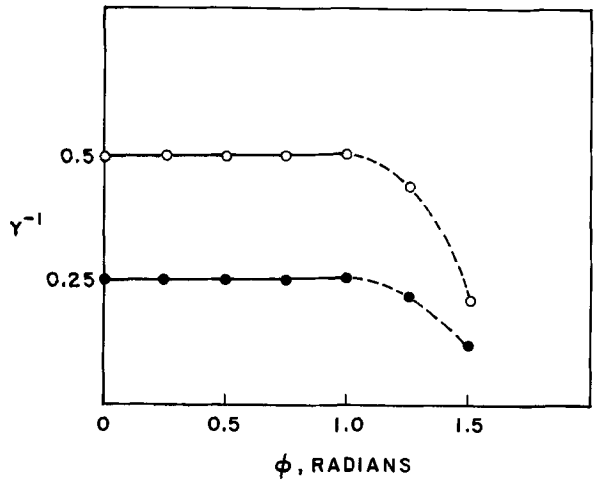

Fig. 8. Theoretical plot of Y^{-1} vs. Φ in the Benton region. Calculated for Fe^{3+} in 1.0M H_2SO_4 from Eq. [A-5]. $D = 4.52 \times 10^{-6}$ cm²/sec, $\nu = 9.18 \times 10^{-3}$ cm²/sec. ○: $L = 2.0$. ●: $L = 4.0$.

The variables in Eq. [A-5] are not separable, and DESUB (10) was used to obtain a numerical solution.

Two plots of Y^{-1} *vs.* Φ in the range $0 \leq \Phi \leq 1.5$ for L-values of 2.0 and 4.0 are shown in Fig. 8. The value of D/ν corresponded to that for Fe^{3+} in 1.0M H_2SO_4. As can be seen, little change in Y^{-1} occurs during the time that it takes for the new hydrodynamic steady state to be established, after the step change in angular velocity. The rapid decrease of Y for $\Phi > 1$ appears to be related to difficulties arising from the use of Eq. [1] to represent the time dependence of the axial fluid flow velocity at longer times. Benton (4) estimated that Eq. [1] would have outlived its usefulness before 2.0 radians. Hence, considering the time scale of our experiments, the assumption that $\omega = \omega_2$ at $t > 0$ is a reasonable one. This assumption is also supported by the results obtained in the experiment shown in Fig. 1.

The Transient Response of a Disk Electrode with Controlled Potential

Kemal Nişancioğlu* and John Newman**

Inorganic Materials Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A mathematical treatment is given for the transient behavior of a disk electrode when the potential is varied. The characteristic time constant for decay of the double-layer capacity is assessed.

The authors have recently treated the transient response of a disk electrode to a step change in the applied current (1). The present paper reports a mathematical analysis developed for the same model but with the electrode potential put under control instead of the current. The results could be relevant to some electroanalytical applications of the disk electrode, *e.g.*, interrupter methods under potentiostatic control are already in common use (2).

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: current distribution, time constant, double-layer capacity.

The problem was formulated with certain assumptions in the earlier paper (1) and will not be repeated here. The only difference in the present formulation lies in the fact that the electrode potential is set at zero time as a step to a given value V and is maintained at that value thereafter. Our purpose here is therefore to simulate the transient decay of the cell current from an initial value I_0 corresponding to the primary distribution (3, 4) to a final steady-state value I_∞.

Analysis

The potential in the solution can be expressed in terms of a steady-state and a transient contribution

$$\Phi = \Phi^{ss} - \Phi^{t} \qquad [1]$$

Detailed analyses for the steady-state problem have been given elsewhere (1, 5). Earlier treatment of the ideally polarizable electrode (1), however, does not apply for the present situation; Φ^{ss} vanishes in the absence of an electrode reaction since no net current is associated with the working electrode at steady state when the potential is fixed.

In terms of rotational elliptic coordinates (3) η and ξ, the transient part of the potential can be expressed as

$$\frac{\Phi^{t}}{V} = \sum_{i=0}^{\infty} G_i e^{-\theta(\lambda_i + J)} T_i(\eta,\xi) \qquad [2]$$

where T_i is a dimensionless potential independent of time, λ_i is an eigenvalue characteristic of the potential T_i, and θ and J are the dimensionless time and exchange-current density (1), respectively. Since Φ^{t} satisfies Laplace's equation, the functions T_i also satisfy

$$\nabla^2 T_i = 0$$

The boundary conditions associated with T_i are

$$\left.\begin{aligned} &\frac{\partial T_i}{\partial \eta} = 0 \quad \text{at} \quad \eta = 0 && \text{(on the insulating portion of the disk)}\\ &T_i = 0 \quad \text{as} \quad \xi \to \infty && \text{(far from the disk)}\\ &T_i \text{ well behaved at} \quad \eta = 1 && \text{(on the axis of the disk)} \end{aligned}\right\} \qquad [4]$$

and

$$\frac{\partial T_i}{\partial \xi} + \lambda_i \eta\, T_i = 0 \quad \text{at} \quad \xi = 0 \qquad \text{(on the disk electrode)} \qquad [5]$$

which is obtained by a direct substitution of Eq. [2] into the boundary condition on the disk electrode (1).

Equations [3] and [5] constitute an eigenvalue problem, which can be solved in a straightforward fashion (1). The solution to Eq. [3] satisfying the conditions [4] is

$$T_i = \sum_{n=0}^{\infty} \mathcal{B}_{i,n} P_{2n}(\eta) M_{2n}(\xi) \qquad [6]$$

where $P_{2n}(\eta)$ is the Legendre polynomial of order $2n$ and $M_{2n}(\xi)$ is a Legendre function with known properties (5). Substitution into Eq. [5] for each i and inversion of the resulting set of linear equations with the normalization condition, $\mathcal{B}_{i,o} = 1$, yield the numerical values of the eigenvalues λ_i and the coefficients $\mathcal{B}_{i,n}$ (see Table I). The first four eigenfunctions are plotted with respect to the radial position on the surface of the disk in Fig. 1.

The functional behavior of $T_{i,o}$ has much the same significance as the corresponding eigenfunctions $U_{i,o}$ of the galvanostatic problem (1) in depicting the nonuniform state of charge and the pattern of local current flow on the surface of the disk during the transient process. One may note, in fact, that $T_{i,o}$ in Fig. 1

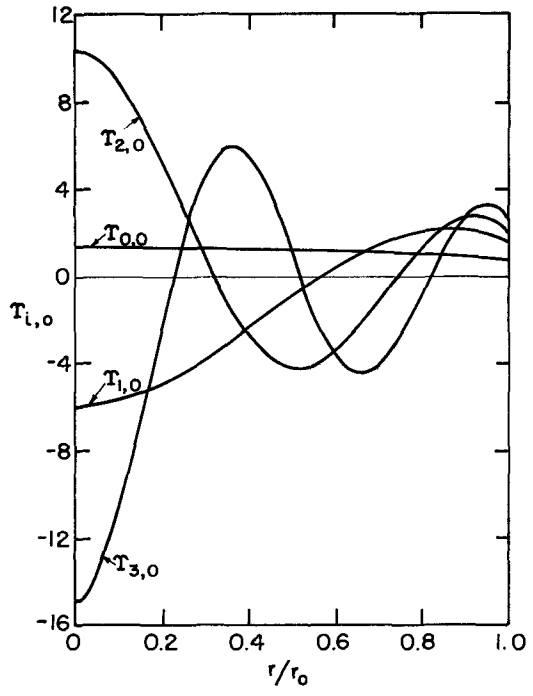

Fig. 1. Behavior of the first four eigenfunctions on the surface of the disk electrode.

are quite similar to the corresponding curves for $U_{i,o}$ given in Ref. (1) for $i > 0$. The eigenvalues λ_i also become more similar in numerical value to Λ_i of the galvanostatic series with increasing i.

An important departure from the galvanostatic case is clearly that Φ^{t} does include a net current in the present situation. This additional contribution is contained, for example, in the first eigenfunction T_o, which unlike U_o is nonzero. the fact that $T_{o,o}$ exhibits no extrema nor any zeroes suggests that it persists the longest during the decay process and is therefore associated with the largest time constant.

The eigenfunctions $T_{i,o}$ satisfy the orthogonality relationship

$$\int_0^1 \eta T_{i,o} T_{j,o}\, d\eta = \begin{cases} 0 & \text{if } i \neq j \\ -\dfrac{1}{\lambda_i} \displaystyle\sum_{n=0}^{\infty} \frac{M'_{2n}(0)}{4n+1} \mathcal{B}^2_{n,i} & \text{if } i = j \end{cases} \qquad [7]$$

From the initial condition

$$\Phi = V \quad \text{at} \quad \theta = 0+, \quad \xi = 0 \qquad [8]$$

the coefficients G_i can now be calculated from the equation

$$G_i = \frac{2\lambda_i}{\pi(\lambda_i + J) \displaystyle\sum_{n=0}^{\infty} \frac{M'_{2n}(0)}{4n+1} \mathcal{B}^2_{n,i}} \qquad [9]$$

The current is given by

$$I = -2\pi r_o \kappa \int_0^1 \left.\frac{\partial \Phi}{\partial \xi}\right|_{\xi=0} d\eta = I_o \left[\frac{I_\infty}{I_o} - \sum_{i=0}^{\infty} G_i e^{-\theta(\lambda_i + J)}\right] \qquad [10]$$

where r_o is the radius of the disk electrode and κ is the solution conductivity. The ratio I_∞/I_o is a known quantity once the value of J is specified and can be obtained directly from the steady-state analysis. Some calculated values are given in Ref. (1) (reciprocal of $V^{ss}/\Phi_o{}^{p}$). Figure 2 shows current *vs.* time traces for

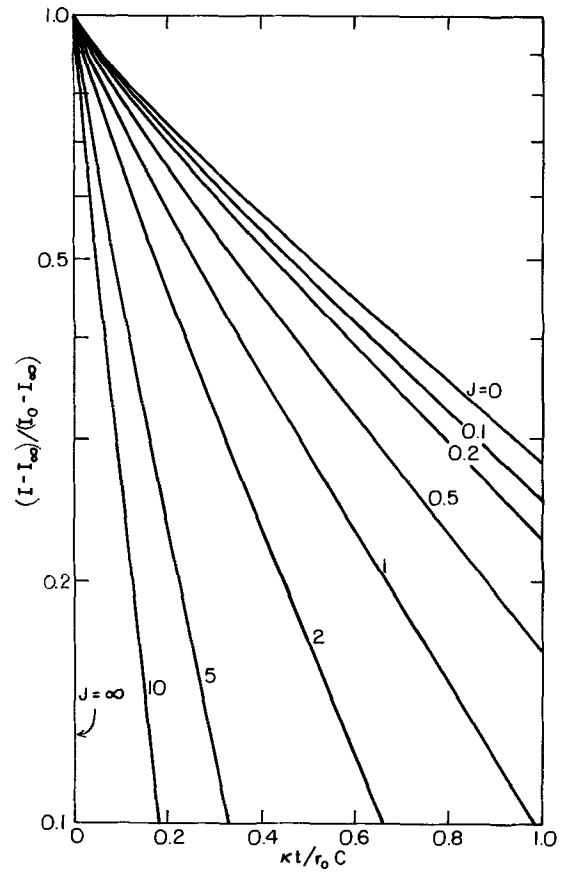

Fig. 2. Current traces at various J values for decay (or charging) of the double-layer capacity. The slope of each curve at large times is related to $\lambda_1 + J$.

various J values. Each curve is characterized by a time constant for decay given by

$$\tau = \frac{1}{1.16 + J} \frac{r_0 C}{\kappa} \qquad [11]$$

where C is the double-layer capacity.

The analysis can be generalized by superposition to incorporate an arbitrary time dependence of the applied potential $V(\theta)$. The current is then given by

$$\frac{I}{4r_0\kappa} = V(\theta) + \sum_{i=0}^{\infty} G_i(\lambda_i + J)e^{-\theta(\lambda_i+J)} \times \int_0^{\theta} e^{\theta(\lambda_i+J)}V(\theta)\,d\theta \qquad [12]$$

The present results should apply for large and moderately small times without much difficulty in the numerical calculations. For very short times, however, numerical difficulties are inevitable because the current distribution is equal to the primary distribution everywhere on the disk except in a small region near the edge. A large number of terms are thus required in the summation in both Eq. [2] and [6]. The same problem is encountered for large J values (5). A separate treatment of the edge region for short times or large J values overcomes these difficulties. The authors have formulated this problem, and the results should be published shortly.

Conclusions

The transient response of a disk electrode to step changes in the applied potential has been formulated to yield a well-defined eigenvalue problem, which can readily be solved to give solutions in terms of a series of characteristic potential functions. Each function is related to a certain mode of decay of the double-layer capacity and is associated with a characteristic time constant, the first being the dominant one in determining the system behavior at large times. These time constants can accurately be calculated from the eigenvalues of the boundary-value problem. The results can be generalized for arbitrary changes in the applied potential with time by a straightforward application of the superposition integral.

Technical Note

A Spectroelectrochemical Study of Mixed-Valence μ-Pyrazine-decaamminediruthenium(II,III) Complex

V. S. Srinivasan[1] and F. C. Anson*

Arthur Amos Noyes Laboratory of Chemical Physics, California Institute of Technology, Pasadena, California 91109

Much of the recent interest (1-4) in the redox behavior of the complex [Ru(II) N⊜N Ru(III)]$^{5+}$, first described by Creutz and Taube (5), focuses on the absorption band in the near infrared that is displayed by the mixed-valence complex but not by its one electron oxidation or reduction products. In this note we describe a thin-layer electrochemical cell with which the visible and near infrared spectrum of the mixed-valence complex could be monitored while it was being electrochemically generated by oxidation of the corresponding diruthenium(II) complex in an aqueous solution (D_2O). The spectra obtained matched those reported for the same complex prepared by chemical oxidations.

The cell employed resembles some previously described thin-layer cells for spectroelectrochemical studies (6-10). Its design shares with certain of the earlier cells (7) the desirable features of low ohmic potential drops and ready applicability at wavelengths from the ultraviolet to the near infrared.

Experimental

The design of the optically transparent thin-layer electrode cell assembly is shown in Fig. 1 and 2. A thin layer of the solution is trapped between a conducting transparent electrode (a thin deposit of platinum on quartz) and a quartz window. The window is part of the innerside of an annular cell, with a Teflon ring to contain the test solution. The Teflon ring and the quartz window were precision made. The Teflon ring was made a few hundred microns longer than the inner tube which contained the window. A platinum gauze was wrapped around the cylindrical window to serve as the auxiliary electrode. A salt bridge connected to a reference electrode (nonisolated) made contact with the solution through a small hole in the top of the Teflon ring. The size of the cell allowed it to be introduced into the sample compartment of the spectrophotometer.

The whole cell assembly, including the demountable, transparent electrode, the tubular window, and the Teflon ring were held together by a set of machined aluminum cell holders. A pair of neoprene O-rings held in the groove of the Teflon ring prevented

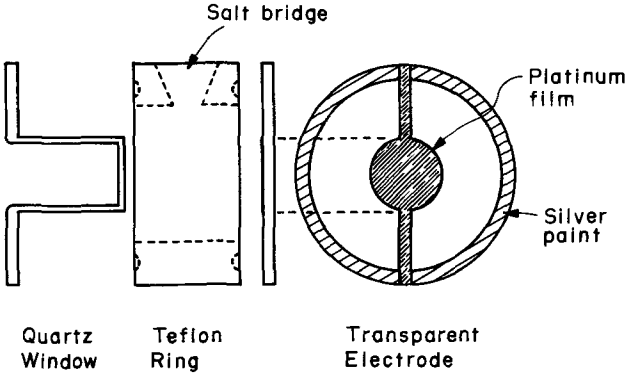

Fig. 1. Exploded view of the optical thin-layer cell assembly

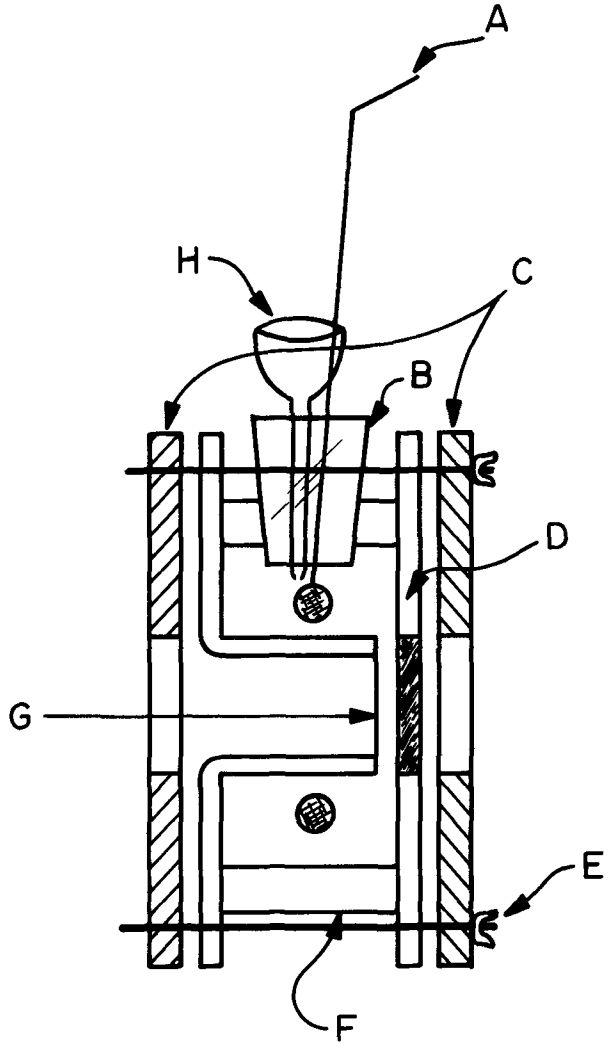

Fig. 2. Cross section of the assembled thin-layer cell. A, Pt wire connecting to Pt gauze auxiliary electrode; B, connector; C, aluminum holders; D, transparent platinum film electrode; E, threaded stock with wing nut; F, Teflon body; G, quartz window; and H, salt bridge.

direct contact between the hard Teflon and glass surfaces. The neoprene rings could be squeezed gently by exerting pressure on the aluminum holders so that the thickness of the thin layer could be varied. The average thickness of the thin layer was *ca.* 300μ, as determined from the absorbance of the diruthenium(II) complex. A matching quartz plate with a platinum deposit was used in the reference compartment of the spectrophotometer.

The conducting electrode was a thin deposit of platinum vacuum deposited on spectrosil quartz, with a large circle of deposit in the center and two channels for electrical connections to silver paint around the rim. The areas of the channels were very small compared to the area of the circle that trapped the thin layer of liquid. Platinum deposition was done after cleaning the surface of the quartz with a glow discharge achieved by exposing the surface to a nitrogen atmosphere (100 Torr) and initiating a radio frequency discharge. For deposition of the platinum a metallic mask was used to produce the desired geometry and the platinum was evaporated from a tungsten filament in a metal deposition apparatus.

A Cary XIV-R Spectrophotometer was used with the sample compartment lid modified to permit electrical connections to be made to the cell.

The chemicals used were of reagent grade. μ-Pyrazine-decaamminediruthenium(II) *p*-toluenesulfonate was synthesized according to Ref. (1). The purity was checked spectrophotometrically. The tosylate anions were removed by ion exchange to produce the trifluoroacetate salt in D_2O. The solutions used for the experimental measurements were 0.6 mM in the complex and 0.2M in trifluoroacetic acid. Oxygen was removed from the solutions before they were introduced into the cell by bubbling with prepurified argon.

Results and Discussion

Cyclic voltammograms for solutions of Ru N⬭N Ru^{4+} in the thin-layer cell showed two clear oxidation and corresponding reduction peaks, but the peak potentials at low sweep rates, *e.g.*, several millivolts/second, were shifted by about 50 mV from the values obtained previously in conventional cells, *i.e.*, E_p(anodic) = 140 and 535 mV; E_p(cathodic) = 76 and 465 mV *vs.* SCE (4). These shifts were in the direction to be expected from the small ohmic potential drops likely to be present in the thin-layer cell, and the potentials used for the controlled potential electrochemical oxidations were adjusted accordingly.

With the electrode potential at 0V *vs.* SCE in a solution of Ru N⬭N Ru^{4+} there is no current flow, and the visible and near infrared spectra given in curves A of Fig. 3 were obtained. The value of λ_{max} (557 nm) agrees with value of Creutz and Taube (1) as does the absence of the band at 1570 nm.

When the electrode potential is changed to 400 mV *vs.* SCE, anodic current flows and the spectra obtained after *ca.* 5 min of electrolysis are shown in curves B of Fig. 3. Both the shift in λ_{max} and the decrease in absorption intensity of the visible peak correspond to those reported by Creutz and Taube (1), and the band that develops at 1570 nm agrees with their reports. The spectra could be shifted back and forth between the two cases by alternately reducing and oxidizing the solution at 0 or 400 mV, respectively. Thus the same mixed valence species, Ru N⬭N Ru^{5+}, results from both the chemical and electrochemical oxidation of Ru N⬭N Ru^{4+}.

In a second experiment the absorbance at 1570 nm was monitored continuously when the electrode potential was stepped from 0 to 640 mV *vs.* SCE. At this potential the oxidation product at the electrode is Ru N⬭N Ru^{6+} which does not absorb at 1570 nm.

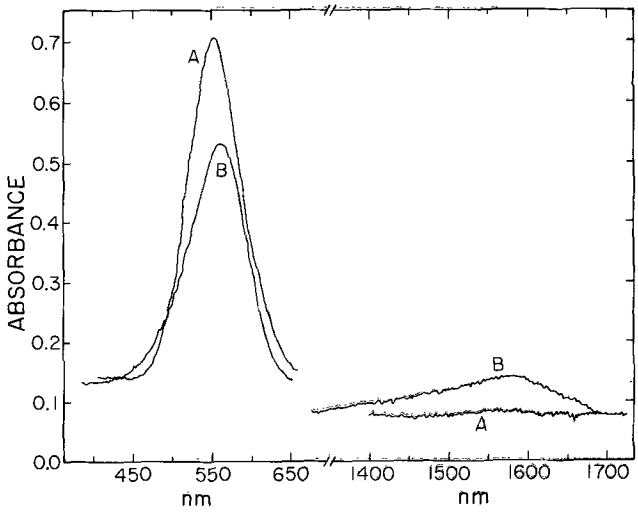

Fig. 3. Visible and near infrared spectra of Ru N⬭N Ru^{4+}, curves A, and Ru N⬭N Ru^{5+}, curves B, generated in the thin-layer cell.

However, the electrode reaction product diffuses back into the thin solution layer where it can react with the unoxidized Ru N⬭N Ru^{4+} that has not had time to reach the electrode surface. The product of this reaction is the Ru N⬭N Ru^{5+} ion which does absorb at 1570 nm. As expected, the measured absorbance at 1570 nm increases during the first 2–3 min of electrolysis, reaches a maximum, and then decreases to zero after *ca.* 10 min. At this point the spectrum of the solution matched that reported for Ru N⬭N Ru^{6+} (1).

These results illustrate the utility of the cell for spectral observation of electrode reaction products in the visible and near infrared and demonstrate the identity of the chemical and electrochemical oxidation products of Ru N⬭N Ru^{4+}.

Brief Communication

Induction Periods in Anodization of Aluminum

S. Ikonopisov* and L. Andreeva

Department of Physical Chemistry, Higher Institute of Chemical Technology, Sofia 56 (Darvenitza), Bulgaria

Two different kinetics are generally observed in galvanostatic anodization of valve metals. The first, in electrolytes with little tendency to dissolve the oxide, is characterized by a linear increase of the potential drop, U_f, across the film with the charge passed, Q. In the second, where the film is rather soluble in the anodizing solution, the slope dU_f/dQ decreases continuously with time, thus with Q. A third type of kinetics, *viz.*, a retarded anodization, has recently been observed with Bi (1), Mo (2), W (3), and Sb (4). Under appropriate conditions the process begins with an induction period (IP) during which U_f remains close to its initial value, followed by a more or less linear potential rise up to high voltages[1] (several tens or hundreds volts). It is the purpose of this communication to point out that an IP can be developed in the anodic film formation on aluminum also.

Specimens (99.99% Al) with an exposed surface area of 10 cm^2 were annealed for 4 hr at 550°C, electropolished, and brightened as previously described (5). The cell was a four neck glass flask, with glass stoppers supporting the anode, a glass stirrer furnished with a hydraulic gate, a thermometer, and a back flow condenser assembled with the counter and reference electrodes. The electrolyte was a 2.5% aqueous solution of H_3BO_3 adjusted with NH_4OH to the required pH. The anodization was carried out under automatic galvanostatic and thermostatic regulation and stirring of the electrolyte.

In galvanostatic anodization of aluminum IP's proved to appear only within narrow limits of appropriate anodizing conditions. This can explain why this phenomenon has not been observed so far, although the anodic oxidation of Al has been subject to extensive kinetic investigations. The appearance and prolongation of the IP requires an almost neutral anodizing electrolyte and is favored by high temperatures and lower current densities. In a borate solution with pH = 6 which is known to cause a "normal" anodization with 100% efficiency at temperatures below 40°C (6), a well-expressed IP appears at a sufficiently high temperature and low current density (*e.g.*, 90°C and 0.3 mA/cm^2), as shown in Fig. 1. The increase of the current density causes a sharp decrease or disappearance of IP (Fig. 1). All described features of the IP with Al seem similar to those with the above-mentioned metals and quite different from those with zirconium (7), where the IP is caused by the surface roughness and is absent with chemically polished Zr.

In solutions of simple H_3BO_3 (without addition of NH_4OH, pH = 3.5) IP's were not observed. The attempts to reveal a retarded anodization by increasing *pH* at decreased temperatures also failed. The known (8) accelerated dissolution of the film, increased electronic conduction, and decreased dielectric constant were only found at low current density under these conditions.

* Electrochemical Society Active Member.

Key words: anodic films, aluminum, induction period.

[1] The appearance of an induction period in the low-voltage passivation has been well known for a long time.

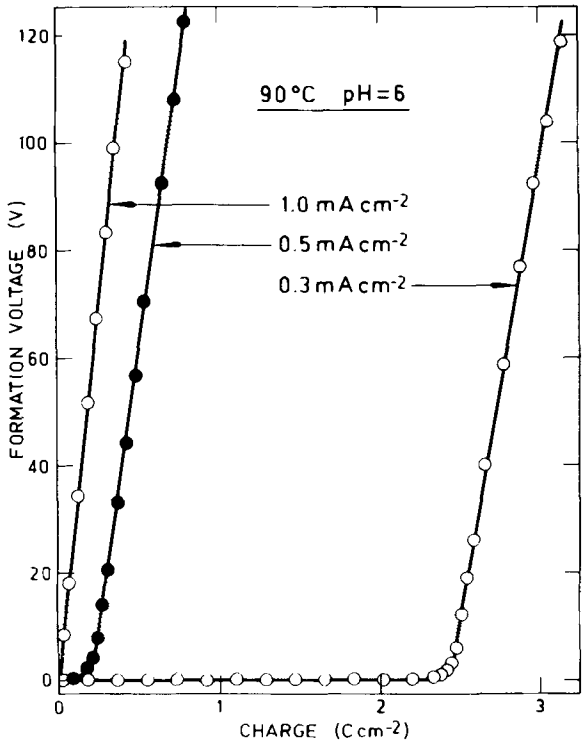

Fig. 1. Galvanostatic anodization curves for three current densities

In conclusion, an IP with Al can be observed under strictly defined conditions only. Yet the existence of IP's in the anodic oxidation, not only of the aforementioned metals but also of such a typical true film former as Al, suggests that a retarded film formation is a much more general phenomenon in the anodization at high voltages than it was supposed.

Sulfidation Properties of a Nickel-20 w/o Chromium Alloy at 700°C and Low Sulfur Pressures

J. A. Chitty[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The sulfidation kinetics and the morphological development of the reaction product for a Ni-20 weight per cent Cr alloy have been determined at 700°C and sulfur pressures below 5×10^{-10} atm. The kinetics were observed to be parabolic; the parabolic sulfidation rate constant was found to vary as a semilogarithmic function of the sulfur pressure. The reaction product consisted of an external scale identified mainly as Cr_3S_4 with dissolved nickel up to 5 atomic per cent, and a chromium sulfide subscale with morphological breakdown of the alloy/external scale interface. Approximate determinations for the diffusion rates of chromium in the scale and sulfur in the alloy were made. Tentative mechanisms are proposed to explain the diffusion-controlled reaction and the stabilization of the external scale by dissolved nickel.

An increased interest in sulfur corrosion has developed in recent years due to the natural occurrence of sulfur and its compounds in fuels and the difficulty of purifying these fuels. The behavior of Ni-Cr alloys of various compositions in sulfidizing gaseous environments has been fundamentally investigated by several workers (1-7). Romeo *et al.* (5) studied the diffusional growth of the duplex scale containing chromium and nickel sulfides on a Ni-20 w/o (weight per cent) Cr alloy at 700°C in H_2-H_2S atmospheres with sulfur partial pressures ranging from 8×10^{-10} to 2×10^{-2} atm. The present study is a continuation of this work using the same alloy composition and temperature, but under conditions of extremely low sulfur potentials ($P_{S_2} < 5 \times 10^{-10}$ atm). It is known that under these conditions chromium sulfide is the only reaction product, both externally and internally (7). Our purpose, accordingly, was to precisely establish the morphology of the scale and to ascertain the dependence of the nature of the chromium sulfide and the reaction kinetics on sulfur pressure.

Experimental

A Ni-20 w/o Cr alloy exists as a solid solution over a broad temperature range (8). The impurity contents of the alloy used in the investigation are recorded in Table I. Formation of a liquid phase in the Ni-Cr-S system is possible at temperatures above 600°C when the sulfur pressure is less than 10^{-8} atm (9). Preliminary experiments at 700°C with $P_{S_2} < 5 \times 10^{-10}$ atm showed, nevertheless, that the reaction is of the gas-solid type. Thermodynamic considerations show that only chromium sulfide formation is possible at these sulfur pressures and this influence is experimentally supported by the work of Lifshin *et al.* (7).

The sulfur pressures used were obtained by controlling the H_2/H_2S ratio of the atmosphere obtained by passing hydrogen through molten sulfur according to the method described by Rosenqvist and Dunicz (10) and by Brigham *et al.* (11). The H_2/H_2S ratio varies with temperature of the molten sulfur which is controlled in turn by a constant-temperature oil bath. This apparatus which yields atmospheres at sulfur potentials as low as 2×10^{-12} atm is shown in Fig. 1. Measurement of the H_2/H_2S ratio was determined from the sulfur analyses using the iodide titration method (12).

Alloy plates, 1.5 × 0.5 × 0.1 cm, metallographically polished to 1μ diamond abrasive as previously described were used as test specimens (5).

The assembly for the sulfidation experiments is shown schematically in Fig. 1. For measurement of the reaction kinetics the specimen was suspended in the reaction chamber from a McBain balance. The balance spring was manufactured from a Ni-span-C wire and the weight gain of a specimen was measured by following the spring elongation with a cathetometer (13). The assembly was evacuated to 10^{-2} Torr while the furnace was brought to temperature, and it was flushed with helium prior to passing the reaction gas. A specimen was then lowered into the reaction zone and the weight gains followed for suitable periods of time. At the end of each run, the specimen was winched into the upper portion of the column where the temperature drop was sufficient for quenching it.

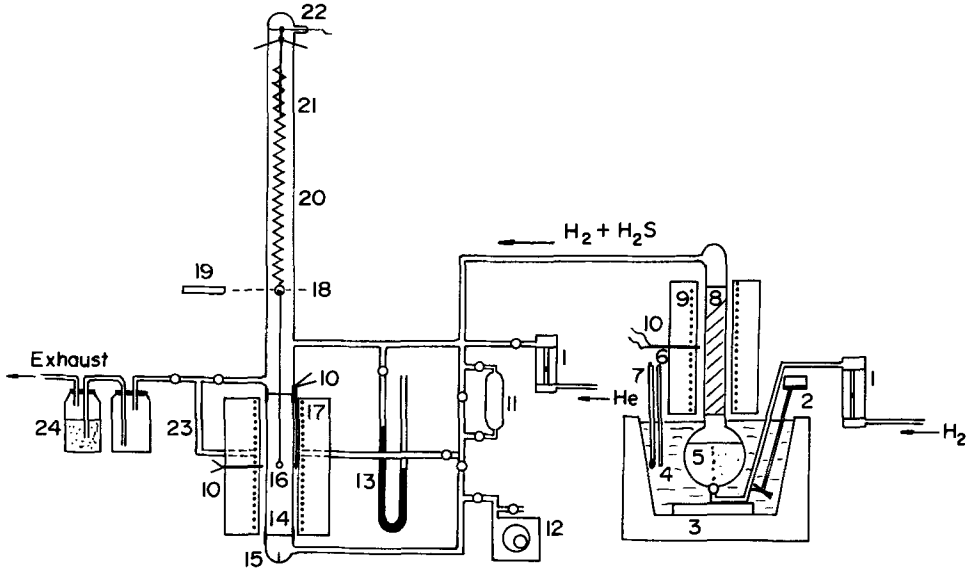

Fig. 1. Schematic of kinetic assembly: 1, rotameter; 2, stirrer; 3, heating element; 4, constant temperature oil bath; 5, sulfur bath; 6, temperature control; 7, thermometer; 8, porcelain packing; 9, furnace 500°C; 10, thermocouple; 11, gas sampler; 12, vacuum pump; 13, manometer; 14, mullite tube; 15, alignment spike; 16, specimen; 17, furnace 700°C; 18, target; 19, cathetometer; 20, spring chamber; 21, marker; 22, winch and forks for positioning specimen; 23, gas bypass; 24, ballast and absorption flask.

Specimens at various stages of scale growth were obtained by replacing the spring chamber with a column containing four winches and quartz rods for lowering and raising specimens from the reaction zone held at 700°C.

Cross sections of the sulfidized specimens were examined metallographically. The scales were protected for polishing by nickel plating of the specimens before their mounting in epoxy resin. Scale thicknesses and subscale penetration were measured with an optical microscope and the volume fraction occupied by the subscale was measured by point counting. Features of the scales were also examined with a scanning electron microscope. X-ray analysis by the powder technique was used to identify the sulfide constituents. Nickel-filtered copper radiation at low intensity was found to give the best resolution of the lines on the x-ray film. An electron microprobe was used to collect information about phase compositions and the diffusion profiles of the elements in the alloy and across the scale. Nickel, chromium, and sulfur counts were analyzed with respect to standards (the metals, NiS, Cr_7S_8) mounted with the specimens and the results were corrected for atomic number and mass absorption.

Results

Kinetics and scale morphology.—The results of the kinetic measurements at sulfur potentials in the range 5.5×10^{-12}-2.3×10^{-10} atm are shown in Fig. 2. After an induction period of 1-2 hr parabolic kinetics were observed. The values of the parabolic rate constants, K_p, determined from the slopes of the reaction curves are given in Table II.

The reaction product when observed microscopically appeared as a single-layer scale combined with a subscale. Morphological breakdown of the alloy interface was also observed which appeared to increase with increasing sulfur potential and time. A photomicrograph of a typical cross section is shown in Fig. 3.

In all cases the depth of subscale penetration appeared as approximately double the external scale thickness. Both increased parabolically with time as shown in Fig. 4. Subscale penetration was initially irregular but became regular with increasing time. The subscale particle size was finer with increasing penetration. A grain boundary etch showed that the sulfide particles occurred at inter- and transgranular sites in the alloy and that morphological breakdown of the alloy/scale interface was particularly severe at alloy grain boundaries.

Light colored stringers were observed in several of the external scales obtained after long sulfidation times. Two cases are shown in Fig. 5. The stringers, which became coarser with increasing sulfur potential, were observed to occur at grain boundaries within the sulfide scale. They extended from the peaks of the alloy at the broken down interface. Most of the stringers penetrated through the external scale although a few ended within the layer or hooked back on themselves. There was no evidence of stringers in the scale formed at the lowest sulfur pressure (5.5×10^{-12} atm) for the longest exposure periods. The scales formed in all other atmospheres did exhibit stringers, their occurrence being observed after 8 and 6 hr for specimens exposed in the atmospheres corresponding

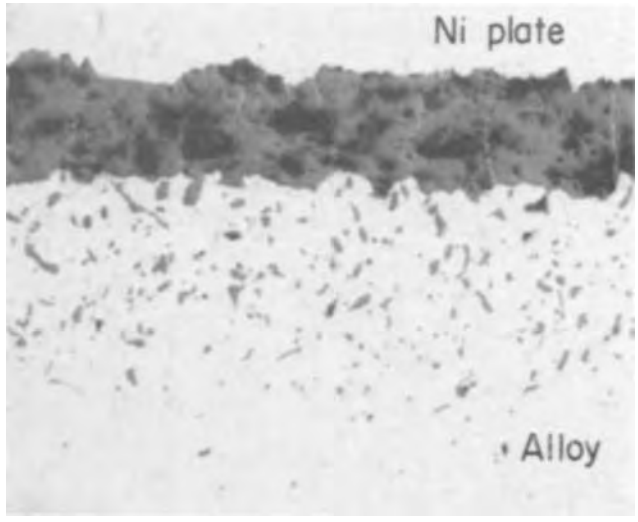
to $P_{S_2} = 1.6 \times 10^{-11}$ and 2.3×10^{-10} atm, respectively.

Phase identification.—Three techniques were employed to identify the phases present in an external scale. Due to the inherent difficulty in identifying the various forms of chromium sulfide the results from each technique alone are insufficient but when combined certain conclusions can be made.

Electron microprobe scans were made from the alloy interior across the subscale and through the external scale. Point counts at various distances were also obtained. The electron beam spot is about 2μ which is the same order of magnitude as a scale thickness and larger than the sulfide particle size in the subscale. As a consequence the probe results can only be considered as a qualitative representation of the concentration profiles, especially at the alloy/external scale interface where there is morphological breakdown. Typical composition distance profiles are shown for specimens exposed at the lowest and intermediate sulfur potential atmospheres in Fig. 6 and 7. It appears that much of the chromium in the subscale region was consumed in chromium sulfide formation and that the alloy was extremely nickel-rich at its interface.



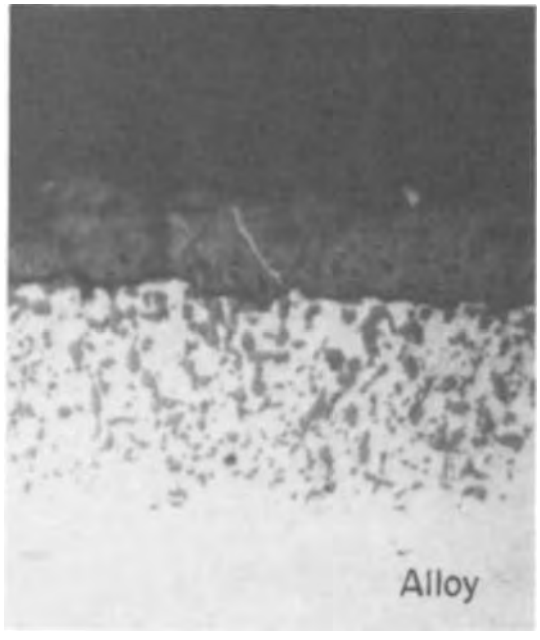


Fig. 5. Micrographs of Ni-20 w/o Cr alloy specimens sulfidized at different sulfur pressures. Magnification × 1650. (a, top) Exposure for 15.5 hr at $P_{S_2} = 1.6 \times 10^{-11}$ atm, (b, bottom) exposure for 8 hr at $P_{S_2} = 2.3 \times 10^{-10}$ atm.

The phase compositions identified in the external scale by the electron microprobe are summarized in Table III. The powder x-ray analyses are also included. There are problems in analyzing for chromium sulfides using ASTM x-ray cards since the six phases existing in the range CrS to Cr_2S_3 yield similar patterns (14). The x-ray technique identified the scale as mainly Cr_3S_4 with lines that could be assigned to Cr_2S_3. The probe technique also identified compositions near $(CrNi)_3S_4$ but other compositions nearer to $(CrNi)_5S_6$ and $(CrNi)_2S_3$ were also observed.

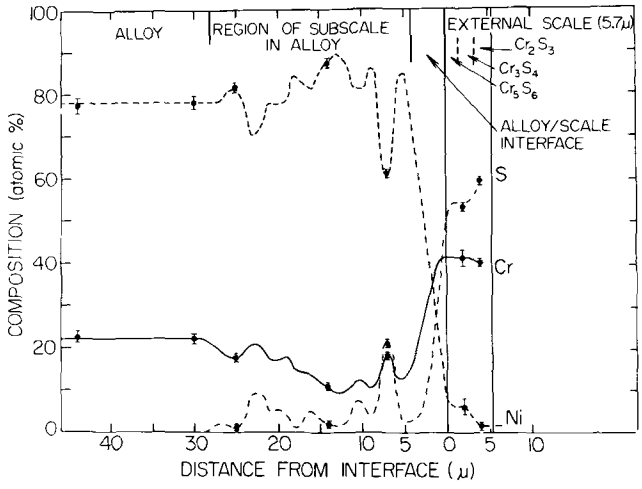

Fig. 6. Composition profiles of Cr, Ni, and S in a Ni-20 w/o Cr alloy specimen exposed for 24 hr in an H_2-H_2S atmosphere at a sulfur pressure $P_{S_2} = 5.5 \times 10^{-12}$ atm.

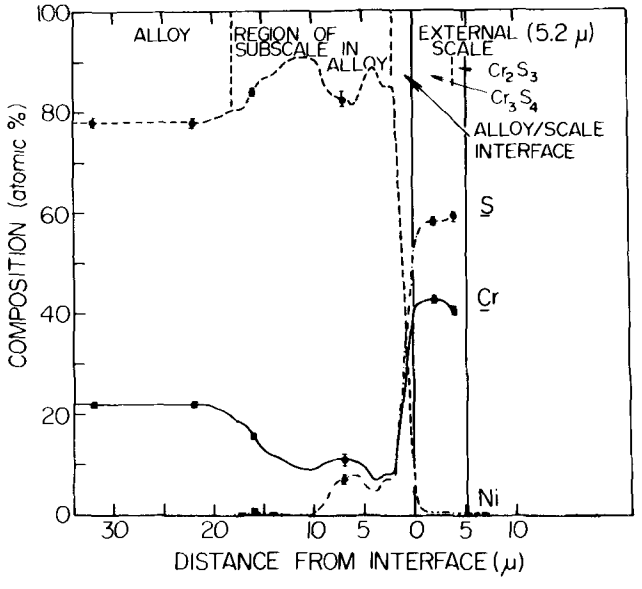

Fig. 7. Composition profiles of Cr, Ni, and S in a Ni-20 w/o Cr alloy specimen exposed for 8 hr in an H_2-H_2S atmosphere at a sulfur pressure $P_{S_2} = 6.5 \times 10^{-11}$ atm.

An attempt was made to positively identify the stringers using a x-ray microdetector mounted on the scanning electron microscope. Figure 8 shows SEM micrographs of stringers traversing the scale by three grain boundaries and compositional maps of the scale at regions of these stringers. This mapping demonstrates that the stringers in comparison to the scale are nickel-rich and depleted of sulfur. Actual counts obtained at points in a stringer and the scale are recorded in Table IV. These counts also show that the stringers are enriched in nickel and depleted of sulfur with respect to the adjacent scale. Although the electron beam possibly penetrates through stringers, since its intensity could not be reduced below 15 keV for effective counting of nickel, the metal/sulfur ratios based on the point counts vary from 1.01 within the stringer to 0.65 in the scale far from the stringer. The sulfide compositions, accordingly, correspond closely to the phases (NiCr)S and $(CrNi)_2S_3$ at these respective regions.

Discussion

The parabolic kinetics observed demonstrate that the reaction processes are diffusion controlled. Marker measurements have previously shown that metal is

the diffusing species in the chromium sulfide scale (5). A requirement to be met for concurrent subscale formation accompanied with morphological breakdown of the alloy interface is that the chromium diffusivity in the scale be several orders of magnitude larger than its diffusivity in the alloy. Thus, diffusion of chromium in these phases and sulfur in the alloy play fundamental roles in the formation of chromium sulfide on and in the alloy.

The external scale was identified as consisting mainly of $(CrNi)_3S_4$ although both lower and higher sulfide phases were present. An analysis of the nonstoichiometry and thermodynamics of the various binary forms of the chromium sulfides at 700°C has been made by Young *et al.* (15). All the sulfides approximate to the NiAs structure which may be described as hexagonally close-packed with the cations in the octahedral interstitial positions of the sulfide anion structure. Full occupation of these octahedral sites is found only in the case of CrS. The sulfides higher than Cr_7S_8 have a cation sublattice consisting of alternately filled and partially filled layers and, it has been proposed (16), that the partially filled layers are occupied by Cr^{+2} ions while the completely filled layers are occupied by Cr^{+3} ions. Cr_3S_4 has the largest nonstoichiometry ranging over the metal-excess and metal-deficiency sides of the stoichiometric formula ($1.286 < x < 1.377$ at 700°C when Cr_3S_4 is expressed as CrS_x and the intrinsic defect density is $\delta = 3.3 \times 10^{-2}$ at $P_{S_2} = 3.2 \times 10^{-11}$ atm).

According to this description of chromium sulfide, formation of the scale is expected to be controlled by metal diffusion via vacancies in the Cr^{+2} sublattices. The relationship between the parabolic rate constant and sulfur pressure is semilogarithmic as shown in Fig. 9. The significance of this relationship can be assessed from equations derived by Wagner (17) to describe the diffusion of metal from a binary alloy through its scale consisting of a ternary solid solution undergoing parabolic growth in terms of the metal diffusivities, the composition, and the activity gradients. His first-order differential equation expressing these parameters in terms of the parabolic rational rate constant for growth of a Ni-Cr-S solid solution layer exhibiting ideal or Henrian solution behavior would be (18)

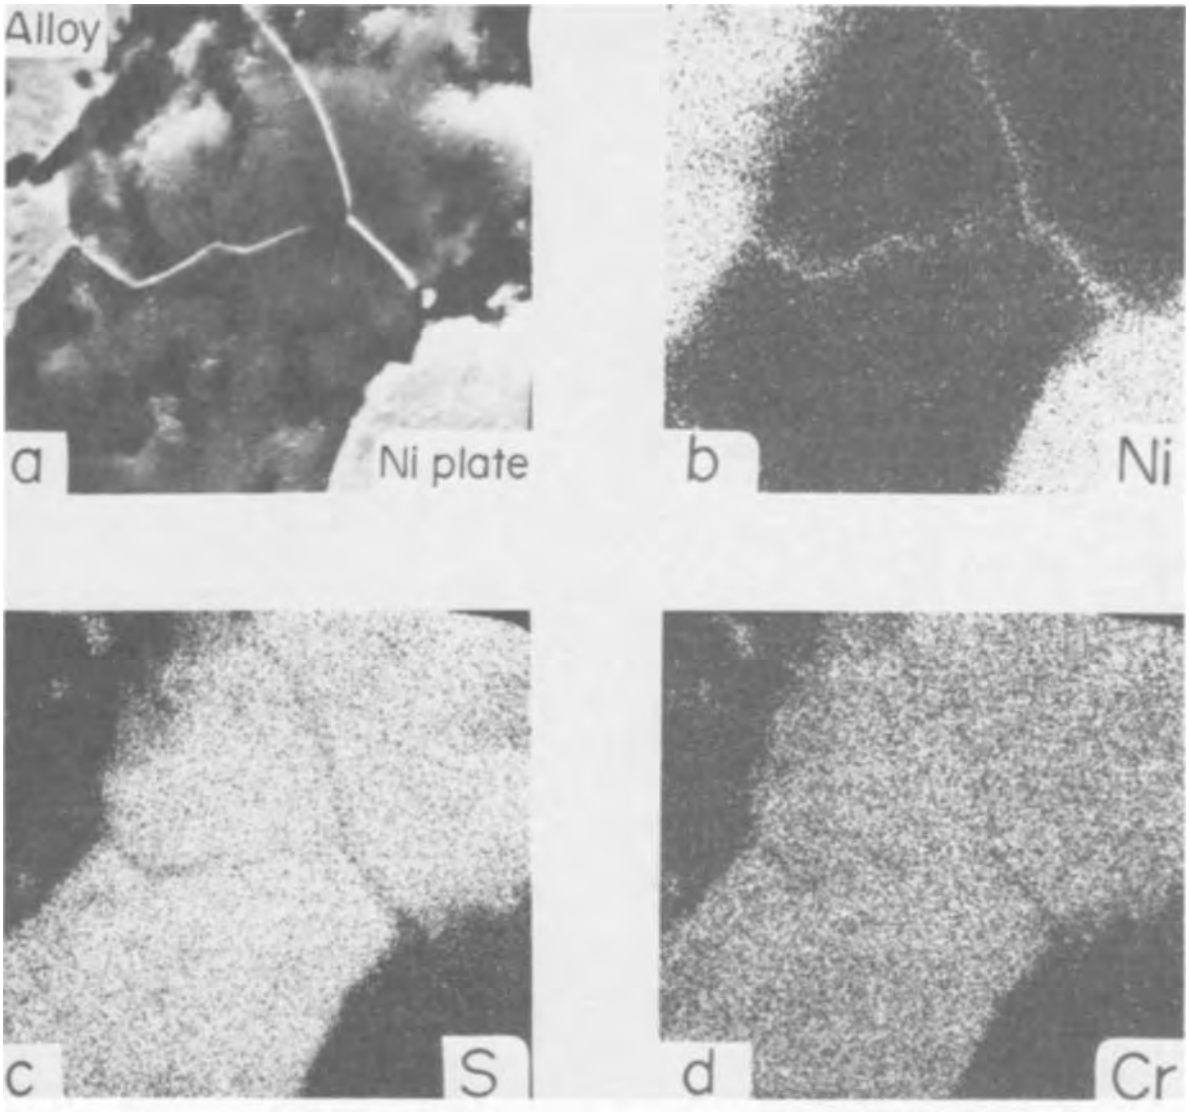

Fig. 8. SEM micrographs of the external scale in the region of stringers showing the stringers at grain boundaries and the Ni, S, and Cr composition maps. Magnification × 3500.

$$D_{Ni}(1-\epsilon)\left(-\frac{d\ln a_{Ni(S)}}{\partial\epsilon}\frac{d\epsilon}{dy}+\frac{z_{Ni}}{Z_S}\frac{d\ln a_S}{dy}\right)$$
$$+D_{Cr\epsilon}\left(-\frac{d\ln a_{Cr(S)}}{\partial\epsilon}\frac{d\epsilon}{dy}+\frac{z_{Cr}}{Z_S}\frac{d\ln a_S}{dy}\right)=k_r \quad [1]$$

where D_{Cr} and D_{Ni} are the metal self-diffusion coefficients, $1-\epsilon$ and ϵ are the local concentrations of nickel and chromium cations in equivalents, Z and a represent an appropriate valency and activity, y is the fractional distance x/x_s where x_s is the total scale thickness, and k_r is the parabolic rate constant in eq./cm sec. This equation can be applied to the present results by assuming that the chromium sulfide scale is a phase exhibiting continuous activity gradients for the diffusing species and that the above-expressed metal self-diffusivities act as appropriate average self-diffusion coefficients for total scale growth.

Certain assumptions can be made about several of the parameters in Eq. [1] from the scale compositions. First, the compositions and hence the activity gradients for the nickel and chromium sulfide constituents of a scale exhibit very little variation with respect to the much larger sulfur activity gradient. Second, the nickel concentration in the scale is very small [<5 a/o (atom per cent)] so that the value of ϵ can be approximated to unity. Equation [1] may then be written as

$$k_r \simeq D_{Cr\epsilon}\frac{z_{Cr}}{|Z_S|}\frac{d\ln a_S}{dy} \quad [2]$$

which corresponds to the expression for the parabolic rational rate constant describing growth of a binary sulfide layer on a pure metal (19).

Equation [2] is placed in the form

$$\frac{dk_r}{d\ln P_{S_2}}=\frac{\epsilon}{2}\frac{z_{Cr}}{|Z_S|}D_{Cr} \quad [3]$$

since the slope of the plot for the parabolic rate constant *vs.* $\ln P_{S_2}$ is proportional to the chromium diffusion coefficient. This slope (Fig. 9) gives a value of 1.5×10^{-11} cm²/sec for the diffusivity of chromium in the chromium sulfide scale.

The above analysis is but a first approximation to a complex reaction. It enables one, nevertheless, to obtain an evaluation for an average chromium self-diffusivity in the scale for comparison to that for the alloy. Since the phase changes between chromium sulfides are first order (15), the composition profiles at the phase boundaries are discontinuous. Unfortunately the resolving power of the electron probe was insufficient to define these compositional changes. The constant value obtained for the chromium diffusivity over the sulfur pressure range examined demon-

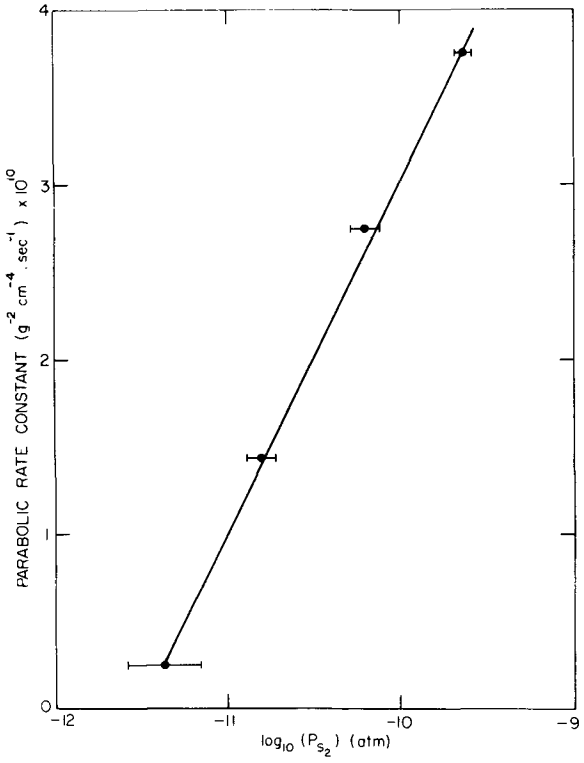

Fig. 9. Semilogarithmic plot of the parabolic sulfidation constants vs. the sulfur pressure in the H_2-H_2S atmospheres.

strates that this metal gradient and consequently the cation vacancy gradient across the scale was not strongly dependent on sulfur activity. This finding is consistent with the observations that $(CrNi)_3S_4$ was the fastest growing phase since pure Cr_3S_4 possesses an intrinsic disorder ($\delta = 3.3 \times 10^{-2}$) equal to one-third of its total possible nonstoichiometric disorder.

The diffusivity of chromium in a Ni-19.9 w/o Cr alloy has been investigated by Monma and co-workers (20) and at 700°C a value of 1.5×10^{-15} cm²/sec has been obtained. This is four orders of magnitude smaller than the value estimated for chromium diffusivity of the scale. These diffusion results can be used to examine the theoretical instability criteria for a planar interface of a binary alloy during its sulfidation advanced by Wagner (21). He established that the necessary but insufficient condition for instability is given by

$$\frac{X_{Cr}\,(D_{Cr}/V)_{alloy}}{1 - X_{Cr}\,(D_{Cr}/V)_{sulfide}} < 1 \qquad [4]$$

where X_{Cr} is the chromium mole fraction in the bulk alloy, and the terms in parentheses refer to the diffusivities and molar volumes of the alloy and chromium sulfide phases. The value of the above ratio from the results of this investigation is $\sim 10^{-5}$ which demonstrates as was found that morphological development of the external scale led to a very irregular alloy interface.

Since subscale penetration also obeyed parabolic kinetics, the diffusivity of sulfur in the alloy can be estimated from a relationship deduced by Wagner (22) between the volume fraction of the internal precipitates and the diffusivities. If the depth of subscale penetration and the distribution of the chromium sulfide particles are determined by outward diffusion of chromium and inward diffusion of sulfur, the volume fraction of chromium sulfide ϕ is given to a limiting approximation by

$$\phi = \frac{2}{\tilde{\pi}} \frac{X_{Cr}}{X_S^{o}} \left(\frac{\tilde{D}}{D_S}\right)_{alloy} \qquad [5]$$

Here, $\tilde{D}$ and D_S are the metallic interdiffusion coefficient and the sulfur diffusivity in the alloy, respectively, and X_S^{o} is the sulfur solubility in the alloy taken to be equal to that for pure nickel. The volume fraction was approximately 30% and the solubility of sulfur is the order of 30 ppm (11). This treatment yields $D_S \sim 10^{-11}$ cm²/sec which can be compared to the value of chromium diffusivity quoted previously $\sim 10^{-15}$ cm²/sec. Thus sulfur diffusion in the alloy is several orders of magnitude faster than the counter diffusion of chromium which meets the condition for internal precipitation of chromium sulfide. Since the subscale has a vague dendritic appearance with the formation of large irregular particles at the alloy grain boundaries, these boundaries acted as preferred sites for nucleation and growth of chromium sulfide.

A study of the scale compositions shows that the stoichiometry of the ternary chromium sulfides obtained exist at lower sulfur pressures than expected from the binary equilibrium study (15). The compositions nearest to the outer edge of the scales as obtained by the microprobe were used for this comparison since these values are most closely related to those for equilibrium with the determined sulfur pressures in the H_2-H_2S atmospheres. It appears that the presence of nickel in the scales in quantities up to 5 a/o has the effect of stabilizing the chromium sulfides by lowering their dissociation pressures. It is known that the presence of chromium in nickel sulfide has this effect (5). In order to illustrate this behavior, the Ni-Cr-S isothermal phase diagram for 700°C due to Kirkaldy and co-workers (9) has been converted into a tentative phase diagram of sulfur pressure *vs.* metal composition. The result is given in Fig. 10. In this diagram, the terminal phase compositions are known to a good degree of certainty from

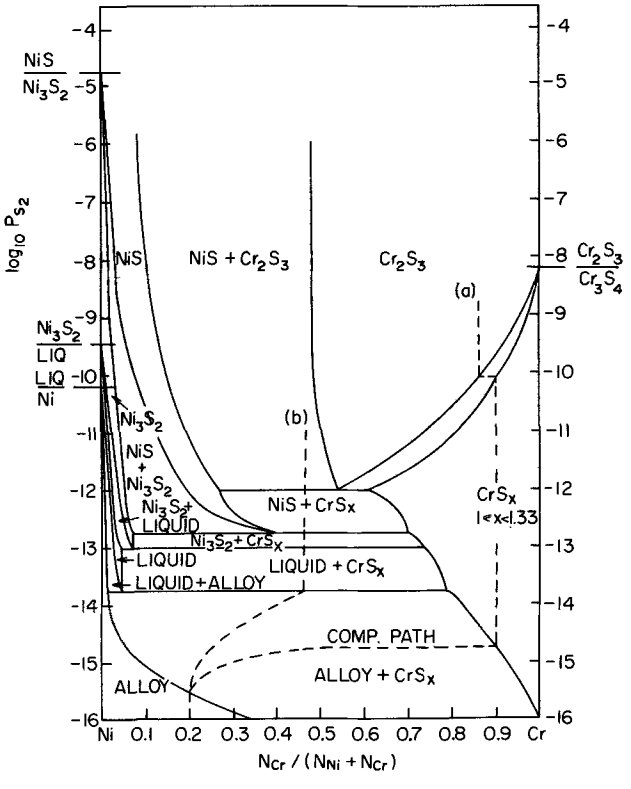

Fig. 10. Plot of the logarithm of the sulfur pressure vs. the metal atom fraction in the alloy and nickel-chromium sulfide phases to yield a tentative phase diagram representation of the Ni-Cr-S system at 700°C. The compositional paths (a) and (b) refer to the compositions within the alloy and the scale at the main regions of the scale and the regions of the scale boundaries containing nickel-rich sulfide stringers, respectively.

the phase diagram study but the sulfur pressures for stability of the phases are only of qualitative significance since they are approximations from the compositions of the chromium sulfide found in the scales at the different sulfur pressures under kinetic growth conditions. It would appear therefore that nickel solubility in a chromium sulfide phase, or vice-versa, decreased the sulfur pressures at which the various ternary sulfide phases are stable relative to those pressures for the pure binary compounds.

This representation of phase equilibria at 700°C suggests several compositional factors relevant to the morphological development of the reaction product. It has been found that the scales consisted essentially of chromium sulfide except at several grain boundaries where an additional phase as stringers extended from the tips of the irregular alloy interface. Representative compositional paths are shown in Fig. 10 which are in qualitative accordance with the electron microprobe results for compositions at these regions of the scale and subscale. Path (a) corresponds to compositions in the major regions of a scale. This path is shown to cut the (alloy + CrS_x) phase field at increasing sulfur pressure in order to account for the internal formation of chromium sulfide particles as a subscale. A large sulfur activity gradient subsequently occurs across the chromium sulfide phase fields of the external scale. Formation of the (NiCr)S stringers, however, implies that this compositional path at the regions of these stringers would be displaced toward the nickel side of the diagram. If the alloy tips could be depleted of chromium to approximately 1 a/o, a compositional path for these regions would possibly pass through the (liquid + CrS_x), (Ni_3S_2 + CrS_x), (NiS + CrS_x), and (NiS + Cr_2S_3) phase fields. This behavior which is shown by the compositional path (b) would account for stringers which, at the reaction temperature, would exist as liquid in contact with the solid alloy and they would extend directly from the alloy tips. This latter consideration appeared to be the case. The stringers, however, did not measurably increase the sulfidation rate because they existed as solid at the higher sulfur activities within the major portion of the external scale. A more detailed account cannot be given for these phenomena due to the limitations of the techniques for chemical analyses of the phases of small spatial extent. It has been possible to demonstrate, notwithstanding, that this behavior of the stringers is different than in a sulfidation example at the higher temperature of 850°C where it was found that the formation of completely liquid nickel sulfide stringers was associated with enhanced sulfidation and rapid degradation of a Ni-Cr alloy (6).

The results from this investigation may be compared to those previously obtained upon exposing a Ni-20 w/o Cr alloy to H_2-H_2S atmospheres supporting higher sulfur pressures at 700°C (5). At pressures greater than 8×10^{-8} atm a superficial layer of nickel sulfide was formed on the chromium sulfide layer. Both of these layers grew by parabolic kinetics without subscale formation and development of an irregular alloy interface. Consequently these latter features can be avoided in the sulfidation of a Ni-20 w/o Cr alloy when there is an outermost layer of nickel sulfide to act as a sink for nickel and subsequent rapid inward displacement of the alloy-scale interface.

Summary

Sulfidation of a Ni-20 w/o Cr alloy at 700°C in H_2-H_2S atmospheres supporting sulfur pressures for formation of chromium sulfide proceeded by parabolic kinetics. Chromium sulfide appeared as an external scale and subscale accompanied by morphological development of an irregular alloy interface. The parabolic rate constant varied semilogarithmically with sulfur pressure and the reaction processes were governed by the diffusion rates of chromium in both the external scale and alloy and sulfur in the alloy. The average self-diffusivity of chromium in the scale, 1.5×10^{-11} cm²/sec, was of the same magnitude as the sulfur diffusivity in the alloy, $\sim 10^{-11}$ cm²/sec, but four orders of magnitude larger than the chromium diffusivity in the alloy. These relative values for the diffusivities satisfied theoretical considerations for formation of a scale and subscale with simultaneous development of an irregular alloy interface. An explanation was also given for the formation of (NiCr)S stringers at grain boundaries in the chromium sulfide scale by reference to the thermodynamic stabilities of the various ternary metal sulfide phases.

ABSTRACT

The presence of mobile sodium ions in SiO_2 films, thermally grown on silicon, can lead to time-dependent conduction and subsequent dielectric breakdown. When this occurs, it will be shown that anomalously high (ten orders of magnitude) electronic currents can result, presumably because of a modification of the shape of the injecting barrier, due to the high electric field created by the presence of the uncompensated positive charge. The time (t) required to break down the SiO_2 film under an applied field (E) was found to approximate the empirically known Peek's law relationship, *i.e.*, $E \propto t^{-1/4}$. Moreover, it will be demonstrated that field enhancement in the oxide due to space charge effects provides the fundamental breakdown mechanism. Capacitance-voltage measurements of the silicon flatband voltage were used to determine the internally created field, and thereby to demonstrate that breakdown occurred when the total field reached the breakdown strength of the film. It will be seen that the limiting time before breakdown, with sodium-contaminated samples, correlates with the kinetics of ionic motion, *e.g.*, it exhibits the same activation energy and varies roughly as the square of the oxide thickness. The other statistical variations in breakdown times can be quantitatively attributed to defects present in the starting oxide films.

Despite the high reliability of solid-state semiconductor devices, increasing reliability requirements, particularly for large MOSFET memory arrays, make a thorough understanding of any time-dependent deterioration mechanism necessary. Since the gate oxide region of an FET is normally subjected to electric fields approaching one-fourth of the intrinsic breakdown strength of SiO_2 (*i.e.*, $\sim$ 9 mV/cm), it is subject to dielectric breakdown. It has been known for some time that mobile ions (1) can be responsible for threshold voltage shifts over a period of time; nevertheless, little work has focused on the influence of mobile ions on the dielectric integrity of thermally grown SiO_2 films. Recently, Raider (2) found that mobile ions can be responsible for time-dependent dielectric breakdown.

Several recent papers (3-9) have been concerned with the dielectric breakdown of SiO_2 layers on thermally grown Si. Wide variabilities in breakdown strength across a Si wafer were usually observed and attributed to oxide defects. Various materials and processing parameters were tested to determine their influence on defects. For example, sodium contamination was introduced during oxide growth in one study (7), but it did not increase the defect density although it did lower the maximum breakdown strength. Unfortunately, however, very little attention has been directed in the earlier work to the time dependence of breakdown in relatively defect-free SiO_2 films, such as would be present in high quality MOSFET devices. Worthing (5) reported a time-dependent breakdown mechanism in MOS structures for silicon biased negatively and an intrinsic, time-independent mechanism for silicon positive. The breakdown time for Si(−) followed an empirical Peek's law relationship, *i.e.*, $E \propto t^{-1/4}$, where t is the time to breakdown at field E; this time dependence is the same as that observed earlier by Raider (2) in sodium contaminated SiO_2 films. Other work (4, 6-8) has failed to find this Peek's law behavior in high quality oxides. A second time-dependent breakdown mechanism, (*i.e.*, one that could not be described with Peek's law) was first observed experimentally by Raider (2). It was later described by DiStefano (9) in terms of a barrier-height lowering which leads to breakdown as a result of Na ion buildup at the Si/SiO_2 interface. This barrier lowering is similar to work-function lowering which occurs with Cs on Si [see Ref. (9)] and leads to breakdown triggered by excessively high current in SiO_2.

This paper focuses more extensively on the effect of sodium ions on the time dependence of SiO_2 breakdown as well as the breakdown mechanism. Primary consideration is given to the high internal fields (10) that can be associated with uncompensated charge in the SiO_2. It is shown that Worthing's results can be explained by the motion of ions in the oxide.

Experimental Procedure

Metal-oxide-semiconductor capacitors were fabricated on 2 ohm-cm, p- and n-type, <100>-oriented silicon wafers. The wafers were ultrasonically cleaned using NH_4OH-H_2O_2, HCl-H_2O_2 (11), and HF solutions, while the quartz glassware was etched with HNO_3-HF. Oxides were grown from 200 to 2000Å thick at 1000°C in dry oxygen; the oxide thicknesses were measured ellipsometrically.

Contamination was introduced by evaporating a small amount of NaCl onto the freshly oxidized surface. To complete the capacitors, 3000Å thick aluminum dots (32 mil diam) were evaporated through metal masks in a clean evaporation system, and the wafers were then annealed for 30 min at 400°C in dry nitrogen. Samples prepared in this fashion had mobile charge densities from 10^{11} to $10^{15}/cm^2$, as measured by the charge-time (Q-t) technique (12). Although films having such high mobile Na contamination levels are not acceptable for technological applications, locally high sodium concentrations may be present even though the average level is low. Control wafers typically had mobile ion concentrations less

Key words: dielectric breakdown, silicon dioxide, sodium contamination, electrical conduction, field enhancement.

than $5 \times 10^{10}/cm^2$ as determined by the capacitance-voltage flatband shift method (1).

Measurements were made of both the time to breakdown and the time dependence of the capacitance-voltage flatband voltage for stressed samples. In the first measurement, a constant voltage was applied to an MOS capacitor dot with the aluminum dot biased positively. Breakdown was identified by an almost instantaneous jump in the current density to well over 10 mA/cm². Often current spikes occurred which were generally correlated with the appearance of small black specks or holes in the capacitor (seen with 500X magnification) in the aluminum electrode and were attributed to self-healing breakdown events (2). The times at which each breakdown event occurred were recorded. Usually the MOS capacitor would finally short out; this time was also recorded. Capacitance-voltage measurements for monitoring ionic drift have been described previously (1, 12), are straightforward, and are not discussed further here.

Results and Discussion

Conduction.—When a high field (4-8 MV/cm) is applied to a contaminated MOS capacitor with the metal electrode biased positively, the current is observed initially to increase with time. If the contamination level or the applied field is high enough, breakdown occurs after a given period of time has elapsed. When the applied field is low enough so that breakdown does not occur, the current reaches a maximum and then decays with time as shown in Fig. 1. Current densities up to 150 mA/cm² have been observed in 1000Å thick films. The current observed here is much too large to be explained by ionic motion and is attributed to enhanced electron injection into the oxide as a result of the high internal field created by the ions. The time at which the current maximum occurs as well as the maximum current density are shown as functions of applied field in Fig. 2.

The time dependence of this current through an SiO_2 film contaminated with sodium ions (viz., Fig. 1) can be explained by the variation of the tunneling distance with the position of the sodium sheet (13)

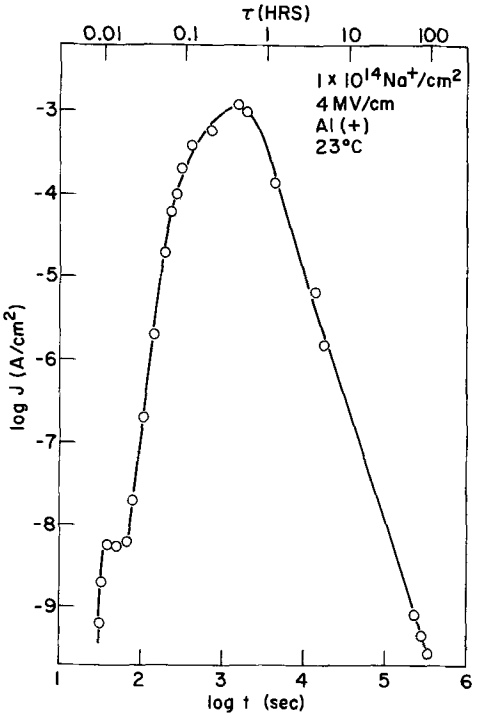

Fig. 1. Current through a Na^+-contaminated, 2000Å SiO_2 film as a function of time.

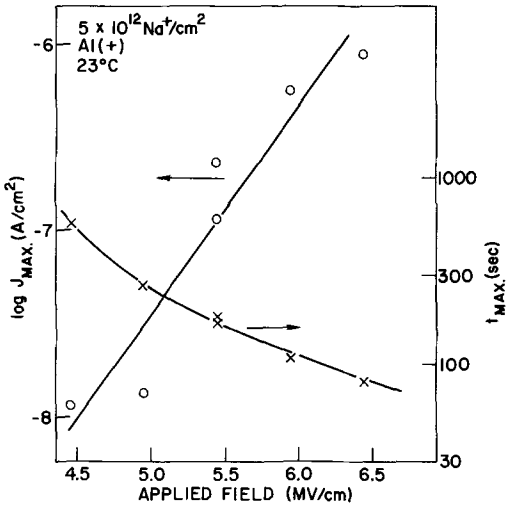

Fig. 2. Dependence of the maximum current and the time at which the current peak occurs on applied field.

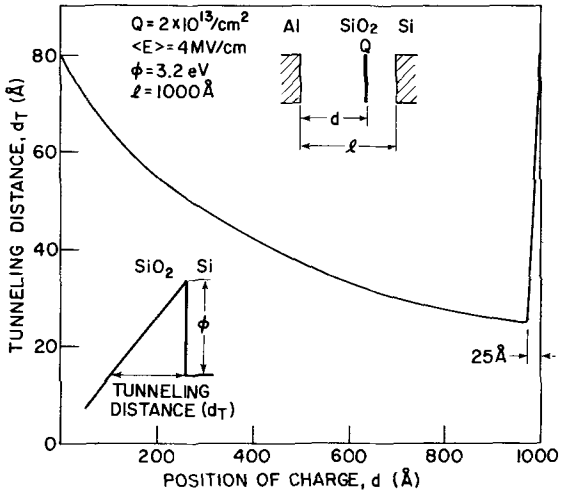

Fig. 3. Variation of tunneling distance with position of charge inside oxide.

(Fig. 3). In the absence of ionic effects, room temperature conduction through SiO_2 has been shown (8, 14) to take place via a Fowler-Nordheim tunneling mechanism in which conduction electrons from the injecting electrode (silicon in the case of Fig. 1) tunnel through a triangular-shaped potential barrier into the oxide conduction band. The slope of the oxide conduction band forming the barrier is given by the internal electric field. The tunneling distance (d_T) is determined by the barrier height (ϕ) and the applied field (E) when no charge is present in the film. The effect of the electrically uncompensated sheet of positive charge in the oxide is to reduce the tunneling distance by increasing E internal near the Si. As seen in Fig. 3, the F-N barrier thickness becomes progressively smaller as the charge sheet penetrates the oxide until it is almost to the Si/SiO_2 interface (25Å away, estimated using the system parameters for the case considered here). Once the charge is located less than the tunneling distance away from the silicon, further charge motion actually increases the tunneling distance. When all of the charge is at the Si/SiO_2 interface, the tunneling distance is the same as if the charge were at the metal/SiO_2 interface. Calculations (10) (neglecting strain energy) do show that the equilibrium position for sodium ions (10^{13}/cm²) under even low bias (1 MV/cm) is less than 5Å from the silicon. Accordingly, the shape of the current-time plot (Fig. 1) can be now understood: the

small peak (at ~ 30 sec) is caused by ion motion; the large maxima at 1000 sec is developed as the tunnel distance minima is reached; and, the slow current decay at longer times take place as the charge sheet reaches the SiO_2/Si interface. The rapid current increase followed by a slow decrease must then reflect rapid motion of charge through the bulk of the film followed by slower motion near the interface.

It should be noted that although high (0.1 A/cm^2) current densities have been observed in these contaminated capacitors, the current levels expected with a space-charge limited mechanism are much higher (~ 10^5 A/cm^2 assuming an electron mobility of 1 cm^2/V-sec), and electrode-limited conduction is still seen here. Samples that were immersed in liquid nitrogen at the peak of the current time curve (Fig. 1) continued to show the very high conduction level. The current was reduced by only a factor of five which would correspond to an activation energy less than 0.02 eV. From this unreasonably low energy it can be concluded that the conduction mechanism at the highest current levels remains Fowler-Nordheim tunneling which is only weakly temperature dependent (8, 14). Thermal runaway leading to breakdown was not observed although runaway would be likely for current densities above 1 A/cm^2.

Dielectric breakdown.—When the field is high and breakdown does occur, the time to breakdown is determined by the field applied, the contamination level, the oxide thickness, and the measuring temperature. Figures 4 and 5 give typical breakdown field *vs.* breakdown time characteristics; the data reasonably describe the equation $E_{BD} = E_o + \alpha t^{-1/4}$. This Peek's law dependence for SiO_2 films on Si was empirically observed first by Worthing (5) and was attributed to conduction and thermal instability rather than mobile ions at that time. It should be noted that each point in Fig. 4 or 5 represents the longest time observed when a reasonably large sampling, 10-20, of identically prepared and stressed capacitors are allowed to break down. Often breakdown would occur earlier if a defect were present in the oxide; accordingly, thin metal electrodes were used so that these randomly occurring, early breakdown events would recover by the well-known self-healing breakdown process (3). The rate of these breakdown events would increase with time until final shorting occurred, with total destruction of the capacitor. The times for final shorting (in Fig. 4 and 5) are the maximum ones that will elapse before breakdown, and are believed to be representative of uniform, defect-free SiO_2 films. An actual FET device would suffer a failure in less time. The early breakdowns are scattered, of course, but they do generally follow the same behavior as the limiting times shown in Fig. 4. A correlation of the limiting or longest time to breakdown was made to the time for the current maxima (viz., Fig. 1). Actual breakdowns were seen both before the peak (*i.e.*, when the current was increasing with time) was reached and after the peak. However, the limiting breakdown time was seldom greater than the time for the current maximum. It should be emphasized that the field-enhancement type of breakdown occurred before all the sodium drifted to the Si/SiO_2 interface.

The effect of oxide thickness on the time-to-breakdown relationship is shown in Fig. 4 while the effect of measuring temperature is given in Fig. 5. In each case we find a common intercept, that is a field below which breakdown does not occur regardless of the temperature or oxide thickness. The time to breakdown varies almost as the square of the oxide thickness while Fig. 6 indicates that it is also thermally activated in the temperature range studied.

These results can be explained in terms of the internal field created by the presence of the charged ions. The electric field in the oxide at the SiO_2-Si interface (E_{Si}) at any time is given by

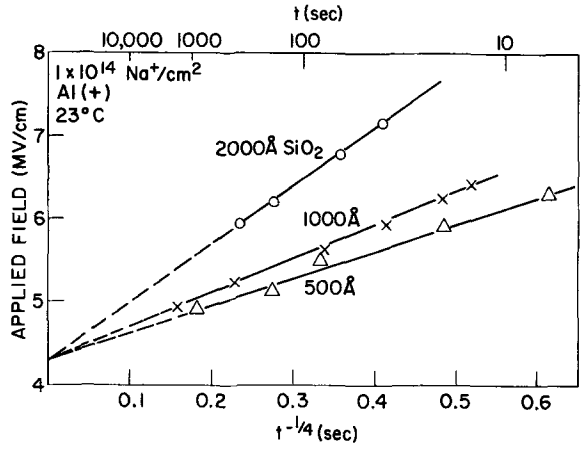

Fig. 4. Effect of oxide thickness on time interval before breakdown.

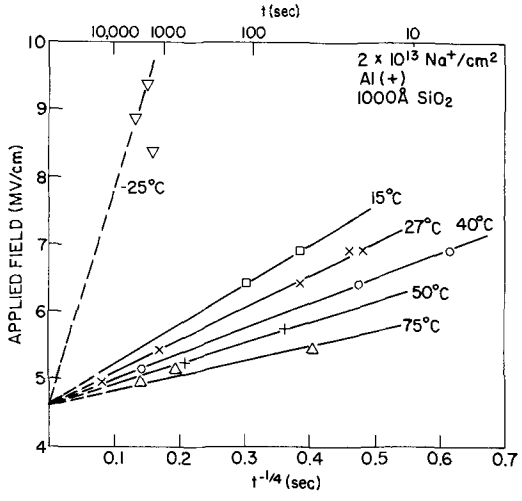

Fig. 5. Effect of temperature on breakdown time

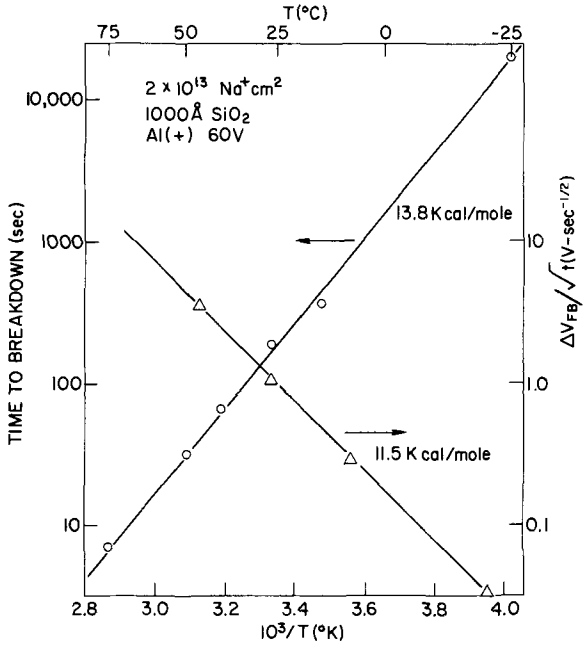

Fig. 6. Temperature dependence of time to breakdown and of C-V shift.

$$E_{Si}(t) = E_{appl} + \frac{\Delta V_{FB}(t)}{d_{ox}} \quad [1]$$

where E_{appl} is the applied field, $\Delta V_{FB}(t)$ is the Si flatband voltage shift at time t, and d_{ox} is the oxide thickness. The term $\Delta V_{FB}(t)$ is seen to be (1)

$$\Delta V_{FB}(t) = \frac{1}{\epsilon}\int_{x=0}^{x=d_{ox}} q(x, t)\, x\, dx \quad [2]$$

where ϵ is the oxide dielectric constant and $q(x)$ is the charge density at the position x in the oxide. The point $x = o$ corresponds to the oxide surface, and $x = d_{ox}$ corresponds to the silicon-SiO_2 interface. If only positive charge is present in the oxide, the maximum internal field is that at the Si/SiO_2 interface and is given by E_{Si} in Eq. [1].

An applied field can shift the mobile charge even at room temperature. As the sodium ions drift under the applied field toward the silicon, the flatband voltage becomes larger, resulting in an increase in the oxide field near the silicon. When E_{Si} exceeds the maximum breakdown strength of the oxide (E_{max}), breakdown occurs [see Ref. (7) for the dependence of E_{max} on oxide thickness and Si doping]. The maximum field enhancement occurs when all of the sodium is near the silicon in which case Eq. [2] reduces to

$$\Delta V_{FB} = \frac{Q d_{ox}}{\epsilon} \quad [3]$$

where Q is the total amount of sodium/cm^2 present. Breakdown will not occur at all with this model when the maximum breakdown strength (E_{max}) satisfies

$$E_{max} > E_{appl} + \frac{Q}{\epsilon} \quad [4]$$

As an example when Q is 10^{13} Na^+/cm^2, Q/ϵ becomes 4.6 MV/cm; for a 1000Å SiO_2 film E_{max} is 9 MV/cm[7]. Thus breakdown should not occur for applied fields less than $9 - 4.6 = 4.4$ MV/cm.

Based on the above findings, the essential condition needed to cause breakdown in these systems can be written as

$$E_{max} = E_{appl} + \frac{\Delta V_{FB}(t_{BD})}{d_{ox}} \quad [5]$$

where E_{max} is a function of oxide thickness and Si doping. This relationship was verified, within experimental error, for a wide range of controlled sodium levels from 10^{12}/cm^2 to 10^{15}/cm^2, over the temperature interval from −25° to +75°C, and SiO_2 thicknesses from 200 to 2000Å. For example, by using a contamination concentration of 2×10^{13} Na^+/cm and a 1000Å thick SiO_2 film stressed with a nominal 60V potential, it was seen that the dependencies of the flatband voltage shift and of the time to breakdown activation energies for Na^+ drift and oxide breakdown are essentially the same. See Fig. 6. In light of the sample-to-sample variability of most breakdown results which will be discussed shortly, this agreement to within 2 kcal/mole must be considered quite good.

Although the experimental data fit the empirical Peek's law relationship well, the fundamental relationship governing the above behavior is given actually by Eq. [5]. The flatband voltage shift is a complicated function of the initial sodium concentration, temperature, and the field. Furthermore, the rate of flatband voltage shift is subject to considerable changes over a period of time and is still not completely understood. In view of this complexity it is not possible to obtain a simple E_{appl} *vs.* t equation. The simplest expression arises when log $\Delta V_{FB}/\sqrt{t}$ is proportional to the field as seen in one segment of Fig. 8 and is more fully explained in the section on Sodium drift. With this proportionality, it can be shown that the limiting time to breakdown, t_{BD}^{max}, is given by

$$t_{BD}^{max} = \left[\frac{E_{max} - E_{appl}}{K \cdot \exp(kE_{appl})}\right]^2 \quad [6]$$

where K and k come from the intercept and slope, respectively, of the log $\Delta V_{FB}/\sqrt{t}$ *vs.* E plot. Although Eq. [6] is too restrictive and complex to be very useful, it is more fundamental than Peek's law.

A considerable amount of variability in the results was observed. As mentioned earlier, breakdown events do occur at times considerably shorter than the limiting times presented here and these short time failures are the most important ones for actual devices. Only the process of self-healing, whereby the electrode above weak spots is vaporized, allows us to determine the limiting time. If the electrode metalization is too thick or if an oxide defect is large, shorting occurs during a breakdown and gives a time which is shorter than the limiting time. This phenomenon made it difficult to obtain data that had little scatter. Because of it, minor, but expected, deviations from an exact Peek's law behavior could not be seen.

Although the occurrence of breakdown after the current has reached a maximum is rare, *i.e.*, in about 1% of the capacitors tested, it is significant in formulating the details of the breakdown model. Electronic breakdown in SiO_2 has been postulated previously (8) to occur via collision ionization: injected electrons gain sufficient energy from the electric field to ionize centers in the oxide. With Fowler-Nordheim injected electrons, the first possible ionizing collision occurs at a distance of about $\lambda + d_T$ where λ is the mean free path and d_T is the tunneling distance. (Note: the electrons do not gain energy during tunneling.) For breakdown to occur the high field region must extend that far into the oxide; thus the centroid of the mobile ions must be at least $\lambda + d_T$ away from the silicon. To first order, the tunneling distance is given by the barrier height, ϕ, divided by the field E and is minimized when the centroid of the mobile charge is located at d_T and thereby results in the current maxima. Thus it is argued that ionization and breakdown from Fowler-Nordheim injected electrons would occur before the current peak was reached. Electrons injected over the top of the barrier (Schottky emission), on the other hand, do not have this restriction. If the mean free path of these electrons is less than the tunneling distance, then breakdown can take place after the current peak has occurred. Our data indeed show that the conditions required for breakdown to be substantially later than the current peak also results in a Fowler-Nordheim tunneling distance (given by the barrier height divided by the field) that is 35-50Å and hence longer than the reported mean free path of 34Å (15).

When the aluminum was biased negatively no time dependent conduction or breakdown was observed. The sodium contamination was introduced just before metalization. Negative bias would keep the Na in place where it would not enhance the applied field. If the contamination was uniformly distributed through the oxide, a time dependence would be expected.

Sodium drift.—The breakdown time dependence can be explained from the kinetics of the flatband voltage shift. Mobile ion drift in SiO_2 films has been extensively examined (1, 16-20); however, a complete characterization of the drift process has never been presented, particularly at room temperature and for high applied fields. Figure 7 presents a typical plot of the capacitance-voltage flatband shift as a function of time and applied field at room temperature. When the flatband voltage shift is small compared to the total possible flatband shift, the voltage shift varies

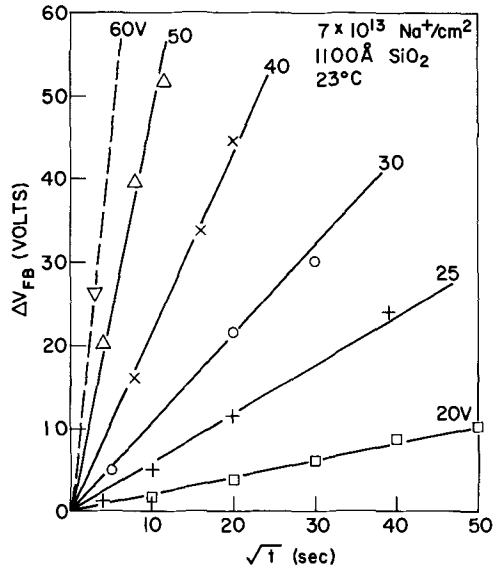

Fig. 7. Capacitance-voltage flatband shift as a function of time and applied voltage.

as the square root of time. Snow *et al.* (1) attributed their kinetic results to a field-free boundary layer while Hofstein (16-17) showed that the drift could better be explained in terms of sodium emission from interfacial traps. If the trapping band is less than few kT wide, then a linear ΔV_{FB} *vs.* $\sqrt{t}$ plot would be expected for short times. Other work has supported the model of sodium release from traps (18-19). Figure 8 gives the slope of the ΔV_{FB} *vs.* $\sqrt{t}$ curves as a function of applied field. Eldridge and Kerr (20) have explained the field dependence of the flatband shift due to Na^+ ions drifting through phosphosilicate glass-SiO_2 films in terms of the lowering of the barrier of a potential well. They found

$$\Delta V_{FB}(t) \propto \sqrt{t} \exp\{(-\phi + qEW/2)/kT\} \quad [7]$$

where ϕ is the depth of the potential well and W is its width. The field dependence seen in SiO_2 films without PSG does show log $\Delta V_{FB}/\sqrt{t} \propto E$ over a segment of the data but not over the entire field range.

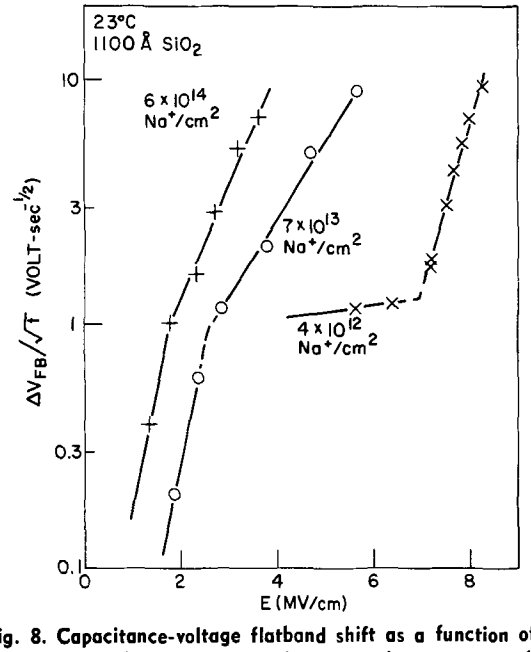

Fig. 8. Capacitance-voltage flatband shift as a function of field for different Na^+ contamination levels showing apparent changes in Na^+ drift mechanism.

As Fig. 8 shows, two line segments do a reasonable job of approximating the data. Thus these drift data might be interpreted in terms of sodium emission at the electrode from two (or more) different trap levels. It should be noted that plots of $\Delta V_{FB}/\sqrt{t}$ *vs.* E (*i.e.*, replacing E by $\sqrt{E}$ in Eq. [7] for the case where the barrier lowering is proportional to $\sqrt{E}$) also show two line segments. With two trapping levels one would expect a higher slope of the plot log $(\Delta V_{FB}/\sqrt{t})$ *vs.* E at higher fields. When the total sodium concentration is small, ($<5 \times 10^{12}/cm^2$) this expected change in slope is seen (Fig. 8).

However at the high fields required for breakdown to occur in lightly contaminated films, the kinetics of Na drift become nearly identical for drift in either direction (2) suggesting that it may well be at least partially controlled by the bulk rather than the interfaces. When sufficient amounts of Na are released from interface traps, one might expect motion to be diffusion limited. This hypothesis is further supported by the observation that the breakdown time increases nearly as the square of the oxide thickness.

The highly contaminated samples ($> 10^{13}/cm^2$) on the other hand, show slope changes (Fig. 8) in the opposite direction and cannot readily be explained by a dual trap level model. The case of high doping is particularly interesting since the internal field due to the ions can be significantly greater than the applied field. In addition for these high contamination levels it has been observed that the breakdown times vary nearly as the square of the oxide thickness (see Fig. 4) suggesting a bulk-limited diffusion. A substantial concentration of ions in the oxide could even reverse the direction of the field and probably cause ion drift to cease. Here the rate-limiting step for sodium ion motion is probably not emission from traps but rather the necessity for maintaining a positive electric field. Only a minor sodium concentration dependence of the drift would be expected above $10^{13}/cm^2$ since that concentration could be sufficient to reverse the direction of the field. When the amount of diffusing sodium is limited by the applied field, the internal field is small and the concentration gradient could become the driving force for motion; thus it is likely that kinetics of sodium motion should be similar to those for bulk-limited diffusion. Breakdown data further support the model of field-limited drift and will be considered later. In light of the present data for high sodium concentrations it seems possible then to account for the two slopes of the log $\Delta V_{FB}/\sqrt{t}$ *vs.* E plot (7×10^{13} and 6×10^{14} Na^+/cm^2 curves of Fig. 8): one segment (at low applied field) being electrode emission-limited and the other (at high fields) being field-limited. It is apparent, however, that the problem of sodium drift in SiO_2 films is more complicated than previously realized and that considerably more work needs to be done to understand the ion motion.

For each point on the time-to-breakdown plot (Fig. 4-5) the flatband voltage shift can be determined from the flatband voltage *vs.* time curve or a plot similar to Fig. 7 for the wafer under consideration at the temperature of interest. When the flatband shift term is added to the applied voltage to determine the internal field, E_{Si}, at the interface as in Fig. 9, it is found that in the region where breakdown occurs rapidly (*i.e.*, <1000 sec), the internal field at breakdown is equal to the maximum dielectric strength of thick SiO_2. For longer times (>>1000 sec) before breakdown, the internal field is even higher. These phenomena can be qualitatively accounted for by realizing that the high field region near the Si/SiO_2 interface ultimately becomes very narrow as the Na^+ ions reach the SiO_2/Si interface. In an earlier paper (7), one of the present authors had already established

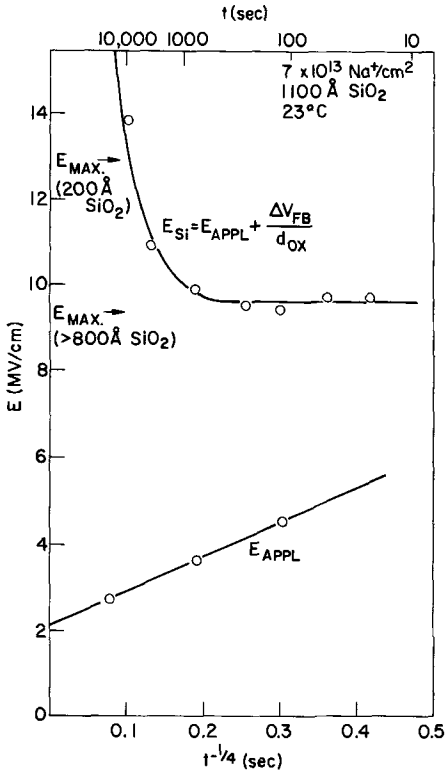

Fig. 9. Internal and applied fields in SiO_2 at breakdown as functions of time. The lower curve gives measured breakdown time as a function of applied field; the upper curve gives the oxide field at the silicon as calculated using C-V data. The maximum dielectric strength of thick (> 800Å) and thinner (200Å) SiO_2 are included for reference.

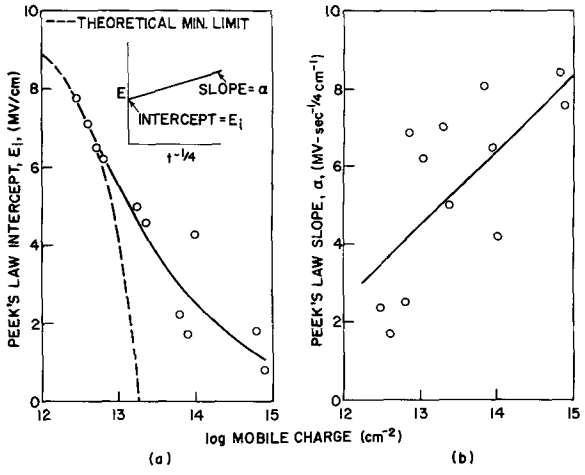

Fig. 10. Sodium ion concentration dependence of Peek's law plot. (a) intercept, (b) slope.

that the maximum dielectric strength increases very rapidly with decreasing oxide thickness for films $\lesssim$400Å thick. Thus the internal field required to cause breakdown increases as the time to breakdown increases because the oxide thickness of the high field region decreases. In Fig. 9 the maximum dielectric strengths of 200Å thick and >800Å thick SiO_2 films are included for reference. Apparently after 10,000 sec of mobile ion drift, the effective thickness of the high field region is about 200Å.

Variability was seen in the rate of Na^+ drift. Measurements made on different days gave results that differed by a factor of two or three. Although this behavior remains unexplained, it is surmised that if the diffusion of Na^+ is limited by emission from the interface (that is, controlled by the release of sodium from traps at the electrode interface) rather than bulk diffusion limited, changes in humidity, thermal history, and previous stressing might result in large variations in the data.

The effect of total sodium concentration on breakdown characteristics was recorded during this work. Figure 10 shows the concentration dependence of the intercept and the slope of a Peek's law plot. The dotted line in Fig. 10(a) represents the expected theoretical intercept as computed from Eq. [5] where $\Delta V_{FB}/d_{ox}$ is replaced by Q/ϵ (Q is the total sodium density) and the thick oxide limit of E_{max} (9.2 MV/cm) was used. For large sodium concentrations, the intercept was higher than expected. This observation supports the conclusion that the internal field in the oxide can be very high without causing breakdown if this high-field region is narrow. A field of 500 MV/cm results from 10^{15} Na^+/cm^2 inside the oxide; nevertheless, it is indeed possible to move this amount of charge through the film without causing breakdown. Apparently the sodium can be concentrated into a narrow region even though coulombic repulsion and stress effect do not favor a high concentration. If the high-field region is to be narrow during biasing, it must be argued that the transit time through the SiO_2 should be short compared to the time of release from traps at the electrode. Otherwise the distance from the silicon to the center of charge and hence the width of the high-field region becomes substantial and results in breakdown.

The high intercept in Fig. 10 also supports the field-limiting model for sodium ion motion. Above 10^{13} ions/cm^2, the number of sodium ions that can move through the oxide (and hence the magnitude of the field enhancement) without reversing the direction of the internal field is controlled more by the applied field than by the surface ion concentration. Calculations with a simple model assuming uniform and sheet ion injection into the oxide and a uniform ion velocity show that the maximum charge injection into the film should contribute three to four times the applied field; hence, a minimum intercept of about 2 MV/cm would be expected. A more precise treatment would require knowledge of the exact ion profiles as a function of time. Data are too limited to even attempt such calculations; nevertheless, this elementary consideration provides a qualitative explanation of the seemingly high intercepts of Peek's law plots.

A phosphosilicate glass layer (400Å, 7% P_2O_5) was added to one oxide film (1000Å total thickness) prior to sodium evaporation (10^{14}/cm^2) and the breakdown time-voltage relationship was determined from room temperature to 300°C. The improvement with the PSG was quite dramatic. Breakdowns that occurred in a few seconds at room temperature in the samples without PSG took several hours or did not occur at all even at 300°C. The intercept of the Peek's plot was about 2 MV/cm for the control sample at room temperature and 5 MV/cm for the PSG sample at 300°C; at room temperature the PSG sample had an intercept of over 7 MV/cm. The temperature dependence of the breakdown time at a fixed field was found to be considerably less than that of sodium drift seen earlier (20). The improvement in breakdown times seen with a PSG layer is believed to be more accentuated than is the retardation of the flatband shift. In the extreme case of emission-limited ion motion (where, for all practical purposes, the sodium is either trapped at the metal interface or is at the Si-SiO_2 interface), no breakdown should occur. As shown earlier, breakdown only occurs when a substantial amount of charge is at least 30Å away from the Si-SiO_2 interface. When the sodium is at the interface, breakdown must occur via a mechanism other than simple field enhancement. The discrepancies between control- and

PSG-sample intercepts as well as the different temperature dependencies of sodium drift and breakdown time in PSG samples are evidence that the ion motion through a PSG layer is a better approximation to a completely emission-limited process than is ion motion in a pure SiO_2 film.

Effect of defects.—Statistical measurements of the times to the first breakdown at constant voltage of an array of capacitors in a heavily contaminated sample are shown in Fig. 11 where the fraction of MOS capacitors is plotted as a function of breakdown time [Fig. 11(a)]. A very considerable spread in the times was observed. When the breakdown fraction of the same data is plotted as a function of $t^{-1/4}$ [Fig. 11(b)], a well-defined peak is seen with a tail at larger values of $t^{-1/4}$. By using the Peek's law plot to transform the ordinate from increments of $t^{-1/4}$ to increments of voltage and by determining the absolute internal field at breakdown for one sample, it was possible to calculate the voltage distribution of breakdown [Fig. 11(c)]. Details of the transformation are given in the Appendix. This calculated distribution was nearly identical to a breakdown distribution on a control wafer [Fig. 11(d)]. No significant difference could be discerned between voltage distributions either as calculated from the time distribution of breakdown or as measured with a voltage ramp on a control wafer [note the differences between Fig. 11(c) and 11(d) reflect normal variations in distributions as a consequence of using discrete intervals and do not reflect any substantial difference between the two]. The large variations in time to breakdown are indeed surprising in light of the tightly clustered voltage distribution. It is fortunate that the time and the voltage distributions are equivalent; nevertheless, it is obvious that the time distribution is much more sensitive to sample variations than is the voltage distribution.

Summary

Mobile Na ions are seen to be responsible for one type of time dependent dielectric breakdown in MOS structures. Breakdown occurs because of the high internal field associated with the presence of ions in the oxide film. As mobile Na ions drift through the oxide, the electric field strength at the Si-SiO_2 interface increases. When the field becomes as large as the breakdown strength of the oxide, breakdown occurs. The capacitance-voltage flatband shift is a direct measure of the field enhancement at the Si-SiO_2 interface.

The time lapse before breakdown in a Na-contaminated MOS was found to depend on the applied field, the contamination level, the oxide thickness, and the temperature. The breakdown time-applied field relationship was found to approximate the empirical Peek's law ($E \propto t^{-1/4}$) although its more fundamental theoretical form is much more complex than Peek's law. The contamination level, the oxide thickness, and the temperature dependence of the breakdown time correlated with the rate of flatband shift. Higher contamination reduced the time to breakdown. The breakdown time varied almost as the square of the oxide thickness and was exponentially activated by temperature (14 kcal/mole from −25° to +75°C, 2×10^{13} Na^+/cm^2).

As sodium ions moved through the oxide film of an MOS capacitor, the electronic conduction varied with time. Electronic current density increases up to 150 mA/cm^2 were observed. If the sample did not break down, the current would reach a maximum and then decay slowly. An analysis (13) showed that the Fowler-Nordheim tunneling distance decreased and then increased as ions moved from the metal to the silicon. The minimum tunneling distance (maximum in current) occurred when the ions were about 25Å from the silicon.

The kinetics of sodium drift were measured in the process of verifying that the sum of the applied voltage plus the flatband voltages shift must equal the breakdown voltage for breakdown to occur. The rate of flatband voltage shift ($d\Delta V_{FB}/d\sqrt{t}|\ t = 0$) was found to vary exponentially with the applied field over the range of the data. Such a field dependence was reported earlier (20) for sodium emission and motion from traps in phosphosilicate glass-SiO_2 structures. To account for all of the data, however, it was necessary to consider at least two exponential field dependencies. In some cases the results could be accounted for by consideration of two distinct trapping levels for the sodium. The heavily contaminated case could not be explained in terms of multiple trap levels. Evidence was seen in this case for a field-limiting injection where injection is limited by the necessity of having the field remain in the same direction throughout the sample.

Statistical measurements of the time to breakdown of contaminated capacitors were made. The previously established relationship between breakdown time and voltage was used to convert the time-based distribution to a voltage-based one. This voltage-based distribution was then compared to a statistical distribution of the breakdown voltages of uncontaminated capacitors. Quantitatively, the distributions were essentially the same showing that the capacitors that broke down early were those capacitors that had low breakdown strengths to begin with.

The results obtained in this work are very similar to those of Worthing (5): with Al(−) no time dependence of breakdown was seen, and with Al(+) a Peek's law type of behavior was recorded. In view of these facts, it may be possible to attribute his results to the presence of mobile ions. Ion concentrations of $10^{13}/cm^2$ (at least locally) could account for Worthing's results.

A second breakdown process, which was suggested (9) to be the result of barrier lowering due to sodium contamination at the Si/SiO_2 interface, requires times considerably longer than the transit time of the sodium through the SiO_2. At such long times all of the sodium should be near the Si/SiO_2 interface and

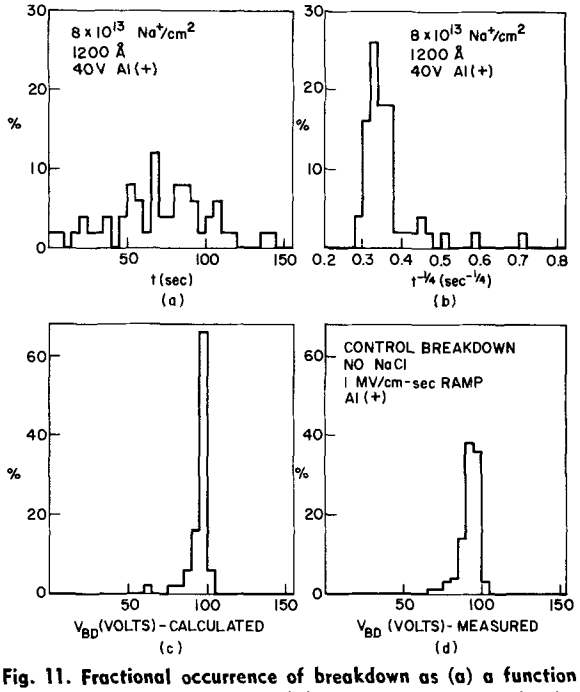

Fig. 11. Fractional occurrence of breakdown as (a) a function of time, (b) a function of (time)$^{-1/4}$, (c) as a function of voltage, V_{BD}, (calculated from the time dependence), and (d) as a function of voltage, V_{BD}, on a control wafer.

should not cause field-enhancement breakdown since the enhanced field region is too narrow to sustain an avalanche.

Acknowledgments

The authors would like to thank Drs. A. Berman, N. Chou, J. Eldridge, D. Kerr, and W. Pliskin for stimulating conversations, access to unpublished data and calculations, and samples. Measurements and sample preparation were skillfully done by D. Ormond, E. Vishnesky, and E. Weitzman.

APPENDIX

Relationship of Breakdown Time to Ramp Breakdown Field

Transforming a distribution of breakdown times to a distribution of breakdown fields requires information about (*a*) the time *vs.* field dependence of breakdown and (*b*) the nature of the oxide defects. In the case of field-enhancement breakdown, Peek's law provides an adequate empirical description of breakdown time as a function of field. Two limiting cases of oxide defects can be considered: Case 1 in which the oxide is locally thin (*i.e.*, oxide pinholes, or a rough silicon surface) and case 2 in which the defect is electrical in nature. The internal field, E_{int}, in each case is greater than the applied field, E_{appl}, and is given by

$$E_{int} = kE_{appl} \quad \text{Case 1}$$
$$E_{int} = E_{appl} + E_{enhance} \quad \text{Case 2} \qquad [A\text{-}1]$$

where k is the ratio of the nominal oxide thickness to the minimum oxide thickness at the defect, and $E_{enhance}$ is the magnitude of the field enhancement due to the electrical defect. The parameters k and $E_{enhance}$ give the magnitude of the physical or electrical defect. Associated with the higher internal field is a shorter time to breakdown. Since Peek's law empirically holds, then

$$E_{int} - E_{appl} = (dE/dt^{-1/4})\,(t^{-1/4} - t_m^{-1/4}) \qquad [A\text{-}2]$$

where $dE/dt^{-1/4}$ is the Peek's law slope, t_m is the limiting breakdown time at a field E_{appl}, and t is the breakdown time of a capacitor with a defect.

Breakdown under a ramp voltage occurs when the internal field equals the maximum breakdown field, E_{max}. Thus

$$\left.\begin{aligned} E_{BD} &= \frac{E_{max}}{k} \quad \text{Case 1} \\ E_{BD} &= E_{max} - E_{enhance} \quad \text{Case 2} \end{aligned}\right\} \text{at breakdown} \qquad [A\text{-}3]$$

Once a Peek's law plot is determined, each breakdown time of a distribution of times can be inserted into Eq. [A-2] to obtain the corresponding field enhancement. Equation [A-1] gives the parameters describing the defect magnitude. Equation [A-3] is then used to compute the ramp breakdown field associated with each defect size. Thus a series of breakdown times t_i (obtained at a field E_{appl}) can be transformed to a series of breakdown fields, $(E_{BD})_i$, by

$$(E_{BD})_i = \frac{E_{max} \cdot E_{appl}}{E_{appl} + (de/dt^{-1/4})\,(t_i^{-1/4} - t_m^{-1/4})} \quad \text{Case 1}$$
$$(E_{BD})_i = E_{max} - (dE/dt^{-1/4})\,(t_i^{-1/4} - t_m^{-1/4}) \quad \text{Case 2} \qquad [A\text{-}4]$$

An illustration of this transformation is seen in Fig. 11. Part (a) gives the distribution of t_i's, part (b) the $t_i^{-1/4}$'s, and part (c) the field-based distributions. The assumption of an electrical defect (case 2) is given in Fig. 11; nevertheless, the assumption of a geometrical defect (case 1) gives similar results. Of course, the general case would include both electrical and geometrical defects.

Accelerated Dielectric Breakdown of Silicon Dioxide Films

C. M. Osburn* and N. J. Chou*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The time dependent, dielectric breakdown of thermally grown SiO_2 films in metal-SiO_2-Si structures was studied as a function of oxide thickness and growth conditions, stressing temperature and electric field, and electrode material. With no field applied, thermal annealing of Al-SiO_2-Si capacitors markedly increased the measurable defect density. In the range 200°-350°C, the time required to form 20 defects/cm^2 is proportional to $d_{ox}^{1.7}e^{-\Delta H/RT}$ where d_{ox} is the oxide thickness and ΔH is 14 kcal/mole. The degradation without bias was much less, comparatively, when Mo, Pt, and polycrystalline-Si electrodes were used, as well as when a phosphosilicate glass film was formed on the SiO_2 surface. Under electrothermal stressing, the breakdown time decreased almost exponentially with applied field and, in films over 200Å thick, was thermally activated with an energy 1.4 ± 0.2 eV. The oxide thickness dependence of the wear-out under bias varied according to the applied field and ranged from the 2.1 power of the thickness at 2 MV/cm to the 5.5 power at 7 MV/cm. A model is described according to which the generation of the interface states, leading to a decrease of the injecting barrier height and attendant large increases in current, is probably responsible for the subsequent dielectric breakdown.

In order to practically assess the long term reliability of the gate insulator in MOSFET devices, it is necessary to determine failure rates under accelerated stress conditions (*e.g.*, using temperatures and electric fields higher than would be encountered during normal device operation) and then to extrapolate these rates to the usual operating conditions. As a result of extensive testing in many laboratories, it is quite clear that the dielectric breakdown of the thin (typically 1000-1500Å) thermally grown SiO_2 film on silicon, used for the gate dielectric, constitutes a major FET failure mode. Already several authors (1-6) have observed that the dielectric breakdown strength of SiO_2 films can be significantly dependent on the duration of the applied field, while others (7-8) have reported that the oxide can be degraded by the so-called "post-metalization anneal" in the 400°-500°C range, in the absence of an applied field.

Since some ions have been observed (9, 10) to be mobile in metal oxide semiconductor structures, much of the early work (3-5) dealing with time dependent breakdown has focused on the influence of such ions. Two models of mobile ion induced degradation have been proposed: field intensification due to charged ions (4, 11) and barrier height lowering (5, 12). In the field intensification model, charged ions within the oxide film enhance the internal electric field as described by Gauss's law. As ions move through the oxide it is possible for the internal field to equal the dielectric strength of the film and thereby cause breakdown. Worthing (2) first reported a Peek's law dependence of the breakdown time, t, of MOS capacitors with the silicon biased negatively, *i.e.*, $t^{-1/4} \propto E$ where E is the applied field; he found no time-dependent breakdown when the metal electrode was biased negatively. More recently (3-4) similar breakdown characteristics were attributed to field intensification associated with sodium. In the absence of any complicating mechanism such as ion trapping, the field intensification mechanism (4) was found to be very rapid (~ 1 hr) and required a very high contamination level (~ 10^{13} ions/cm^2); as such this mechanism is probably not responsible for long term device failures. The barrier height lowering model (5, 12) proposes that breakdown occurs as a result of the lowering of the barrier between the silicon and SiO_2 conduction bands. The barrier lowering occurs because of the dipole set up when contaminant ions are near the Si-SiO_2 interface. Both electrical (13) and photoemission (12) measurements have exhibited this lowering after tens or hundreds of hour's stressing. Many questions remain unanswered about this model and it is not possible to definitely assess the importance of this failure mode.

In addition to mobile ions, many different electrochemical processes have been reported that could influence breakdown. High temperature annealing in a N_2 ambient was previously shown (7-8) to result in a degradation of breakdown strength as statistically measured on arrays of MOS capacitors. Chou and Eldridge (7) found that the edge of a capacitor electrode attacked the underlying SiO_2 and Si. Crystallization of SiO_2 films has been observed both at room temperature (14-16) as well as after high temperature processing in the presence of impurities such as sodium (15-18). Crystallization might be expected to produce microcracks, interfacial charge, and electric field inhomogeneities and thereby promote breakdown; Meek and Braun report a correlation between crystallization and breakdown (19). Reaction of the electrode metal with the SiO_2 has been reported at elevated temperatures for Al (20-22), Pt (21), Si (23), and Cr (24-25) electrodes. Such reaction leads to ion injection and possibly filament formation and therefore might account for dielectric failure. Furthermore, interface state and oxide charge generation and trapping have been seen (6, 26-29) as a function of bias-temperature (B-T) stressing. This type of charge generation should lead to field enhancement and barrier lowering just as mobile ions. Finally, Jorgensen (30) has studied the solid-state electrolysis of SiO_2 in MOS samples, and asserts that Si^{+4} in the oxide can be reduced to elemental silicon. The silicon formation, either uniformly or in dendrites, should make the dielectric film thinner and more susceptible to breakdown.

This study was initiated to gain a more complete understanding of the mechanism responsible for long term wear-out (by dielectric breakdown) of SiO_2 films such as those employed in MOSFET devices. It was also undertaken in part to obtain a sufficient data

base in order to make reliability predictions for MOS structures from data obtained under accelerated testing conditions. Electrical measurements were made up to the time of breakdown to help determine which, if any, of the previously observed electrochemical processes are responsible for the degradation.

Experimental Procedure

Sample preparation.—Silicon wafers, as received from Semimetals and Monsanto were cleaned sequentially in solutions of NH_4OH-H_2O_2, HCl-H_2O_2 (31), HF, and thoroughly rinsed in deionized H_2O, just prior to the oxidation step. Each processing step was closely controlled and transistor grade reagents were used to optimize the quality of the films. The resistivity and the dopant of the silicon were varied, although 2 ohm-cm, p-type <100>-oriented material wafers were used in most of this work. The so-called "standard SiO_2" films were grown at 1000°C in dry oxygen. Some oxide films were grown at 1000°C in an ambient of 3 volume per cent HCl, 97 volume per cent O_2 in order to further upgrade the SiO_2 quality. Mobile charge was found to be less than $10^{10}/cm^2$ by the triangular-voltage-sweep (TVS) technique (23). Phosphosilicate glass (PSG) layers were added to a few films by depositing P_2O_5 onto SiO_2, followed by a drive-in at 975°C.

One hundred electrode contacts (10-50 mil diam) were added to each wafer by depositing metal through masks, using an electron beam heated source. The resulting capacitors were then annealed in nitrogen to remove radiation damage, sustained during metalization. Aluminum was the most widely used electrode metal although Al-4% Cu (32), Mo, Pt, and polycrystalline-Si electrodes were also employed. The polycrystalline-Si electrodes were doped with a deposition and drive-in of P_2O_5 at 975°C to ensure a low resistance contact.

Electrical measurements.—Breakdown characterization studies fell into two categories: the determination of statistical distribution of breakdown voltages of large numbers of identically prepared capacitors; and the time to break down a capacitor under fixed stress conditions. Statistical distributions are determined by applying a slowly varying ramp voltage to an array of capacitors and measuring the voltages at which each capacitor breaks down (7, 8, 33). A histogram giving the number of failures as a function of applied voltage can then be constructed.

In order to evaluate the effects of the well-known postmetalization annealing process, wafers were annealed for various times in dry N_2 at temperatures in the 200°-500°C range, and the resultant breakdown voltage distributions were then measured at room temperature. The combined effects of field and temperature on breakdown were determined by stressing capacitors in a high temperature biasing cell filled with dry N_2. In these experiments, the current flowing through the capacitor was monitored until breakdown occurred, and the breakdown time was recorded. In testing large numbers of identically prepared capacitors, the time to breakdown under stressing was found to vary from sample-to-sample in a statistical manner. In the present paper, only the longest or limiting time to breakdown results are discussed since they are believed to be representative of the effects of field and temperature on the breakdown time of uniform defect-free SiO_2 films, and as such were easier to analyze. A detailed study of the influence of oxide defects on breakdown is underway also, and the results will be published elsewhere.

Additional measurements were used to supplement breakdown data. Capacitance voltage, C(V), curves giving the silicon flatband voltage were used to monitor the fixed charge at the SiO_2-Si interface and also oxide polarization (9), while the Gray and Brown method (34) (*i.e.*, comparison of C-V curves at 77° and 300°K) gave a measure of the fast surface state density. Room temperature current-voltage characteristics (35) were observed in order to determine the height of the injecting barrier during testing.

Results and Discussion

Oxide degradation in the absence of electric fields.—Breakdown voltage distributions of capacitor arrays can be altered by the annealing process (7, 8). As an example of this effect, Fig. 1 gives the distribution or breakdown fields of identically prepared Al-SiO_2-Si capacitors before and after a 350 hr anneal at 250°C. Extended annealing clearly shifts the breakdown distribution to lower fields. The rate of this degradation depends on the annealing temperature and electrode metal, and could be markedly reduced by the presence of a phosphosilicate glass layer. In order to manageably handle the large volumes of statistical data, a single defect density was computed from each statistical breakdown distribution. More precisely, the fraction of capacitors which break down at electric fields $< 0.8\ E_{max}$ (where E_{max} is the maximum dielectric strength and is a function of oxide thickness and Si doping) has been shown (7, 8) to be proportional to the capacitor area, and the defect density can be calculated from the proportionality constant. By using this approach, changes in the oxide defect density (ρ) could be quantitatively followed as a function of annealing time and temperature. In assessing annealing effects in a study involving the use of a wide range of material and processing parameters, it is also convenient to determine the conditions needed to produce a given but arbitrary increase in ρ. Thus, Fig. 2 illustrates both the SiO_2 thickness and temperature dependences of the time necessary for ρ to increase by 20 defects/cm^2 (τ). The data indicate that two thermally activated processes are present: one degradation mechanism has an activation energy of 55 kcal/mole and predominates above 350°C while the other has an energy of 14 kcal/mole from 200°-350°C. Excessively long testing times prohibited measurements below 200°C; such low temperature measurements would be helpful because of the danger inherent in extrapolating data to lower temperatures. Chou and Eldridge (7) found that the capacitor degradation after 500°C annealing resulted from electrode attack at the edge of the capacitor. Presumably this edge attack is responsible for the high temperature failures seen here;

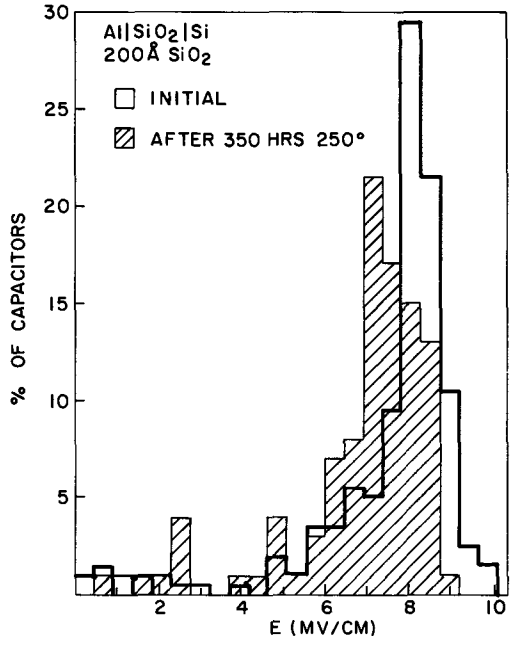

Fig. 1. Shift in breakdown distributions after high-temperature annealing without bias.

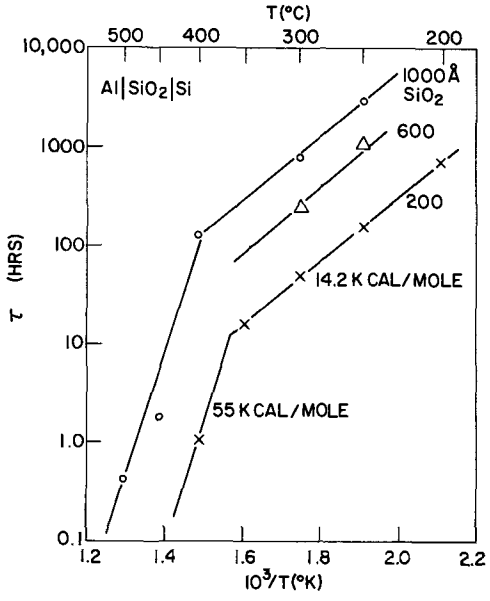

Fig. 2. Temperature dependence of annealing-induced degradation for 200, 600, and 1000Å films.

nevertheless the basic mechanism remains obscure. These results are replotted in Fig. 3 in order to dramatize the strong thickness dependence of the lower temperature degradation process where

$$\tau \propto [\text{oxide thickness}]^{1.7} \qquad [1]$$

The defect generation rate depends on the electrode material and can be retarded markedly by the presence of a thin, dilute phosphosilicate glass layer of the type used to block Na^+ drift effects on the FET threshold (36). Table I summarizes the time for the defect density to increase by 20/cm² for a variety of electrode metals and PSG. It was seen that an addition of 4% Cu to the aluminum did not influence the deteriorization process while a substantial PSG layer gave very significant improvements. The copper was added to make the electrodes more resistant to electromigration (32). Platinum, molybdenum, and polycrystalline Si electrodes also increased the lifetime. Poly-Si gave the most substantial improvement, while molybdenum was only a factor of about two better than aluminum. It was noted in several instances that polycrystalline Si

Mo	1000	300	>1000
Si (poly)	1000	500	>200

electrodes had abnormally high initial defect levels despite their long term resistance to wear-out. Presumably this was a consequence of the high temperature processing needed to dope the poly-Si in order to obtain low electrode resistance. After deposition of the poly-Si, the electrodes are exposed to temperatures as high as 1000°C. Hence it is not surprising that these capacitors have high initial defect levels but are resistant to further degradation at 500°C.

Oxide degradation in the presence of electric fields.— Under sufficiently high electric fields and temperatures, breakdown will obviously occur. Just as the breakdown voltage of capacitors can vary from sample to sample when a slowly increasing, or ramp voltage, is applied, the time to breakdown for capacitors held for long times at elevated temperatures under a fixed field can exhibit a wide distribution of values. Nevertheless, upon testing an array of identically prepared specimens under a given set of stressing conditions, a well-delineated, maximum breakdown time could be obtained in the same way as a maximum breakdown strength is found using the ramp breakdown technique. A typical statistical distribution of breakdown times, under a constant field, is presented in Fig. 4, and the maximum breakdown time is taken as the time required to cause 100% failures of all devices. When thin (*e.g.*, $\lesssim$ 1000Å) electrodes are used so that defected oxide regions are eliminated by the well-known nonshorting (or self-healing) breakdown mechanism (37), the time at which final shorting occurred agreed very closely with the statistically determined t_{max} value. Many samples must be tested to accurately establish t_{max}; in this study, five to twenty capacitors were measured for each set of experimental conditions. As can be seen in Fig. 4, the time required for 80-90% failures are factors of two to three

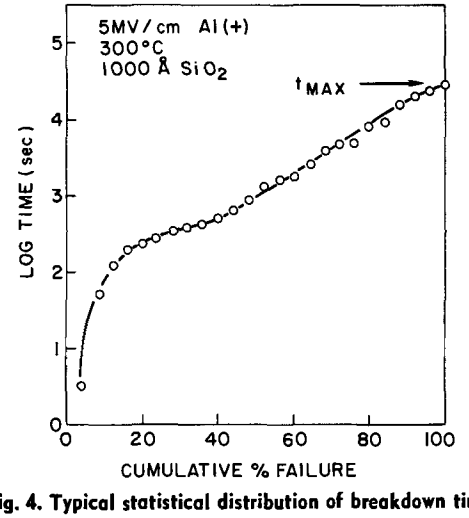

Fig. 4. Typical statistical distribution of breakdown time

lower than t_{max}. Thus the error associated with measuring t_{max} from five to ten capacitors is only a factor of two to three which is small compared to the wide range of failure times observed under varying conditions. Maximum times to breakdown of several hundred hours have been observed under moderate fields; all evidence points to the existence of a maximum breakdown time even when quite modest fields are applied, although these times are prohibitively large to measure.

Values of the maximum time to breakdown were used extensively since they should be representative of wear-out times for uniform SiO_2 films free of significant structural and/or impurity defects. It must be emphasized at this point, however, that the earlier failures are much more germane for making MOSFET device reliability projections than are the t_{max} ones. In other words, the oxide lifetime results discussed here are representative of essentially ideal MOS structures. Presumably the same wear-out mechanisms will be operative, in varying degrees, in SiO_2 films of lesser perfection.

Proceeding with this approach, it was then found that t_{max} is a strong function of the applied field, as seen in Fig. 5 and 6 for 1000 and 200Å films of SiO_2, respectively. The time for the defect density to increase by 20 defects/cm^2 (τ) as determined from Fig. 2 and 3 for degradation with no bias are given for reference. It is seen that the t_{max} times vary over seven orders of magnitude and extrapolate slightly above the τ time value at zero bias. Since τ represents the time for a partial wear-out only, such a value should be less than t_{max} at zero applied field. The polarity dependence of t_{max} is also evident in Fig. 5 and 6 where the breakdown times are considerably shorter for the Al(+) bias than for Al(−). Furthermore, the intercepts of the Al(+) and the Al(−) curves should coincide at zero field. In addition, higher temperatures shorten the life of capacitors. At high applied fields, the breakdown times decrease roughly exponentially with increasing field but this dependence is less at smaller E. These observations suggest that both field-dependent and field-independent wear-out mechanisms are operative.

Oxide film thickness is a very important parameter, as already seen by comparing Fig. 5 and 6, and illustrated more fully in Fig. 7 for Al/SiO_2 (100-1000Å)/Si structures. At constant field, it can be seen that t_{max}

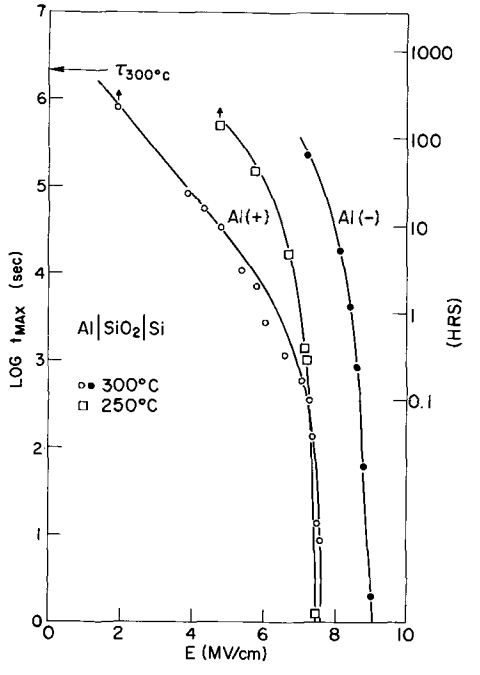

Fig. 5. Maximum breakdown time as a function of applied field in 1000Å SiO_2 films.

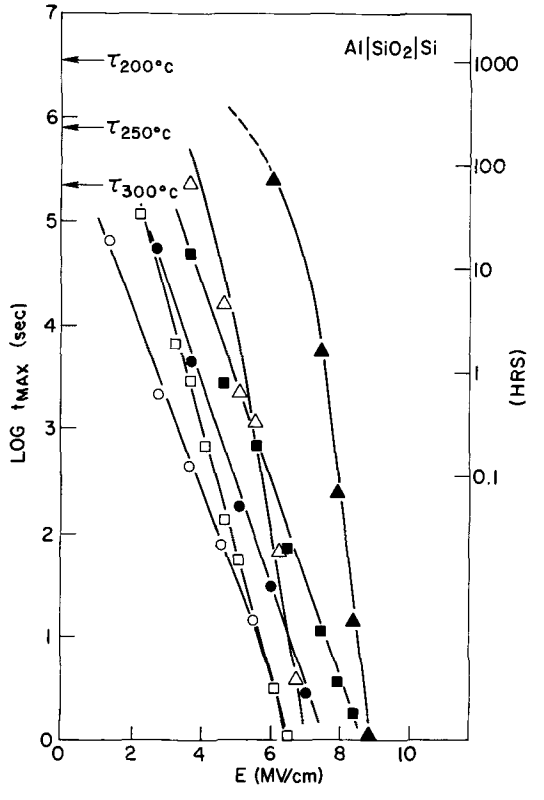

Fig. 6. Maximum breakdown time in 215Å SiO_2 films as a function of applied field at ○, 300°C; □, 250°C; and △, 200°C. Open symbols represent Al(+) bias and closed ones Al(−).

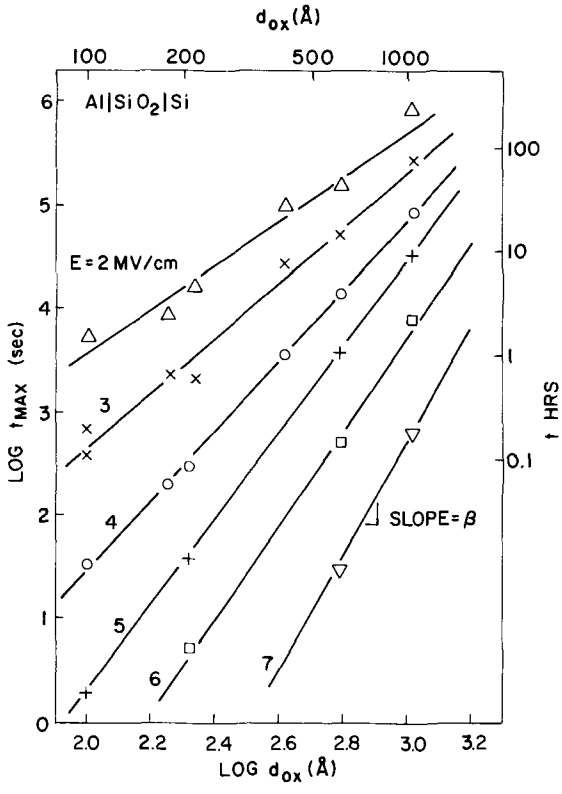

Fig. 7. Oxide thickness dependence of limiting breakdown time for 300°C Al(+) biasing.

$\propto (d_{ox})^{\beta}$. The thickness dependence power (β) increases linearly with increasing E, going from 2.1 at 2 MV/cm to 5.5 at 7 MV/cm, as shown in Fig. 8. From the linear relationship of Fig. 8, one can write

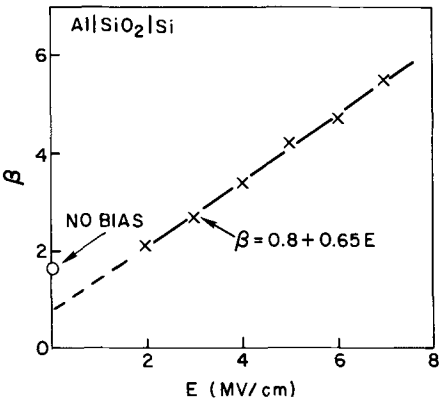

Fig. 8. Electric field *vs.* β, the power of the oxide thickness dependence for 300°C Al(+) biasing.

$$t_{max} \propto d_{ox}^{(0.8+0.65E)} \quad [2]$$

where E is given in megavolts per centimeter.

The temperature dependence of t_{max} is shown in Fig. 9, over the range 100°-400°C. The limiting time is thermally activated with a reasonably well-defined energy of 1.4 ± 0.2 eV, as calculated from the slopes of the log t_{max} *vs.* T^{-1} plots. The same energy was observed for both biasing polarities with 200Å films although failure times were considerably longer in the Al(−) case. Silicon dioxide films up to 1000Å thick also exhibit a 1.4 ± 0.2 eV activation energy with Al(+) (Fig. 10). For 100Å SiO_2 films, however, the activation energy is 1.1 ± 0.2 eV at 6 MV/cm at ~250°C, and appears to fall to 0.9 ± 0.3 eV at 2 MV/cm near 300°C.

Many other parameters influence the breakdown time of MOS capacitors. For example, Fig. 11 shows that samples stressed in a moist N_2 ambient (17 Torr H_2O) broke down in much less time than those biased in dry N_2. Presumably MOSFET devices that have been heavily glassed during packaging would not be as moisture sensitive. In addition, an effective post-metalization annealing treatment (*e.g.*, 5 min in N_2 at

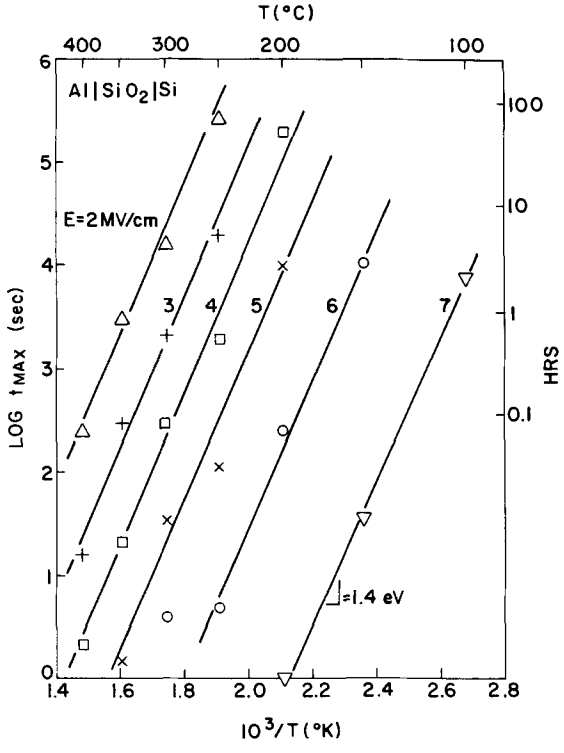

Fig. 9. Temperature dependence of limiting breakdown time in 200Å SiO_2 films for Al(+) stress.

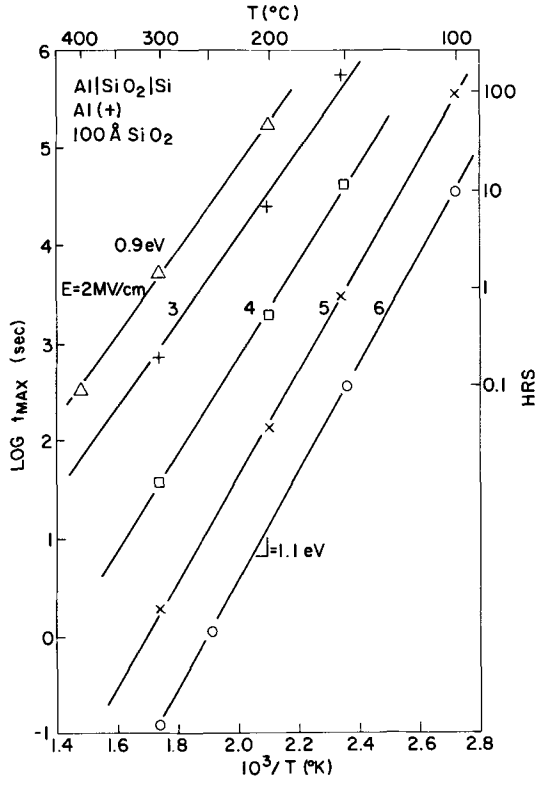

Fig. 10. Temperature dependence of limiting breakdown time in 100Å SiO_2 films for Al(+) stress.

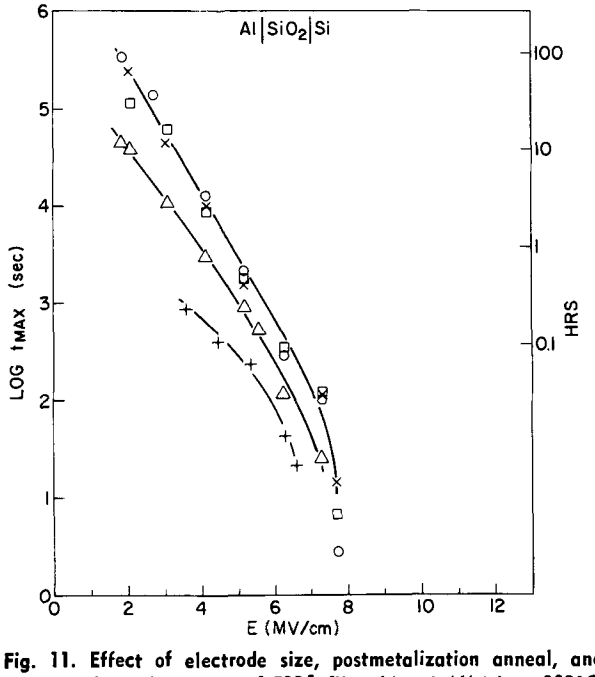

Fig. 11. Effect of electrode size, postmetalization anneal, and ambient on breakdown time of 500Å films biased Al(+) at 300°C. □, 0.05 mm²; X, 0.5 mm²; and ○, 1.25 mm² electrodes measured in dry N_2 ambient; △, measured in N_2 containing 17 Torr H_2O; +, without postmetalization anneal.

500°C) in nitrogen is also necessary to insure maximum reliability. This may be accounted for by the fact that annealing reduces the oxide conduction (35), eliminates surface states at the Si-SiO_2 interface, and improves over-all statistical breakdown distributions (8). It should be emphasized that t_{max} is area independent since capacitors from 10 to 50 mil diam gave identical t_{max} values (see Fig. 11). This area independence suggests that this time is characteristic of defect free SiO_2 films because any deterioration process

involving the presence of randomly occurring oxide defects would presumably scale with the electrode area.

Significant effects attributable to the electrode material are seen in Fig. 12, where aluminum electrodes gave longer life than platinum or molybdenum ones. Most important technologically are the findings that t_{max} can be substantially improved with a phosphosilicate glass addition or by growing the SiO_2 in 97% O_2-3% HCl.

Degradation mechanism and discussion.—In order to better understand the degradation mechanisms, some studies were made in which the currents through the oxide films were continuously monitored until breakdown occurred. See Fig. 13, where the current densities are plotted against time for both polarity cases. The initially low currents increase by several orders of magnitude in a relatively short time under these severe stressing conditions and current noises increase until breakdown occurs. The same sort of current enhancement occurred with both polarities although a longer time was required to see the Al(−) enhancement. The current density, as averaged over the entire electrode area, immediately prior to breakdown was usually less than 10^{-2} A/cm^2; this value is less than would be expected were the final breakdown process to take place via a uniform thermal runaway mechanism. The same kind of conduction enhancement occurs under smaller fields but the current is more likely to remain constant for even hundreds of hours before the onset of current enhancement noise preceding breakdown. In addition, the current changes are typically more steplike in appearance of J *vs.* t plots, rather than the gradual changes indicated in Fig. 13.

Once current enhancement had taken place due to prolonged stressing, the enhancement persists even at room temperature provided the capacitor is quenched under bias, at a rate fast enough to avoid breakdown during cooling. Such enhanced room-temperature conduction can be obtained for both bias polarities, after which the capacitors will last many hours without breakdown under the same bias at room temperature.

Effect of electrode material, phosphosilicate glass, and HCl-oxidation on breakdown time of 250Å films biased Si(—) at 300°C. ○, Al electrode, 4% P_2O_5 film; △, Al electrode, oxide grown in 3% HCl/97% O_2; X, Al electrode, standard oxide; ●, Pt electrode, standard oxide; +, Mo electrode, standard oxide.

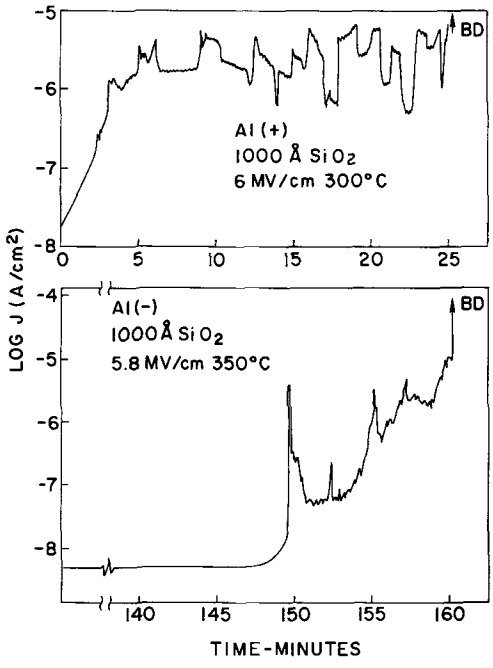

Fig. 13. Current enhancement after accelerated stressing

The enhanced current level depends more or less on the rate of cooling as well as the current level prior to quenching and may vary by several orders of magnitude. Under comparable conditions, the enhancement is usually greater for the capacitors with larger electrodes although it is not proportional to either the area or the perimeter of the electrode. The enhanced conduction cannot be removed by reheating the capacitor up to 300°C under a field of reversed polarity, but can be readily eliminated by moist ambients. While hydrogen, oxygen, and forming gas did not affect the enhanced conduction process, monochromatic illumination from a xenon source was found to be capable of reducing the conduction at low enhancement levels only.

The effect of moisture and light exposure on the enhancement is demonstrated in Fig. 14, where the current in an Al-SiO_2-Si capacitor (0.35 cm^2 in area) had been enhanced to a level of 10^{-6} A at 6.5 MV-cm^{-1}, Al(+) at room temperature. After a 2-min exposure

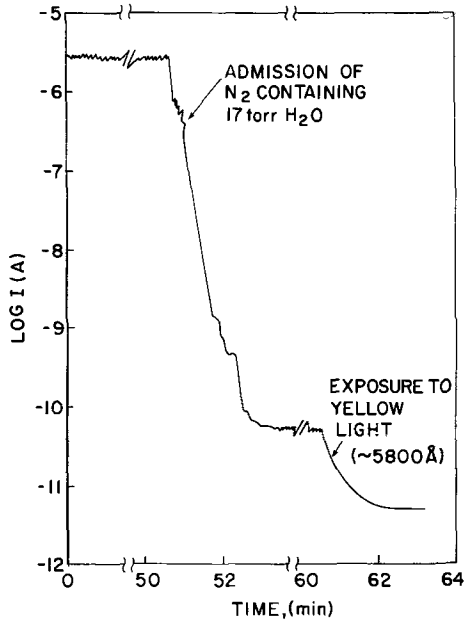

Fig. 14. Moisture and light sensitivity of conduction enhancement

to wet nitrogen (containing 17 Torr water vapor) the current dropped five orders of magnitude to 10^{-10} A. At this level the current was further reduced to 10^{-11} A by monochromatic radiation with wavelengths shorter than 5800Å. It should be noted at this point that, while a longer exposure to moisure can always completely remove the room-temperature enhancement, monochromatic irradiation is ineffective at high conduction levels (10^{-6} A in this particular example) even in the uv region ($\geqq$ 2000Å). Furthermore, the moisture effect can also be nullified if a moderate field of reversed polarity is applied to the capacitor during the exposure. Finally, and most importantly, the removal of current enhancement is not permanent in the sense that when the capacitor is restressed, the current enhancement and subsequent breakdown will occur in a much shorter duration than that observed in the first treatment.

Typical, room-temperature *I-V* characteristics of capacitors, in which enhancement had occurred, are shown in Fig. 15. The normal conduction in SiO_2 was previously shown (35, 38) to be via Fowler-Nordheim tunneling through a 3.2 eV barrier. A similar analysis of the sample curve in Fig. 15 showed a high-field conduction identical (within experimental error) to the control conduction. At low fields, however, a very low barrier height (0.3 eV) was obtained. A large polarity (*i.e.*, electrode) dependence and only a minor temperature dependence of this low-field conduction was observed and was similar to that found in control oxides and shows that the conduction mechanism was Fowler-Nordheim. Such a low barrier height would result in extremely high current densities ($>>$ 1 A/cm^2) and could be expected to ultimately result in thermal runaway and breakdown. The apparent current density as shown in Fig. 15, while considerably enhanced from the normal conduction, is still not of the order of that expected if the enhancement were uniform. Thus it can be inferred from these data that the conduction is localized. The ratio of the measured current to that expected with the lowered barrier could be used to estimate the area of the conducting channel. In this manner, the conduction was found to occur through extremely small channels having a diameter on the order of 20-1000Å. At very low barrier heights, Schottky conduction could be expected to predominate over Fowler-Nordheim conduction; nevertheless this alternate mechanism does not radically alter either the calculated local current density or the size of the conducting channel.

The fact that breakdown can be arrested during the B-T treatment by rapid cooling is another indication that the mode of dielectric failure in the degraded SiO_2 films now occurs not by electronic, but by thermal breakdown. Such contention is also supported by the observation that specimens with enhanced conduction can last many hours under the same bias at room temperature, since the critical field for thermal breakdown increases with decreasing temperature (39).

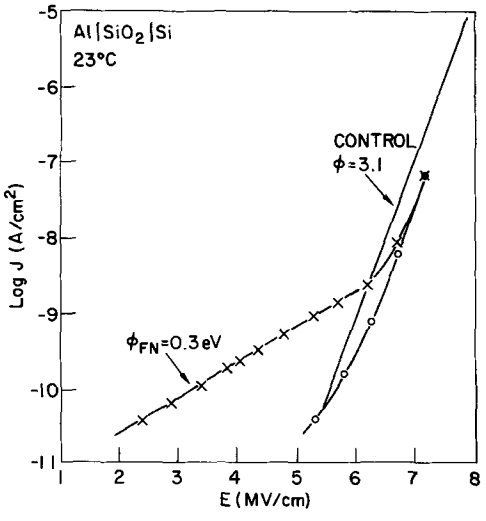

Fig. 15. Barrier height lowering as a result of stressing a 1000Å film at 6 mV/cm, Al(+) at 300°C for 1 hr. X, after stressing; ○, after stressing and subsequent exposure to moisture.

Capacitance-voltage flatband measurements were made on selected capacitors during the interval prior to breakdown. When the aluminum electrode was biased positively under high B-T stressing (5 MV/cm at 300°C for 2 hr) voltage shifts corresponding to 10^{11} positive charges/cm^2 were monitored. Since this flatband voltage shift could be attributed to mobile charge, the direction of the bias was reversed to drive any mobile species away from the Si-SiO_2 interface. The reverse bias did not reduce the flatband voltage; instead, the flatband often became even more negative implying the presence of additional positive charge. Annealing the stressed capacitors for 5 min at 500°C in N_2 was effective in reducing the flatband voltage to its original value. The fact that this charge is removed by annealing but not by reverse bias suggests that it is not due to mobile ions but rather is a result of stressing.

The method of Gray and Brown (34) was used to measure fast state densities after Al(+) stressing in order to eliminate the possible ambiguity in the interpretation of flatband voltage shifts. Figure 16 shows the increase in fast state density, N_{ss}, as a function of biasing time. This density was calculated from room temperature and liquid nitrogen *C-V* measurements by

$$N_{ss} = \frac{C_{ox}}{q}\left[V_{FB}\ (\text{room temp}) - V_{FB}\ (\text{liq. } N_2\ \text{temp})\right] \quad [3]$$

where C_{ox} is the oxide capacitance and V_{FB} is the flatband voltage. Over 10^{11} states/cm^2 were generated by positive B-T stressing. Deal *et al.* (28) found the same behavior with negative bias stressing. It should be emphasized that capacitance measurements reflect the average charge levels and are not useful in measuring localized buildup of charge particularly of the degree inferred from the electrical conduction measurements in Fig. 15.

Measurements with aluminum negative repeatedly showed the generation of positive charge in the oxide as previously reported (26-29). This negative-bias type of instability, although widely observed, is generally not given as much attention as the mobile ion instability. Different models have been proposed to account for this instability. Hofstein (26) considered trapping of holes by donor states near the Si valence band; Deal *et al.* (28) have proposed silicon ion injection; and Miura and Matukura (29) examined the generation of positively charged oxygen vacancies at the Si-SiO_2 interface. Despite the uncertainty as to the species responsible for the instability, all observations point to an electrochemical generation or transport of a species intrinsic to the MOS system.

It thus appears that the deterioration of SiO_2 films during the accelerated testing is a consequence of lo-

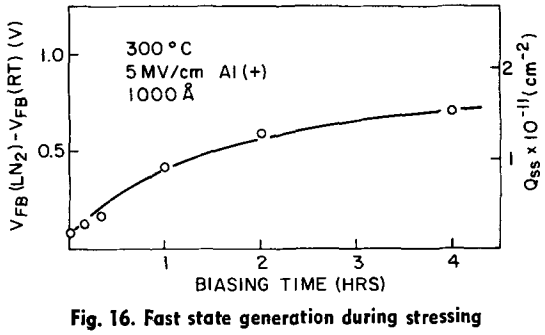

Fig. 16. Fast state generation during stressing

calized barrier lowering which has developed chemically or electrochemically at an unspecified number of spots under the electrode in the otherwise defect-free films. The localized barrier lowering can be attributed to the pile-up of positively charged centers of yet unknown species, which have been generated or mobilized and transported to the electronically injecting electrode during the biasing treatment. It can be also ascribed to the dendritic growths during the solid-state electrolysis of the SiO_2 film (30), whose pointed tips are undoubtedly the sites of intense field, which in turn can generate positively charged centers in their vicinity by high-field ionization (35).

The experimental data accumulated so far do not allow us to differentiate between the two alternate degradation mechanisms. Either mechanism can be invoked to explain qualitatively the observed field, temperature, and thickness dependencies of the accelerated breakdown; and, either mechanism can result in the formation of charge centers and interface states which have been observed after the B-T treatment by $C(V)$ techniques, and thus account for the ambient sensitivity and nonpermanent removal of enhanced conduction. It is evident that much work has to be done before one can discuss the degradation mechanism in quantitative terms.

Summary

Time-dependent breakdown of thermally grown SiO_2 films representative of those employed in the gate region of MOSFET's was investigated under accelerated conditions using MOS capacitors with various oxide thicknesses, electrode metals, and growth conditions. Extended heating in the absence of an electric field resulted in an increase in the defect density in Al-SiO_2-Si capacitors. In the temperature range from 200° to 350°C, the time required to form 20 defects/cm^2 (τ) was found to be thickness dependent, and can be ascribed empirically by the relationship

$$\tau \propto d_{ox}^{1.7}\ e^{-\Delta H/kT}$$

where d_{ox} is the oxide thickness and $\Delta H = 0.6$ eV. The formation of defects in the absence of bias was also found to be slower with Mo, Pt, and polycrystalline-Si electrodes and retarded by a PSG film on the oxide. The degradation without bias thus seems to originate from the reaction between the oxide and the electrode metal.

Under high-temperature biasing conditions, the limiting time for breakdown exhibited a nearly exponential decrease with increasing applied field. Its oxide thickness dependence was empirically an increasing function of the field

$$t_{max} \propto d_{ox}^{(0.8+0.65E)}\ e^{-\Delta H/kT}$$

where ΔH is 1.4 eV for 200 to 1000Å films. These results demonstrate that reliability will become more of a problem in thinner oxides.

The mechanism for the degradation under bias appears to be of electrochemical origin. The results of various $I(V)$ and $C(V)$ measurements suggest that the emergence of charge centers near the injecting electrode causes localized barrier lowering and formation of highly conductive channels which eventually lead to thermal instability and dielectric breakdown.

The fact that a single thermal activation energy is observed between 100° and 400°C is evidence that a single wear-out mechanism is operative and that the data possibly could be extrapolated even further to room temperature. With such an extrapolation, the acceleration factor between 300°C and room temperature becomes 10^{11}. Since defect-related breakdowns are most important to device reliability, statistical measurements under accelerated conditions are required to obtain a complete room-temperature characterization.

The Anodic Oxidation of GaAs in Aqueous H_2O_2 Solution

R. A. Logan, B. Schwartz,* and W. J. Sundburg

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The characteristics of GaAs anodization at constant applied voltage, V, in a concentrated (30%) H_2O_2 electrolyte are examined in detail. Uniform oxides, with a refractive index of 1.8 and oxide thickness, t, proportional to V, are grown over the pH range 1-6. The pH can be adjusted by the addition of NH_4OH or H_3PO_4 to the electrolyte but the presence of other common acids at concentrations of a few parts per million can transform the anodization process into an etching procedure. In 10 min anodizations at $p\text{H} = 2$, 18 Å/V of oxide are grown and 12 Å/V of GaAs are consumed on chemically polished surfaces (for $V \leq 225$V). The resistance of the electrolyte causes significant voltage drops in the electrolyte at all pH values and limits the initial current flow. Most of the oxide is grown during the initial anodization (typically in the first minute) where the current is decreasing rapidly with time and the voltage drop across the oxide is increasing. The oxide is insoluble in the HNO_3 but is soluble in most other acids and bases. Limited MOS measurements yield a dielectric constant of 5.4 and a breakdown field of 3×10^6 V/cm. The use of the oxide as a mask for chemical etching was demonstrated by forming passive optical waveguides in GaAlAs-GaAs-GaAlAs epitaxial layers.

The growth of a native oxide on a semiconductor surface is an essential factor in the utilization of the semiconductor in many device applications. Native oxides have been grown on GaAs by galvanic techniques (1) and on GaP by both galvanic and anodic techniques (2) using concentrated (30%) H_2O_2 as the electrolyte. Galvanically grown oxides have been shown to be useful in passivating the surface of electroluminescent GaP p-n junctions (3) and GaAs-GaAlAs heterojunction lasers (4). It has also been noted that the oxides are useful as masks for the selective etching of local areas of these semiconductors (5) since the oxides are soluble in most acids and bases (permitting windows to be cut through the oxidized surface) and yet insoluble in common semiconductor etchants involving halogens dissolved in alcohols (*e.g.*, bromine-methanol).

The properties of the GaAs anodization process, at constant voltage, are examined in detail in the present studies. The oxide thickness is shown to depend upon the anodization voltage, the time of anodization, and upon the impurity content and the pH of the concentrated H_2O_2 electrolyte bath. The latter can be adjusted by the addition of either NH_4OH or H_3PO_4 to the electrolyte. However the adjustment of the pH with HCl or HNO_3 causes the anodization procedure to transform into an etching process, and intermediate results were obtained using H_2SO_4.

In addition, a description is given of some other factors which characterize the anodization of GaAs at constant bias: the voltage drop in the electrolyte as a function of pH of the bath; the role of surface imperfections (occlusions, surface preparation, etc.); the time dependence of the layer thickness and anodization current at fixed bias; the anodization voltage range over which uniform oxides can be grown; and the amount of GaAs consumed during anodization.

Limited measurements on MOS structures indicate an oxide dielectric constant of 5.4, and a breakdown field of 3×10^6 V/cm with low prebreakdown currents ($\sim 10^{-5}$ A/cm^2) at room temperature.

The application of oxide masking with photoresist techniques to selectively etch local areas of GaAs is described. While the definition achieved in surface oxide protected regions with standard photoresist techniques shows dimensional fluctuations of $\pm 0.5\mu$, the subsequent chemical etching to develop mesas can reduce these fluctuations by more than an order of magnitude. To illustrate the device applications that can be achieved using these techniques, a description is given of the etching of mesas, 0.5 cm long, $\sim 5\mu$ wide, and 10-30μ deep, in GaAlAs-GaAs-GaAlAs epitaxial layers to form passive optical waveguides.

Key words: gallium arsenide, anodization, native oxide.

Experimental Procedure

The anodic oxidation of GaAs at room temperature in concentrated H_2O_2 was studied using a cell previously described for similar studies of the anodization of GaP (2); the electrolyte was contained in a quartz beaker with a platinum cathode. The GaAs sample was immersed in the bath to a depth such that the platinum clamp holding the sample did not contact the bath. Since accumulation of gas bubbles on the test sample would cause nonuniform anodization, the bath was vigorously stirred and a quartz baffle was inserted between the sample and the cathode where most of the bubbles originated. The anodization was performed at constant voltage and the current flow was monitored during the process.

The pH of the bath was measured before and after use and was found to be stable in time. The pH of concentrated (30%) H_2O_2 (J. T. Baker Chemical Company, electronic grade) is typically 3.6, and was decreased or increased by the addition of small quantities of H_3PO_4 or NH_4OH, respectively. In addition, some baths were prepared with the addition of both of these additives. The effect of common acid contaminants (HCl, HNO_3, and H_2SO_4) on the anodization process was investigated by adding to the bath a drop of the test acid diluted in 30 cm^3 of deionized water with sufficient NH_4OH added to produce a solution with a pH ~ 7. In this way, about 2 ppm of the test acid could be added to the bath without changing the pH of the bath.

The anodization studies were generally performed on undoped, (100)-oriented GaAs with a net donor concentration of $\sim 10^{17}$ cm^{-3} and with limited studies performed on similarly oriented p-type samples containing a net Zn acceptor concentration of $\sim 10^{18}$ cm^{-3}. The samples were chemically mechanically polished (6) with 0.075% bromine-in-methanol solution using a PAN-W polishing cloth. One set of experiments was performed to evaluate the oxide growth on (100)-oriented GaAs polished with Tizox-6500 abrasive (Tizon Chemical Corporation, Flemington, New Jersey 08822). The abrasively polished samples were both undoped n-type GaAs and p-type GaAs with a net acceptor concentration of $\sim 3 \times 10^{18}$ cm^{-3}. The MOS

structures were made on n-type, $N_D - N_A \sim 10^{17}$ cm^{-3}, (111)-oriented GaAs etched in chlorine-methanol.

Following procedures developed in similar studies with GaP (2), the samples were routinely dried in air after anodization by heating for 1 hr at 95°C followed by heating for 2 hr at 250°C.

The thickness and index of refraction of the oxide were measured with an ellipsometer using procedures described for similar studies of the oxidation of GaP (2). The layer thickness was also measured with a Talystep (Taylor-Hobson Company) by measuring the step height formed where the oxide was locally dissolved in HCl.

The initial attempt to determine the amount of GaAs consumed during anodization was made by waxing a portion of the polished sample surface with Apiezon wax, anodizing the exposed surface, dissolving the oxide in HCl ,and measuring the step height developed in the surface after removing the wax. Because of undercutting of wax in the anodization process, it was found necessary to use the following procedure: (*i*) anodize the entire surface of the test sample; (*ii*) apply the wax mask; (*iii*) dissolve the exposed oxide in HCl; (*iv*) anodize the exposed surface; and (*v*) remove the wax in organic solvents and then dissolve the oxide in HCl. In this way, a well-defined step due to the GaAs consumed in the second anodization was developed; the step height formed in this way was measured using a Talystep.

The electrical properties of the oxide were determined by making simple MOS structures. After alloying a Sn ohmic contact to one end of the n-type sample, the sample was anodized while contacted in the region of the alloyed Sn and then dried. Metal field plates were obtained by evaporation of Pb through a mask with 0.030 in. diameter openings. Since a thin Pb film crept over the surface during the evaporation, this excess Pb was removed by dipping the samples in HNO_3 (in which the oxide is insoluble) and rinsing the samples in water prior to measurement. Similar procedures using Au evaporation were unsuccessful. The current voltage characteristics of the Au barriers appeared to be regular Schottky barriers (rather than the high impedance MOS structures), suggesting that at the high temperatures required for Au evaporation, this metal penetrated the oxide.

Results and Discussion

Anodization process.—For a given time of anodization the oxide thickness, t, varied with the anodization voltage, V, and the pH of the H_2O_2 electrolyte. The current of anodization, I, decreased with time at constant V. Typical data are shown in Fig. 1 where the logarithm of I is plotted against time for samples 2 cm^2 in area, using a bath with a pH = 2.0 and for several values of V. After the rapid initial decrease in current, I decreases linearly with time.

With a platinum anode of 2 cm^2 area (equal to that of the test sample) the bath resistance was observed to be 2.0 k-ohms, independent of current. The voltage drop across the oxide is thus less than the applied bias during the initial growth at large I and approaches V as I decreases. The growth of the oxide thickness with time at 100V and pH = 2.05 is shown in Fig. 2. The rapid initial oxide growth is followed by a slower increase with time. It is apparent that after rapid initial growth the resistance of the oxide limits the current flow, retarding the layer growth. The resistivity of the as-grown oxide on GaAs is apparently much higher than that in GaP where only the exponential decrease of I with V was observed in the first 10 min of anodization (2).

All thickness measurements reported here were performed on samples which were dried by heating in air for 1 hr at 95°C, followed by heating for 2 hr at 250°C. This procedure was developed in similar studies in GaP (2) where it was designed to remove water from the oxide layers where measurements indicated that

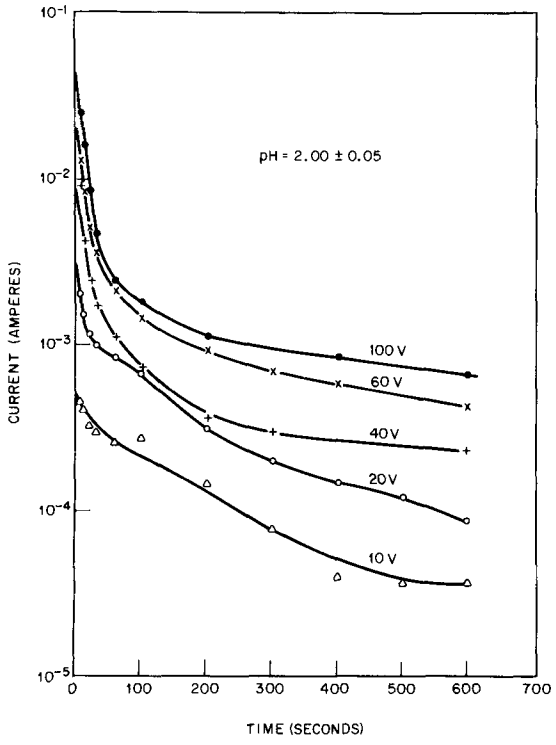

Fig. 1. A semilogarithmic plot of the variation of anodization current with time for a series of anodization voltages. The pH of the bath is 2.00 ± 0.05 and the area of the GaAs sample is ~2 cm^2 with faces in the <100> directions.

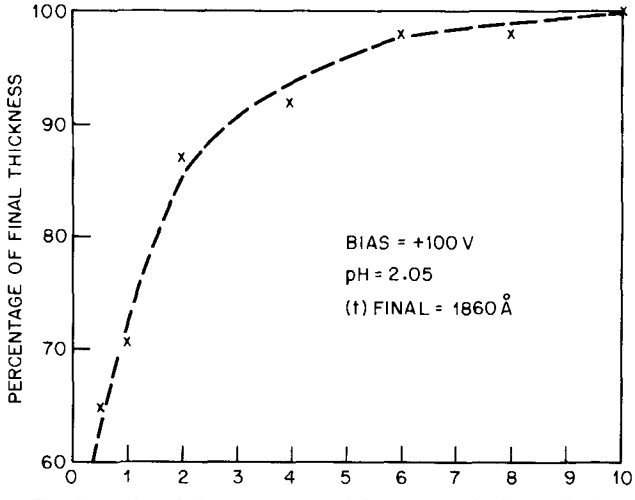

Fig. 2. A plot of the percentage of final oxide thickness obtained vs. time of anodization in a bath with pH = 2.05 and with anodization voltage of 100V. The anodization time was standardized at 10 min in this work and the final thickness of the oxide was 1860Å in this case.

the drying procedure reduced the layer thickness ~20%. The layer thickness, t, and the index of refraction, n, of the as-grown layer on GaAs were often indistinguishable from those of dried layers but occasionally were both 10% greater in t and lower in n. Due to the reproducible results obtained using the dried oxide layers the drying procedure was routinely followed in obtaining the results described here.

The dependence of oxide thickness, t, upon the anodization voltage, V, is shown in Fig. 3 for chemically (Br-methanol) and abrasively (Tizox) polished (100)-oriented GaAs samples, using an H_2O_2 bath with a pH = 2.0 ± 0.05. The oxide thicknesses are linear in V, with 18 Å/V on the chemically polished surface and 20 Å/V on the abrasively polished surface. The excellent reproducibility of the oxide growth is shown

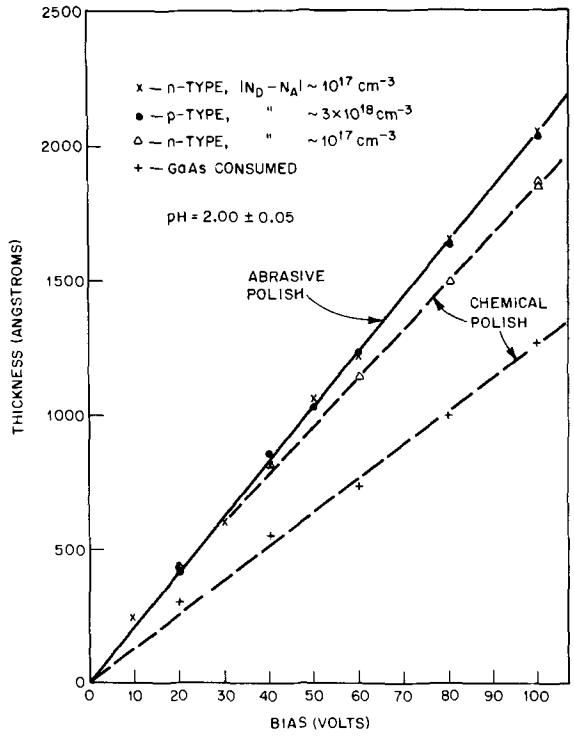

Fig. 3. The oxide thickness plotted against anodization voltage (for 10 min anodization) for (100)-oriented samples with doping levels indicated and using a bath with a pH = 2.00 ± 0.05. The linear dependence of thickness upon bias is 20.6 Å/V on the abrasively polished samples and 18.6 Å/V on the chemically polished samples. In the latter case, GaAs was consumed during the anodization at a rate of 12.5 Å/V.

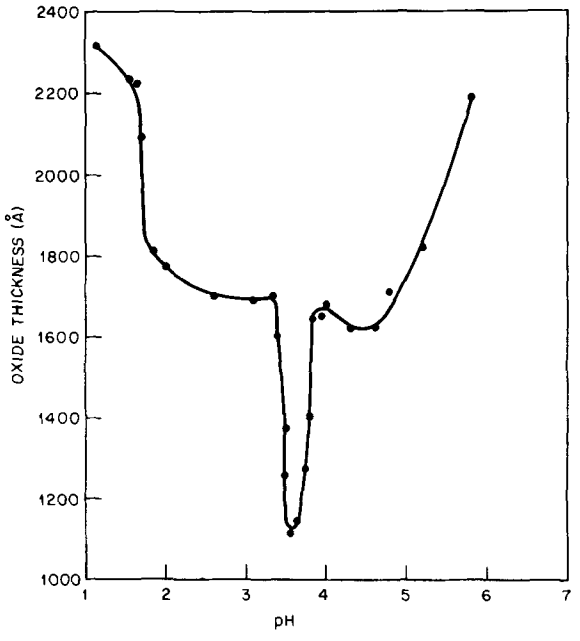

Fig. 4. The oxide thickness obtained in 10 min anodizations at 100V as a function of the pH of the electrolyte (H_2O_2). At higher pH values (~6.5) the oxide became nonuniform in thickness.

for the two sets of data on p- and n-type abrasively polished GaAs. The refractive index, n, of the oxide was 1.8 in all cases. The oxide growth rate is sensitive to surface perfection and the oxidation is, in fact, a useful tool (7) to examine surfaces for scratches, compositional or doping inhomogeneity, occlusions, etc.

The dependence of t upon V remained linear to 150V. The oxide layers produced at 175 and 200V were uniform in color and the ellipsometer measurements of t and n were 1030Å, 2.2 and 500Å, 2.7, respectively. To confirm this decrease in t and increase in n the oxide was locally removed by waxing and etching in HCl, and from the step-height measurement with the Talystep the linear relationship between t and V was found to hold for $V \leq 225$V. Thus the ellipsometry measurement technique fails in oxides formed at the higher anodization voltages where some nonuniformities apparently occur in the oxide. With $V > 225$V, the oxide was gray and granular in appearance and the portions of the original GaAs surface from which the oxide was dissolved were discolored. Using the procedures of oxidization, masking, and dissolving the oxide as described above, and then reanodizing and dissolving the exposed oxide in HCl, the measurement of the step developed in the surface of the sample indicated the amount of GaAs consumed in the anodization. For chemically polished GaAs, the GaAs consumed in anodization was linear in V, with the value 12 Å/V (compared to the oxide thickness of 18 Å/V).

While basic solutions of H_2O_2 are etchants, uniform oxidation occurs over a wide range of pH values in acidic solutions of H_2O_2. The pH of concentrated (30%) H_2O_2 is typically 3.6 and was decreased (or increased) by the addition of very small amounts of phosphoric acid (or ammonium hydroxide). The results of anodization at 100V for 10 min are shown in Fig. 4 where t is plotted against the pH of the bath.

The pH dependence of t shows two general features: an increase in t towards each end of the pH range and a decrease in t, near pH = 3.6, where the concentration of additives in the bath is minimal. The decrease in I during anodization exhibited the normal dependence of Fig. 1 except near pH = 3.6 where I decreased linearly to a value of only ~50% of the initial I. The initial and final anodization currents at 100V as a function of pH are shown in Fig. 5. The dependence of the initial current flow upon pH is due to the variation of the bath conductivity with pH as shown by the plot in Fig. 5 of the current flow through the bath at 100V, with the test sample replaced by a platinum anode of

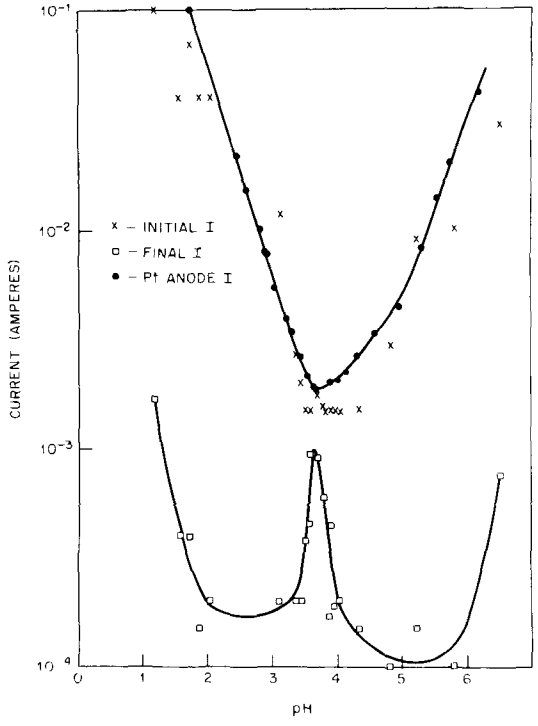

Fig. 5. A semilogarithmic plot of the initial and final current of anodization at 100V for 10 min as a function of the pH of the electrolyte (H_2O_2) for (100)-oriented samples of GaAs, ~2 cm^2 in area. Also shown is the current flow as a function of pH obtained with a platinum anode of 2 cm^2 area replacing the test sample.

equal area (~2 cm²). The bath conductivity, measured with two platinum electrodes, was linear in I. The initial and final voltages across the oxide for anodization at 100V are plotted in Fig. 6 as a function of the bath pH. It is evident that near pH = 3.6, the pH range of reduced oxide growth is much narrower than that of the broad conductivity minimum centered about the same pH value.

The importance of the amount of additives in the bath rather than the value of the adjusted pH of the electrolyte is shown by the anodization results obtained with both NH_4OH and H_3PO_4 added to the bath. For example, if the pH of the bath is increased to ~6 by the addition of NH_4OH, and afterwards is decreased to 2, then the dependence of t, the initial and final currents, and the bath conductivity are all insensitive to further increases of pH by the addition of NH_4OH (with no discontinuities near pH = 3.6). In this case, the bath resistance is only ~750 ohms and the initial and final voltages across the oxide are ~60 and ~100V, respectively.

However, as described above for anodization at $V >$ 150V (pH = 2), the ellipsometry measurements on these layers indicate low values of t (~1000Å) and high values of n (~2.8). The determination of t using the Talystep technique showed that t = 1900 ± 100Å for 2 < pH < 5.5. Ellipsometry measurements, on oxides formed by anodization in this compensated bath with $V \lesssim 60$V, gave values of t and n in agreement with those obtained at pH = 2 with only H_3PO_4 added to the bath (Fig. 3). For $V > 60$, the ellipsometry measurements again failed to give the correct t (and presumably n value also) of oxides formed in the doubly compensated bath. Hence while the conductivity of the bath can be increased, and the dependence of t upon pH can be reduced by adding both H_3PO_4 and NH_4OH, the properties of the oxide films with $V > 60$V ($t > 1000$Å) cannot be determined by ellipsometry measurements.

Electrical properties.—MOS structures were formed by evaporation of Pb through a mask containing 0.030 in. diameter holes onto anodized n-type, $N_D - N_A$ ~10^{17} cm^{-3}, samples of GaAs. These (111)-oriented samples had been polished by immersion into chlorine-methanol etchant. An ohmic contact was then formed by alloying Sn in a hydrogen atmosphere at ~500°C in a brief heating cycle. Samples were then anodized at 30, 50, 70, and 100V, respectively, (pH = 2.0) and dried. After the Pb evaporation the surfaces were cleaned of a thin film of Pb between the 0.030 in. diameter islands by dipping the samples into concentrated HNO_3 (in which the oxide is insoluble) and then rinsing them in water. At room temperature, the pre-breakdown currents were in the 10^{-8}-10^{-9}A range, independent of bias and the reverse bias breakdown field was 3 ± 0.5 × 10^6 V/cm in all units. From the limiting value of the capacitance in forward bias and using the known oxide thicknesses, the dielectric constant was evaluated on two metal barriers per sample. From the eight measurements, the average dielectric constant and mean deviation were found to be 5.4 ± 0.2.

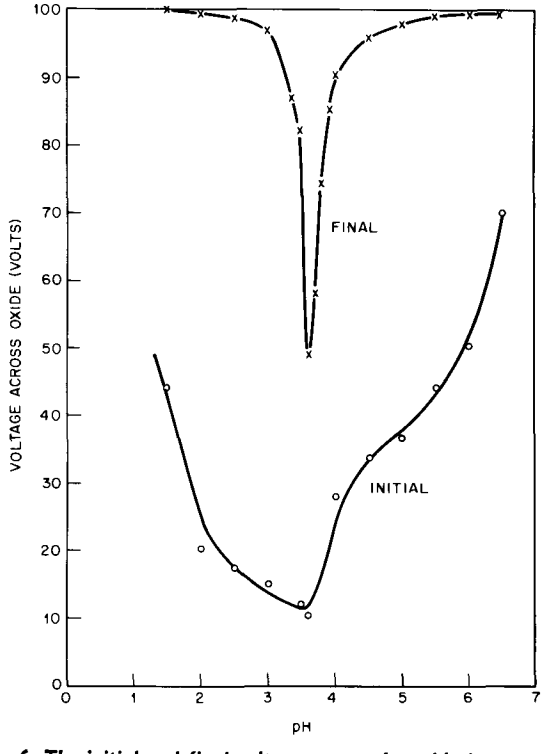

Fig. 6. The initial and final voltage across the oxide layer on the anodized sample as a function of the pH of the electrolyte (H_2O_2) for anodization at 100V for a period of 10 min.

Effects of contaminants on anodization.—Uniform oxides have been grown (with V selected as 100V), using electrolytes of concentrated H_2O_2 with or without the addition of either H_3PO_4 or NH_4OH to adjust the pH in the range from 1 to 6. The effect of contaminants on this process was revealed in one instance when the pH of pure H_2O_2 (pH = 3.52) was increased slightly to pH = 3.65 by the addition of a drop of NH_4OH diluted in distilled water in a well-rinsed beaker which had previously contained HNO_3. While uniform anodization had previously been achieved over a wide pH range, this bath produced an etching of the sample instead of anodization. It was therefore decided that it would be of interest to those applying the anodization process to make some assessment of the effects of contaminants. The common acids HCl, HNO_3, and H_2SO_4 were selected as contaminants. By dilution of one drop of these acids in 30 cm³ of water and then by adding enough NH_4OH so as to form a contaminant solution with a pH ~7, it was estimated that one drop of this dopant solution added 2 ppm of the selected contaminant acid to the electrolyte bath without changing the bath pH. Using baths with a pH of ~3.5, 2 ppm of HCl or HNO_3 caused etching instead of anodization while fairly uniform anodization occurred with the bath containing H_2SO_4. Using baths with a pH ~2 (adjusted with H_3PO_4), the addition of 2 ppm of the contaminant acid did not disturb the anodization process. Adjustment of the bath pH to 2 with H_2SO_4 instead of H_3PO_4 also produced fairly uniform anodization. The behavior of the contaminants is rather complex since the oxide is insoluble in HNO_3 (which severely affects the anodization), soluble in H_3PO_4, NH_4OH, and H_2SO_4 (which assist the oxide growth in H_2O_2 solutions), and soluble in HCl which also severely affects the anodization.

Oxide masking in device fabrication.—Native oxides form ideal etching masks on many of the III-V compound semiconductors (5) since they are insoluble in common etchants (halogen-alcohol solutions); and because of their growth on the semiconductor surface, there is no separation of the mask from the surface during the etching. Native oxide masking is obviously useful in any device application where mesas have to be formed on a processed semiconductor wafer. To demonstrate the properties of this procedure a description is given of the etching procedures used to form mesa stripes, 0.5 cm long, ~5-30μ wide, and 3-40μ high, on GaAs and on GaAlAs-GaAs-GaAlAs epitaxial layers grown on GaAs. The ability to develop mesas on the latter structures has obvious uses in fabricating GaAs, GaAlAs heterojunction lasers (8), and optical waveguides.

To etch mesas on the surface of samples, the surface is first oxidized and dried and then treated with photo-

resist AZ111 and exposed through a mask containing opaque stripes of the desired dimensions (9). The regions protected by the opaque portions of the mask remain oxidized after the photoresist treatment with the unprotected oxide dissolved in the caustic photoresist developer solution. With a bromine-methanol polished (100) GaAs sample and a mask containing 30μ wide stripes, 1 cm in length, the surface oxide stripes remaining after the photoresist process are shown in Fig. 7(a). It is noted that the edge dimensional fluctuations are $\sim \pm 0.5\mu$. After etching for 1.5 hr in a stagnant solution of 0.1% bromine in methanol the top view of the mesa (after dissolving the oxide in HCl) is shown in Fig. 7(b) and the cross-section view, obtained by cleaving in a (110) plane, is shown in Fig. 7(c). The etching to a depth of 3μ has reduced the edge dimension fluctuations by at least an order of magnitude. The flat sides of the etched mesas are (111) planes. To permit observation of the cross section of the mesa, the direction of the oxide stripes is made normal to a (110) cleavage plane. With the stripes in the [110] direction in the (100) surface of the GaAs sample, the flat mesa sides are (111) planes.

Application of the same procedures to GaAlAs-GaAs-GaAlAs epitaxial layers grown upon a GaAs (100) substrate produced the structures shown in cross section in Fig. 8. These mesas extend about 0.5 cm in length and are passive optical waveguides for infrared radiation which is confined in the GaAs middle layer due to the decreased index of refraction in the adjacent Al rich layers ($X_{Al} \sim 10\%$) and air interface on the sides. It is noted that the etched sides in Fig. 8(a) are smooth curves but are (111) planes in Fig. 8(b). While both waveguides lie in <110> directions in the (100) plane they are mutually perpendicular. Thus the cleavage planes are $(0\bar{1}\bar{1})$ in Fig. 8(a) and $(01\bar{1})$ in Fig. 8(b). The straight sides of the mesas in Fig. 8(b) are (111) and $(1\bar{1}\bar{1})$ planes which etch more slowly (10) than the corresponding {111} planes in Fig. 8(a) where the mesa sides are curved. The bright line at the top of the surface of the crystal in Fig. 8(b) is the oxide and shows that the depth of etching can be monitored by noting that it is about double that of the oxide overhang which is visible under microscopic inspection of the top of the structure.

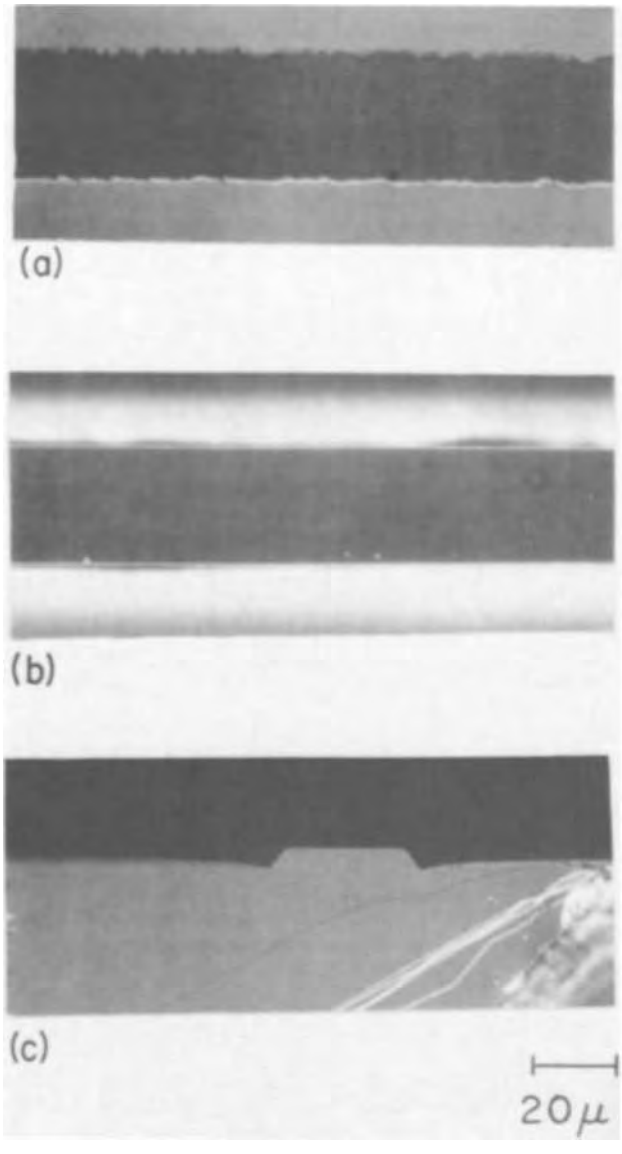

Fig. 7. (a) A 30μ wide stripe of oxide on a GaAs surface defined with photoresist techniques. (b) The same region after developing a mesa by etching in Br-methanol (and dissolving the oxide in HCl). (c) Cross-section view of (b).

Summary

These studies describe many of the factors which influence the anodic growth of a native oxide on GaAs in an aqueous H_2O_2 electrolyte at constant anodization voltage and may be summarized as follows:

1. Uniform oxide layers, with a refractive index equal to 1.8 and with layer thickness proportional to the anodization voltage, may be grown over extended ranges of anodization voltages and pH of the electrolyte. The pH of the electrolyte may be increased (or decreased) by the addition of NH_4OH (or H_3PO_4). The oxide layer thickness is sensitive to surface imperfections as evidenced by an oxide growth of 20 Å/V on an abrasively polished surface and 18 Å/V on a chemically polished surface (with a bath pH = 2 and $V \leq 225$V). In the latter case the growth of the oxide consumed 12Å of GaAs per volt of anodization voltage.
2. Since the oxide is of high resistivity the anodization current (and the voltage drop in the electrolyte) decrease as the oxide is grown at constant bias. The voltage drop across the oxide becomes essentially equal to the applied bias after about 1 min of anodization.
3. The resistance of the electrolyte causes significant voltage drops in the electrolyte at all pH values and limits the initial current flow during anodization.
4. Most of the oxide is grown during the initial anodization (typically in the first minute) when the current is decreasing rapidly with time (and the voltage drop across the oxide is increasing). For example at pH = 2 and 100V applied, 70% of the oxide is grown during the first minute of anodization of a 10 min cycle.
5. As-grown oxides were often indistinguishable from those which were air dried at temperatures of 95°-250°C. The reproducibility of the layer properties is improved by drying, but the effects are less severe than in similar oxides on GaP where t decreased by 20% using the same drying procedure.
6. For $1 < pH < 6$, the pH dependence of t (at fixed V) shows a small increase in t towards each end of the pH range and a decrease in t near pH = 3.6. The reduced oxide growth near pH = 3.6 correlates with the absence of additives (NH_4OH or H_3PO_4) in the bath rather than with the broad conductivity minimum of the electrolyte centered about the same pH value.
6. At pH = 2 and $V > 150$V, the oxide properties cannot be characterized by ellipsometry measurements, but Talystep measurements of t showed the linear relationship between t and V extended to $V \leq 225$V.
7. Contaminants such as HCl and HNO_3 at concentrations of a few parts per million in the bath can cause the anodization process to transform into an etching process.
8. The oxide is insoluble in HNO_3 but is soluble in most other acids and bases.

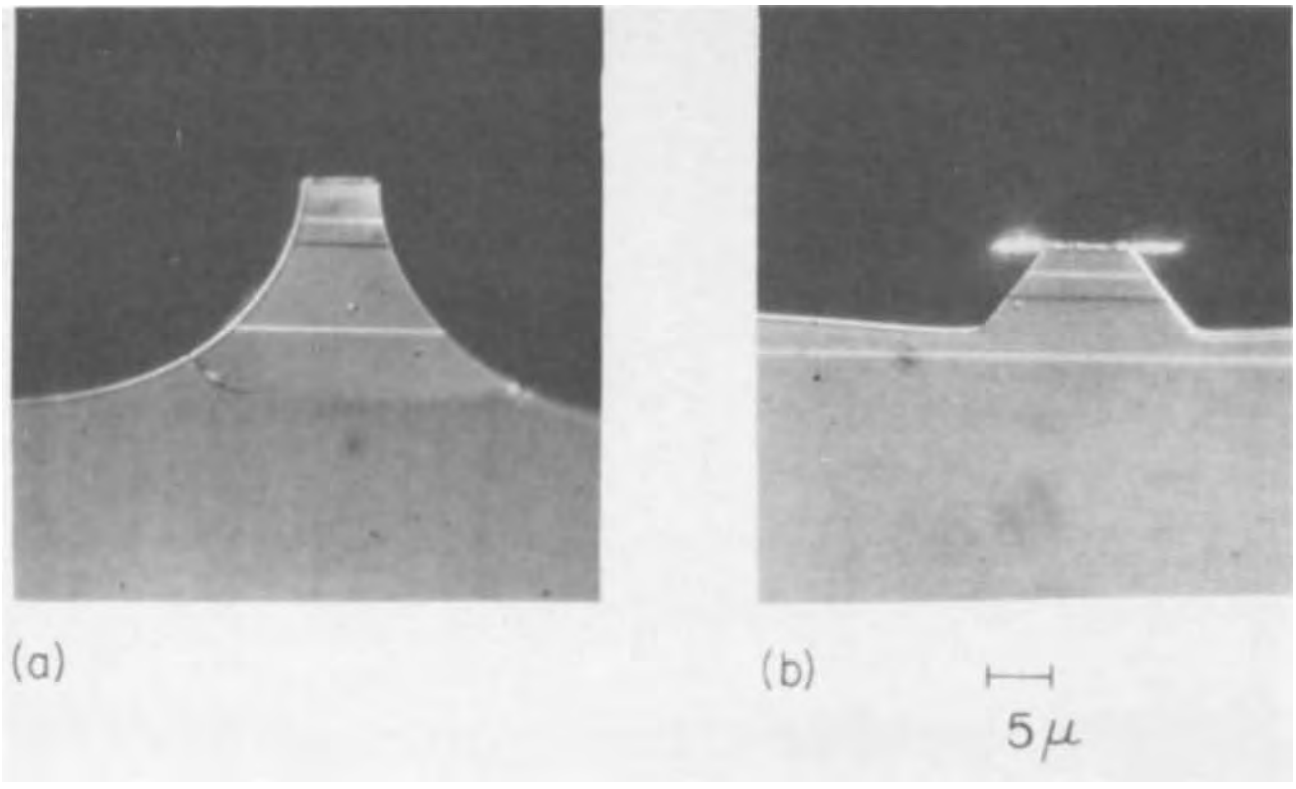

Fig. 8. The cross-section view of mesas formed in GaAlAs-GaAs-GaAlAs epitaxial layers grown on a GaAs substrate using the technique of masking by growth of a native oxide, defining area by photoresist techniques, and etching in Br-methanol. The mesas lie in the <110> directions in the (100) plane and are viewed on cleavage planes: (a) in the [01$\bar{1}$] direction and (b) in the (01$\bar{1}$) direction. The straight sides of the mesas in (b) are (111) and (1$\bar{1}$1) planes which etch more slowly (10) than the corresponding {111} planes in (a) where the mesa sides are curved.

9. Limited measurements on MOS structures suggest the oxide should be useful in such applications.

10. The use of the oxide as a mask for chemical etching was demonstrated by describing the formation of passive optical waveguides by the etching of mesas, 0.5 cm long, 5μ wide, and 10-30μ deep in GaAlAs-GaAs-GaAlAs epitaxial layers.

11. Anodization, followed by dissolving the oxide, is a useful etching procedure to remove a small, predetermined thickness of the crystal. The amount of GaAs consumed in anodization is linear in V. This procedure should be useful in diffusion studies and as a general cleaning procedure for cleaning crystal surfaces while maintaining geometrical control.

12. These anodization procedures should extend directly to other III-V compound semiconductors; for example, an anodic oxide has been grown on InSb. In addition, an oxide has been grown on silicon by this technique.

While many of the properties and applications of the anodization process have been described, it is apparent that there is little understanding of the kinetics of the process. Anodization at constant bias can produce uniform oxides with predetermined properties but the kinetics are obscured since most of the oxide is grown in the initial anodization where there are rapid changes in the anodization current and the voltage across the oxide. Impurities play an important role in the kinetics since the rate of oxide growth depends upon the concentrations of H_3PO_4 and NH_4OH in the electrolyte rather than only on the pH of the bath. Moreover, some additives, such as HNO_3 and HCl, can transform the anodization process into an etching procedure.

Measurements are now being attempted to directly measure the oxide composition; only then can firm models be proposed to explain the observed results. It is presently assumed that the oxidation proceeds via the hydrated forms of gallium oxide and arsenious oxide (*i.e.*, $Ga_2O_3 \cdot mH_2O$ and $As_2O_3 \cdot nH_2O$) which are both generated on the GaAs surface. However, if the conditions in the solution are such as to cause the removal of either of these products (*e.g.* the pH effect on the dissolving of arsenious oxide to form arsenious acid or the influence of nitrates or chlorides on the rate of oxide formation) then the kinetics can be drastically altered.

Acknowledgments

We appreciate the assistance of R. C. Manz and A. J. Sayko with the chemically polished samples and of S. Bortas with the abrasively polished samples. The Talystep measurements were obtained by F. B. Alexander and the photoresist procedures were applied by D. L. Deppen.

Manuscript submitted March 5, 1973; revised manuscript received May 3, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

The Migration of Oxygen during the Anodic Oxidation of Tantalum

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Oxygen-18 concentration profiles in thin oxide films have been measured by combining a sectioning technique for locating the isotope with a nuclear method for detecting it. The system studied was the anodic oxidation of tantalum, and the oxide was sectioned by slow dissolution in concentrated HF almost saturated with NH_4F; the ^{18}O present was detected by bombarding the oxide with 3.042 MeV protons and counting neutrons emitted in $^{18}O(p,n)^{18}F$ reaction. On anodizing first in ^{16}O electrolyte and then in ^{18}O electrolyte, the ^{18}O incorporated last was found outside the ^{16}O layer incorporated first. There was, however, a small mixing of the populations at the boundary between them, and the degree of mixing was found to be proportional to the square root of the thickness added in the ^{18}O electrolyte. The results could be analyzed very well in terms of forced diffusion (under the influence of the electric field during anodization) from a constant source (the electrolyte) into a semi-infinite medium (the oxide), thus confirming that oxygen indeed migrates during the anodic oxidation of tantalum.

The sectioning technique described in previous papers (1, 2) has been combined with a least squares fit analysis (3) and used to study transport processes in the anodic oxidation of tantalum (4). Radioisotopes of the noble gases were found to approximate quite closely to the inert immobile markers required for transport number experiments, and it was then possible to show that the oxide thickens largely by oxygen migration. The next step, therefore, was to find out how the individual oxygen atoms moved through the oxide film, and this required a tracer for the oxygen itself. Results obtained in such experiments are described below.

The configuration of a tracer experiment depends on the methods used to incorporate, detect, and locate the tracer species. Thus the noble gas atoms used in the previous study (4) were incorporated by ion implantation, detected by means of their radioactivity, and located using the sectioning technique. No long-lived radioisotopes of oxygen exist, and so one of the rare stable isotopes, ^{17}O or ^{18}O, must be used instead. These can be detected either by means of nuclear reactions (5, 6) or by mass spectrometry (7), but the detection efficiency of these methods is much less than that for radioactivity. Accordingly, much more tracer is required, and since implantations at high fluence alter the properties of the anodic oxide (2), this was an undesirable method for the incorporation of the oxygen isotopes. The only alternative was to anodize in water enriched with the appropriate isotope.

In their pioneering study on the migration of oxygen during anodic oxidation, Amsel and Samuel (6) incorporated ^{18}O tracer by anodizing in $H_2{}^{18}O$, detected it by counting α particles emitted from the nuclear reaction $^{18}O(p,\alpha)^{15}N$, and located it by taking advantage of the extremely narrow 1165 keV proton resonance in this reaction. Such nuclear methods of location depend on measuring the energy lost by charged particles in traversing the solid, and the resolution is limited by the energy straggling that occurs. This straggling is quite sufficient to mask the effect of small variations in the concentration profile, so that gross changes alone can be observed (8). Using specimens prepared in these laboratories, Evans and Pemsler (7) have detected and located ^{18}O tracers by means of ion microprobe mass spectrometry, in which the oxide is gradually sputtered away with 2 keV argon ions. By feeding the sputtered atoms to a mass spectrometer, the ^{18}O isotope could be detected and located as a function of the sputtering time. The resolution is, of course, limited by the uniformity of the sputtering and appears to be little better than that for the nuclear method.

In the present experiments, ^{18}O was incorporated by anodizing in $H_2{}^{18}O$ electrolyte, detected by counting neutrons from the $^{18}O(p,n)^{18}F$ reaction, and located by means of the sectioning technique described in previous papers (1, 2). The use of separate techniques for detection and location improved the resolution by about an order of magnitude.

The Principle of the Tracer Experiments

As in the previous paper (4), an ideal oxidation system will be assumed; one in which the oxide is homogeneous, of uniform thickness, and grown on a plane metal surface. The experiments were performed by anodizing to an initial thickness, h_i, in ordinary $H_2{}^{16}O$ electrolyte, and then to a final thickness, h_f, in identical electrolyte made up with $H_2{}^{18}O$. Under these circumstances, three basic possibilities for the ^{18}O profile exist, as illustrated in Fig. 1.

I. If the oxide thickens entirely by metal migration, the ^{18}O atoms will be incorporated on top of the ^{16}O atoms, and populations will not mix. Since the ^{16}O layer is of extremely uniform thickness (1), the ^{18}O concentration will fall abruptly to the natural abundance at the boundary between the layers.

If the oxide thickens entirely by oxygen migration, there are two extreme possibilities.

II. The oxygen atoms could move in succession as space becomes available, thus preserving their order in queues. Due to the statistical nature of the motion, some queues will move faster than others, and so some of the leading ^{18}O atoms will overtake some of the trailing ^{16}O atoms. The population mixing that results serves to distinguish this possibility from the previous one.

III. The other extreme is to suppose that once the oxygen atoms are incorporated in the oxide, they move right across until they are stopped at the metal/oxide interface. Under these conditions, the oxygen order will be reversed, since the ^{18}O atoms incorporated last will be found underneath the ^{16}O layer formed first.

Key words: tantalum, anodic oxidation, oxygen tracer, nuclear microanalysis, oxygen migration.

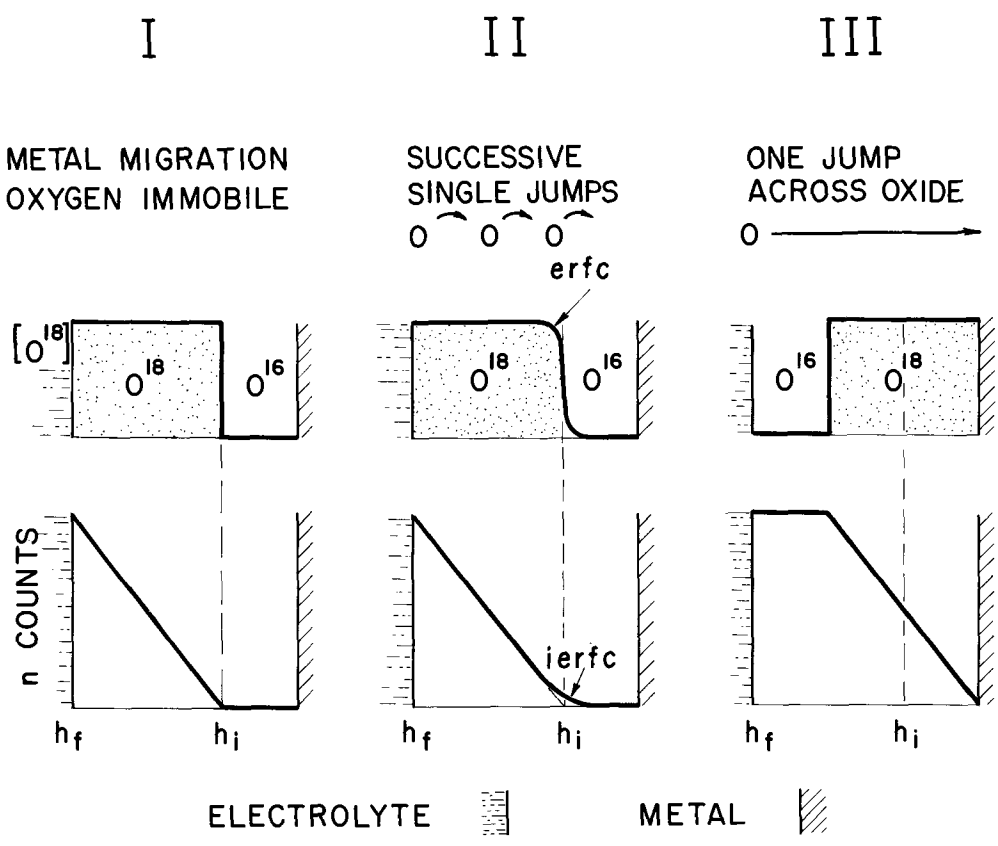

Fig. 1. The three basic ^{18}O concentration profiles in anodic tantalum oxide when the oxide is formed initially to a thickness, h_i, in $H_2{}^{16}O$, and then to h_f in $H_2{}^{18}O$. The lower curves show the corresponding neutron count profiles when the films are analyzed by the $^{18}O(p, n)^{18}F$ method described in the text.

These three profiles are the simplest and most easily interpretable, but many others are possible. Thus, profiles intermediate to II and III will occur if the atoms move several interatomic distances at a time, instead of one as assumed in II, or all as in III. When both metal and oxygen move, with a new oxide being formed at the interfaces, the ^{18}O distribution will be a combination of I with II or III, or some intermediate thereof. If a new oxide is formed within the existing oxide, the ^{18}O profile will depend on the location of this new oxide as well. Certain types of profile could, therefore, be rather difficult to interpret.

Fortunately, most of these possibilities can be eliminated by the evidence already available. Transport number measurements (4) show that both tantalum and oxygen migrate, and that the new oxide is formed at the metal/oxide and oxide/electrolyte interfaces only. The possible profiles, therefore, are those in which I is combined with II or III, or with some intermediate between II and III.

Measurement of the ^{18}O Concentration Profiles

Incorporation of the ^{18}O.—Tantalum foils, 35 × 10 × 0.37 mm³, were cut from 0.015 in. sheet supplied by the Fansteel Metallurgical Corporation. The middle 28 mm on each side was divided into seven areas, each 4 × 10 mm, by means of scratches running across the foil. A 0.5 mm (0.020 in.) diameter tantalum wire was spot welded on one corner, and the foils were then chemically polished as described previously (1). After a 2 min dip in the NH_4F-HF stripping solution to remove any film left by the polishing (9), the foils were anodized to the desired initial thickness using 0.01M KI in ordinary water as the electrolyte. This particular electrolyte was chosen to avoid dilution of the enriched oxygen electrolytes; the anion contains no oxygen, and the salt does not crystallize with water of hydration.

Two $H_2{}^{18}O$ samples were obtained from YEDA, Israel, and KI, dried at 150°C for 2 hr, was dissolved in them to make up approximately 0.01M solutions; 26.10 mg were dissolved in 15 ml of 11.43% $H_2{}^{18}O$ (0.0105M), and 2.60 mg in 2 ml of 97.56% $H_2{}^{18}O$ (0.0087M). The tantalum foils were then reanodized to the final thickness in one or other of these electrolytes, using specially designed Lucite cells. A platinum wire served as cathode, and because the anodizing circuit (10) required a reference electrode, a silver wire was added for the purpose. The intended Ag/AgI electrode, however, did not have the necessary impedance, and so the other end of the silver wire was electrically connected to the usual glass electrode by dipping both in a beaker of ordinary 0.01M KI.

Anodization behavior with this arrangement was normal, as determined from angstroms/volt and seconds/volt measurements. The use of 0.01M KI in place of 0.1M H_2SO_4 did not noticeably affect the thickness calibration (1) for the tantalum oxide. No temperature control was provided for the anodizing cell, with the result that the heat liberated during anodization raised the temperature of the small quantity of electrolyte present; indeed, the temperature rose sufficiently to produce considerable condensation on the walls of the cell above the electrolyte. At 10 mA/cm², the heating was so pronounced that the final thickness was very much greater than that intended, and so much hydrogen was discharged at the cathode that the specimen was anodized in a froth.

Detection of the ^{18}O.—Several charged particle nuclear reactions can be used for the detection of ^{18}O. If the reaction product is itself a charged particle, as in the case of the $^{18}O(p, \alpha)^{15}N$ reaction used by Amsel and Samuel (6), the detector must be placed inside the vacuum system of the accelerator. Such apparatus was not available at the time these experiments were performed, and so reaction products that would pass through the accelerator wall were needed. These could only be neutrons or γ rays, and neutrons from the $^{18}O(p, n)^{18}F$ reaction were in fact used. The other product of this reaction, radioactive ^{18}F, has been employed by Thompson (11) to measure the ^{18}O content of natural anodic oxide on tantalum.

The $^{18}O(p, n)^{18}F$ reaction has a proton threshold energy of 2.574 MeV (12), above which there are a series of resonances (13). To optimize the conditions

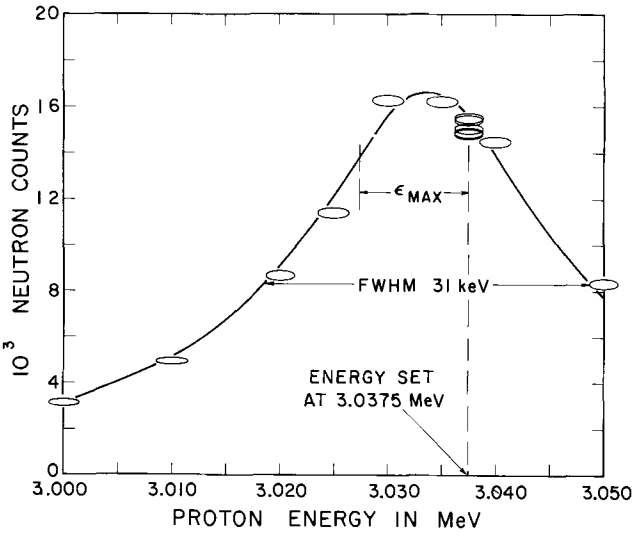

Fig. 2. The 3.037 MeV resonance in the $^{18}O(p, n)^{18}F$ reaction measured with an anodic $Ta_2{}^{18}O_5$ sample 490Å thick in proton bombardment ii; 3 MeV protons lose approximately 2 keV in traversing this thickness of oxide. The scale along the abscissa is a working scale, which has been calibrated only approximately; it appears to be about 5 keV low. The random standard error in each energy measurement is known to be about 1 keV, and the standard error in each count is 2.1 times $\sqrt{}$ (observed count). Error ellipses have been drawn at two standard errors from the points actually measured to show the 95% confidence limits. The maximum energy lost in an oxide film during the course of these experiments is indicated by ϵ_{max}.

for neutron counting, it was necessary to consider three factors.

First, neutrons can be produced by p, n reactions on nuclei other than ^{18}O. In this respect, it was fortunate that the p, n threshold for ^{16}O is 17.4 MeV, and that ^{181}Ta, with its high Z, has a large coulomb barrier. Tests with chemically polished tantalum showed that the background count decreased by an order of magnitude for every MeV reduction in the proton energy below 5.5 MeV; this observation is in agreement with published data for the $^{181}Ta(p, n)^{181}W$ cross section (14). To keep the background down, therefore, the proton energy had to be as small as possible.

The second requirement was to maximize the neutron yield from the ^{18}O, and this meant using a resonance in the $^{18}O(p, n)^{18}F$ reaction. According to the literature (13), the lowest resonance occurs at 2.649 ± 0.005 MeV; when tested here, this gave acceptable neutron counting rates. It was not used for the actual experiments, however, because it could not meet the third requirement; that the p, n cross section be constant at all points in the oxide film.

The maximum thickness of the ^{18}O profiles studied here was about 2700Å. From energy loss data (15), it can be calculated that 3 MeV protons lose approximately 13 keV in traversing this thickness of tantalum pentoxide, so that a proton incident on one side with an energy 6.5 keV above resonance would emerge from the other with an energy 6.5 keV below resonance. The third requirement meant, therefore, that the p, n cross section had to be approximately constant for 6.5 keV on either side of the resonance peak. Since the full width at half maximum for the 2.649 MeV resonance was only 8 keV, this resonance was obviously much too narrow.

The next resonance in the $^{18}O(p, n)^{18}F$ reaction occurs at 3.037 MeV, with an FWHM reported as 33 ± 3 keV (13); the latter was confirmed here, as demonstrated in Fig. 2. This resonance is the broadest available below 3.5 MeV (13), and therefore had to be used in the present experiments. The incident proton energy was fixed at 3.042 MeV, 5 keV above resonance, to keep the average cross section for any oxide film up to 2700Å in thickness as constant as possible; the residual variation was estimated to lie within a range of 4%.

Location of the ^{18}O.—The anodized foils were thinned by means of the sectioning technique (1) in such a way as to leave a series of steps in the oxide surface, as indicated schematically in Fig. 3. The area of each step, 4 × 10 mm, was defined by the scratch marks on the tantalum surface, and the oxide thickness at each step adjusted to a preselected value by controlling the time spent in the NH_4F-HF stripping solution. Once the desired thickness had been reached,

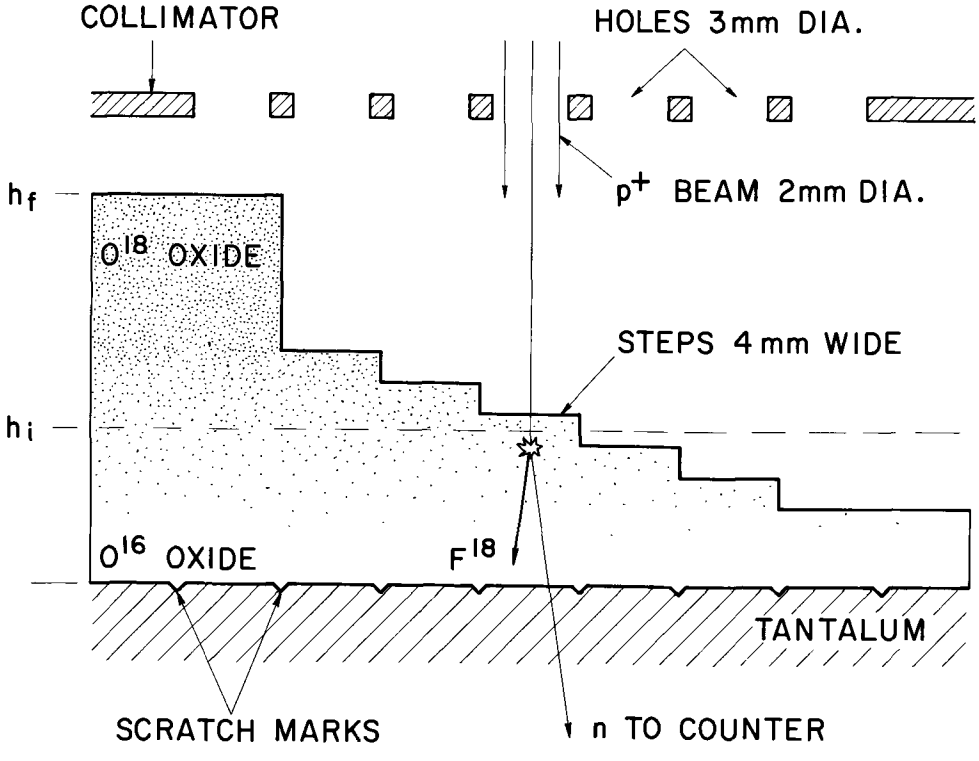

Fig. 3. Schematic diagram illustrating the measurement of an ^{18}O concentration profile by means of the $^{18}O(p, n)^{18}F$ reaction. The film was anodized initially to h_i in $H_2{}^{16}O$, and then to h_f in $H_2{}^{18}O$; one step was left at h_f, and the others stripped back to give a series of thicknesses about h_i. The scratch marks on the tantalum surface defined the area of each step.

the step was covered with Apiezon N grease to prevent further attack as thinning continued elsewhere; the grease was subsequently dissolved in trichlorethylene. Comparison of the intended thicknesses with those actually measured by the spectrophotometric technique showed that the difference was rarely more than 10Å and frequently less than 5Å. The uniformity of the thinning and the errors in the thickness measurements have been discussed elsewhere (1, 3, 4).

Two types of oxide samples were prepared for the present study. Those intended to investigate the gross features of the ^{18}O concentration profile were anodized first to 880Å in ^{16}O electrolyte, and then to more than 3000Å in ^{18}O electrolyte; steps of 150Å or more were then placed in the oxide surface to cover the whole range of thicknesses from 3000 to about 700Å. These samples showed that the ^{18}O profile was of the form II in Fig. 1, and so the second type of sample was designed to measure the mixing at the $^{16}O/^{18}O$ boundary. They therefore required much smaller steps of 10-20Å, centered about the initial thickness, normally 880Å, of ^{16}O oxide. This thickness was chosen as standard because it is close to the bottom of the range that can be continuously measured with spectrophotometer (1).

The composite $^{16}O/^{18}O$ oxides were thus thinned down, as illustrated in Fig. 3, to leave seven different thicknesses on each side of the tantalum foil, for a total of fourteen different thicknesses in all. By bombarding each thickness with the same dose of 3.042 MeV protons, the relative amount of ^{18}O beneath a given depth in the composite oxide could be determined. The results, in the form of neutron counts *vs.* oxide thickness remaining, described the integrated concentration profile, from which the ^{18}O profile itself could be obtained by differentiation.

Proton bombardments.—Four tantalum foils prepared as above were mounted longitudinally in an aluminum target holder. The latter was electrically insulated, so that the proton charge deposited in the tantalum foils could be passed to a current integrator as a measure of the proton dose. Collimating plates were placed about a centimeter away on each side of the foils, and twenty-eight 3 mm diameter holes bored in each plate at positions opposite the individual steps on each foil (Fig. 3). The whole assembly was then inserted into the target chamber of a High Voltage Engineering EM Van der Graaff accelerator.

To make a measurement, the proton beam was first focused to a spot 2 mm in diameter on a quartz viewing screen placed in front of the target assembly. By means of a rack and pinion, the target assembly could be moved so that any one of the twenty-eight positions could be selected for bombardment; the quartz was then removed, and the protons passed through the collimating holes to strike the oxide surface. Neutrons emitted in the $^{18}O(p, n)^{18}F$ reaction peak strongly in the forward direction, and were detected by means of a conventional long counter placed as close as possible behind the target chamber. The amount of material between the oxide film and the long counter was minimized to reduce neutron scattering; neutrons knocked out of the ^{18}O nuclei passed first through the underlying tantalum foil 0.015 in. thick, and then through the 1/16 in. aluminum end plate of the Van de Graaff vacuum system. The scattering was in any case small; on one occasion a 1/2 in. steel plate was inadvertently left under the end plate, and reduced the neutron counting rate by about 10%.

Measurements on a series of foils were made as follows. A standard sample, containing 490Å of 97.56% ^{18}O oxide, was bombarded first to establish the position of the resonance with respect to the energy scale of the accelerator; this sample was about 2 keV "thick" to 3.042 MeV protons. The energy region about 3.037 MeV was scanned in 10 keV steps, and, once the peak had been located, the proton energy was fixed 5 keV above, as illustrated in Fig. 2. The oxide steps on the prepared targets were then bombarded successively, going down one side of the target holder, rotating it through 180°, and back up the other side. The target assembly was then removed and replaced by its twin, carrying a new load of targets which were measured in the same way. Finally, when all positions on all prepared targets had been bombarded, the standard sample was again inserted in the proton beam to make sure that conditions had not changed in the course of the experiments; no significant discrepancies were in fact observed.

The proton dose was 150 μcoulombs at a beam current of about 1 μA; this corresponds to an implantation fluence of about 3×10^{16} $^1H^+/cm^2$ over the area implanted. A single dose of this magnitude had no discernible effect on the appearance of the foils, but the repeated doses applied to the standard changed the interference colors in such a way as to indicate a thickening. This thickening has been attributed to the deposition of carbon from traces of pump oil in the vacuum system (2), and had no effect on the neutron counting rate.

The total neutron count varied from a background of about 100 to a maximum of 90,000, and was subject to the following errors: (*i*) the usual statistical error, equal to the square root of the number of counts; (*ii*) inaccuracies in the measurement of the proton dose, due partly to contamination of the proton beam by other ions or by neutral hydrogen atoms, and partly to fluctuations in secondary electron emission by the target oxides; (*iii*) fluctuations in the efficiency of the neutron counter; (*iv*) fluctuations in the average proton energy and/or the energy spread, leading to fluctuations in neutron yield; and (*v*) variation of the beam position within the collimator holes, leading to variations in the number of neutrons generated in the foils, and also in the collimator itself. The collimator material was therefore of some importance, and originally gold was chosen on the ground that it is the only metal of high atomic number which does not support a surface oxide at room temperature. Experience showed, however, that the gold collimator gave a rather high background, and so it was replaced with one made of tantalum. The latter was chemically polished, and then treated with the $HF-NH_4F$ reagent to remove as much surface oxide as possible (9). This tantalum collimator gave a much lower neutron background, and proved satisfactory.

Duplicate measurements on several different samples showed that the average error was 2.1 times the statistical error [see (*i*) above] and so the former was taken as the standard error for the purposes of least squares fit analysis. There was, however, considerable variation between individual samples, due presumably to the effects of (*ii*)–(*v*).

Originally, it had been intended to bombard one side of the foils only. When the holder was modified to allow bombardment of both sides, the two orientations presented different geometries to the neutron counter. By bombarding the seven steps of a particular oxide film in both orientations, a conversion factor of 0.825 ± 0.006 (standard error) could be calculated. Since the oxide film was thinned alternately on each side of the foil, two seven-point samples could in principle be obtained; by applying the conversion factor, these could be combined in a single fourteen-point sample, which proved more suitable for analysis. On reversing the foil in the target holder, a second fourteen-point sample was obtained for comparison with the first; within experimental error, two such samples agreed.

Results

The experimental results were obtained as a series of neutron counts *vs.* oxide thickness remaining, their general form being illustrated in Fig. 4 and 5. These plots correspond to the integrated ^{18}O distribution in the oxide, and reference to Fig. 1 will show that they are most closely related to condition II or a combination of I and II. In order to eliminate the possibility of condition I alone, it is necessary to show that the mixing of the ^{16}O and ^{18}O populations in Fig. 5 is real, and not just an artifact due to uneven stripping of the oxide layers. The uniformity of the oxide stripping process has been studied in detail (1), and the magnitude of the irregularities is definitely not great enough (4) to account for the effects observed. Migration of the oxygen is therefore confirmed, and it most probably occurs via mechanism II; that is, the oxygen atoms all migrate in succession as space becomes available, so that their order is largely conserved. The system can then be regarded as a form of bulk diffusion, and has been analyzed mathematically in the Appendix.

The analysis predicts that the ^{18}O concentration profile should be an error function complement (erfc), and hence that the neutron count profile actually observed should be an integrated error function complement (ierfc). As indicated in Fig. 6, these functions involve five parameters, whose individual significance is as follows:

C(1), expressed in neutron counts/angstrom of oxide/150 μcoulombs of proton charge, is a proportionality constant relating neutron counts to ^{18}O enrichment.

C(2), measured in angstroms from the metal/oxide interface, defines the midpoint, or mode of the error function complement within the oxide film.

C(3), also in angstroms, is the standard deviation associated with the error function complement, and measures its dispersion about the mode.

C(4), in the same units as C(1), relates neutron counts to the natural ^{18}O background.

C(5), in neutron counts/150 μcoulombs of proton charge, are those due to impurities in the oxide and the underlying tantalum.

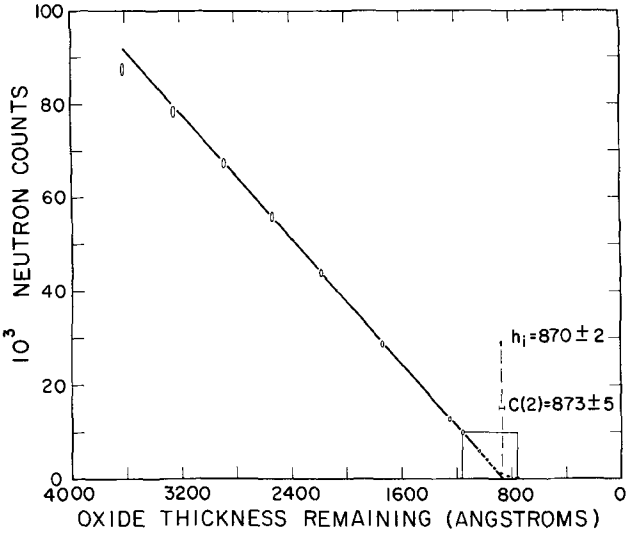

Fig. 4. Neutron counting profile obtained with the trial specimen in the first set of proton bombardments. Initial anodization to 870Å in $H_2{}^{16}O$, final anodization to 3622Å in $H_2{}^{18}O$, both at 1 mA/cm² in 0.01M KI. The error ellipses define the 95% confidence limits around the measured points, and the straight line has been fitted through the five points from 1254 and 2893Å. The small square in the lower right hand corner defines the area covered by Fig. 5.

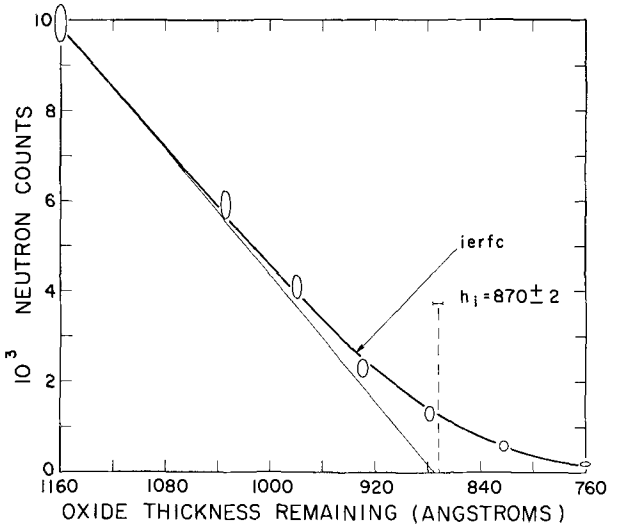

Fig. 5. Ten times magnification of the $^{16}O/^{18}O$ boundary region in Fig. 4, illustrating the fit of an integrated error function complement (ierfc) to the data points in the vicinity of h_i.

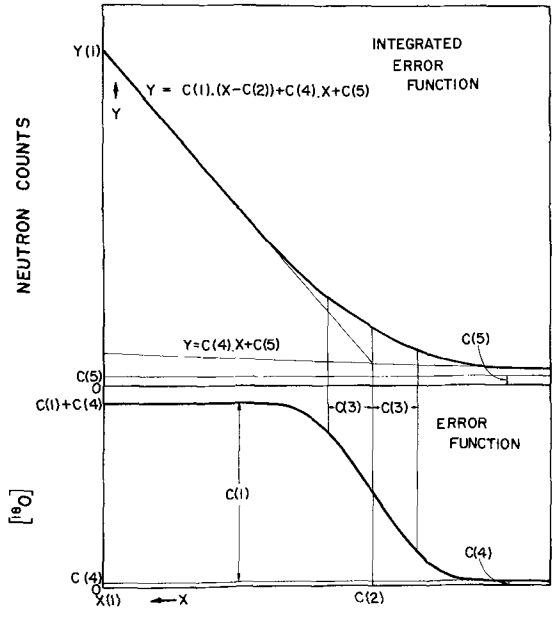

Fig. 6. The relationship between the error function complement

$$Y = (C(1)/\sqrt{2})\cdot\mathrm{erfc}[-(X-C(2))/\sqrt{2}\cdot C(3)] + C(4)$$

and its integral

$$Y = (C(1)\cdot C(3)/\sqrt{2})\cdot\mathrm{ierfc}[-(X-C(2))/\sqrt{2}\cdot C(3)] + C(4)\cdot X + C(5)$$

The relationships between these parameters are defined by a series of equations ([A-1]–[A-19]) in the Appendix, and these were tested experimentally in three sets of proton bombardments. The first set, i, was used to establish the best conditions for the experiments, which were then reproduced in sets ii and iii. The reproduction was not, however, completely accurate; the bombardment energy in set ii appeared to be slightly different, while the neutron counts in set iii were all 10% low due to the presence of the ½ in. steel plate.

The relationships tested were as follows:

(i) The neutron counts obtained from an oxide film formed entirely in ordinary water should be proportional to the oxide thickness remaining (Eq. [A-16]).

A sample of this kind was bombarded twice during set i, and once during set iii when, to save time,

Table I. Least squares fit of the straight line $Y_b(I) = C(4) \cdot X(I) + C(5)$ to the neutron counts vs. oxide thickness data for anodic tantalum oxide formed entirely in ordinary aqueous electrolyte (natural ^{18}O abundance 0.204%). Same sample used in both runs.

Run	Parameter C(4) (counts/Å)	Parameter C(5) (counts)	Number of data points fitted N	Fitting probability $p(\chi^2)_{N-2}$
i	0.061 ± 0.006	64 ± 10	28	0.084
iii	0.047 ± 0.013	66 ± 24	9	0.008

only nine of the fourteen positions were bombarded; the results are given in Table I. In view of the uncertainty in the calculation of the fitting probabilities (see Appendix), no good evidence against a linear relationship has been obtained, and so this has been assumed. In subsequent tests, these values of $C(4)$ and $C(5)$ have been used to correct the observed data for background, those for set ii being assumed identical to those for set i.

(*ii*) For an oxide formed first in ordinary water, and then in $H_2{}^{18}O$, the neutron counts due to the enrichment should, for oxide thicknesses much greater than the initial ^{16}O thickness, be linearly dependent on the oxide thickness remaining (Eq. [A-18]).

(iii) Furthermore, this linear relationship should extrapolate to zero counts when the remaining oxide thickness equals the initial thickness of ^{16}O oxide (Eq. [A-14] and [A-18]).

A trial specimen was prepared for the first set of proton bombardments by anodizing a tantalum foil to 870 ± 2Å in ordinary aqueous electrolyte, and then to 3622 ± 6Å in 97.56% $H_2{}^{18}O$. One side was stripped in approximately 400Å steps to leave seven thicknesses between 3622 and 1254Å, while the other was stripped to leave a series of thicknesses about 870Å. The observed neutron counting profiles for the two sides are illustrated in Fig. 4 and 5.

After correction for background, a straight line was fitted to the seven points on the first side, and the fitting probability found to be well below 0.001. The fit was therefore decidedly not acceptable, and reference to Fig. 4 shows why; the two points at the largest oxide thickness fall below an extension of the straight line drawn through the other five. The same sample was re-analyzed twice more in set ii, when this decrease in the neutron counts at the largest oxide thicknesses was not observed; all seven points could now be fitted to a straight line (fitting probabilities 0.041 and 0.064). The phenomenon was therefore peculiar to set i, and was almost certainly due to an erroneous setting for the incident proton energy. If this is too low, protons nearing the end of their track in a thick ^{18}O oxide will have an energy substantially below resonance, and so the neutron yield from these protons will be reduced.

Within experimental error, therefore, the results were consistent with a linear relationship between neutron counts and oxide thickness, and it but remained to obtain estimates for $C(1)$ and $C(2)$. Due to the variation in the average (p, n) cross section with oxide thickness, it was decided to fit a straight line repeatedly to the experimental data, dropping the point with largest oxide thickness between each fit, and to take $C(1)$ and $C(2)$ from that fit which gave the greatest fitting probability. "Best" estimates for $C(1)$ and $C(2)$ thus obtained are listed in Table II, from which it can be seen that $C(2)$ is, within twice the combined individual standard errors, identical to the initial ^{16}O oxide thickness, h_i. Similar but

Table II. Least squares fit of the straight line $Y_c(I) = C(1) \cdot (X(I) - C(2))$ to the neutron counts vs. oxide thickness data for an oxide film formed first in ordinary water (^{18}O abundance 0.204%) to h_i and then in water enriched with ^{18}O to an abundance of 97.56%. Neutron counts due to the enrichment (97.36%) were fitted only at oxide thicknesses greater than $h_i + 3 \cdot C(3)$; see Appendix for details.

iii	30.16 ± 0.34	923 ± 10	10	0.078

[a] Configuration in specimen holder reversed.

less accurate results were obtained using the ^{18}O enrichment of 11.23%.

Predictions (*ii*) and (*iii*) are thus verified.

(*iv*) For oxide thicknesses approximately equal to the original ^{16}O thickness, the neutron counting profile should have the form of an integrated error function complement (Eq. [A-17]).

(*v*) This ierfc function should have its mode at h_i (Eq. [A-14] and [A-17]).

For the purpose of fitting Eq. [A-17], $C(1)$ was taken from Table II as 33.2 ± 0.2 (standard error) for sets i and ii, and 30.2 ± 0.3 for set iii; $C(2)$ was taken as h_i with standard error $\sqrt{[(\epsilon(h_i))^2 + (0.00144\ h_i)^2]}$, where $\epsilon(h_i)$ is the random measurement error in h_i (1), while $(0.00144\ h_i)$ is the standard error due to the uncertainty in the refractive index (1,4). Reference to Table III will show that all but two of the twenty separate data samples had fitting probabilities greater than 0.025, and that the two exceptions were duplicated by acceptable fits. Within experimental error, therefore, the ierfc function, with $C(2) = h_i$, does adequately fit the experimental data, and so predictions (*iv*) and (*v*) have been confirmed experimentally.

(*vi*) The standard deviation of the ierfc function should be proportional to the square root of the thickness added in the $H_2{}^{18}O$ electrolyte, provided that the latter is not too small (Eq. [A-19] and discussion in the Appendix).

In testing for the relation between $C(3)$ and $(h_f - h_i)$, three of the eighteen acceptable fits in Table III were eliminated from consideration. The sample anodized by 26Å in the ^{18}O electrolyte was eliminated because $(h_f - h_i) < 5.C(3)$; and both samples from the specimen anodized between 256 and 1041Å were eliminated because the thickness measurements were atypical, for reasons described in the next section. A least squares fit of Eq. [A-19] to the remaining fifteen samples gave the constant of proportionality, β, as 1.725 ± 0.026Å$^{1/2}$ (standard error), with $p(\chi^2)_{14}$ as 0.845. The latter is more than adequate, and so prediction (*vi*) is established.

(*vii*) The standard deviation of the ierfc function should be independent of h_i provided h_i is not too small (Eq. [A-19] and discussion in Appendix).

This follows from the fit of Eq. [A-19] to the data in Table III, section B.

The oxide thicknesses for the first sample in section B had to be measured in first order. As noted elsewhere (1), first order minima are rather broad and

Table III. Least squares fit of the integrated error function complement $Y_e(I) = (C(1)\cdot C(3)/\sqrt{2})\cdot \text{ierfc}\ [-(X(I)-C(2))/\sqrt{2}\cdot C(3)]$ to the neutron counting profile with $C(2) + 2\cdot C(3) > X(I) > C(2) - 2\cdot C(3)$. The variation of $C(1)$ and $C(2)$ was restricted as described in the Appendix. When two results are quoted for the same specimen, the second was obtained by reversing the orientation in the target holder. Unless otherwise stated, the anodizing conditions were 1 mA/cm² in 0.01N KI at about room temperature.

[c] First figure obtained from thickness measurements in first order, the second using thickness measurements converted from second order; see text for details.

difficult to measure accurately; furthermore, the range of thicknesses that can be measured in the satisfactory 300-400 mμ region is limited to 197-330Å. As an added check, therefore, the oxide steps were incorporated from the starting thickness of 1041Å, so that their magnitude could be measured in second order. The stepped oxide was then thinned down in such a way as to place the middle step as close as possible to 256Å. If the oxide thins uniformly, the step heights measured in second order can be combined with the measured first order thickness for the middle step to calculate the final thickness for all the other steps. The estimates for $C(3)$ obtained from the two sets of measurements do not differ significantly from each other, or from those in the rest of section B, Table III.

All six relationships involving the ^{18}O tracer have thus been confirmed experimentally. Three additional factors were considered.

(*viii*) Current density.

From Eq. [A-4] and [A-5], the standard deviation of the ierfc function would appear to vary as the reciprocal of the current density, i. However, it also varies directly as the diffusion constant, D, and if D is linearly proportional to i, the ratio D/i will be constant. In that case, the standard deviation, $C(3)$, would be independent of the current density during the anodization process.

The data in Table III, section C, were used for the fit of Eq. [A-19], and the adequacy of the fit shows that $C(3)$ does not vary significantly with current density.

(*ix*) Isotopic ratios in oxide and electrolyte.

If there is no isotope effect during the incorporation of oxygen, the isotopic ratio in the oxide should be the same as that in the electrolyte.

From Eq. [A-14] and [A-15], $C(1)$ and $C(4)$ are proportional to the ^{18}O enrichment and the natural ^{18}O abundance, respectively. A comparison of neutron counting rates *vs.* ^{18}O enrichment of the electrolyte is given in Table IV. Least squares fits of straight lines passing through the origin gave a slope of 0.34 for sets i and ii, and 0.32 for set iii, but $p(\chi^2)_2$ was far less than 0.025 in both cases. The best that can be said, therefore, is that the isotopic ratios are approximately proportional.

(*x*) Kirkendall Effect.

The differing masses of ^{16}O and ^{18}O might lead to a difference in migration rate, and hence to a type of Kirkendall effect (16). This would be manifest as a neutron count profile significantly different from an ierfc function, for which there is no evidence.

Discussion

Nature of the oxygen migration.—The experimental results show quite clearly that the oxygen atoms move, and that they all move. Since the analysis is based on a statistical system in which a large number of atoms all make a series of small jumps, it follows that the mean distance traveled by each oxygen atom during each charge transfer event must be small compared to the total distance migrated. Just how small can be estimated, very crudely, from the following analysis.

Suppose that the mean distance between adjacent oxygen sites is a, and that the "high field approximation" (17) applies. It follows that the oxygen jumps will cluster about the axis of the field and in the forward direction; that is, towards the metal/oxide interface. The average distance jumped in the direction of the field will then be close to a; for simplicity, it will be assumed constant and equal to a. If the oxide thickens by an amount $(h_f - h_i)$, the leading ^{18}O atoms travel a distance $t_o\cdot(h_f - h_i)$, in an average of n jumps so that

$$n\cdot a = t_o\cdot(h_f - h_i)$$

A second equation including these quantities can be obtained by considering the standard deviations. That of the left hand side is $a\cdot\sqrt{n}$, as discussed for the derivation of Eq. [19] in Ref. (4); that of the right hand side is in fact $C(3)$, because it can be shown (18) that Eq. [A-11] describes the broadening of an infinitesimally thin layer of ^{18}O. Substituting for $C(3)$ by means of Eq. [A-19]

$$a\cdot\sqrt{n} = \beta\cdot\sqrt{(h_f - h_i)}$$

Solving for a

$$a = \beta^2/t_o = 3.9\text{Å}$$

Nearest neighbor oxygen distances in the crystalline forms of tantalum oxide range from 2.02 (19) to 3.19Å (20) with an average that appears to be about 2.7Å; the observed figure is therefore somewhat greater. Considering the crudity of the analysis, however, the agreement is quite reasonable. On this basis, then, it would appear that oxygen migrates by jumping from one site to the next.

Table IV. Comparison of neutron counting rates per angstrom of anodic oxide with the ^{18}O enrichment of the electrolyte, as quoted by the supplier (YEDA)

^{18}O enrichment e(%)	Runs i and ii $C(1)$ or $C(4)$	Run iii $C(1)$ or $C(4)$
0.204	0.061 ± 0.006	0.047 ± 0.013
11.23	4.15 ± 0.08	3.69 ± 0.04
97.36	33.2 ± 0.2	30.2 ± 0.3

The real situation is, however, much more complex. Results reported elsewhere (4) show that implanted noble gases behave in a very similar fashion to oxygen; that is, the noble gas atoms move, and it may reasonably be inferred that they all move. When the preceding analysis was applied to them, however, the results were absurd, and it was then concluded that their movement was a form of Brownian motion (4). If so, the migration of the oxygen may well proceed by two processes: the forced directional migration discussed so far, and a more or less random diffusion due to a Brownian-type motion.

This second process will have little or no effect on the ^{18}O profile mode, but it will contribute to the standard deviation. An estimate for this contribution may be obtained by assuming that the broadening parameter, β, associated with the motion of the noble gases varies with mass. Extrapolation of the data in Table III of Ref. (4) to oxygen of average mass 17 gives β as 1.37Å½, which may be compared with the observed value of 1.725 ± 0.026Å½. If the forced migration and Brownian motion are completely independent processes, the square of the observed β will be equal to the sum of the squares of its components; β for the forced migration alone will then be 1.05Å½, so that a would be 1.46Å. This calculation is, however, probably not justified, since the Brownian process is almost certainly a consequence of the forced migration, and therefore not independent of it.

The nature of the oxygen migration is thus rather obscure, but the present results are not inconsistent with the hypothesis put forward in the previous paper (4), that charge is transferred during the anodic oxidation of tantalum via the simultaneous movement of a group of atoms, both tantalum and oxygen. Such a process would require some mixing of the ^{16}O and ^{18}O populations, but would generally conserve their order, as is observed.

Conclusions

1. Concentration profiles for oxygen isotopes in anodic tantalum oxide can be measured with excellent precision by combining the sectioning technique for locating the isotope with a nuclear method for detecting it.

2. This scheme requires that the detection efficiency shall be independent of the oxide thickness. Oxygen-18 was detected by means of neutrons produced in the $^{18}O(p, n)^{18}F$ reaction; bombardment with 3.042 MeV protons ensured that the detection efficiency was sensibly constant.

3. On anodizing first in ^{16}O electrolyte and then in ^{18}O, it was found that the oxygen order was largely, but not completely, conserved.

4. The mixing of the ^{16}O and ^{18}O populations across the boundary between them could be analyzed very well in terms of forced diffusion from a constant source into a semi-infinite medium, thus confirming that oxygen migrates under the influence of the electric field.

5. The jump distance associated with the oxygen migration was found to be of the order of 4Å, which is little more than the expected nearest neighbor oxygen distance.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

APPENDIX

Theory of the migration.—The oxide film may be regarded as a semi-infinite medium, bounded by a plane corresponding to the oxide/electrolyte interface but otherwise extending to infinity. This concept is valid in discussing the ^{18}O migration provided that the metal/oxide interface is sufficiently far from the $^{16}O/^{18}O$ boundary that it does not influence the mixing of the populations; this would appear true for the experiments reported here. Arguments presented elsewhere (4) suggest that thermal diffusion is negligible at room temperature, and hence that the oxygen moves solely under the influence of the electric field present during anodization; that is, it is a forced migration, with the electrolyte acting as a constant source of ^{18}O. The diffusion system is one, therefore, of forced diffusion from a constant source into a semi-infinite medium.

The kinetics of forced diffusion have been discussed in detail by Boltaks (18), who treats the problem as free diffusion coupled with a superimposed drift velocity due to the applied field. For forced diffusion from a constant source into a semi-infinite medium, he cites the following equation

$$C(x,t) = \frac{C_o}{2}\left[\left(1 - \text{erf}\left(\frac{x - vt}{\sqrt{2}\sqrt{(2Dt)}}\right)\right) + \exp\left(\frac{vx}{D}\right)\cdot\left(1 - \text{erf}\left(\frac{x + vt}{\sqrt{2}\sqrt{(2Dt)}}\right)\right)\right] \quad [A\text{-}1]$$

where C is the concentration of the diffusing species at time t and distance x into the medium, C_o is the steady-state concentration of the diffusing species at the boundary plane $x = o$, v is the average velocity of the diffusing particles in the direction of the applied field, and D is the diffusion constant of the free component that arises in consequence of the concentration gradient set up by the forced migration.

The second term of Eq. [A-1] is effectively a perturbation due to the presence of the boundary plane; as t increases, it tends to zero. Computations were made to find out how rapidly it approached zero, using appropriate values of v and D calculated from the experiments. It turned out that the second term was considerably less than 1% of the first for all values of x once vt was greater than $5\cdot\sqrt{(2Dt)}$; that is, once the mean distance traveled by the leading particles, vt, was more than five times their standard deviation, $\sqrt{(2Dt)}$, about that mean. This condition was met in the present experiments, and so Boltaks equation reduces to

$$C(x,t) = \frac{C_o}{2}\left[1 - \text{erf}\left(\frac{x - vt}{\sqrt{2}\sqrt{(2Dt)}}\right)\right] \quad [A\text{-}2]$$

Application of Eq. [A-2] to the migration of oxygen in anodic oxides requires some changes in format, and these are illustrated schematically in Fig. 7. Suppose the reanodization in $H_2{}^{18}O$ be performed for a time, t, at constant current density, i, and that the oxide thickens from an initial thickness, h_i, to a final thickness, h_f. If the current efficiency is 100% (17), the charge passed will be related to the oxide formed by Faraday's law; that is

$$it = (\rho\mathbf{F}/Q)\cdot(h_f - h_i) \quad [A\text{-}3]$$

where ρ is the oxide density, $\mathbf{F}$ the Faraday constant, and Q the equivalent weight of Ta_2O_5. The factor $\sqrt{(2Dt)}$ in the error function of Eq. [A-2] can then be replaced by $\beta\sqrt{(h_f - h_i)}$ where β is given by

$$\beta = \sqrt{(2D\rho\mathbf{F}/iQ)} \quad [A\text{-}4]$$

Examination of Fig. 7 will show that by changing the reference plane from the oxide/electrolyte interface to the metal/oxide interface, and reversing the sense of the axes, the quantity $(x - vt)$ in Eq. [A-2] can be replaced by $-(h - h_i)$, where h is a variable measured relative to $h = o$ at the metal/oxide interface.

Equation [A-2] then becomes

$$C(h, h_f - h_i) = \frac{C_o}{2}\left[1 - \text{erf}\left(\frac{-(h - h_i)}{\sqrt{2}\cdot\beta\sqrt{(h_f - h_i)}}\right)\right] \quad [A\text{-}5]$$

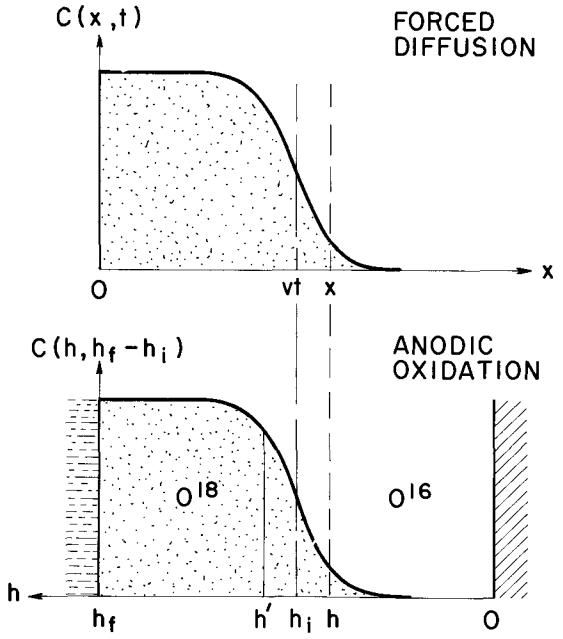

Fig. 7. Diagram illustrating the relation between the quantities used in the theory of forced diffusion and those used in the anodic oxidation.

Substituting

$$\sigma = \beta\sqrt{(h_f - h_i)} \qquad [A\text{-}6]$$

Eq. [A-5] becomes

$$C(h, h_f - h_i) = (C_o/2)\cdot\mathrm{erfc}(-(h - h_i)/\sqrt{2}\cdot\sigma) \qquad [A\text{-}7]$$

Equation [A-7] describes the ^{18}O profile to be expected if the oxygen migrates by forced diffusion. The neutron counts actually observed, however, will be proportional to the integral of this equation; thus if the oxide is thinned from h_f to a certain thickness h', the neutron counts, K, will be given by

$$K(h') = \int_o^{h'} P\cdot(C_o/2)\cdot\mathrm{erfc}(-(h - h_i)/\sqrt{2}\cdot\sigma)\cdot dh \qquad [A\text{-}8]$$

where P is a constant of proportionality, determined by the cross section for the $^{18}O(p, n)^{18}F$ reaction and the efficiency of the neutron counter. The integration is taken from the metal/oxide interface at $h = o$ to the existing oxide surface at h' (Fig. 7). If the ^{18}O concentration in the metal is assumed zero, the lower limit may be changed to $-\infty$ without affecting the value of $K(h')$. Replacing $-(h - h_i)/\sqrt{2}\cdot\sigma$ by y, and making the appropriate substitutions, Eq. [A-8] becomes

$$K(h') = \int_\infty^{-(h'-h_i)/\sqrt{2}\cdot\sigma} P\cdot(C_o/2)\cdot\mathrm{erfc}(y)\cdot(-\sqrt{2}\cdot\sigma)\cdot dy \qquad [A\text{-}9]$$

Reversing the limits of the integration

$$K(h') = (\sigma P\, C_o/\sqrt{2})\cdot\int_{-(h'-h_i)/\sqrt{2}\cdot\sigma}^{\infty}\mathrm{erfc}(y)\cdot dy$$

$$= (\sigma P\, C_o/\sqrt{2})\cdot\mathrm{ierfc}(-(h' - h_i)/\sqrt{2}\cdot\sigma) \qquad [A\text{-}10]$$

Equation [A-10] describes the expected variations in neutron counts as a function of distance, h', from the metal/oxide interface. For reasons given in the discussion of Eq. [A-1], neither Eq. [A-7] nor [A-10] is strictly correct when $(h_f - h_i)$ is small, for then the perturbing effect of the oxide/electrolyte boundary cannot be ignored. There must also be a perturbing effect due to the metal/oxide boundary when h_i is very small, and although no calculations have been made, it seems reasonable to suppose that the two perturbations would be similar. Equations [A-7] and [A-10] should therefore be valid provided both $(h_f - h_i)$ and h_i are greater than about $5\beta\cdot\sqrt{h_f - h_i}$.

Least squares fitting procedure.—These erfc and ierfc functions are the first and second integrals of a normal distribution. Using the nomenclature of previous papers (3, 4) the parent normal distribution may be written

$$Y(I) = C(1)/(\sqrt{(2\pi)}\cdot C(3))\cdot\exp[-(-(X(I) - C(2))/\sqrt{2}\cdot C(3))^2] \qquad [A\text{-}11]$$

where the parameter $C(1)$ is a normalizing constant, $C(2)$ the modal value, and $C(3)$ the standard deviation. Integration of this equation gives

$$Y(I) = (C(1)/2)\cdot\mathrm{erfc}[-(X(I) - C(2))/\sqrt{2}\cdot C(3)] + C(4) \qquad [A\text{-}12]$$

where $C(4)$ is a constant of integration. On integrating again

$$Y(I) = (C(1)\cdot C(3)/\sqrt{2})\cdot\mathrm{ierfc}[-(X(I) - C(2))/\sqrt{2}\cdot C(3)] + C(4)\cdot X(I) + C(5) \qquad [A\text{-}13]$$

where $C(5)$ is another constant of integration. The relationship between Eq. [A-11] and [A-12] has been illustrated in Fig. 5 of Ref. (3), while that between Eq. [A-12] and [A-13] is illustrated in Fig. 6 of the present paper.

Equation [A-13] is the function that must be fitted through the experimental points $I = 1, 2, \ldots\ldots N$. The first term on the right hand side corresponds to Eq. [A-10], so that

$$\begin{aligned} C(1) &\equiv P\cdot C_o \\ C(2) &\equiv h_i \\ C(3) &\equiv \sigma \\ X(I) &\equiv h' \end{aligned} \qquad [A\text{-}14]$$

$C(4)$ accounts for the ^{18}O present in natural abundance, C_n, in the ^{16}O layer, so that

$$C(4) = P\cdot C_n \qquad [A\text{-}15]$$

while $C(5)$ accounts for neutrons produced from the underlying tantalum and any impurities that may be present.

Equation [A-13] contains five adjustable parameters, which is too many to be characterized successfully with a maximum of only fourteen points per sample. Fortunately, two of them, $C(4)$ and $C(5)$, can readily be eliminated. If a tantalum specimen is anodized solely in ordinary water, the neutron counting profile due to the natural ^{18}O will be

$$Y_b(I) = C(4)\cdot X(I) + C(5) \qquad [A\text{-}16]$$

The least squares fit of a straight line through the experimental points from such a sample will then provide estimates for $C(4)$ and $C(5)$, so that by subtracting Eq. [A-16] from Eq. [A-13]

$$Y_e(I) = Y(I) - Y_b(I) = (C(1)\cdot C(3)/\sqrt{2})\cdot\mathrm{ierfc}(-(X(I) - C(2))/\sqrt{2}\cdot C(3)) \qquad [A\text{-}17]$$

where the $Y_e(I)$ are the neutron counts due to the ^{18}O enrichment.

When $X(I) << C(2)$, ierfc $[-(X(I) - C(2))/\sqrt{2}\cdot C(3)]$ tends to zero, and so $Y_e(I)$ also tends to zero. When $X(I) >> C(2)$, however, ierfc $[-(X(I) - C(2))/\sqrt{2}\cdot C(3)]$ tends to $2\cdot(X(I) - C(2))/\sqrt{2}\cdot C(3)$, so that Eq. [A-17] becomes

$$Y_e(I) = C(1)\cdot(X(I) - C(2)) \qquad [A\text{-}18]$$

which is a straight line. For least squares fitting purposes, Eq. [A-18] was indistinguishable from [A-17] once $X(I) > C(2) + 3\cdot C(3)$. If Eq. [A-18] is fitted to the appropriate data, estimates for $C(1)$ and $C(2)$ can be obtained; the latter is expected, from Eq. [A-14], to equal the initial ^{16}O oxide thickness, h_i.

In making the least squares fit of a function with several parameters, it frequently happens that information on some of the parameters is already available, as in the case of $C(2)$ above. Such information is wasted if the least squares fit is used to obtain

additional estimates for these parameters; *i.e.*, if the parameters are allowed to vary freely. By fixing the parameters at known values, or by allowing them to vary within limits dictated by known standard errors, such information can be incorporated in the least squares fitting program. The more the variation of the parameters is restricted, the less accommodating does the procedure become, and the greater the difficulty in obtaining a satisfactory fit. The most stringent goodness-of-fit test, therefore, is obtained by restricting the variation as much as possible.

This principle has been applied in the least squares fit of Eq. [A-17]. It was assumed that $C(2)$ should be equal to h_i, and this assumption was then incorporated in the fitting procedure by restricting the variation of $C(2)$ about h_i to the standard error in h_i. Values of $C(1)$ together with their errors were obtained from least squares fits of Eq. [A-18], and these were incorporated in similar fashion. Equation [A-17] was fitted to data with $C(2) + 2 \cdot C(3) > X(I) > C(2) - 2 \cdot C(3)$, while Eq. [A-18] was fitted only to data with $X(I) > C(2) + 3 \cdot C(3)$; the information used to obtain $C(1)$ was not therefore used again in fitting Eq. [A-17].

Operationally, the least squares fitting was performed as described in Ref. (4), with the error, $EX(I)$, in $X(I)$ taken proportional to 0.067 times the difference between the "kick" wavelengths (1), and the error, $EY(I)$ in $Y(I)$ as 2.1 times the statistical counting error. As noted earlier, the multiplication factor in $EY(I)$ tends to vary from sample to sample, and since the fitting probabilities are extremely sensitive to the magnitudes of the experimental error, their correct values are in some doubt. Furthermore, the use of restricted parameters raises a prob'em in connection with the number of degrees of freedom, which is of importance for calculating the χ^2 probability (3). Since there is no obvious answer to this, the most unfavorable case was assumed; that is, the number of degrees of freedom in the fit of Eq. [A-17] was reduced to a minimum by treating $C(1)$ and $C(2)$, for this purpose only, as varying freely. The actual magnitude of the individual χ^2 probabilities is fortunately not of great significance; what does matter is whether they are, in general, greater or less than the chosen acceptance level of 0.025 (3). And for that purpose, the present computations were good enough.

By combining Eq. [A-6] and [A-14]

$$C(3) = \beta\sqrt{(h_f - h_i)} \qquad [A\text{-}19]$$

so that $C(3)$ is expected to be proportional to the square root of the oxide thickness formed in the ^{18}O electrolyte.

The Choice and Evaluation of Phosphors for Application to Lamps with Improved Color Rendition

J. J. Opstelten, D. Radielović, and W. L. Wanmaker*

N. V. Philips' Gloeilampenfabrieken, Eindhoven, The Netherlands

ABSTRACT

The optimum color rendering index was calculated both for low- and high-pressure mercury vapor lamps by adding spectral lines or emission bands of various wavelengths to the relevant mercury spectrum. The optimum wavelengths were calculated. In fluorescent lamps they depend both on the type of lamp and on the luminous efficacy. In high-pressure mercury-vapor lamps it is desirable to add both a blue and a red emission to the mercury spectrum. From these specifications a certain choice of phosphors to be used can be made. The merits of these phosphors are evaluated and some suggestions are given concerning the design of lamps with an improved color rendition.

The choice of the phosphors to be used in fluorescent lamps with improved color rendition can be made by constructing lamps with various phosphor blends and evaluating the color rendering indices. This is a rather complicated and time-consuming method, however. Accordingly, when fluorescent lamps with improved color rendition were introduced in an early stage, calculations were carried out with "theoretical" lamps (1, 2). For instance Kruithof and Ouweltjes (1) studied the color rendition (using both the spectral band method and the behavior of test samples as a criterion) of mixtures of calcium halophosphate, magnesium arsenate, and willemite phosphors. When using these phosphor blends they found from their calcula-

Key words: color rendition, fluorescent lamps, phosphors.

tions that it is useful for the emission of the violet and blue mercury emission lines (404.7, 407.8, and 435.8 nm) to be partially absorbed. In another paper, Ouweltjes (2) describes the way in which the spectral power distribution of lamps can be computed and their color rendition with respect to test color samples evaluated by starting with various mixtures of three phosphors.

Several papers have been published in recent years in which the optimization of the spectral power distribution of lamps is reported, in order to achieve improved color rendition. For instance, Koedam *et al.* (3), Thornton (4), and Koedam *et al.* (5) calculated the optimum combinations of three spectral lines or emission bands for light sources of different correlated color temperatures. For fluorescent lamps, Walter (6) calculated the optimum for two emission bands to which the low-pressure mercury-vapor spectrum was added. Koedam *et al.* (5) calculated the General Color Rendering Index (R_a) for fluorescent lamps, using the emission bands of existing phosphors.

In the present optimization study the spectrum of the mercury discharge was taken as a starting point, both for low- and high-pressure mercury-vapor lamps. Optimum combinations of the mercury spectrum and spectral lines or emission bands were calculated. These calculations permit conclusions to be drawn about the required emission characteristics of the phosphors to be used. This leads to a choice of certain phosphors, the merits of which can be evaluated by using the same computer program as used for the optimization study.

Experimental

Optimization of the Color Rendition of Fluorescent Lamps

The work on fluorescent lamps was restricted to the three current types, viz., Warm White, Cool White, and Daylight. The optimization was carried out by adding two or three spectral lines or emission bands to the visible spectrum of the 40W low-pressure mercury-vapor discharge as it is found in a fluorescent lamp. The relative spectral power distribution in the visible part of this spectrum is given in Table I. It corresponds to chromaticity co-ordinates: x; $y = 0.221$; 0.208. The exciting power (P_e) of the mercury discharge appears to be: $P_{e(253.7\ nm)} = 45 \times P_{(435.8\ nm)}$ (7). P_e determines the number of ultraviolet photons available for the excitation of the phosphor.

The General Color Rendering Index (R_a) was calculated in accordance with the C.I.E. Publication 13 (8). For this purpose the visible wavelength region was divided in 5 nm intervals, the centers of these intervals lying at 382.5, 387.5, . . . 742.5 nm.

Optimization by adding two spectral lines.—Two spectral lines of varying wavelengths were added to the visible mercury spectrum of the fluorescent lamp. The wavelengths of the lines were varied in steps of 5 nm. As the chromaticity co-ordinates of the total spectrum are given, it follows from colorimetric principles that the intensities of the two lines with respect to that of the mercury spectrum are fixed by their chromaticity co-ordinates. The luminous efficacy of the resulting spectrum can be calculated by considering the lumen contribution of the added lines.

Optimization by adding three spectral lines or emission bands.—The relative intensity of three spectral lines or emission bands added to the mercury spectrum of the fluorescent lamp are not defined entirely by the prescribed chromaticity co-ordinates of the lamp under consideration.

In a 40W fluorescent lamp about 200 lumens stem from the mercury spectrum. Since commercial fluorescent lamps with an improved color rendition rates at about 50 lm/W, we have assumed in most calculations that the lumen contribution of the added light (either spectral lines or emission bands) is nine times that of the mercury spectrum. This leads to 2000 lm (50 lm/W) for a 40W fluorescent lamp. It can also be calculated which fraction (we called this the quantum-conversion fraction: Q) of the ultraviolet photons available is converted into visible light. When applying a phosphor in a lamp a reasonable value of Q is 0.80, since this value corresponds to an absorption of the exciting radiation of 90% and a quantum efficiency (254 nm excitation) of 90%. If in a calculation a Q value lower than 0.80 is found, it means that a theoretical lamp can be made with a higher efficacy than 50 lm/W.

In the case of emission bands being added to the mercury spectrum, the form of the bands was taken as Gaussian when the number of emitted photons was plotted *vs.* photon energy, following the method used by Walter (6).

Table I. Relative spectral power distribution of the low-pressure mercury-vapor discharge in the visible part of the spectrum

Wavelength (nm)	Power P (rel. units)
404.7	382
407.8	27
435.8	1000
546.1	483
578.1	153

Optimization of the Color Rendition of the Color-Corrected High-Pressure Mercury-Vapor Lamp

In the optimization of the color-corrected high-pressure mercury-vapor lamp we started from the visible spectrum of a 400W lamp. The optimum color rendering index was calculated by adding one or two spectral lines or emission bands with varying wavelengths to this spectrum.

The exciting ultraviolet radiation of a high-pressure mercury-vapor lamp consists of both line and continuum radiation which extend to 400 nm. This implies that phosphors with a broad excitation spectrum will be most suitable.

In the calculations it was assumed that all ultraviolet photons available (emitted between 200 and 310 nm) are used for conversion into visible light, *i.e.*, $Q = 1$. In contrast to the fluorescent lamps the chromaticity co-ordinates of the color-corrected high-pressure mercury-vapor lamp have not been standardized. Therefore the spectral lines or emission bands were added at constant Q value.

Results and Discussion

Fluorescent Lamps

The results of the optimization study by adding two and three spectral lines are given in Tables II and III, respectively. In these tables the optimum wavelengths of the spectral lines are given, together with the General Color Rendering Index (R_a), the R_9, . . . R_{14} values, and the value of Q. The first solution of Table II gives the optimum R_a value, yielding however a very low R_9 value. As in practice the color rendering of saturated red object colors (R_9) is important, and in fact is often one of the most important criteria in color rendition. A second solution is also given in Table II. This is a kind of compromise solution yielding a higher R_9 and a somewhat lower R_a value.

It follows from Table II that in the case of the addition of two spectral lines to the low-pressure mercury-vapor spectrum an optimum color rendition can only be reached with an incomplete utilization of the ultraviolet photons available (*i.e.*, Q has a low value). This leads to a low lumen/watt value.

Table III, however, shows that both a higher efficacy and a much better color rendition can be achieved by adding three spectral lines instead of two. Since in our calculations the mercury spectrum of the fluorescent lamp has been included, a better color rendition is achieved than in the case of only three spectral lines (3, 4). Comparing the optimum wavelengths of Table

$$^*Q = \frac{\text{number of photons emitted}}{\text{number of ultraviolet photons available}}.$$

III with those of a pure three-line spectrum it appears that the addition of the mercury spectrum shifts the added blue line to longer wavelengths, viz., a shift of 10-30 nm being observed. This is due to the presence of the blue mercury lines.

It can be seen from Table III that the value of Q is low, viz., about 0.50. Therefore calculations were carried out with a lumen contribution of the added light (as a percentage of the total light output) above 90% (as used in Table III). The result is that in the case of a Warm White fluorescent lamp an efficacy of 75 lm/W can be reached with $R_a = 90$, but the color rendering of the yellow-green saturated color is somewhat decreased ($R_{11} \sim 40$).

The color rendition of a fluorescent lamp can be further improved by adding spectral emission bands instead of spectral lines to the mercury spectrum. It can be seen from Table IV that in the case of three emission bands with the same bandwidth the color rendition of both Daylight and Cool White fluorescent lamps increases by broadening the emission bands. With Warm White fluorescent lamps, however, such a broadening of the emission bands leads to a decrease of the color rendition. This is due to the fact that with the use of broad-emission bands the required blue-green emission band is located at a longer wavelength. As a result a gap in the spectrum of the theoretical lamp exists between this added blue-green band and the blue mercury line leading to a decrease of the color rendition. When absorbing a part of the blue mercury emission lines, however, this gap is narrowed and as a consequence the color rendition improves (see Table

$$^*Q = \frac{\text{number of photons emitted}}{\text{number of ultraviolet photons available}}.$$

** $\overline{R_{14}}$ means the average of $R_1 - R_{14}$.

IV). When adding emission bands of varying bandwidths, the following picture can be deduced from Table IV. When using a broad-emission band and two narrower ones (see Table IV, No. 5, 6, and 7) nearly the same color rendition can be obtained as in the case with three broad-emission bands. If the broad-emission band is a blue or a green one, the calculated Q value is lower than in the case of a broad, red-emission band, due to the relatively low luminous efficacy of the latter band. For the same reason the combination of a broad, blue- and a broad, green-emission band with a very narrow, red-emission band is most favorable for obtaining both good color rendition and a high efficacy (see No. 8, 9, and 10 from Table IV).

Since the Q values calculated for an efficacy of 50 lm/W are lower than 80%, lamps with higher efficacies might be made.

Summarizing the results of Table IV the combination of a good color rendition and a high efficacy in a fluorescent lamp can be reached with a narrow-band red-emitting phosphor combined with blue- and green-emitting phosphors with both or either having a broad-emission band (see cases 5 and 6 in Table IV). The location of the bands depends on the type of fluorescent lamps, the required peak wavelengths shifting to longer wavelengths as the color temperature decreases. The location of the bands not only depends on their own widths but also on the widths of the neighboring bands. Finally it may be remarked that it follows from our calculations that the location of a band becomes more critical as the width of the band decreases.

A more detailed discussion of the results obtained by this optimization study will be given elsewhere (9).

Choice and evaluation of the phosphors required.—The requirements of the phosphors to be used in fluorescent lamps can be deduced from the data of Table IV.

When we make a choice among the existing phosphors, we should also keep in mind that Table IV applies to single Gaussian bands. In practice in many cases the spectral power distribution of phosphors covers either several separate bands (No. 7-9 from Table V) or partly overlapping bands (No. 10 from Table V). About 30 phosphors were evaluated. The phosphors giving the best results are tabulated in Table V. Only numbers 2, 9, and 10 are conventional lamp phosphors, the others being recently discovered new phosphors, such as Tb-activated $CaNaBO_3$ (10), showing a poor performance in lamps. $SrWO_4$-Tb,Na (11) is also a new phosphor, which should give a good maintenance in lamps. $(Ba,Mg)Al_2Si_2O_8$-Eu^{2+} is a blue-emitting phosphor with a high quantum efficiency (12).

The merits of various phosphor blends were evaluated by means of the same computer programmes as used in the optimization study.

Red phosphor.—The required emission peak is located at 618-624 nm. Therefore the $Y(P,V)O_4$-Eu^{3+} (phosphor No. 9 from Table V) is well suited.

Green phosphor.—Using a narrow-band phosphor the maximum wavelength is located at about 560-570 nm (see No. 5 from Table IV) and in the case of a broad-band phosphor at 525-560 nm depending on the type of the fluorescent lamps involved. Up until now we have not found any suitable narrow-band green-emitting phosphor at the required wavelength. The Tb-activated phosphors (No. 7 and 8 from Table V) have their emission peaks at too short a wavelength. As far as the broad-band-emitting phosphors are concerned, no good choice is available. The emission peak of the Tb-phosphors matches the requirements but their emission bands are too narrow.

Blue phosphor.—Using a narrow-band phosphor the maximum required wavelength lies at 460-490 nm and with a broad-band phosphor at 480-530 nm. No narrow-band blue-emitting phosphors of the right wavelength peak are available. $BaZrSi_3O_9$-Eu^{2+} fulfills the location of the emission band, but it has a broad-emission band. $(Ba,Sr)Si_2O_5$-Eu^{2+} (No. 6 from Table V), however, fulfills the requirements of a broad-band green-emitting phosphor (required wavelength 505 nm).

From the foregoing it might be concluded that there is some need for a narrow-band blue-emitting phosphor ($\lambda_{max} \sim$ 460-490 nm), a narrow-band green-emitting phosphor ($\lambda_{max} \sim$ 560-570 nm), and a broad-band-emitting one ($\lambda_{max} \sim$ 525-560 nm).

Evaluation of various phosphor blends.—Cool White fluorescent lamps (Table VI).—According to the cal-

[a] The numbers refer to the list of phosphors given in Table V.

[b] — means: lamp cannot be made, since a Q value above unity is required.

culations the combination of phosphors 3, 7, and 9 gives quite a satisfactory result. The same applies to the combination of phosphors 4, 7, and 9. Both combinations are broad-band blue-, narrow-band green-, and narrow-band red-emitting phosphors. Although the emission of the $(Sr,Mg)_3(PO_4)_2$-Sn (No. 10) not only consists of a red band but also contains an emission peak at about 550 nm, the combination of phosphors 3, 6, and 10 (giving a very high R_a) illustrates the aforementioned results that a combination of a high R_a and a high luminous efficacy can only be reached when using a narrow-band red-emitting phosphor.

Daylight fluorescent lamps (Table VII).—Here again the evaluation corresponds to the foregoing calculations. Since $SrWO_4$-Tb,Na contains more blue radiation than phosphor No. 7 ($CaNaBO_3$-Tb), the combination of phosphors 1, 8, and 9 is more favorable than 1, 7, and 9. Combination of phosphors 2, 6, and 10, containing three broad emission band phosphors, is also quite a good one, but as discussed earlier, with the broad red emission band the luminous efficacy is too low (see Q-value = 0.95 at a calculated efficacy of 75 lm/W). Combination of phosphors 3, 7, and 9, consisting of a broad blue emission band and both a narrow green emission band and a red one is also suitable.

Warm White fluorescent lamps (Table VIII).—In this case also the expectations are fulfilled, *e.g.*, combination of phosphors 3, 7, and 9 is a good one. When using phosphor No. 10 as a broad-band red emitter, the combination of a high luminous efficacy and an excellent color rendition could only be reached by the partial absorption of the blue radiation of the mercury lines.

In order to substantiate the afore-mentioned theoretical calculations some test lamps were made. The properties of the lamps were consistent with the calculations: *e.g.*, it was calculated for a Warm White fluorescent lamp that a Color Rendering Index of 94 should be reached by using a mixture of a broad red-emitting phosphor ($\lambda_{max} \sim 625$ nm) and a narrow green-emitting one ($\lambda_{max} \sim 505$ nm). Making fluorescent lamps (color temperature 3000°K) with a mixture of 86 w/o (weight per cent) of $(Sr, Mg)_3(PO_4)_2$-Sn (phosphor No. 10 of Table V) and 14 w/o of $Mg(Ga, Al)_2O_4$-Mn (phosphor No. 5 of Table V) with a Color Rendering Index of 92 and an efficacy of 52 lm/W could be reached.

Color-Corrected High-Pressure Mercury-Vapor Lamps

Adding spectral lines to the mercury spectrum.—In general, it is desirable for the color point of the high-pressure mercury-vapor lamp to be located close to the Black Body Locus. It follows from Fig. 1 that this can be realized by adding to the spectrum of a 400W HPMV lamp a red spectral emission line with a wavelength between 595 and 625 nm. A longer wavelength is both unnecessary and undesirable, since it lowers the lumen output of the lamp too much. The color point of the high-pressure mercury-vapor lamp is also located close to the Black Body Locus when a blue spectral line with a wavelength between 460 and 470 nm has been added to the mercury spectrum (see Fig. 1). This will lead, however, to a high color temperature, which is unacceptable in practice due to the poor color rendering of red objects. Figure 2 shows that the color rendition of a HPMV lamp can be improved by adding to the mercury spectrum either a red spectral line ($\lambda_{max} \sim 620$ nm) or a blue spectral line ($\lambda_{max} \sim 480$ nm). Figure 3 shows the color rendition of HPMV lamps in which both a blue spectral line (with varying wavelength) and a red spectral line ($\lambda_{max} \sim 622.5$ nm) are added to the mercury spectrum. The conclusion can be drawn that about 30% of the red spectral line has to be replaced by a blue or bluish-green one ($\lambda_{max} \sim 485$ to ~ 520 nm), in accordance with the results of Thornton (23). Since the color point of the lamp should lie near the Black Body Locus, a blue emission of about 480-495 nm is to be preferred as is illustrated in Fig. 4.

Evaluation of phosphors.—In evaluating phosphors for color-corrected high-pressure mercury-vapor lamps one should not only consider the spectral requirements of the phosphor (as discussed above) but also its suitability for use in these lamps. The special requirements for a phosphor to be used in this type of lamp are: (*i*) high brightness at elevated temperature (see Fig. 5 for the brightness at elevated temperature of some blue-emitting phosphors); (*ii*) an efficient excitation at both 254 nm and 365 nm radia-

tion; and (*iii*) good stability against the intense ultraviolet radiation.

It was shown in Fig. 2 that the most pronounced improvement in color rendition can be achieved by adding a red spectral line to the mercury spectrum. In accordance herewith it has been common practice for several years to coat the outer bulb of the HPMV lamp with a red-emitting phosphor, such as $Y(P,V)O_4$-Eu (17, 18). Since Fig. 3 showed that a further (although rather small) improvement can be achieved by adding also a blue emission, the merits of mixtures of $Y(P,V)O_4$-Eu with some blue-emitting phosphors

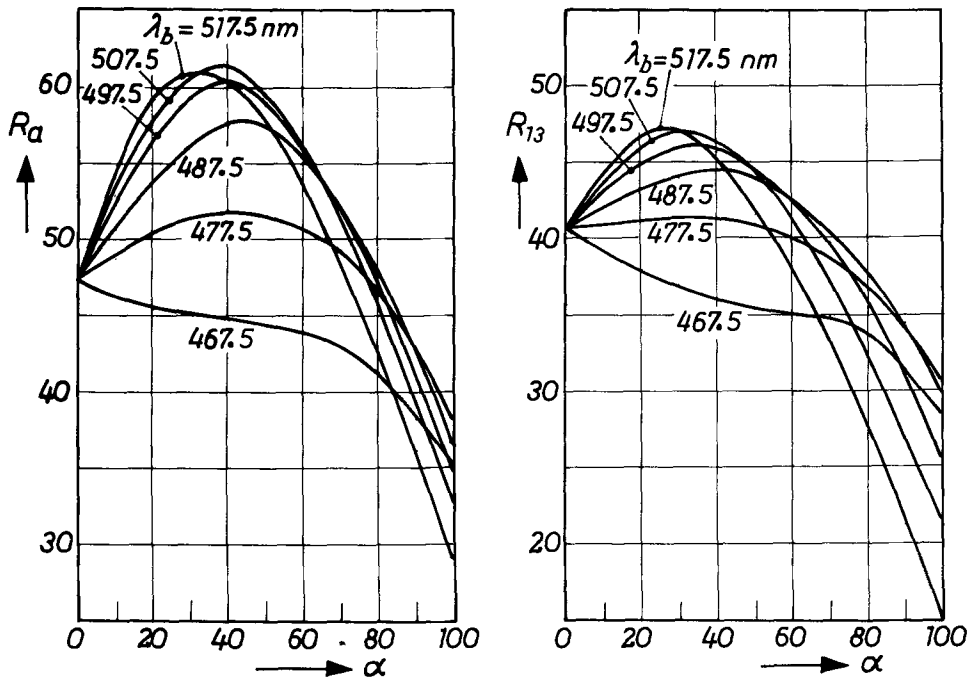

Fig. 3. Effect of addition of (1 — α) per cent of a red spectral line (λ ~ 622.5 nm) and α per cent of blue spectral lines of various wavelengths on the color rendition of a 400W HPMV lamp. All calculations: Q = 0.75.

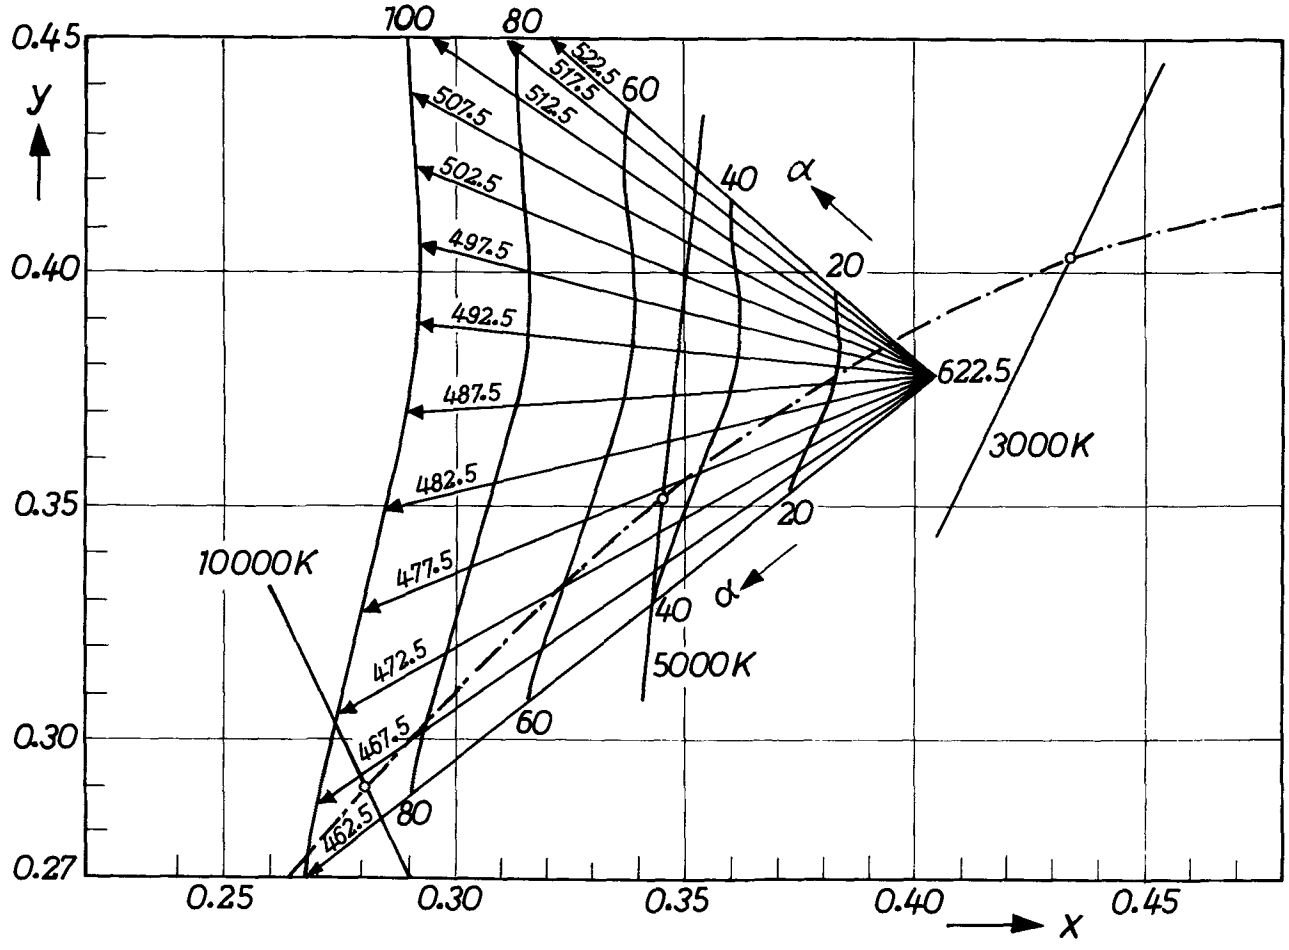

Fig. 4. Chromaticity co-ordinates of a 400W HPMV lamp to which a red (λ ~ 622.5 nm) spectral line of (1 — α) per cent and blue spectral lines of α per cent of various wavelengths are added. All calculations: Q = 0.75.

have also been evaluated. Phosphors were chosen having a high brightness at elevated temperatures, as shown in Fig. 5.

The Y(P,V)O_4-Dy phosphor of Fig. 6 was made with the addition of boric acid (in the same way as the corresponding Eu-activated phosphor). This preparation method gives a higher intensity of the 484 nm emission line with 254 nm excitation, viz., intensity ratio of the 484 and 573 nm emission line in our phosphor 0.65-0.70, whereas a ratio of about 0.40 was reported by Faria and Palumbo (24).

The merits of europium-activated strontium chlorapatite (22) were also evaluated, since Thornton (23) reported that a better color rendering of the human complexion and an R_a value of 67 can be reached with this phosphor (λ_{max} ~ 450 nm). The results of the calculations are given in Fig. 6 and Table IX. It follows from these data that the best results, as far as color

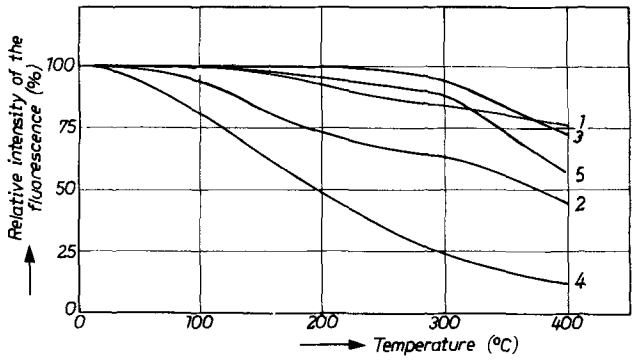

Fig. 5. Variation of fluorescent intensity with temperature for various blue-emitting phosphors.

x/y	Curve	Phosphor	λ_{max} (nm)	Half-width (nm)

0.148/0.150	2	$Sr_2P_2O_7$-Sn^{2+}	455	128
0.153/0.136	3	$(Ba,Mg)Al_2Si_2O_8$-Eu^{2+}	444	96
0.154/0.023	4	$Sr_{10}(PO_4)_6Cl_2$-Eu^{2+}	449	34
0.217/0.382	5	$(Sr,Mg)_3(PO_4)_2$-Cu^{+}	490	80

nearly the same. The former phosphor has the advantage of being excited more efficiently (giving a higher quantum conversion fraction) by the long wavelength ultraviolet radiation (365 nm) of the HPMV lamp. When using a blend with a phosphor strongly absorbing the 365 nm radiation of the HPMV lamp, however, the absorption of this radiation by the second phosphor is of minor importance.

The importance of a high quantum conversion fraction (Q) is illustrated in Table IX, showing that in mixtures of $Y(P,V)O_4$-Eu and strontium chlorsilicate-Eu an increase of the Q-value from 0.7 to 1.0 not only results in an increase of the luminous efficacy by about 6%, but also in an improved color rendition.

When comparing the quality of a 125 and a 400W lamp, it should be remembered that the mercury spectra of these lamps are not the same, due to differences in lamp constructions (arc length, pressure, etc.). For instance, with a given phosphor blend the best color rendition can be achieved with a 125W HPMV lamp (see Table IX).

Summarizing the data concerning the color rendition of HPMV lamps, it may be concluded that the partial substitution (about 30%) of a blue-green emitting phosphor for a red-emitting one will yield very useful results.

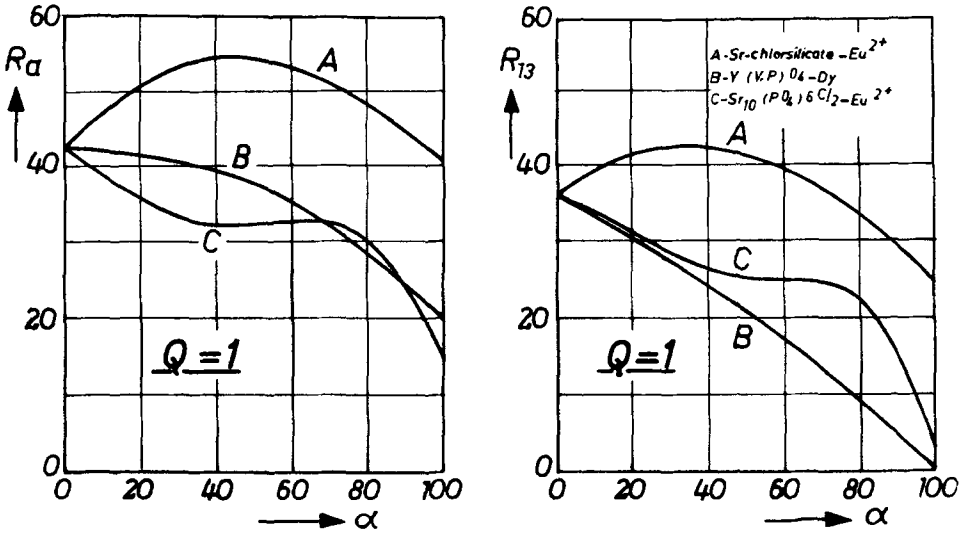

Fig. 6. Effect of addition of (100 — α) per cent of the red-emitting phosphor $Y(P,V)O_4$-Eu^{3+} and of α per cent of various blue-emitting phosphors on the color rendition of a 400W HPMV lamp. Curve A, Sr-chlorsilicate-Eu^{2+}; curve B, $Y(P,V)O_4$-Dy; curve C, $Sr_{10}(PO_4)_6Cl_2$-Eu^{2+}.

rendition is concerned, are reached with mixtures of europium-activated $Y(P,V)O_4$ and strontium chlorsilicate-Eu. We have found a lower color rendition than Thornton, however. This difference can be ascribed to the use of a different reference source. Thornton used the D_{65} Daylight reference, whereas in our study reference sources were used, as recommended in the C.I.E. Publication 13, with a color temperature corresponding to that of the lamp to be evaluated.

The poor performance as regards color rendition of $Y(P,V)O_4$-Dy is due to the strong emission at 573 nm. It can be seen from Table IX that the merits of strontium chlorsilicate-Eu and $(Sr,Mg)_3(PO_4)_2$-Cu (21) are

Manuscript submitted Dec. 21, 1972; revised manuscript received April 9, 1973. This was Paper 75 presented at the Houston, Texas, Meeting of the Society, May 7-11, 1972.

Replication of Relief-Phase Holograms for Prerecorded Video

R. A. Bartolini, N. Feldstein,*[1] R. J. Ryan

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

This paper describes the replication process used for the HoloTape® system. HoloTape is a clear plastic tape that has relief-phase holograms embossed on its surface, each hologram corresponding to a frame of a color-encoded motion picture. The replication process is based on the electroforming of a metal master and on the embossing of a transparent thermoplastic film.

Prerecorded video systems have created intense interest in the electronics industry within the last few years with the announcement of a variety of tape and disk systems for use in the home (1-3). These include the magnetic tape and photographic film systems, several disk systems based on mechanical and optical pickup, and the HoloTape[2] system. HoloTape is a clear plastic tape that has relief-phase holograms embossed on its surface, each hologram corresponding to a frame of color-encoded motion picture.

There are many ways to encode picture information so that it can be stored as a relief pattern. Eidophor projections (4) utilize a scanning electron beam to deform a special liquid. Similar systems have been developed that employ thermoplastic material instead of liquids (5). The advent of holography, coupled with the development of lasers, has led to a new method for encoding picture information which offers the following advantages:

(*i*) Scratch and dirt resistance. Highly redundant holograms (6) can be scratched, obscured by dirt and otherwise mutilated without serious image degradation.

(*ii*) Image immobilization. Fraunhofer holograms (7) produce stationary images even though the holograms are continuously moving through the readout beam. Flicker-free images can be produced at any tape speed with no need for servo control between tape speed and television scan rate, intermittent tape transport, or moving shutters.

(*iii*) Low cost replication. Relief-phase holograms can be replicated onto a metal master using electroless and electrolytic processes and embossed into a low cost thermoplastic tape. The processes involved in replication are the basis for this paper.

Relief-Phase Holograms

Replication of holograms has attracted attention since the laser was first successfully used in the making of holograms (8). To date, most attempts at replication have been with amplitude holograms (9-13). This paper describes an inexpensive and reliable method of relief-phase hologram replication.

Holography is an imaging process in which one records not an image of the object, but rather the wave pattern of the light that emanates from the object. The record (hologram) is thus in the form of an interference pattern which exists when the diffraction pattern of the object is made to interfere with a coherent reference beam.

If this interference pattern is stored in photographic film by changes in density of the film, an amplitude hologram is produced. To replicate this type of hologram, contact printing techniques are necessary. The film required for this type of replication is expensive due to the need for high-resolution capability (1000-2000 cycles/mm). A high degree of precision is also needed to minimize diffraction effects. A vacuum chuck hold-down is usually necessary in this case (14).

When the interference pattern is stored in the recording medium by changes in the surface structure, a relief-phase hologram results. The information in a relief-phase hologram is stored in the amplitude and periodicity of the surface corrugation. This type of hologram modulates the phase of the playback beam on transmission because of the variations in the optical path introduced by the relief pattern.

A common material for recording relief-phase holograms is photoresist. Both positive and negative photoresists can record relief-phase holograms. The positive photoresist has the advantage that only the exposed portions are removed, so that most of the material remains on the substrate, maintaining good bonding between the two. Negative photoresists remain after development only where they are exposed sufficiently to be hardened all the way to the substrate. The hologram therefore consists of very fine lines of photoresists that tend to detach from the substrate.

Shipley AZ-1350,[3] a commercial positive photoresist, was found to be an acceptable recording medium for the HoloTape system. The HoloTape processing se-

quence is shown schematically in Fig. 1 and typical processing equipment in Fig. 2.

For the HoloTape system, AZ-1350 photoresist is coated onto a polyester tape such as Cronar[4] to provide a dry-film thickness in the order of 1 μm. Contact roller coating off a grooved steel wheel in a clean room (class 100 hood within a class 10,000 room) has been found to produce a photoresist layer of adequate cleanliness and uniformity. The photoresist is applied directly to the polyester base as the AZ-1350 type photoresist interreacts with most resin-subbing layers to reduce its effective sensitivity. An antireflection layer absorbing greater than 95% of the transmitted light is coated onto the back side of the tape to prevent fringes in the recording due to back reflections from the tape/air interface.

Discussion of Process

Hologram recording.—For the recording of color holograms, monochrome transparencies spatially encoded (by means of an electron beam recorder) with the color information serve as the object. The holographic recording system includes a He-Cd laser, photoresist tape and object film transports, the usual beam expanders, pinholes, mirrors, and beam splitters, and a special optical pinhole array which enables highly redundant holograms to be recorded (6, 7). The recording system functions automatically, recording a sequence of holograms on photoresist tape, each hologram corresponding to a frame of the color-encoded motion picture. After exposure, the photoresist-coated tape is passed through a developing machine in which the areas exposed to more intense light are etched away, leaving the surface corrugations which form the relief-phase holograms.

Exposure characteristics of a positive photoresist for holography are much different than those normally encountered in photolithographic applications. In holographic exposure, the photoresist layer is exposed in an analog fashion due to the interference of the reference and object beams. In the simplest case, two plane waves of equal intensity create a sine-wave exposure pattern in the photoresist with amplitude proportional to the first order Bessel function, J_1. Maximum grating efficiency can be achieved with exposures of approximately 10 mJ/cm^2 corresponding to a very low reaction level of the photoresist sensitizer. (Full reaction of the sensitizer in a 1.2 μm layer requires an exposure of approximately 300 mJ/cm^2.)

The mechanism for positive photoresist development involves dissolving away the exposed areas of the photoresist while leaving the unexposed areas essentially intact. This is essentially a binary process which is ideal for applications such as the fabrication of in-

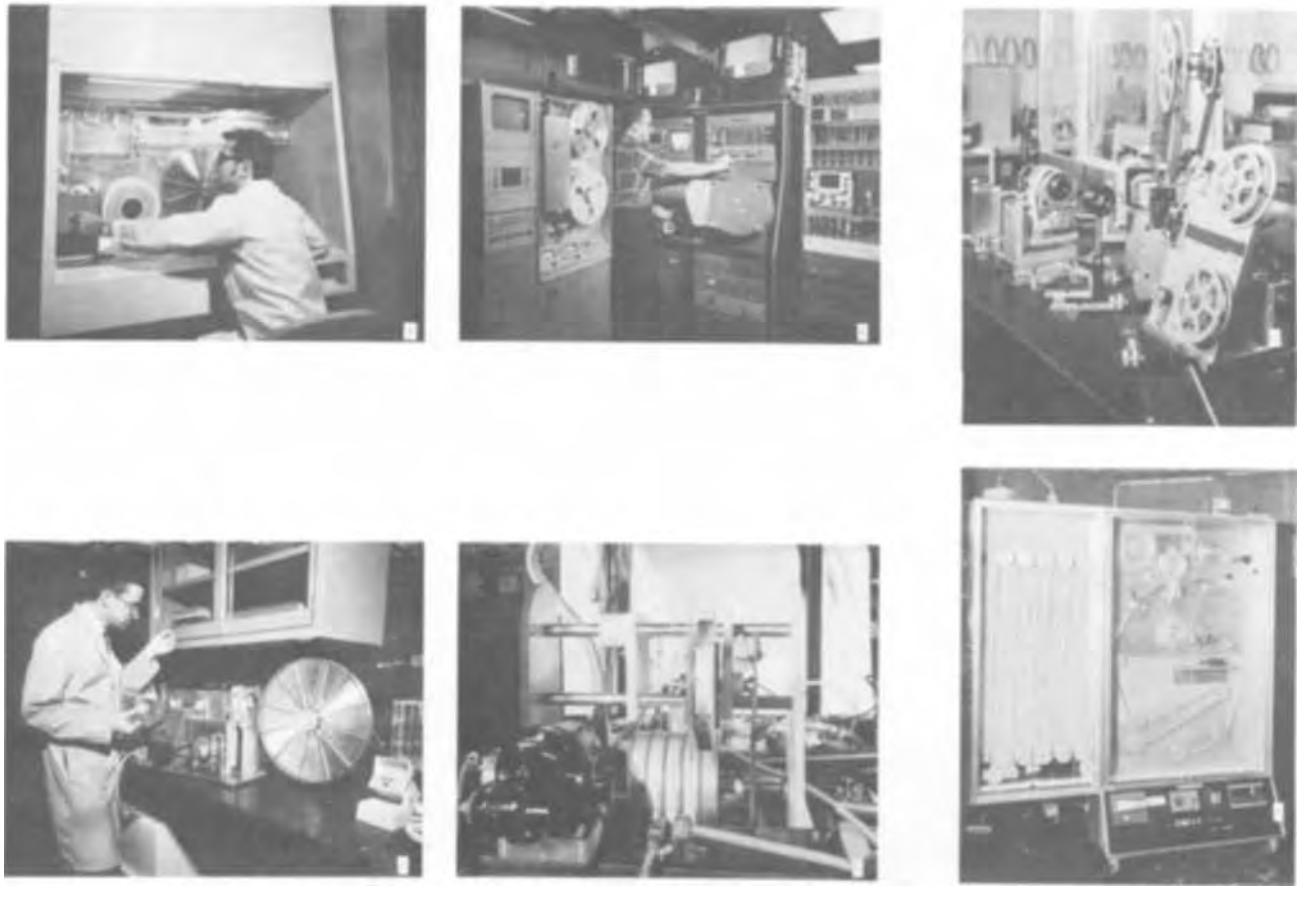

Fig. 2. Laboratory equipment used to manufacture experimental HoloTape. a, Coating; b, encoding; c, recording; d, developing; e, plating; and f, replicating.

tegrated circuits. However, for holographic recording, an analog process is desired. Moreover, to avoid nonlinear distortion, it is desirable to have a depth *vs.* exposure characteristic which is approximately linear over a wide exposure range. When using AZ-1350 developer, as is normally used with AZ-1350 photoresist, the photoresist appears to act nonlinearly; the hologram diffraction efficiency for a given intermodulation distortion is limited to a greater degree by this material nonlinearity than by the intrinsic nonlinearity of thin-phase holograms. It has been found that the use of the more alkaline AZ-303 developer with the AZ-1350 photoresist relieves the photoresist nonlinearity, thereby allowing higher image readout efficiencies and a net increase in material sensitivity (15).

Maximum average usable hologram efficiency is restricted, by intermodulation effects from the intrinsic nonlinearity, to approximately 5% which is equivalent to a peak-to-peak corrugation depth of approximately 0.1 μm. Photomicrographs of simple and Fraunhofer hologram relief patterns recorded in AZ-1350 photoresist and developed in AZ-303 developer are shown in Fig. 3. The line spacing (periodicity) of the contour structure is approximately 1 μm (1000 cycles/mm). The sinusoidal grating pattern produced by the interference of two simple plane waves is shown in Fig. 3(a). Figure 3(b) is the interference pattern of a complex object (such as a film transparency) and a plane reference wave. These SEM photographs were taken at an angle of 80° from the perpendicular and at a 7500× magnification. Faithful replication of this fine pattern in the subsequent plating and embossing steps requires proper choice and control of all materials and processes.

Processing of metal embossing masters.—Replication is accomplished by a two-step process: (*i*) electroforming a metallic stamper master and (*ii*) embossing this stamper into a transparent flexible thermoplastic to produce replicas. The electroforming process involves electroless nickel plating of a thin conductive layer and electrolytic nickel plating to a metal thickness of 2.5 mils. The over-all process is similar to that used in the production of audio record stampers. Equipment and control conditions are unique, however, due to the high resolution of the holographic information and the tape format. The use of an all nickel process has the advantage of producing a hard, corrosion-resistant master requiring no additional surface treatments.

Figure 4 shows the highlights of the electroforming sequence. In this sequence, two new developments facilitated a good reproducible process; (*i*) an improved sensitizer composition (16, 17) which ensures uniform sensitization of hydrophobic surfaces such as photoresists and (*ii*) a room temperature, electroless, nickel plating formulation (18) which provides continuous and conductive surfaces, ready for subsequent electrolytic buildup.

Electroless plating.—The electroless nickel layer forms the surface of the final master and determines the quality and faithfulness of the hologram replication. Properties required of the nickel deposit include fine grain size, good hardness and corrosion resistance, uniform coverage, and no adverse effects of processing solutions on the photoresist surface. Other chemically deposited metals such as Cu or Ag are softer and more corrosive and are generally deposited from high alkaline baths. The electroless plating sequence involves four main steps as shown in Fig. 4. All steps are followed by double 1 min rinses in deionized water. Plating is normally carried out under yellow light conditions to insure uniformity of the photoresist surface. Variable exposure of the positive photoresist layer could alter the layer characteristics during subsequent processing.

Surface preparation is important to insure removal of any particulate matter or films from the surface of the photoresist recording tape due to prior processes. Generally a 1-2 min rinse cycle with mild agitation in a neutral detergent solution is sufficient. It has been found, however, that residual films can be carried over from the photoresist development cycle which appear as microroughness in the electroformed surface. These are effectively removed by prerinsing in a mild alkaline solution for 15-30 sec prior to detergent cleaning. An alkaline solution is chosen which does not affect further development of the photoresist layer.

The sensitization step is most important in determining coverage and uniformity of the subsequent

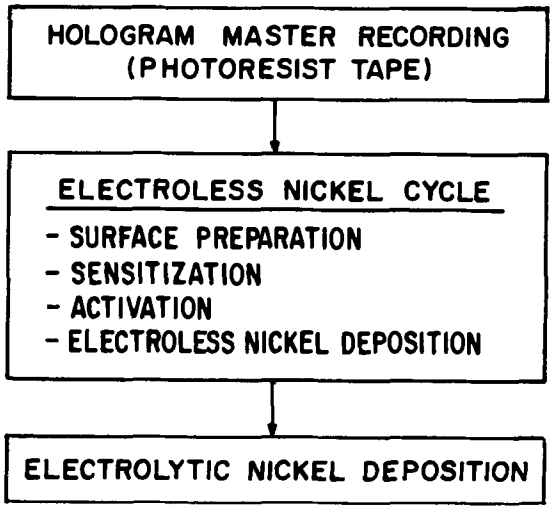

Fig. 4. Plating sequence in the electroforming of HoloTape metal embossing masters.

nickel deposition. Shipley AZ-1350 photoresist is inherently hydrophobic and nonwetting in most commercial sensitizing solutions or in colloidal catalytic solutions. Sensitizing solutions (16, 17) in which tin (II) and aged tin (IV) are incorporated produce complete wetting of tape surfaces and the formation of an absorbed layer of tin (II) on the surface during a 1 min immersion. A typical composition of sensitizer is given in Table I. The aged tin (IV) component has been properly conditioned prior to its incorporation into the solution.

Activation is accomplished in an acidic palladium chloride solution such as listed in Table I by immersion for 1 min. This step requires only the normal maintenance associated with electroless activating solutions. During the immersion, palladium nuclei are formed on the surface of the tape by reduction with absorbed tin (II) ions and provide catalytic sites for initiation of the electroless nickel deposition.

The electroless nickel cycle must provide a thin conductive layer of fine grain nickel uniformly over the entire tape surface with sufficient adhesion to with stand the subsequent electroplating cycle. A room temperature bath described previously (18) and based on the nickelpyrophosphate ammonia system with dimethylamine borane (DMAB) as a reducing agent was found to provide the necessary properties. Bath composition is shown in Table I. Although the bath is alkaline in nature, no adverse effects are observed on the AZ-1350 photoresist surface. The adherence of the nickel layer is dependent on the stress levels in the deposit and layer thickness. Control of the stress level is critical due to possible lifting from the flexible tape surface during subsequent processing. Since total stress of the deposit is a function of the deposition rate and layer thickness, rates must be maintained to provide a suitable low stress level and reproducible thickness of nickel. Rates are controlled by maintaining the dimethylamine borane reducing agent content to produce a nickel thickness of approximately 150Å in 7 min. Sheet resistivity at this thickness is on the order of 250 ohms/□ and is adequate for the subsequent electroplating step.

Curves showing deposition rate as a function of DMAB concentration are shown in Fig. 5. The data were determined from Cronar tape samples plated in freshly prepared baths under equivalent plating conditions. The amount of nickel deposited for a given time and tape area was analyzed by colorimetric methods. Standard curves were also plotted relating nickel deposition to light transmission. This provides an easy method of analysis for thin nickel deposits on transparent substrates. For batch type work, rates are controlled by addition of DMAB daily based on analysis. Continuous type plating would require replenishment on a more frequent or continuous basis. Good bath life is achieved by controlling carry-over of chemicals from the activation step with thorough rinsing in deionized water and by maintaining levels of DMAB, Ni, NH_4OH, and pH through analysis. Apparatus for electroless nickel plating of HoloTape masters has been developed as a batch immersion type which provides tape masters up to 50 ft in length (equivalent to 100 sec of video playback) and as continuous in-line steps for longer time programs.

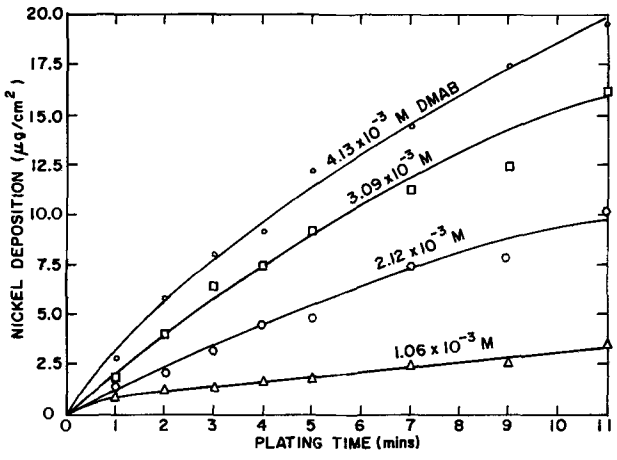

Fig. 5. Electroless nickel deposition as a function of plating time and reducing agent concentration.

Electrolytic nickel plating.—The electroforming step consists of a continuous, two-stage nickel sulfamate bath similar to those used in record stamper processing. Bath makeup data is given in Table II. Rolled depolarized nickel anodes in Dynel bags are used in both baths. A wetting agent such as Duponal WA[5] is generally used in the preplate bath and controlled to produce a solution surface tension of 37±2 dynes/cm. The baths are continuously filtered with 10μ filters. Ion exchange cartridges are used with both baths and a carbon cartridge included with the high-speed bath off an inlet manifold.

Typically, nickel deposits from these baths show a tensile stress of 5000-10,000 psi, a tensile strength of 80,000-90,000 psi, and an elongation of 15-20%. Plating rates are ample for practical production schedules.

Laboratory continuous plating apparatus is shown in Fig. 6. In the first stage, the electroless plated tape is fed onto metal cathode contact wheels partially immersed in the bath. Approximately 0.05 mil of nickel is deposited on both sides of the tape at a current density of 2.5 A/dm². The second stage is designed as a series of loops to increase the deposition area in the bath and to provide suitable through-put rates. Cathode contact is made out of solution to the back of the tape via metal contact wheels. The wheels are designed either as direct drive or with a slip pressure plate to compensate for tape expansion at the elevated temperature. The bottom wheels immersed in the bath are plastic. The tape is shielded in the solution by baffle plates to direct the plating to the front of the tape. Current density is controlled at approximately 4 A/dm². The tape is electroformed to a uniform thickness

of 2.5 mils in a continuous manner and reeled up at the exit end of the plating line at a through-put rate of 2.5 in./min. Production type equipment of 34 loops has been constructed and operated at speeds of 15 in./min.

The electroformed nickel master is completed by separating the nickel tape from the photoresist tape. To provide good edges on the master, the thin nickel layer on the back of the photoresist tape is spray etched prior to separation. Tapes are generally separated in a hot cleaner solution to avoid mechanical distortion. The nickel master is then cleaned, dried, and wound, interleaved with a plastic tape to prevent abrasion of the hologram surface.

In order to determine performance of the electroforming process in replicating the hologram surface, a series of sine-wave grating patterns of various efficiencies were recorded in the photoresist and processed. Diffraction efficiency was measured on the photoresist tapes and the completed nickel master. Surface studies were also run using scanning electron microscopy. No significant difference in efficiency or surface structure was found. These studies also show that no deterioration of the positive photoresist surface occurs with use of the alkaline electroless Ni bath at a pH of 10.2

Embossing of holographic masters.—Replication of the recorded holographic information is completed by thermal mechanical embossing of a clear thermoplastic film. The process is shown schematically in Fig. 7. During the embossing cycle, a 1-2 mil thick thermoplastic film is placed in contact with a heated nickel holographic master and passed between pressure rollers, thus impressing relief patterns identical to the phase holograms into the softened plastic surface. After passing through the pressing station, the tapes are cooled, and the embossed plastic film is separated from the nickel master. The process provides a simple inexpensive method for the replication of holographic films. Important material and process considerations are presented below.

The important material requirements include: high optical quality, controllable thermosoftening behavior, and good stability for playback and storage. This confines the choice of materials to the clear thermoplastic films, such as, vinyls, polyesters, acetates, polycarbonates, and polyolefins.

The optical quality of a thermoplastic film is dependent upon the method of polymer preparation, compounding, and the film fabrication process. Ideally, the polymer should have a narrow molecular weight distribution and be free of reactants or reaction by-products. Additives required for compounding should be completely miscible with the polymer and not produce any significant scattering with coherent light transmission (less than 1%).

Calendering, extrusion, and casting are the principal methods of plastic film fabrication. Of these, casting methods have been shown to produce the highest quality films. The film fabrication process has a marked effect on optical quality and determines the surface flatness and parallelism. In general, these types of defects far outshadow those due to bulk film nonuniformities. Abrupt changes in the surface will result in variation in color or shading of the reproduced image on playback. Wedge effects produce image displacement.

Embossing is a thermomechanical process in which the surface of a plastic film is molded by compression in contact with a patterned master. In order to reproduce faithfully the patterned information in the plastic film, the temperature of the film surface must be above the glass transition point for the material. Vinyl materials, for example, fall in a range of 60°-90°C. In practice, sufficient heat is required to raise the temperature above this point and to a sufficient depth that is greater than the maximum depth of the patterned information. This implies that with holograms, the

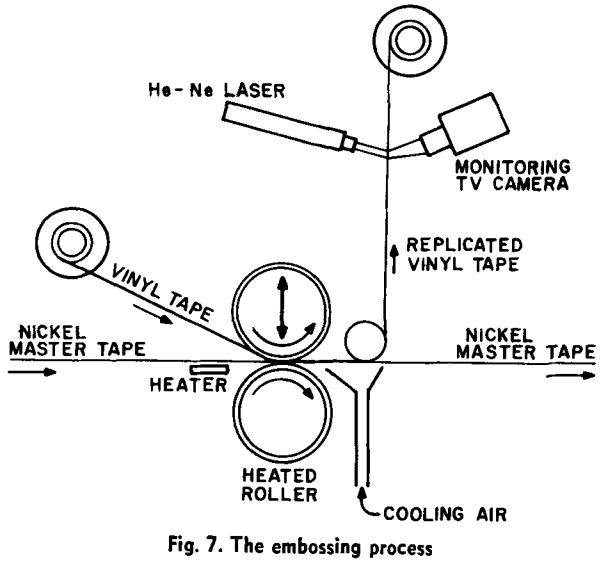

Fig. 7. The embossing process

Fig. 8. Embossing apparatus

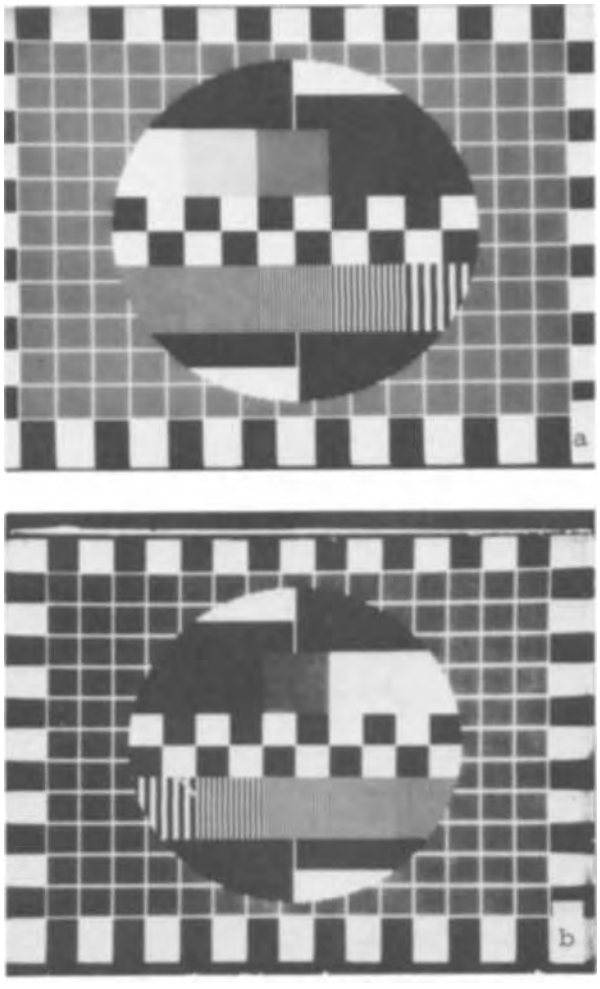

Fig. 9. Resolution of embossed hologram in vinyl film. a, High resolution silver-halide object film; b, vinyl hologram replica.

plastic surface must be heated to a depth beyond the maximum grating amplitude in order to achieve exact replication.

The mechanical aspects of the embossing process are equally important to the thermal cycle in producing distortion-free replicated films. Tape guiding, roller alignment, and tape windup must be adjusted to prevent edge distortion in the film in order to provide a flat film during holographic readout. The compression roller is coated with a uniform smooth resilient elastomer to equalize pressure at the nip between the plastic film and nickel master surface. Experimental apparatus for replication speeds up to 10 in./sec is shown in Fig. 8. Vinyl tapes have been replicated with this equipment which exhibit no change in signal-to-noise ratio or efficiency of embossed holograms between the initial replica and the 5000th copy. Comparison of Fraunhofer hologram test patterns, recorded in photoresist, with film embossed from equivalent electroformed nickel masters show no significant loss in efficiency, resolution, or signal-to-noise ratio. A comparison between an image from an original hologram and an embossed film replica hologram is shown in Fig. 9. Other equipment has been designed for high speed embossing using RF heating of the nickel master and demonstrations have been given at replication speeds up to 60 in./sec.

Optically Erasable Cathodochromic Coloration in Sodalites Containing Sulfate

Takeshi Takeda and Akinori Watanabe

Matsushita Research Institute Tokyo, Incorporated, Ikuta, Kawasaki, Japan

ABSTRACT

Optically erasable cathodochromic coloration was studied in sodalite of which halogen ions were partially substituted by sulfate radicals. The materials were prepared by a solid-state sintering method in air. The achievable contrast ratio, decay time, optical erasability, and color changed considerably depending on the substitution amount of sulfate radicals. The composition $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$ showed the best compromise among these properties. In this composition the maximum contrast ratio 7.7 was achieved at 20 kV without a significant residual coloration. The peak wavelength of induced absorption spectrum was 553 nm and the thermal decay time was about 30 min.

Photochromic and cathodochromic properties of sodalite have been widely investigated for the purpose of storage-display applications (1-15). Especially, dark trace tubes using cathodochromic sodalite as a screen material are under current development (13-15), since they give improved features over the early KCl tubes (16).

Sodalite has the chemical formula $Na_6Al_6Si_6O_{24}\cdot 2NaX$, where X = halogen. Photochromic and cathodochromic sodalites are colored by ultraviolet and electron-beam irradiation, respectively. The induced coloration is bleached upon exposure to visible light or by heating the material.

Photochromic sodalites have usually been doped with sulfur (2, 4, 13) or iron (6), since these ions were found to aid photochromic coloration. As-grown materials are not photochromic and must be sensitized by a heat-treatment in a hydrogen or an inert atmosphere. Photochromic sodalites are also cathodochromic.

To induce only the cathodochromism, S- or Fe-doping is not necessary and these ions have been reported (11, 13, 15) to degrade the cathodochromic performance in some cases. Several variations of synthesis and sensitization processes have been reported. Williams *et al.* (4) reported high-temperature hydrothermal synthesis after which the products were sensitized by heat-treatment in a reduction atmosphere. This process has been used by several workers (5-8). Recently, Schipper *et al.* (9) reported a modified solid-state sintering method and a low-temperature hydrothermal method. The products by these methods were found to show optimum cathodochromic properties when they were treated in an oxidizing atmosphere rather than in a reducing one.

The induced coloration, which is the result of F center absorption, can usually be classified into two categories. One is the "optical-erase mode" coloration that can be erased by light, and the other is the "thermal-erase mode" coloration that can only be perfectly erased by heating to about 200°C. At low levels of electron-beam irradiation, the former mode of coloration is much more efficient, but at high levels of irradiation saturation tends to occur, whereas, in the latter mode, coloration continues to increase with irradiation. The relative sensitivity of these two coloration modes is a strong function of both the composition of sodalite and of the method of preparation. In bromo-sodalite, Faughnan *et al.* (15) succeeded in improving the sensitivity of thermal-erase mode coloration to such an extent that the device applications for this mode of coloration look very promising. Several attempts to reduce the thermal-erase mode coloration also have been performed, since, when the materials are used in the optically reversible dark trace tubes, this mode occasionally gives rise to a residual coloration. Iodo-sodalite was reported to be the most suitable composition for this purpose (6). Some success also has been obtained by firing the products with extra sodium halide (9, 11) or by annealing them in fused sodium halide (6).

The present paper is also concerned with the attempt to reduce the sensitivity of thermal-erase mode coloration, and the results for sodalites in which halogen ions are partially replaced by sulfate radicals will be described.

Key words: color center, absorption spectrum, display, storage.

Crystal Structure and Material Preparation

The crystal structure of sodalite is built up from aluminosilicate cages formed of (AlO_4) and (SiO_4) tetrahedra linked together by their oxygen atoms. The cages are stacked together to form a crystal with over-all cubic symmetry (17). In the center of the cage, there exists a halogen ion surrounded by four Na^+ ions as shown in Fig. 1. Many variations can be synthesized by changing the contents of the cage; for example, instead of sodium halide in sodalite, the mineral noselite contains Na_2SO_4, and the pigment ultramarine contains Na_2S_x.

The sodalites studied in the present work contain sulfate radicals which partially replace the halogen

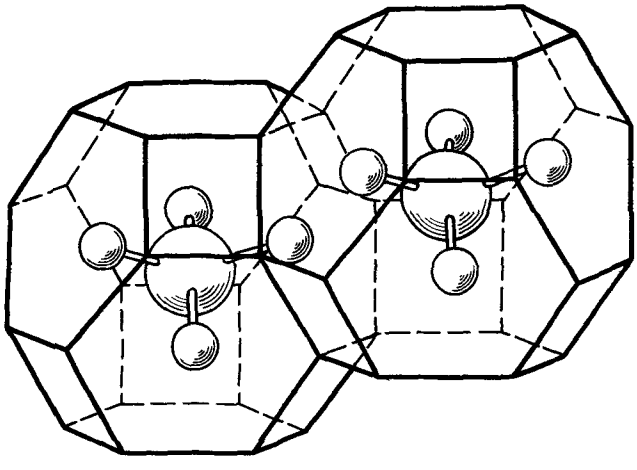

Fig. 1. Cage structure of sodalite [see Ref. (15)]. Large circles on the center of the cage represent halogen ions. The smaller circles represent Na ions. The Al, Si, and O ions forming the aluminosilicate cage are not shown for the sake of clarity.

ions. Chloro- and bromo-sodalites are especially dealt with and the formula can be written as $Na_6Al_6Si_6O_{24}\cdot 2(1 - x)NaX\cdot xNa_2SO_4$, where $0 \leq x \leq 1$.

The materials were prepared by the solid-state sintering method. The reagent grade chemicals Na_2CO_3, Al_2O_3, SiO_2, NaCl, and Na_2SO_4 were mixed in a mole ratio of $3 : 3 : 6 : 2(1 - x) : x$, and the mixture was ball-milled for 10–20 hr. This was followed by a 3-hr prefiring at 800°-850°C in a covered platinum crucible. The partially sintered material was broken up with a mortar in an agate bowl and then milled for 3–5 hr. This material was fired again. The milling-firing cycles were repeated several times before the final firing at 1000°C for 1 hr in air. Firing temperatures, firing period, and milling-firing cycles are interrelated in their effects on the coloration and bleaching properties of final products, and the optimum conditions must be found experimentally. The products were identified by x-ray powder diffraction. The diffraction spectra sometimes showed a small trace of another phase apart from sodalite, especially in the bromo-sodalite containing sulfate.

Experimental Methods

Contrast ratio measurements were performed in two ways: reflectance and transmission measurements.

For reflectance measurements, powder specimens with a particle size of 10-20 μm were deposited on an aluminum foil in a thickness of 40-50 μm by use of an applicator blade, and were colored in a demountable cathode-ray tube. As many as eight different samples were mounted at one time and measured under the same conditions. A reference light beam irradiated the surface of the sodalite screen. The brightness was low enough so that its effect on the decay of coloration could be ignored. The ratio of reflection intensities before and after electron beam irradiation then were calculated. Thus, the coloration is expressed by the constant ratio $C_{ref.} = R_0/R$, where R_0 and R are initial and final diffuse reflectances. In this way, a wide variety of prepared samples were surveyed and this was followed by measurements on a few excellent samples in the transmission mode.

Contrast ratio measurements in the transmission mode were performed in an actual cathode-ray tube with the sodalite screen instead of the usual phosphor screen. The screen density was 3 mg/cm^2 and the particle size was 1-3 μm. A transparent, conductive SnO_2 film was provided for the inner surface of the faceplate and funnel part of the glass bulb. The usual aluminum backing and graphite coating were omitted to facilitate back-screen illumination by both the measuring light and the erasing light (18). Thus, the contrast ratio, $C_{tran.} = I_0/I$, was obtained where I_0 and I are the intensities of transmitted light before and after electron beam irradiation.

A narrow band pass filter with the central wavelength equal to the peak wavelength of the induced absorption spectrum was used in all measurements.

Cathodochromic Properties

Halogen sites in sodalite can be replaced by SO_4^{2-} radicals, partially or fully. That is, the solid solution of sodalite and noselite can be synthesized in a form $Na_6Al_6Si_6O_{24}\cdot 2(1 - x)NaX\cdot xNa_2SO_4$ (X = halogen) in any value of x between 0 and 1. Although a small trace of second phase apart from sodalite is occasionally detected by an x-ray diffractometer and although the evaporation of NaX and Na_2SO_4 in the course of firing might not be negligible, the synthesized specimen is denoted by its starting formula in the following.

The cubic lattice parameter, a_0, increases monotonically with x and the peak wavelength λ of the induced absorption spectrum moves towards longer wavelengths. Figure 2 shows a plot of peak wavelength against lattice parameter. It is desirable that λ is matched to the peak wavelength, 555 nm, of the sensitivity curve for the human eye. Thus, the composition with $x \sim 0.4$ in the solid solution of sodalite and noselite or the pure bromo-sodalite is most suitable. The induced absorption spectrum is shown for $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$ ($x = 0.4$) in Fig. 3. The line width becomes broader with x and is 180-200 nm in this composition. This width is about 2 times broader than that of pure chloro-sodalite.

The contrast ratio $C_{ref.}$ *vs.* x is plotted in Fig. 4. The accelerating voltage was 15 kV, beam diameter was about 8 mm, and charge density was 100 μcou-

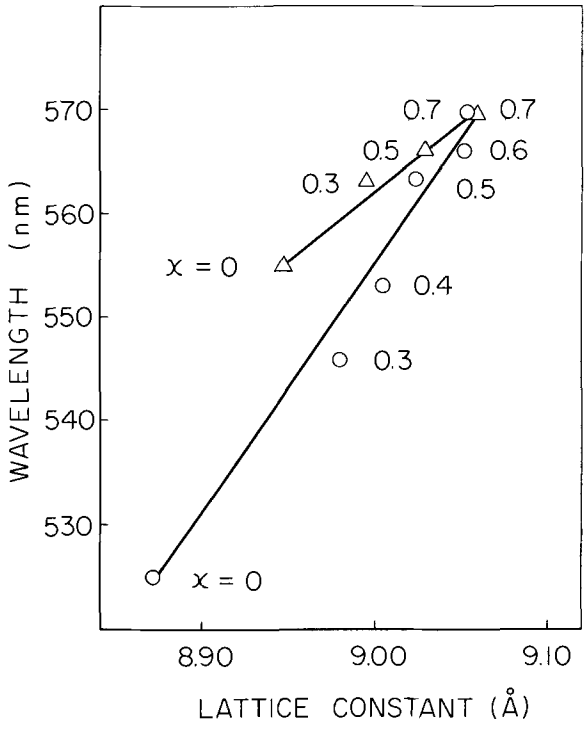

Fig. 2. The dependence of the peak wavelength of the absorption spectrum on the cubic lattice parameter in the composition $Na_6Al_6Si_6O_{24}\cdot 2(1 - x)NaX\cdot xNa_2SO_4$. Circles and triangles correspond to X = Cl and X = Br, respectively.

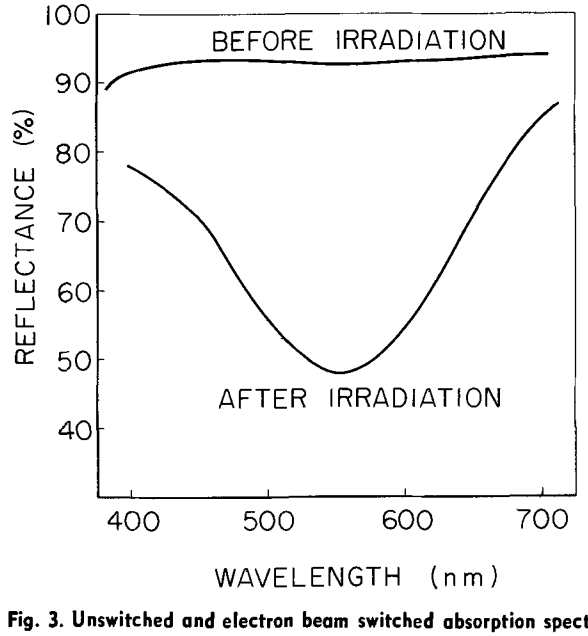

Fig. 3. Unswitched and electron beam switched absorption spectra of $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$.

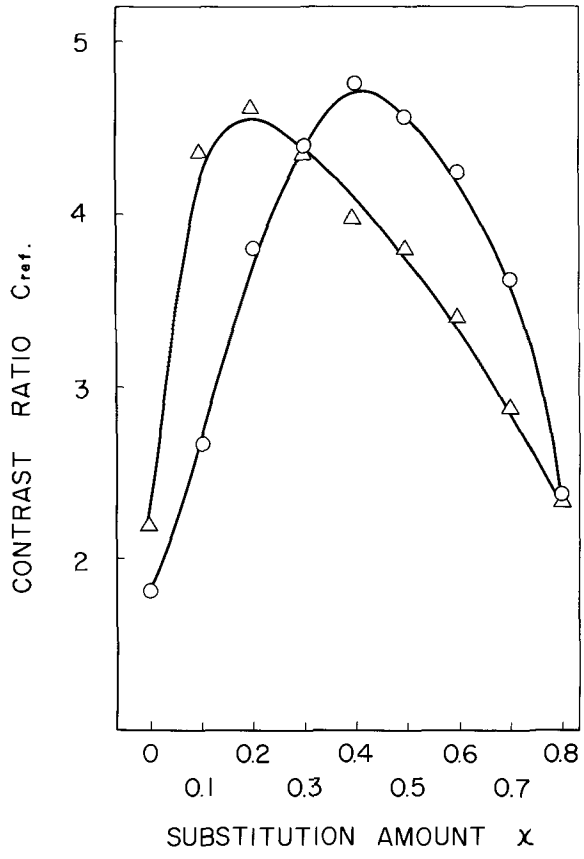

Fig. 4. Relationship between contrast ratio, $C_{ref.}$, and x in $Na_6Al_6Si_6O_{24}\cdot 2(1-x)NaX\cdot xNa_2SO_4$. Circles and triangles correspond to X = Cl and X = Br, respectively. Accelerating voltage is 15 kV and charge density is 100 μcoulombs/cm².

lombs/cm². The current density was 5 μA/cm². As is seen from this figure, $C_{ref.}$ increases with x, reaches a maximum, and decreases again with further increase of x. In the chloro-sodalite and noselite system, the maximum contrast ratio 4.7 is obtained at $x = 0.4$. At $x = 0$, *i.e.*, pure chloro-sodalite, $C_{ref.}$ is only about 2.0. However, when the latter was treated in a hydrogen atmosphere at 800°C for 30 min, $C_{ref.}$ increased to about 3.5. The treated material also showed the weak photochromism as reported by Medved (1). In the products with x higher than 0.3, this treatment did not cause an increase of $C_{ref.}$, but sometimes caused a decrease of $C_{ref.}$ and an increase of residual coloration (residual coloration is described later).

In the bromo-sodalite and noselite system, the maximum contrast ratio is obtained in the composition with $x \sim 0.2$. This value of x is smaller than that in the chloro-sodalite and noselite system. One plausible reason for this difference is that the evaporation of NaBr occurs more actively, and thus the deviation of final Br/SO_4 ratio from the initial one is more significant in the $Br\text{-}SO_4$ system than in the $Cl\text{-}SO_4$ system. The maximum $C_{ref.}$ is 4.5 and comparable with 4.7 in the $Cl\text{-}SO_4$ system.

Bleaching properties also change depending on composition. In Fig. 5 some thermal decay curves at room temperature are shown. The decay rate becomes larger with x. At the composition with $x = 0.4$, a contrast ratio fell to half of its initial value in 30 min. At a typical room environment (200 lux), it takes about 2 min to reach the same situation.

In general, a charge density exceeding a certain threshold value gives rise to a residual coloration after optical bleaching is attempted. Figure 6 shows the relation between the contrast ratio $C_{res.}$ of residual coloration and the substitution amount x. Here,

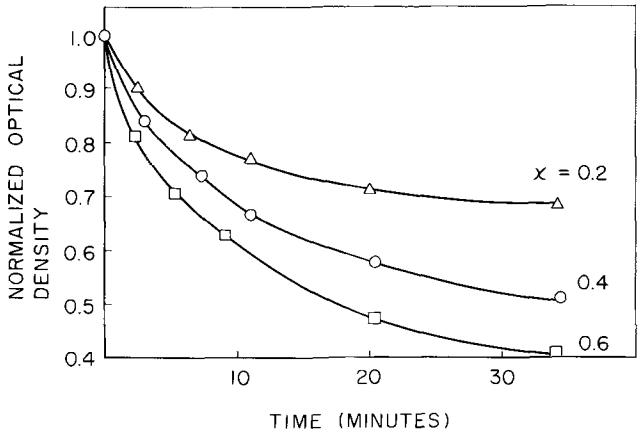

Fig. 5. Thermal decay of induced coloration in $Na_6Al_6Si_6O_{24}\cdot 2(1-x)NaCl\cdot xNa_2SO_4$.

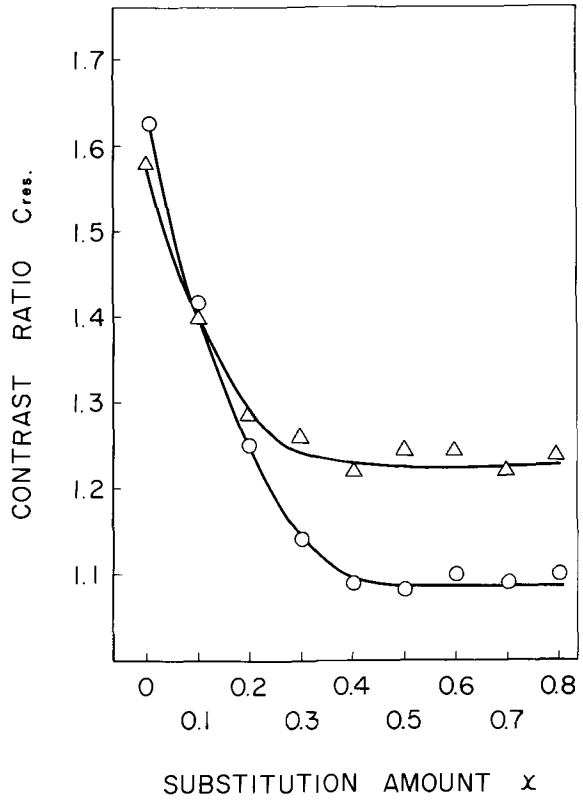

Fig. 6. Relationship between contrast ratio, $C_{res.}$, of residual coloration and x in $Na_6Al_6Si_6O_{24}\cdot 2(1-x)NaX\cdot xNa_2SO_4$. Circles and triangles correspond to X = Cl and X = Br, respectively. Induced coloration was bleached by a tungsten lamp for 1 min.

the coloration induced at 15 kV and 100 μcoulombs/cm² was erased by light from a 300W tungsten lamp positioned at a distance of 40 cm from the sample for 1 min. As shown in this figure, $C_{res.}$ decreases with the increase of x. For instance, in the $Cl\text{-}SO_4$ system, when $x = 0$, $C_{res.} = 1.62$, and when $x = 0.4$, $C_{res.} = 1.09$. When x exceeds 0.4, $C_{res.}$ becomes nearly constant. The color (absorption spectrum) of residual coloration also varies with composition. At $x = 0$, it is the same as for that of the initially developed coloration, that is, magenta. With increasing x, the residual coloration gradually becomes yellowish brown, whereas the electron beam initially develops a purple color. The persistence of this yellowish brown coloration is still a function of the bleaching light. That is, the residual coloration in this case involves both the optical- and thermal-erase mode components. The residual coloration in the composi-

tion with $x = 0.4$ is completely bleached in several hours by the light in a room environment, whereas in the dark it is maintained over 1 day or so. On the other hand, the magenta residual coloration at $x = 0$ is hardly affected by light and it is maintained over 1 week even in a room environment. The thermal-erase mode coloration dominates the residual coloration in this case.

In the Br-SO_4 system, $C_{res.}$ becomes nearly constant for x higher than 0.3. However, the lowest $C_{res.}$ is only 1.22 (optical density 0.09) and higher than the 1.09 (optical density 0.04) obtained in the Cl-SO_4 system. This undesirable result in the Br-SO_4 system might again have a relation with the active evaporation of NaBr during firing. Our attempt to synthesize the solid solution of iodo-sodalite and noselite was unsuccessful, since the evaporation loss of NaI was quite serious. The sintered products exhibited low $C_{ref.}$ and high $C_{res.}$ although the effect of SO_4^{2-} was still observed. It is a future subject to find out the best firing condition for the Br-SO_4 or I-SO_4 system.

The $C_{ref.}$ and $C_{res.}$ *vs.* charge density are shown in Fig. 7 for $x = 0.2$ and 0.4 in the Cl-SO_4 system. An increase in sensitivity by a factor of 2-3 can be achieved in the initially induced coloration by going from $x = 0.2$ to $x = 0.4$. On the other hand, the sensitivity of residual coloration for $x = 0.4$ is about one order of magnitude lower than that for $x = 0.2$. The threshold charge density for the occurrence of residual coloration is below 1 μcoulombs/cm^2 for $x = 0.2$ and about 5 μcoulombs/cm^2 for $x = 0.4$ in the present condition. When the charge density exceeds several hundred μcoulombs/cm^2, the residual coloration at $x = 0.4$ also becomes purple rather than yellowish brown, and the dependence on bleaching light becomes weak.

In the present sample series, the composition $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$ shows the best compromise between $C_{ref.}$ and $C_{res.}$. This compromise in the above composition is also somewhat better than that in iodo-sodalite which has been reported to be most suitable for optically reversible applications (6). The thermal decay time of optically reversible coloration is about one order of magnitude longer than that in iodo-sodalite.

The contrast ratio, $C_{tran.}$, measured in the transmission mode (18) showed a higher value than that in the reflection mode, as pointed out by Faughnan *et al.* (15). The result for the composition $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$ is shown in Fig. 8. As expected, higher accelerating voltages produce higher contrast ratios. To obtain $C_{tran.} = 2$, a charge density of 0.5 μcoulombs/cm^2 at 20 kV is required.

From this result, the number of F centers created per incident electron can be roughly estimated by use of the Smakula equation (19). This can be written

$$Nf = 0.87 \times 10^{17} \frac{n}{(n^2 + 2)^2} k_{max} W_{1/2} \quad [1]$$

where N = number of F centers per cm^3, f = oscillator strength, n = refractive index of the material, k_{max} = absorption coefficient, in cm^{-1}, at the peak of the absorption band, and $W_{1/2}$ = full width, in eV, of the absorption band at half intensity. To produce an optical density, D, in a penetration depth, t, it is necessary that

$$Nt = 6.5 \times 10^{15} D \quad [2]$$

centers per cm^2 switch. The reasonable values $f = 0.5$, $n = 1.5$, and $W_{1/2} = 0.8$ eV are adopted. From Eq. [2], $C_{tran.} = 2$ ($D = 0.3$) yields $Nt \approx 2 \times 10^{15}$ cm^{-2}. The charge density 0.5 μcoulombs/cm^2 corresponds to 3.1×10^{12} incident electrons per cm^2. This means that one incident electron with a voltage of 20 kV creates $\sim$ 650 F centers. Since it takes at least three bandgaps of energy [$\sim$ 18 eV (11)] to create one electron-hole pair (20), the efficiency is about 45%. The efficiency falls with increasing charge density, and it becomes 8% at 10 μcoulombs/cm^2.

In the composition $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$, 20% of the halogen sites are empty and this corresponds to a possible vacancy density of 4.4×10^{17} cm^{-2} within a penetration depth [4 μm at 20 kV (21)]. Maximum contrast ratio 7.7 at 20 kV ($D = 0.86$) yields 5.6×10^{15} F centers cm^{-2}. This amount is two orders of magnitude smaller than that of existing vacancies.

Consideration of the Role of Sulfate

The optically reversible cathodochromic switching will be the result of a charge-transfer process (8). A number of electron-hole pairs are created by the incident electrons. The released electrons are then captured in "already existing" halogen ion vacancies to form F centers giving rise to the coloration. The holes also should be captured by some centers to make the coloration stable. These hole-trapping centers are not yet known with certainty. Sodium ion vacancies, or impurity O^{2-} ions on the halogen sites, have been proposed to be such centers. The trapped electrons and/or holes are released again by erasing light and they recombine to result in the initial uncolored state.

The optically irreversible coloration, that is, the thermal-erase mode coloration, has been assumed to have an intimate relation with the ionic displacement

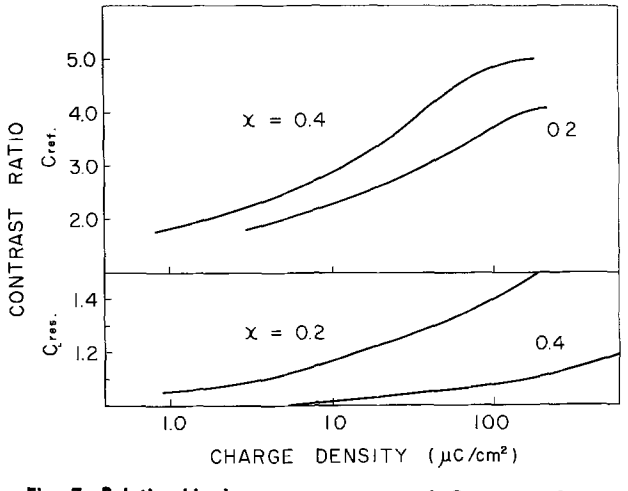

Fig. 7. Relationship between exposure and $C_{ref.}$ and $C_{res.}$ in $Na_6Al_6Si_6O_{24}\cdot 2(1 - x)NaCl\cdot xNa_2SO_4$.

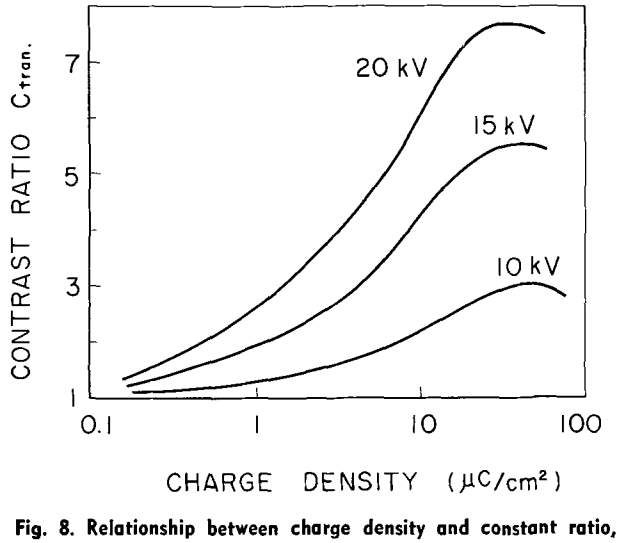

Fig. 8. Relationship between charge density and constant ratio, $C_{tran.}$, at different accelerating voltages, measured in transmission mode in $Na_6Al_6Si_6O_{24}\cdot 1.2NaCl\cdot 0.4Na_2SO_4$.

(15) or motion (11) as the result of radiation damage. Bolwijn *et al.* (11) emphasized the motion of O^{2-} ions incorporated occasionally on the halogen sites. As a result, halogen vacancies are "newly" created and this was followed by the change of nature of hole-trapping centers. The holes trapped by these modified centers are conjectured to have a negligible probability of recombining with electrons until these centers are converted to the initial ones by heating the material.

Cathodochromic sodalites thus far reported contain a halogen deficit of 10-30% (9, 15). This creation of halogen vacancies is usually accompanied by the creation of sodium vacancies and/or the incorporation of oxygen ions on halogen sites, both of which might make the occurrence of thermal-erase mode coloration easy.

The role of SO_4^{2-} radicals can be threefold. First, they could create halogen vacancies without being accompanied by sodium ion vacancies and/or contamination by oxygen. This will improve the sensitivity of optical-erase mode coloration and reduce the sensitivity of the thermal mode. Secondly, the existence of relatively large and immobile SO_4^{2-} radicals in the lattice will block the motion of other ions (22). This also suppresses the occurrence of thermal-erase mode coloration. Thirdly, SO_4^{2-} radicals might act as hole-trapping centers by themselves. The reaction will be written as $SO_4^{2-} + \text{hole} \rightarrow SO_4^{1-}$. This possibility will be confirmed by the fact that the presence of SO_4^{1-} in sodalite was detected by electron spin resonance measurements (23). By these roles of sulfate, the optically reversible coloration can be stabilized. In contrast to S-doped sodalites, SO_4-doped sodalites were found not to be photochromic at 254 nm, and the energy levels of SO_4^{2-} were assigned to be within 1 eV from the valance band (10).

The occurrence of thermal-erase mode coloration in sodalites containing sulfate will be mainly ascribed to the dissociation of sulfate radicals by the electron bombardment. The possible existence of O^{2-} ions may still play an important role. A method for a further reduction of the thermal-erase mode coloration is now under study. The result will be reported elsewhere.

Acknowledgments

The authors acknowledge their thanks to F. Muramatsu for assistance in preparing sodalite materials and to Y. Uno and members of his group for manufacturing the sodalite cathode-ray tubes and evaluating their characteristics. Acknowledgments are extended to Y. Tsujimoto and Y. Fukuda, of the Central Research Laboratory of Matsushita Electric Industrial Company, Limited, for the use of their demountable apparatus.

Properties of Epitaxial Gallium Arsenide from Trimethylgallium and Arsine

Susumu Ito, Tsuneo Shinohara, and Yasuo Seki

Central Research Laboratories, Nippon Electric Company, Shimonumabe, Kawasaki, Japan

ABSTRACT

Electrical and optical properties of epitaxial GaAs layers grown from trimethylgallium and arsine were studied by Hall and photoluminescence measurements. The conduction type of the layers grown on GaAs substrates was changed from p- to n-type with increase of [As]/[Ga], the mole ratio of arsine to trimethylgallium introduced, without intentional doping. An emission (P_2) at 1.488 eV due to shallow acceptors was observed on most of the samples.

Correlations between the carrier concentration and the intensity of the P_2 emission with [As]/[Ga] suggest that the main acceptor impurities in the epitaxial layer are amphoteric ones on As sites, such as carbon and silicon contained in the trimethylgallium source. Results of the mass-spectrographic analysis of the layers are consistent with the above suggestion.

Many GaAs epitaxial growth techniques have been proposed and performed. Among them, the use of trimethylgallium and arsine, as demonstrated by Manasevit *et al.* (1, 2), has many attractive points, such as (*i*) simplicity in apparatus because of a single temperature zone, (*ii*) independent regulation of gaseous components of gallium and arsenic, (*iii*) no gaseous etchants and less autodoping, (*iv*) low growth temperatures ($\geqq$ 600°C), and (*v*) easiness of heteroepitaxial growth on insulating substrates.

Some reports (1-6) have been made on the deposition procedures and on the surface morphology of the epitaxial layers grown on various substrates. Few reports, however, have been presented on the properties of the layer grown on the GaAs substrate, although electrical properties of the heteroepitaxial layers on Al_2O_3 have been reported (7).

This paper presents some electrical and optical properties of the epitaxial layers grown on GaAs substrates from trimethylgallium and arsine in connection with deposition conditions.

Experimental

Apparatus.—The apparatus used here is similar to that used by Manasevit *et al.* (2), as shown in Fig. 1. It consists of a vertical quartz reactor, a SiC-coated graphite pedestal which can be inductively heated, a quartz bubbler containing trimethylgallium (TMG), appropriate flow meters for monitoring carrier gases, TMG, and arsine, and pertinent stainless-steel piping and joints.

All "deposition temperatures" reported here are the readings of a thermocouple inserted into the pedestal. No preparations were made to prevent the rf field from affecting the readings of the thermocouple except for the insertion of a large inductance in the emf measurement circuit. The readings agreed well with those of an infrared radiation thermometer through the quartz reactor.

Substrates.—Although many kinds of materials have been used as the substrate (1, 2, 5), {100} GaAs wafers were used in this experiment to exclude influences of defects that frequently originate at the interface between the substrate and the epitaxial layer in heteroepitaxy. GaAs wafers were mechanically polished and then etched in a $3H_2SO_4$-H_2O_2-H_2O solution. No further treatments, such as gas etching, were made on the substrate preparation.

Key words: chemical vapor deposition, organic gallium source, GaAs substrate, impurity.

Trimethylgallium (TMG).—The TMG was obtained from several commercial sources and was used without further purification.[1] The nominal purity, according to the makers, is better than 99.5%. The bubbler containing this material is kept at 0°C during deposition.

Arsine.—AsH_3 diluted to 1% with argon was used.[2] The AsH_3 flow rate was adjusted by a pressure regulator and a needle valve.

Deposition procedures.—Gallium and arsenic contents in the reaction atmosphere were adjusted by regulating the flow rate of the gases, *i.e.*, hydrogen through the TMG bubbler and 1% AsH_3. Flow rates of TMG and AsH_3 were in the ranges from 1.1×10^{-5} to 1.1×10^{-4} mole/min and from 2.2×10^{-4} to 8.8×10^{-4} mole/min, respectively. An additional hydrogen gas flow was introduced to keep the total gas flow rate constant (2500 cm³/min).

The deposition temperatures were varied from 550° to 850°C. The AsH_3 flow started when the pedestal temperature reached 500°C, prior to introduction of TMG into the reactor, in order to prevent substrate decomposition. After the deposition is completed, the AsH_3 flow is also continued until the temperature has dropped to 500°C.

[1] Three TMG sources, A, B and C, used in this experiment were purchased from Alfa-Inorganics, Incorporated, U.S.A., K & K Laboratories, Incorporated, U.S.A., and Kojundo Kagaku Kenkyujo Japan, respectively.

[2] The diluted AsH_3 tanks (Electronic Grade) were purchased from Nihonsanso, Incorporated, Japan.

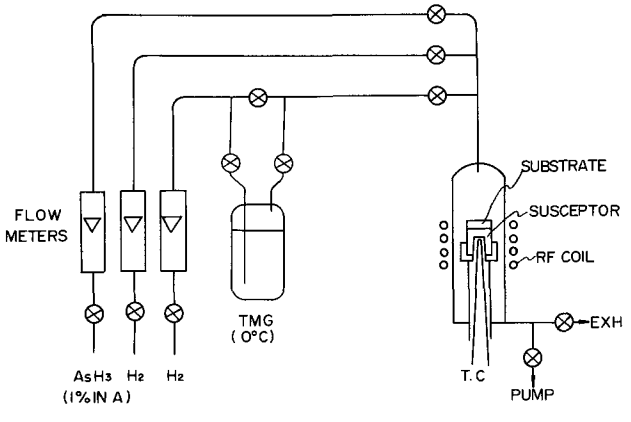

Fig. 1. Deposition apparatus

Evaluation procedures.—Conventional d-c Hall measurements were carried out on a bridge-shaped sample etched in the epitaxial layer grown on the Cr-doped semi-insulating substrate. Contacts of indium for the electrical measurement were alloyed at about 350°C in a hydrogen atmosphere. The magnetic field used in the Hall measurement was 6000 Gauss. The Hall measurements and the C-V measurements, with a palladium Schottky barrier used, gave similar carrier concentrations, and the latter showed flat profiles, independent of the film thickness (2.0 ~ 20μ).

Photoluminescence of the epitaxial layers was measured at 90°K by the same method as reported by Iwasaki and Sugibuchi (8).

Results and Discussion

Effect of deposition parameters and starting materials.—Growth rate of the GaAs epitaxial layers was found to be proportional to the TMG concentration and nearly independent of the deposition temperature in the range from 600° to about 800°C, as reported by Manasevit and Simpson (2). The carrier concentration was not affected by the growth rate in the range from 0.07 to 0.27 μm/min at a fixed temperature when a constant mole ratio of AsH_3 to TMG was used. Increase of the deposition temperature brought a slight increase in the electron concentration.

Electrical properties of the undoped layers were found to effectively depend on the TMG source used and on the mole ratio of AsH_3 to TMG introduced into the reactor. The AsH_3 sources used here had little effect on electrical and optical properties of the layers.

The electron concentrations obtained from three different TMG sources (Sources A, B, and C) used were $(2 \sim 5) \times 10^{16}$ cm^{-3}, $(1 \sim 5) \times 10^{16}$ cm^{-3}, and $(1 \sim 4) \times 10^{17}$ cm^{-3}, respectively, under the same growth conditions (deposition temperature = 600°C, growth rate = 0.2 μm/min, flow rates of TMG and AsH_3 = 5.7×10^{-5} mole/min and 7.2×10^{-4} mole/min, respectively).

Both n- and p-type epitaxial layers were grown on the GaAs substrates by changing the mole ratio of AsH_3 to TMG. Figure 2 shows the variation of the carrier concentration plotted against the mole ratio of AsH_3 to TMG, [As]/[Ga], introduced into the reactor. The variation implies some contributions of vacancies to the carrier concentrations of the layers. Detailed discussions on the variation will be made in the next section.

Optical properties.—Figure 3 shows a typical photoluminescence spectrum of the epitaxial layer. Three peaks, at 1.503 (P_1), 1.488 (P_2), and 1.2 (P_4) eV, were commonly observed in all cases. The weak peak (P_3) at 1.38 eV, which may be due to copper (9, 10), was sometimes observed. The copper atoms may come from residuals on the substrate surface or may be diffused from the substrate into the epitaxial layer. The P_1 emission at 1.503 eV is the near bandgap emission, and the P_4 emission at 1.2 eV may be the self-activated luminescence by gallium vacancy-donor complexes (11).

The P_2 emission at 1.488 eV should be noted. This emission has not been observed so intensively in undoped epitaxial layers prepared by the Ga-$AsCl_3$ system or by the liquid regrowth. A close correlation between the P_2 emission and the carrier concentration in the epitaxial layers can be seen in Fig. 4 for p- and n-type layers, where I_1 and I_2 are the peak intensities of P_1 and P_2, and I_2/I_1 is taken as a measure for simplicity instead of each integrated intensity of the P_2 emission. A main difference in the experimental conditions between the p- and n-type series is on the mole ratio of AsH_3 to TMG, [As]/[Ga], introduced. Both series imply that I_2/I_1 increases with increase of the acceptor concentration in the epitaxial layers. It may be concluded that the P_2 emission is due to shallow acceptors with an energy level of

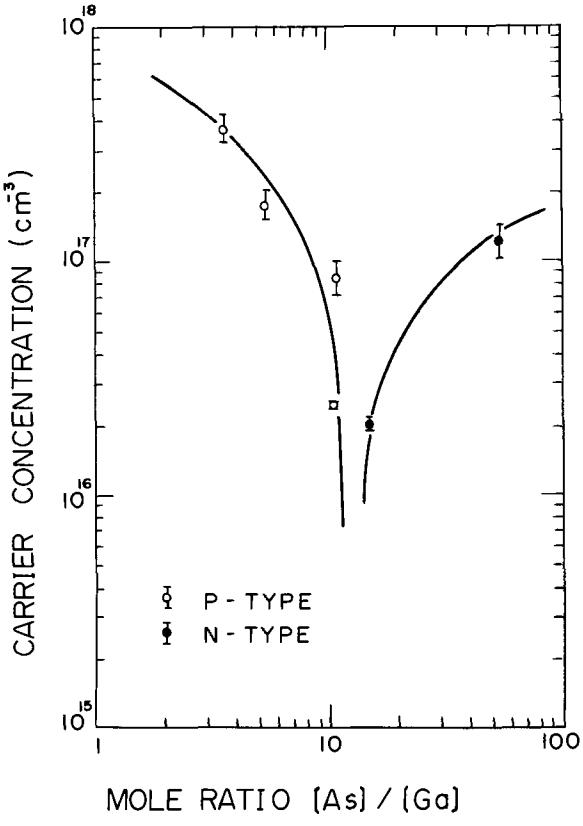

Fig. 2. Carrier concentration vs. introduced gas ratio of AsH_3 to TMG ([As]/[Ga]).

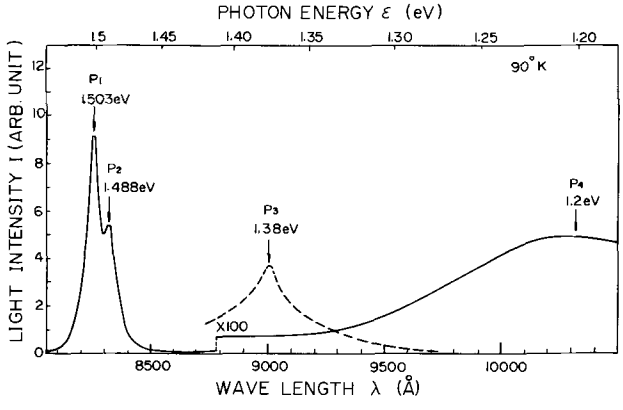

Fig. 3. Typical photoluminescence spectrum of an epitaxial GaAs layer grown by the TMG-AsH_3 system at 90°K.

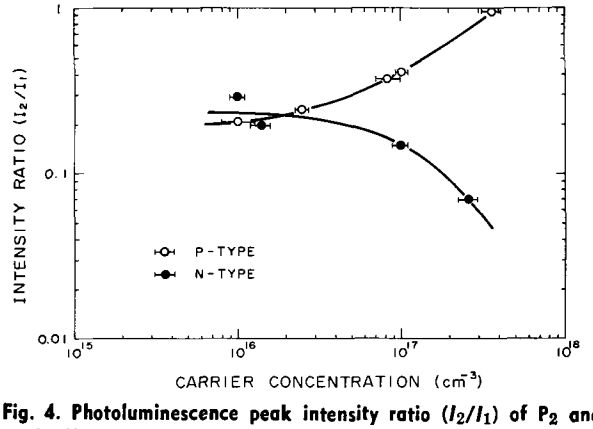

Fig. 4. Photoluminescence peak intensity ratio (I_2/I_1) of P_2 and P_1 at 90°K vs. carrier concentration.

about 20 meV above the top of the valency band and related to the main acceptors in the epitaxial layers.

Some of the group II and IV elements, such as zinc, magnesium, cadmium (12-14), germanium, silicon, and carbon (10, 12, 13, 15), are known to have a similar acceptor level. It seems that Fig. 2 shows a reaction between the impurities and the arsenic or gallium vacancies on the crystal surface during the deposition. Considerations of the vacancies will give a suggestion on the origin of the P_2 emission. If we can represent the deposition process as follows

$$Ga(CH_3)_3(g) + \frac{3}{2}H_2(g) \rightleftarrows Ga(l) + 3CH_4(g) \quad [1]$$

$$AsH_3(g) \rightleftarrows \frac{1-x}{2}As_2(g) + \frac{x}{4}As_4(g) + \frac{3}{2}H_2(g) \quad [2]$$

$$Ga(l) + V_{Ga} \underset{\text{decomposition}}{\overset{\text{deposition}}{\rightleftarrows}} Ga(s) \quad [3]$$

$$\text{and } \frac{1-x}{2}As_2(g) + \frac{x}{4}As_4(g) + V_{As} \underset{\text{decomposition}}{\overset{\text{deposition}}{\rightleftarrows}} As(s) \quad [4]$$

then, by the law of mass action, we have

$$\frac{[V_{Ga}]}{[V_{As}]} = \alpha(T) \cdot \left(\frac{P_{CH_4}}{P_{H_2}}\right)^3 \cdot \frac{P_{AsH_3}}{P_{TMG}} \quad [5]$$

where x indicates the fraction of As_4 to the total arsenic molecules; (s), (l), and (g) indicate the material states (crystalline solid, liquid, and gas states, respectively); V and $[V]$ indicate a vacancy and its concentration; P_i indicates the partial pressure of material i; α indicates the proportional constant of the reactions; and T is the absolute temperature. Here it was assumed that $\frac{1-x}{2}$ and $\frac{x}{4}$ molecules of As_2 and As_4 attack and occupy an As site. It is reasonable to assume that P_{AsH_3}/P_{TMG} in the equilibrium is proportional to [As]/[Ga], the introduced gas ratio, and that the concentrations of the Ga and As vacancies vary according to Eq. [5]. The high [As]/[Ga] value in the deposition atmosphere will suppress the formation of the As vacancy and will enhance the formation of the Ga vacancy in the layer, so that the impurities substitute in Ga sites will increase. The group II elements on Ga sites act as acceptors, whereas the group IV elements are amphoteric and are acceptors on As sites and donors on Ga sites. The layers grown under the different values of [As]/[Ga] will show different features in the photoluminescence spectrum and in the conduction type depending on the origin of the acceptors.

Figure 5 shows the experimental results obtained according to the above suggestion, where the variations of I_2/I_1 are seen as a function of [As]/[Ga]. The points near the upper line are on p-type samples, except for the lowest point of an n-type one, formed in successive runs of a reaction series where source A TMG was used. Those near the lower one are on n-type samples formed in another series where source B TMG was used. In both series, I_2/I_1 increases with decrease of [As]/[Ga], with increase of the As vacancy concentration, and with decrease of the Ga vacancy concentration. These lines suggest that the P_2 emission is related to the group IV elements and not to the group II elements.

Further discussions can be made from the standpoint of the chemical equilibrium and the law of mass action, when the group IV elements are the origin of the P_2 emission. Reactions between one of the group

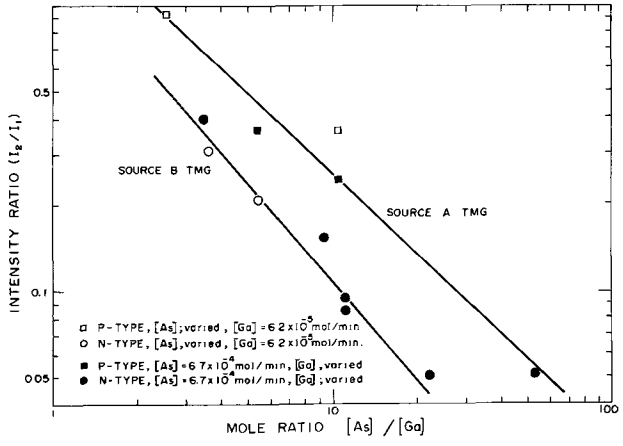

Fig. 5. Photoluminescence peak intensity ratio (I_2/I_1) of P_2 and P_1 of p- and n-type samples grown from source A and B at 90°K vs. introduced gas ratio of AsH_3 to TMG ([As]/[Ga]).

IV elements, M_i, and the vacancies, V_{Ga} and V_{As}, can be written as follows

$$V_{Ga} + M_i(g) \rightleftarrows M_i(\text{Ga site}) \quad [6]$$

and

$$V_{As} + M_i(g) \rightleftarrows M_i(\text{As site}) \quad [7]$$

If the donor and acceptor concentrations, N_D and N_A, in the epitaxial layer are mainly due to the group IV elements, then we have

$$N_D - N_A \cong \sum_i \{[M_i(\text{Ga site})] - [M_i(\text{As site})]\}$$

$$\cong \sum_i P_{M_i} \left\{ \alpha'_i(T) \cdot \frac{P_{CH_4}^3}{P_{H_2}^{3/2}} \cdot \frac{1}{P_{TMG}} - \alpha''_i(T) \cdot P_{H_2}^{3/2} \cdot \frac{1}{P_{AsH_3}} \right\} \quad [8]$$

where i, P_{M_i}, and M_i denote one of the group IV elements, its partial pressure, and concentration in GaAs, respectively; $\alpha'_i(T)$ and $\alpha''_i(T)$ are the proportional constants. It can be expected from Eq. [8] that $N_D - N_A$ may be varied by changing the mixing ratio of the source materials. Figure 2 shows this situation clearly. If the group II elements, instead of the group IV elements, were the main acceptor impurity source, $N_D - N_A$ should increase with increase of [As]/[Ga], contrary to the experiments.

The peak intensity of the P_2 emission also varies with the deposition temperature, T, as shown in Fig. 6. Increase of I_2/I_1 with increase of the deposition temperature may be explained that many more As

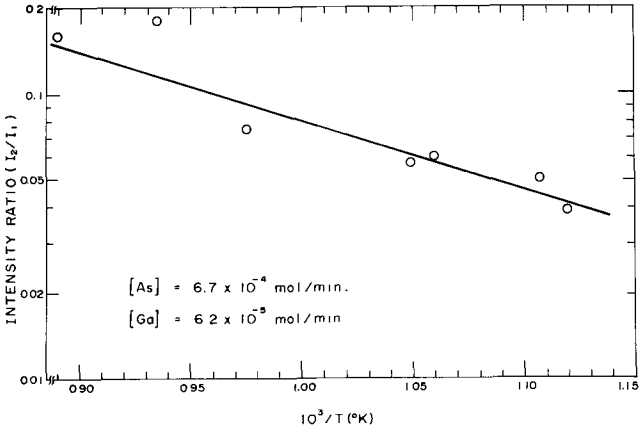

Fig. 6. Photoluminescence peak intensity ratio (I_2/I_1) of P_2 and P_1 of n-type samples at 90°K vs. deposition temperature (T).

vacancies than Ga vacancies are formed at these temperatures (16, 17).

Further evidence on the origin of the P_2 emission or of the main acceptor impurities in the epitaxial layer may be seen in Table I, in which the impurity contents in the layer examined by the mass-spectrographic analysis are tabulated. In the table, the upper data are Rai-Choudhury's (4), and the lower are the data obtained in the present experiment. Both show that the major impurities are carbon and silicon and that the minor ones are magnesium and zinc (oxygen and chlorine are also seen at high contents, but they seem to be not so electrically active in GaAs). These data support the model wherein the group IV elements are the main impurities and mainly contribute to the P_2 emission in the epitaxial layers.

When the growth rate was varied from 0.07 to 0.27 μm/min, there was little change in I_2/I_1 and the carrier concentrations of the epitaxial layers provided a constant value of [As]/[Ga]. This may be explained in the following way. If the group IV elements, *i.e.*, carbon and silicon, come from the TMG source, Eq. [8] can be rewritten

$$N_D - N_A \cong \sum_i \frac{P_{Mi}}{P_{TMG}} \left\{ \alpha'_i(T) \cdot \frac{P_{CH_4}{}^3}{P_{H_2}{}^{3/2}} - \alpha''_i(T) \cdot P_{H_2}{}^{3/2} \cdot \frac{P_{TMG}}{P_{AsH_3}} \right\} \quad [9]$$

and

$$N_D - N_A \propto \sum_i \frac{P_{Mi}}{P_{TMG}} \; (= \text{constant}) \quad [10]$$

when P_{AsH_3}/P_{TMG} = constant or [As]/[Ga] = constant at a fixed deposition temperature. A similar result might be deduced from Eq. [9] if these carbon and silicon atoms come from the AsH_3 source and the TMG container. The amounts of impurities from the AsH_3 source or the TMG container are, however, negligible since no appreciable changes are observed in the carrier concentration and in the photoluminescence spectrum when different AsH_3 sources or different TMG containers, such as quartz, glass, and stainless-steel ones, are used. The fact that the carrier concentrations of the epitaxial layers were changed when different TMG sources were used and that the main metallic impurities in the TMG sources used here were silicon (25 ~ 40 ppm), rather than magnesium (1 ppm) and zinc (not detectable), is another confirmation of the model wherein the main acceptor impurities are silicon and carbon that come from the TMG sources. One of possible sources of carbon may be organic compounds contained in the TMG sources. [The carbon contamination by the decomposition of the methyl radicals of TMG is thought to be small in the light of the chemical equilibrium (4).] It has been reported that carbon contamination of the order of 10^{18} cm^{-3} is observed in the high purity GaAs by the Ga-$AsCl_3$ system (18). The carbon atoms seem not to be the main contributors to the acceptor densities or to the P_2 emission, although the behavior of carbon in GaAs is still uncertain.

An emission at 1.40 eV associated with silicon has been reported (8) in the epitaxial layers by the Ga-$AsCl_3$ system. This emission was, however, not observed in the present experiments. Relatively low concentrations of silicon may be the reason for no appearance of the emission because it could be observed at higher concentrations ($> 10^{17}$ cm^{-3}) (19).

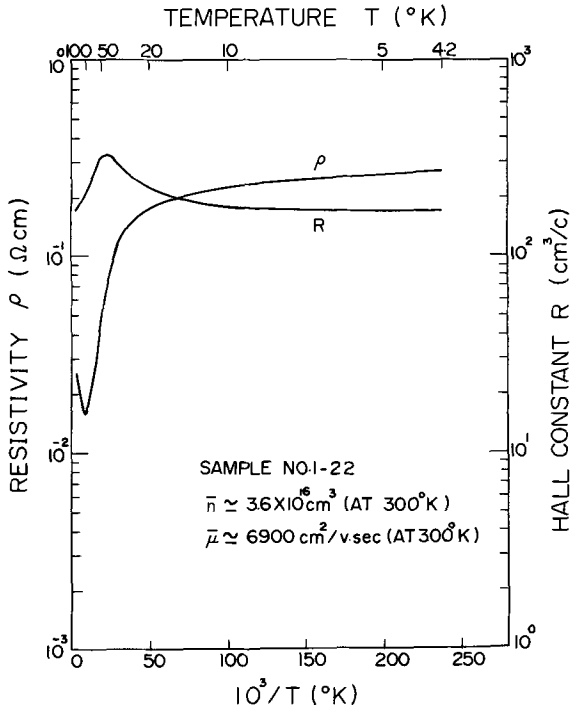

Fig. 7. Hall constant (R) and resistivity (ρ) of a typical epitaxial layer vs. temperature (T).

Electrical properties.—Epitaxial layers with $n < 10^{16}$ cm^{-3} and $\mu > 5000$ cm^2/V · sec at room temperature are desired for GaAs devices such as Gunn effect devices, FET's, Schottky barrier devices, and so on. The Hall constants and resistivities of some samples (2.0 ~ 20.0 μm in thickness) with n and μ near the above values were measured at temperatures from 4.2° to 300°K.

Figure 7 is a typical example of the Hall measurements, where the Hall constant, R, and resistivity, ρ, are shown as a function of the temperature, T. The impurity conduction (20, 21) can be seen as like the other samples examined, that is, the Hall constant has a maximum value at a low temperature. The impact ionization of electrons from the "donor band" to the conduction band at an external field, 12 V/cm, were observed as drastic changes of R and ρ at 4.2°K. This field is quite similar to that (10 V/cm) observed in the epitaxial GaAs layer by the Ga-$AsCl_3$ system (22).

Effective carrier concentrations ($\bar{n}$) and mobilities ($\bar{\mu}$) of this sample at 300° and 77°K are tabulated in Table II, together with some other similar ones, where

$$\bar{n} = -\frac{1}{qR} = \frac{(n_c + bn_d)^2}{n_c + b^2 n_d}, \quad b = \frac{\mu_d}{\mu_c} \quad [11]$$

and

$$\bar{\mu} = -\frac{R}{\rho} = \frac{n_c\mu_c{}^2 + n_d\mu_d{}^2}{n_c\mu_c + n_d\mu_d} \quad [12]$$

where q is the electronic charge; n_c, n_d, and μ_c, μ_d are the electron concentrations and the mobilities of the conduction band and the donor band, respectively; and the scattering factors of the carriers are taken to be unity for simplicity.

Table I. Impurity concentrations in GaAs grown by the TMG-AsH_3 system in parts per million

	C	N	O	Si	S	Fe	Cu	Zn	Mg	Cl
Rai-Choudhury (4)	238.4	1.78	220.4	4.46	1.47	1.60	2.24	0.89	—	—
Present experiment	25	—	5	1 ~ 5	0.1 ~ 3	<0.3	<0.1	0.2 ~ 0.3	0.1 ~ 0.6	1 ~ 28

Table II. Effective carrier concentration ($\bar{n}$), mobility ($\bar{\mu}$), estimated values of impurity concentration (N_A and N_D), compensation ratio ($K = N_A/N_D$), and donor level ($E_C - E_D$) of typical epitaxial layers

Sample No.	Thickness t (μm)	300°K $\bar{n}$ (cm⁻³)	300°K $\bar{\mu}$ (cm²/V·sec)	77°K $\bar{n}$ (cm⁻³)	77°K $\bar{\mu}$ (cm²/V·sec)	Estimated values K (= N_A/N_D)	N_D (cm⁻³)	N_A (cm⁻³)	$E_C - E_D$ (meV)
1-22	2.4	3.6×10^{16}	6,900	2.5×10^{16}	12,500	0.49	7.1×10^{16}	3.5×10^{16}	2.2
1-29	18.0	1.1×10^{16}	6,000	8.5×10^{15}	15,400	0.70	3.6×10^{16}	2.5×10^{16}	2.0
2-5	8.0	7.0×10^{15}	5,100	4.9×10^{15}	12,400	0.79	3.3×10^{16}	2.6×10^{16}	2.4
11-4	7.8	13×10^{16}	5,500	7.8×10^{15}	11,700	0.59	3.2×10^{16}	1.9×10^{16}	5.5

The growth conditions of these samples are as follows: (*i*) deposition temperature = 650° ~ 670°C; (*ii*) [As]/[Ga] = 9 ~ 11; (*iii*) samples 1-22, 1-29, and 2-5 were grown from the source A TMG; and (*iv*) sample 11-4 was grown from the source B TMG. The relatively low mobilities at 77°K suggest that all samples are compensated with acceptor impurities. Donor and acceptor concentrations (N_D and N_A) and μ_c were estimated by the Brooks-Herring's formula (23) where μ_c was calculated by the following equations

$$\mu_c = \frac{2}{1 + b\bar{\mu}} \quad [13]$$

$$b = \left(\frac{2R_{max}}{R_{4.2°K}} - 1\right) - 2\sqrt{\frac{R_{max}}{R_{4.2°K}}\left(\frac{R_{max}}{R_{4.2°K}} - 1\right)} \quad [14]$$

at the temperature when R is maximum. The donor levels ($E_C - E_D$) were also estimated using these N_D and N_A and the following relation (24)

$$\frac{n_c\,(n_c + N_A)}{N_D - N_A - n_c} = \frac{N_c}{g}\exp\left\{-\frac{E_C - E_D}{kT}\right\} \quad [15]$$

In Eq. [15], N_C is the effective density of states of the conduction band and g is the degeneracy of the donor level, where $g = 2$. Table II shows these estimated values together with the compensation ratio ($K = N_A/N_D$). The estimated values of the donor level are quite similar to that observed in GaAs prepared by other epitaxial methods (18). Somewhat greater values of the donor level than that reported before may be in part due to the experimental errors of about 20% in total. Large values of the compensation ratio explain the relatively low electron mobilities at 77°K and agree well with the results of the photoluminescence measurements, in which the 1.488 eV emission due to the shallow acceptors is observed with a relatively high intensity; they also agree with the mass-spectrographic analysis.

Conclusions

Epitaxial GaAs has been grown on GaAs substrates by the pyrolysis of TMG and AsH_3. Both n- and p-type layers were obtained by changing the mole ratio of TMG to AsH_3 introduced into the reactor without intentional doping. Epitaxial layers with a relatively good quality ($n \sim 10^{16}$ cm^{-3}, $\mu \sim 6000$ cm^2/V·sec at room temperature) were grown by use of a suitable TMG source and a suitable flow rate of TMG and AsH_3. Hall measurements indicate that these layers show the impurity conduction at low temperatures, and are heavily compensated with acceptor impurities. Donor levels are estimated to be 2.0 ~ 5.5 meV by the Hall measurements.

Photoluminescence measurements suggest that the main acceptor impurities in the epitaxial layer correspond to an emission with a peak at 1.488 eV beside the near bandgap emission at 1.503 eV. The origin of the acceptor impurities is thought to be carbon, silicon, or both from the TMG source.

Reproducible High-Efficiency GaP Green-Emitting Diodes Grown by Overcompensation

O. G. Lorimor, W. H. Hackett, Jr., and R. Z. Bachrach

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

High-efficiency GaP green light-emitting p-n junctions have been reproducibly grown employing an overcompensation technique in a vertical dipping LPE system. In this technique both the n- and p-type layers are grown in a single LPE crystal growth run, eliminating potential interface problems at the junction. For junction material grown at an initial temperature of 900°C the EL quantum efficiencies of encapsulated mesa diodes ranged from 0.08 to 0.14% and averaged 0.10% at 5 mA (~5-10 A/cm²). Minority carrier diffusion lengths (L_e,L_h) and relative cathode-luminescence efficiency (CL) were measured in a scanning electron microscope. At excitation levels equivalent to current densities of ~1-10 A/cm² in a p-n junction, both L_e and L_h range from 3 to 5μ with maximum measured values of $L_h = 7.2\mu$ and $L_e = 5.6\mu$ for material grown from 900°C. At the same excitation level the CL efficiency of the p-layers was typically found to be approximately 2-3 times that of the n-layers. Typical values for L_e, L_h, CL, and the EL efficiencies were found to be larger by ~50% for material grown from 900°C compared to similarly grown material from 1000°C. The major assets of the overcompensation technique are the high degree of reproducibility in obtaining high efficiencies and that only a single growth process is necessary to form the p-n junction.

GaP p-n junction material used in the fabrication of both red and green LED's is customarily grown in two separate LPE grown runs (1). With this double LPE procedure, the surface of the first grown layer may become oxidized, contaminated, and possibly damaged during the handling and preparation of the crystal prior to the growth of the second layer. Such defects could degrade diode performance by increasing the deep-state space charge recombination, resulting in nonreproducible electroluminescent efficiencies.

There is some direct evidence of nonreproducible junction characteristics in GaP electroluminescent diodes made from material grown by the usual techniques. For example, recent measurements of the charge storage time of GaP green LED's have been made by abruptly switching a forward biased diode into reverse bias (2). These measurements indicate that, for material with similar electroluminescent decay times, the storage time can be a sensitive measure of injection efficiency. Specifically, in cases where the storage time is shortest at 1-10 A/cm², the space charge current is largest resulting in low injection efficiencies and low electroluminescent efficiencies. Variations in the space charge current were found in diodes from the same slice as well as from different slices. Consequently, it appeared that additional measures are required to provide reproducible, "high-quality" space charge regions necessary for consistently high-efficiency GaP green LED's.

In an attempt to achieve reproducibly small space charge currents, a different junction fabrication technique was investigated in which both LPE layers are grown in a single crystal growth run. Since the seed need not be removed from the growth system between LPE layer growths, interface contamination or damage should be eliminated. An overcompensation technique similar to that described by Shih *et al.* (3) was incorporated into our growth system. After growth of the n-layer, sufficient Zn is added to overcompensate the melt, and the p-layer is subsequently grown. This technique reduces the time and effort required for LPE growth by about a factor of two.

Experimental

The LPE layers were grown in an open-flow dipping system similar to that described by Dawson and Whelan (4) for GaAs and presently used for the growth of GaP. Two modified versions of this system were used to grow the overcompensated material. The first was a small-scale system capable of growing on one seed up to ½ × ½ in. in size. Figure 1 shows a schematic of this system. The seed holder is hollow so that Zn can be dropped through the seed holder tube into the melt from the Zn drop tube during a run. The GaP source piece is used to complete the saturation of the melt with P so that no undissolved GaP remains on the melt to serve as competing growth centers (4). In this system the crucible and seed holders are fabri-

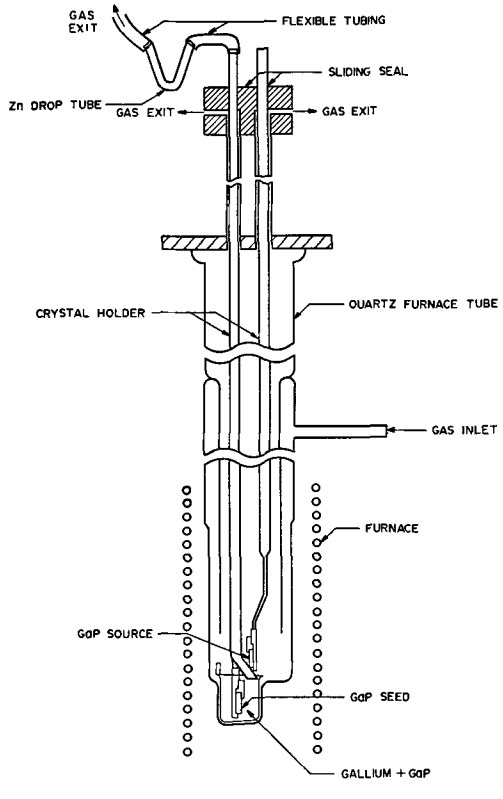

Fig. 1. Vertical dipping system as used for the small, single slice overcompensation technique.

Key words: crystal growth, minority carrier diffusion lengths, material characterization, scanning electron microscope.

cated from quartz. A 15g melt is used. The gas ambient is H_2 flowing at $\sim$ 100 cm^3/min.

The second system for the growth of the overcompensated material is nearly identical to the first except for a larger crucible and modified seed holder, as shown in Fig. 2. Growth is simultaneous on two full wafers up to 0.9-in. diameter. The seeds are mounted back-to-back on the seed holder plate. Again the Zn used to overcompensate the melt is dropped into the melt through the seed holder tube. Both the seed holders and crucible are fabricated from quartz. A 60g melt is used.

In the second system a stirring mechanism is used to produce an $\sim$ 30° oscillatory motion of the seeds about the vertical axis of the seed holder at a rate of four cycles per minute. The purpose of the stirrer is to promote the uniform dopant distribution in the melt and provide more uniform growth of the LPE layers. In previously grown double LPE material it had been found that the stirring increased the uniformity of the EL efficiency within a slice.

The overcompensation system is prepared for crystal growth by placing a Ga melt, slightly undersaturated with GaP, containing $\sim 5 \times 10^{-4}$ m/o (mole per cent) Te in the crucible. A new melt is used for each growth run. An n-type LEC crystal(s) is placed on the seed holder, as is shown in Fig. 1 and 2. The Zn ($\sim$ 0.15 m/o), which is used for overcompensating the melt to dope the p-layer, is placed in the Zn drop tube. The simultaneous N-doping is accomplished by the addition of $\sim 10^{-3}$ atm NH_3 to the H_2 gas stream. This ammonia partial pressure results in a N-concentration in the LPE layer of $\sim 8 \pm 2 \times 10^{+18}$ cm^{-3} at both 900° and 1000°C as determined by optical absorption measurements (5). After the melt is equilibrated at the initial growth temperature, saturation is completed by dipping the GaP source piece into the melt. Prior to dipping the seed, it is removed from the melt and rotated out of the way.

The n-layer is grown by cooling the melt 10° or 20°C from 900°C in 1 hr. Immediately after completion of the n-layer growth, with the seed left in the melt and the furnace held at constant temperature, the Zn is dropped into the melt through the hollow seed holder tube. After waiting 30 min for the Zn to thoroughly dissolve and distribute uniformly in the melt, the p-layer is grown by further cooling over intervals ranging from 10° to 30°C in times varying from 1 to 2 hr. Growth is terminated by removing the seed from the melt. This growth schedule results in both n- and p-layers which range in thickness from $\sim$10 to $\sim$30μ. When the larger cooling intervals are used, both layers are commonly 20 to 30μ thick. One should note that with this technique, only the p-layer is overcompensated.

For comparison purposes some double LPE crystals are also discussed where each LPE layer has been grown in a separate crystal growth run. This has been the standard process prior to the overcompensation technique. Table I compares some of the growth parameters of the double LPE material with the overcompensated material. Note that the differences in material growth are: (a) the standard n-layer is grown from 1000°C, whereas the n-layer in the overcompensated material is grown from 900°C, (b) in addition to Zn and N, the overcompensated p-layer also contains Te, and (c) the crystal was removed from the growth system between layer growths in the double LPE material but was not removed in the overcompensated material. Other growth parameters, for example, ambients, cooling rates, and crucible materials, are the same for both the overcompensated and double LPE material. The growth rates and temperatures given in Table I are those predominantly used. A few crystal growth runs were made where both layers were grown from 1000°C to study the effects of growth temperature. In cases where growth was from 1000°C, the dopant additions were adjusted to keep the net donor or acceptor concentration in each layer the same as when growth was from 900°C.

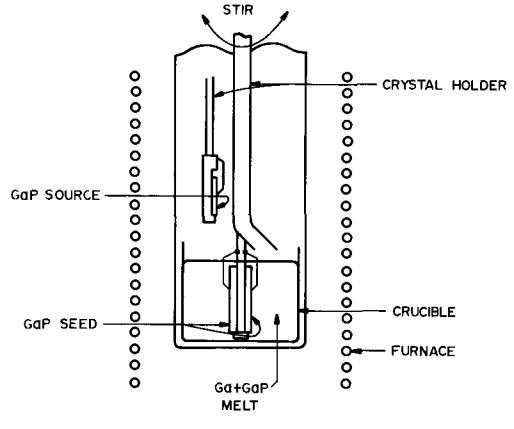

Fig. 2. Modified crucible and seed holder to grow simultaneously on two full-wafer seeds using the overcompensation technique.

Most of the quantum efficiencies were measured on mesa diodes. In the remaining cases, uncontacted diced diodes or contacted diced diodes were used. The mesa structures were formed by masking with 0.015 in. diameter gold balls and sandblasting. After wire bonding for electrical connections, the diodes were mounted on an alumina chip on a TO-18 header. This structure was domed with Maraset epoxy. The diced diodes (6) were 0.015 × 0.015 in. slurry cut dice. Prior to dicing both faces of the slice were polished, after which a SiO_2 layer was deposited onto the LPE layer side. Evaporated and alloyed contacts were formed through a metal mask on the substrate face and through holes etched in the SiO_2 layer on the LPE layer face. The dice were mounted p-side down directly on a TO-18 header. The uncontacted dice were mounted on modified TO-18 headers employing a spring-loaded wire as a pressure contact.

The efficiencies were measured in a close-coupled cavity designed by Ralston (7). Mesa diodes were measured at 5 and 50 mA which correspond to current densities of $\sim$5 and $\sim$50 A/cm^2, respectively. The efficiencies of the diced diodes were measured at twice the current as that used for the mesas to obtain data at equivalent current densities. Unencapsulated contacted diced diode data are multiplied by a factor of two for typical increases in optical coupling achieved by encapsulation (8), which results in efficiencies within ±20-30% of mesa diode efficiencies. The efficiencies of the uncontacted dice were measured only at 10 mA. These efficiencies were multiplied by an empirically determined factor of 1.6 for typical increases in optical coupling achieved by encapsulation, which also results in efficiencies within ±20-30% of mesa diode efficiencies.

The cathodoluminescence (CL) and diffusion length measurements were performed in a Cambridge

Table I. Comparison of growth parameters of double LPE and overcompensated techniques

	Over-compensated	Double LPE
Structure	p/n/LEC	p/n/LEC
n-Layer		
Dopants	Te,N	Te,N, or S,N
Typical N_d-N_a	1-2 × 10^{17}	1-2 × 10^{17}
Initial growth temperature, °C	900	1000
LPE growth run	First	First
p-Layer		
Dopants	Zn,Te,N	Zn,N
Typical N_a-N_d	5-8 × 10^{17}	5-8 × 10^{17}
Initial growth temperature, °C	880-890	900
Equilibration time	½ hr	½ hr
LPE growth run	Same run as n-layer	Second

"Stereoscan" scanning electron microscope (9). The measurements are generally made by scanning a focused electron beam across a polished surface perpendicular to the junction on a 15 × 15 mil die. A photomultiplier detection system is used to measure the cathodoluminescence emitted by the sample due to the electron beam excitation. The diffusion lengths are determined by measuring the induced junction current as a function of scan distance across the junction (9). The electron beam excitation levels are equivalent to diffusion current densities of ~ 1-10 A/cm² through a p-n junction. The low current EL efficiencies were measured at current densities of ~ 5-10 A/cm².

Results

Overcompensation.—A typical doping profile (10), $|N_d - N_a|$ as a function of depth, of the overcompensated material is shown in Fig. 3. Doping levels close to these are currently felt to be optimum for high-efficiency green LED's (11), and are essentially identical to those measured on crystals grown in the double LPE manner. The decrease in $N_a - N_d$ of the p-layer toward the surface is attributed to Zn loss during the crystal growth run, since it far exceeds the decrease expected from the temperature dependence of the Zn distribution coefficient (12, 13). This loss is also seen in the profiles from the double LPE material.

Figures 4 and 5 show the efficiencies measured at low (~ 5 A/cm²) and high (~ 50 A/cm²) current densities, respectively, for test diodes fabricated from nine successive crystal growth runs which were specifically made to obtain high efficiency material. These efficiencies are comparable to those of better diodes fabricated from material grown in the standard manner. In addition, the reproducibility in achieving the efficiencies is very high. Essentially every growth

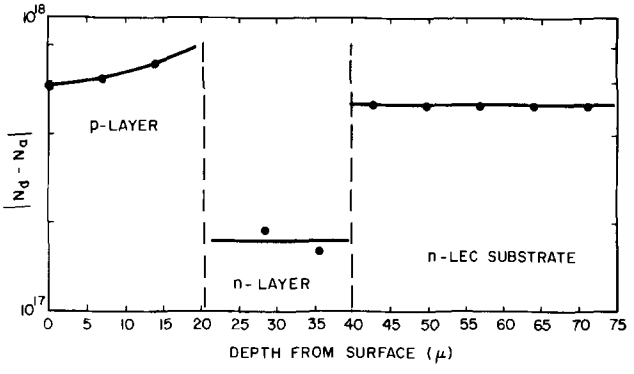

Fig. 3. Typical doping profile of the overcompensated material used for the fabrication of high-efficiency green LED's.

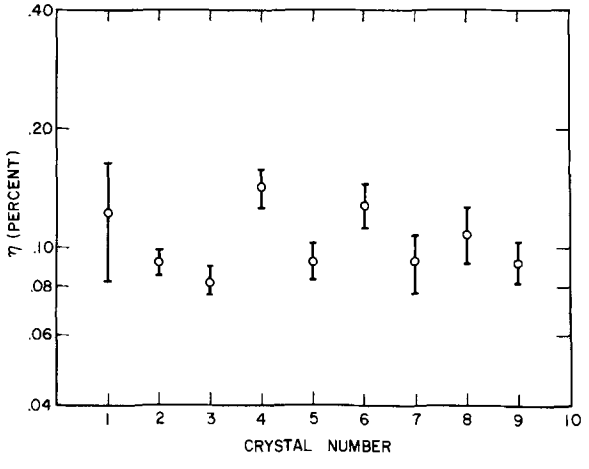

Fig. 4. Quantum efficiencies of encapsulated mesa diodes at 5 mA (~5 A/cm²) for nine successive overcompensation crystal growth runs.

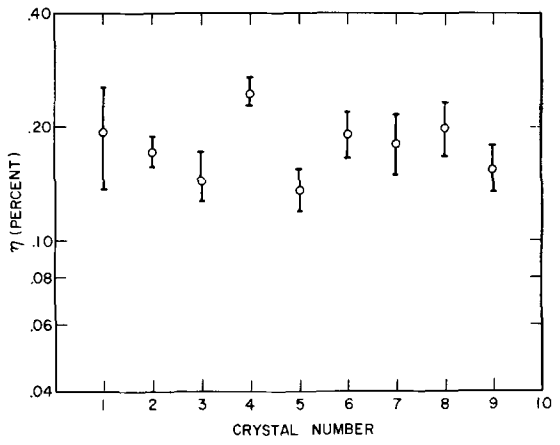

Fig. 5. Quantum efficiencies of encapsulated mesa diodes at 50 mA (~ 50 A/cm²) for nine successive overcompensation crystal growth runs.

which was made with the overcompensation procedure yielded efficiencies as high as those shown in Fig. 4 and 5. This reproducibility is to be compared with that obtained with the standard double LPE procedure where the efficiencies varied from ~0.04 to over 0.2% at 50 A/cm². Approximately half the standard growths resulted in efficiencies less than 0.1% at 50 A/cm². The average efficiency of the overcompensated crystals was 0.10% with the individual slices varying from 0.08-0.14%, at 5 A/cm² and nearly a factor of two higher at 50 A/cm². Thus, the important material improvement realized through overcompensation is reproducibility in achieving high efficiencies. Although equally high efficiencies were achieved with the standard process, the reproducibility was so poor that the average efficiency was approximately half that achieved with overcompensation.

To check whether the improved reproducibility of the overcompensated diodes is due to a uniform reduction of the space charge current, the current through the diodes at a forward bias of 1.4V was measured. At this voltage the current is typically dominated by deep-state space charge current (6). The current through the overcompensated and both good and poor standard diodes was typically $\lesssim 7 \times 10^{-5}$ A/cm². Larger currents were not observed in the overcompensated diodes, while occasionally a larger current was measured in a standard diode which correlated with a low EL efficiency (2). Thus, the overcompensation technique did not result in an obvious reduction of space charge current as was anticipated, but did eliminate anomalously high values. Thus it appears that there were often other problems with the standard technique, such as varying minority carrier lifetimes.

During the half-hour equilibration period and p-growth, one might expect that Zn diffuses into the n-layer and displaces the p-n junction from the metallurgical junction which might have a high concentration of defects. However, this effect does not appear to be important. Zn diffusion data indicates that the junction movement would be small, $\lesssim 1\mu$ (14), for the times and temperatures used in LPE growth. The standard procedure also included a similar half-hour equilibration period which should result in essentially equal Zn diffusions for both growth procedures. These conclusions are corroborated in the SEM, where there is no evidence of an interface of nonradiative recombination centers in the p-layer near the junction using high magnification CL scans. A significant concentration of such recombination centers at a metallurgical interface displaced from the p-n junction would have resulted in a localized decrease in CL.

To investigate whether the overcompensated p-layers were degraded by the presence of Te, measurements

of the minority carrier diffusion lengths, L_e, were made and compared to those for standard p-layers which are not overcompensated. These diffusion lengths are compared in Table II. In both techniques $3\mu \lesssim L_e \lesssim 5\mu$ with no noticeable difference between the two techniques. Thus it is concluded that for these doping levels, overcompensation does not degrade the p-layers.

Effects of growth temperature.—Extensive growth of GaP green LED material has been performed from two temperatures, 1000° and 900°C. Table III presents a summary of the average efficiency of the material grown from these temperatures by both the double LPE and overcompensation techniques. The average efficiency of the 900°C overcompensated growths was 0.104% measured on encapsulated mesa diodes at 5 A/cm². It is felt that this technique and temperature will give reproducible 5 A/cm² efficiencies of ~0.10%. All other combinations of growth techniques and temperatures used to date and listed in Table III result in average efficiencies lower by $\gtrsim$ 50%. We feel that the higher average efficiency of the overcompensated material grown from 900°C is primarily due to the lower growth temperature which in turn results in higher reproducibility.

Table IV presents a summary of the minority carrier diffusion lengths, relative CL intensities, and EL efficiencies for a few specific samples grown from these temperatures both by the double LPE and overcompensation techniques. The minority carrier diffusion lengths presented in this table are generally as long if not longer than those previously reported for LPE grown Zn-doped and Te-doped GaP (9, 15). When growth is from 900°C, the range generally found is $3\mu \lesssim L_h \lesssim 5\mu$ with a maximum of 7.2μ in the n-layers, and in the p-layers also $3\mu \lesssim L_e \lesssim 5\mu$ with a maximum of 5.6μ. When growth is from 1000°C in quartz, the diffusion lengths are reduced, $1.5\mu \lesssim L_{h,e} \lesssim 2.5\mu$ with a maximum of 3.7μ in both the n- and p-layers. In addition, both the n- and p-layers grown from 900°C have approximately a 50% greater CL intensity than similar layers grown from 1000°C. When both layers are grown from the same temperature, the CL efficiency of the

* This sample has an additional n-type LPE layer between the substrate and the n-LPE layer discussed here.
† Relative efficiency of the sample compared to the average of those shown in Table III grown in the same manner.
‡ Quantum efficiency extrapolated from a point contact measurement.
** The layers varied by a factor of two in thickness across this sample. These measurements were made where the layers were the thickest. The CL, L_e, L_h, and η all decreased with decreasing layer thickness.
*** N concentration low by ~ a factor of 2. However, the low N concentration should reduce only the CL and EL efficiencies and not the diffusion lengths.

p-layer is generally two to three times that of the n-layer. Consequently, since all other growth conditions were unchanged, we conclude that the increase in minority carrier diffusion lengths and CL for 900°C growth in quartz compared to 1000°C is entirely due to the temperature difference. However, one should note that the longest diffusion length measured in layers grown at 1000° (3.7μ) is comparable to that measured in many similar layers grown from 900°C. Also, as can be seen from Table IV, there are considerable differences in diffusion lengths for supposedly similar layers grown at the same temperature. It is felt that unknown interactions during LPE growth, which are more severe when growth is from 1000°C rather than 900°C, are both limiting the diffusion lengths to the present values and causing these variations. An experimental program is in progress to define these variations and interactions in an effort to increase the electroluminescent efficiencies in GaP green-emitting diodes.

Conclusions

An overcompensation technique has been successfully used for the growth of GaP LPE layers used in the fabrication of green LED's. In this technique both LPE layers are grown in a single crystal growth run which avoids potential oxidation, contamination and/or damage at the p-n junction interface. An additional advantage of this technique is that only one LPE growth is necessary to form the p-n junction. With an initial growth temperature of 900°C, material with average efficiencies of 0.10% at 5 A/cm^2 for encapsulated mesa diodes with adequately thick layers ($\gtrsim 20\mu$) was grown routinely and reproducibly. Because of the high degree of reproducibility in the efficiencies and the use of a single LPE growth step, this technique is an attractive approach for fabrication of GaP green-emitting junctions.

The EL efficiencies, relative CL, and minority carrier diffusion lengths have been measured and compared for the overcompensated material grown in quartz from both 900° and 1000°C and double LPE 900°C p-layers on 1000°C n-layers. The average EL efficiencies for the 900°C overcompensated material were larger by at least 50% than the efficiencies for the material grown entirely from 1000°C. These results correlate with the fact that the CL and the diffusion lengths in both n- and p-layers grown from 900°C were larger by ~ 50% than that in a corresponding layer grown from 1000°C. The CL of the p-layers was found to be typically two to three times that of the n-layers when both were grown from the same temperature. In material grown from 900°C, the minority carrier diffusion lengths L_e and L_h were both typically found to range between 3 and 5μ with values as large as $L_h = 7.2\mu$ and $L_e = 5.6\mu$. It appears clear that low-temperature crystal growth results in important improvements in material quality.

Etching Studies of Diffusion Source Boron Glass

Lillian Rankel Plauger

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

For selective boron doping of silicon, a SiO_2 diffusion mask is used. In many cases, it is advantageous to retain the same SiO_2 mask on the silicon slice after diffusion and remove the boron diffusion source glass. To accomplish retention of the SiO_2 mask while dissolving boron diffusion source glass, a selective etch is required that favors dissolution of boron-doped glass. Etching solutions that fulfill this need have been found.

When selectively doping silicon with boron, a borosilicate glass is deposited on a SiO_2 diffusion masked substrate (see Fig. 1). This boron diffusion source glass is subsequently removed, and in many instances the SiO_2 diffusion mask must be left in place. In cases such as this, an etching solution must be found that favors the dissolution of borosilicate glass over SiO_2.

It is known that "P" etch [15 parts HF (49%), 10 parts HNO_3 (70%), and 300 parts H_2O] dissolves various types of glass and mixed oxide layers more rap-

Etching Studies of Diffusion Source Boron Glass

Lillian Rankel Plauger

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

For selective boron doping of silicon, a SiO_2 diffusion mask is used. In many cases, it is advantageous to retain the same SiO_2 mask on the silicon slice after diffusion and remove the boron diffusion source glass. To accomplish retention of the SiO_2 mask while dissolving boron diffusion source glass, a selective etch is required that favors dissolution of boron-doped glass. Etching solutions that fulfill this need have been found.

When selectively doping silicon with boron, a borosilicate glass is deposited on a SiO_2 diffusion masked substrate (see Fig. 1). This boron diffusion source glass is subsequently removed, and in many instances the SiO_2 diffusion mask must be left in place. In cases such as this, an etching solution must be found that favors the dissolution of borosilicate glass over SiO_2.

It is known that "P" etch [15 parts HF (49%), 10 parts HNO_3 (70%), and 300 parts H_2O] dissolves various types of glass and mixed oxide layers more rap-

Key words: borosilicates, diborate, diffusion sources, etching borosilicates.

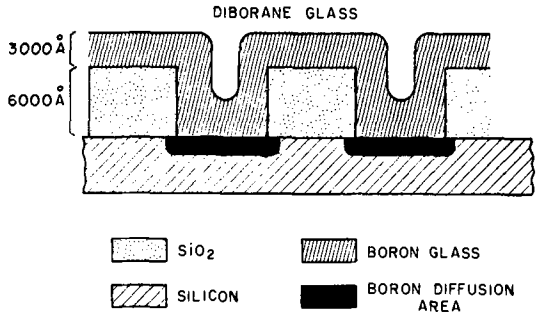

Fig. 1. Doping of silicon with boron diffusion source glass

idly than it dissolves silicon dioxide (1-4). Since "P" etch contains HNO_3, it was decided to investigate etching solutions with a relatively high concentration of oxidizing agents. These etching solutions were evaluated on borosilicate glass formed by low-temperature gaseous diborane with high-temperature anneal of deposited film. Etch rate of each glass was correlated with boron concentration. The etching characteristics of solutions formulated during this study are compared to well known standard solutions such as buffered HF and "P" etch.

Experimental

Silicon slices 3.2-cm in diameter were prepared according to Table I. The diborane glass depositions were done in a bell jar vertical reactor. A resistance-heated platform 8 in. in diameter provided the heat.

Table I. Glass deposition conditions

† Concentration of B in silicon after 1100°C diffusion for ½ hr in N_2 atmosphere.

Table II. Composition of etching solutions, HF(49%) HNO_3(70%)

1.	Buffered HF	113g NH_4F 170 ml H_2O 28 ml HF
2.	"P" etch	15 ml HF 10 ml HNO_3 300 ml H_2O
3.	HNO_3-HF "R" etch	100 ml HNO_3 100 ml H_2O 1 ml HF
4.	HNO_3-HF "S" etch	100 ml HNO_3 100 ml H_2O 4.4 ml HF

SiH_4 was diluted to 1% in N_2 and B_2H_6 was diluted 0.1% in N_2. Nitrogen was the buffer gas with a total flow rate of 3000 cm³/min; SiH_4 flowed at 200 cm³/min and O_2 at 50 cm³/min. The diborane-doped SiO_2 deposition was allowed to proceed until 5700Å of glass had formed. This thick glass deposit allowed more data points for the etching study. However, in device processing, 1500-3500Å is the typical thickness for diffusion source diborane deposited glass. After borosilicate or SiO_2 deposition, the slices used for the etching study were photoresisted with AZ-111. For each etching experiment, a small area of photoresist was developed and the glass underneath etched. With this method, the etching behavior of all solutions could be evaluated on material prepared in an identical manner. Also, this photoresist technique was chosen because cutting or breaking a silicon slice covered with an oxide layer causes stress which changes the etch rate (5). With diborane-deposited glass, the boron concentration could be controlled by gas concentrations in the reaction chamber (6).

Oxide thicknesses 1500Å or less were measured on a Gaertner Model L119 ellipsometer. Film thicknesses greater than 1500Å were measured on a Perkin Elmer 402 uv-visible spectrophotometer with a specular reflectance accessory using the interference fringe technique in the 200-800μ range (7).

The molecular per cent B_2O_3 in the SiO_2 film of the diborane-deposited borosilicate glass was determined by measuring the infrared absorption of 5000-10,000Å films on a Perkin Elmer 457 grating spectrophotometer using procedures previously described (4, 7-9). *IR* measurements were made immediately after deposition. These results were confirmed with measurements of boron concentration made on a Material Analysis Company 400 microprobe analysis instrument (agreement within ~10%).

The four etching solutions and their compositions are listed in Table II. All solutions were allowed to stand for one day in stoppered bottles after preparation and before use since freshly prepared solutions did not give reproducible results. All etching solutions were maintained at 25°C in a Colora Model NB temperature bath, and agitation of the solution was used during etching. Oxide thickness measurements were made before and after 1-min etching intervals. Five data points were taken and the slope of the best straight line through the data points is a measurement of the etch rate (in angstroms per minute).

When the HNO_3-HF-H_2O solutions system is in certain concentration ranges (high concentrated hydrofluoric and nitric) silicon etching can be quite significant (10). Thus, silicon etching was measured in "R," "S," and "P" etch by converting weight loss to thickness loss. Silicon slices with four different boron concentrations were evaluated (see Table III). Silicon etching was also detected by sheet resistance measurements. Increased sheet resistance indicates silicon etching.

Results and Discussion

Annealed diborane deposited glass etches faster than SiO_2 (steam oxidized at 1050°C) with all etching solutions except buffered HF (see Table IV). From Fig. 2 it can be noted that etch rate is linearly concentration dependent upon HF. High concentrations of HNO_3 in

"S" etch	400 (3.0)	600 (4.4)	750 (5.6)	135

* Favorable etch rate differential:

$$\text{etch rate differential} = \frac{\text{borosilicate glass etch rate}}{\text{SiO}_2 \text{ etch rate}}.$$

etching solutions greatly favor the boron glass dissolution as compared to undoped SiO_2 with a favorable etch rate ratio (see Table IV).

When choosing an etching solution, silicon etching must be considered. As boron concentration increases in silicon, the boron-doped silicon becomes less resistant to etching in higher concentrations of HF (see Table III). Below a critical concentration of HF in the etches in Fig. 2, silicon does not dissolve. In the HF concentration range in "R" etch (100 ml HNO_3, 100 ml H_2O, 1 ml HF), silicon does not etch at all until we reach the very highly boron (VHB) doped silicon of 5×10^{20} atoms/cm^3. This silicon (isolation-type diffusion) etches at 0.08 μ/min. When one considers that an isolation-type diffusion is 2-4μ deep, this amount of silicon etching can be tolerated.

When choosing an etching solution for a specific application, etch rate, relative silicon etch rate, and favorable differential oxide etch rate must be taken into account. Of all the etches investigated here, "R" etch (see Table IV and Fig. 2) seems to be the most useful since it offers a favorable etch rate ratio (see Table IV).

Conclusions

From this study, etching solutions have been found that dissolve diffusion source diborane formed glass (350°C deposition and 1100°C anneal) from 2.8 to 6.0 times faster than 1050°C steam oxide grown SiO_2 diffusion masking. With an etch rate differential such as this, the diborane diffusion source glass can be dissolved while allowing the SiO_2 to remain in place. This can eliminate the photoresist protection of SiO_2 diffusion source masking during etching.

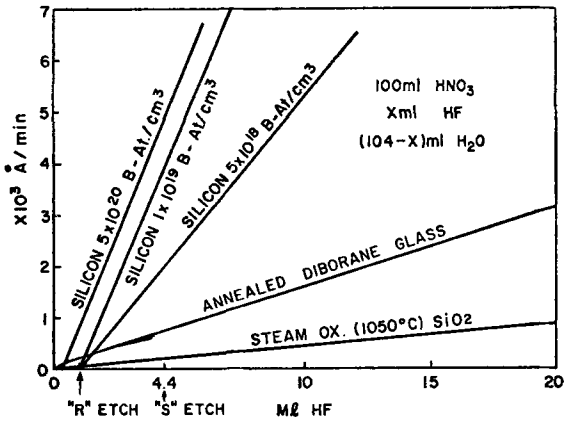

Fig. 2. Etch rates of borosilicate glass (3.7% B) and silicon as a function of HF concentration containing: 100 ml HNO_3, x ml HF, (104 − x) ml H_2O, where when HF = x = 1 ml = "R" etch; x = 4.4 ml = "S" etch.

Solid-State Ionics: High-Conductivity Solid Copper Ion Conductors: N-Alkyl (or Hydro)-hexamethylenetetramine Halide-Copper(I) Halide Double Salts

Takehiko Takahashi,* Osamu Yamamoto, and Shoichiro Ikeda

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

Copper ion conductivity has been found in the system N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide in the solid state. At 20°C, in the system N-methyl-hexamethylenetetramine bromide-copper(I) bromide, the highest conductivity of 0.017 $(ohm\text{-}cm)^{-1}$ was found at 87.5 mole per cent CuBr, which was essentially ionic. The conductivities are discussed also for a number of similar double salts.

In recent years, in order to find high ionic conductivity solids, Ag_3SI (1, 2), $RbAg_4I_5$ (3, 4), KAg_4I_4CN (5), $Ag_{19}I_{15}P_2O_7$ (6), double salts composed of silver iodide and some organic compounds (7-9), and β-Al_2O_3 (10) have been examined and several promising results have been achieved. The charge carrier in these compounds is the silver or alkali ion, and no other ion conductors which exhibit high ionic conductivity at ambient temperature have been reported. From a view point of the application of solid electrolytes, the silver-containing compounds are considered to be expensive, therefore it is of interest to look for other ionic conductors of low price, for example, copper ion conductors. The present paper reports the copper ion conductivity of the system copper(I) halides and N-alkyl (or hydro)-hexamethylenetetramine halides.

Experimental

Copper(I) iodide, which was purified by recrystallizing in hydroiodic acid, was washed repeatedly with acetic acid before being dried in vacuo on P_2O_5. Copper(I) bromide and copper(I) chloride were purified by the same method using hydrobromic acid and hydrochloric acid, respectively. N-methyl-hexamethylenetetramine iodide ($C_6H_{12}N_4CH_3I$) was prepared by the method described in the literature (11), the melting point of which was 189°C, which agreed well with the reported value (190°C), and the iodine content in it coincided with the calculated value ($C_6H_{12}N_4CH_3I$, found: I, 44.7%, calcd.: I, 45.0%). By the same method, the other six kinds of N-alkyl (or hydro)-hexamethylenetetramine halide were prepared, namely, N-hydro-hexamethylenetetramine iodide ($C_6H_{12}N_4HI$, found: I, 47.6%, calcd.: I, 47.4%). N-ethyl-hexamethylenetetramine iodide ($C_6H_{12}N_4C_2H_5I$, found: I, 42.8%, calcd.: I, 42.9%), N-hydro-hexamethylenetetramine bromide ($C_6H_{12}N_4HBr$, found: Br, 36.0%, calcd.: Br, 36.2%), N-methyl-hexamethylenetetramine bromide ($C_6H_{12}N_4CH_3$ Br, found: Br, 33.2%, calcd.: Br, 34.0%), N-ethyl-hexamethylenetetramine bromide ($C_6H_{12}N_4C_2H_5Br$, found: Br, 31.7%, calcd.: Br, 32.1%), and N-hydro-hexamethylenetetramine chloride ($C_6H_{12}N_4HCl$, found: Cl, 20.7%, calcd.: Cl, 20.1%). The appropriate quantities of copper(I) halide and N-alkyl (or hydro)-hexamethylenetetramine halide were mixed with a small amount of ethyl alcohol and dried completely at about 80°C before being pressed by a hand press to form a pellet under 4000 kg/cm², and then heated in a sealed evacuated Pyrex vessel for 10 hr at 100°C for the systems $C_6H_{12}N_4HI$-CuI, $C_6H_{12}N_4C_2H_5I$-CuI, and $C_6H_{12}N_4C_2H_5Br$-CuBr, at 120°-100°C for the systems $C_6H_{12}N_4HBr$-CuBr and $C_6H_{12}N_4HCl$-CuCl, and at 150°-130°C for the systems $C_6H_{12}N_4CH_3I$-CuI and $C_6H_{12}N_4CH_3Br$-CuBr. These reaction temperatures were chosen below the decomposition temperatures of the reaction products, which were determined by thermogravimetric analysis.

The total electrical conductivity was measured with a 1000 Hz conductance bridge, as the frequency dependence of the conductivity was not observed for all the samples investigated. In order to reduce the contact resistance, a mixture of powdered copper (325 mesh) and the sample (2:1 weight ratio) was used for electrodes. The sample of about 1g was stacked between two electrodes, and pressed into a pellet of 13 mm diameter. The conductivity measurements were carried out in nitrogen gas.

Electronic conductivity was measured by Wagner's polarization method (12). To cell (I) with a copper anode and a graphite cathode, d.c. was applied at a voltage less than the decomposition voltage

Cu/sample/graphite [I]

The sample was formed in the shape of pellet, about 2 mm thick and 13 mm in diameter, by pressing at a pressure of about 4000 kg/cm². A constant current supplier was used and the resulting voltage was measured with a recorder preconnected with a high impedance electrometer.

X-ray diffraction patterns of the powdered samples were obtained with a diffractometer using CuKα radiation. The scanning speed was 1°/min.

Results and Discussion

Total electrical conductivity.—The sample composition of the N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide system was between 66.7 and 97.5 m/o (mole per cent) copper(I) halide. The sample pellet with copper electrodes was annealed for several hours at 100°-150°C in nitrogen gas flow before being slowly cooled to room temperature in the oven to measure the conductivity. The conductivities of seven kinds of the N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide system are shown in Table I. For comparison, the conductivities of CuI, CuBr, and CuCl, which were measured by the same method, are also shown in the table. In the systems $C_6H_{12}N_4HI$-CuI and $C_6H_{12}N_4C_2H_5I$-CuI, no high conductivity solid material is obtained at room temperature. The conductivities of these materials are comparable to or less than that of CuI. On the other hand, the high conductivity materials are found in the systems $C_6H_{12}N_4CH_3I$-CuI, $C_6H_{12}N_4HBr$-CuBr, $C_6H_{12}N_4CH_3Br$-CuBr,

[a] [H] = $C_6H_{12}N_4$.

$C_6H_{12}N_4C_2H_5Br$-CuBr, and $C_6H_{12}N_4HCl$-CuCl. In the plot of conductivity *vs.* mole per cent copper(I) halide, the total conductivities pass through a maximum at 85 m/o CuI for the $C_6H_{12}N_4CH_3I$-CuI system, at 87.5 m/o CuBr for the systems $C_6H_{12}N_4HBr$-CuBr, $C_6H_{12}N_4CH_3Br$-CuBr, and $C_6H_{12}N_4C_2H_5Br$-CuBr, and at 87.5 m/o CuCl for the $C_6H_{12}N_4HCl$-CuCl system as shown in Fig. 1. The highest conductivity was found in the system $C_6H_{12}N_4CH_3Br$-CuBr to be 0.017 (ohm-cm)$^{-1}$ at 20°C at the composition of 7CuBr·$C_6H_{12}N_4CH_3Br$, the value of which is five orders of magnitude larger than that of CuBr. These results suggest that the intermediate compounds with high electrical conductivity exist in these systems. The conductivities of these high conductivity materials remained constant for about half a year or more at room temperature, which indicated that decomposition did not occur during storage under ambient conditions.

The temperature dependence of the conductivity was determined for 17CuI·3$C_6H_{12}N_4CH_3I$, 7CuBr·$C_6H_{12}N_4HBr$, 7CuBr·$C_6H_{12}N_4CH_3Br$, and 7CuCl·$C_6H_{12}N_4HCl$. The results in the several temperature cycles are shown in Fig. 2. The conductivity *vs.* the reciprocal of the absolute temperature curves indicate that the phase transition and the decomposition do not occur up to the temperatures investigated. The decomposition temperatures of the samples measured by thermogravimetric analysis were 159°C for 17CuI·3$C_6H_{12}N_4CH_3I$, 106°C for 7CuBr·$C_6H_{12}N_4HBr$, 167°C for 7CuBr·$C_6H_{12}N_4CH_3Br$, and 124°C for 7CuCl·$C_6H_{12}N_4HCl$. Above these decomposition temperatures, the conductivities decreased with time. From the curves shown in Fig. 2, the activation energies can be calculated as 6.1 kcal/mole for 17CuI·3$C_6H_{12}N_4CH_3I$, 4.1 kcal/mole for 7CuBr·$C_6H_{12}N_4HBr$, 4.1 kcal/mole for 7 CuBr·$C_6H_{12}N_4CH_3Br$, and 6.2 kcal/mole for 7CuCl·$C_6H_{12}N_4HCl$. The values of the activation energy correspond to that for the high ionic conductivity solids known so far (2-4 kcal/mole) (6) and suggest that these new compounds have the structural defects similar to those of silver ion conductors (1, 13-15).

Electronic conductivity.—According to Wagner's theoretical analysis (16), the current density J in cell (I) is given by

$$J = I/A = (RT/LF)\,[\sigma_e\{1 - \exp(-EF/RT)\} + \sigma_h\{\exp(EF/RT) - 1\}] \quad [1]$$

where I is the current, A the cross-sectional area, L the thickness of the sample, E the applied voltage, and F the Faraday constant. σ_e and σ_h are the excess

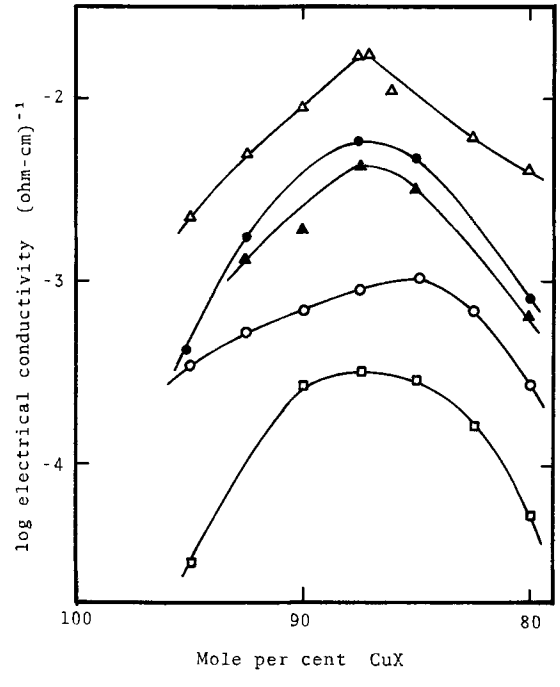

Fig. 1. Composition dependence of the total electrical conductivities of the systems $C_6H_{12}N_4RX$-CuX (X = I, Br, Cl; R = H, CH_3, C_2H_5) at 20°C. ○, $C_6H_{12}N_4CH_3I$-CuI; ●, $C_6H_{12}N_4HBr$-CuBr; △, $C_6H_{12}N_4CH_3Br$-CuBr; □, $C_6H_{12}N_4C_2H_5Br$-CuBr; ▲, $C_6H_{12}N_4HCl$-CuCl.

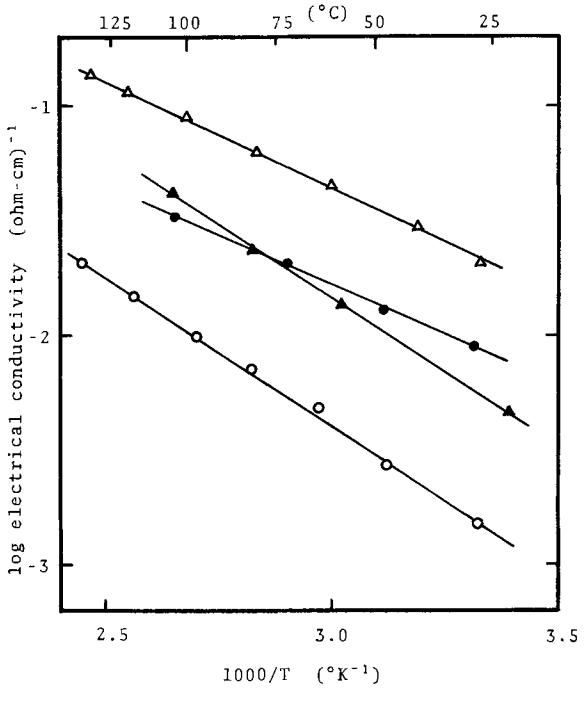

Fig. 2. Temperature dependence of the total electrical conductivities of 17CuI·3$C_6H_{12}N_4CH_3I$ (○), 7CuBr·$C_6H_{12}N_4HBr$ (●), 7CuBr·$C_6H_{12}N_4CH_3Br$ (△), and 7CuCl·$C_6H_{12}N_4HCl$ (▲).

electron and hole conductivities of the sample which is in equilibrium with metallic copper, and the other symbols have their usual meanings. Typical *I vs. E* curves for $37CuBr \cdot 3C_6H_{12}N_4CH_3Br$ at various temperatures are shown in Fig. 3. These curves show a quasi-exponential increase of *I*. Since the excess electron conduction is negligible, Eq. [1] may be written as

$$\log I = \log(\sigma_h ART/LF) + EF/2.30\,RT \qquad [2]$$

if $EF/RT >> 1$. The plots of log *I vs. E* shown in Fig. 3 give virtually straight lines whose slopes are close to the value of $F/2.30\,RT$. The values of σ_h were then calculated from Eq. [2]. Figure 4 shows the values of σ_h for the $C_6H_{12}N_4CH_3I$-CuI, $C_6H_{12}N_4HBr$-CuBr, $C_6H_{12}N_4CH_3Br$-CuBr, and $C_6H_{12}N_4HCl$-CuCl systems as a function of the composition of copper(I) halide at 100°C. For comparison, the electronic conductivities of CuBr and CuCl were measured at 100°C to be about 3×10^{-9} (ohm-cm)$^{-1}$ and 8×10^{-12} (ohm-cm)$^{-1}$, respectively, which were obtained by extrapolating the data at 160°-200°C, because the reproducible current-voltage curve was difficult to obtain at low temperature. The electronic conductivity of CuI at 100°C, obtained by extrapolating the data at 130°-350°C, is about 3×10^{-6} (ohm-cm)$^{-1}$ (17). The electronic conductivity in each system decreases with decreasing copper(I) halide content; this conductivity of the highest conductivity solid is less than 10^{-11} (ohm-cm)$^{-1}$ at 100°C. Thus, it is concluded that the conduction in the new compounds prepared in the N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide systems is essentially ionic. The temperature dependence of the electronic conductivities of $17CuI \cdot 3C_6H_{12}N_4CH_3I$ and $7CuBr \cdot C_6H_{12}N_4CH_3Br$ is shown in Fig. 5. At room temperature, these conductivities were too small to measure by this method. Thus, the transport number of ions in these compounds are considered to be nearly unity.

X-ray diffraction analysis.—Analysis was carried out at room temperature for the samples containing various compositions of copper(I) halide in the N-alkyl (or hydro)-hexamethylenetetramine halide-copper(I) halide system. The results obtained are summarized in Table II. For the samples in the $C_6H_{12}N_4HI$-CuI and $C_6H_{12}N_4C_2H_5I$-CuI systems, only the peaks due to the starting materials were observed, which indicated that no intermediate compounds were obtained in both systems. In the $C_6H_{12}N_4CH_3I$-CuI system, the sample containing 15 m/o CuI gave a single-phase pattern, which was named phase 1. In the composition range of 33.3-60 m/o CuI the patterns of three phases corresponding to CuI, $C_6H_{12}N_4CH_3I$, and an intermediate compound, which was named phase 2, were observed. According to the results of the electrical conductivity measurements, phase 1 has the high ionic conductivity and phase 2 is a poor conductor at room temperature.

The x-ray results for the $C_6H_{12}N_4HBr$-CuBr system showed that only an intermediate compound, phase 3, existed at the composition near 87.5 m/o CuBr. It has high ionic conductivity at room temperature. In the system $C_6H_{12}N_4CH_3Br$-CuBr, three intermediate compounds at the composition of 87.5 m/o CuBr, phase 4, 50 m/o CuBr, phase 5, and 33.3 m/o CuBr, phase 6, were found. Phase 4 has high ionic conductivity and

Table II. Results of x-ray investigation

System	Mole per cent CuX (X = I,Br,Cl)	Phase observed at room temperature
$C_6H_{12}N_4HI$-CuI	90	$C_6H_{12}N_4HI$, CuI
	80	$C_6H_{12}N_4HI$, CuI
$C_6H_{12}N_4CH_3I$-CuI	90	CuI, phase 1
	85	Phase 1
	66.7	Phase 2, CuI, $C_6H_{12}N_4CH_3I$
	50	Phase 2, CuI, $C_6H_{12}N_4CH_3I$
	33.3	Phase 2, $C_6H_{12}N_4CH_3$
$C_6H_{12}N_4C_2H_5I$-CuI	90	CuI, $C_6H_{12}N_4C_2H_5I$
	85	CuI, $C_6H_{12}N_4C_2H_5I$
$C_6H_{12}N_4HBr$-CuBr	90	CuBr, phase 3
	87.5	Phase 3
	66.7	Phase 3, CuBr, $C_6H_{12}N_4HBr$
	50	Phase 3, CuBr, $C_6H_{12}N_4HBr$
	33.3	CuBr, $C_6H_{12}N_4HBr$
$C_6H_{12}N_4CH_3Br$-CuBr	90	CuBr, phase 4
	87.5	Phase 4
	80	Phase 4, phase 5
	66.7	Phase 5
	50	Phase 6
	33.3	Phase 6, $C_6H_{12}N_4CH_3Br$
$C_6H_{12}N_4C_2H_5Br$-CuBr	90	CuBr, phase 7
	87.5	CuBr, phase 7
	80	CuBr, phase 7
$C_6H_{12}N_4HCl$-CuCl	7.5	CuCl, phase 8
	12.5	CuCl, phase 8
	15	Phase 8
	17.5	Phase 8

phases 5 and 6 are poor conductors at room temperature. The x-ray pattern of phase 4 showed a strong resemblance to that of phase 3.

All samples in the system $C_6H_{12}N_4C_2H_5Br$-CuBr were prepared at 100°C. Their diffraction patterns showed almost the same peaks as those of CuBr and small peaks which were different from those of the starting materials. Electrical conductivity measurement suggested that an intermediate compound may exist at the composition near 87.5 m/o CuBr, and, therefore, the small peaks may be due to a new compound, phase 7. In the system $C_6H_{12}N_4HCl$-CuCl, an intermediate compound, phase 8, was found at the composition near 15 m/o CuCl.

Conclusion

High copper ion conductivity solids are found in the systems $C_6H_{12}N_4CH_3I$-CuI, $C_6H_{12}N_4HBr$-CuBr, $C_6H_{12}N_4CH_3Br$-CuBr, $C_6H_{12}N_4C_2H_5Br$-CuBr, and $C_6H_{12}N_4HCl$-CuCl. The highest conductivities in each system are found at the composition $17CuI \cdot 3C_6H_{12}N_4CH_3I$, $7CuBr \cdot C_6H_{12}N_4HBr$, $7CuBr \cdot C_6H_{12}N_4CH_3Br$, $7CuBr \cdot C_6H_{12}N_4C_2H_5Br$, and $7CuCl \cdot C_6H_{12}N_4HCl$. The conduction in these materials is essentially ionic.

In electrolysis experiments, the properties of the electrical contact with the sample are of prime importance. The main difficulty arises from the fact that this contact must be electrically isolated from and chemically protected against the liquid to prevent its corrosion as well as the formation of a current path which bypasses the sample. For simplicity, contact is generally made to the backside of the sample. In the anodic oxidation of integrated circuit (IC) interconnection Al layers, however, contact to the frontside of the samples, *i.e.*, to the Al layer itself instead of to the supporting wafer, is to be preferred. We have found a technique to produce suitable electrodes having the required qualities without taking up much of the sample's area.

Key words: anodization contacts, noncorroding contacts.

Electrode Description

The idea of the electrode is to protect the contact wire by a suction pad. Figure 1 gives a schematic view. The mechanical problem of how to make a suction pad of small diameter, housing a contact wire, and fitting tight into the holder has been solved by the use of polymerizing silicone rubber, which was molded in the holder around the wire. The suction pad's surface is simply the surface of the meniscus which forms on the surface of any liquid contained within walls, in this case of the fluid rubber. The pad will be set free after

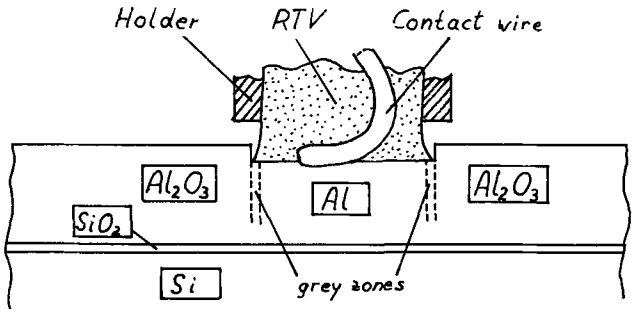

Fig. 1. Schematic cross section of sample and contact electrode after anodization.

hardening of the rubber in order to give the arrangement of Fig. 1.

In the present execution, electrodes have been fabricated with suction pads of 5 and 3 mm diameter. Contact is made by a gold wire, 0.5 mm diameter. Holder material is PVC (polyvinyl-chloride); silicone rubber quality is RTV 501 (Rhone Poulenc). Anodizations are done in 10% H_2SO_4. Three such electrodes are set up for one 1½ in. diameter IC wafer. With this system, the sample has only to be pressed against the electrode. The end of the wire, lying flat on the surface of the suction pad, will establish a good electrical contact to the sample, and the pad will adhere to the sample surface and form a tight barrier against penetration of the liquid.

Results

As an illustration of the effectiveness of the suction pad, Fig. 2 represents the picture of a dot left by the suction pad during the anodization of an aluminum layer evaporated on top of an oxidized silicon IC wafer. The dot, reflecting, appears in white, whereas the formed Al_2O_3 is transparent and thus shows the black color of the silicon underneath. Note the neat metal surface which has not been attacked at all, proving the efficiency of the suction pad as a penetration barrier.

Figure 2 also represents a Talystep reading the border profile. The step results from the thickness differences between the Al and the Al_2O_3 layers. Step width is 20 μm, indicating the good mechanical resolution of the system. It is interesting to note that the gray bordering zone, which appears on the picture of the dot, does not appear in the profile reading. It might represent a region of more or less complete transformation of Al into Al_2O_3 without difference in thickness of the metal layer. This transition zone has been indicated in the schematic picture of Fig. 1. Another interesting detail illustrated in Fig. 2 is the print, on the right-hand side, left by the contact wire as it dug into the aluminum, scratching away any superficial oxide layer. This print makes evident the good mechanical quality of the contact.

The resistivity of the electrode depends much on the PVC used and on the quality of fabrication. The mentioned silicone rubber has specified resistivities of 10^{14} ohm-cm.

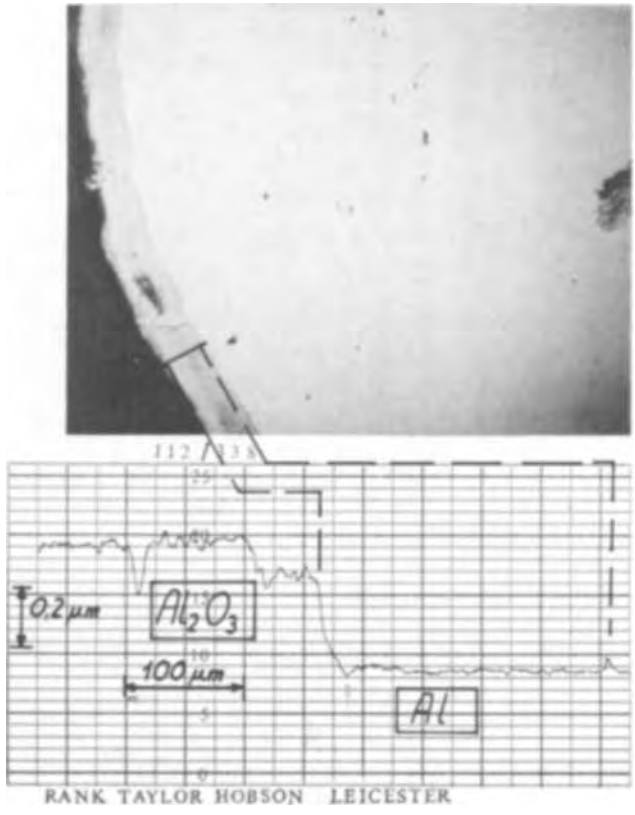

Fig. 2. (top) Picture of anodized IC wafer with part of a contact dot. Magnification 28X. Black tone, Al_2O_3; gray tone, transition zone; white tone, Al. (bottom) Talystep profile reading along line in picture, across dot border.

Protection by a suction pad is thus a good means to prevent corrosion of a contact. The system described gave good electrical and mechanical performances and offers full protection of the contact. It is versatile, can be easily fabricated, and has a purely mechanical action, without need of a thermal or chemical treatment of the sample. This feature opens another protection application: a suction pad might replace protection by resist layers, waxes, or other masking substances which are polluting in themselves or by their cleaning solutions, methods which are often used, *e.g.*, in step etching or other monitoring procedures of IC technology.

Electrical Characteristics of MOS Structures on <111> and <100> Oriented N-Type Silicon as Influenced by Use of Hydrogen Chloride during Thermal Oxidation

G. Baccarani and M. Severi

and G. Soncini

C.N.R.—Laboratorio LAMEL, Bologna, Italy

It is well known that the electrical properties of the SiO_2-Si interface are strongly affected by the semiconductor crystallographic orientation (1-4). In particular, the high and low-frequency C-V characteristics of MOS capacitors, obtained by thermal oxidation of <111> oriented n-type Si slices, show, with respect to simultaneously processed <100> oriented slices of the same resistivity: (*i*) a higher value of the flatband voltage, V_{FB}; (*ii*) a higher ratio of the high-frequency capacitance value measured in strong inversion, C_{min}, to the value measured in strong accumulation, C_{ox} (4); and (*iii*) stronger deviations from ideal MOS characteristics. In particular the low-frequency C-V curve for the <111> orientation exhibits a plateau in the inversion region, and the minimum in this region is expanded along the voltage axis (4).

Observation (*i*) could be explained by assuming that <111> oriented MOS structures are characterized, with respect to <100> oriented ones, by a larger amount of oxide charge, Q_{ox},[1] and by a smaller acceptor-type or a larger donor-type interface-state charge.

Observation (*ii*) could be accounted for by a more efficient doping redistribution process during thermal oxidation due, possibly, to the higher oxide growth rate for the <111> oriented slices (5) and by the presence of donor-type defect centers within the <111> oriented Si, which would result in an apparent increase in doping concentration (4).

Finally observation (*iii*) could be due to a higher interface-state density (6), to the presence of defect centers within the Si, giving localized energy levels in the lower half of the semiconductor bandgap (4), or to larger surface potential fluctuations, which would explain the broadening of the low-frequency minimum. These fluctuations, however, cannot account for the plateau in the low-frequency curve (4).

The purpose of this note is to discuss the above hypotheses on the basis of new experimental results obtained by adding small amounts of high-purity gaseous HCl to the oxygen gas stream during thermal oxidation of Si. The addition of HCl to the oxidizing atmosphere is known to affect the SiO_2-Si interface by strongly reducing the apparent interface-state density (7, 8)[2] and by increasing the generation lifetime (9). Furthermore, it will be shown that the (HCl) oxidation step, followed by a standard low-temperature annealing treatment after Al evaporation, allows us to obtain, in a very convenient way, nearly ideal MOS C-V characteristics for both <111> and <100> oriented structures, which differ only in the value of the flatband voltage. These experimental results may possibly help to a better understanding of the physical nature of the interface states, and their correlation with processing parameters.

Key words: (HCl) SiO_2, MOS structures, crystallographic orientation.

[1] We define Q_{ox} as the charge per unit area (located either within the oxide or at the interface) which does not depend upon bias at room temperature.

[2] By "apparent interface-state density" we mean the density obtained on the basis of the analysis suggested by Berglund (10), which has been shown (11) to be affected by errors when effects such as deep defect centers in the semiconductor space charge region or surface potential fluctuations influence the low-frequency C-V characteristic.

Sample Preparation and Experimental Results

To ensure meaningful comparisons, 1 ohm-cm, n-type <111> and <100> oriented Si slices were simultaneously processed to form MOS capacitors. Thermal oxidation was performed in a dry oxygen gas stream to which small amounts of high-purity gaseous HCl could be added. In our experiments an HCl content of 0.3% was used, since the best electrical properties of the Si-SiO_2 interface were obtained under these conditions (8). Oxidation time (2 hr 18 min) and temperature (1100°C) were kept constant. After thermal oxidation, Al dots were evaporated on the front oxide through a metal mask. Back contacts were obtained by the usual back oxide etching and subsequent Al evaporation on the bare Si surface.

Typical high and low-frequency C-V characteristics for <100> and <111> oriented MOS capacitors subject to four different processing procedures are shown in Fig. 1 and 2, and their most relevant parameters are listed in Table I. Figure 1 refers to capacitors whose

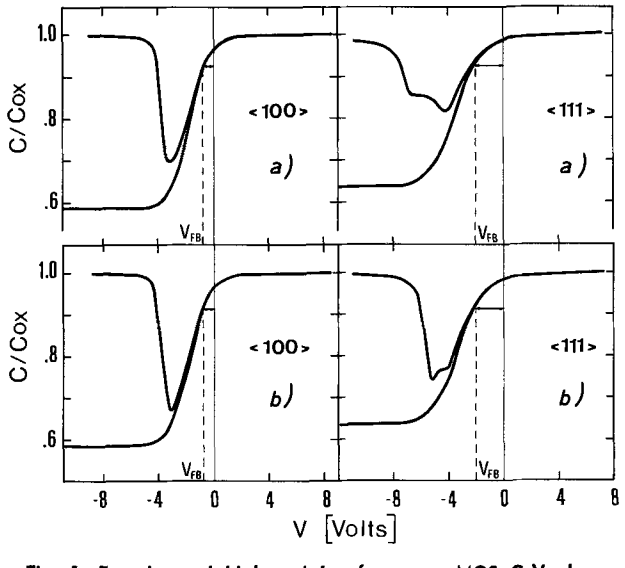

Fig. 1. Experimental high and low-frequency MOS C-V characteristics for <100> and <111> oriented standard MOS capacitors. The low-frequency curves are those which exhibit a minimum under negative bias voltage. Curves a, oxide grown in dry oxygen at 1100°C; curves b, oxide grown in dry oxygen at 1100°C, sample annealed at 525°C after Al evaporation.

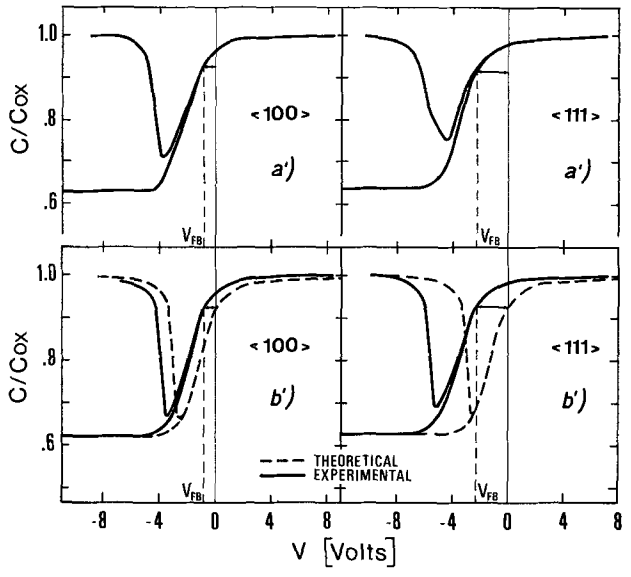

Fig. 2. Experimental high and low-frequency MOS (C-V) characteristics for <100> and <111> oriented MOS capacitors with oxide grown in the presence of HCl. The low-frequency curves are those which exhibit a minimum under negative bias voltage. Curve a', oxide grown in dry oxygen mixed with 0.3% HCl by volume; curves b', oxide grown in O_2-HCl mixture, sample annealed at 525°C after Al evaporation.

oxide was grown in a dry oxygen gas stream. Figure 2 refers to capacitors whose oxide was grown in a dry oxygen stream to which 0.3% by volume of gaseous HCl was added, all the other processing steps being the same as in Fig. 1. Cases a and a' (see Fig. 1 and 2) refer to capacitors without any low-temperature heat-treatment, while cases b and b' refer to capacitors that were processed together with those of cases a and a' but were further subjected to a 525°C annealing for 10 min in a dry N_2 ambient after Al evaporation.

The high-frequency C-V characteristics were measured at 1 MHz with a Boonton 71 AR capacitance meter, while the low-frequency C-V curves were obtained by the voltage ramp technique (12). In the low-frequency measurements, care was taken to ensure quasi-equilibrium conditions by using very low ramp speeds (13). For samples with oxide grown in the presence of HCl a ramp speed of less than 20 mV/sec was usually necessary, due to the high generation lifetimes. During the measurements the samples were kept in the dark, at room temperature, in a dry N_2 ambient.

The apparent interface-state density, N_{ss}, (Table I gives only the mid-gap value) was obtained by comparing the theoretical with the experimental low-frequency characteristics (10); the semiconductor doping concentration, N_{sp}, used in these calculations was determined from the ratio C_{min}/C_{ox}. This procedure is known to minimize errors due to doping redistribution (14).

Generation lifetime τ was measured by simultaneously displaying the capacitance and current transients due to the application of a voltage step at the metallic gate (15). This method does not require any knowledge of doping concentration, and it avoids the uncertainty of the graphical differentiation of the capacitance *vs.* time curve which is necessary to obtain the Zerbst plot (16). Finally, oxide thickness was measured by a Talystep.

The C-V characteristics of the MOS structures obtained by thermal oxidation in a dry O_2 ambient (Fig. 1, case a) show the typical features outlined in the opening paragraphs of this paper. In particular the <111> oriented capacitor exhibits, with respect to the <100> oriented one, a larger flatband voltage, V_{FB}, and a larger relative value of the high-frequency capacitance minimum, C_{min}. In addition the low-frequency <111> characteristic shows a plateau in the inversion region, and the minimum is much broader than in the corresponding <100> characteristic. After the low-temperature annealing treatment (Fig. 1, case b) the low-frequency <111> characteristic still exhibits stronger deviations with respect to the ideal one, even though the broadening is reduced in comparison with case a. No changes in flatband voltage, V_{FB}, or high-frequency capacitance minimum, C_{min}, are observed.

When HCl is added to the oxidizing atmosphere (Fig. 2) the <111> low-frequency C-V curve for case a' is much less distorted than for case a of Fig. 1. The equivalent surface charge, $Q_{eq} = C_{ox} V_{FB}$, is practically unaffected, while for the <111> oriented structure the doping concentration, N_{sp} (determined from C_{min}/C_{ox}), decreases considerably. Finally, after the annealing treatment (Fig. 2, case b') the shapes of the experimental characteristics become practically the same for the <100> and <111> oriented structures, and very similar to the theoretical ones. However V_{FB} and Q_{eq} remain essentially unchanged, as is clear from Table I.

A large increase in generation lifetime is observed for samples with oxide grown in the presence of HCl, while the 525°C (Al) sintering does not seem to affect this parameter (see Table I).

Discussion

The experimental results obtained by the four processing procedures described above will be used to evaluate the consistency of the hypotheses proposed in the opening paragraphs of this paper to account for the different properties of MOS capacitors prepared on <100> and <111> oriented Si by oxidation in dry oxygen.

With reference to the two possible explanations concerning observation (*i*), we note that the shapes of the C-V characteristics become practically ideal for both orientations in case b'. Correspondingly the apparent interface-state density, N_{ss}, becomes $\simeq 0.7 \times 10^{10}$ cm^{-2} eV^{-1} at midgap (see Table I). Since the real surface states are surely less than the apparent ones, we may conclude that in case b', Q_{eq} is primarily due to the oxide charge, Q_{ox}, rather than the interface-state

The flatband voltage, V_{FB}, is corrected for metal-semiconductor work function difference. N_{sp} represents the doping concentration determined from C_{min}/C_{ox}. N represents the doping concentration determined from resistivity measurements. The interface-state density N_{ss} is reported at midgap. Due to the scatter of data, the range of generation lifetime (τ) values is given for cases a' and b'.

charge, Q_{ss}. In the other cases the constancy of Q_{eq} suggests, as a reasonable hypothesis, that Q_{ox} is always larger than Q_{ss}; otherwise an eventual change of Q_{ss} should be exactly balanced by an equal (and opposite) change of Q_{ox}. This seems to support the assumption that the difference in flatband voltage observed between the two orientations is due to a different amount of oxide charge and not to a difference in interface-state charge.

Regarding observation (*ii*) we may exclude the possibility that doping redistribution plays an essential role in increasing the value of N_{sp} (determined from C_{min}/C_{ox}) for the <111> orientation in cases a and b. In fact, the addition of HCl enhances the oxidation rate and should consequently enhance the redistribution; but Table I, case b', shows that N_{sp} assumes in these conditions the expected value, not only for the <100> orientation but also for the <111> orientation. It is worthwhile to observe that the presence of the plateau in the inversion region of the <111> low-frequency C-V curve (cases a and b) occurs together with the higher values of N_{sp}, and that when the plateau is strongly reduced (case a') or totally disappears (case b'), N_{sp} decreases toward its expected value. This suggests a common origin for the two effects, and seems to support the model proposed by Castagne and Vapaille (4) which is based on a defect within the <111> oriented Si. This defect should behave like a donor-type center to account for the apparent increase in doping concentration, and its energy level should be localized in the lower half of the semiconductor band-gap to justify the position of the plateau in the low-frequency curve. Our experimental results show that this defect is definitely related to the oxidation step since its concentration can be strongly reduced by performing the oxidation of <111> oriented Si in the presence of HCl.

The fact that the semiconductor generation lifetime is practically the same for the <100> and <111> standard MOS structures (Table I, cases a and b) demonstrates that the proposed defect in <111> oriented Si does not act as an efficient generation-recombination center. This is consistent with the energy level of these defects in case a [$\simeq$0.2 eV below the intrinsic Fermi level, in agreement with Ref. (4)]. The low-temperature annealing treatment (case b) seems to shift this level closer to the semiconductor midgap, without sensibly altering the generation lifetime. This result could possibly be interpreted by assuming for these centers a very small capture cross section.

With regard to observation (*iii*), it is well known from MOS conductance measurements that <111> oriented SiO_2-Si interfaces are characterized by a higher density of real interface states than <100> oriented ones (6). However we emphasize that the stronger deviations from ideal MOS characteristics of the <111> low-frequency C-V curve cannot be caused only by a higher interface-state density. In discussing observation (*ii*) the presence of defect centers within the <111> oriented Si has emerged as the most probable hypothesis to account for the apparent increase in doping concentration, and it is well known that such defects are responsible for deviations in the theoretical high and low-frequency C-V curves (17, 4).

Finally, we cannot specify the role of the surface potential statistical fluctuations in altering the MOS C-V characteristics, since from our experiments it is not possible to separate the effect of the real interface states from that of the fluctuations.

Summary

The influence of sample orientation on the electrical properties of the standard SiO_2-Si interface has been critically discussed on the basis of new experimental results obtained by performing the oxidation of n-type Si slices in the presence of HCl. It has further been shown that the (HCl) oxidation, followed by a 525°C annealing treatment, gives <100> and <111> MOS structures with high generation lifetimes practically no interface states, and nearly ideal high and low-frequency C-V characteristics.

Low Temperature Chemical Vapor Deposition of Boron Doped Silicon Films

Lou H. Hall* and K. M. Koliwad

Texas Instruments Incorporated, Dallas, Texas 75222

Chemical deposition of polycrystalline silicon is finding increasing application in the fabrication of integrated circuits, such as silicon-gate MOS devices (1), dielectric isolations (2), and two-phase CCD's (3). Polycrystalline silicon is also used in photomask fabrication. Doping of silicon films can occur during an *in situ* codeposition or during a subsequent high tem-

* Electrochemical Society Active Member.
Key words: silane, diborane, catalysis, thin films, activation energy.

perature source-drain diffusion. Many workers have reported on doped and undoped polycrystalline films (4-8).

Eversteyn and Put (8) have reported the effect of the addition of arsine, phosphine, and diborane in growing doped silicon films in the temperature region of 600°-900°C. We report here the use of diborane to grow boron doped silicon films in the region of 300°-550°C. The effect of deposition temperature and gas stream dopant concentration on the growth rate and apparent activation energies are discussed.

The catalytic effect of diborane on the decomposition of silane was studied by measuring the deposition rate of silicon as a function of substrate temperature and gas stream dopant concentration. The silane concentration was kept constant at 0.44% (20 cc/min) of the total flow, 4.5 liters/min. Nitrogen was used as a carrier and diluent gas. Diborane, 1.0% in ultrahigh purity argon, was used as the dopant source. Silicon wafers with approximately 5000Å thermal oxide were used as substrates. The gas stream boron/silicon atom ratio was varied from 6×10^{-3} to 24×10^{-3}. Semiconductor grade silane from Matheson was used without additional purification.

The reactor used was a horizontal 2 in. I.D. quartz tube heated by rf loading into a 5½ in. × 1¾ in. × ⅜ in. carbide-coated graphite susceptor. The temperature was measured by use of an infrared radiation pyrometer. Emissivity and absorption corrections were made for the substrates and quartz tube. The temperature range studied was from 300°-550°C with the uncertainty ±5°C or less.

The thicknesses of boron doped silicon films were obtained by partial masking of the film and removin' the unmasked portion with an HF, HNO_3, and acetic acid solution. The thicknesses were mechanically measured by use of the Talystep I; accuracy is ±2% for films in a 1,000-20,000Å thickness range. The majority of the films had thicknesses of approximately 5,000-10,000Å. Thickness variation across a slice was less than 10%, while variation in deposition rate over several depositions was ±10% or less.

At temperatures below 500°C the growth rate of undoped silicon films becomes negligibly small. Yasuda *et al.* (9) have reported an activation energy of 1.1 eV for the reaction above 500°C. The addition of diborane significantly lowers the film growth temperature. Figure 1 shows the deposition rate as a function of gas stream dopant concentration at deposition temperatures T = 300°, 375°, and 550°C. At the higher boron/silicon ratio in the gas stream the film growth is less sensitive to additional dopant increase.

The decomposition rate of silane as measured by the film growth rate exhibits two distinct regions of temperature dependence. The Arrhenius plot of deposition rate is shown in Fig 2. In the deposition temperature range 350°-550°C the apparent activation energy is 0.18 eV; while, at temperatures below 350°C the film growth is governed by a higher apparent activation energy, 0.54 eV. Eversteyn and Put (8) have reported an activation energy of 0.30 eV for the boron doped silicon deposition below 620°C. While we show two distinct activation energy regions, it is interesting to note that the value of 0.30 eV is closed to the average of our observed values. Taking the high temperature work of Eversteyn and Put (8) into account, the growth of boron doped silicon films exhibits three regions of temperature dependence: 0.87 eV at T = 620°-900°C, 0.18 eV at T = 350°-550°C, and 0.54 eV at T = 300°-350°C. The activation energies obtained from this study were at a boron/silicon gas stream ratio of 6×10^{-3}.

In addition to a temperature dependence on growth rate, there is also a dopant concentration dependence. This dependence manifests itself in a decrease in apparent activation energy with increasing diborane concentration.

The growth of boron doped silicon films can be considered to be a sum of two growth rates; an uncatalyzed rate and a diborane catalyzed rate. The diborane catalysis of silane may be very similar to the use of diborane and hydrogen to produce other higher boranes by complex, reversible reactions at temperatures in the region of 100°-250°C (10). It is believed that borine, BH_3, is an intermediate in these borane syntheses. The effect of hydrogen as compared to inert gas ambients on the decomposition of silane has been previously reported by Yasuda (9) and Richman (11).

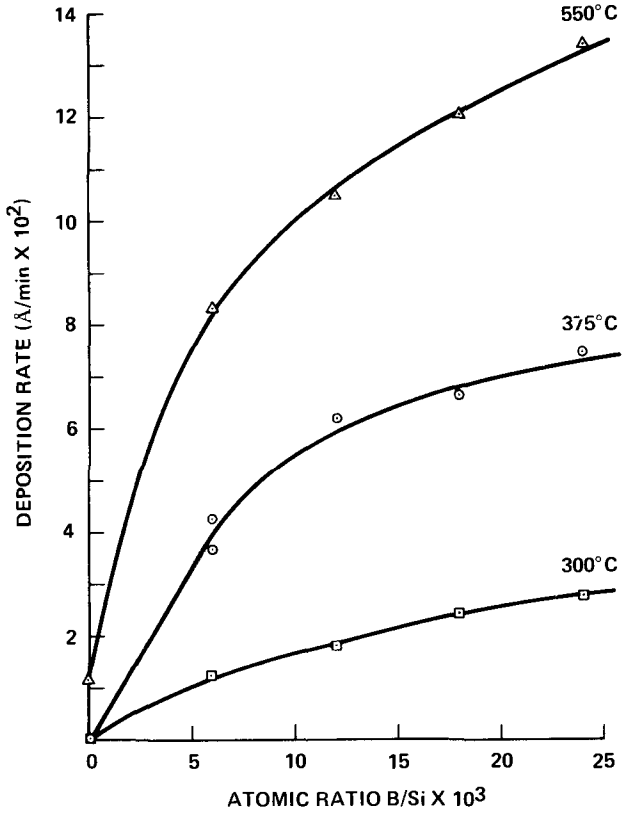

Fig. 1. Deposition rate (Å/min) vs. gas stream dopant concentration at deposition temperature T = 550°, 375°, and 300°C.

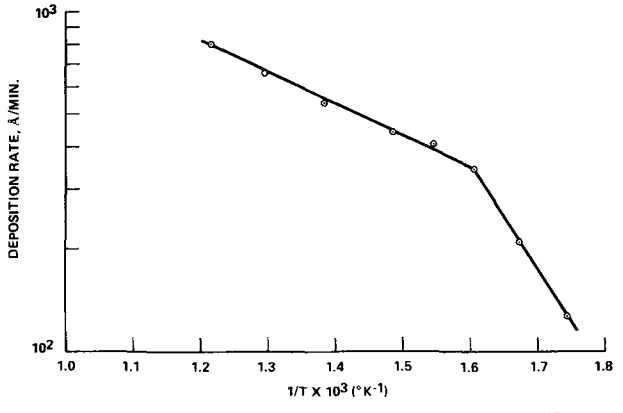

Fig. 2. Growth rate dependence on temperature at B/Si atom ratio 6×10^{-3} in the gas stream.

Below 350°C the activation energy of the diborane catalyzed decomposition of silane is 0.54 eV (12.5 kcal/mole). Between 350° and 550°C the activation energy is low, <0.20 eV (4.5 kcal/mole). While the rate controlling mechanism is not established, the low-temperature catalysis mechanism may be the formation of borine or similar boron active species.

Whatever the catalysis mechanism, diborane can be used to lower the growth temperature of silicon films several hundred degrees below the temperature needed to grow undoped silicon films.

In conclusion, we observed that both the diborane concentration and substrate temperature affect the

growth of boron doped silicon films in a temperature region 300°-550°C. Two distinct activation regions were observed: 350°-550°C and below 350°C; apparent activation energies were 0.18 eV and 0.54 for the two regions.

Solid Electrolyte Properties and Crystal Forms of Lead Fluoride

John H. Kennedy,* Ronald Miles,* and James Hunter*

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Electrolyte properties of α-PbF_2 and β-PbF_2 were studied using single crystals, pressed pellets, and thin films. Ionic conductivity and heat of movement of mobile species were determined for both forms of lead fluoride. In addition, the electronic conductivity and transport number for the cubic β-PbF_2 were determined. Converison of α-PbF_2 to β-PbF_2 was studied by differential thermal analysis, with an observed transition temperature in the range 334°-344°C. Partial reconversion of β-PbF_2 back to α-PbF_2 was effected by pressing the material at pressures above 30,000 psi. A voltage of 1.7 mV (α-PbF_2 positive) generated between pellets of α-PbF_2 and β-PbF_2 separated by a salt bridge implied that the β-PbF_2 is the more stable form at room temperature and atmospheric pressure.

Some of the solid electrolyte properties of lead fluoride have been known since the early work of Tubandt (1) who reported a value of 1.0 for the transport number for the fluoride ion. However, it was not clear which of the two crystal forms of lead fluoride was being measured in these early studies. One form of lead fluoride is α-PbF_2, with orthorhombic symmetry and a density of 8.445 (2). This is the predominant form in commercial lead fluoride powder. The other form is β-PbF_2, with cubic symmetry and a density of 7.750 (2). The orthorhombic form can be converted to the cubic form by heating to about 315°C (2). After cooling, the material remains in the cubic form. This situation bears some resemblance to the silver iodide and lithium sulfate systems, where a low-conductivity, low-temperature, stable form converts at a specific temperature to a higher conductivity cubic form (3). However, in these cases the material reverts to the low-conductivity form on cooling, while the lead fluoride remains in the cubic form. One might expect to find that the orthorhombic, high-density lead fluoride would have lower conductivity than the lower density cubic form.

There is some uncertainty about the nature of the transition between the two forms of lead fluoride, and about which form is the more stable at room temperature. Values for the transition temperature between the two phases vary from 200° to 400°C (2). It might be assumed that the orthorhombic form is more stable at room temperature and that the cubic form is more stable at higher temperatures, and much of the literature follows this assumption. However, there is evidence to the contrary. Sauka (2) found that rapid precipitation of PbF_2 from solutions of $Pb(NO_3)_2$ and NH_4F gave mostly the orthorhombic form, while very slow precipitation gave predominantly the cubic form, thus implying that the cubic form is the more stable at room temperature.

Key words: differential thermal analysis, lead fluoride, ionic conductivity, solid electrolyte, thin film.

The alkaline earth fluorides, which have the same crystal structure as cubic lead fluoride, have been studied in great detail (4-6). Similarly, the other lead halides, which have the same structure as orthorhombic lead fluoride, have also been extensively investigated (7-9). Lead fluoride however, with crystal modifications common to both of these groups, has received little attention since Tubandt's work. We report here the results of a more extensive study of the electrolyte properties of both forms of lead fluoride.

Experimental

Lead fluoride synthesis.—Orthorhombic α-PbF_2 (ROC/RIC 99.9% pure) was used without further purification. Powder x-ray results confirmed its orthorhombic nature and showed no lines due to impurities. Cubic β-PbF_2 was made from the α-form by heating to over 400°C under a nitrogen atmosphere. Only a short time period was necessary to ensure that all of the sample had converted. The β-PbF_2 may be quenched by removing it quickly from the oven, or it may be allowed to cool slowly. No conversion to the α-form was noted either way. DTA studies of the α to β conversion showed an endothermic phase change at about 342°C. Neither x-ray nor DTA could detect a phase change on cooling. The β-PbF_2 was slightly gray whereas the α-form was white. This might have been due to some small decomposition, although no lead was detected in the powder pattern.

Thin films.—Thin films of PbF_2 were prepared by vacuum evaporation from resistance sources. Initial attempts to evaporate PbF_2 from tungsten or molybdenum boats gave durable, clear films, but were brown in color, indicating possible decomposition of the PbF_2. Evaporation from alumina-coated molybdenum boats gave much clearer, although much more brittle films. The PbF_2 was evaporated onto glass microscope slides approximately 6 in. above the source. Evaporation was monitored with a Sloan Omni-II and 5-MHz quartz crystal oscillator. The films were deposited at about

5000 Å/min, with thicknesses ranging from 6000 to 84,000Å. Pb and Au films for electrodes were vacuum evaporated from Ta and W boats, respectively.

Two types of cells were constructed; one type consisted of successive layers of electrode material, electrolyte, and electrode material (Fig. 1a), while the other type had thin fingers of electrode material covered by a layer of electrolyte (Fig. 1b). In the first type of cell, the current moved vertically between the electrodes through the thin layer of electrolyte. The electrodes were either both lead, or one lead and one gold. In the second type of cell, the current traveled horizontally between the electrodes. In these cells, the electrodes were lead.

Thin films of PbF_2 for x-ray study were made concurrently with many of the conductivity cells by using a second substrate holder. On these slides, half of the slide was protected for the initial deposit of lead. Then PbF_2 was deposited over the entire slide. In this way the crystal form and orientation of PbF_2 films over glass and lead substrates were observed.

Blocking electrode cells.—A Harrison 6203-B power supply was used to vary the voltage across Wagner-type polarization cells (13-16), and the current measured by reading the voltage drop across a series resistor with a Hewlett Packard 412A VTVM.

X-ray diffraction patterns.—A Philips Electronics x-ray diffraction unit No. 12045, with No. 52572 scintillation counter, was used with CuK_α x-rays (1.54178Å) at 40 kV for powder and thin-film studies. The powder was ground with a Crescent Dental "Wig-L-Bug" Model 5A amalgamator using a stainless steel vial. Powder x-ray spectra of samples less than 100 mg could be taken by sprinkling the powder on a glass slide that had a uniform smooth film of silicone grease smeared on it. X-ray spectra of thin-film cells, which were deposited on glass microscope slides, were recorded directly after the slides were cut to fit the holder.

Pellet preparation.—Pellets were pressed with a Perkin-Elmer evacuable die, 13 mm diameter. Graphite electrodes were painted on with colloid graphite suspension (d.a.g. 154) and dried at 100°C for 12 hr. Gold and lead electrodes were either pressed on or applied by vacuum deposition. In the transport number experiments, a layer of mixed Pb and PbF_2 was pressed at the interface to lower polarization.

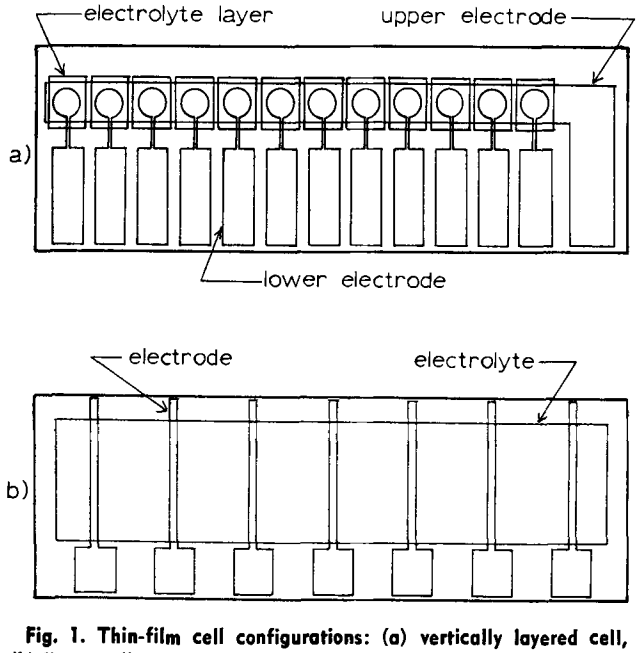

Fig. 1. Thin-film cell configurations: (a) vertically layered cell, (b) linear cell.

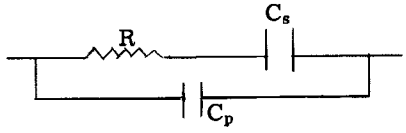
Conductivity measurements.—A GRC 1650-A impedance bridge linked to a Wavetek VCG III frequency source was used to measure a-c resistances, and parallel and series capacitances. The d-c resistances were measured with a Keithley 602 electrometer. The thin films or pressed pellets were heated from 25° to 150°C in an Associated Testing Laboratories environmental chamber and to 250°C in a Blue M oven.

For a-c measurements the bridge voltages used were well below the electrolyte decomposition potential. At each temperature, there was a strong frequency dependence. A cell can be represented by the following equivalent circuit:



where R is the actual resistance and C_s and C_p are series and parallel capacitances.

The impedance of a capacitor is $X_c = 1/\omega c$ where $\omega = 2\pi f$. The measured cell resistance (R_m) when C_s is large satisfies $1/R_m = \omega C_p + 1/R$. For pressed pellets from 25° to 200°C, plots of $1/R_m$ *vs.* f gave straight lines whose zero frequency intercepts were $1/R$. Above 200°C, straight lines were obtained from $R_m = k\omega^{-1/2} + R$. This semi-empirical equation allows for concentration polarization. The square root of the frequency dependence comes from the random walk aspect of the current being limited by the diffusion of the current carrying species to the electrode (10).

Transport number of β-PbF_2.—The Hittorf method of weighing the electrodes after the passage of a current was used. A Keithley 261 picoampere source was used to provide a constant current of 3 μA. The current was integrated with a Bissett-Berman E-cell coulometer. The voltage drop across the cell was about one volt. The cell was maintained at 150°C in air. At that temperature, Pb electrodes developed an oxide coating. To avoid this, cathodes were made of vacuum-deposited gold on PbF_2, and they alone, not the anodes were weighed. Middle sections of PbF_2 were also weighed to ensure no weight change.

Differential thermal analysis.—DTA measurements were made on the α- to β-phase transition of PbF_2. A Fisher Model 260P Differential Thermalyzer with platinel thermocouples was used. The samples were placed in quartz crucibles, and the temperature difference noted *vs.* the α-Al_2O_3 standard. Experimental temperatures were calibrated with the AgI phase transition at 147°C.

Single-crystal synthesis.—A single crystal was grown by Stockbarger's technique as described by Jones (11). Graphite electrodes were applied by painting on d.a.g. 154, and thin-film electrodes of lead by vacuum deposition. High internal resistance made a-c measurements possible only at high temperatures. However, d-c measurements with lead electrodes gave Arrhenius plots as low as room temperature.

Results and Discussion

Relative stability.—As we stated earlier, the stability relation between the α- and β-form of PbF_2 is still uncertain. Differential thermal analysis was carried out to observe the transition temperature and how it varied with heating and cooling rates. For a rapidly occurring phase change, DTA patterns up or down do not vary appreciably with the heating or cooling rate. But, if the energy barrier for interconversion is sufficiently high, this is not true, and the transition temperature can be passed with little observed conversion to the now more stable form. The true transition temperature may have to be far exceeded before the rate of interconversion becomes rapid. In this case, the rate of interconversion will be highly temperature de-

pendent, and the observed "transition temperatures" will depend on how fast the material is heated and how long it is at a given temperature. It appears that this is the case with lead fluoride, for which transition temperatures have been reported from 200° to 400°C. Our studies showed no DTA peaks on cooling cycles. As further evidence, it was found that even over a small range of heating rates of 5°-25°C/min, there was a noticeable change in the observed transition temperature, as shown in Fig. 2. As a check, a series of DTA's of AgI at different heating rates gave no variation from the single 147°C transition temperature. This evidence strongly implies that the observed phase change of α-lead fluoride to β-lead fluoride in the temperature range of 335°-345°C was from a metastable to a stable state and was rate controlled.

Sauka's precipitation work is evidence that the cubic β-PbF_2 is more stable even at room temperature. As further evidence, a cell of the type: Pb/β-PbF_2// KF(aq)//α-PbF_2/Pb was constructed by slipping filter paper saturated with KF solution between two pellets. After several hours, an equilibrium cell potential of +1.7 mV was reached. With the following half-cell reactions

Left half-cell: $Pb + 2F^- \rightarrow \beta\text{-}PbF_2 + 2e^-$

Right half-cell: $\alpha\text{-}PbF_2 + 2e^- \rightarrow Pb + 2F^-$

Cell reaction: $\alpha\text{-}PbF_2 \rightarrow \beta\text{-}PbF_2$

the positive 1.7 mV observed indicates that the β-PbF_2 form is the more stable at room temperature, with a free energy difference between the two forms of 78 cal/mole.

α-PbF_2 has a higher density (8.75) than β-PbF_2 (7.68). By pressing pellets of β-PbF_2 at different pressures, the β-phase was converted to the α-phase (Fig. 3). This indicated that α-PbF_2 was the stable form at room temperature at high pressure. All pressed pellets of β-PbF_2 used in this work showed some reconversion. Pellets of α-PbF_2 could be converted to pure β-PbF_2 by heating, but there was a marked increase in size which caused them to be brittle, and they often crumbled.

Conductivity of polycrystalline PbF_2.—The d-c resistances, and the frequency-independent resistances obtained from the a-c measurements, were the sum of the bulk resistance and the electrode contact resistance. When the resistances of cells of various thicknesses were plotted *vs.* thickness, the slope times the contact area was equal to the contact independent resistivity.

The intercept values (contact resistance) were not reproducible indicating that the contact resistance varied appreciably from sample to sample. One series of pellets was prepared by cleaning the surfaces by glow-discharge followed by vacuum deposition of gold electrodes. In this case the zero thickness intercept was well defined and equal to 1700 ohms at 200°C as an example. Resistivity values for the lead fluoride were the same as those found for the other pellets.

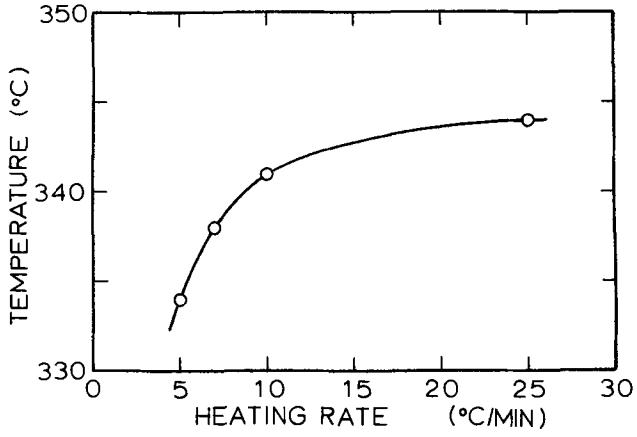


Fig. 2. Conversion temperature of α-PbF_2 to β-PbF_2 as a function of DTA heating rate.

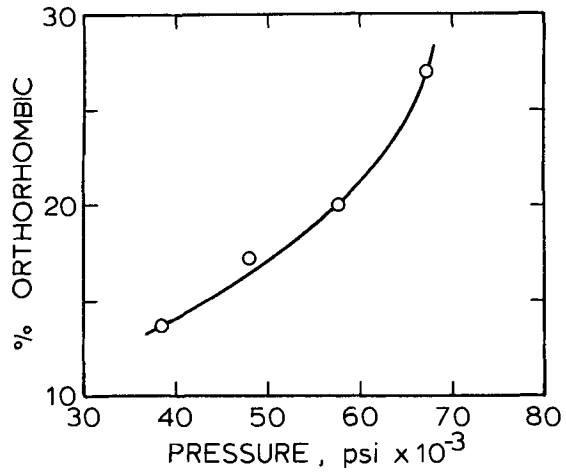

Fig. 3. Conversion of β-PbF_2 to α-PbF_2 as a function of pressure at room temperature.

Arrhenius plots of the conductivities are shown in Fig. 4 and 5. Log σ was used instead of the more exact log σT because the temperature change was not large enough to cause appreciable deviation from linearity. All of the Arrhenius plots gave only one slope over the temperature range 25°-250°C. If the effect were due to defects present in a fixed concentration, this slope would be related to ΔH_m, the heat of movement. On the other hand, if the concentration of defects were varying with T, the slope would contain contributions from ΔH_m and ΔH_f, the heat of formation. It is probable that the first situation pertains, *i.e.*, the PbF_2 was not sufficiently pure to exhibit intrinsic conductivity at temperatures below 250°C. The ΔH values are given in Table I and are in line with ΔH_m values for other crystals (Table II). Both forms of PbF_2 exhibited the same heat of movement. Also, ΔH_m for polycrystalline PbF_2 followed the halogen trend toward higher energy for lower atomic numbers and fell between the reported values for CdF_2 and CaF_2 which are thought to be fluoride ion vacancy conductors.

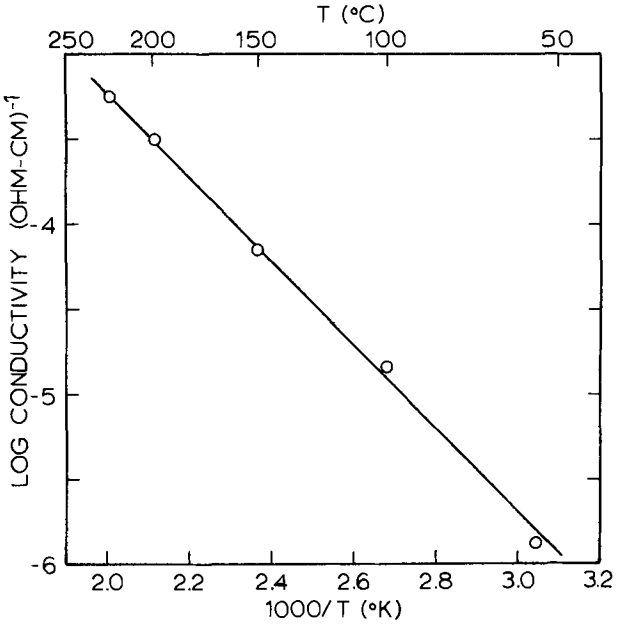

Fig. 4. Ionic conductivity of Au/β-PbF_2/Au pressed pellet cell vs. temperature measured by a-c technique.

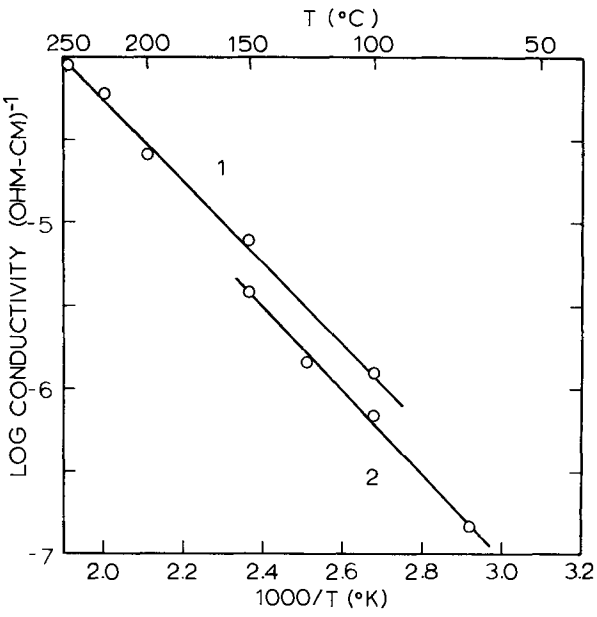

Fig. 5. Ionic conductivity of α-PbF_2 pressed pellet cells *vs.* temperature. Curve 1, Au/α-PbF_2/Au a-c technique; curve 2, Pb/α-PbF_2/Pb d-c technique.

There was some variation in ΔH_m measured for various cells. ΔH_m appeared to depend more on the type of cell than on the crystal modification of PbF_2 used in the cell. All values were about 0.5 eV, but the pressed pellet and thin-film cells of both α- and β-PbF_2 with lead electrodes gave slightly higher values for ΔH. Single-crystal PbF_2 exhibited the highest observed activation energies which may indicate that the lower values for polycrystalline samples reflected some grain boundary conduction. A-C measurements with the lead electrode cells gave the same results as d-c measurements.

The conductivity depended on the phase of the lead fluoride and its history. Aging was noted for all cells, thin films being the most notable. In general, the β-PbF_2 was about an order of magnitude more conductive than the α-form.

Single-crystal conductivity.—Resistance measurements were made on a β-PbF_2 crystal using both a-c and d-c techniques. For the a-c measurements, d.a.g. electrodes were used, and for d-c measurements vacuum-evaporated lead was used.

Room temperature conductivity could not be reliably determined by the a-c technique as the conductivity was too low at room temperature. However the d-c technique with an electrometer worked satisfactorily, and the conductivity measured was 2.0×10^{-8} $(ohm\text{-}cm)^{-1}$. At 150°C, the conductivity measured by the a-c method was 4.1×10^{-5} $(ohm\text{-}cm)^{-1}$ and by the d-c method was 6.0×10^{-5} $(ohm\text{-}cm)^{-1}$. As the d-c study was run after the a-c study, the difference could be attributed to aging effects, which were observed to occur even during a single run when the crystal was left for several hours at elevated temperatures. These conductivity values agree reasonably well with the values for pressed pellets of β-PbF_2.

Arrhenius plots of σ *vs.* $1/T$ gave ΔH as 0.60 eV by the a-c technique and 0.65 eV by the d-c technique. These values are somewhat larger than those obtained from the pressed pellets, but reasonable, since a grain boundary conduction mechanism with a somewhat lower ΔH_m may be contributing to polycrystalline conductivity.

Conductivity of thin films.—Conductivity measurements on thin-film cells were made using both a-c and d-c techniques. The PbF_2 studied in this case was found by x-ray analysis to be (within the accuracy of the x-ray equipment) exclusively the cubic form. Also, the x-ray data indicated that there was considerable preference of orientation of PbF_2 films in the (100) plane, when deposited over either glass or lead.

A-C resistance measurements were made on several vertical type cells (Fig. 1a). Interpretation of these measurements was made difficult because of a large frequency dependence of the resistances. In these cells the electrolyte thickness was very small, thus the resistance due to the electrolyte may not be large compared to the resistances due to the electrode interfaces, and these contact resistances can tend to mask the electrolyte resistance. Ignoring the contact resistance, and calculating the conductivity from a-c resistance values at 1000 Hz, gave conductivity values at 25°C from 0.9×10^{-6} to 5.8×10^{-6} $(ohm\text{-}cm)^{-1}$, for various cells. By plotting resistance *vs.* electrolyte thickness one should be able to subtract out the contact resistance, as was done with the pressed pellets, and find the true conductivity. However, difficulties were encountered in getting consistency from one cell to another, and thus this method of finding the conductivity was not effective.

In order to avoid the above-mentioned problems, cells of the linear type (Fig. 1b) were constructed. In these cells the current path through the electrolyte was much longer, the effective electrode area much smaller, and thus, the resistance much higher than in the vertical cells. The problem of interpreting frequency dependence of a-c resistance was avoided by using d-c resistance instead, measured with an electrometer. Because of the linear geometry, it was also possible to plot resistance *vs.* conduction path distance through the electrolyte for each cell, and subtract out any contact effects. Figure 6 shows the resistance *vs.* conduction path distance for a typical linear cell. The contact resistance is seen to be very small in relation to the electrolyte resistance, and the slope of the line gave a conductivity value of 5.4×10^{-6} $(ohm\text{-}cm)^{-1}$ at room temperature. Other cells gave conductivity values from 5.5 to 6.6×10^{-6} $(ohm\text{-}cm)^{-1}$ at room temperature. These are the values initially after the cells were made. Upon standing the cells aged, and the conductivity dropped. This aging was accelerated by heating, with the conductivity dropping to 1×10^{-6} $(ohm\text{-}cm)^{-1}$ or less (see Table I).

An Arrhenius plot of log σ *vs.* $1/T$ for a typical cell is shown in Fig. 7. The cell was heated, cooled, and then reheated. Upon initial heating, log σ *vs.* $1/T$ was linear with a slope corresponding to a ΔH of 0.53 eV.

Table I. Conductivity and activation energy for lead fluoride samples

	$-\Delta H_m$, eV	Conductivity, 25°C $(ohm\text{-}cm)^{-1}$	Conductivity, 150°C $(ohm\text{-}cm)^{-1}$
Pressed pellets			
C/α-PbF_2/C	0.51	—	3.9×10^{-6}
C/β-PbF_2/C	0.50	—	3.2×10^{-5}

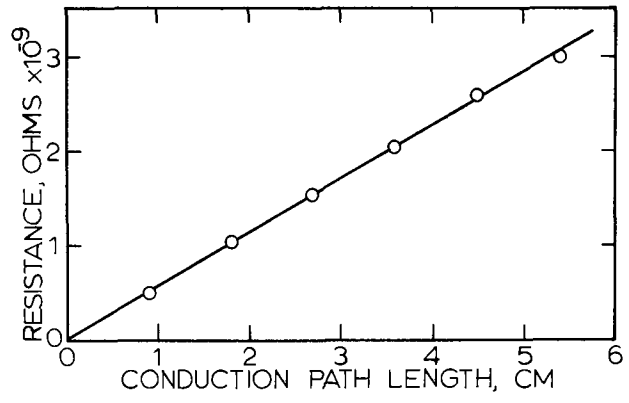

Fig. 6. Resistance of linear thin-film cell as a function of conduction path distance.

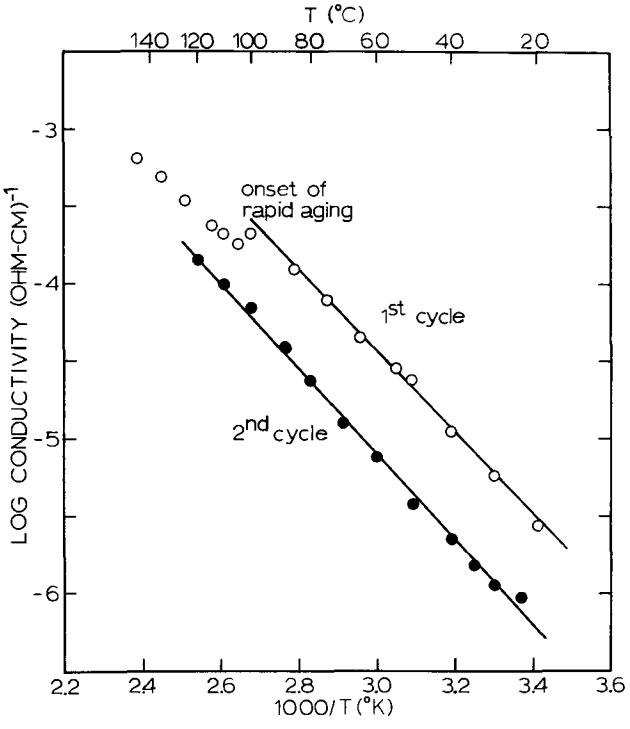

Fig. 7. Ionic conductivity of thin-film β-PbF_2 vs. temperature, measured by d-c technique.

At about 100°C however it appeared that the aging process in the film accelerated, and the resistance increased rapidly, changing the apparent slope of the graph. Upon cooling it was observed that there was some crazing of the PbF_2 film. However the cell was still operable, with a room temperature conductivity of about 1×10^{-6}. Data for a second heating cycle are also shown in Fig. 7. For this second heating cycle the slope yielded a ΔH of 0.55 eV, essentially the same as for the initial section of the first heating cycle. The ΔH values for all the linear cells ranged from 0.53 to 0.57 eV. These values are in good agreement with the results from the pressed pellets, but somewhat lower than those from the single crystal. However, the conductivity values were not at all in agreement with either the single crystal or pressed pellet measurements, rather they tended to be an order of magnitude larger (see Table I). One possible explanation is that the calculations for the thin films were erroneous because of the unusual geometry of the cell. However, a similar cell reported in a previous paper (12), using $RbAg_4I_5$, gave results entirely consistent with those from pressed pellets. Another possibility is that the films contained large amounts of impurities, possibly from decomposition during evaporation, or even from the evaporation source, so that the material was effectively doped, whereas the pressed pellets were as pure as the original PbF_2 powder.

Electronic conductivity.—Electronic conduction in solid electrolytes which are primarily ionic conductors can be studied by direct current polarization (13-16). Excessive electronic conduction, either by electrons or electron holes, would hinder the use of PbF_2 in a galvanic cell. Cells of the type Pb/β-PbF_2/Au were fabricated and polarized with the gold electrode positive. The lead and gold electrodes were vacuum deposited on the β-PbF_2 pressed pellets.

Electronic current which flows after steady state is reached is the sum of the currents due to electrons and holes

$$i = i_e + i_h = RT/LF\,[\sigma^o_e\,(1 - \exp(-EF/RT)) + \sigma^o_h\,(\exp(EF/RT) - 1)]$$

where L = cell constant (thickness/area), E = applied potential, and σ^o_e and σ^o_h = specific conductivities for electrons and holes in PbF_2 in contact with Pb.

For a polarization cell of the type M/MX/Blocking electrode, a plateau current will be observed with increasing potential for conduction by electrons, but an exponentially increasing current shows conduction by electron holes.

The graph of current *vs.* potential for β-PbF_2 was exponential (Fig. 8), and the plot of LF/RT log i *vs.* potential was linear (Fig. 9). If we assume only electron hole current, the equation for the current reduces to

$$i = RT/LF\,\sigma^o_h\,[\exp(EF/RT) - 1]$$

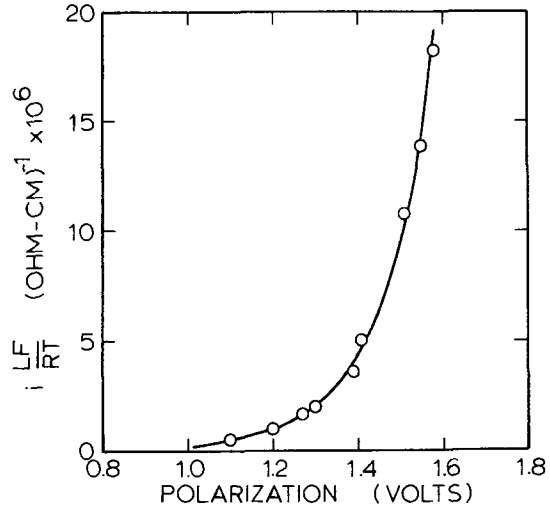

Fig. 8. Electronic current of β-PbF_2 pressed pellet cell vs. applied voltage at 150°C.

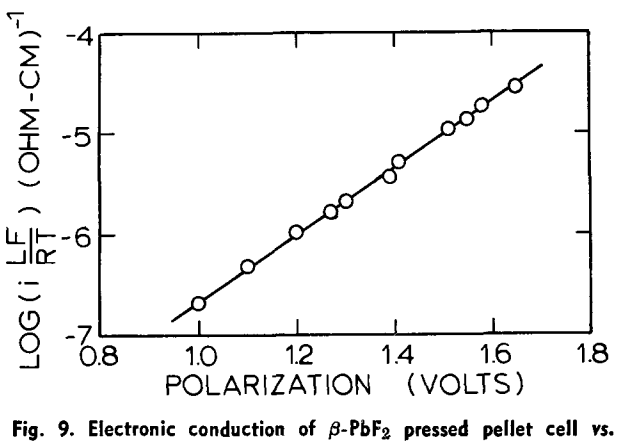

Fig. 9. Electronic conduction of β-PbF_2 pressed pellet cell vs. applied voltage at 150°C.

The slope of Fig. 9 should be $F/2.3\ RT$, or 11.9 $(V)^{-1}$. Data from two cells gave slopes of 3.36 and 3.41 $(V)^{-1}$. The slopes were, therefore, about three times smaller than theoretical. Wagner and Wagner also noted slopes about four times smaller than expected for $PbCl_2$ and $PbBr_2$ (17).

A value for the apparent hole conductivity can be calculated from the intercept of Fig. 9. Table III compares the calculated σ^0_h for β-PbF_2 with other lead halides.

Schoonman reported PbO formation at the cathode interface (18). Tetragonal lead oxide is an oxygen ion vacancy conductor, and the following analogous reaction could be postulated for PbF_2

$$\tfrac{1}{2}\,O_2 + 2PbF_2 \rightarrow PbF_4 + PbO$$

The cell voltage calculated from free energies of formation is -1.59V. In Fig. 8, the observed voltage at which the current dramatically increased was very near this potential. Therefore, if this were the case, all faradaic processes were not blocked, and the observed current still contained an ionic contribution. Therefore, the current due to electron holes then would be even lower than that observed. From this we see that electronic conductivity can represent at most only 10^{-4}% of the total conductivity at 150°C.

Transport number.—The transport numbers for Pb^{2+} and F^- in β-PbF_2 were measured using the cell

$$Pb/\beta\text{-}PbF_2//\beta\text{-}PbF_2//\beta\text{-}PbF_2/Au$$

The cell consisted of three pellets held together under pressure. The gold electrode was then cathodically polarized at 150°C. The blocking electrode study showed that only a minute fraction of the total conductivity could possibly be electronic. Therefore, the weight change could be attributed to the migration of fluoride ions away from the cathode and lead ions into the cathode section.

The observed weight change at the cathode was used to calculate the fluoride ion transport number. The weight change per coulomb of charge is $+1.075$ mg/coulomb for lead and -0.197 mg/coulomb for fluoride. A total of 4.90 coulombs was passed through the cell at about one volt. There was a weight loss of -0.51 mg in the cathode section (the middle β-PbF_2 section showed no weight change within experimental error). The fluoride ion transport number was then calculated

$$-t_- \text{ (0.197 mg/coulomb)} + (1 - t_-)\text{ (1.075 mg/coloumb)} = -0.51 \text{ mg/4.90 coulomb}$$

$$t_- = 0.93 \pm 0.02$$

Therefore, the lead ion transport number was 0.07 $\pm$ 0.02. This showed the conduction mechanism to be predominantly fluoride ion. Tubandt measured t_- for PbF_2 (crystal form unspecified) at 200°C and found it to be 1.0 (1).

‡ Conductivity experiment on $PbBr_2$ in Br_2 atmosphere.

Summary

The evidence presented supports the conclusion that the β-form of PbF_2 is the more stable form at atmospheric pressure and all temperatures from room temperature to melting. The high density α-form is the stable form at high pressure.

Cubic PbF_2, like many other cubic-structured compounds, is more conductive than the orthorhombic. However, a similar heat of movement of about 0.5 eV for both forms indicates that they conduct by the same mechanism. Transport number measurements show that the mechanism is predominantly fluoride ion and analogy to other compounds suggests that the fluoride ion vacancy is the mobile species. Furthermore other cubic fluorides form Frenkel defects while orthorhombic lead halides exhibit Schottky defects. This, too supports the hypothesis that lead fluoride conducts by fluoride ion vacancy since this alone is common to the two defect mechanisms.

A doping study with aliovalent cations will be necessary to prove the fluoride ion vacancy conduction mechanism. Also, high purity PbF_2 samples might yield information on the energy needed to form the defects needed for conduction.

Controlled Porosity and Pore Size Substrates for Nickel-Cadmium Cells

D. J. Gordy, E. Luksha,* and C. J. Menard*

Gould Inc., Gould Laboratories, Energy Technology, Mendota Heights, Minnesota 55118

ABSTRACT

A novel process for the preparation of improved cadmium electrode plaques with precisely controlled pore size and porosity is described. The requirements for these plaques include far better uniformity, reproducibility, and life than is currently available with conventional materials. The key features of the work were preparation of plaques via a powder metallurgical technique which consisted of isostatically compacting a blend of a nickel powder with a fugitive pore-former and subsequently sintering the "green" compact. Cadmium electrodes were prepared from these materials and cycle tested in negative-limited cells using an accelerated, torturous test regime. Results were obtained which showed the new structures yielded electrodes that were superior to the conventional structures in mechanical properties and performance. BET surface areas, SEM photomicrographs, and mechanical strengths using a three-point bend test were used to help in the thorough characterization of the electrodes and the components prepared.

There is currently a need for very long-lived, highly reliable secondary batteries. Nickel-cadmium batteries of the sealed type are uniquely suited for such applications mainly because of their long lives if suitably constructed and if employed under the proper set of operating conditions, *e.g.*, partial discharges, low temperatures, and low rates of charge and discharge. Under torturous conditions the utility of nickel-cadmium batteries becomes severely limited because cells can fail due to any number of factors, a very common one being cell failure due to excessive gassing on overcharge. This can be a result of aging effects on both electrodes and especially degradation of the cadmium electrode.

Such failures can be blamed on lack of uniformity and reproducibility of the battery components. This is resonable, for if components are not uniform and reproducible, it is not possible to effectively account for them in the design of the system.

Past efforts to produce uniform materials have been concerned with bulk or macroscopic uniformity, that is, special attention was given to produce, for example, plaques and electrodes of thickness, loading, porosity, etc. within tighter limits (1). In spite of this, electrodes that were apparently uniform on a bulk basis have shown widely differing aging characteristics indicating that perhaps not all key variables have been considered.

Rather than concentrating on macroscopic uniformity, in the work discussed herein the uniformity on the microscopic scale was controlled, and its role on the life and aging characteristics were evaluated by testing highly porous plaques of very closely controlled porosity, pore size, and pore-size distribution.

To this end, powder metallurgical techniques were chosen to prepare uniform plaques because these are the most versatile and direct processes for the fabrication of porous materials suitable for practical electrode components. A pore-former type process was selected as the most promising. With the use of a pore-former, one can precisely control both induced and interstitial porosity to make a structure to meet a specific application. Interstitial porosity is the naturally occurring void volume between neighboring particles in a more or less close-packed aggregate. Induced porosity, on the other hand, is formed by the addition of a fugitive pore-former to the unconsolidated powder. An interconnected void volume is subsequently formed by the removal of the added powder (2).

* Electrochemical Society Active Member.

Key words: electrode substrates, nickel plaques, nickel-cadmium cells.

To prepare an induced-pore electrode plaque, a nickel powder was first screened to yield an average particle diameter of the desired size. Then a powdered pore-former of the proper particle size to form pores of the necessary diameter was blended with the nickel powder. The blended powder mixture was then compacted to cold-sinter the nickel particles. The pore-former was removed from the compact leaving a structure that was subsequently sintered at the desired times and temperatures.

Pressure was applied to the powder blend isostatically in a flexible mold in a pressurized fluid. Because a powder does not behave in an ideal hydrodynamic manner under pressure, a consequence of interparticle and die wall friction, die pressing usually results in variations in microstructure throughout the compact. Uniform microstructures can best be achieved by isostatic pressing.

The isostatic compaction process used in this work was the so-called wet-bag process. Parts were compacted, via pressurized liquid against rubber diaphragms from two directions. A detailed description of the process is given in the Experimental section.

Experimental

The experimental work involved pore-former preparation, nickel powder preparation, blending of the two powders, compaction of the powder blend, removal of the pore-former, sintering of the "green" plaque, and electrode fabrication, and testing. The following is a brief outline of these procedures.

Plaque preparation.—Figure 1 illustrates the process flow of the various operations required in the fabrication of the plaques. Each operation is described in some detail in the paragraphs that follow.

Pore-former.—$(NH_4)_2CO_3$ was used as a pore-former. It was prepared by grinding Fisher purified grade powder in a porcelain ball mill. The powder was sieved and when a sufficient fraction of -37μ powder was obtained, it was sieved again in a 3-in. micro mesh sieve stack (44μ, 30μ, 20μ, 10μ). The various fractions were then stored until needed. All operations on the pore-formers (grinding, sieving, etc) were performed in a dry room (R.H. 3-5%).

Nickel powder.—Inco Type 287 powder was used in the work except where otherwise stated. It was treated by heating in a vacuum oven for 1 hr at 210°C, and then cooled in a dry room. The powder was sieved and the -37μ fraction was stored in the dry room and the remaining fractions discarded.

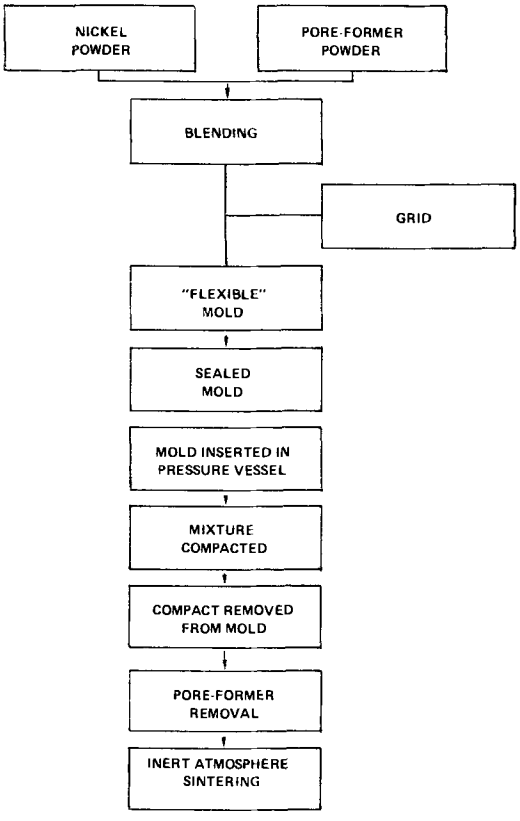

Fig. 1. Process flow chart, plaque fabrication

Powder blending.—To prepare a blend for an 80% porous structure, for example, the nickel and $(NH_4)_2CO_3$ were weighed out to obtain Ni: $(NH_4)_2CO_3$ ratio of 1.5:1, the ratio required to yield an 80% plaque. The normal working weight was 200g. This was used to aid in handling and to avoid changes in composition due to storage. The powders were then mixed and brushed through a sieve. The blend was placed in a Patterson-Kelley twin-shell dry blender and allowed to mix for 30 min. After mixing, the material was again brushed through a sieve and then stored in the dry room. All the above operations were carried out in a dry room. The blend for a 60% porous structure was prepared in a similar manner except that the Ni: $(NH_4)_2CO_3$ ratio was 9:1, the value required to prepare a plaque of 60% porosity.

Powder compaction.—The blend was then loaded into the cavity of a flexible mold (Fig. 2) which already contained an annealed 20-mesh, 7-mil wire, woven screen, by brushing through an appropriate size sieve. For the -37μ size pore-former, a 45μ sieve was used. The essential feature of this mold was the two flexible ends which permitted compaction, via the rubber parts, from both sides of the specimen. This mold allowed the preparation of a part 3 in. in diameter. All excess material was struck off, and the mold closed and inserted into an Autoclave Engineers 4-in. isostatic press and compacted at a pressure of 7000 psi for 1 min.

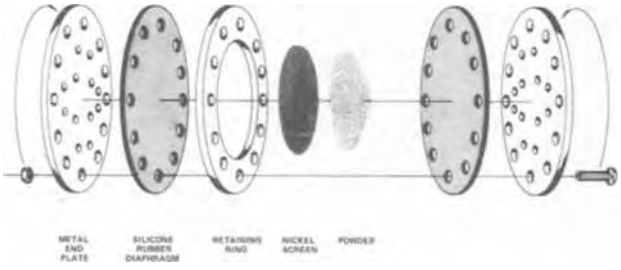

Fig. 2. Exploded view of flexible mold used to isostatically compact powders.

Pore-former removal.—After compaction, the "green" sintered specimen was removed from the mold and the $(NH_4)_2CO_3$ pore-former was removed by placing the sample in a vacuum oven and decomposing under vacuum at 210°C for 20 min.

Green plaque sintering.—The "green" plaques were then removed from the decomposition oven and immediately placed into a vacuum oven where they were sintered in a TM Vacuum Products oven at a pressure of less than 50μ at 870°C for 10 min. Helium was used as a back fill and cooling media.

Plaque characterization.—Mechanical testing.—Mechanical strengths were measured for representative specimens on an Instron Tensile Tester by a three-point bend method.

Photomicrographs.—Scanning electron photomicrographs of selected specimens were taken and measurements made on them to determine induced pore size and ratio of induced to interstitial porosity. Examination of photomicrographs was also used as a criteria for microscopic uniformity, along with such items as $Cd(OH)_2$ crystal size and distribution, in virgin and cycled electrodes.

BET surface area.—Surface areas of selected sintered plaques were determined with a Numinco-Orr Surface Area Pore-Volume Analyzer, Model 2100, using krypton as the adsorbate. Surface areas were utilized for comparison with other properties.

Cadmium electrode processing.—The structures prepared as described above were impregnated by a thermal process (3) in a manner that minimized plaque damage. All electrodes in this study were loaded to 2.452 ± 0.053g CdO/cm^3 of plaque (0.0706 ± 0.0048 A/cm^2 $Cd(OH)_2$ loading). It was felt that a constant loading per cubic inch of free space would yield electrodes far too low in energy density.

The electrodes were then placed in 30% KOH (prepared from mercury cell grade 45% KOH) and charged against nickel dummies to a minimum of 50% overcharge (based on the calculated theoretical capacity) during a 16-hr charge cycle. They were then discharged to 0.0V *vs.* a nickel oxide reference electrode at a current of 200 mA, washed free of KOH in hot deionized water, and air dried at 70°C for 1 hr.

Electrochemical testing.—Cadmium electrodes thusly prepared were cycled in 2.35×1.62 in. sizes in specially constructed prismatic hardware in a nickel-cadmium sandwich configuration, using nickel electrodes of sufficient capacity to assure negative-limited performance under all test conditions. These cells were cycled on fully automatic equipment to 100% depth (0.00V) using the regime shown in Table I.

All the charge and discharge data were recorded on a L&N Speedomax Type G multipoint recorder and a statistically significant sample size was tested for each type of electrode prepared.

The use of negative-limited cells assured that these electrodes will receive more torturous treatment than they would receive in a practical cell. In this way, performance differences and aging characteristics between different type electrodes would show themselves with the expenditure of a minimum amount of test effort.

Table I. Charge and discharge data

Cycle No.	Charge rate	Discharge rate, A
1-3	150 mA for 16 hr	0.24
4	150 mA for 16 hr	1.20
5	150 mA for 16 hr	2.40
6	150 mA for 16 hr	4.80
7-end	1.20 A for 1 hr	1.20

Results

Mechanical strengths of isostatically compacted plaques.—The mechanical strengths of cadmium electrode substrates are important properties to consider when one is preparing electrodes that are expected to be long lived. Furthermore, mechanical strengths are useful tools for general characterization of electrodes and plaques.

Flexural yield strengths were evaluated with an Instron three-point bend test jig; the results are shown as the square of the powder content, $(1 - P)$, where P is the fraction porosity in Fig. 3.

The values of the flexural yield strengths varied between 900 and about 8000 psi between porosities of 80 and 60%. The relationship between mechanical strength and porosity was, $(1 - P)^2 = 2 \times 10^{-5}S$ where S is the flexural yield strength in units of psi.

Especially noteworthy was the exceptionally high values of mechanical strength of the 60% plaques, in the 8000 psi range. Conventional, gravity-sintered plaques sintered under the same conditions had mechanical strengths of 643 psi for a 79.2% porous plaque.

BET surface areas of substrates.—Surface areas of special specimens were determined using a modified BET method with krypton as the adsorbate. The surface areas were in the range of 0.11 to 0.17 m^2/g of powder content in the plaque. The contribution of the screen weight to the total plaque weight was subtracted for the sake of this discussion. The specimens whose surface area was measured did have support screens however. The specific surface areas in terms of powder weights are shown as a function of total porosity including screen in Fig. 4. The specific surface area is seen to be a linear function of porosity in this range for the two different pore sizes. The reduction in surface area with decreasing porosity is a reflection of the packing of the nickel powder. With the low porosity materials, a particle has more neighbors to bond with during pressing and to form necks with during sintering. There is, therefore, a marked decrease in powder surface area with decreasing porosity.

The surface areas of the compacted plaques also show some dependence on induced pore size. This effect is rather small however. One may easily visualize changes in the number of interparticle bonds and, therefore, surface area when the size and quantity of pore-former particles are varied. The use of larger pore-former particles with the same quantity of metal powder results in a plaque with a thicker pore wall. As a result, each particle will have a different number of neighbors to form necks with during sintering, depending on the size of the pore-former. The surface area will, therefore, exhibit small differences.

Figure 4 shows the two lines intersecting. On the basis of the above discussion, one would not expect this to happen. In reality, different ratios of pore-former to nickel powder were required to prepare plaques of differing porosity irrespective of the pore size.

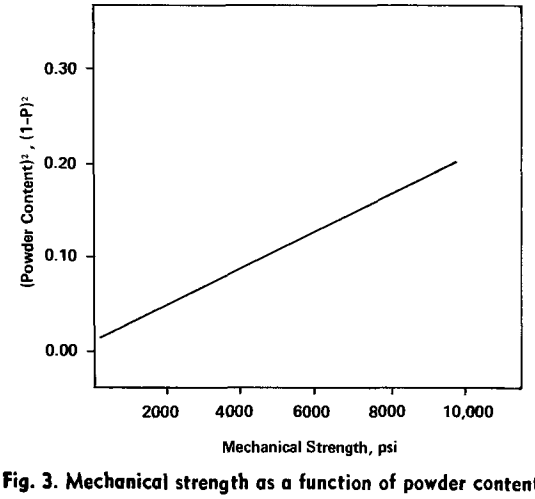

Fig. 3. Mechanical strength as a function of powder content

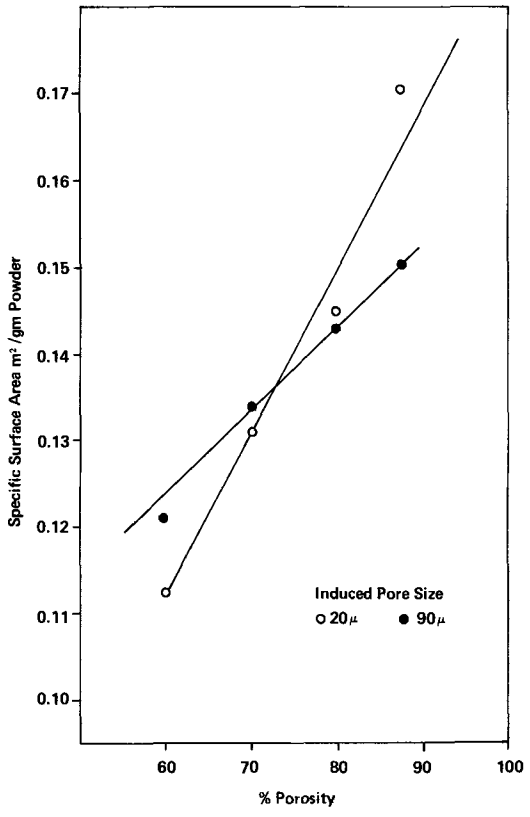

Fig. 4. Specific surface area as a function of plaque porosity

Results of cycle testing.—Accelerated testing of the cadmium electrodes prepared was performed in specially constructed negative-limited cells at high charge and discharge rates. This was an extremely punishing regime for cadmium electrodes. It was employed in an effort to minimize the amount of experimental time in evaluating the differences between various electrodes. The results are therefore not necessarily typical of cadmium electrodes in conventional positive-limited systems in which they are never discharged to 100% depth. The results are therefore best used only for comparative study of this type. Eighty per cent porosity plaques at the 90, 50, 25, and 15μ inducted pore-size levels were tested. Also, performance of state-of-the-art electrodes (gravity-sintered plaques) were evaluated for the purpose of comparison. In addition, a blended powder, Inco Type 287 with Sherritt-Gordon 1μ powder, was evaluated.

A summary of the test results of the accelerated cycle data obtained is given in Table II. The degradation of capacity rates was determined via a linear regression analysis of the test data, using the seventh to the last cycle. A straight line was found to fit the data well. Since the differences in the test data were small, a numerical summary made it easier to compare the isostatically compacted electrodes and conventional electrodes prepared from gravity-sintered plaques from the point of view of efficiency and degradation rates. As far as degradation rates were concerned, there were no statistically significant differences, with one exception, between all the electrodes tested. The electrodes prepared from the 60% 25μ plaques inexplicably had higher degradation rates than all the other electrodes. Therefore, it seemed that the degradation rate under the test conditions employed were independent of the plaque properties and were not used as a criterion for cell life. Some real differences were observed in electrode efficiencies. The 80% structures

with pore sizes 25μ or less had efficiencies higher than conventional electrodes.

The electrodes prepared from the higher induced porosities, 91% *vs.* 40%, had considerably higher efficiences at the end of 50 torturous cycles. We could not account for this difference on the basis of increased loading per unit volume of the free space of the 60% electrodes. (Recall that all electrodes had the same loading per unit total volume.) On the basis of their loadings alone, we expected 60 and 80% porous electrodes to have essentially the same efficiencies. The low efficiencies of the 60% electrodes were perhaps related to their low induced porosity. Further work will be required if this phenomenon is to be clarified.

Scanning electron microscopy of isostatically compacted plaques and cadmium electrodes.—The SEM was used as a tool for judging the extent of microscopic uniformity.

Figure 5 shows representative SEM photomicrographs, 60 and 80% 25μ, of isostatically compacted structures and are qualitatively quite revealing as far as microscopic uniformity is concerned. The micrographs at approximately 70X magnification show the nature of the induced porosity, rather large pores uniformly distributed throughout the plaque. The 80% porosity material apparently is a little bit more uniform in this respect. The actual size of the induced pores was less than the size of the pore-former particles. The reduction in size was probably due for the most part to shrinkage during sintering.

Small interstitial pores well under 10μ are evident which no doubt contribute substantially to the total porosity and performance of the electrode. No very extensive agglomerates of material are visible, that is, all the porosity is seemingly interconnected.

These observations are contrasted with the details also shown in Fig. 5 for a state-of-the-art gravity sintered plaque prepared under identical conditions of sintering time and temperature. Very large irregular pores not uniformly distributed are evident. Also present in the gravity-sintered structure are islands of large agglomerates of nickel metal.

Routinely at the end of the accelerated test program, SEM photomicrographs of selected specimens of the cycled cadmium electrodes were taken in an effort to find morphological changes that may have occurred during the cycle testing. Typical examples are shown in Fig. 6 for electrodes made from 60% 25μ and 80% 15μ plaques. The $Cd(OH)_2$ crystal size variation with the plaque structure is important because the crystal

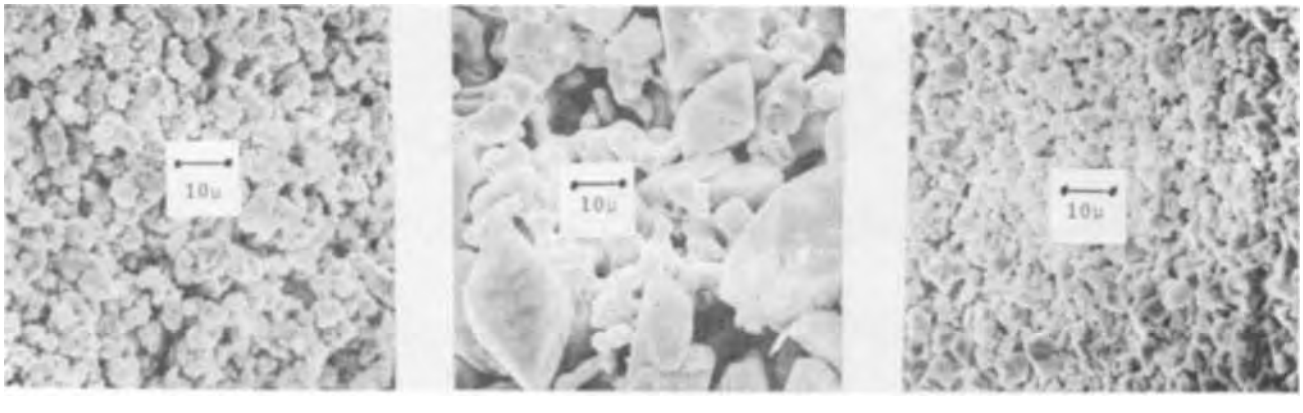

Fig. 6. SEM photomicrographs of cadmium electrodes. (Left), cycled electrode prepared from 60%, 25μ pore-former, isotatically compacted plaque; (center), cycled electrode prepared from 80%, 15μ pore-former, isostatically compacted; (right), formed but not cycled electrode prepared from 60% 50μ pore-former, isostatically compacted plaque.

size is perhaps a key property governing the performance degradation of cadmium electrodes during cycling.

Of interest in the micrographs is the appearance of the nickel substrate. A typical example of a formed but not cycled electrode is also given in Fig. 6. Note that the plaque substructure is completely covered with $Cd(OH)_2$ crystals. With cycling, morphological changes occurred in which cadmium active mass migrated from the nickel surfaces onto other cadmium hydroxide particles. Also prominent in the micrographs is the evidence of corrosion of the nickel substrate. This was due either to the electrode processing or to the cycling.

The $Cd(OH)_2$ crystal sizes, $\bar{d}$, were determined in this way for all the electrodes prepared in this program and are given in Table III along with the smoothed 50th cycle efficiency.

The $Cd(OH)_2$ crystal size was dependent on the substrate porosity, the 60% porous substrates have crystal sizes in the 0-2μ range and the 80% porous substrates have crystal sizes of about 7-10μ. This difference in crystal sizes is evident in Fig. 6. However, the crystal size was perhaps confounded with the depth of discharge and perhaps porosity, of the two different groups of electrodes. Intuitively one would generally expect higher discharge efficiencies for electrodes with the smaller crystal sizes, yet the opposite was observed.

No definite relationship between crystal size and electrode efficiency was observed. A trend of decreasing crystal size with increasing induced pore size was evident however.

As an additional point of interest, the formed but uncycled electrodes had average crystal sizes of 3.0μ, so that upon cycling, crystal sizes of the electrodes with the 60% porous substrates decreased while those with the 80% porous substrates increased.

It thus appears that the $Cd(OH)_2$ crystal size in these electrodes at the loading levels studied is dependent on both the plaque pore size and porosity.

Conclusions

Cadmium electrode substrates with precisely controlled microstructures were prepared having 60% and 80% porosities, each at 15, 25, 50, and 90μ induced pore-size levels. Cadmium electrodes were prepared from these materials and tested using an accelerated regime. The results reveal that cadmium electrodes prepared from 60% porosity 25μ induced pore-size plaques had efficiencies only 5-10 percentage points lower than state-of-the-art electrodes judging from the results of an accelerated test regime. These plaques had vastly superior mechanical properties, about 8000 psi as compared to 645 psi for the conventional gravity-sintered material in use today. This added strength was observed to eliminate cracking and physical degradation of the electrodes during processing and cycling. The electrical performance of these electrodes was poorer than state-of-the-art electrodes.

Table III. $Cd(OH)_2$ crystal size after cycling

Electrode type	Smoothed 50th cycle efficiency	$\bar{d}$ (μ)
60% 15μ	18.7	2.3
60% 25μ	24.1	1.4
60% 50μ	18.8	1.0
60% 90μ	19.0	0-1.0
80% 15μ	34.3	9.8
80% 25μ	37.1	6.8
80% 50μ	34.9	7.3
80% 90μ	33.7	4.7

Cadmium electrodes prepared from 80% porous 25μ induced pore-size plaques, under the torturous test regime employed, proved to be the best electrodes made during the course of this program from the point of view of highest efficiency. They were superior to state-of-the-art electrodes in this respect, in addition to having somewhat superior mechanical strengths and better uniformity.

It was also observed that the plaque pore size and porosity were contributing factors to $Cd(OH)_2$ crystal size. No relation between crystal size and efficiency was found however.

The induced porosity was observed to be a factor in electrode performance. Higher induced porosity apparently yielded better electrodes. This property was confounded with loading, however. The best performance at both the 60% and 80% porosities was observed with the 25μ induced pore sizes.

Morphological changes of $Cd(OH)_2$, determined from SEM photomicrographs, were identified after the cycling procedure. With the 60% structures, the crystals apparently decreased in size with cycling, while with the 80% porosity structures the crystals increased in size.

Some small degree of corrosion of the plaques was evident from photomicrographs. The corrosion was due either to processing or cycling.

BET surface areas were measured and varied between 0.11 and 0.17 m^2/g depending on plaque pore size and porosity.

Three-point bend tests were performed on selected specimens and varied between about 900 and 8000 psi between porosities of 80% and 60%. As a point of comparison, a 79% sintered material had a bend strength of 643 psi.

Anion Effects on the Dissolution of Steel in ECM Binary Electrolyte Systems

James P. Hoare* and Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Steady-state potentiostatic polarization, galvanostatic stripping, and current efficiency measurements were carried out on mild steel (Type 1020) anodes in O_2-stirred solutions of Na_2SO_4 to which increasing amounts of NaCl were added. A salt layer is formed at steel anodes in Na_2SO_4 solutions. A precipitate is deposited from this salt layer onto the anode surface and is converted to a protective anodic film at sufficiently anodic potentials. In the presence of Cl^- ions, the salt layer becomes more soluble and the protectiveness of the anodic film is lessened. With increasing Cl^- ion concentration, a family of curves with increasing current in the passive region is obtained. If the anodic film is formed by the direct oxidation of the anode surface (as in $NaNO_3$/NaCl mixtures), a different family of curves is obtained. For the case where a noncomplexing, film-dissolving anion, such as ClO_4^-, is present (Na_2SO_4/$NaClO_4$ or $NaNO_3$/$NaClO_4$), a third family of curves is found. This behavior is related to the interaction between the type of film-dissolving anion present in solution, and the type of anodic film formed on the electrode surface.

The number of electrolytes composed of water solutions of a single salt suitable for the electrochemical machining (ECM) of steel is limited to only a few systems including NaCl, $NaClO_3$, $NaClO_4$, and $NaNO_3$. If one considers mixtures of salts, the number of suitable electrolytes is greatly increased.

Since the ECM process takes place at potentials corresponding to the transpassive region of the anodic polarization curve obtained on steel in the given electrolyte (1-3), it is necessary to determine the kind of anodic films formed on steel in this electrolyte and how anions present in the solution interact with these films (4). Such ECM parameters as control of dimensions and geometry, tapering, out-of-roundness, and surface roughness depend on the presence of a potential-dependent, protective, anodic film (4-6).

This report describes some experiments which were carried out on steel anodes in electrolytes composed of solutions of Na_2SO_4 and NaCl and designed to shed light on the nature of the interaction of the anions present in solution with the anodic film on the steel surface as a function of potential and electrolyte composition.

Experimental

As described earlier (1, 4), anodes were prepared from mild steel (Type 1020) wires and mounted in triplicate in a two-compartmented Teflon cell. To a 1M solution of Na_2SO_4, the required amount of 0.1M NaCl was added to give the desired mixed electrolyte composition (see Table I). Steady-state, anodic polarization measurements and galvanostatic film-stripping data were obtained in O_2 stirred (~300 cm^3/min) solutions according to procedures presented previously (1, 4). Current efficiency determinations were carried out in the closed-cell system of the laboratory ECM test rig by using methods detailed in the literature (7). The anodes in this case were mild steel tubes.

Results

The results of the steady-state polarization studies obtained on mild steel anodes in O_2 stirred solutions of 1M Na_2SO_4 and 1M Na_2SO_4 containing from 3×10^{-3} to 1M NaCl are presented in Fig. 1a as the average data of three complete runs on three different anodes. It requires the presence of only a relatively small amount of Cl^- ions to cause considerable changes in the polarization curve obtained on steel anodes in 1M Na_2SO_4 solutions. As the Cl^- ion content of the electrolyte increases, the passivation current increases rapidly so that in the 1M Na_2SO_4 + 1M NaCl solution, the behavior is the same as in $SO_4^=$-free NaCl solution. Results similar to these were reported by Condit (8) for the anodic polarization of Fe-Ni alloys in 1*N* H_2SO_4 solutions containing Cl^- ions.

Shown in Fig. 1b is the total charge, Q, associated with the anodic film formed on the steel surface as a function of potential. In the presence of small amounts of Cl^- ions, Q is much larger for steel in Na_2SO_4 mixed electrolytes than in Cl^--free Na_2SO_4 solution. A considerable portion of the large values determined for the charge in Fig. 1b may be due to a large increase in the anode area caused by the severe pitting which takes place in the low Cl^- content Na_2SO_4 solutions as noted in Fig. 2a. In such cases, the roughness factor used in the calculation of Q is larger than 10 which is the value used in determining the data in Fig. 1b. It is interesting to note that a large increase in Q occurs at a potential (1.2V *vs.* SCE) where O_2 evolution begins.

The film on steel in Cl^--free Na_2SO_4 solution is precipitated on the anode surface from a salt layer because the active-passive transition of the polarization curve is shifted with stirring as noted in rotating-disk studies (9). At a threshold anodic potential, this fluffy, nonprotective precipitate is converted to a more compact, protective, oxide film.

This transition from the fluffy precipitate to the compact film can be observed on the series of traces in Fig. 3 obtained from the stripping pulses applied to the steel anode which had been held in the Na_2SO_4 solution containing 3×10^{-3}M NaCl at a given potential. For the electrode potentiostated at 0V (*vs.*

Table I. Threshold potential for formation of compact film on steel in Na_2SO_4 solution containing Cl^- ions

Solution composition	Threshold potential (V)

SCE), Fig. 3a, only one arrest appears on the trace which grows in length with increasing potential (see Fig. 3b at 0.6V). Above 0.6V, a second arrest appears on the trace as in Fig. 3c (electrode held at 1V) at higher overvoltage values. This lower arrest grows at the expense of the upper arrest in Fig. 3d (at 1.2V) and Fig. 3e (at 1.6V) until only the lower arrest remains (Fig. 3f at 2.0V). We believe that the upper arrest corresponds to the fluffy, nonprotecting precipitate which is more easily reduced, and hence, appears at a low overvoltage; whereas, the lower arrest corresponds to the compact, protective, oxide layer which, being more difficult to reduce, appears at the higher overvoltage.

Above a threshold potential (~0.7V) in the case of Fig. 3, the fluffy precipitate is converted to a protective oxide layer which grows with increasing potential at the expense of the fluffy precipitate as shown in the plots of Q associated with the fluffy precipitate (open symbols) and that with the compact layer (closed symbols) in Fig. 4. As noted in Fig. 4 and in Table I, the threshold potential is shifted to more noble values with increasing Cl^--ion content until the appearance of the compact film is no longer detected at potentials below 2V (*vs.* SCE).

The results of current efficiency measurements at mild steel anodes in Na_2SO_4/NaCl mixed electrolytes are recorded in Table II. For Cl^--free 1M Na_2SO_4 solu-

tion, the compact protective film is quickly formed on the metal surface, and because nearly all of the current is consumed in O_2 evolution, this film must possess a high degree of electronic conductivity. Virtually no attack of the anode is observed on steel in 1M Na_2SO_4. When Cl^- ions are present in small amounts, they can cause local breakdown of the protective film producing the severe pitting observed in Fig. 2a. Still, more than half the current goes into O_2 evolution (Table II) and many sites are covered by the protective film (triangles in Fig. 1b) on steel anodes in 1M Na_2SO_4 solutions containing about 10^{-3}M NaCl. When the Cl^- content reaches 1M, the protective film is absent and virtually all current is consumed in the uniform removal of metal through the porous, fluffy precipitate as noted in Fig. 2b. The metal removal in this case is similar to that found in $SO_4^=$-free NaCl solution (see Fig. 2c and Table II).

Table II. Current-efficiency data on mild steel anodes

Electrolyte composition	Current (A/in.^{2})	Current efficiency for metal removal (%)	Current efficiency for O_2 evolution (%)
1M Na_2SO_4	300	5.5	90

1M Na_2SO_4 + 1M NaCl	240	95.0	0
4.5M NaCl	240	96.0	0

Discussion

These data along with other similar investigations (4, 10, 11) indicate that the interaction of anions with the anodic film present produce definite patterns in the shape of the anodic polarization curve. Consequently, the analysis of these patterns in the polarization curves along with current efficiency studies can provide hints as to the nature of the anodic films present at the anode surface in a given electrolyte.

In Fig. 5, three idealized patterns of anodic behavior are sketched from polarization data obtained on steel anodes in various mixed electrolytes as a function of the electrolyte composition. Figure 5a describes the case where the passivating current is shifted to the right towards increasing current density. For the case where the active-passive transition is shifted upwards towards more noble potentials, the pattern in Fig. 5b is applicable. Finally, the third case is represented by the pattern in Fig. 5c where the

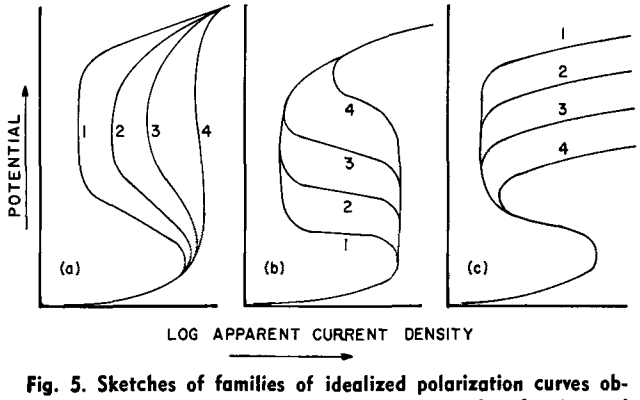

Fig. 5. Sketches of families of idealized polarization curves obtained on mild steel anodes in mixed solutions of a film-forming and a film-dissolving anion numbered in the direction of solutions with increasing concentration of the film-dissolving anion.

transpassive region is lowered towards less noble potentials.

The Cl^- ion is known to form highly soluble complexes with iron and to be a highly efficient agent for the dissolution of anodic films on iron (12-16). In this case, concentrated salt layers are formed at the iron surface but a protective film is not produced at any potential. Both $SO_4^=$ ions and ClO_4^- ions form concentrated salt layers at iron anodes from which porous, nonprotective precipitates are deposited on the iron surface as noted by the stirring dependency of the active-passive transition in such solutions (9). Above a threshold potential, these precipitates are converted to protective anodic films. A compact, protective film is formed by the direct oxidation of the metal surface on iron anodes in solutions of NO_3^- or ClO_3^- ions since the shape of the polarization curve is independent of stirring. These protective films possess a high degree of electronic conductivity (7).

In a solution of Na_2SO_4, the protective film forms from the salt layer at relatively low potentials on steel anodes (Fig. 4a), but when Cl^- ions are added, the salt layer is made more soluble, the precipitate is deposited at higher potentials, and the protective film appears at more noble potentials as noted by the data of Table I. Since the presence of Cl^- ions lowers the protective qualities of the anodic film on steel in $SO_4^=/Cl^-$ mixed electrolytes, the current in the passive region increases with increasing Cl^- content, and the family of polarization curves at various Cl^- ion concentrations follow the pattern of Fig. 5a.

If the protective anodic film is formed by the oxidation of the electrode surface (such as steel in $NaNO_3$ solution), the addition of Cl^- ions to the $NaNO_3$ solution lowers the oxidizing power of the electrolyte by providing competition with NO_3^- ions for adsorption sites on the electrode surface. Consequently, a more anodic potential must be reached before the protective film can be formed on the steel surface. Once this film is formed, however, the steel surface is strongly protected so the current in the passive region does not increase. Instead, the active-passive transition is shifted to more noble potentials (11), and the family of polarization curves for increasing Cl^- content of the NO_3^-/Cl^- mixed electrolyte produces the pattern shown in Fig. 5b.

In the transpassive region, it appears from the data in Fig. 1b and 2a that the Cl^- ion does not remove the passive film uniformly. The film is dissolved at weak points (such as inclusion or dislocation sites) in the film producing localized attack without complete removal of the film. Severe pitting and uneven metal removal takes place. This behavior was also observed (11) for the NO^3-/Cl^- case.

Another good agent for the dissolution of passive films on iron is the ClO_4^- ion (17). Since ClO_4^- ions do not form complexes with iron, and since they are not as strongly adsorbed on the electrode surface as Cl^- ions are, the presence of ClO_4^- ions in a solution of $NaNO_3$ has little effect on the formation of the passive film on a steel anode. However, ClO_4^- ions remove the passive film in the transpassive region uniformly and completely by a suggested ion-exchange mechanism (4) after a threshold concentration of adsorbed ClO_4^- ions on the surface of the film is reached. As the ClO_4^- ion concentration added to a solution of $NaNO_3$ is increased, the threshold concentration of adsorbed ClO_4^- ions for film dissolution is attained at less noble potentials, thus shifting the transition from the passive to the transpassive region on steel anodes in NO_3^-/ClO_4^- mixed electrolytes to less anodic potentials (4). As a result, a family of polarization curves for various ClO_4^- concentrations follows the pattern pictured in Fig. 5c. A similar family of curves was reported by Leckie and Uhlig (18) on 18-8 stainless-steel anodes in $Na_2SO_4/NaCl$ mixed electrolytes.

When ClO_4^- ions are added to a Na_2SO_4 solution, the transpassive region of the curve is also lowered towards less noble potentials on steel anodes in the SO_4^-/ClO_4^- mixed electrolytes (10) according to the pattern of Fig. 5c. However, since perchlorate salts are generally more soluble than sulfates (19), the salt layer becomes more soluble in the presence of ClO_4^- ions and the protective film is formed on the steel surface at slightly more anodic potentials in the mixed electrolyte than in the ClO_4^--free Na_2SO_4 solution. In the case of $NaClO_3$ solutions, where the protective anodic film is formed by the oxidation of the steel surface, the addition of $NaClO_4$ has virtually no effect on the active and passive regions of the polarization curves (10). For the anodic polarization of steel in ClO_3^-/ClO_4^- mixed electrolytes, the transpassive region is shifted to less noble values, as in Fig. 5c, with the addition of ClO_4^- ions to the $NaClO_3$ solution (10).

In general, because Cl^- ions are strongly adsorbed and complex with iron, their presence in mixed electrolyte systems affect the formation and protectiveness of the anodic film. Therefore, the Cl^- content of the electrolyte greatly affects the position of the active and passive regions of the polarization curves in the low concentration range. Since Cl^- ions dissolve anodic films unevenly in the transpassive region by local attack, their presence causes virtually no effect on the position of the transpassive region. These systems are exemplified by Fig. 5a and 5b. The ECM process takes place in the transpassive region. So the uneven, localized dissolution of the anodic film causes severe pitting and nonuniform metal removal in both the low current density (lcd) and the high current density (hcd) region of the machined surface (11) (see also Fig. 2a).

On the other hand, ClO_4^- ions are weakly adsorbed and do not complex with iron. Consequently, they have little or no effect on the active or passive regions of polarization curves obtained on steel anodes in the $NaClO_4$ mixed electrolytes studied. In the transpassive region, ClO_4^- ions remove the film uniformly by an ion-exchange mechanism, and their presence greatly affects the shape and position of the transpassive region of the polarization curve. This behavior results in the pattern of Fig. 5c. Since the passive film is uniformly thinned by the presence of ClO_4^- ions, the surface of the electrochemically machined steel in such mixed electrolytes is electropolished in the hcd region (4, 10), although in some cases, some pitting is found in the lcd region (10).

Figure 6 summarizes the results found for the polarization of mild steel anodes in binary mixed electrolytes containing both a film-forming and a film-dissolving anion as a function of the composition of

the electrolyte. Those systems such as $NaNO_3/NaClO_3$ which do not contain a film-dissolving anion are of no interest to this investigation. Also included in Fig. 6 along the diagonal is the type of film formed in the single electrolyte indicated.

From data obtained on the ECM of high strength alloys (21), it was concluded that no universal electrolyte exists for the machining of all metals. Consequently, one must tailor the electrolyte to the metal to be machined. The use of mixed electrolytes as shown here greatly increases the number of electrolytes available for ECM application; and by proper choice of the components of the solution and their relative concentrations, the tailoring of the electrolyte becomes more feasible. Such data as that obtained from polarization, film stripping, and current-efficiency studies are invaluable as aids in determining the proper choice of electrolyte.

The Behavior of Resistive Layers in the Localized Corrosion of Stainless Steel

H. S. Isaacs*,[1]

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The dissolution of austenitic stainless steels in artificial crevices has been studied as a function of potential and chloride ion activity. Impedance measurements have shown the presence of a resistive layer on the steel which limited the rate of the electrode reaction in the localized corrosion of stainless steels. The potential across the layer, equal to the product of the direct current and layer resistance, varied linearly with the electrode potential indicating ohmic ionic conduction across the layer. The growth of the layer was limited by its solubility and the diffusion of metal cations in the aqueous phase in the cavity. The layer had the properties of a metal chloride with a given solubility product. Increased chloride activity decreased the saturation concentration of the metal cation, its concentration gradient, and gave decreased dissolution rates or currents.

Austenitic stainless steels are highly susceptible to various forms of localized corrosion including crevice corrosion (1-3), pitting (1, 3-15), and stress corrosion cracking (16, 17). The dissolution kinetics within the localized cells would be expected to differ from that of a surface in direct contact with the bulk solution as the concentration of species within the localized area of corrosion are highly concentrated in dissolved cations, hydrogen ions, and chlorides (5-9). The differences in kinetics have been considered to involve the formation of surface layers or films on the anode (10-13), chloride salts (7), and hydrogen bubbles (5). The present investigation is a limited study of dissolution and interfacial characteristics of austenitic stainless steels within artificial crevices or occluded cells (18), where the solution within the crevices was restricted from mixing with the bulk solution.

Key words: diffusion controlled dissolution, impedance measurements, chloride activity, simulated crevices.

Experimental

With all forms of localized corrosion the anode is in contact with a volume of solution restricted from mixing with, and markedly different in composition from, the bulk solution. Two anode systems simulated these conditions. The first system (3) was modeled on a covered pit (19, 20) as shown in Fig. 1, similar to that used by Suzuki and Kitamura. A hemispherical hole 3.2 mm in diameter was drilled into a plate of Type 304 stainless steel to which an electrical lead was spot welded. The surface of the steel, except for the hemisphere, was coated with a thin layer of silicone rubber to act as a bond, and an aperture in a clear plastic was placed centrally over the hemisphere as in Fig. 1. This aperture was 1.0 mm in diameter and about 0.3 mm deep. The saturated calomel reference electrode (SCE)

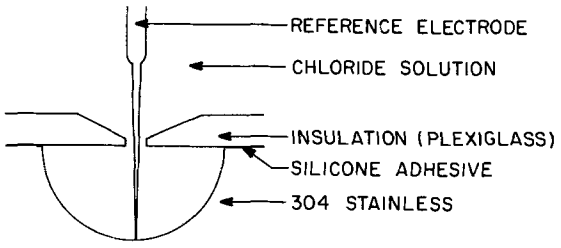

Fig. 1. Schematic of hemispherical cavity

probe with a diameter of about 0.2 mm passed through the aperture and was positioned just above the surface of the hemisphere. The hemispherical cavity had the advantage that the reference electrode was close to the steel surface and would reduce any ohmic potential drops due to solution resistance or precipitation of salts within the cavity (7).

The second anode system which consisted of a wire imbedded into an axial hole drilled in a 25 mm diameter polytetrafluoroethylene cylinder also has been used to simulate pits (4-7). The wires, 0.75 ± 0.03 mm in diameter, were of Types 308 and 321 stainless steels. The face of the cylinder and the cross section of the wire were dry abraded down to 600-grade emery. The cylinder was then inserted into a glass tube with the abraded surface forming the bottom of a container, and the wire protruding from the bottom of the cylinder acted as the electrical lead.

The impedance apparatus employed a constant magnitude square wave current excitation and was similar to that described previously (21). The current wave was superimposed on the direct current from a potentiostat, which controlled the d-c potential of the specimen. The time constant of the potentiostat was sufficiently large to prevent compensation for the potential response to the current wave. The potential responses were less than 10 mV and were displayed on an oscilloscope after amplification and could also be compared or balanced with the response of a variable analog circuit of capacitor and resistor in parallel. Any series resistance could also be measured.

The nominal compositions of the steels are shown in Table I. The solutions used were made from analytical grade reagents and distilled water. All experiments were conducted at room temperature.

Results

The polarization behavior of the hemispherical cavity was found to be more dependent on time than potential once pitting had initiated. A polarization curve obtained in 1.0*N* NaCl is shown in Fig. 2. The potential was held initially at −0.2V (SCE), increased in steps of 0.1 to 1.0V and back for two cycles, and held at each decivolt for 2 min in this experiment. The initial currents were small (<10 μA/cm^3) until the potential was increased to 0.2V, where pitting initiated. The current variations to 0.5V were similar to that expected for a stainless steel surface exposed directly to the bulk solution (15). However, above 0.5V the current decreased, an effect not observed with freely exposed surfaces. The current continued to decrease for all subsequent measurements for the first cycle and was significantly lower on the second cycle at positive potentials. Observation of the hemisphere after polarization showed it was etched but with no deep pits,

Table I. Nominal composition of stainless steels

Type	Weight per cent Cr	Ni	Ti
304	18-20	8-10	—
308	17-19	10-13	—
321	17-19	9-12	0.4 max

indicating the entire surface had been active in contrast to the localized pitting on freely exposed surfaces. The breakdown of the remaining passive surface was probably accelerated by the changes in composition within the cavity. Compositional changes could be seen after pitting initiated as the solution within the cavity changed to a light green and then to a very dark green.

The current-time behavior for a hemispherical cavity at a constant potential is shown in Fig. 3. The current initially increased to a maximum and then decreased with time, after the solution became dark green. Comparison of the shape of this curve with that in Fig. 2 on considering the potential axis in terms of the time of each measurement suggests that the current behavior was more dependent on time than on the potential. The over-all shapes of both the polarization and current-time curves in replicate experiments were always the same but their magnitudes and the position of the maximums varied. For example, when the current-time behavior was recorded, the time taken to reach the maximum was from 3 to 8 min at 0.3V, while at higher potentials the range of times to reach the maximum decreased. These variations are probably a result of the statistical variations in the number and growth of pits (14). The greater the number of pits or the current from them, the more rapid would be the compositional changes of the solution within the cavity and the shorter the time taken to reach the current maximum.

Changes in color of the solution were obviously due to change in concentration of the dissolving cations, but as chloride ion concentrations would also increase (9), the influence of chloride concentration in the bulk solution was studied. The polarization measurements are shown in Fig. 4 with 1.0*N* NaCl, 4.0*N* LiCl, and

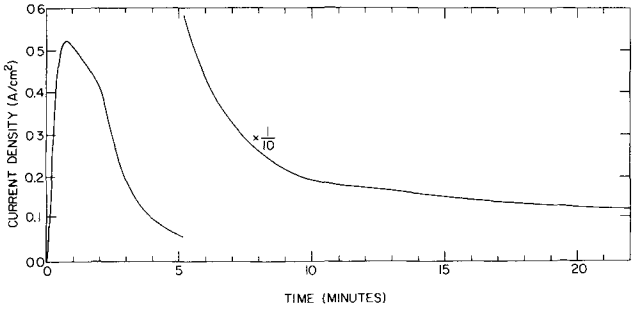

Fig. 3. Variation of the current with time for a hemispherical cavity held at E_{SCE} = 0.5V.

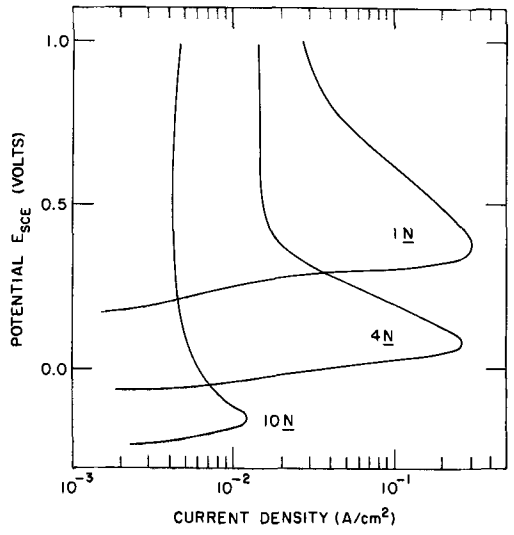

Fig. 4. Polarization behavior of hemispherical anodes in 1*N* NaCl, 4*N* LiCl, and 10*N* LiCl on increasing the potential and holding at each decivolt for 1 min.

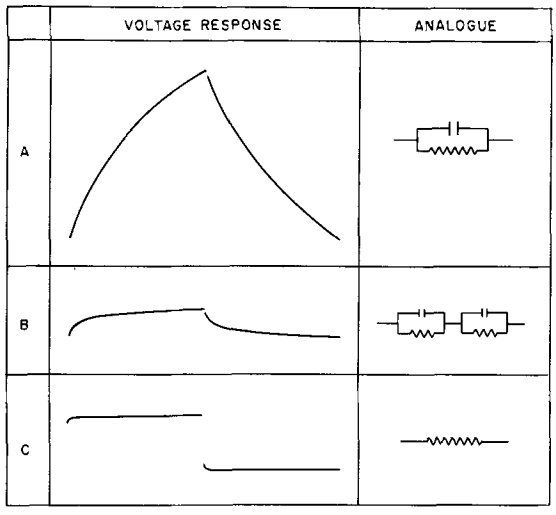

Fig. 5. Voltage responses and approximate electrical analogs of a hemispherical anode interface to a square wave current of constant magnitude. Cycle time: 10 msec. Voltage changes in A: approximately 6 mV.

10.0*N* LiCl solutions. As expected, the pitting potential decreased with increased chloride concentration (15) but the current then decreased more rapidly with potential, indicating higher chloride concentrations were more effective in inhibited dissolution. Measurements with dilute chloride solutions below one normal were unsuccessful probably as a result of this trend. For example, when 0.75*N* NaCl solution was used the current increased rapidly after pitting initiated but the higher currents lead to boiling of the liquid at the aperture and steam bubbles periodically broke the electrical circuit. The rapidity with which the bubble contracted and disappeared after the circuit was broken was inconsistent with the bubble being hydrogen as had been suggested (5).

The behavior of the hemispherical steel solution could, from the polarization measurements, be divided into three regions, viz. (A) the passive surface prior to pitting, (B) the surface when pitting initiates and the current increases (with time, Fig. 3; or potential, Fig. 2), and (C) the surface when the current decreases after the maximum is reached.

The impedance characteristics of the interface obtained using square wave current excitation, could also be defined in these three regions, A, B, and C. The shapes of the voltage responses to the current wave are shown in Fig. 5 for these regions with a repeat cycle of 10 msec. The shape in Fig. 5A was characteristic of the passive surface and was closely approximated by a capacitor and resistor in parallel. The values at −0.2V were close to 30 μF/cm² and 550 ohm-cm², and on increasing the potential the capacitance decreased and the resistance increased. This equivalent circuit was observed until pitting initiated and the current increased rapidly with time. The increased current at pitting sites is analogous to a leakage path across the interface or from an equivalent low resistance in parallel with the analog components of the passive surface. This low resistance would be expected to decrease as the current increases (22). The voltage response, Fig. 5B, observed after pit initiation only approximated this equivalent circuit, in that the magnitude of the response decreased as the current increased, but its shape was more complex and indicative of an equivalent circuit of more than one capacitor in series, each with a parallel resistor.

The shapes of the voltage responses in Fig. 5A and 5B are representative of those observed for a wide range of metals (21, 22) and show a time dependence for the period of each half-cycle. Any equivalent circuits of these responses must involve capacitors to give the potential changes with time. In contrast, a series resistance would only give an instantaneous potential change when the alternating current switches from one-half cycle to the next and then remain constant. The presence of a small series resistance of 0.8 ohm-cm² also accounts for the separation of the half-waves in responses A and B and was probably the result of solution resistance.

The response in Fig. 5C, observed after the current maximum was reached (in Fig. 2, 3, and 4) differs markedly from those of A and B, and from responses observed with a wide range of metal electrodes. This response is closely approximated by a series resistance. The departure from pure resistive behavior was due to some initial curvature indicating a time constant of less than 10^{-4} sec, but this detail was not studied. The magnitude of this response, or that of its analog series resistance, varied with time and potential and these changes were unambiguous.

The potential dependence of the measured series resistance, shown in Fig. 6, was measured with the same cavity and just prior to the currents given in Fig. 2. Above 0.5V (SCE) the resistance increased rapidly as the current decreased and the hysteresis of the resistance on the second cycle was the inverse of that

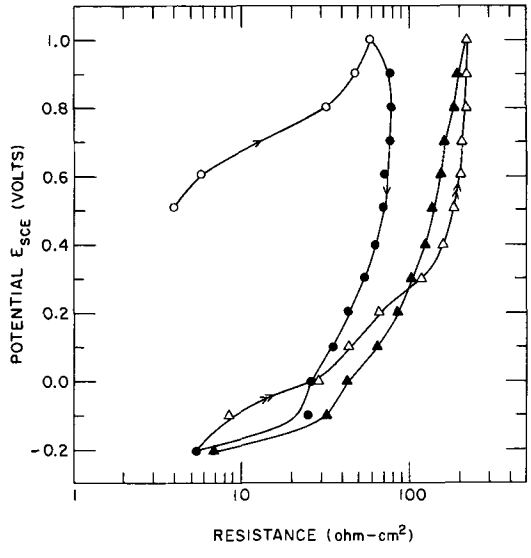

Fig. 6. Variations of the measured series resistance with potential during polarization measurements shown in Fig. 2.

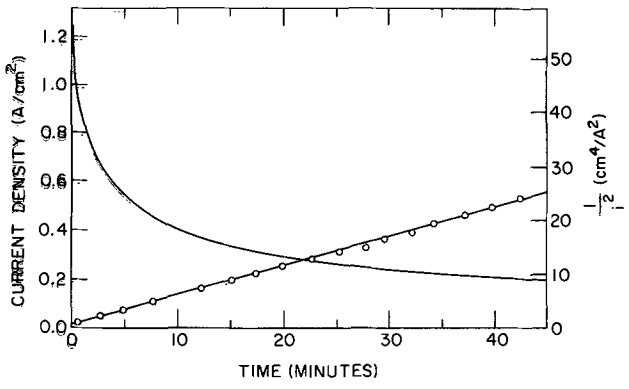

Fig. 7. Variations in current and the square of reciprocal current (○) with time for a wire type anode at E_{SCE} = 0.8V in 1.0*N* NaCl.

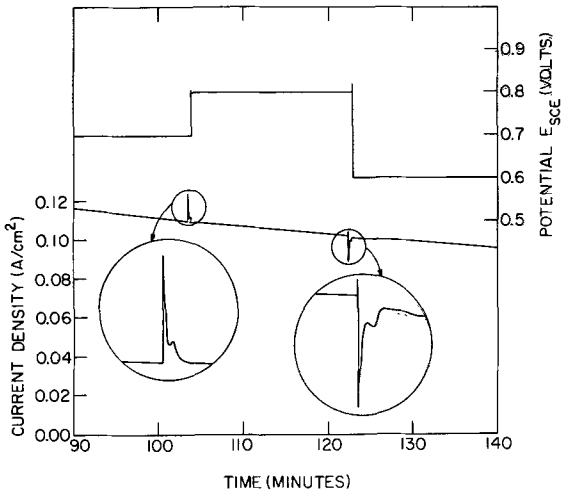

Fig. 8. Variations in current with potential changes for a wire-type anode in a mixed solution of 1.5*N* $MgCl_2$ plus 0.1*N* H_2SO_4 after being held at E_{SCE} = 0.7V for 105 min.

of the current, suggesting the series resistance and the direct polarization current were interrelated. Resistance measurements were also made with the hemispherical cavity in other chloride solutions and showed the same inverse relation to the current.

The experiments conducted on the wire-type electrode were similar to those of Novakovski and Sorokina (7). In general, the potential was held constant and the current-time curve was recorded. An example of the current variations with time is shown in Fig. 7 for a Type 308 stainless steel wire in 1.0*N* NaCl at 0.8V. The current decreases with time and the square of the reciprocal current was proportional to the time as plotted in Fig. 7. A series of measurements were conducted at different potentials in different chloride solutions and the resulting slopes (di^{-2}/dt) and the intercepts as the ordinate (i_o^{-2}) are given in Table II. In some cases breaks in the curves were observed and are noted in Table II.

In runs 1 to 4 with the mixed solution of 1.5*N* $MgCl_2$ and 0.1*N* H_2SO_4, the influence of the potential was not marked in the range 0.35–0.85V (SCE) nor were the breaks (or parallel shifts) of the curves after about 10 to 30 min. These results disagree with those of the previous investigators (7) who indicated a much greater potential dependence, with a stainless steel containing titanium. However, in Table II, for runs 3 and 4 or 6 and 7, the presence of titanium or changes in chromium and nickel concentrations did not influence the results significantly.

An example of the effect of changing the potential on current during a run is given in Fig. 8. Except for the perturbations following the potential change, these changes had no significant influence on the basic shape of the curve indicating that the major factors controlling the current were independent of the potential. The perturbations were complex and lasted for up to 5 min and consisted of a rapid change followed by further damped oscillations, but the current then approached its value prior to the change. The perturbations are enlarged in the insets in Fig. 8 and were found to be dependent on the potential change and its direction.

Utilizing the wire electrodes it was observed that the magnitude of the current decreased markedly with increased chloride concentrations above 4*N*. Once again this was an indication that the chloride ion inhibited the anodic current or dissolution of the steel. The slopes of the plots of the square of the reciprocal current are given in Table II for different lithium chloride concentrations in runs 9 to 14. Above 4*N* LiCl the position of the intercept at zero time also increased markedly with increased chloride ion concentration. This indicated that the currents observed were low soon after the experiments were initiated. In the case of the 10*N* solution marked perturbations were observed at the initiation of the tests other than those associated with the breakdown of passivity, and more akin in shape to those shown in Fig. 8.

The inhibition of the dissolution of the steel in the cavities was marked in the case of chloride ions, but a smaller dependence on the cation was also found. At 4*N* chloride concentration the lithium chloride and hydrochloric acid solutions gave smaller currents (or greater slopes, runs 8, 11, and 15 in Table II) than those in sodium chloride solutions.

Table II. Slopes, intercepts, and calculated additional diffusion paths obtained from the linear variations of the square of the reciprocal current with time for wire-type anodes

Discussion

The dissolution behavior of stainless steel in a cavity may be divided into three stages. During the first stage the steel surface is passive. The second stage involves the breakdown of passivity followed by rapid dissolution. The initiation of breakdown has been investigated in detail in pitting experiments (6, 14, 15), but there is little knowledge of the subsequent undermining of passivity as the composition of the solution changes within the cavity. The third stage which occurs when the surface is no longer passive will be considered here. The currents or dissolution rate of the steel are extremely high, but the surface during the third stage is not in the same "active" state as defined by potentials below the Flade potential.

The surface properties in the third stage are markedly different from those normally encountered. This is shown by the potential response of the interface to a square current wave that is approximated by a series resistance. A closer analogy would involve the presence of a capacitor in parallel with the resistor. The approximate value of the capacitance may be calculated from the time constant of the initial response of the potential as the time constant is the product of the capacitance and resistance. The observed time constant was about 10^{-4} sec and taking the resistance as 100 ohm-cm^2 gives a capacitance of about 1 μF/cm^2. This value is too low to be accounted for in terms of a metal-solution electrochemical double layer which usually has a value greater than about 20 μF/cm^2 (23) and indicates that no double layer plays a part in the major interfacial characteristics. In view of this it is unlikely that classical concentration polarization is involved as the impedance characteristics would be significantly different (22). Hydrogen bubbles (5) also would not account for the observed changes in shape of the potential response from one similar to that in Fig. 5B to that in Fig. 5C. If hydrogen increased the solution resistance, the effect would be one of a pure series resistance which would only influence the response when the current stepped from one half-cycle to the next. If hydrogen bubbles decreased the effective surface area the time constants (or curvature) of the interface would not be changed but the current density and hence the magnitude of the response would be increased and would not account for the shape observed in Fig. 5C.

The characteristics of the interfacial region are probably the result of a compact layer (10, 11) approximately 100Å thick (asuming a dielectric constant of 8) having a resistivity of about 10^8 ohm-cm. These values are calculable from the voltage response. In comparison, the thickness of passive layers on iron (24) and steels (25) can be up to 50Å, while for anodic oxide films on the "valve" metals the films may be approximately this value and considerably thicker (26, 27). In the case of the valve metals, however, the resistivity of the major part of the oxide is considerably greater than 10^{10} ohm-cm (27), and orders of magnitude greater than that of the resistive layer.

The potential (V) across the layer is given by the product of the polarization current (i) and the series resistance (R) at each electrode potential (E_{SCE}) and time at which they were measured. The relation between these potentials as shown in Fig. 9 is linear. The slope of the line closely approximating unity, indicates that Ohm's law is obeyed within experimental error. The ohmic behavior also leads to the conclusion that conduction occurs via a "low field" mechanism, or that current through the film is directly proportional to the field within the layer. If a "high field" conduction process was operative, the current could be expected to increase logarithmically (or possibly some other function) with the field in the oxide. For this reason and as a result of other probable complications

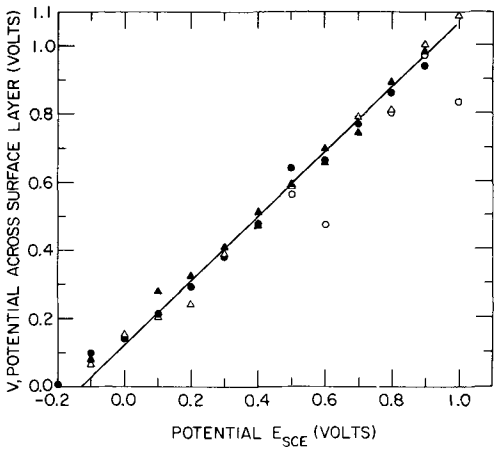

Fig. 9. Variations of potential across the surface layer with electrode potential. The potential across the layer was obtained from the product of the polarization current (Fig. 2) and series resistance (Fig. 3).

(28), the relation shown in Fig. 9 would not be obtained.

The results in Fig. 9 also show that when the electrode potential is changed the potential change occurs within the resistive layer. The current flowing is a function of the layer's resistance and the potential across the film which is given by

$$V = E_{SCE} + 0.125 \qquad [1]$$

This relation has also been obtained with solutions containing higher chloride concentrations, *e.g.*, 4.0*N* NaCl and 10.0*N* LiCl. The electrochemical reactions taking place at both the steel-layer and layer-solution interfaces were, therefore, not changed by the higher chloride concentrations. There is, nevertheless, a marked dependence of the current on chloride concentration and this dependence must result from other factors taking place in the highly concentrated solution.

Independent of the mode of ionic conduction within the layer it can be considered that the effective rate of arrival of metal ions at the solution-layer interface is equivalent to the current. The arriving ions may then either increase the thickness of the layer or enter the solution and diffuse away from the interface. One simplification will be considered; the rate of diffusion predominates and the contribution to the growth of the layer is negligibly small.

The diffusion processes are more easily considered in the wire-type cavity as opposed to the hemispherical cavities where the concentration gradients will depend on distance from the interface and could be complicated by convection processes within the cavity.

When the steel wire had dissolved to a depth equal to l, the rate of diffusion or the diffusion current will be given from Fick's first law as

$$i = \frac{n\mathbf{F}D(Cs - C)A}{l + \Delta} \qquad [2]$$

where n is the average valency of the diffusion ions, **F** the Faraday, D the diffusion coefficient of the ions, Cs the concentration at saturation in the solution at the solution-layer interface, C the concentration in the solution which, in the tests conducted, may be considered to be zero, and A is the cross-sectional area of the wire. The value of Δ may be considered as an additional diffusion path.

The depth to which the wire has dissolved, l, is a function of the total charge passed and is given by

$$l = \frac{M}{An\mathbf{F}\delta} \int_0^t idt \qquad [3]$$

where M is the average molecular weight of the steel of density δ and t is the time. Substitution of Eq. [3] for l in Eq. [2] and integrating between $i = i_0$ when $t = 0$ and $i = i$ when $t = t$ gives

$$\frac{1}{i^2} - \frac{1}{i_0^2} = \frac{2M}{A^2 D \delta n^2 \mathbf{F}^2 (Cs - C)} t \qquad [4]$$

When $t = 0$, $l = 0$ and the value of i_0 can be obtained from Eq. [2], giving

$$\frac{1}{i_0} = \frac{\Delta}{n\mathbf{F}D(Cs - C)A} \qquad [5]$$

According to Eq. [4] the reciprocal of the square of the current should be proportional to time. This is observed to be the case as shown in Fig. 7. Assuming the steel to have 19% chromium and 9% nickel and taking $M = 55.4$ g/mole, $n = 2.2$, $\delta = 8$ g/cm^3, $D = 0.5 \times 10^{-5}$ cm^2/sec (29), and $A = 1$ cm^2 the derivative of Eq. [4] gives

$$\frac{di^{-2}}{dt} = \frac{6.15 \times 10^{-5}}{Cs - C} \qquad [6]$$

The slope of the plot in Fig. 7 is $0.010 \mathrm{A}^{-2}$ cm^4 sec^{-1} (Table II) and on substitution in Eq. [6] with the bulk concentration (C) as zero gives a value of approximately $6 \cdot 10^{-3}$ moles/cm^3 or a 6 molar concentration. This calculated saturation concentration is close to that expected for the metal chlorides involved and indicates that a model based on simple diffusion and solubility of a chloride layer is in reasonable agreement with the experimental results for bulk concentrations from 1 to about 4N chloride ion. Increased chloride and different chloride salts influenced the slopes in Table II, which, in turn, would change the calculated saturation concentration. The slopes are a function of the activity of chlorides in the bulk solution. For example, the mean activity coefficients of lithium chloride and hydrochloric acid are approximately equal at a given concentration, while that of sodium chloride is significantly lower (30). Comparing the slopes for runs 11, 15, and 8 in Table II indicated the same dependence: lithium and the acid gave approximately the same slope, while that with sodium chloride was significantly lower. These results are interpretable in terms of a solubility model (Eq. [3]). The chloride layer formed on the anode surface can be considered as a compound with a given solubility product and any increase in chloride concentration or activity would lead to a decreased metal ion saturation concentration and an increased slope.

The variation of slope with lithium chloride concentration (runs 9-14) is complex. In concentrated solutions the mean activity coefficient of the salt increases with increased concentration rather than decreases as is well known for dilute solutions (30). These changes led to an increased slope which was marked above bulk concentrations of 4N. The rate of increase in slope was also more rapid than the square of the concentration but approximated the square of the activity calculated from the square of the product of the concentration and mean activity coefficients (30) of lithium chloride. At and below 4N concentrations the effect of bulk activity was small probably as a result of the significantly higher activities within the cavity.

The intercepts on the ordinate (i_0^{-2}) of the i^{-2} *vs.* t plots as shown in Table II depended on the solution and increased with increased concentration as has been observed previously (7). In the derivation of Eq. [4] and [5] the presence of this intercept has been attributed to an effective additional diffusion path Δ. This value may be obtained on dividing Eq. [5] by the derivative of Eq. [4] which gives

$$\Delta = \frac{n\mathbf{F}A\delta}{2M} \Big/ i_0 \frac{di^{-2}}{dt} \qquad [7]$$

The values of Δ have been determined and are also given in Table II and vary from 0.025 to 0.10 cm. The shift in the curves observed in the sulfate-containing solutions giving values of Δ of approximately 0.1 cm suggest that this is due to an increased diffusion path possibly as a result of a precipitate forming at the mouth of the pit. The lower values may either result from a "lid" although no "lid" could be seen after the experiments in 10N LiCl. The magnitude of Δ can also be accounted for in terms of a diffusion layer (31) in the increased density of solution (9) existing from the cavity. The high density solution could reduce the effects of convection currents that normally control the magnitude of the diffusion layer and give rise to an unusually large value.

The above discussion shows that the current is controlled by (*i*) the resistance of the resistive layer and the potential across it, and (*ii*) the diffusion of metal ions from the cavity. There is, however, no anomaly as the arrival of metal ions at the layer-solution interface at constant potential must be almost equal to the flux of metal ions diffusing from it. If the rate of arrival was greater than the diffusion flux the thickness of the resistive layer must increase as the excess would not enter the saturated solution. This, in turn, would increase the resistance of the layer and reduce the current until both fluxes are again equal. The system is thus self-regulating as concluded by other authors (7).

The potential would also not be expected to influence the currents because of the self-regulation of the system and this was found experimentally in runs 1 to 5 in Table II. If the potential was stepped during a run it would be expected that the perturbations in the current would be observed for a short period following the potential change. If the potential was increased the current across the layer would increase above that of the diffusion flux. The thickness of the layer would then increase until its resistance at the new potential reduced the current to a value equal to the diffusion flux. Similarly, when the potential is decreased the current would initially drop, the layer would dissolve and the current would then rise to the value once again equivalent to the diffusion flux. Figure 8 shows the experimental results. Following the potential change, the current does again approach a value equal to that prior to the change. However, the perturbations in the observed current (shown in insets in Fig. 8) are more complex than the above model would indicate. These perturbations are probably the result of the rapid changes in the current and the movement of the ions which led to changes in composition and complex chemistry of the solution within the cavity. These transient changes, in turn, could influence the solubility of the resistive layer, its thickness, and the flow of current.

Summary

1. High currents or corrosion rates are observed over a wide range of potential in localized corrosion.

2. A resistive layer forms on the surface of stainless steel anodes in concentrated chloride solutions containing high concentrations of metal ions present in restricted cavities.

3. The resistivity of the layer is approximately 10^8 ohm-cm and field-assisted migration across the layer is ohmic.

4. The thickness of the layer is a function of the electrode potential and the rate of diffusion of metal ions from the layer-solution interface.

5. The solubility of the metal ions and the current depends markedly on the chloride concentration and the complex chemistry within the cavity.

Acknowledgments

The author wishes to thank Dr. D. H. Gurinsky for his interest in this work, Drs. L. Newman and S. W. Feldberg for their many helpful discussions, and Mr.

G. Kissel for his assistance. This work was performed under the auspices of the United States Atomic Energy Commission.

Initial Stages of Electromonocrystallization of Nickel on Copper-Film Substrates

Shohei Nakahara and Rolf Weil*

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey 07030

ABSTRACT

The first stage of electromonocrystallization, the growth of single-crystal electrodeposits, in a number of instances is the development of three-dimensional, epitaxial crystallites (TEC). The absence or presence of TEC as well as their morphology is determined by the codeposited foreign species, either intentionally added or apparently resulting from a high pH in the solution adjacent to the cathode. When a complete deposit layer has formed, strains result from the difference between the lattice dimensions of the deposit and substrate as well as from the coalescence of TEC. Surface undulations are also related to the joining of TEC. Dislocations of the misfit type develop at certain deposit thicknesses; their spacing and straightness again are related to the presence of foreign substances. The coalescence of TEC and possibly of atom layers too thin to be visible also results in dislocation and twin formation.

Many recent fundamental studies of electrocrystallization have involved single-crystal substrates and deposits in order to avoid the complications of grain boundaries and the variation of the growth processes with orientation. In order to differentiate between the electrolytic growth processes within one single crystal and those in polycrystalline deposits, the term "electromonocrystallization" is introduced here. Many investigations of electromonocrystallization have been primarily concerned with describing the transition of an ion from the electrolyte to the metal structure. Other studies on a much larger than atomic scale have employed optical observations (1-6) or special x-ray-diffraction techniques (7-8). There have been only a few studies of electromonocrystallization processes which used electron microscopy. Of course, there have been many observations of electrodeposits using both transmission and scanning electron microscopy, but they have yielded very little information of how the structures developed. Unfortunately, it has not been possible to perform the *in-situ* experiments (9) which have been so valuable in studying the growth processes of vapor deposits. The electron microscopic examinations by Lawless (10-11) of the initial stages of electromonocrystallization of deposits while still attached to thin-film substrates have elucidated the growth mechanisms. However, Lawless did not systematically investigate the effects of the plating variables and foreign substances in the electrolyte which are known to alter the crystallization processes. This study is therefore primarily concerned with the effects of the pH, metal-ion concentration and buffering of the plating bath as well as the deliberate additions of three organic substances (coumarin, saccharin, and phenosafranine) on electromonocrystallization using essentially the same types of samples as Lawless.

Key words: electrocrystallization, thin films, nickel.

Experimental Procedure

The substrates were produced by vapor depositing about 50 nm of copper onto cleaved and polished {001} faces of potassium-chloride crystals. During the evaporation in a vacuum of about 10^{-5} Torr, the KCl crystals were in contact with a heater, which maintained their surface temperature at 350°C. After evaporation, the samples were held at 400°C for several hours to anneal them. When the coated KCl crystals had cooled, they were removed from the vacuum chamber, cleaved into pieces 0.5 cm by 2 cm and stored in a desiccator.

Just before plating, the KCl was dissolved by floating the sample on the surface of distilled water. The copper films, which continued to float after the salt had dissolved, were rinsed several times by transferring them on a wet glass slide onto the surfaces of several water-filled dishes. The final dish contained a 10% H_2SO_4 aqueous solution to remove any oxide film. With one end touching a piece of copper foil for electrical contact, the film was floated in a dish containing the plating solution. A nickel anode lay on the bottom and had a platinum wire attached to it for electrical contact.

The compositions of the plating solutions are listed in Table I. Coumarin was chosen as an addition agent because it reduces macrostress in polycrystalline deposits (12). Saccharin results in compressive macrostress (12). Phenosafranine was selected as an additive because of the large size of its molecule, which was known to be included wholly in electrodeposits and because it increases tensile macrostresses (13). The structures of phenosafranine and coumarin are schematically represented in Fig. 1. The current density was 5 mA/cm² and the *p*H was either 1.5, 3, or 6 as also shown in Table I. The plating thicknesses were 1-200 nm. The temperature at the surface of the plating bath was maintained at 30°C. The current was preset using a constant-current source. The plating solutions were prepared with triple-distilled water (two distillations in the presence of oxidizing agents to remove organic impurities) and reagent grade chemicals. The electrolyte was purified by treatment with activated charcoal and by low-current-density electrolysis for at least 48 hr. The *p*H was adjusted either with sulfuric acid or nickel carbonate.

After plating and rinsing, the samples were cut into pieces about 0.3 cm², placed on 200-mesh electron-microscope sample grids and dried. In general, bicrystal films, *i.e.*, nickel deposits still attached to the copper substrates, were examined. Unplated samples of each lot of the copper-substrate material were also examined. In some instances the copper was dissolved in an aqueous solution composed of 50 g/liter H_2SO_4 and 500 g/liter CrO_3 so that only the thin nickel deposit could be studied. A few samples which were too thick for transmission electron microscopy were thinned by electropolishing (14a). Some surface replicas (14b) were also examined. In some instances, the nickel films on the copper substrates were shadowed (14b) to enhance the contrast due to surface features. Stereo electron microscopy of both replicas and the thin samples themselves was also employed. In order to see the location of codeposited molecules, phase-contrast electron microscopy (15) was used. A few nickel films still attached to the copper substrates were also annealed for 20 min at 200° and 400°C.

Table I. Composition and pH values of plating baths

Bath	Composition (moles/liter)	*p*H values
A	0.43 $NiSO_4$	1.5, 3

Results

The {001}-oriented copper substrate films contained about 10^8 twin faults per square centimeter extending in both <110> directions. In addition, there were some vacancy clusters and a number of dislocations mostly with mixed Burgers vectors. As a result of contact with the sulfuric acid solutions, about 10^8 etch pits per square centimeter developed as manifested by stereo electron microscopy. Copper films when examined prior to the sulfuric acid treatment exhibited rectangularly shaped oxide particles.

The general results of the electron microscopic studies of the early stages of electromonocrystallization of nickel on copper-film substrates were that under a number of plating conditions, isolated, three-dimensional, epitaxial crystallites, hereafter called TEC, developed. In all samples, when a continuous deposit covered the substrate, elastic strains and surface undulations were observed. Subsequently, misfit and other dislocations and in some instances twins developed. The specific results for the several baths and *p*H values are listed in Table II and described below.

At *p*H 1.5 in deposits from the bath containing only nickel sulfate in the lower concentration (bath A) only a few, relatively large, rectangularly shaped TEC were observed. The average length of the edges, which were straight, was 130 nm. In addition to the TEC, some triangularly shaped crystallites were observed and identified as nickel hydroxide from their electron diffraction patterns. The addition of boric acid (bath B) resulted in a slight decrease in the size of the TEC in the plane parallel to the substrate as well as in the

Table II. Results

Bath	pH	TEC structure	Misfit dislocation structure: Estimated minimum deposit thickness of formation (nm)	Misfit dislocation structure: Type	Misfit dislocation structure: Spacing (nm)

perpendicular direction. Increasing the nickel-ion concentration and maintaining that of boric acid (bath C) resulted in a further decrease in the TEC size in the plane parallel to the substrate, but an increase in height, *i.e.*, in the perpendicular direction. Figure 2 shows TEC as grown in the higher nickel-ion-concentration electrolyte (bath C). The sides of TEC tend to be parallel to <110> directions. By means of replicas it was established that these TEC had a pyramidal shape.

The addition of coumarin to the baths of both nickel concentrations also containing boric acid (baths E and F) at *p*H 1.5 resulted in deposits in which TEC were not observed. Saccharin additions (bath G), on the other hand, caused a large increase in the number of TEC accompanied by a considerable decrease in their dimensions in the plane parallel to the substrate surface as seen in Fig. 3. The height of the TEC appears to be about the same as that of the ones in Fig. 2 as judged from their transparency to electrons. Another noteworthy feature of the TEC, which developed in the bath containing saccharin, is that the sides are no longer straight. Some triangular nickel hydroxide crystallites were also observed in samples produced in this bath. These crystallites developed, however, after the nickel deposit became continuous. The addition of

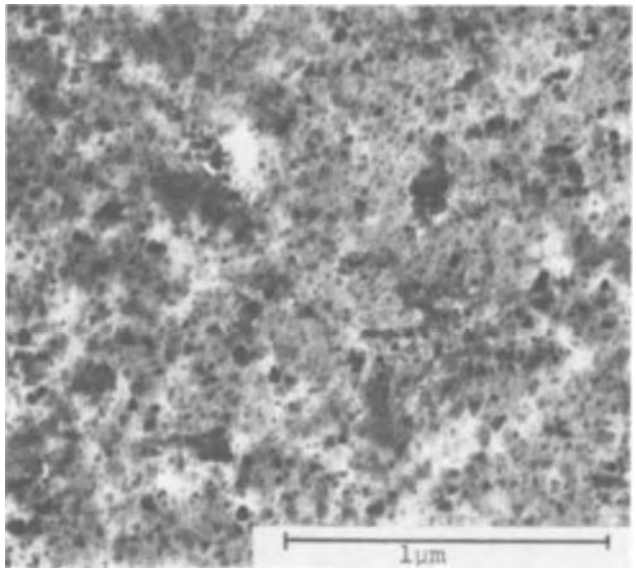

Fig. 3. Small, irregularly shaped TEC. Plated in bath G at *p*H 1.5

phenosafranine to the electrolyte (bath H) also resulted in a great increase in the number of TEC. However, as seen in Fig. 4 the sides of the TEC are straight. If the sample shown in Fig. 4 is examined under phase-contrast conditions, a number of small white dots are seen. The dots have been interpreted (15) as being the sites of incorporated molecules. A majority of the sites appeared to be at the edges of the TEC. The rest of the sites were found within the TEC.

At *p*H 3, in the bath with only nickel sulfate in the lower concentration (bath A) the formation of irregularly shaped TEC measuring about 80 nm parallel to the substrate-surface plane was observed. The TEC are shown in Fig. 5. In some samples plated for a slightly longer time, the size of the TEC increased up to 300 nm. These larger crystallites were no longer transparent to electrons. In addition to the TEC, the triangular nickel-hydroxide crystallites were observed again. No TEC were visible in deposits produced at *p*H 3 in the bath to which boric acid had been added (bath B). In one experiment, the current density was inadvertently raised to 15 mA/cm^2, *i.e.*, three times that used in all the other experiments. The deposits so produced showed irregularly shaped TEC. No TEC were seen in deposits produced in the bath (D) to

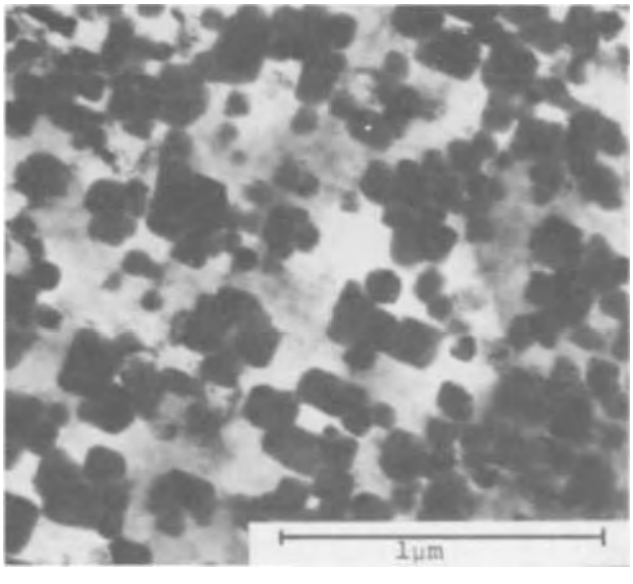

Fig. 2. Relatively large TEC with straight sides plated in bath C at *p*H 1.5.

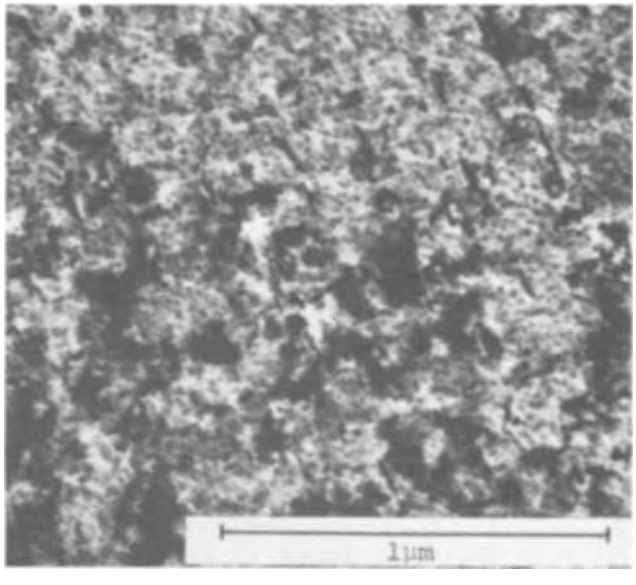

Fig. 4. Small, straight-sided TEC. Plated in bath H at *p*H 1.5

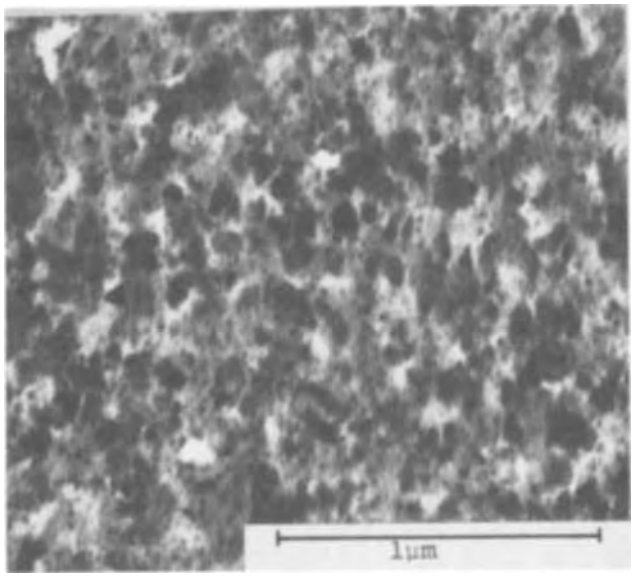

Fig. 5. Irregularly shaped TEC. Plated in bath A at pH 3

which a stronger buffering agent, nickel acetate, had been added.

At pH 3, the addition of coumarin to the low-nickel-concentration bath which also contained boric acid (bath E) resulted in the growth of small (about 35 nm) irregularly shaped TEC. It may be recalled that there were no observed TEC in bath E at pH 1.5. The addition of phenosafranine (bath H) resulted in structures essentially the same as those produced at the lower pH. Irregularly shaped TEC were observed in samples plated in a bath containing both phenosafranine and saccharin (bath I).

At pH 6, no visible TEC resulted from deposition in the bath with the lower nickel concentration and boric acid (bath B).

The structures which developed after the nickel deposit became continuous were similar in all samples. This structure is shown in Fig. 6. The thicknesses at which the deposits became continuous depended, of course, on the previous structure. When there were no TEC, the deposits became continuous essentially immediately. When there were TEC, the average thickness was estimated from the plating times to have been about 2-5 nm. The contrast in Fig. 6 is due to Moiré patterns, thickness variations, and strains. There were point-to-point thickness variations as determined by the use of replicas of the surfaces as well as by a contrast enhancement when the samples themselves were shadowed. In the electron diffraction patterns of the samples shown in Fig. 6, there was no recognizable separation of the spots due to copper and nickel also indicating that lattice-misfit strains were present.

There were some differences between the structure of samples which had exhibited straight and irregularly shaped TEC, respectively. The sample shown in Fig. 6 at an earlier stage of growth had exhibited regularly shaped TEC. Here the Moiré pattern consists of rather straight lines which are indicated by the arrow. These lines lie essentially parallel to <100> directions in this case. Figure 7 represents a sample which showed irregularly shaped TEC at the earlier growth stage. Here the lines are not straight. The electron diffraction patterns of samples such as are shown in Fig. 7 consisted of small arcs of circles instead of spots, indicating a tendency toward polycrystallinity. When the TEC stage was not visible, the structure of a continuous nickel film was similar to that of Fig. 6. The lines were again rather straight, however not as pronounced.

The relaxation of some of the elastic strains was indicated by the separation of the electron diffraction spots of copper and nickel as well as by a decrease in their size and was accompanied by the appearance of misfit dislocations. The Burgers vectors of these dislocations, which are indicated by an arrow in Fig. 8 were found to be of the ½ <110> type and to have an edge character. The fact that their images were not seen in nickel films separated from their substrates proved that the dislocations were located at the interface between the copper and nickel and therefore of the misfit variety. Rough estimates of the average deposit thicknesses at which misfit dislocations were first observed are listed in Table II.

The degree to which the misfit dislocations were straight also could be related to the TEC structure. In the samples in which TEC were not visible at the earlier stage of growth, well-defined, straight misfit dislocations such as seen in Fig. 8 were observed. Also when the TEC were large in the plane parallel to the substrate surface and had straight sides, such as in the baths without additives at pH 1.5, the dislocations were straight and well defined. In areas wherein dislocations had not formed, the lines that characterized the earlier stage of growth were still visible. Figure 9

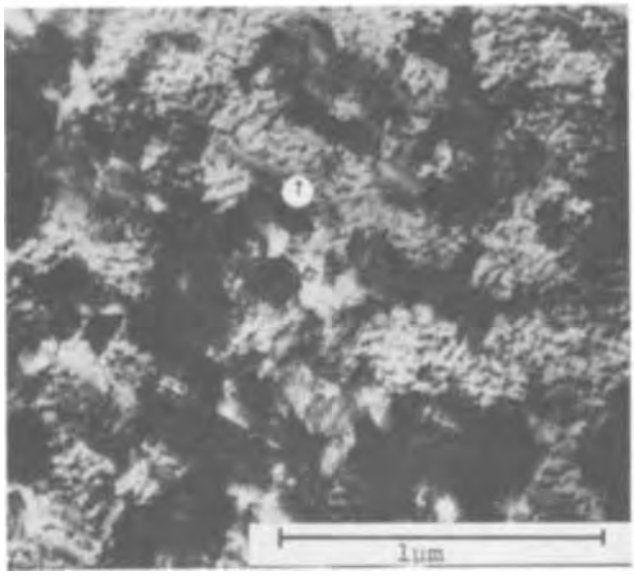

Fig. 6. Structure after nickel deposit was continuous. At earlier stage, TEC had straight sides.

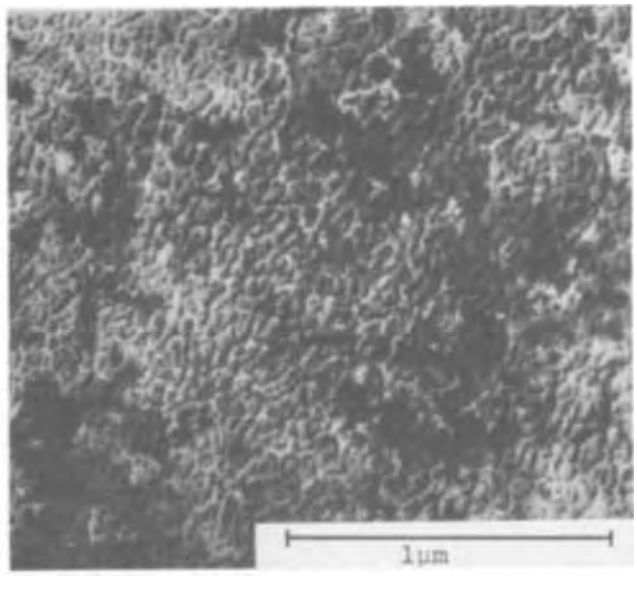

Fig. 7. Structure after nickel deposit was continuous. At earlier stage, TEC had irregularly shaped sides.

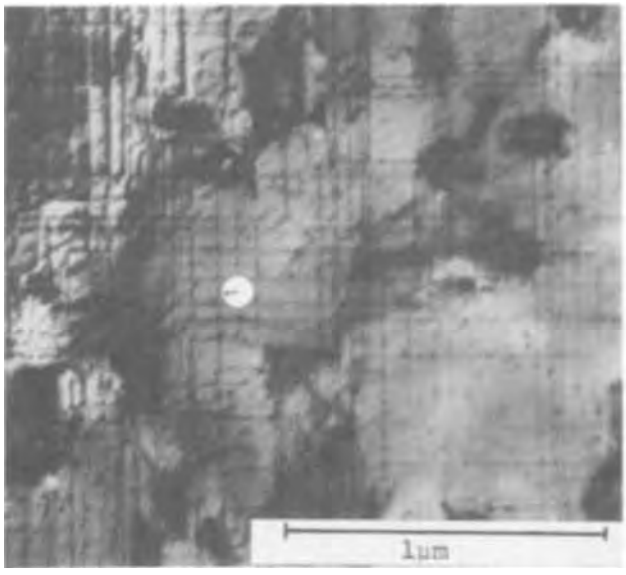

Fig. 8. Straight misfit dislocations. At earlier stage, sample showed no TEC.

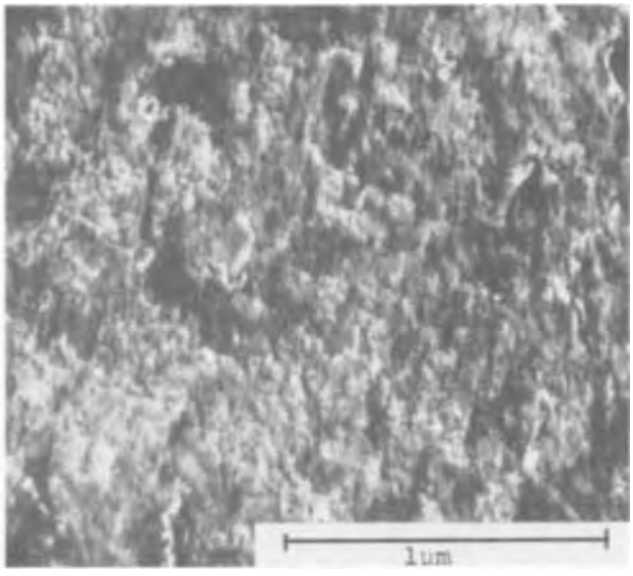

Fig. 10. Irregularly shaped dislocation structure. At earlier stage, TEC had irregularly shaped sides.

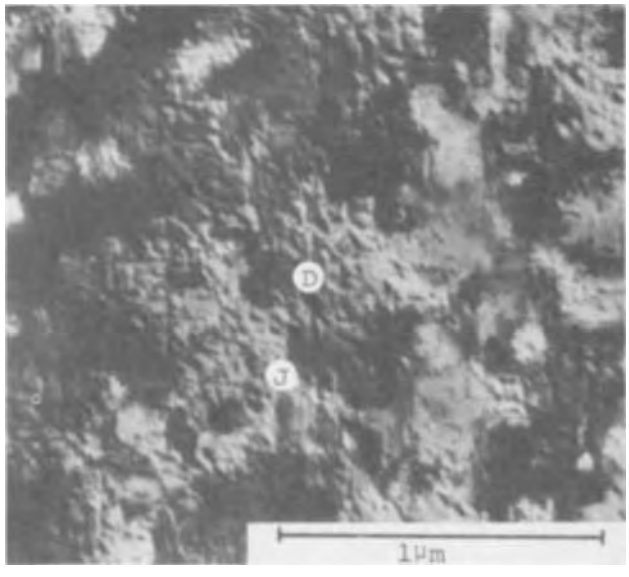

Fig. 9. Straight misfit dislocation at D and structure from continuous-deposit stage at J. At earlier stage, TEC were straight sided.

shows straight misfit dislocations, the orthogonal network of lines, one of which passes under "D." The structure which developed prior to the misfit-dislocation formation, which was shown in Fig. 6, is also still visible in Fig. 9 in regions such as the one marked "J." Samples plated under conditions which resulted in very small TEC or irregularly shaped, large ones exhibited dislocations which were not straight as shown in Fig. 10. After the copper substrates had been dissolved, the nickel deposits still contained a high dislocation density. These dislocations did not lie in the nickel-copper interface and were therefore not of the misfit variety, *i.e.*, caused by the difference in lattice dimensions between deposit and substrate. The electron diffraction patterns of samples which did not exhibit straight dislocations, consisted of rings or arcs which are indicative of some degree of polycrystallinity.

The average spacings of the misfit dislocations are listed in Table II. At *p*H 1.5, coumarin resulted in a wide spacing. Saccharin caused a smaller increase, while phenosafranine reduced the spacing. At *p*H 3, the stronger buffer, nickel acetate resulted in a large average distance between misfit dislocations. The greatest spacing occurred in samples plated at *p*H 6. In some samples, especially those with irregular, rather than straight misfit dislocations, it was difficult to determine the spacing accurately. This difficulty arose because the misfit dislocation could not be readily distinguished from those which resulted from other causes.

One sample which was plated in the bath containing phenosafranine at *p*H 3 to a thickness of approximately 500 nm on examination in a high-voltage (800 kV) electron microscope while still attached to the copper substrate exhibited essentially the same dislocation structure as one only 100 nm thick. The fact that the dislocation contrast did not change with a five-fold thickness increase suggests that the elastic relaxation due to their formation is limited to the immediate neighborhood of the interface. This short range of the misfit strains was further confirmed when the substrate was thinned by partial dissolution and the misfit dislocations remained. The samples plated in the bath with phenosafranine had a much higher twin density than the copper substrates.

The fine dislocation structure in a sample plated in the bath containing phenosafranine at *p*H 1.5 did not change upon annealing for 20 min at 300°C in vacuum. However, the number of twins decreased. The electron diffraction pattern confirmed the decrease in the twin density. Spots or arcs due to oxide which were present in the diffraction pattern before annealing, also disappeared. Annealing at 400°C for 20 min resulted in alloying between the deposit and substrate and the disappearance of misfit dislocations.

Discussion

The TEC stage of electromonocrystallization has been previously reported in deposits of platinum on gold (16), gold on silver (17) and on iron (18), and copper on nickel (10) and on copper (19). The development of TEC in evaporated films has been frequently observed (9). It had not been seen in nickel electrodeposits. In two studies nickel was plated on a thin copper substrate at *p*H 4 (10) and at *p*H 2.6 (20) in a Watts bath and the bicrystals examined by transmission electron microscopy; no TEC were observed. In this study, no TEC were seen either in the additive-free bath with boric acid (bath B) at *p*H 3. Evidently, whether TEC are formed depends not only on the type of metal plated and the substrate but also on the plat-

ing conditions and whether there are foreign substances present in the bath.

In order to explain the effects of addition agents, the pH and buffering of the bath, and the metal-ion concentrations, which were the variables of this study, it is necessary to consider how and why TEC form. Gradmann (21) postulated that a deposit should grow as monolayers if its surface energy is lower than that of the substrate. Actually, the surface energy of nickel is greater than that of copper (22). Therefore, it would be expected that the deposition of nickel on copper should occur by TEC formation. Of course, the relative values of the surface energies can be altered by absorbed foreign substances, other plating variables, and the crystallographic orientation.

It has been generally postulated that electromonocrystallization occurs by the first arriving atom of the deposit attaching itself to a kink site in the substrate. Subsequent atoms would join to fill the row. The mechanism of spiral growth from emerging screw dislocations has been invoked so that there would be no need for the nucleation of new rows or layers. However, under nonideal conditions, the dislocations in the substrate have not been observed to affect the structure of the deposits unless there were foreign substances associated with them (1, 2, 7, 8). The motion of layers in copper deposits from a perchlorate bath on {100} planes of the same metals was also interpreted (2) on the basis of the potential data as indicating that the atoms did not go to kink sites. It thus appears probable that there is two-dimensional nucleation (23) associated with foreign substances. In many instances it is likely that defects in the substrate also play a role in the nucleation. Sard and Weil (19) observed twins under most of the visible TEC in copper plated in acid-sulfate baths. However, in some samples of the present study, nucleation could not have occurred on defects in the substrate. For example, in Fig. 4, there are 10^{11} TEC per square centimeter, whereas the number of defects in the substrate was of the order of 10^8 cm^2. In the sample shown in Fig. 4, the phenosafranine molecules, the sites of which were found to occur within TEC, could have nucleated the growth. The nucleation by foreign substances has been postulated by Eichhorn, Schlitter, and Fischer (24), and it seems reasonable that it could occur if the molecule had the right shape and orientation with respect to the underlying crystal lattice. The three-dimensional epitaxial growth could occur by bunching (1). Here foreign substances would impede the spreading of layers. The observed sites of phenosafranine at the edges of TEC are suggested to be those of molecules which resulted in bunching.

On the basis of the growth mechanisms suggested above, it would appear that there was very little or no impediment to lateral layer spreading when no TEC were observed. When there were only a few large TEC, which had a small height-to-width ratio (*i.e.*, the dimension perpendicular and parallel to the substrate, respectively), the impediment to lateral growth was also small. Possibly, these TEC were nucleated at defects in the substrate. As expected, impediment to lateral growth was lowest in the additive-free baths as in deposits produced therein, either no TEC or the larger, but flatter ones were observed.

The effect of boric acid at pH 1.5 on the initial electrocrystallization phenomena appears to have been the prevention of the formation of the triangular, nickel-hydroxide crystallites. These hydroxide crystals were also observed in thin nickel deposits on copper by Ives, Edington, and Rothwell (20) and were said to require a high pH in the cathode films. The data of Knödler and Neugeboren (25) however indicate that at pH 1.5, the value used in this study, and 5 mA/cm^2, the acidity of the solution adjacent to the cathode should be the same as that in the bulk. At higher current densities, there is an increase in the pH of the cathode film over that of the bulk; the increase being much greater if boric acid is absent. However, the solutions studied by Knödler and Neugeboren (25) contained 1 mol/liter nickel ions, while the hydroxide crystallites developed in the 0.43 molar solutions (bath A). Equivalent hydrogen evolutions would be expected in a low nickel-ion-concentration solution at a low current density and in a more concentrated electrolyte at a high plating rate. Thus the conditions of this study would be equivalent to those under which Knödler and Neugeboren found the larger increase in pH in the absence of boric acid. Thus, it is possible to explain why the absence of boric acid caused the formation of the hydroxide crystallites even at relatively low current densities. The reason why no TEC or hydroxide crystallites were observed in deposits plated at the high pH may be that the type of hydroxide, which forms, depends on pH (20). Apparently the type which forms at pH 6 did not impede lateral growth so as to cause TEC to develop. The effect of the pH, the presence or absence of boric acid, and the nickel-ion concentrations on the formation of TEC and their sizes would be expected to depend on the hydroxide species which form, how they are adsorbed, and the amount which is present as crystallites.

The effect of coumarin on the development of TEC also can be explained on the basis of lateral-growth impediment. Rogers and Taylor (26) reported that several reaction products are present in nickel-plating baths containing coumarin. The amount of each product depends, among other factors, strongly on pH. At pH 4 (26, 27), melilotic acid was said to be the principal reaction product for coumarin concentrations in the order of 10^{-3} molar, *i.e.*, the amount used in baths E and F. At pH 1.5, o-hydroxyphenylpropanol and o-propyl phenol (28) are the principal products. These compounds are not as strongly adsorbed as melilotic acid. Thus at the pH 3 of this study, the formation of TEC was probably due to melilotic acid. At pH 1.5, with less adsorption of foreign material, lateral growth would not be impeded and no TEC would form.

The irregular shape of the TEC, which formed in the baths containing saccharin, at pH 3 in the presence of coumarin and at pH 3 in the additive-free without boric acid, was probably caused by the size and mode of adsorption and incorporation of foreign substances either from the bath additives or hydroxides. At this point, it is only possible to postulate a mechanism. The fact that the sites of codeposited products from coumarin were not observed by phase-contrast microscopy suggests that the small dimension of the molecules was essentially perpendicular to the electron beam, which, in turn, was perpendicular to the substrate surface. As the phenosafranine-molecule sites were visible by phase-contrast microscopy, it is suggested that this additive was adsorbed with the large dimensions perpendicular to the beam. The sketches of the coumarin and phenosafranine molecules in Fig. 1 are drawn approximately to scale. It has been found (28) that only sulfide ions from saccharin molecules are codeposited. Therefore the structure of saccharin is not shown in Fig. 1. The basic substances which resulted in the TEC formation in bath A at pH 3 could also have been small in size. Thus it may be postulated that if the size and orientation of the codeposited molecules are such that they could have stopped a whole row of atoms from growing parallel to the substrate surface as apparently in the case of phenosafranine, straight-edged TEC would develop. On the other hand, if the impediment is such that part of a row was stopped from growing and the rest could continue, irregularly shaped TEC would result. This type of growth impediment would be expected from small molecules or large ones which are oriented with their small dimensions facing the advancing row. Further studies of the way that molecules are adsorbed and interefere with growth are needed before the reasons for the shapes of the TEC can be confirmed.

The effect of the substrate on the development of TEC was not a variable in this study. It is known (16) that the shape of TEC changes with orientation of the substrate. Even slight deviations from the {100} orientation appear to have affected TEC formation. In another study (29) deposition of nickel from bath B at pH 3 resulted in visible TEC when cube-textured copper was the substrate, whereas on the more closely [100]-oriented vapor-deposited copper films grown on KCl, there were none. It is also possible that the difference in the defect densities and surface morphologies of the two types of copper substrates affected the development of TEC.

The strain contrast in Fig. 6 which was generally observed after a complete layer of the deposit had been laid down was undoubtedly due primarily to the difference in the lattice parameters of copper and nickel. Strains must have been present already in the TEC stage, but other contrast effects probably masked them. The fact that the separation of the diffraction spots was not the equilibrium distance was evidence of strain. As the thicknesses of the deposit and substrate was comparable, it is likely that both were in a state of stress of opposite signs.

The coalescence of TEC and even the meeting of layers too thin to be visible because of lack of thickness contrast was another probable source of strain. It is very likely that there were misorientations between the joining TEC and even the layers too thin tc be seen. The misorientations probably lead to strains as well as the introduction of defects which are discussed below. The requirement to minimize the surface energy would probably lead to coalescence before the regions between the structural components have been completely filled in and thus increase the strains. The coalescence of irregularly shaped TEC also must have resulted in their rotation, again probably because of surface-energy requirements or to lower the strains. The arcs of circles in the electron diffraction patterns of the samples which exhibited irregularly shaped TEC in the earlier stage of growth are indicative of rotation of the crystallites on joining. Rotation of TEC has been observed (9) during vapor-deposition experiments carried out in an electron microscope. The lines visible in Fig. 6 and 7 are probably Moiré patterns and partially due to strain contrast; the strain resulting from the coalescence of the structural components, *i.e.*, TEC and atom layers too thin to be seen by electron microscopy. The structure shown in Fig. 6 bears a strong resemblance to that observed by Matthews and Crawford (30) in vapor-deposited nickel-copper bicrystals and said to be a Moiré pattern. The thickness variations which also contributed to the contrast particularly if the TEC stage preceded the formation of a complete deposit layer, were also very likely due to coalescence. The fact that the lines in Fig. 6 and 7 were more pronounced when there was a TEC stage and the evidence from the replicas and shadowed bicrystals supports this conclusion. It can be readily seen why the region of coalescence of TEC would be thinner. Tanabe and Kowasaki (18) found it to be so also.

The coalescence of TEC as well as the meeting of layers one or more atoms high and slightly misoriented with respect to one another can lead to the formation of dislocations. If there are misorientations in the plane parallel as well as in that perpendicular to the substrate, the dislocations would have mixed Burgers vectors. The formation of dislocations due to the joining of slightly misoriented structural components is a well-known phenomenon. The formation of dislocations due to coalescence of TEC in vapor deposits has been seen (9). The joining of layers to form dislocations has also been observed in copper deposits (7). The dislocations which did not disappear when the substrate was dissolved probably formed from the joining of structural components. These dislocations had mixed Burgers vectors, in general. In addition to dislocations, the coalescence of TEC can also lead to twin formation. Matthews and Allison (31) have described a mechanism by which the smaller TEC rotates into a twin orientation if it is easier than attaining parallel alignment. The very large number of twins observed in deposits plated in the baths for which phenosafranine was the additive may have been due to the small size of the TEC which allowed them to rotate into a twin orientation. In order to form a twinning plane, it is obviously necessary that the TEC have straight sides bounded by {111} planes. The TEC produced in the phenosafranine bath probably conformed to this requirement. The necessity to align in a twin orientation rather than parallel may have been due to the large phenosafranine molecules at the edges of the TEC in the way suggested by Hinton, Schwartz, and Cohen (32). The possibility that mechanical twins are formed to relax high stresses should also not be discounted.

The development of dislocations to relieve the misfit strains between the crystal lattices of the deposit and substrate has been widely observed in vapor deposits. Misfit dislocations have also been previously observed in electrodeposited bicrystals (11, 33).

The deposit thicknesses at which misfit dislocations developed appear to have varied considerably with the plating conditions and bath compositions. This variation is probably real in spite of the inherent uncertainties involved in determining the values. The uncertainties arose because the experiments were not specifically designed to determine the critical deposit thicknesses. In general, the plating times were varied in a geometric progression. Thus, the deposit in which the misfit dislocations were observed was twice as thick as the one in which these defects were not present. Also the values listed in Table II were calculated from the plating times which at best yield an average thickness. The local thickness variations have already been discussed. The plating efficiency also was not known accurately. However, it appears that the thickness values in Table II are larger than the value of 1.46 nm which Matthews and Crawford (30) determined by a more accurate method in nickel vapor deposits on copper. The value, which Matthews and Crawford (30) found, is also close to the theoretical thickness which they calculated for the nickel-copper system. The reason for the greater critical thickness in Table II may be that codeposited foreign substances such as additive molecules or hydroxides interfered with the glide, which Matthews and Allison (31) said was necessary for misfit-dislocation formation.

The interference of codeposited foreign substances on dislocation glide may also have been responsible for the variation in the spacings listed in Table II. The misfit-dislocation spacing for nickel deposits on copper was calculated by Matthews and Crawford (30) to be about 8 nm. All values in Table II exceed this theoretical spacing. When the spacings of the misfit dislocations are greater than the theoretical value, the strains have obviously not been completely relieved. The misfit dislocations which were not straight probably experienced local pinning by codeposited, foreign substances.

The results of the annealing experiments are included for information only. There are not enough data to draw any significant conclusions.

Conclusions

1. The influence of addition agents, the pH, and buffering of the bath and the nickel-ion concentration on the formation and shape of TEC can be explained by the interference of codeposited, foreign substances on the lateral spreading of the deposit.

2. When a complete deposit layer has been formed, strains and surface undulations develop, which can be related to the presence and shape of TEC in the earlier growth stage.

3. The coalescence of TEC results in the formation of dislocations and probably in some instances, twins.

4. Misfit dislocations form in the deposit-substrate interface. Their spacing, configuration, and the deposit thickness at which they are first observed apparently depend on the presence of codeposited foreign substances.

Acknowledgments

The permission to publish this paper and the support of the American Electroplaters' Society, Inc. are gratefully acknowledged. The members of the Project Committee, Messrs. U. Bertocci, H. Brown, C. Cupp, D. Hardesty, R. Sard, and K. Willson provided many useful suggestions and discussion while the work upon which this paper is based, was in progress and reviewed this manuscript. The U. S. Steel Corporation Research Laboratories permitted us to examine several samples in the high-voltage electron microscope. The electron microscope used to examine most of the samples was obtained partially through a grant of the National Science Foundation.

Manuscript received April 11, 1973. This was Paper 132 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1974 JOURNAL.

Sensitizer Aging Effects on Metalization and Imaging in the Photoselective Metal Deposition (PSMD) Process

J. F. D'Amico* and M. A. DeAngelo

Western Electric Company, Engineering Research Center, Princeton, New Jersey 08540

ABSTRACT

The PSMD imaging system employs aqueous $SnCl_2$ sensitizer solutions to generate electroless metal photopatterns on dielectric substrates. We have measured how aging in several typical sensitizer solutions affects their ability to generate electroless copper photopatterns on polyimide H film (DuPont Kapton®). Specimens, consecutively sensitized as the solution aged, have been characterized with respect to (*i*) tin deposition (by x-ray fluorescence), (*ii*) catalytic activity for metalization (by optical density determination of the deposited electroless copper), and (*iii*) imageability (by image contrast measurements of the developed copper patterns). The system imageability is found highly dependent on the sensitizer solution age, while the capability for blanket metalization was relatively unaffected.

Photoselective metal deposition (PSMD), a process for metal patterning dielectric substrates by uv light exposure and electroless (chemical) plating, has been the subject of several recent papers (1-4). These have reported a general outline of this system and its applications (1, 2), an analysis of the sensitization mechanism by Mössbauer spectroscopy (3), and a description of the optical response in a typical imaging system (4). In this paper, we shall elaborate on still another aspect, that of sensitizer aging in normal room am-

* Electrochemical Society Active Member.

Key words: sensitizer, sensitizer aging, electroless plating, electroless patterning, photoimaging.

bient, and shall describe how this phenomenon affects both metalization and imaging in a typical PSMD system.

The process of electroless metalization is, of course, a subject of broader technological interest than that of electroless metal imaging, and as such has been studied extensively for many years (5). Among very recent papers on this topic, those by Cohen and West (6), Feldstein and Weiner (7, 8), and Feldstein, Weiner, and Schnable (9) are of particular relevance to the subject covered in this paper.

Photoselective metal deposition combines electroless plating with a step involving uv light exposure through a mask to develop an image. The electroless metalization process requires that surfaces to be covered be made "catalytic," so that the plating reaction may be initiated. The most common catalyst is palladium, which can be conveniently microdeposited by the sequence:[1] (*i*) sensitization [immersion in $SnCl_2$; deposits Sn(II) species] and (*ii*) activation (immersion in $PdCl_2$; deposits Pd).[2] For imaging, a uv light exposure after step (*i*) eliminates Sn(II) by photooxidation, thus pre-empting Pd deposition and thereby making the exposed regions "noncatalytic." Thus PSMD imaging is positive working, since it generates a replica of the photomask.

Photoreactive deposits in the PSMD process are formed on substrates which are briefly immersed in an aqueous sensitized solution containing a Sn(II) salt. The work reported here deals exclusively with sensitizers of a specific chemical composition, namely, dilute stannous chloride dihydrate ($SnCl_2 \cdot 2H_2O$) acidified with HCl. In terms of chemical ingredients, this is our least complex solution and accordingly is a good starting point for sensitizer research.

In aqueous $SnCl_2$-HCl solutions, the Sn(II) is present in a variety of forms (10-12), *i.e.*, a soluble aquo complex as well as soluble complexes of chlorides, oxychlorides, hydroxides, and hydroxy-chlorides. In addition, insoluble oxides (these may or may not be readily visible) are also present. On standing in the laboratory, the soluble species undergo a continuous hydrolysis and polymerization to become irreversibly converted into the insoluble oxides. The insoluble oxides combine to form a colloid or sol which has been observed to play an important role in the sensitization process (1-4, 6, 7). In this paper we give a general description of colloid formation in typical sensitizer solutions. We also relate the observed solution and colloid properties to their effects on the sensitization and metalization of the substrate.

An important factor affecting sensitization is the extent of "wetting" of the substrate by the solution (7, 9, 13). In "wetting," the liquid containing soluble tin complexes forms a film on the substrate. During the subsequent water rinse, the *p*H in this film is rapidly raised to the point where the soluble complexes are hydrolyzed to the insoluble oxide which then deposits on the substrate and contributes to the sensitization.

In attempting to understand sensitizer film formation, it is clear that we must look not only at the deposit on the substrate but also at the condition of the solution at the time of sensitization. The ultimate objective of a detailed study of the mechanism and kinetics of sensitization is to provide a basis for tailoring formulations and process procedures to optimize the imaging characteristics on a wide variety of useful substrates.

[1] A one-step tin-palladium solution is also widely used to generate electroless deposits. This sensitizator/activator, however, cannot be used for PSMD image generation.

[2] There is some disagreement in the literature as to the state of the deposited Pd. In ref. (3), the results of Mössbauer analysis for $SnCl_2$/HCl sensitized Kapton are interpreted in terms of a Sn(II)-Pd(II) redox. In ref. (8), radio tracer results for $SnCl_2$/HCl sensitization of Teflon are explained in terms of a substrate-adsorbed ionic Pd complex.

Experimental

Solutions of varying initial tin concentrations were prepared and allowed to stand in the laboratory ambient. At selected times, coupons of polyimide film were sensitized in these solutions. The coupons were then divided into three parts, each measured as follows:

Part I: X-ray fluorescence analysis to determine the total weight of tin deposited.

Part II: Metalization of the specimen with electroless copper to correlate the extent of metalization with the tin deposited on the substrate. The extent of metalization was determined by measuring the optical density of the copper layer deposited after a fixed time in the electroless bath. A greater value of optical density indicates a substrate more highly catalytic to the metalization. This technique is detailed in ref. (4).

Part III: Exposure to ultraviolet radiation, then repeat the metalization as in Part II. This step evaluates the imaging sensitivity of the specimen.

Preparation of solutions.—The sensitizer solutions were prepared by dissolving[3] 0.15, 0.30, and 3.0g of $SnCl_2 \cdot 2H_2O$ in 300 ml of deionized water, then immediately adding 3 ml conc HCl to all solutions. The order of addition of ingredients and the time before acidification of the solution affects the rate of colloid formation and must be standardized if reproducible results are to be obtained.[4] The solutions described have nominal initial tin concentrations[5] of 0.0022, 0.0044, and 0.044M and are designated as solutions C, B, and A, respectively. Nominal *p*H value in these solutions was 1.0. (The measured *p*H's varied from 0.95 to 1.05 due to stannous chloride hydrolysis, the more concentrated solutions becoming the slightly more acidic.) Also prepared was a solution containing 4.7g of $SnCl_4 \cdot 5H_2O$ and 3 ml conc HCl in 300 ml of deionized water. This solution, 0.0044M in Sn(IV), is the stannic counterpart of solution B.

Ambient conditions for solution aging.—Standard ambient.—Solution aging was carried out in the laboratory ambient under normal fluorescent lighting. Sensitizer solution volumes of 300 ml were placed in 500 ml polypropylene beakers and left undisturbed on the laboratory bench. When not in use, the beakers were covered (but not sealed tightly) with waxed cardboard tops to prevent particulate contamination.

Aging in bubbled nitrogen or air.—Exceptions to the above procedures were made in order to discover how solution aging was affected by the elimination or the enhancement of oxygen in the solutions. A 200 ml volume of solution A was placed in a stoppered 500 ml Erlenmeyer flask through which N_2 was gently bubbled. Nitrogen escape was through a side arm plugged to a very small opening to prevent back diffusion of air. A duplicate setup bubbling air at the same rate was also run along with a control solution (unstirred A in beaker). Observations to detect colloid formation and the presence of Sn(II) (by indicator paper) were made at selected times in the aging cycle.

Preparation and metalization of substrates.—Standard process.—Test specimens were 3 × 2½-in. coupons of 2 mil polyimide H-film (DuPont Kapton®) which were prepared by the following process:

a. Etch 5 min in room temperature 10*N* NaOH, then rinse 5 min in a gently flowing cascade washer with 22°-24°C deionized water. (Water resistivity exceeded 2 megohm-cm).

b. Sensitize by a 3-min immersion in the unstirred sensitizer solution, 300 ml in a 500 ml polypropylene beaker. Rinse for 1 min as in *a.*

[3] The initial solids readily dissolve but the solutions formed contain a cloudy white suspension which clears on addition of the acid.

[4] Addition of the $SnCl_2 \cdot 2H_2O$ to the acid followed by water dilution slightly inhibits the colloid formation while a delay of 15 min in acidification of the solution slightly enhances the colloid formation. These conclusions are based on visual observations of the rate of haze formation of the solutions on standing.

[5] Some of the initial salt may be in the stannic state due to air oxidation of the reagent. The reagent is also hygroscopic.

c. Dry in N_2 jet and remove a ¾ × 2½-in. section for tin analysis.

d. Immerse remaining section for 30 sec in activator solution, 0.5g reagent $PdCl_2$ and 5 ml conc HCl diluted to one liter. Then rinse for 2 min as in *a*.

e. Dry in N_2 jet, then divide specimen. Expose one part to uv radiation, the other remaining unexposed.

f. Metalize both parts by a 1.5-min immersion in a 300-ml bath of Enthone 400 electroless copper at room ambient temperature (23° ± 1°C). The Enthone bath was prepared fresh each day with dilution as recommended by the supplier.

Alternative process using an acid tin rinse.—For several specimens, a modified procedure employing an acid tin rinse in place of the water rinse, step b above, was used. Specimens were immersed for 30 sec into a beaker containing 300 ml of 0.1M HCl, then given a 30-sec rinse in the cascade washer. The normal process sequence was then continued at step c.

Detection of stannous species in solution.—Detection of stannous in the sensitizer solutions was made using an indicator paper prepared by depositing ammonium phosphomolybdate on filter paper (14). The prepared paper has a bright yellow color which is reduced by stannous to a deep "molybdenum" blue. The intensity of the blue color gives a semiquantitative indication of the concentration of stannous tin present in the solution.

Stannous detection was made at specified times, a few drops of solution being withdrawn and deposited onto the filter paper. The stated limits of detection for this test are 1.5 mg/liter, which corresponds to a stannous concentration about 0.3% of the initial value in our most dilute solution. Experimentally, we were able to verify detection down to 10 mg/liter of Sn(II). We assume this higher value is due to the presence of dissolved oxygen in our initial solutions, since no attempt was made to purge this species. [The equilibrium solubility (15) of oxygen in 0.1M HCl at 25°C, 1 atm is about 0.00025M. This quantity of oxygen should react 28 mg/liter of stannous species.]

Determination of total tin deposit.—Tin deposits on the substrates were determined by x-ray fluorescence using a General Electric XRD-6VS vacuum spectrometer. Calibration was made using tin oxide/polyimide standards determined by atomic absorption analysis of tin after removal from the substrates. The precision of this method for total tin analysis is estimated to be about 5%, the absolute accuracy of the calibration 25%.

Specimen preparation for x-ray fluorescence measurements of the tin deposit required removing the sensitizer deposit from the "back" side of the specimen. This was accomplished by a local etch with 10*N* NaOH.

Exposure of sensitized specimens.—The polyimide specimens were sensitized in solution A (10 g/liter initial $SnCl_2 \cdot 2H_2O$) at various times during the solution aging, then exposed to 250 nm radiation. Exposure was made by passing the output from a 900W high-pressure xenon arc through a Bausch & Lomb high intensity monochromator, the specimen being placed at the monochromator exit slit. The monochromator grating dispersion was 3.2 nm/mm, and thus the wavelength spread in the 1.5 mm slit image was 4.8 nm. The light intensity incident on the sensitizer was 0.77 ± 0.02 mW/cm², as determined by an Eppley thermopile placed at the same position as the exposed specimen.

After exposure, specimens were metalized with copper to develop a positive slit image, *i.e.*, the slit outline was non- or partially metalized, while elsewhere blanket metalization occurred. The procedure for the metalization was as described in the section on Preparation and metalization of substrates. The exposure technique and related apparatus were discussed in an earlier paper (4).

Following metalization, optical densities, *D*, of the copper deposits in both exposed and unexposed regions were measured at 670 nm using a Cary 14 spectrophotometer. This instrument was used in the double beam mode with a blank polyimide substrate in the reference beam. The results for *D* thus refer only to the copper deposit.

Results

Tin deposit vs. solution age.—In Fig. 1, tin deposits produced by solutions A-C in the standard ambient are plotted as a function of solution age at the time of the sensitization.

Repeat measurements on adjacent portions of the same specimen showed a reproducibility of 0.04 μg/cm², average deviation. The observed scatter is due to processing variations from specimen-to-specimen.

The curves in Fig. 1 are indexed to correlate the deposition with visual observations of the solutions. The index key and observations are presented in Table I.

Tin deposition from stannic solution.—In Fig. 2 we have plotted tin deposition results in the standard ambient for the 0.0044M Sn(IV) solution. The deposition curve for solution B, replotted from Fig. 1, is also shown for comparison. At the earliest times, deposits from the stannic solution are comparable to those obtained only after the stannous solution is well aged. Precipitation and settling are seen to occur at earlier times in the stannic solution. The results in Fig. 2 are consistent with a sensitization model in which the rate of colloid formation (and the subsequent tin deposition) are controlled by the Sn(II) oxidation to Sn(IV), as was suggested earlier by Cohen, D'Amico, and West (3). This limitation is not present in the stannic solution and thus the tin deposition rate, rather than build slowly, begins at its highest value.

Detection of stannous in solution: mean solution activity.—The observed times when negative tests for stannous first occurred are indicated in Fig. 1 by the stars. At the times indicated, the solutions are estimated to contain less than 1.5 mg/liter (or 6.6 μM) of Sn(II), a value based on the detection limit stated in ref. (14).

The approximate lifetimes of the solutions are given in Table II. The mean rate of conversion of the initial stannous into the stannic form is also given in this table.

In addition to testing the solutions for the presence of stannous, substrates were also continuously sensitized in the solutions to observe whether or not they continued to catalyze metalization. When stannous detection was positive, uniform metalization also occurred. When the stannous test became negative, metalization became marginal (*i.e.*, spotty) or nonexistent.

Solution aging in bubbled nitrogen and air.—Solution A, aged in bubbled N_2 for up to 600 hr, showed no signs

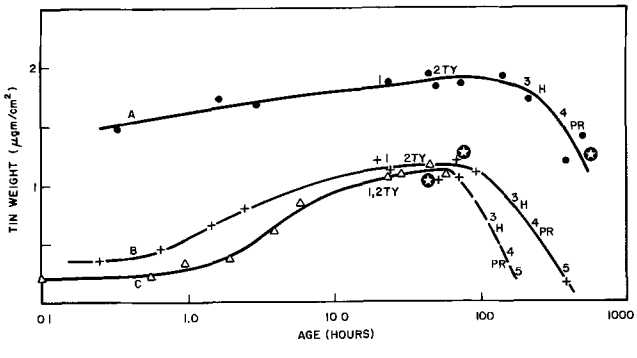

Fig. 1. Tin deposition vs. sensitizer solution age. ● Solution A, + solution B, and △ solution C containing initial $SnCl_2 \cdot 2H_2O$ weights of 10, 1, and 0.5 g/liter, respectively. Visual observations made during aging are also indicated. (Key, see Table I.)

(3) H Solution haze prominent.
(4) PR Onset of colloid precipitation.
(5) Precipitation completed; solution clear and colorless.
✪ First negative test for Sn(II) by indicator paper.

of colloid formation, *i.e.*, no Tyndall effect, hazing, precipitation or yellowing. Furthermore, phosphymolybdate tests for Sn(II) showed no noticeable depletion of Sn(II), as evidenced by the depth of the blue color on the indicator paper.

The solution aged in bubbled air, on the other hand, showed an enhanced rate of colloid formation and Sn(II) depletion. Solution yellowing and a Tyndall effect were observed within an hour, and the indicator paper test for Sn(II) became negative at 40 hr. For control solution A, this point in the aging cycle was reached at times greater than 533 hr.

Electroless copper deposits vs. solution age.—Results of the 1.5-min metalization are shown in Fig. 3 where we have plotted optical density D of the copper film *vs.* the solution age at the time of sensitization. Maximum error limits based on repeated determinations under "identical" conditions are also shown in the figure. (These values are calculated to be ± 0.03.)

Table II. Duration of Sn(II) detection in the sensitizer solutions

Solution	Initial conc of $SnCl_2 \cdot 2H_2O$ (g/liter)	Range of solution active life* (hr)	Mean rate of $SnCl_2 \cdot 2H_2O$ conversion (g/liter/hr)
A	10	533-700	0.014-0.019

B	0.25	0.32	0.02	—	—
	22	0.98	0.61	—	—

Tin and copper deposition for acid rinsed sensitizer.—Specimens sensitized using the acid tin rinse showed tin and copper depositions as presented in Table III. For fresh solution B, 94% of the normal tin deposit is removed by the acid rinse while in fresh solution A, 75% is removed. As aging occurs, the acid soluble contribution to the sensitization decreases in both solutions.

The copper deposition results for solution A show a decrease in the metalization, indicating a decrease in the surface concentration of palladium, presumably from a decrease in surface concentration of Sn(II) resulting from the acid rinse. This removal is clearly not complete, since the metal deposition has not been reduced to zero.

Imaging sensitivity vs. solution age.—Specimens sensitized in solution A at various ages were exposed to 250 nm radiation then metalized with copper. Measurements of the 670 nm optical density D *vs.* solution age, with exposure time at constant light intensity as a parameter are presented in Fig. 4. Similar measurements for the unexposed regions are also shown in this figure. Increased exposures, we observe, are required to maintain image contrast as the sensitizer solutions age.

Discussion

Tin deposit vs. solution age.—In Fig. 1 we observe that the tin weights increase with solution age but at long times this trend is reversed. If sufficient time is allowed, the tin deposits approach zero. In reviewing Fig. 1 and Table I, we observe that the general increase in deposit weight follows the colloid development in

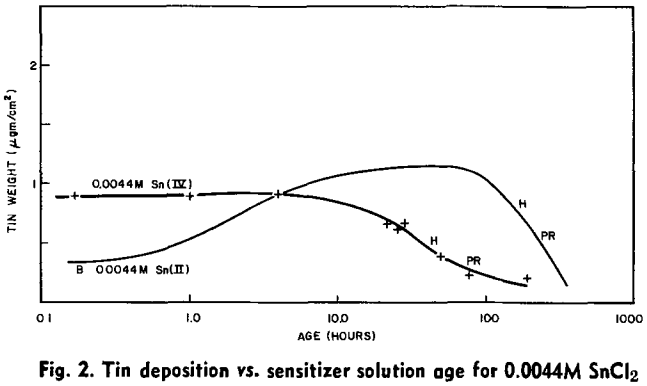

Fig. 2. Tin deposition *vs.* sensitizer solution age for 0.0044M $SnCl_2$ and $SnCl_4$ solutions, both at pH ~1.

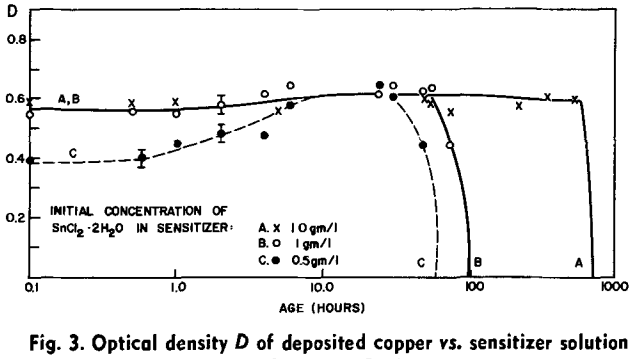

Fig. 3. Optical density D of deposited copper *vs.* sensitizer solution age. Electroless plating time fixed at 1.5 min.

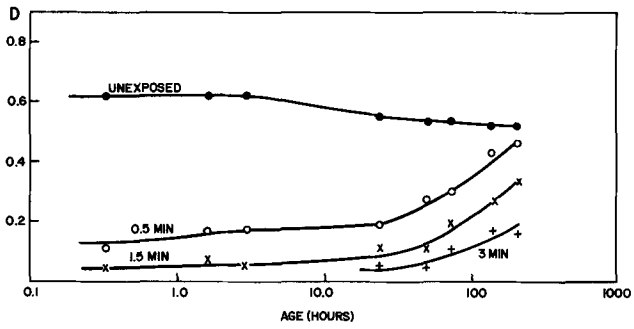

Fig. 4. Obtainable image contrast vs. age of sensitizer solution A. Exposure time to 250 nm radiation as a parameter. Light intensity constant at 0.77 mW/cm².

solution. However, when the colloid particles become quite large, as evidenced by the presence of a strong haze and then a settling precipitate, the amount of deposit begins to fall and the solution clears. The clear solution no longer sensitizes the substrate, although it can still produce a non-negligible deposit. This deposit is presumed to contain only Sn(IV) species, a conclusion supported by the Mössbauer results in ref. (3).

We envision the sensitization to occur by a combination of two processes: (*i*) formation on the substrate of an adsorbed liquid film containing soluble aquo, chloro, and hydroxy-chloro tin complexes (during subsequent rinsing, these complexes are immediately hydrolyzed to form insoluble oxides and hydroxides, some of which adhere to the substrate) and (*ii*) formation of the colloid in solution, with adsorption of colloid particles onto the substrate during immersion in the solution.

In general, we expect both processes to be operative in the buildup of the sensitizer layer although the relative contribution of each may not be readily identifiable. We could reason, however, that (*i*) should be favored when colloid formation is minimal, *e.g.*, very fresh solutions (the colloid needs time to form), or highly acidic solutions (where hydrolysis is suppressed). When extensive colloid formation has occurred, (*ii*) should play an appreciable role.

Our division of sensitization into two processes was made to identify the participating mechanisms and is not meant to imply that (*i*) and (*ii*) are necessarily independent of each other. In fact, it is likely that the deposit via (*ii*) has a strong influence on the solution wetting of the substrate and thus affects the amount of adsorbed liquid which participates in process (*i*). This interaction makes it difficult, with our present knowledge, to give a clear-cut interpretation of experimental results.

At this point one might legitimately question whether process (*ii*) does, in fact, contribute an appreciable tin deposit to the sensitizer layer formation under any circumstances. One could, as an alternative, view process (*ii*) not as a layer building step, but as one which regulates the liquid layer thickness by control of the wetting. This regulation could presumably be accomplished by a deposit insignificant compared to that made later when the liquid layer undergoes hydrolysis. The validity of this view is tested in the acid rinse experiments described above. In Table III we observe an appreciable tin fraction deposited after acid rinse (except for fresh B solution). Thus we have demonstrated that the colloid process (*ii*) does in fact contribute appreciably to the sensitizer layer formation.

At very long times the colloid formation culminates in the precipitation and settling of the insoluble oxide. In solutions B and C this precipitate is apparently all stannic since no stannous species was detectable at the time of precipitation. In solution A, precipitation occurs prior to the complete depletion of the stannous species, so that from this data alone it is not evident what the chemical state of the precipitate may be. Precipitates from A, in fact, are pale yellow, while those from B and C are white. This implies the presence of stannous in the A precipitate.

Relation between the tin oxidation and the colloid formation.—It is clear from the results presented that the tin oxidation in solution plays a dominant role in the colloid formation. The slowly increasing tin depositions with solution age can be explained as due to the gradual buildup of colloid (presumably a form of SnO_2) as the oxidation process proceeds. This buildup and the other signs of aging, solution yellowing and the depletion of Sn(II), stopped completely when oxygen was removed from the system by N_2 bubbling. The aging process, on the other hand, was markedly accelerated when air bubbling was used.

As suggested earlier (3), the colloid may be principally a stannic oxide or hydroxide form, produced by generation of stannic species in excess of their equilibrium concentration by the air oxidation. The solubility products for tin oxides, reported as $Sn(OH)_2$ and $Sn(OH)_4$ by Latimer and Hildebrand (16), are 5×10^{-26} and 1×10^{-56} M/liter, respectively. For solutions of $pH = 1$, the equilibrium concentrations of uncomplexed stannous and stannic species are calculated to be 5M and 10^{-4}M, respectively. Thus the solubility of stannous oxide in our solutions is appreciable while that of the stannic oxide would be quite small, its exact value depending on the equilibrium concentrations of the complexes, mostly chlorides, which are formed.

If the colloid is entirely stannic, then sensitizer deposits due only to process (*ii*) should be incapable of metalizing the substrate[6] and the required stannous species must be provided by process (*i*). This aspect of the model can be tested by comparing the metalization results for the water and acid tin rinses. With the acid rinse, the soluble tin complexes in the liquid film would be washed off the substrate rather than deposited, leaving only the colloid deposit from process (*ii*). In Table III, a 43% reduction in the copper absorbance is noted for the 3-hr acid rinsed specimen, as compared to its water-rinsed counterpart. A 14% reduction is noted for the 100-hr solution.

The metalization differences noted in Table III cannot be immediately translated into a fractional depletion in stannous species on the substrate, since the relation between D and [Sn(II)] is not yet known. However, we feel safe to assume that even when acid rinsed, the colloid deposit still contains a non-negligible component of Sn(II) since it continues to deposit electroless copper. This Sn(II) component is very likely the result of entrainment during the colloid formation, or possibly adsorption at the colloid particle surface. This entrainment/adsorption apparently increases as the colloid system becomes more developed, since the older of the solutions produced lesser changes in D after the acid rinse.

Detection of stannous in solution: lifetime of solution activity.—The ability of the sensitizer to promote metalization was found to coincide with a positive test for stannous in solution; the failure of metalization likewise coincided with a negative test result. These results are consistent with our basic assumption (1-4) that the imaging reaction is, in fact, a Sn(II) to Sn(IV) photo-oxidation.

In Table II we estimated the mean rate of conversion of the initial stannous chloride dihydrate, based on the duration of stannous detection in solution. These values should be considerd as order estimates since the reaction end point was semiquantitative. In Table II we note that the mean $SnCl_2 \cdot 2H_2O$ conversion

[6] The authors have sensitized polyimide substrates using solutions made with $SnCl_4 \cdot 5H_2O$ in place of $SnCl_2 \cdot 2H_2O$. While appreciable tin deposits were found (Fig. 2, this paper) no metalization was produced.

rates are not too different in each of the solutions, but it would not be correct to conclude from this data that the oxidation reaction is necessarily zero order in [Sn(II)], *i.e.*, independent of the concentration of reactant.

The auto-oxidation of stannous tin solutions has received considerable attention in the literature (17-22). The reported results deal mainly with the kinetics of stannous chloride and oxygen in HCl solutions, with vigorous stirring or shaking of the solutions to insure that the measurements were not limited by the diffusion rates in the solution. There is poor agreement in the published work. In ref. (17) and (19), the reaction rate was found first order in stannous chloride concentration for dilute solutions, but independent of the stannous chloride concentration (*i.e.*, zero order) at higher concentrations. In ref. (20) and (22), the reaction was found half order in the analytical concentration of stannous chloride and, in ref (20), first order with respect to the dissolved oxygen. The reaction rate was also found to be strongly dependent on the HCl content of the solutions (17, 18, 22) although again the published results are not in quantitative agreement.

We have already presented results which prove that agitation produces an appreciable acceleration of aging in our solutions. In the published work, Filson and Walton (18) describe experiments which demonstrate that the solution aging can be appreciably altered by the extent of agitation with an air jet in solution.

Thus it is apparent that diffusion effects play an important role in determining the reaction rates, at least in poorly stirred solutions. One might assume that the rate limitation must be due to oxygen diffusion from the ambient into solution. The diffusivity of gases in dilute electrolytes, however, is characteristically quite large (23), which implies the replenishment of the dissolved, reacted oxygen should be rapid enough to maintain the equilibrium solubility of oxygen in the solution. This conclusion was also reached by Filson and Walton (18). The final resolution of this problem awaits an actual measurement of the oxygen and stannous concentration profile in the solutions.

Electroless copper deposits vs. solution age.—In Fig. 3 we observe that solutions A and B produce nearly identical copper films over a wide range of solution ages, although the B solution becomes spent earlier, as we have already discussed. Solution C by contrast produces an initially thinner deposit which becomes comparable to the others after about 5 hr. (The error bars in the figure indicate to what extent we can differentiate the behavior of the various solutions.)

In Fig. 1 a significant difference in the tin deposit from solution A compared to that from B was observed, yet the copper deposits were essentially identical. For solution C, copper deposits in the first several hours were slightly less than the others; the tin deposit from C was simultaneously reduced.

The copper weight deposited should depend on the amount and distribution of the palladium metal, which in turn is presumed to depend on the amount and distribution of stannous in the sensitizer layer. The stannous in the sensitizer has not yet been quantitatively determined. It is present in very minute amounts and in air is spontaneously converted to the stannic state, both factors leading to difficulty in the determination.

In qualitative terms, we expect that the stannous to total tin ratio in solution decreases with age. A similar (but probably not identical) decrease should also occur in the sensitizer layer. In solution the mean colloid particle size appears to increase with age, so the observed increase in tin deposit might well be due to coverage of the substrate by larger particles, with or without a change in the fraction of the surface covered.

In viewing Fig. 1 it seems reasonable to conclude that the sensitizer deposits from solutions A, B, and C must be differently formed, at least for times less than 10 hr. Yet A and B produce nearly identical copper deposits over their entire active lifetimes while C produces an equal deposit after about 6 hr. Thus, the metalization process as carried out here is not highly dependent on the sensitizer structure. These results are consistent with a model for the metalization in which the deposits are initially enhanced by increased sensitizer (and thus palladium) but after some minimum deposit of palladium, no further enhancement of the metalization occurs. Applying this model here, we conclude (Fig. 3) that the Pd deposits generated from solutions A and B exceed this "minimum" from the earliest measured times, but that those from C do not attain the "minimum" until the solution ages for about 6 hr.

Imaging sensitivity vs. solution age.—As indicated in Fig. 4, image contrast is reduced as the A solution ages and thus greater incident light energy is required to produce images. We have already noted that the solutions, up to a point, deposit steadily increasing amounts of tin so that the loss in imaging sensitivity could be the result of having to react a greater amount of sensitizer to produce the nonmetalized portions of the images. This explanation, however, has some serious problems:

1. The continuous oxidation of stannous in solution should produce a decrease in stannous on the sensitizer and thus improve the sensitivity by making it easier to inhibit the metalization. Recall that the unexposed substrate retains its metalizing capability (Fig. 3) for nearly the entire solution active lifetime.

2. We reported earlier (4) that the sensitizer deposits are quite uv transparent ($D \sim 0.05$ at 250 nm) so that only a small per cent of the incident light is absorbed, the major part of the light energy being absorbed or transmitted through the substrate. Thus, any increase in the sensitizer deposit should merely absorb more of the incident light, with the result that the image contrast would remain unaltered. To explain the image contrast reduction we could, as an alternative, assume that the form of the deposit changes with age, producing a film of reduced optical density and/or reduced quantum efficiency for the oxidation reaction. Experimental verification of such an explanation for sensitizers on the polyimide substrate is not possible at present, since this substrate is not uv transparent.

Conclusions

1. Tin sensitization depends on solution variables such as the initial stannous tin concentration, pH, and the solution age. The oxidation of tin in solution generates a colloid system, principally stannic oxide or hydroxide species, whose state and presence play a dominant role in the sensitization process.

2. The substrate metalization was found relatively insensitive to the weight of sensitizer deposit or its stannous content. This, however, was not the case for imaging sensitivity, which was markedly reduced as heavier, more stannic deposits were produced by solution aging. The use of the solutions must evidently be terminated prior to the time when metalization stops, in order to avoid the need for excessive light exposures.

3. Sensitizer solutions stored/used in a nonoxidizing ambient or nitrogen bubbled could be used for much longer periods and should maintain relatively constant imaging characteristics. The usefulness of this approach in terms of cost factors will depend on the specific application.

4. The general hypothesis that stannous-based PSMD imaging is a photoinduced oxidation was further supported by our observations that the metalization capability on the substrate is coincident with the positive detection of stannous species in solution, and the converse.

A Study of Transient Processes Preceding the Electrodeposition of Cr on Pt

J. C. Saiddington and G. R. Hoey*

Corrosion Section, Extractive Metallurgy Division, Mines Branch, Department of Energy, Mines and Resources, Ottawa, Ontario, Canada

ABSTRACT

Galvanostatic polarization data with simultaneous microscopic observations of a Pt cathode surface were obtained in conventional chromium plating baths. The results show that the deposition of chromium on bright activated platinum is preceded by heavy evolution of hydrogen and a prolonged shift of potential during which the formation of a chromic oxide film may be observed at the cathode surface at higher current densities. The final shift of potential just prior to the establishment of metal deposition was found to be associated with a distinct decline of gas evolution regardless of the presence or absence of the chromic oxide film which, when formed, was observed to disintegrate before steady-state conditions of Cr deposition were reached. These observations are compared with those made earlier with Fe electrodes and the results are discussed in the light of possible processes involved in bringing about the shift of the potential to the value of Cr deposition.

An earlier investigation (1) of the deposition of Cr on Fe electrodes has shown that, under reproducible galvanostatic experimental conditions, certain transient phenomena occur at the cathode surface prior to the commencement of the chromium plating processes. These results were discussed in detail in the previous work but are here simplified by dividing the whole transition period into two transient regions, I and II.

Transient region I was found with Fe electrodes to be characterized by heavy gas evolution and by a gradual shift of the potential from the initial hydrogen evolution to a level at which formation of a chromic oxide film could be observed under the microscope. Transient region II coincided with the disintegration of the chromic oxide film with an accelerated shift of potential to the value of chromium deposition, and with a change in the pattern of gas evolution.

Transient region I was attributed to electrode reactions that can proceed without bringing about the deposition of chromium. Transient region II, on the other hand, was attributed to processes that are associated with the establishment of the reduction of hexavalent chromium to metal. These processes, it was concluded on the basis of microscopic observations, involve changes in the consistency of the liquid layer adjoining the cathode surface resulting in the formation of a transparent viscous film.

The term "viscous film" was chosen arbitrarily to differentiate between the solid chromic oxide film that forms during potential region I and the liquid film that comes into existence during potential region II.

Vagramyan and Solov'eva (2) call the liquid film a "phase film," a term perhaps more appropriate since the viscous conditions in the liquid layer have never been determined. However, this term is also not completely satisfactory even though it is meant to indicate phase transformations in the $Cr(OH)_3$-CrO_3 system as a possible cause of the film formation. The processes involved are apparently more complex since they are potential dependent, they do not occur in the absence

* Electrochemical Society Active Member.

Key words: hydrogen evolution, microscopic observations, cathodic films.

of $SO_4^=$, and, as is shown in the present paper, they affect the evolution of gaseous hydrogen.

Solov'eva, Petrova, Klimasenko, and Vagramyan (3) investigated the composition of the liquid film present at the cathode surface during chromium plating. They found that the concentration of Cr^{3+} and of $SO_4^=$ ions in the film is higher than in the bulk of the electrolyte, while that of Cr^{6+} is lower.

Weiner and Schiele (4) have shown that the chromic oxide film that forms in potential region I contains only Cr_2O_3 with some traces of the cathode metal.

Okada and Yamamoto (5) assumed that the increase in thickness of the chromic oxide film is the cause of the increase of hydrogen overpotential on Pt in region II. Their explanation was at variance with our inferences made on the basis of the investigation with Fe electrodes (1). Since the above authors did not observe potential region I during polarization of steel and we did not study the formation of chromic oxide on Pt, some corroborating work with Pt cathodes was in order.

The experimental results of the present investigation show that the whole transition period with Pt electrodes can also be divided, as in the case of Fe, into two distinctly different regions of polarization. The first region, corresponding to region I on Fe electrodes, is characterized by a continuous heavy gas evolution and by a gradual and very protracted shift of potential toward more negative values with time. This region may or may not terminate with the formation of a visible chromic oxide film, which depends on the current density. The second region of polarization, corresponding to II on Fe, is associated with distinct inhibition of visible gas evolution, with disintegration of the chromc oxide film whenever such film is observed to form at region I, and with the establishment of the Cr deposition process. This second region is concomitant with some transformations within the liquid layer adjoining the cathode surface. The transformations may lead to the formation of an adsorbed cathode film. The chromic oxide film that forms in region I disintegrates prior to the commencement of chromium deposition and this evidence contradicts the hypothesis of Okada and Yamamoto (5) about its role in the increase of hydrogen overvoltage values during region II.

Experimental

The experimental technique employed in this study was similar to the one used in the investigation of chromium deposition on iron (1) except that smaller Pt cathodes were employed.

High-purity (99.9%) platinum wire 2 mm in diameter, was mounted, cross sectioned, and metallographically polished, producing a geometric section area of 0.03145 cm^2. To obtain reproducible potentials of initial hydrogen evolution it was necessary to activate the polished surface by dipping it into hot (80°-90°C) chromic acid (750 g/liter of CrO_3) for 1 min, to double-rinse with distilled water, and to dry, as recommended by Breiter (6). Dry electrodes were then placed into the plating cell and were allowed to soak for 1 min in the plating bath to acquire the solution temperature which in all instances was 50°C. The potential-time curves were obtained by running the potentiometric recorder at a predetermined speed while the electrode was immersed in the bath with the current off. After 1-min period the current was then switched on. The initial transient from the potential of rest to the inflection was a straight line at all current densities investigated. The inflection coincided with the beginning of visible hydrogen evolution.

All electrolyses were performed in conventional plating solutions containing 250 g/liter of CrO_3 and 2.5 g/liter of H_2SO_4 using galvanostatic current control. Simultaneous microscopic observations were recorded photomicrographically and were subsequently correlated with the polarization data.

Results and Discussion

Preliminary investigations.—To control the reproducibility of initial Pt surface conditions a brief activation treatment (6) was necessary. In the absence of such a treatment neither the potential of rest nor the potential of initial hydrogen evolution was reproducible.

Table I shows electrode potentials at various surface conditions. With specimens not subjected to the activation treatment (experiments 1 and 2) both, the rest potential and the initial evolution of hydrogen, varied considerably. After activation treatment these potentials were rigorously reproducible (experiments 3 and 4). Under these conditions the potential of initial hydrogen evolution corresponded closely to the calculated potential of hydrogen evolution on Pt, as is shown later on.

The initial evolution of hydrogen and the rest potentials were considerably different when a previously activated and polarized electrode were reused without again reactivating it (experiments 5, 6, 7, and 8, Table I). The rest potentials were then more active and so was the potential of initial hydrogen evolution presumably due to the adsorption at the cathode surface of the products of electrolysis and of impurities from the plating bath. Reactivation would restore the reproducible potentials.

The requirements of Pt activation for electrochemical measurements were studied by a number of workers (7-9). The theories of activation were reviewed by James (10). His study indicates that the removal of adsorbed impurities is by far the most important result of a brief activation treatment. An oxygen layer that forms on the surface during chromic acid treatment (6) apparently protects the electrode until cathodic current is applied. When the electrolysis is started, the oxygen layer is first removed but the active surface soon becomes inactive, probably due to the adsorption of the products of the electrochemical or of secondary chemical reactions.

When electrolysis was continued uninterrupted, the conditions at the surface continued to change with time. Such changes were indicated by the shift of the potential to more negative values, a phenomenon reflecting higher activation energy requirements for the over-all current carrying processes.

Although some workers (11, 12) expressed an opinion that hydrogen evolution is the only reaction taking place at higher current densities, at more negative potentials prior to the deposition of chromium, other work suggests (13-15) that partial reduction of chromic acid ($Cr^{6+} \rightarrow Cr^{3+}$) is also in progress but to a much smaller degree, leading to the formation of chromic oxide films (4). These films are assumed to be porous (16) or semiconductive (17), thus allowing the

discharge of hydrogen ion to proceed. Since the structure and the rate of formation of such films does depend on the current density and the method of the surface preparation (14) so will the inhibition of hydrogen evolution.

To examine the reproducibility of polarization under the experimental conditions adopted, a series of potential-time curves was obtained with activated electrodes, after first subjecting them to a number of polarizing cycles in the conventional plating bath at the same C.D. of 0.440 A/cm^2 and a temperature of 50°C. Each polarization was carried out from the potential of rest to the potential of chromium deposition which in some instances (*e.g.*, curve 3) would be delayed for up to 2 hr. Usually in such situations there was still a significant shift of potential toward more negative value after about 30 min of polarization. If after 30 min the shift of potential was not significant the electrolysis would be terminated after 45 min for experimental expediency because it was found, in separate extended runs, that under such conditions no further shift of potential occurred and no chromium deposition resulted after several hours of electrolysis. When chromium did deposit at reasonable short periods of time, it was stripped with hydrochloric acid and the electrode was then thoroughly rinsed and reactivated but not repolished, before the next sequence. The curves obtained in this manner are shown in Fig. 1a.

Curve 1 represents surface conditions after about ten polarizing sequences. Under these conditions the electrode could not be polarized to the potential of chromium deposition at the C.D. of 0.440 A/cm^2 at any reasonable period of time. After about 30 min the shift of potential would level off at approximately −0.7V and additional polarization would have no further marked effect. The curve was then considered experimentally reproducible.

Curve 2 is similar to curve 1 and was obtained with a smaller number of polarizing cycles (eight cycles). This curve runs at slightly more negative potentials and like curve 1 would begin to level off after about 30 min of electrolysis.

Curve 3 terminated with the deposition of Cr after approximately 2 hr of electrolysis. It was obtained after six to seven polarizing sequences and could not be exactly reproduced.

Curve 4 represents polished and activated surface without previous polarization history. All other surface conditions (curves 1-3 and 5-7) would revert to curve 4 after repolishing and reactivation.

Curves 5, 6, and 7 were obtained with an intermediate number of polarizing cycles (two to five cycles) and could not be reproduced in duplicate experiments. Their shape could not be correlated with the number of previous polarizations nor with their duration. Thus, for instance, curve 5 was obtained after five polarizations, curve 6 after two, and curve 7 after three cycles.

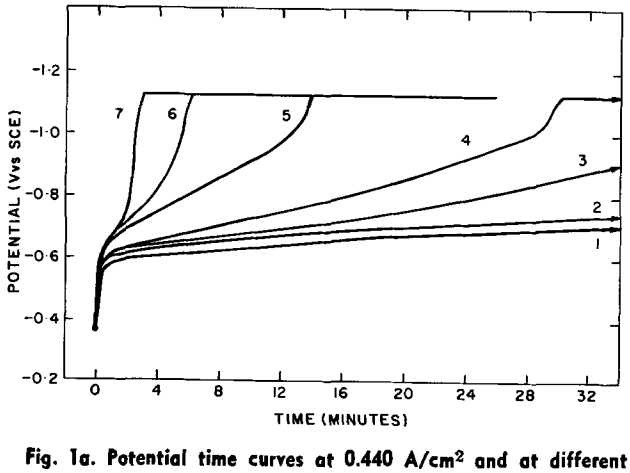

Fig. 1a. Potential time curves at 0.440 A/cm^2 and at different polarization histories of the electrodes.

The phenomenon of the variation of the shift of potential with the polarization history is of a certain fundamental interest. One can speculate that each polarization affects platinum electrode in depth just underneath the surface since repolishing restores the original conditions. The initial evolution of hydrogen, however, appears not to be affected by previous polarization history and can always be reproduced by reactivation of the surface. Full explanation of this phenomenon would require a separate detailed study which could not be considered within the scope of this work.

For the purpose of the present investigation surface conditions resulting from polishing and activation but without previous polarization history were found most appropriate. They were associated with curve 4 shown in Fig. 1a and provided reproducible transitions within the potential ranges I and II. In addition such surface conditions appeared to be similar to those used by Reinkowski and Knorr (11) and were, therefore, employed in the present work.

Potential vs. time curves at various current densities. —The preliminary experimental work summarized in Table I and Fig. 1a shows that activation treatment was essential to obtain the reproducible inflection that coincided with the initial evolution of hydrogen.

The transients from the potential of rest to the initial evolution of hydrogen were investigated by Okada, Nakamura, and Ishida (18), who studied potential-charge curves in this region by oscillographic technique.

They found that four inflection points are observed in the conventional plating bath when a C.D. of 0.200 A/cm^2 is used. The first two points were attributed to the reduction of oxides present on the surface. The third inflection was assumed to be associated with the formation of a chromic-chromate film, while the fourth corresponded to the initial evolution of hydrogen at −0.412V *vs.* SCE at 20°C. At lower current densities (0.05 and 0.005 A/cm^2) current carrying reactions were detected and they were considered to be the result of the partial reduction of chromic acid ($Cr^{6+} \rightarrow Cr^{3+}$). In pure chromic acid (absence of $SO_4^=$), in which hydrogen evolution proceeds with practically 100% current efficiency (17), potential-charge curves were the same at all current densities as those obtained in the plating bath (presence of $SO_4^=$) at 0.200 A/cm^2.

This observation shows that the partial reduction of chromic acid contributes little to the over-all current carrying processes at 0.200 A/cm^2 and that these processes can be considered as being mainly due to the discharge of hydrogen ion.

In the present investigation, which was performed with the same equipment as the earlier work (1), potential-time curves were recorded using a potentiometric recorder wth a one-half second response time over a 9-in. grid. Under these conditions it was not possible to resolve the three intermediate inflection points, and the trace was a straight vertical line until the evolution of hydrogen began at measurable rates. This point corresponded to the inflection 4 on the charging curves recorded by Okada, Nakamura, and Ishida (18). This point is accepted as a start of the potential-time transients in the present work.

Reproducible potential-time curves at four current densities of 0.220, 0.440, 0.660, and 1.320 A/cm^2 are shown in Fig. 1b. The initial evolution of hydrogen at the C.D. of 0.220 A/cm^2 was observed to take place at −0.300V *vs.* SCE (at 50°C). At higher current densities this potential was progressively more negative as indicated by the starting point on all four curves.

To check the potential of hydrogen evolution on bright smooth platinum at 0.220 A/cm^2 calculation of the overpotential was made using the following Tafel equation (19)

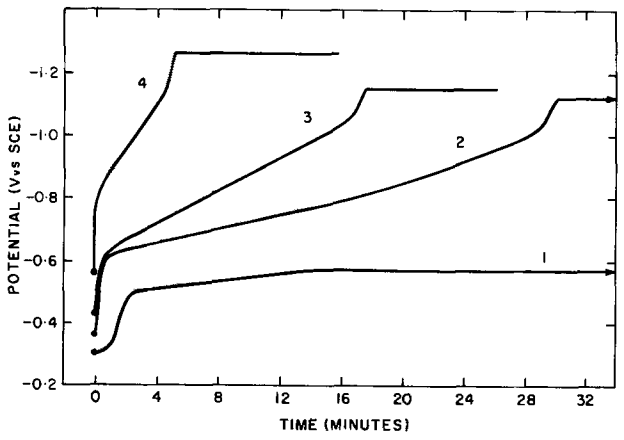

Fig. 1b. Potential time curves at the following current densities: C.D. A/cm²: curve 1, 0.220; curve 2, 0.440; curve 3, 0.660; curve 4, 1.320.

$$\eta = \frac{RT}{\alpha F} \ln \frac{i_o}{i}$$

where α (transfer coefficient) = 2 and i_o (exchange current density) = 10^{-3} A/cm² (20). At 0.220 A/cm², η was found to be −0.075V at 50°C. Using the reversible potential of +0.0134V *vs.* NHE, calculated for a solution containing 250 g/liter of CrO_3 ($pH = -0.212$), the potential of hydrogen evolution was found to be −0.303V *vs.* SCE. Applying the temperature correction to the overvoltage value in the manner recommended by Latimer (21), that is 2.5 mV increase for each 1°C decrease of temperature, the overvoltage at 20°C would be about −0.150V and the potential of hydrogen evolution about −0.38V *vs.* SCE which is fairly close to the value observed by Okada, Nakamura, and Ishida (−0.41V), particularly if one considers that no surface roughness corrections were made.

Schuldiner (22) found experimentally that the current-overvoltage relationship for hydrogen evolution on bright platinum in 0.1*N* H_2SO_4 solution fits the equation $\eta = a - b \log i$ where $a = -0.26$, $b = 0.12$, and i is the true current density corrected by the roughness factor 2.16 (determined experimentally). The equation is applicable to the relatively low current density range 0.015-0.050 A/cm² (nominal C.D. approximately 0.03-0.100 A/cm²). If the nominal C.D. is extrapolated to 0.220 A/cm², the overvoltage η = −0.14V *vs.* 25°C. After correcting to 50°C the potential of hydrogen evolution becomes −0.305V *vs.* SCE which is in good agreement with the first calculation and with our experimental observations (−0.300V *vs.* SCE).

Since the above equation applies only to lower current densities and the surface roughness of platinum used in the present work was not determined, more accurate calculations cannot be made. However, even these approximate values show that the potential of initial hydrogen evolution was within the range generally observed by other investigators, thus, at an acceptable level of reproducibility.

Continued polarization at 0.220 A/cm² resulted in a shift of potential to −0.57V *vs.* SCE at which hydrogen evolution proceeded for over 50 min without deposition of Cr.

The difficulty of polarizing platinum to the potential of chromium deposition at the same range of C.D. and potentials (at equivalent temperatures) was also observed by Reinkowski and Knorr (11). They had to increase the current to 0.300 A/cm² to bring about the shift of potential to the level of chromium deposition.

Chromium deposition is easily brought about at the 0.220 A/cm² current density on Fe cathodes as was shown in earlier work (1). The reason is higher hydrogen overvoltage characteristics of Fe associated with shorter transients in potential region I.

To effect the deposition of Cr on Pt under the reproducible surface conditions, three current densities (0.440, 0.660, and 1.320 A/cm²) were used in the present work. At each current density two transient regions could easily be detected. Transient region I characterized by heavy evolution of hydrogen extended over protracted periods of time even at the highest current density investigated. This region as is shown in Fig. 1a was significantly affected by previous polarization history of the platinum electrode. Although the cause and effect of this phenomenon was not established, it is reasonable to assume that surface changes that occur during each polarization affect the inhibition of hydrogen ion discharge which is the main current carrying reaction in this region. Whether diffusion of the discharged hydrogen into the bulk of the metal is involved it is not known. Weiner (23) has shown that current-voltage curves on platinum are shifted to more negative values if the metal is saturated with hydrogen. Hoare and Schuldiner (24) found, however, that the permeation of Pt with hydrogen is detectable only in the presence of catalytic poisons. This observation was confirmed by Gileadi, Fullenwider, and Bockris (25). Thus in order to accept the concept of hydrogen diffusion into platinum and associated changes of overpotential with time one would have to assume in the present work that chromic acid or some products of its decomposition act as catalytic poison, an assumption that, thus far, has not been verified experimentally.

The second transient II observed with curves 2, 3, and 4, (Fig. 1b) was characterized by an accelerated shift of potential to the level of chromium deposition in a manner similar as in the case of Fe cathodes (1). This shift of potential was not affected by the previous polarization history of the electrode and by the duration of transient region I. When region I was very short (curves 6 and 7, Fig. 1a) it would merge in transition with region II thus obliterating the distinct step observed with curves 3, 4, 5 (Fig. 1a) and curves 2, 3, 4 (Fig. 1b). A short region I is indicative of processes that suppress the low overvoltage characteristics of Pt. It is perhaps noteworthy to emphasize that regardless of the progress of polarization during region I transient region II would always start at about −1.02V and terminate at the same potential of −1.12V *vs.* SCE at which the deposition of Cr would begin at the C.D. of 0.440 A/cm².

This final shift of potential in region II was attributed by Okada and Yamamoto (5) to the increase of hydrogen overpotential as a result of the thickening of the chromic oxide film that forms in region I. Microscopic observations correlated with curves 2 and 3 (Fig. 1b) show, in the next section, that the transient region II is associated with the decline of the evolution of gaseous hydrogen regardless of whether the chromic oxide forms on the surface or not.

Transient region II does not occur in the absence of $SO_4^=$ (1, 5), thus indicating the involvement of such an anion in the electrochemical processes that contribute to the inhibition of visible hydrogen evolution.

Correlation of microscopic observations with potential-time curves.—Microscopic observations made during experiment 1, Fig. 1b (C.D. 0.220 A/cm²) are illustrated by a series of photomicrographs in Fig. 2. The individual photomicrographs show (a) the appearance of the surface immersed in the plating bath before commencement of the electrolysis, (b) very few hydrogen bubbles observed in the first 10 sec, (c) continued low gassing at the 20th second, (d) similar low gassing after 1 min of electrolysis, (e) increase of gassing coinciding with the shift of potential to −0.57V, and (f) the same intensity of hydrogen gas evolution after additional 53 min of electrolysis.

The above microscopic observations correlate well with the changes of the potential with time. The initial range of potential (−0.300 to −0.302V) coincided with

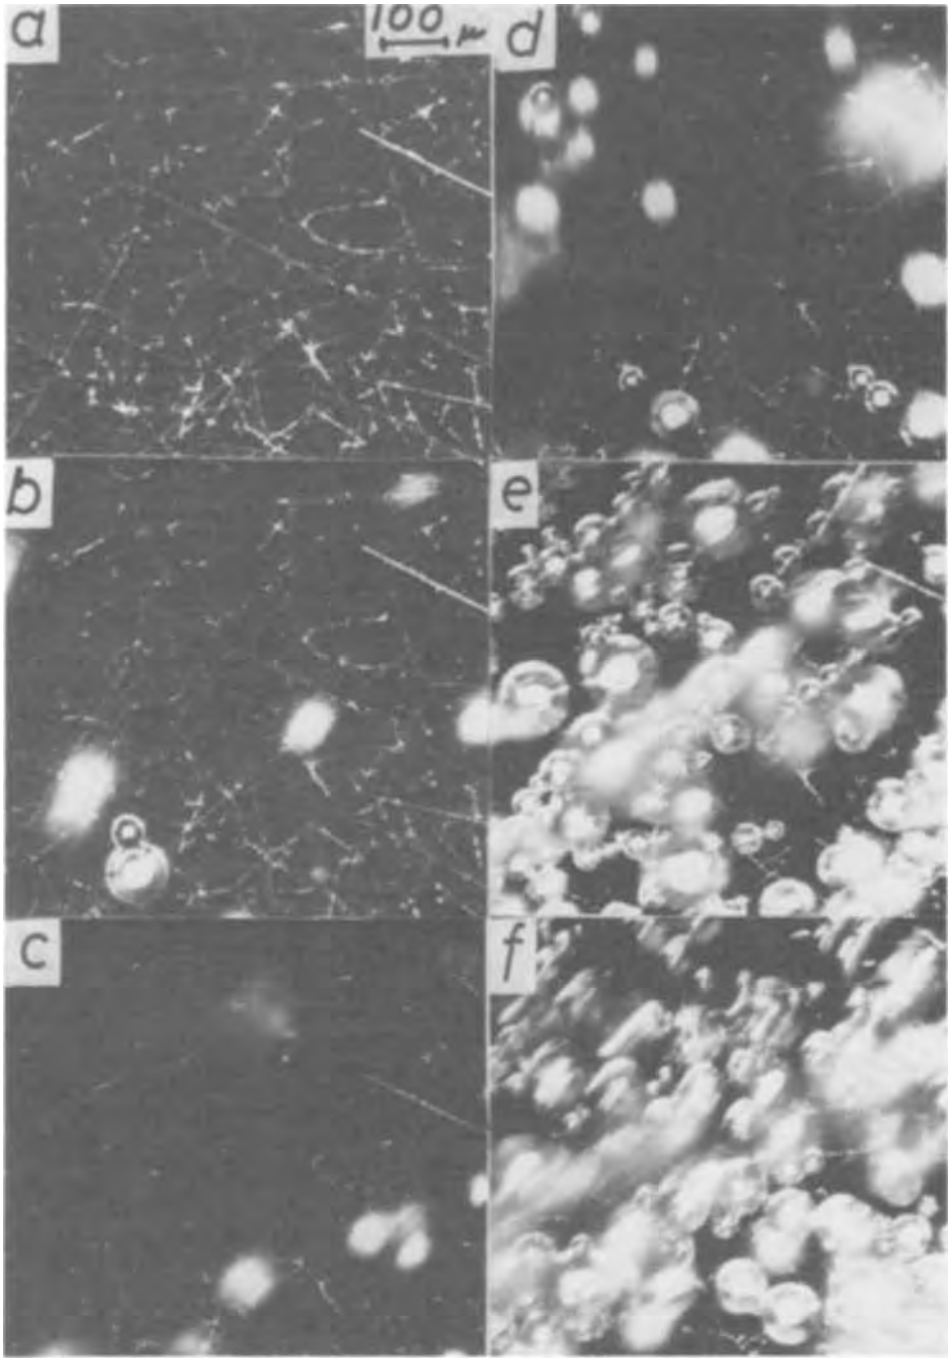

Fig. 2. Photomicrographs of the cathode surface polarized with a constant C.D. of 0.220 A/cm². Original magnification X100. Dark field illumination. Exposures 1/125 sec. a, Immersion before electrolysis, time 0. Rest potential vs. SCE + 0.950V. b, 10 sec; c.p. −0.300V. c, 20 sec; c.p. −0.305V. d, 1 min; c.p. −0.320V. e, 2 min; c.p. −0.470V. f, 54 min 45 sec; c.p. −0.570V.

low level of gassing. This probably means that the concentration of dissolved molecular hydrogen in the diffusion liquid layer was still below saturation (26).

The sharp increase of gas evolution coincided with the shift of the potential to −0.57V as is evident from comparison of curve 1 with Fig. 2e. Apparently upon saturation of the diffusion layer, the process of gas bubble formation reached steady-state conditions and continued unaltered for over 53 min.

To bring about the deposition of chromium the current density was increased to 0.440 A/cm² (Fig. 1b, curve 2). At this value, the potential of about −0.6V was reached rather rapidly, but from then on up to about −1.00V the potential shifted gradually over a period of about 26 min and this shift was accompanied by changes in the gassing pattern as is illustrated in Fig. 3A. The individual photomicrographs show (a) Pt surface immersed in the solution before electrolysis, (b) hydrogen evolution approximately 1 sec after the current was turned on, (c) hydrogen evolution in the fourth minute of the electrolysis, (d) hydrogen evolution in the 18th minute, (e) gassing pattern at −1.01V just before the final shift of the potential to the chromium deposition level, and (f) the beginning of the decrease of gassing coinciding with the potential shift from −1.01 to −1.08V.

The beginning of the decline of gassing observed in photomicrograph (f) was recorded before the steady-state potential of chromium deposition was reached.

A plausible explanation of this phenomenon would be to assume that some chromium is deposited on platinum at potentials less negative than the steady-state value (−1.12V *vs.* SCE at 0.440 A/cm²) and, that because of higher hydrogen overpotential on Cr, the discharge of hydrogen ion ceases when a thin layer of chromium is established. The undisputable evidence is, however, that hydrogen evolution on chromium begins vigorously as soon as $SO_4^=$ is removed from the bath as was shown in the previous work (1). This observation demonstrates, thus, that the decline of gassing is not due to higher overvoltages associated with chromium and that the key factor is the

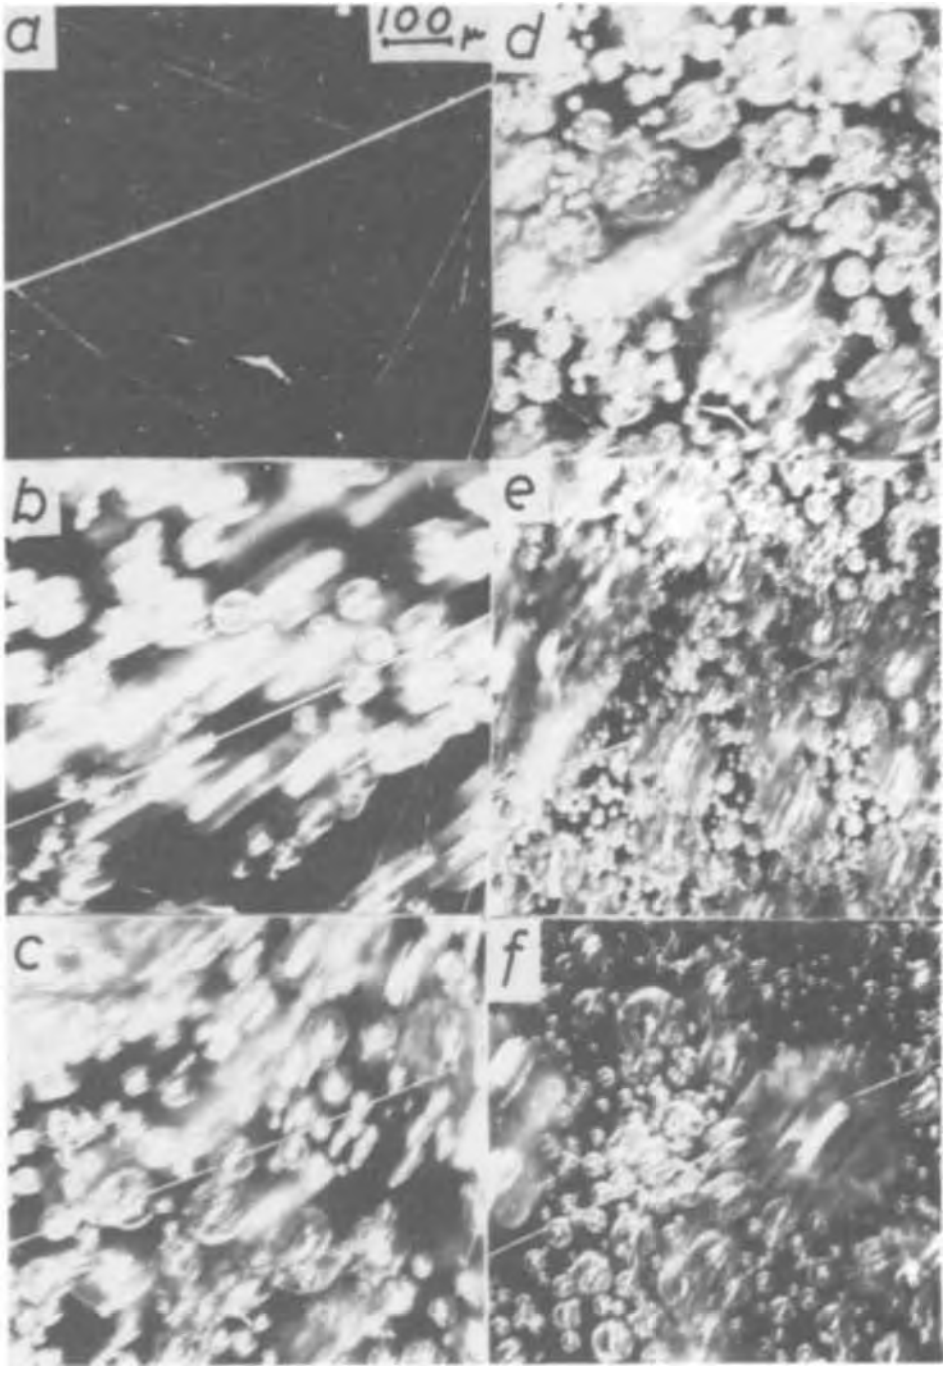

Fig. 3A. Photomicrographs of the cathode surface polarized with a constant C.D. of 0.440 A/cm^2. Original magnification X100. Dark field illumination. Exposures a-c 1/125 sec, d-f 1/250 sec. a, Immersion before electrolysis, time 0. Rest potential +0.950V vs. SCE. b, 1 sec; c.p. —0.360V. c, 4 min; c.p. —0.650V. d, 18 min; c.p. —0.820V. e, 29 min 10 sec; c.p. —1.010V. f, 29 min 45 sec; c.p. —1.080V.

presence of $SO_4^=$. The $SO_4^=$ ion itself does not inhibit the evolution of hydrogen and for this reason solutions of sulfuric acid are used extensively in investigations of hydrogen overvoltages on various metals (19). The presence of $SO_4^=$ in the plating bath must, therefore, induce some potential dependent conditions that are not associated with permanent changes of the surface characteristics. These conditions inhibit reversibly the visible evolution of hydrogen.

The decline of visible evolution of hydrogen observed in (f) became quite distinct 10 sec later on and is illustrated in photomicrograph (g) in Fig. 3B which is a continuation of Fig. 3A. The photomicrographs in Fig. 3B show (g) the decline in the number of gas bubbles and the increase of their size as the potential approaches the value of —1.09V, (h) continuation of the same phenomenon 10 sec later on, (i) further decrease of gassing as the deposition of chromium begins at —1.12V, (j) visual evidence of chromium deposition 15 sec later on, (k) complete cessation of gassing (white streaks are reflections of light from gas bubbles in movement), and (l) a burst of gassing along an initial crack formed in the deposit after 2 min 45 sec of plating.

The above experimental evidence demonstrates that the establishment of the chromium deposition processes is concomitant with the inhibition of gaseous hydrogen evolution. The decline of gas evolution precedes the deposition of chromium and the cause of the decline is open to speculation.

The diffusion of molecular hydrogen into the bulk of platinum is a possible cause but it seems unlikely that such a process would begin suddenly after the previous prolonged gassing during the shift of the potential from —0.6 to —1.0V. The phenomenon, which is potential dependent, is more likely to be caused by the commencement of certain electrochemical reactions that either contribute to the blocking of the bubble generating processes or change the conditions in the liquid layer adjoining the cathode surface. The discharge of hydrogen ion over the entire cathode during chromium deposition is not considered impeded because it

was shown by many investigators (27-29) that Cr plating is only 15-20% efficient owing to the evolution of hydrogen.
